Abstract. The review surveys and generalises data on the use of the Cambridge Structural Database (CSD) for studying and revealing general structural features of organic molecular crystals. It is demonstrated that software and facilities of the CSD allow one to test the applicability of a number of known concepts of organic crystal chemistry (the principle of close packing, the frequency of occurrence of space groups, the preferred formation of centrosymmetrical molecular crystals, *etc.*) on the basis of abundant statistical data. Examples of the use of the Cambridge Structural Database in engineering of molecular crystals and in the systematic search for compounds with specified properties are given. The bibliography includes 122 references.

I. Introduction

Presently, the Cambridge Structural Database (CSD) is one of the most powerful information databases, which contains exhaustive data (atomic coordinates, molecular geometry and crystal symmetry) on crystal and molecular structures of organic, bioorganic, organoelement and organometallic compounds and to a large extent coordination compounds which have been studied by X-ray diffraction and/or neutron diffraction analysis. (The term organic crystals is used to denote crystals containing at least one 'organic' carbon atom, *i.e.*, that involved in formation of C–C or C–H bonds.) Data on crystals which can hardly be called true organic molecular crystals (for example, data on inorganic alkylammonium salts, *etc.*) are also included in the CSD.

Therefore, the CSD involves information on diversified organic crystals. Hence, the correct choice and rejection of compounds in the search for structural regularities in series of related and structurally similar crystals is one of the most important problems in the use of the CSD. Presently, the CSD

contains data on 181 000 crystal structures and the body of information in the CSD increases annually by 7000–8000 new structures. Clearly, the availability of the sizable database gave impetus to a search for various special structural features of particular classes of compounds as well as to a search for general regularities of organic crystal structures with the use of the CSD on the basis of statistically reliable analysis of large samples. The first line of investigation began actually after the first CSD release has appeared. Studies of the general regularities of organic crystal structures using statistical analysis became possible only with the appearance of computer versions of the CSD and with the development of special programmes for statistical treatment of a large body of data.

There are two approaches to the elucidation of the general rules and regularities of organisation of crystalline solids from isolated structural elements (atoms, molecules and their associates and ions). The first approach involves the use of computational methods, in particular, those used for *a priori* prediction of new crystal structures. In recent years, much progress in this field has been achieved.^{1–4} The second approach is based on the correct statistical analysis of numerous crystal-structural data accumulated in information databases. We dwell on the results and prospects of the second approach with the use of modern tools and facilities of the CSD.

Useful new crystal-chemical information can be obtained by performing correct systematic statistical analysis of the large available body of experimental structural data. This idea appeared rather long ago. Thus many chemists and crystal chemists still use the values of the van der Waals radii which were determined by Pauling⁵ and Bondi⁶ based on the analysis of scarce crystal-structural and other (in particular, gas-kinetic) data available at that time. The fundamental principles of structures of organic molecular crystals (among them, the principle of close packing), which have been explicitly stated for the first time by Kitaigorodskii,⁷ were also established on the basis of relatively scarce statistical data. In the 1970's and in the early 1980's, these systematic studies were believed to be very promising. However, as the experimental published data on crystal structures were accumulated, these investigations became more complicated. The major obstacle (which is believed to be insurmountable) lay in the fact that non-computerised search and processing of abundant numerical data were extremely tedious procedures.

Received 23 April 1998

Uspekhi Khimii 68 (1) 3–22 (1999); translated by T N Safonova

It is worth noting that since the early days of crystallography (crystal chemistry), the researchers involved in this field have realised that data obtained in their studies are of fundamental importance and can have a wide use. Consequently, they were the first to systematically amass results of their studies. Thus as soon as 16 years after the development of the X-ray diffraction method, a beginning has been made in systematically reviewing X-ray structural data.⁸ In this country, results of X-ray diffraction studies of organic crystals were first surveyed by Struchkov and were reported by Kitaigorodskii⁷ in 1955. More recently, the well-known handbooks by Kitaigorodskii, Zorky and Belsky were issued.^{9,10} The complete bibliography concerning these sources was published by Watson.^{11,12}

First computer databases were compiled based on the available publications. Two of them, *viz.*, 'Powder Diffraction File'¹³ and 'NBS Crystal Data: Database Description and Applications'¹⁴ became available totally as a computer version. These banks contain exhaustive (from the chemical standpoint) information but do not include atomic coordinates and were primarily used (and are still used) for identification and comparative studies of unit cell parameters and crystal symmetry.

The compilation of structure databases which contain atomic coordinates along with crystallographic data, details of chemical structures and bibliographic description dates back to the mid-1960's. When creating these databases, one would have to process information from current publications and to collect data on structures which have been studied previously and which are scattered over numerous literature sources. Therefore, in the initial stage, priority was given to works on the development of software for collecting, testing, processing and depositing data. Subsequently, programmes were developed for the search, selection and statistical analysis of information as well as for the distribution of databases. Systematic statistical studies with the use of all the data accumulated in databases appeared only in the last decade.

Presently, information on virtually all types of chemical compounds can be found in four structure databases: the Cambridge Structural Database (University of Cambridge, UK) contains data on 181 000 structures, the Inorganic Crystal Structure Database (University of Bonn, Germany) contains data on 41 500 structures, the Metals Data File (National Research Council of Canada, Ottawa, Canada) contains data on more than 11 000 structures and the Protein Data Bank (Brookhaven National Laboratories, USA) contains data on more than 1500 structures.

Presently, the CSD¹⁵ is the biggest database. Using the information bases of the CSD, one can perform statistically reliable systematic studies of structural data. The knowledge of precise molecular geometry is necessary for the understanding of the nature of chemical bonds and chemical structures. Therefore, early studies were devoted to the determination of mean ('typical') values of bond lengths and bond angles in various classes of chemical compounds^{16,17} and the acquisition of data on structural features of particular fragments or classes of chemical compounds as a whole.^{18–20}

Systematic investigations into the mutual arrangement of molecules in crystals were begun with studies of geometrical characteristics of intermolecular interactions. In particular, statistical values of van der Waals atomic radii^{21,22} and geometrical characteristics of specific interactions (hydrogen bonds,^{23–27} and the CH...O(N), Hal...Hal and some other contacts^{28–33}) were determined.

More recently, with the increase in the size of the CSD and the perfection of software for correct selection and statistical analysis of results, some researchers formulated problems based on the belief that the CSD contains, in some form, information on general regularities of molecular crystal structures. In this respect, noteworthy is the paper by Motherwell³⁴ in which distributions of positions of geometrical centres in molecular crystals were analysed and the preference for the realisation of

the principle of close packing was statistically confirmed. Recently, some researchers have cast doubt on the firmness of this principle.³⁵ The doubts were substantiated by the fact that the principle of close packing should contradict a tendency of molecules to form strong intermolecular hydrogen bonds and by the fact that experimental crystal structures do not necessarily correspond to the calculated global energy minima.

The question of the frequency of occurrence of space groups has received the most study based on the CSD data. Numerous statistical studies were devoted to this problem.^{36–44} Admittedly, the most detailed investigations were carried out by Belsky⁴² and by Brock and Dunitz.⁴⁵ The considerable attention given to this problem is quite justified because many physical properties of crystals depend on the symmetry of the molecular arrangement and hence, the *a priori* estimation of the crystal symmetry is an important practical problem. For example, this is of importance in the design of materials with nonlinear-optical properties, which are constructed using organic chromophore molecules.^{46,47}

Often, in studies using the CSD researchers attempt to establish the reasons for which compounds crystallise preferentially in centrosymmetrical (achiral) space groups rather than restrict themselves to simple statement of the facts (for example, about the considerable predominance of racemic crystals.⁴⁸) Thus efforts to estimate the effect of molecular dipoles on the crystal packing were applied,⁴⁹ a comparative analysis of densities and stabilities of compounds that crystallise in both racemic and chiral space groups was carried out⁵⁰ and the correlations between densities, calculated packing energies and some thermodynamic properties of crystals were considered for pairs of polymorphic modifications existing at room temperature.³

In recent works devoted to analysis of the frequency of occurrence of space groups,⁴⁵ much attention was given to the number of formula units per asymmetric unit (Z'). Belsky and Zorky were the first to note the importance of the consideration of this parameter.^{51,52} Studies of crystals with $Z' > 1$ brought up many questions. For example: are conformations of independent molecules in the unit cell identical or not? Are independent molecules related by any symmetry transformations? What is meant by pseudosymmetry? How do pseudosymmetry elements and true symmetry of real crystals relate to each other? Do crystals with $Z' > 1$ possess any characteristic properties? Abrahams attempted to give the answer to the last question.⁵³ He suggested that if pseudosymmetry is present, phase transitions of the second kind can occur in crystals of a number of inorganic compounds as the temperature is increased.⁵³ This hypothesis provided the basis for the development of a procedure for the search for new potential ferroelectrics,⁵⁴ which is successfully used for predicting inorganic compounds with high-temperature phase transitions.⁵⁵

Interestingly, unit cells with $Z' > 1$ are more frequent in crystals containing molecules that can form stable associates through hydrogen bonds.⁵⁶ The occurrence of unit cells with $Z' > 1$ and the existence of pseudosymmetry are highly probable for compounds exhibiting liquid-crystal properties on melting.^{57–59}

The results of studies of characteristic types of supramolecular fragments (supramolecular synthons) that formed in crystals through the strongest nonbonded intermolecular interactions for molecules of similar types or for molecules containing similar chemical functional groups may be very useful in revealing general regularities of organisation of crystal structures.^{60–62} These studies fall within the realms of crystal engineering (a new intensively developing branch of science that appeared at the borderline between materials technology and crystal chemistry), which involves the development of procedures for the design of organic crystalline materials with predetermined properties. The crystal symmetry describes the topology of molecules in crystals and determines many physical properties of solids, namely, electrical, magnetic, linear-optical and nonlinear-optical properties, electronic and ionic conductivity, *etc.* Therefore, the current prime objective of crystal engineering is to reveal factors that

affect the formation of crystal structures with a particular molecular architecture, which causes the manifestation of a desirable physical property.

An important role of databases, in particular of the CSD, in the design of new materials was discussed in the review by Aakeroy.⁶³ It was noted that the development of software of the CSD (new algorithms and statistical and cluster analyses) and the incorporation (wherever possible) of a number of thermodynamic and/or other physicochemical characteristics of compounds into the CSD will favour the directed search and design of new compounds with preset properties.

Therefore, the use of the CSD has promise in the search for fundamental structural features of organic molecular crystals. However, it should be borne in mind that even very large statistical samples cannot assure automatically that statistically reliable characteristics and properties will be obtained without appropriate rejection and processing of the data. Therefore, when considering examples of the use of the CSD, we concentrated most attention on the analysis of schemes applied in the original publications cited for creating representative statistically significant samples. Modern versions of the CSD allow one to compile and reject particular data on the basis of a series of criteria and indications, each being a subject of special discussions in the literature.

The present review is the first attempt to consider the CSD as a tool in studying general structural regularities of organic molecular crystals.

II. Organisation and software of the Cambridge Structural Database

As has been mentioned above, the CSD contains results of complete three-dimensional X-ray and neutron diffraction studies of organic, bioorganic, organometallic and coordination compounds. The CSD is compiled by reviewing original publications in 1025 scientific journals and other sources (data as of 1988). Presently, the majority of crystal chemists and crystallographers as well as many chemists consistently use the above-mentioned databases in their routine work. For example, the 1998 version of the CSD is employed by researchers at about 40 scientific institutes of Russia and Newly Independent States of the Former Soviet Union. About 150 articles were devoted to the use of the CSD. The major principles of selection and systematic numerical analysis of information in crystallographic databases were considered and analysed in detail in one of the latest papers, namely, in the review by Allen⁶⁴ 'Crystallographic Data Bases: Samples and Analysis of Precise Structure Information from the Cambridge Structural Database'. Therefore, we mention only briefly the essentials of organisation and software of the CSD.

The use of the CSD requires special software, namely, the programme package developed for the search, selection of required data, analysis of geometrical parameters of molecules and crystal structures and their representation with the use of computer graphics tools. The search for the required information in the CSD is performed using the QUEST programme, which specifies the query. This query can be formulated in the form of three major packages, *viz.*, 1D, 2D and 3D.

A query specified by the QUEST1D option allows one to obtain bibliography, the name of a compound, the molecular formula or the amino acid sequence, unit cell parameters, the *R* factor and required comments (the presence of disorder, errors, *etc.*).

A query specified by the QUEST2D option allows one to obtain information on the atom and bond properties, the formal chemical type of the bond, tables of atom connectivities and the structural formula.

A query specified by the QUEST3D option allows one to obtain the description of a crystal structure, *i.e.*, the space group, symmetry operations, three-dimensional atomic coordinates,

crystallographic connectivity determined by the covalent radii and data on the correspondence between the 'crystallographic' and 'chemical' atoms from tables of connectivities of 2D diagrams.

Queries are specified with the use of special menus (BILD, SEARCH and QUEST). Information can be rejected by specifying a set of BITSCREEN indications.

The QUEST3D option compiles a data file FDAT from information selected according to the query. This file serves as an input file for the GSTAT(VISTA) and/or PLUTO programmes. The GSTAT programme was originally developed for calculations of intra- and intermolecular geometry and geometry of molecular fragments.⁶⁵ Presently, GSTAT is a programme package which allows one to analyse geometrical characteristics with the use of statistical and numerical methods.⁶⁶ The VISTA programme (graphical supplement to GSTAT) is destined mainly for numerical, statistical and graphical analysis of the geometrical information extracted from the CSD.

The PLUTO programme is applied not only by crystallographers but also by chemists. This programme is destined for the preparation of various graphical illustrations, including visualisation of both molecular structure and crystal packing based on three-dimensional coordinate data sets.

The most precise data in the CSD are used in the analysis of geometrical characteristics. In the simplest case, entries containing errors and disordered structures are rejected. The CSD contains two major parameters characterising the accuracy of the crystal structure, namely, the *R* factor and the *AS* parameter. The former characterises the overall discrepancy between the diffraction data and the crystal structure solved on the basis of these data. The latter characterises the average standard deviation of bond lengths. These parameters can be used both in QUEST (for preliminary rejection in the course of the search) and GSTAT (in statistical averaging).

Calculations of average molecular geometrical parameters used in statistical analysis were discussed in many papers (see, for example, Refs 67–69). Generally, either an average or a weighted average is calculated. A weighted average is better suited for cases where environmental effects are insignificant (for example, for rigid parameters, such as bond lengths). If environmental effects are substantial (torsion angles and bond angles), simple unweighted averages should preferably be determined. It is desirable to use an unweighted average also in statistical verifications of hypotheses. The absence of standard deviations of parameters for the majority of structures in the CSD does not allow one to calculate weighted averages without recourse to the original literature. However, Taylor and Kennard⁶⁹ demonstrated that an unweighted average can be sufficient even for rigid parameters provided the scatter of the experimental values is limited by the *AS* criterion. The authors believe that when the value of *AS* is 1.2, estimates of, for example, bond lengths in organic structures are quite correct. An unweighted average is used in the GSTAT programme for calculations of standard statistical characteristics.

It should be noted that only selected crystal-structural data, which are obtained by X-ray diffraction analysis of single crystals, are included in the CSD. In particular, atomic anisotropic displacement parameters (previously, they were called thermal ellipsoids) cannot be analysed. These parameters contain unique information on the dynamics of crystal structures and characteristics of atomic movements and/or disorder in crystals. Unfortunately, these data are absent in the CSD. Trueblood and Dunitz⁷⁰ were the first to call attention to this disappointing fact. They have demonstrated how information on the dynamics of crystal structures can be used for estimating energy characteristics (for example, barriers) of slow intramolecular movements in crystals, which is important in studies of properties of organic crystals.

III. Van der Waals atomic radii and nonbonded intermolecular distances in organic crystals

The atoms of elements can be, in a rather rough approximation, represented by rigid spheres with radii which are geometrical characteristics of the corresponding elements.⁷ The effective values of these characteristics are called van der Waals radii (WR) of elements. Needless to say these concepts are very simplified because atoms in molecules (the more so, in molecules in crystals) cannot be rigid, and their effective sizes depend also on the nearest environment as well as on the hybrid state of the atom. The first studies^{71,72} carried out with the use of the CSD have demonstrated that some bound atoms are flattened rather than spherical.⁷³ However, the simple 'rigid' spherical model appears to be a very persistent and extremely useful formalism.

Frequent application of WR stems from the necessity of comparing lengths of expected nonbonded intermolecular atom–atom contacts in crystals, which are determined as the sum of the corresponding WR, with the corresponding distances observed in crystal structures. Besides, in early work⁷ WR were used for choosing force-field parameters in calculations of the energy of intermolecular interactions in crystals. Presently, the CSD is finding increasing use for choosing these parameters,^{1–4} and the parameters of pairwise $X \cdots Y$ interactions are chosen based on the analysis of statistical distributions of bond lengths of the corresponding contacts retrieved from a large body of data in the CSD.

Several systems of WR are known. They were suggested by Pauling,⁵ Kitaigorodskii,⁷ Bondi,⁶ Zefirov and Zorky,⁷⁴ Nyburg and Faerman,⁷⁵ and Batsanov.⁷⁶ Bondi's system (table) of WR⁶ is most commonly used in spite of the fact that it has been repeatedly criticised in more recent works.^{71,74,77} In this country, the system of radii suggested by Zefirov and Zorky⁷⁴ has gained acceptance.

Rowland and Taylor performed systematic analysis of nonbonded contacts in organic molecular crystals.^{23–26,78} In one of their recent works, the authors decided to test the compatibility between the commonly accepted systems of WR of nonmetals H, C, N, O, F, P, S, Cl, Br and I and the observed nonbonded interatomic distances in crystals studied over a period of the last 30 years.²² Studies were carried out with the use of the 1995 version of the CSD containing 126 353 crystal structures. Only precise (R factors < 5%) and ordered structures that contained exclusively the above-listed atoms were considered. Structures containing charged groups were also rejected to exclude the effect of electrostatic interactions on interatomic distances. A total of 28 403 structures satisfying all the above-mentioned requirements were selected. For a pair of atoms A and B under consideration, all intermolecular distances falling within the interval $(R_A + R_B) \pm 1.5 \text{ \AA}$, where R_A and R_B are the corresponding WR according to Bondi, were taken into account. The broad range ensured that the sample thus obtained would not lead to results expected in advance.

Distribution histograms of nonbonded distances for various atom pairs were constructed²² with a bin size of 0.1 Å. Different types of histograms were obtained. Some of them showed a monotonic dependence of the number of atom pairs (n) on the distance ($H \cdots H$). Other histograms had a well-defined peak ($Cl \cdots Cl$). In some cases, a maximum was poorly defined ($H \cdots F$) or absent [histograms had only a shoulder ($C \cdots N$)] (Fig. 1).

Histograms of the first type were not analysed because they gave no numerical characteristics of the distribution.[†] Rowland

[†] These histogram patterns are due to the fact that all intermolecular distances (in particular, $H \cdots H$) are taken into consideration, among them distances that do not correspond to the real van der Waals ('reference'⁷) contacts in crystals. However, the last-mentioned contacts serve as a basis for the determination of WR of atoms in crystals. Consequently, an approach used by the authors of the work²² is of limited utility and cannot be used for estimating values of typical van der Waals $H \cdots H$ contacts.

Figure 1. Distribution histograms of nonbonded intermolecular distances for selected atomic pairs:²² $H \cdots H$ (a); $Cl \cdots Cl$ (b); $H \cdots F$ (c); $C \cdots N$ (d).

and Taylor²² suggested the use of the parameter d (the distance corresponding to the histogram half peak or shoulder height; Fig. 2) as a characteristic of histograms of all the other types. The stability of this parameter is the major argument in favour of its application as a numerical characteristic. Other possible (and most commonly used) characteristics, such as the shortest contacts[‡] or the position of the distribution maximum, appeared to depend strongly on the choice of the bin size and the boundaries of the distribution. Because of this, the value of d can be estimated much more reliably than the position of the maximum of the histogram or the shortest contacts.

Figure 2. Scheme for the determination of the parameter d ;²² n_k is the height of the maximum of the histogram.

The distributions of the lengths of $O \cdots O$, $N \cdots O$ and $N \cdots N$ nonbonded distances have a pronounced peak at short distances corresponding to typical lengths of hydrogen bonds (Fig. 3). Since only van der Waals contacts were considered in the work cited,²² all contacts of the NH and OH groups were also excluded. This restriction resulted in the removal of maxima corresponding to H bonds from all three distributions.

[‡] It is self-evident that the expression 'interatomic contacts' makes sense only for the left portion of the histogram where the distances are close to the sum of WR.

Figure 3. Distribution histograms of nonbonded intermolecular distances O...O (a), O...N (b) and N...N (c).²²

As expected, the values of d (Table 1) for the (O,N)H...N(O) distances are markedly smaller than those for the (C)H...O(N) distances (Fig. 4). On the contrary, the values of d for (O,N)H...Cl(Br) are larger than those for (C)H...Cl(Br). This can be explained by the fact that the OH and NH groups are almost always involved in strong hydrogen bonds with oxygen or nitrogen atoms, while bonds with halogen atoms appear to be 'secondary' and hence, are substantially weaker. If this assumption is true, the concept of WR for the oxygen and nitrogen atoms (at least, for the OH and NH groups) in organic crystal structures containing hydrogen bonds is meaningless. Taking into account the aforesaid, Rowland and Taylor²² estimated the values of d for the H...O, H...N and H...S distributions considering only hydrogen atoms at carbon atoms.

Table 1. Observed values of d (Å).²²

Atom	H	C	N	O	F	S	Cl	Br	I
H		3.02	2.59		2.54	2.91	2.88	2.99	3.14
C	3.02	3.59	3.31	3.24		3.61

The authors calculated the values (r_i) that characterise WR of the atom of the i th type using the values for all kinds of pairs of atom-atomic contacts (see Table 1) by minimising the following function:

$$f = \sum_i \sum_{j < i} w_{ij} [d_{ij} - (r_i + r_j)]^2,$$

where d_{ij} is the value of d for the pair of atoms i and j , w_{ij} is the weighting coefficient, which is equal to 1 and 0.25 for bin sizes of 0.1 and 0.2 Å, respectively. The summation was made over all types of atoms.

We recall that Rowland and Taylor²² proposed to use d as a characteristic of the distribution of intermolecular distances based on the numerical constancy of this value regardless of the choice of

Figure 4. Distribution histograms of nonbonded distances (O,N)H...O (a), (C)H...O (b), (O,N)H...N (c) and (C)H...N (d).²²

the bin size and boundaries of the distribution rather than on the expectation that d can be equal to the sum of WR of the corresponding atom pair. The authors only assumed that the values of r_i thus determined would correlate with the values of WR (R_w): $r_i = cR_{wi}$, where c is the correlation coefficient. The coefficient c appeared to be close to unity.

The values of r_i determined as described above as well as the values of WR determined independently are given in Table 2. It can be seen that the values of r_i agree most closely with Bondi's system of radii. The authors²² believed that this is most likely a random coincidence. It was noted that, on the whole, the radii which were determined in the work cited from a large number of interatomic distances in crystals agree well with WR determined by Bondi, yet some exceptions were observed. In particular, WR of hydrogen atoms in Bondi's system are 0.1 Å larger. The calculation taking account of the distribution of the H...H contacts determined only by the neutron diffraction method gave a radius of 1.19 Å. This value is close to that determined by Bondi. When H...O and H...N contacts were included in the consideration, the value of the radius under consideration decreased. The values of WR in Bondi's system were determined primarily from the H...H contacts in adamantane. It is known that covalently bound hydrogen atoms are partially positively charged in the majority of organic compounds. Therefore, H...H distances would be expected to be somewhat elongated due to

Table 2. Van der Waals radii of selected atoms (Å).

electrostatic repulsions. On the contrary, the H $\cdots$ O distances can be somewhat shortened due to electrostatic attractions. Therefore, the radii which were determined²² with the use of all types of H $\cdots$ X contacts based on a large body of statistical data are presumably more accurate than those determined by Bondi. Yet another noticeable difference in the values of WR was observed for the nitrogen atoms. A larger (compared to Bondi's radius) value of r_N was obtained due to the unexpectedly large value of d for the N $\cdots$ N distance distribution. The authors²² believe that the value of WR for the nitrogen atom suggested by them is more appropriate for interpreting N $\cdots$ N contacts in crystals.

It should be noted that with only a few exceptions, the dispersion of the values of WR for atoms determined by different authors is small (~ 0.1 Å). It is with this (or even narrower) accuracy that WR are generally determined in experiments.⁷⁶ Therefore, the results discussed in this section can be considered as the demonstration of a new statistical approach to the estimation of these values rather than as yet another attempt to refine WR of atoms. In our opinion, a possible line of further investigation in this field with the use of the CSD can involve analysis of typical intermolecular distances in crystals at different temperatures. It is known that cooling of molecular crystals results in contraction of intermolecular contacts, which is more substantial (up to 0.2 Å) than those of other contacts. Therefore, systematic analysis of these changes in crystals with a decrease in temperature (generally, from room temperature to -100 °C and below) is of special interest.

IV. Principle of close packing in crystals and distribution of molecular centres in crystallographic unit cells

The major principle of organic crystal structures, namely, the principle of close packing, was stated by Kitaigorodskii in 1955.⁷ In recent years, several researchers concerned with computational modelling of crystal packings noted that if calculations were based on the molecular geometry of compounds, several close-packed structures were generally observed, all with packing energies within 5 kJ mol^{-1} of the global minimum.⁷¹ The observed crystal structure is often the one found to coincide with the global minimum, but not always.^{1–4}

Some researchers believe that the principle of close packing contradicts the tendency of molecules to form stable associates in crystals through hydrogen bonds or other specific intermolecular interactions, at least in the case of polyfunctional or bulky and branched molecules.³⁵ On the whole, the problem of *a priori* calculations of a crystal structure of a particular compound is far from an unambiguous solution. However, considerable progress has been observed in this field in recent years. In the recent review,⁴ Gavezzotti noted that nowadays the answer to the question 'Are crystal structures predictable?' would have to be 'Yes, sometimes'. This question was also discussed in detail in another paper.⁶³

The major aim of *a priori* calculations of crystal structures is to search for optimum packings of molecules and/or their associates. In this case, the principle of close packing can provide a basis for these calculations. Therefore, the examination of its applicability with the use of abundant statistical data in the CSD is an urgent problem.

Motherwell³⁴ attempted to find regularities of molecular arrangements in crystalline compounds. He expected to reveal preferred molecular arrangements for the purpose of using the rules found in computational modelling of crystal structures.

First, the most common space groups were revealed. In the 1996 version of the CSD (160 000 structures), 82% of all organic structures encompassed by seven space groups. These are: $P\bar{1}$ (19%), P_2 (6%), P_2/c (35%), $C2/c$ (7%), $P_212_12_1$ (9%), $Pbca$ (4%) and $Pnma$ (2%). Crystal structures belonging to the above-listed groups were retrieved from the CSD with the use of the

QUEST search programme. The selection was restricted to structures with one molecule per asymmetric unit ($Z' = 1$). Disordered and polymeric structures were rejected. An exception was made for the space group $Pnma$, where all molecules have an inherent mirror plane coinciding with the crystallographic plane m . For this study, a selection was made with $Z' = 1/2$.

It was decided to use the coordinates of the molecular geometrical centre as the characteristics of the molecular position. These coordinates were calculated as the average of all atomic coordinates (including hydrogen atoms if present). The molecular centre coordinates were transformed as to place the molecule into the first quarter of the unit cell. The calculations were performed with the use of a modification of the standard programme PLUTO CSD. Then the data obtained were used as input parameters to the statistical display programme VISTA.

The distribution patterns of the molecular centres were displayed as three-dimensional maps, which readily illustrate the cluster character of the distributions. The maps were presented as planar projections onto the coordinate planes and distribution histograms along the coordinate axes.

1. Group $P\bar{1}$

For the group $P\bar{1}$, 967 structures that satisfy the above-mentioned requirements were selected. The results of calculations of the molecular geometrical centres are shown in Fig. 5. In the normalised distribution (*i.e.*, with the coordinates brought into the first quarter of the unit cell; Fig. 5b), the points corresponding to clusters form a distinct cross with the following coordinates of the centre: $x = 0.25$, $y = 0.25$, $z = 0.25$. As expected, in this space group the patterns are very similar for all three projections. The regions of the increased density of the distribution have the coordinates $(x,y) = (0.25, 0.25)$. The regions of the decreased density of the distribution have the coordinates $(x,y) = (x,z) = (y,z) = (0, 0)$, $(0, 0.5)$, $(0.5, 0)$, $(0.5, 0.5)$. The

Figure 5. Distributions of geometrical molecular centres in the group $P\bar{1}$:³⁴ scattergrams for the total unit cell (a); scattergrams adjusted to bring the reference molecule to the first quarter of the unit cell (b); distribution histograms of positions of the geometrical molecular centres along the axes of coordinates of the unit cell (c). Hereinafter N is the number of points.

areas of low population correspond to the positions of the symmetry elements in this space group, *i.e.*, to the centres of symmetry.

Motherwell³⁴ suggested that this distribution pattern of the molecular centres is a graphical illustration of the principle of close packing. Clearly, the molecules cannot occupy inversion centres since asymmetrical molecules, which have no inherent centre of symmetry, were chosen. The reasons why the molecules will tend to 'avoid' regions about the inversion centres are obvious if one considers the location of this molecule between two centres of symmetry at a distance d from each of them. Evidently, the best location of a 'spherical' molecule is halfway between these centres. However, the shapes of real molecules are far from spherical ones and, in addition, the molecules have functional groups which can be involved in specific directional interactions (for example, hydrogen bonds). Nevertheless, judging from the results obtained, a general tendency exists according to which the molecules prefer to occupy the midpoints between centres of symmetry at a distance equal to one-quarter along each coordinate axis.

2. Group $P2_1$

For the group $P2_1$, 1000 structures were selected. To simplify consideration, the projection along the y axis was used as an informative projection. It was established that the molecular centres cluster predominantly halfway between the screw axes $(x,z) = (0.25, 0.25)$ (Fig. 6). In the regions $(x,z) = (0, 0)$, $(1.0, 0.5)$, $(0.5, 0)$, $(0.5, 0.5)$, *i.e.*, on the screw axes, areas of the minimum density of the distribution are observed. This confirms the above-mentioned tendency of molecules to occupy the midpoints between symmetry elements (in this case, between screw axes).

Figure 6. Scattergram (a) and distribution histograms (b) of molecular centres in the group $P2_1$.³⁴

3. Group $P2_1/c$

The group $P2_1/c$ contained 994 structures after elimination of structures with $Z' > 1$. The distribution histogram (Fig. 7) shows

Figure 7. Scattergrams (a) and distribution histograms (b) of molecular centres in the group $P2_1/c$.³⁴

one narrow peak on the axis x . The histograms along the axes y and z have substantially less pronounced peaks with the coordinates $(0.125, 0.375, 0.5)$ and $(0.125, 0.25, 0.375)$. The characteristic feature of the distribution pattern in this group is a broad band of points in the plane defined by $x = 0.25$, which corresponds to positions of molecules along the glide plane. The areas of low population in the plane (x,z) are located at the positions corresponding to the centres of symmetry: $(0, 0)$, $(0, 0.5)$, $(0.5, 0)$, $(0.5, 0.5)$.

4. Group $C2/c$

The sample for the group $C2/c$ consisted of 984 structures. The distribution histograms show pronounced narrow peaks at $x = 0.125$ and 0.375 (Fig. 8). The distribution pattern along the axis y is less distinct but the histogram has a narrow peak at $y = 0.25$. The distribution histogram along the direction z , as well as the histogram along x , have distinct peaks at 0.125 and 0.375 . The distribution patterns consist of narrow bands in the plane xy ($x = 0.125$ and 0.375). It may be noted that there is an obvious increase in the density extending in the direction of the glide plane c and large voids in the regions $(x,z) = (0, 0.25)$ and $(0.5, 0.25)$, which correspond to the positions of rotation twofold axes. This is an expected result because it is obvious that molecules related by rotation axes cannot be closely packed.

Figure 8. Scattergrams (a) and distribution histograms (b) of molecular centres in the group $C2/c$.³⁴

The regions of low population are also observed at the inversion centres, like in other space groups.

5. Group $P2_12_12_1$

The sample for the group $P2_12_12_1$ consisted of 999 structures. The histograms and the distribution densities of molecular centres in the crystal unit cell appeared to be most uniform. The only characteristic feature is the low density along the screw axis parallel to the axis z .

6. Group $Pbca$

The distribution of molecular centres for the group $Pbca$ (999 structures) shows clear maxima on each axis at the positions 0.125 and 0.375 . The points are distributed as distinct bands in all three planes with the coordinates $(0.125, 0.375)$ along each crystal axis. The regions of low population correspond to the positions of centres of symmetry and positions of screw axes. As in the groups $P\bar{1}$ and $P2_12_12_1$, all three directions are equivalent.

7. Group $Pnma$

The distributions of molecular centres for the group $Pnma$ were constructed based on the data on 731 compounds. Since all molecules in this group have a mirror plane, the only informative

distribution histogram is the projection (x, z). This projection has clusters of points in the regions about (0.25, 0) and (0.25, 0.5). However, these clusters are very diffuse. Regions of low population at (0, 0), (0.5, 0) and (0.5, 0.5), which correspond to the centres of symmetry, are better defined.

Let us emphasise again that all the structures considered above were selected regardless of chemical atom types. The distributions of molecular centres were obtained without taking into account hydrogen bonds, electrostatic interactions and the fact that approximately 45% of all the structures under consideration belonged to complex organometallic molecules whose shapes are far from spherical. To exclude possible objections, the distribution patterns of molecular centres were considered for a subset of the $P2_1/c$ sample consisting of hydrocarbons only (126 structures) and no significant difference could be seen in the distribution of molecular centres.

With the aim of analysing the molecular environment in crystals in more detail, an extension was written for the programme PLUTO to display the molecular coordination sphere about the reference molecule according to the approaches of Kitaigorodskii⁷ and Gavezzotti.⁷⁹ The coordination sphere was determined based on calculations of the energy of intermolecular interactions. Only molecules whose energy of interactions with the reference molecule is not lower than 4.18 kJ mol⁻¹ were included in the calculations. The typical coordination numbers of molecules in the CSD were found to be 12–14, which confirmed the suggestion of Kitaigorodskii.⁷ The potential energy was calculated by summing energies of pairwise atom-atomic interactions using Gavezzotti's empirical potential.⁷⁹ The electrostatic term was ignored. Analysis of several hundreds of coordination spheres determined as described above demonstrated that, almost without exception, a close-packed layer of six adjacent molecules can be observed in this coordination sphere. Needless to say that the real situation is far from simple. Many examples can be presented where the molecules form strongly bound dimers or chains. However, in these cases the molecules also tend to form a coordination sphere, which is the nearest to the closest packing of spheres.

Therefore, the distribution histograms of molecular centres in the symmetry groups under consideration show peaks or clusters corresponding to the preferred positions of molecular centres in unit cells. These centres are located halfway between the inversion centres or screw axes in unit cells. The calculations of the energy of intermolecular interactions with the adjacent molecules in the coordination sphere confirmed that these assumptions are energetically justified. It is useful to approximate molecules by spheres to visualise the preferential formation of close-packed layers of molecules and tendencies to close packings of spheres.

V. Relative frequencies of occurrence of space groups

Analysis of relative frequencies of space-group occurrence for the known crystal structures is one of the most evident areas of application of the CSD in studies of general regularities of crystal structures. This analysis is of interest not only from the theoretical, but also from the practical standpoint, because crystal symmetry determines a number of important properties manifested by many crystals. Evidently, the problem of the choice of a particular space group by a molecule is thus currently the most studied.

Kitaigorodskii⁷ was the first to demonstrate that only a few of 230 theoretically plausible groups are of rather frequent occurrence. Examples of crystal structures belonging to other groups are few in number, while certain space groups are 'prohibited'. Among the most populated groups, centrosymmetrical space groups are by far 'favourites'. Kitaigorodskii ascribed this selectivity to the difference in the packing energy of symmetric arrangements of molecules in crystals. On the whole, it was concluded that organic molecules crystallise preferentially in

space groups (SG) that can ensure the close packing of spheres or tri-axial ellipsoids (which are most commonly used as approximations for organic molecules). In this respect, the groups $P2_1/c$ and $P\bar{1}$ were assigned to most convenient.

More recently, Belsky and Zorky^{40, 51, 52, 80} published a series of papers in which the most populated space groups were established based on a rather large body of data.^{9, 10} It appeared that there are only 9 such groups, viz., $P2_1/c$, $P\bar{1}$, $P1$, $P2_1$, $P2_12_12_1$, $Pbca$, $C2/c$, $Pna2_1$ and $Pnma$. They account for 79.2% of all the structures known at that time. The results obtained demonstrated that organic molecules actually crystallise preferentially in centrosymmetrical SG. Over 50% of all known organic structures belong to only two space groups, viz., $P2_1/c$ and $P\bar{1}$. In addition, it was noted that the inherent molecular symmetry and the number of crystallographic orbits occupied by molecules must be taken into account.

More than a dozen of recent publications were devoted to studies of the relative frequencies of occurrence of SG for both organic (Wilson,^{36–39} Padmaja *et al.*,⁴¹ Belsky *et al.*,^{42, 81} Mighell *et al.*,^{44, 82} and Brock and Dunitz⁴⁵) and inorganic (Mackay,⁴³ Mighell *et al.*,^{44, 82} and Baur and Kassner⁸³) crystals based on statistically reliable data using computer databases.

All authors noted the prevailing occurrence of centrosymmetrical SG. However, the frequency of occurrence of these groups for organic compounds reported in different works varies from 66% to 75%. Among inorganic compounds (Inorganic Crystal Structure Database, 1992), this frequency is, on the average, even higher (78%). Proteins and other natural polymers consisting of pure enantiomeric molecules are the exceptions, where chiral SG prevail.⁴¹

Note that the preference of a particular SG (centrosymmetrical or noncentrosymmetrical) for a molecule is of exceptional importance from the practical standpoint to researchers involved in the design of new organic materials. In particular, compounds that can possess nonlinear-optical properties and are potentially able to generate the second harmonic of laser radiation crystallise most often in centrosymmetrical SG excluding the manifestation of the above-mentioned properties in crystals. Below we dwell on works aimed at establishing the reasons why the majority of organic molecules tend to crystallise in centrosymmetrical SG.

The preferential occurrence of centrosymmetrical SG may be only indicative of the fact that organic compounds can exist as racemic mixtures of enantiomers rather than reflects the fact that these SG are energetically more favourable. Strictly speaking, to determine correctly the actual frequency of occurrence of SG it is necessary to know whether the crystals were obtained from a solution of a pure enantiomer, from a mixture of enantiomers or from a solution of an achiral compound. The great majority of crystals were grown from mixtures of enantiomers. Therefore, it is not surprising that they belong to centrosymmetrical SG. If this is the case, the problem of the preparation of noncentrosymmetrical materials can be reduced to the problem of spontaneous resolution of enantiomers or to the development of procedures for their forced resolution. It was noted⁵² that in recent years the number of noncentrosymmetrical groups in the CSD increased somewhat, which may be indicative of an increase in the number of the natural compounds and products of the stereoselective synthesis studied.⁸

For the crystalline compounds studied to date, virtually all 230 possible space groups are observed, except for 7 groups for inorganic compounds and 28 groups for organic and organometallic compounds.⁸³ This fact can be considered as the experimental corroboration of the Kitaigorodskii theory. However, as for their frequency of occurrence, only certain of space groups are

§ This example provides further evidence that care is required in the data rejection and sample creation. Even a very large body of structural data does not necessarily assure that the statistical characteristics or property is reliable.

Table 3. Distribution of organic crystals among space groups.⁴²

Number	SG	<i>m</i>	<i>n</i> (%)
1	<i>P2₁/c</i>	7634	37.97
2	<i>P2₁2₁2₁</i>	3052	15.18
3	<i>P1</i>	2658	13.22
4	<i>P2₁</i>	1684	8.38
5	<i>C2/c</i>	1149	5.71
6	<i>Pbca</i>	998	4.96
7	<i>Pna2₁</i>	414	2.06
8	<i>Pnma</i>	257	1.28
9	<i>Pca2₁</i>	199	1.00

Note. The following notations are used: SG is the space group; *m* is the number of structures belonging to a particular SG; *n* is the ratio between structures belonging to a particular SG and the total number of the structures under consideration.

rather populated.^{7,80} Only a few examples of the remaining groups are available.

Thus only 18 most 'popular' (according to Baur and Kassner⁸³) space groups account for 92.71% of all known structures of organic compounds. Belsky⁴² has distinguished 9 most frequently occurring groups, which account for 89.8% of all compounds. The nine groups mentioned by Belsky (Tables 3 and 4) enter into 18 groups of Baur (Fig. 9).

Table 4. Distribution of organic crystals among crystal systems.⁴²

System	<i>m</i>	<i>n</i> (%)
Triclinic	2823	14.04
Monoclinic	11061	55.01
Orthorhombic	5563	27.67
Tetragonal	360	1.79
Hexagonal	268	1.33
Cubic	32	0.16

Note. The following notations are used: *m* is the number of structures belonging to a particular crystal system; *n* is the ratio between structures belonging to a particular system and the total number of structures under consideration.

For inorganic compounds, Baur has also distinguished 18 most frequently occurring groups. However, these groups account for only 56.86% of all structures. The distribution histogram of space groups for inorganic compounds is more shallow than that observed for organic compounds (see Fig. 9). In the case of inorganic compounds, it is more difficult to reveal 'leading' group. The dominant space groups for organic and inorganic compounds are also substantially different in spite of the above-mentioned common predominance of centrosymmetrical SG. The most substantial difference is that inorganic compounds crystallise in higher-symmetry space groups, namely, in trigonal, tetragonal, hexagonal and cubic systems. Thus 31.58% of the total number of inorganic compounds crystallise in groups belonging to the symmetry classes *3m*, *4/mmm*, *6/mmm* and *m3m*. Only 0.63% of organic compounds belong to the above-listed groups.

According to the data reported by Brock and Dunitz,⁴⁵ in the case of protein and polymeric structures, the tetragonal and trigonal systems are also more abundant (13% and 16%, respectively) than in chiral crystals of organic compounds (3% and 2%, respectively). The groups *C2* and *C222₁* in the Protein Data Bank account for 13% and 5% of structures, respectively, while these groups in the CSD (for chiral crystals) account for only 4% and 1% of structures, respectively. The populated SG of

**Figure 9.** Most populated space groups for organic (a) and inorganic (b) crystal structures (in percent of the total number of structures).⁸³

organic compounds belong exclusively (95.38%) to triclinic, monoclinic and orthorhombic systems (Fig. 10). These crystal systems account for only 48.92% of inorganic compounds. Thus the distribution of inorganic compounds is more diversified.

**Figure 10.** Distributions of frequencies of abundance of crystals of organic and inorganic compounds over classes of point symmetry (a) and crystal systems (b).⁸³

Among the above-listed 18 most frequently occurring SG of inorganic compounds, all crystal systems are present (see Fig. 10).

The majority of organic molecules crystallise in low-symmetry space groups, while the majority of elements, intermetallic compounds and inorganic salts crystallise in high-symmetry groups. However, this does not imply that the packing rules for these compounds are different. The difference in structure is most likely determined by the shape of the initial structural unit as well as by the presence or absence of strong long-range electrostatic interactions. For inorganic compounds, the structural units are most often nearly spherical atoms or ions as well as octahedral or tetrahedral fragments. That is the reason that a large number of inorganic compounds crystallise in high-symmetry groups. The vast majority of organic compounds archived in the CSD consist of low-symmetry electroneutral molecules. Therefore, it is not surprising that organic compounds crystallise predominantly in low-symmetry groups.

Presently, it is generally agreed that the molecular shape affects the symmetry of the crystal structure formed.^{38,39,45,84} When estimating the frequency of occurrence of SG, this fact must be taken into account. Brock and Dunitz,⁴⁵ like Kitaigorodskii,⁷ exemplified this fact by crystals of molecules possessing inherent symmetry elements, namely, a twofold rotation axis (2) and a mirror plane (*m*). In spite of the obvious fact that these elements are unfavourable,⁷ space groups containing the plane *m* are rather frequent, which is exclusively due to molecules possessing the inherent symmetry *m*. The plane *m* in the corresponding SG is virtually always 'occupied'. If molecules possessing the inherent mirror symmetry are excluded from consideration, the distribution pattern of space groups is changed (the above-mentioned group *Pnma* no longer belongs to abundant groups). In a half of the cases, a twofold rotation axis is occupied and in the remaining cases, it is free. In the latter case (for chiral molecules), this axis plays the same role as an inversion centre in the case of a racemic pair, namely, stable dimers are formed due to a twofold axis. Concave-shaped protein molecules often consist of such dimers, which allows them to be closely packed. Apparently, for this reason space groups containing a twofold axis occur more frequently in the Protein Data Bank than in the CSD.⁴¹

From the analysis of the frequency of occurrence of space groups for organic crystals in the CSD, Brock and Dunitz⁴⁵ found what symmetry elements are relatively more favourable. Thus it appeared that the screw axis 2₁ is much more favourable than the simple translation or the screw axes of higher orders. It is generally believed⁷ that the axis 2₁ is favoured over the glide plane, which, in turn, is favoured over the translation. However, Brock and Dunitz believe that glide planes play the same role as translations in organisation of crystal structures. This conclusion is not quite without doubt, because the translation is a symmetry element of the first kind under the action of which the chirality of the molecule is retained, while the glide plane is a symmetry element of the second kind, which inverts the chirality. Therefore, it may be that comparisons were carried out based on different classes of compounds, which is not quite correct.

The number of formula units per asymmetric unit (*Z'*) (the number of occupied orbits) is yet another important characteristics necessary for analysing the frequency of occurrence of space groups. Belsky and Zorky, who developed the concept of structural classes,^{51,80} were the first to note the importance of the consideration of *Z'*. Recently, other authors also pointed to the importance of account of this parameter. Padmaja *et al.*⁴¹ found that structures with *Z'* > 1 belong predominantly to low-symmetry crystal systems (particularly often, to the group *P1*). Analysis of the results obtained by Brock and Dunitz with the use of the 1991 version of the CSD⁴⁵ confirmed the above conclusions. It appeared that the overall number of structures with *Z'* > 1 in the most populated chiral groups is larger than in the corresponding centrosymmetrical groups:

<i>n_{Z'}</i> > 1, %	45.0	14.0	11.2	4.5	11.3	5.7	3.0	3.0

Brock and Dunitz suggested that many acentric crystals with *Z'* > 1 are actually pseudosymmetrical structures. First sampling tests demonstrated that of 55 of a total of 256 structures with *Z'* > 2 belonging to the group *P2*₁ can be described by the pseudogroup *P2*₁/*c*. The pseudosymmetry elements $\bar{1}$, 2, 2₁ and *t* are most often observed in the above structural type. The phenomenon of pseudosymmetry and problems associated with this effect are discussed below in more detail.

VI. Why do organic crystals prefer centrosymmetrical groups?

1. The effect of molecular dipoles on the crystal-packing organisation

Whitsell and coworkers⁴⁹ were among the first to perform studies aimed at elucidating the reasons for the preferential occurrence of centrosymmetrical packings with the use of the CSD. The authors attempted to verify the thesis that molecules with large dipole moments crystallise preferentially in centrosymmetrical space groups. This concept is commonly accepted by researchers involved in studies of nonlinear optics of molecular crystals.^{46,47} It is based on simple inferences that the role of the electrostatic component in stabilisation of the crystal structure increases in the case of the antiparallel arrangement of molecular dipoles, which ultimately leads to the formation of centrosymmetrical crystals.

As early as 1955, Kitaigorodskii⁷ noted that electrostatic interactions (in the dipole–dipole approximation) must be taken into account for crystals of strongly polar molecules. However, recent calculations performed by Gavezzotti and Filippini^{85,86} for small molecules containing C=O and N≡C groups demonstrated that dipole-dipole interactions make only an insignificant contribution to the total energy of crystal stabilisation.

In the estimation of the role of the molecular dipole moment in the crystal symmetry, it was suggested⁴⁹ that if the antiparallel orientation of molecules with large dipole moments is preferable, the number of crystals containing such molecules should be substantially larger among centrosymmetrical crystal structures than among noncentrosymmetrical structures.

This suggestion was verified when crystal structures belonging to three space groups (*P* $\bar{1}$, *P1* and *P2*₁) were retrieved from the CSD (1994 version). Typical schemes of the molecular arrangements in these groups are shown in Fig. 11. In the group *P1*, all molecular dipoles are parallel to each other due to the absence of symmetry operations other than translations *t*. Therefore, the average dipole moment of the crystal is determined by the sum of all molecular dipole moments. In the group *P* $\bar{1}$, an antiparallel neighbour corresponds to each molecular dipole and the total dipole moment is equal to zero. In the group *P2*₁, pairs of molecules are related by a combination of rotation and translation operations and the value of the structural dipole should depend on the orientation of the molecular dipole relative to the screw axis (angle θ). Since the experimental data on molecular dipole moments (μ) are scarce, these values for a large series of

Group	<i>P1</i>	<i>P2</i> ₁	<i>C2</i>	<i>P2</i> ₁ 2 ₁	<i>P</i> $\bar{1}$	<i>P2</i> ₁ / <i>c</i>	<i>C2</i> / <i>c</i>	<i>Pbca</i>

compounds were calculated using the AMPAC programme with the AM1 parameterisation.⁸⁷

Crystal structures in the CSD were chosen so that the values of μ could be correctly calculated within the framework of the above-mentioned approximation. Therefore, when statistical samples for the three above-listed space groups were created, the following objects were rejected: (1) compounds in which d -orbital interactions can occur; (2) organometallic ionic and polymeric structures; (3) structures containing molecules of solvation; (4) structures in which molecules occupy several systems of equivalent positions and (5) structures in which molecules form strong hydrogen bonds (*i.e.*, compounds containing OH or NH groups). As a result, a

<i>P</i> 2 ₁	179	3.14	0.15	3.04

Note. The following notations are used: *n* is the number of structures under consideration; σ is the error of calculation of μ ; $\bar{\mu}$ is the value of the dipole moment for the midpoint of the distribution.

total of 28, 161 (out of 1229) and 179 (out of 722) examples were selected in the groups *P*1, $\bar{P}$ 1 and *P*2₁, respectively.

The results obtained in the work⁴⁹ are presented in Table 5 and in the histograms (Fig. 12). It can be seen that the average molecular dipole moments in centrosymmetrical and noncentrosymmetrical SG are virtually identical within the rather small dispersion. No statistically reliable correlation was observed between the dipole moments of molecules and their orientations relative to the polar direction in the group *P*2₁. Hence, the molecular dipole moment is not the governing factor in choosing the space group and does not account for the observed predominance of racemic space groups over chiral groups. However, some effects, such as hydrogen bonds, specific interactions of polar groups and the shape of the molecule, can affect the crystal packing. Apparently, interactions of molecular dipoles play an important role at large distances. In crystals, adjacent molecules are located at distances comparable with their dimensions. Moreover, dimensions of the majority of molecules are substantially larger than the shortest distances between them. Therefore, it is hardly probable that attempts to construct the molecular packing

Figure 12. Distribution histograms for molecular dipole moments in the space groups *P*1 (a), $\bar{P}$ 1 (b), and *P*2₁ (c).⁴⁹

based primarily on the consideration of total molecular dipole moments will succeed.

2. Density and stability of racemic crystals and their chiral counterparts

The commonly accepted postulate that explains the preference of centrosymmetrical crystals is known as Wallach's rule.⁸⁸ According to this rule, racemic crystals tend to be denser than their chiral counterparts.

The question of whether molecules in racemic crystals are packed more closely than in the corresponding chiral crystals has been a subject of speculations since 1895.⁸⁸ This question has in essence two aspects:⁸⁹ are racemic crystals generally more stable than their chiral counterparts and is this greater stability reflected in a larger density of racemic crystals?

Wallach has deduced his rule by considering 8 chiral–racemic pairs, and only one of these pairs was an exception. More recently, Jacques, Collet and Wilen⁸⁹ considered 12 corresponding pairs and found 4 exceptions to Wallach's rule. The improved accuracy of determination of X-ray densities ($\sim 0.15\%$) made it possible more correctly to verify the validity of Wallach's rule. Mason⁹⁰ was the first to perform this verification. He analysed 14 pairs of compounds and found 9 exceptions to Wallach's rule. Apparently, only statistical analysis of a large sample can provide a reliable answer to the above question.

For this purpose, Brock and coworkers⁵⁰ used the CSD (1989 version). The authors created two files. The first file contained data on only noncentrosymmetrical groups ($\sim 25\%$ instances). The second file contained data on only racemic groups ($\sim 75\%$ instances). The data of the files were sorted according to chemical compositions of compounds and compared. The sets of structures having the same chemical composition were considered as potential objects of investigation. In several instances, compounds filed in the CSD under the same code turned out to be diastereomers. In this case, they were excluded from consideration. Particular attention was given to the problem of ambiguities of space-group determination. The space groups differing only by the presence or absence of an inversion centre were subjected to special scrutiny. For each pair, the relative differences between the densities of racemic (D_r) and chiral (D_c) crystals were calculated as follows:

$$\Delta D = \frac{100(D_r - D_c)}{0.5(D_r + D_c)}.$$

The final list contained 129 pairs. This number of examples was insufficient to obtain the smooth distribution (the shape of the histogram depends on the choice of the bin size and boundaries). Thus, the authors presented two variants of distributions of the values of ΔD , which differ by the choice of the initial boundaries (Fig. 13). In spite of the differences, both distributions exhibit a pronounced bimodal character. The average value of ΔD for 129

Figure 13. Distribution histogram for the values ΔD for 129 chiral–racemic pairs of the structures under study (two variants of the choice of the initial bin size are given).⁵⁰

pairs was 0.56%. However, this value is too small to confirm the rule, but it is too large to demolish it.

Taking into account the bimodality of the ΔD distribution, the authors attempted to divide the selected objects into two groups. One way of dividing objects is to separate pairs which are polymorphic modifications. An alternative way is to separate pairs which are not polymorphs. This separation was carried out according to the definition of polymorphs suggested by McCrone.⁹¹ According to McCrone, polymorphs are different solids that give the same liquid upon melting or dissolution. Therefore, crystal pairs of the first group (polymorphic modifications) contain either achiral molecules or chiral molecules that can rapidly undergo racemisation in solutions. Crystal pairs of the second group consist of enantiomers that can be readily resolved

Figure 14. Distribution histograms for the values ΔD for 64 pairs of structures of the first group (enantiomers that can be rapidly interconverted, achiral compounds) (a) and for 65 pairs of the structures of the second group (enantiomers that can be resolved) (b).⁵⁰

(consequently, they are difficultly interconvertible).

For 64 pairs of the objects of the first group, the average value of ΔD was *ca.* +0.20% (Fig. 14a). Consequently, a comparison of polymorphic pairs showed no noticeable difference between the packing densities of racemic and chiral crystals.

The average ΔD value for the second group of objects consisting of 65 pairs was +0.92% (Fig. 14b). The packing densities of racemic crystals of the second group are, on the average, $\sim 1\%$ higher than those of their chiral counterparts. Therefore, it was concluded that Wallach's rule is apparently valid only for enantiomers that can be resolved.⁵⁰

It is not inconceivable that the difference in the average values of ΔD for the groups of crystals under consideration is due to different initial conditions of crystallisation. Compounds of the first group are always crystallised from solutions of achiral compounds or mixtures of enantiomers, while compounds of the second group are crystallised from solutions of both enantiomeric mixtures and pure enantiomers.

Crystallisation of compounds of the first group from solutions depends on the relative stability of possible solid phases and sometimes affords several crystal forms. Evidently, the stabilities of these forms should be approximately equal. Enthalpies of polymorphic modifications rarely differ by more than 1 kcal mol⁻¹. Therefore, it is hardly probable that less stable modifications of compounds of the first group will be obtained.

For compounds of the second group, the situation is quite different. Racemic solutions may yield racemic crystals, racemic conglomerates of chiral crystals or mixtures of both types depending on their relative stability. In contrast, crystals obtained from enantiomerically pure solutions must be chiral. Therefore, chiral crystals can be obtained even if they are thermodynamically much less stable than the racemic crystals. This implies that the second group of compounds is statistically biased. Thus, pairs in which racemic crystals are energetically more favourable can be more

frequent in the second group than in the first one. This is reflected in different distributions of ΔD .

Jacques and coworkers⁸⁹ compared thermodynamic characteristics of the melting process for 36 pairs of chiral and racemic crystals belonging to the second group. The average values of such characteristics as ΔH , ΔS and ΔT are 7.54 kcal mol⁻¹, 18.5 kcal mol⁻¹ K⁻¹ and 405 K for racemic crystals and 6.28 kcal mol⁻¹, 15.7 kcal mol⁻¹ K⁻¹ and 395 K for chiral crystals. Based on these data, the authors concluded that racemic crystals are thermodynamically more stable than chiral crystals.

However, it is hardly reasonable to consider this conclusion to be the general rule because the statistical data (in particular, the thermodynamic characteristics) are still scarce. It is quite probable that racemic crystals appear to be more stable because pairs in which they are less stable are absent only among compounds that have already been studied rather than among naturally occurring compounds.

Therefore, statistically reliable evidence for the higher density and thermodynamic stability of racemic crystals compared to their chiral counterparts has not yet been found.

3. Comparison of thermodynamic characteristics of polymorphic modification of organic crystals

The phenomenon of polymorphism in organic crystal structures has long been known. Such aspects as thermodynamic stability, pharmaceutical properties of polymorphs, conformational polymorphism, *etc.* have been studied in considerable detail.^{4, 92–98} Unfortunately, the data available in the literature are primarily descriptive and each instance of polymorphism was considered by itself. Accumulation of a large body of structural data on polymorphic modifications (PM) in the CSD brought systematic statistical studies in this field to reality. The existence of polymorphs is still a headache problem for scientists involved in computational modelling of molecular packings. However, it is evident that due to the constancy of the chemical composition in polymorphic pairs (triads, *etc.*) these systems can serve as a potential source of detailed information on the structure–property relationship in organic solids because in this case the difference in the physical properties can be explained by the difference in their structural organisations.

The first investigation devoted to this problem was performed by Gavezzotti and Filippini.³ The authors compared the thermodynamic and structural characteristics of the polymorphs available in the 1993 version of the CSD. They selected only objects which were studied at room temperature, had more than one polymorphic modification and consisted of C, H, N, O, Cl and S atoms. A total of 163 compounds which satisfy these requirements were found, 147 of them with two, 13 with three and three with four polymorphic modifications. A total of 345 crystal structures were found.

For these polymorphic modifications, thermodynamic characteristics of crystals were calculated according to procedures reported in the Refs 3, 86, 99 and 100. The parameters for the 6-exp potential function for intermolecular interactions were chosen^{98, 100} so as to reproduce the values of thermodynamic characteristics at room temperature. Generally, the calculated values of thermodynamic characteristics agree, at best, only qualitatively with the experimental values (due to an inaccuracy of both calculated and experimental values). Nevertheless, the regularities found by the authors can be considered as justified because possible inaccuracies affect in the same manner the results of calculations for both forms, while the differences between the calculated values used by the authors are free from errors.

The polymorphic pairs of compounds were placed in order of decreasing density. Therefore, the differences between the densities ΔD for polymorphic modifications are positive by definition. The differences (%) in the other properties (*P*) were determined as follows:

$$\Delta P = \frac{100(P_i - P_j)}{P_j}, \quad j > i.$$

The total number of points was 204. The following parameters P were calculated: D , the crystal density; V , the molecular volume; K , Kitaigorodskii's packing coefficient; E , the packing energy; S , the lattice-vibrational entropy; G , the lattice free energy, and Z' , the number of molecules per asymmetric unit.

The ΔD , ΔE , ΔS and $\Delta Z'$ distribution histograms are shown in Fig. 15. It appeared that the difference in the density between polymorphs is small and seldom exceeds a few percent. Thus 93%

Figure 15. Distribution histograms for the packing energy ΔE (a), ΔD (b), ΔS (c), and $\Delta Z'$ (d).³

of the values of ΔD are smaller than 5%, which confirms the results reported in the work.⁵⁰ This implies that molecules can be packed in different fashions, but, apparently, not at the expense of a decrease in compactness. Cases with $\Delta D > 7\%$ occur either due to inaccuracy in determination of atomic coordinates or to large conformational differences in the molecules.

Similar conclusions are drawn by examination of the ΔE histograms: the packing energies of PM are generally close. A few exceptions can be attributed to the structural disorder or to inaccurate positioning of some key atoms of the system. The differences in the lattice entropies ΔS between polymorphs in pairs are also very small (see Fig. 15).

Thus the density, packing energy and lattice entropy for a polymorphic pair have close values. The results on the number of molecules per asymmetric unit (Z') are unexpected: 62 structures (18% of the pairs selected) have $Z' > 1$ [this value is substantially higher than the overall percentage in the CSD (8.3%)] and 46 compounds (28%) of 163 compounds selected have modifications with different values of Z' .

The authors considered also possible relationships between the calculated values (bivariate statistics). The dependence of ΔD on ΔE (Fig. 16a) demonstrates that in most cases higher packing energy is accompanied by higher density. The existence of crystal structures with high energies and low packing densities can be attributed to the presence of exceptionally strong and directional hydrogen bonds in a crystal. In all cases under consideration, the differences in the free energies ΔG between polymorphs in pairs have the same sign as the differences in the packing energies ΔE (Fig. 16b). As expected, the higher the density the lower the entropy (Fig. 16c). These results demonstrate that higher crystal

Figure 16. Relationships between ΔE and densities ΔD (a), ΔG and enthalpies ΔH (b), ΔS and ΔD (c), and $\Delta Z'$ and ΔE (d).³

density corresponds to higher packing energy and lower vibrational entropy.

The dependence of $\Delta Z'$ on ΔE is shown in Fig. 16c. The structures with $Z' > 1$ are more stable in ~ 50% of the occurrences. Hence, the presence of more than one molecule per asymmetric unit does not lead to a decrease in the stability of a crystal.

Therefore, the knowledge of thermodynamic characteristics of polymorphs existing at room temperature is insufficient for explanation of their relative stability because the differences in these characteristics are generally small. Thus, it is useful to analyse molecular-packing symmetry to gain insight into the ways of formation of crystal structures in different polymorphic modifications.

The space group remains the same for 28% of the polymorphic pairs under consideration; 82% of all structures belong to the group $P2_1/c$ and the remaining 18% of the structures are distributed among the groups $P\bar{1}$, $Pbca$, $C2/c$ and $P2_12_12_1$. The greatest number of plausible arrangements of the same molecule was observed for organic crystals belonging to the group $P2_1/c$.

As mentioned above, one of polymorphic forms often has $Z' > 1$. Although a detailed analysis of such cases has not been performed, preliminary consideration of the data revealed instances in which molecules in the asymmetric unit are related by pseudosymmetry operations. A detailed examination of pseudosymmetry relations in crystals will allow one to 'visualise' possible ways of formation of crystal structures, which have not been realised.

The authors also noted that in 20 polymorphic pairs (24%) the molecules decide between centrosymmetrical and noncentrosymmetrical space groups. Ten pairs $P2_1/c - P2_12_12_1$, six pairs $P2_1/c - P2_1$, four pairs $P2_1/c - Pc$ and four pairs $P2_1/c - Pna2_1$ were found.

Comparison of thermodynamic characteristics of the polymorphs did not allow the authors of the works cited (Refs 3, 49 and 50) to reach definite conclusions about regularities of organisation of crystal structures. However, although the analysis of structural regularities in polymorphic modifications did not provide answers to the problems under considerations, it doubtlessly made it possible to mark the route and develop a strategy of further investigations in this field.

Figure 17. Molecular structure of 2,6-dimethyl-4-(diphenylmethylene)cyclohexa-2,5-dienone (DMFUSC).^{101, 102}

We attempted to search for PM containing chiral–racemic partners in the 1996 version of the CSD. A total of 102 such pairs were found. The same distribution pattern of chiral and racemic modifications was observed: 45 pairs (44.1%) $P2_1/c - P2_12_12_1$, 17 pairs (16.7%) $P2_1/c - P2_1$, 14 pairs (13.6%) $P2_1/c - Pna2_1$, 10 pairs (9.8%) $P2_1/c - Pc$, 3 pairs (2.9%) $P2_1/c - P\bar{1}$, 7 pairs (6.9%) $P\bar{1} - P2_12_12_1$, 2 pairs (2.0%) $P\bar{1} - P2_1$, 2 pairs (2.0%) $P\bar{1} - Pc$ and 2 pairs (2.0%) $P\bar{1} - Pna2_1$. We hope to reveal reasons for the preferential occurrence of these chiral–racemic pairs from a detailed analysis of structures of these polymorphic modifications.

Let us offer an example of a typical situation for the $P2_1/c - P2_12_12_1$ pair. In the case of 2,6-dimethyl-4-(diphenylmethylene)cyclohexa-2,5-dienone^{101, 102} (DMFUSC),[†] the molecules adopt identical conformations in both polymorphic modifications. The chirality in the molecule (Fig. 17) is determined by the difference in the rotation of the phenyl rings. In solutions, both enantiomeric forms are present due to rotation of the rings. In both crystals, molecules of one enantiomeric form are packed in identical layers (Fig. 18). The adjacent layers in the β form ($P2_12_12_1$) are stacked in a congruent fashion, while in the α form ($P2_1/c$) the adjacent layers are related by centres of symmetry. The $\alpha - \beta$ phase transition was observed at 383 K. Therefore, in this case two polymorphic modifications exist due to different modes of packing of layers and the enantiomeric forms readily undergo interconversion with a small consumption of energy. Analogous

Figure 18. Structure of the layer in the orthorhombic modification of DMFUSC (projection onto the $xy0$ plane). The layer in the monoclinic modification has an analogous structure.

situations were observed in di(1-piperidyl) disulfide¹⁰³ (DPIPDS),[‡] *o*-chlorobenzamide¹⁰⁴ (CLBZAM),[‡] *m*-nitrophenol^{105, 106} (MNPOL),[‡] and bis(trimethylbenzylammonium) tetrachlorocuprate(II)¹⁰⁷ (MBAMCC).[‡] These compounds can be assigned to the first group, *i.e.*, they are enantiomers that interconvert rapidly.

VII. Number of molecules per asymmetric unit and pseudosymmetry

As mentioned above in the section devoted to the relative frequency of occurrence of space groups, the increasing attention is paid to crystal-chemical analysis of structures with $Z' > 1$. Several computer programmes have already been developed for revealing pseudosymmetry in such crystal structures.^{108, 109} These programmes were devised originally for revealing improper symmetry in structural studies and therefore they treat pseudosymmetry as a ‘negative factor’. The main purpose of these programmes is to determine deviations of atoms from certain ideal symmetry positions, which imply that some symmetry operations were missing in the course of determination of crystal symmetry.

Initially, when only a few instances of crystals containing two independent molecules per asymmetric unit were known, researchers pinned hopes on comparison of their conformations and molecular geometry. This approach seemed to be very promising for studying the effect of crystal environment on molecular structure. However, expectations were not realised completely because such structures remained for long few in number.

Studies of noncrystallographic (pseudosymmetrical) symmetry operations that related independent molecules in crystals have attracted growing interest as the corresponding structural data has been accumulated.^{45, 53, 54} Analysis of the data in the 1991 version of the CSD demonstrated that in 27% of structures with $Z' > 1$, the molecules are related by approximate pseudosymmetry elements $\bar{1}$, 2, 2_1 and t (translation), *i.e.*, by elements which are also present most often in space groups of crystals.[†] Undoubtedly, a pseudocentre of symmetry is the most frequently occurring element.

In the next stage, relationships between space groups describing the crystal symmetry and pseudosymmetry transformations were searched for. The symmetry of real crystals often appeared to be a symmetry subgroup of a certain ‘hypothetical’ crystal. It is derived by ‘eliminating’ the corresponding symmetry element (which becomes a pseudoelement) from the symmetry group of the hypothetical crystal. Thus, Brock and Dunitz⁴⁵ found 256 crystals belonging to the group $P2_1$ with $Z' = 2$ in the 1989 version of the CSD of which 55 crystal structures contain an inversion pseudocentre and are described by the symmetry pseudogroup $P2_1/c$. It was suggested that the great majority of structures with $Z' > 1$ belonging to the group $P1$ are actually pseudosymmetrical structures.

The application of the CSD made it possible to reveal also some other statistical regularities. Padmaja *et al.*⁴¹ noted that structures with $Z' > 1$ are substantially more frequent in low-symmetry crystal systems (especially in the group $P1$). These results were confirmed.⁴⁵ It was demonstrated that structures with $Z' > 1$ are, on the whole, more abundant in chiral groups than in the corresponding centrosymmetrical groups (see Section IV). Certain preliminary conclusions were made about classes of chemical compounds for which structures with $Z' > 1$ are most often realised. In particular, ~40% of crystals of aliphatic alcohols in the CSD have $Z' > 1$. Craven¹¹⁰ noted that in ~50% of crystals of cholesterol derivatives, $Z' > 1$.

We performed sampling of structures of 3- and 4-hydroxy derivatives of hydropyridine in the 1996 version of the CSD. A total of 320 structures were found of which 21% instances have

[†] The reference code of the compound in the CSD.

[‡] R Davies and A Willer (private communication; see Ref. 45).

Figure 19. Projection of the crystal structure of 3,4-dihydroxy-1-methyl-2-oxo-4-phenylpiperidine onto the $x0z$ plane (a) and the hypothetical crystal structure obtained by shifting pseudosymmetrical chains in the crystal (b).¹¹¹

$Z' > 1$. Apparently, for all classes of compounds containing hydroxy groups there is a high probability of formation of crystals with $Z' > 1$. It is known that compounds containing hydroxy groups form stable associates in crystals through hydrogen bonds. It can be assumed that these associates are present even in the initial mother liquor from which crystals are grown. Thus single crystals can be formed from associates rather than from isolated molecules. The packing of associates does not necessarily lead to the optimum symmetry due to insignificant shifts required for closer packing.

Let us exemplify the aforesaid by the crystal structure of 3,4-dihydroxy-1-methyl-2-oxo-4-phenylpiperidine,¹¹¹ which crystallised in the space group $Pca2_1$, $Z' = 2$. Two independent molecules are linked in a pseudocentrosymmetrical dimer through hydrogen bonds. These dimers are linked in infinite chains through hydrogen bonds, and the crystal structure as a whole is formed from these layers (Fig. 19a). This noncentrosymmetrical structure can be transformed into the centrosymmetrical one (symmetry $Pbcn$) by slightly shifting the chains with respect to each other. The shift is equal to ~ 1.5 Å. The pseudocentrosymmetrical dimers can be seen in Fig. 19a. Chains formed in the structure through hydrogen bonds are located perpendicular to the plane of the paper. The hypothetical crystal structure and the molecular arrangement are shown in Fig. 19b. It can be seen that the shift of chains in the real crystal with respect to each other leads to a closer packing.

The probability of the detection of $Z' > 1$ and consequently, of the presence of pseudosymmetry is also very high for crystals of mesogenic compounds, which are solid-crystalline precursors of liquid crystals (among them are cholesterol derivatives).¹¹⁰ It is known that mesogenic compounds are prone to aggregation in the liquid state, which does not necessarily occur through hydrogen bonding. For example, in four of eight crystal structures of cholesteryl benzoate derivatives, which do not form intermolecular hydrogen bonds,⁵⁸ $Z' > 1$. Calculations of the energy of intermolecular interactions demonstrated that molecules are packed in crystals in a layered-stacked fashion and the strongest interactions occur between molecules related either by screw axes or by translations along the stack axis. The existence of this energy-distinguishable direction is very important because weaker interactions between layers and stacks are primarily weakened when passing to the mesophase. In this case, shifts of stacks with respect to each other as well as slight mutual rotations of adjacent molecules in stacks about stack axes become possible. Rotations result in the appearance of a supramolecular structure twisted about the stack direction. This structural feature emphasises the

role of screw axes in cholesterogenic crystals. The results reported in the work⁵⁸ suggested that a genetic relationship exists between crystalline and liquid-crystalline structures and can provide the basis for further systematic studies with the use of the CSD data aimed at the design of new compounds potentially exhibiting liquid-crystalline properties.

Interestingly, at least one polymorphic form often has $Z' > 1$. The overall percentage of structures with $Z' > 1$ in the CSD is 8.3%, while twice as many such structures are observed among polymorphic modifications (16%).³ Thus, the presence of more than one independent molecule per asymmetric unit may indicate that several different crystal packings can exist.

The existence of pseudosymmetry in a particular crystal structure is an indication that a distorted higher-symmetry structure can exist. Based on this fact, Abrahams^{53, 54} suggested that if this distortion is rather small, the crystal structure would be expected to become more symmetrical at higher temperature as a result of phase transition. Recall that in the cases of phase transitions of the first and second kinds, the crystal symmetry changes abruptly at the transition point. In the case of phase transitions of the first kind, a correlation between the structures of the initial and newly formed phases can be either present or absent. The characteristic feature of phase transitions of the second kind is that the symmetry group of the low-symmetry phase is a subgroup of the symmetry group of the other phase, because only some symmetry elements disappear as a result of displacements of atoms, while other elements persist. It is the latter that form a subgroup. A higher-symmetry phase corresponds, as a rule, to the high-temperature modification. These reasonings provided the basis for a procedure proposed by Abrahams for a search for new crystals possessing ferroelectric properties in the crystallographic databases. This method is based on the analysis of the available structural data. The ferroelectric phase transition is accompanied by loss of an inversion centre, a mirror plane m or a rotation axis 2. If H is a polar space group of the structure under study, the minimum supergroup G of the paraelectric phase can be written as follows:

$$G = H + \left(\frac{g}{t} \right) H,$$

where the operator $g(\bar{1}, m, 2)$ represents the rotational component. In the general case, the orientation of a plane m or an axis 2 is limited by the space group H , but the translation term (t) of the equation can take any value within limits determined by the group G . To put it differently, an inversion centre, a mirror plane or a

rotation axis that are lost can be located in any position with respect to the original one chosen for the description of the group H . Abrahams restricted the consideration to pseudocentres and mirror pseudoplanes. Polar crystal structures in which deviations (shifts) of atoms Δr with respect to hypothetical nonpolar configurations lie in the range between 0.1 and 1 Å were considered as materials that will, most probably, exhibit ferroelectric–paraelectric phase transitions. It was suggested that the maximum deviation of atoms Δr along the polar axis from the totally symmetrical position be considered as a quantitative parameter for estimating the degree of pseudosymmetry of the structure. On the basis of this parameter, the following empirical equation was derived for predicting the transition temperature:

$$T_c = C(\Delta r)^2,$$

where $C \approx 2.0 \times 10^4 \text{ K } \text{Å}^{-2}$. Abrahams has cast doubt on space groups determined for structures with $\Delta r < 0.1 \text{ Å}$. Compounds satisfying the above conditions⁵⁴ were selected in the Inorganic Crystal Structure Database (1987). For these compounds, more than 50 new ferroelectric crystals were predicted.

Based on the approach developed by Abrahams, Igartua and coworkers⁵⁵ suggested a procedure for systematic studies of materials exhibiting both kinds of high-temperature phase transitions. The authors suggested that compounds possessing pseudosymmetry under ordinary conditions would possess structural phase transitions at elevated temperatures. This was exemplified with the space group $P2_12_12_1$. A total of 442 structures were retrieved from the Inorganic Crystal Structure Database and for 407 of them the values Δr were calculated. It appeared that in all 14 compounds, for which high-temperature phase transitions and pseudosymmetry were reported, $\Delta r < 1.5 \text{ Å}$. About 20 structures with pseudosymmetry and $\Delta r < 1 \text{ Å}$ were additionally found for which phase transitions are highly probable.

Therefore, it is evident that systematic studies of pseudosymmetrical crystals are promising for establishing structural regularities and for design of materials possessing desired physical properties.

An analogous search for organic crystals in the CSD was not carried out. However, it is possible to trace the route to a search for compounds with the desired physical properties in the database based on certain crystal-structural ‘indications’ (for example, values of $Z' > 1$). In particular, systematic analysis of structures of long-chain molecules with $Z' > 1$ will apparently allow one to reveal crystals of new mesogenic compounds. A successful search for new nonlinear-optical noncentrosymmetrical crystals in the CSD was carried out based on a search for molecules similar in geometry to dicyanovinylanisole (a known nonlinear-optical material).¹¹² It appeared that the CSD already contained data on the crystal structure of *p*-chlorodicyanovinylbenzene,¹¹³ which possesses high ability to generate the second harmonic of laser radiation in the crystal.

VIII. Supramolecular synthons and the possibility of prediction of crystal structures

A governing role of intermolecular interactions, in particular of hydrogen bonds, in crystal structures of organic molecules became apparent about 40 years back.^{114,115} At that time, it was already noticed that hydrogen bonds favour the formation of stable molecular associates in crystals. A series of works by Leiserowitz and coworkers in 1969–1978^{116–118} can be considered as the first systematic study in this field. In these works, the authors attempted to derive possible molecular associates that are realised in some classes of chemical compounds, namely, in carboxylic acids and in primary and secondary amides. The geometrical characteristics of hydrogen bonds in crystals were determined for the first time¹¹⁹ based on statistical data on the published crystal structures and the theory of graphs was applied for deducing theoretically possible fragments formed through hydrogen bonds in crystals. In addition, typical and anomalous modes of forma-

tion of such molecular associates were determined based on the analysis of more than 2000 structures.¹²⁰

The determination of the geometrical parameters of different types of hydrogen bonds based on more detailed statistical data became possible as the CSD data have become available. Taylor and Kennard²³ were the first to determine the geometrical parameters of $\text{CH} \cdots \text{O}$ interactions. These interactions are commonly assigned to weak hydrogen bonds. Berkovitch-Yellin and Leiserowitz¹²¹ noted that these weak $\text{CH} \cdots \text{O}$ interactions in crystals along with hydrogen bonds can lead to the formation of stable molecular associates. The works devoted to the consideration of the role of $\text{CH} \cdots \text{O}$ hydrogen bonds in the formation of crystal structures were most completely surveyed in the review.²⁹

More recently, it was shown that the majority of functional groups form a limited number of graph-sets of associates, which are found repeatedly in different structures. Moreover, even chemically different functional groups often form associates described by the same graph-sets.¹²² Each type of interaction is characterised by an inherent ideal geometry of the contact. Therefore, the knowledge of functional groups of a molecule makes it possible to predict, with a high probability, associates that will be present in crystals.

Etter¹²² derived rules for formation of hydrogen bonds in crystals. She has supplemented Donohue’s principle, according to which all ‘acid’ hydrogen atoms in solids participate in hydrogen bonds, by the addition of the following concepts: (1) the hydrogen-bond acceptors are used to the maximum extent if H-bond donors are available and (2) in crystals containing several potential donors and acceptors, H bonds are preferentially formed between the best donor and the best acceptor. The latter principle is very helpful in the analysis of crystal structures of polyfunctional molecules because it makes it possible to reveal a ‘hierarchy’ of formation of hydrogen bonds. Based on this principle in the case of branched systems of H bonds in crystals, Bernstein *et al.*⁶¹ suggested that systems of H bonds be divided into separate subfragments with account of intermolecular distances and symmetry operations of space groups. This approach allows one to unify a procedure for revealing molecular associates formed through H bonds in all crystals listed in the CSD. Etter and Bernstein were the first to perform studies in the field of crystal engineering.^{61,122}

Presently, investigations in this field follow two paths. The first aim is to reveal principles of molecular aggregations in crystals based on studies of the diversity of the available crystal structures. The second line of investigation is aimed at the development of calculation procedures for crystal structures design on the basis of only the molecular geometry.^{1–3} These two lines are ‘two sides of a coin’ and are aimed at solving the direct and inverse problems of crystal engineering.

In studies devoted to the first problem, the nature of forces owing to which molecules in crystal structures are linked in associates (hydrogen bonds, other weaker specific interactions or even usual van der Waals interactions) is first established and then one tries to reveal structural fragments consisting of most strongly bound molecules (supramolecular synthons). Works devoted to the second line of investigation are based on the molecular geometry. One tries to calculate the most favourable mutual arrangement of two molecules (dimers), of chains or planes formed by molecules and finally of a three-dimensional structure.¹ Alternative calculation algorithms are also available (see Ref. 31).

Note that chemists involved in computation of crystal structures address themselves more and more often to structural databases (most often to the CSD) primarily for choosing potential-function parameters and also for testing calculation procedures with the use of a large number of the published crystal structures. The algorithm (FlexCryst) which was developed¹ for predicting organic crystal structures was used for calculating 131 crystal structures belonging to the space group $P1$ and 95 crystal structures belonging to the space group $P\bar{1}$ retrieved from the

CSD. The agreement between the calculated and the real structures was 98% and 85% for the groups $P1$ and $P\bar{1}$, respectively. Needless to say that these results are very promising. However, this algorithm does not presently allow calculations for other space groups. The algorithm MOLPAK² allows one to treat also the space groups $P2_1$, $P2_1/c$ and $P2_12_12_1$. A total of 242 crystal structures were calculated with the use of this program. The programme PROMET allows one to make rather reliable predictions about realisation of a particular space group. This programme made it possible to calculate polymorphic modifications of sulfathiazole, probucol and aspirin.³

IX. Conclusion

Investigations with the use of the CSD as a tool in studying general regularities of organic crystal structures demonstrated that this approach produces good results. Thus the principle of close packing of organic and organometallic compounds in crystals was confirmed by statistical analysis of positions of molecular geometrical centres in crystal unit cells. The statistical values of the van der Waals radii of nonmetals were determined based on the analysis of a large sample of nonbonded interatomic distances in the published structures. The preferential types of molecular packings of organic molecules were revealed and an overwhelming predominance of centrosymmetrical space groups was noted. However, statistical analysis demonstrated no evidence that centrosymmetrical packings are energetically preferable to non-centrosymmetrical structures. Neither gain in density nor noticeable differences in the thermodynamic characteristics were revealed.

Conceivably, a predominance of centrosymmetrical space groups reflects the fact that compounds can exist as racemic mixtures of enantiomers rather than the fact that they are energetically more favourable. If this is the case, then crystals belonging to noncentrosymmetrical space groups can be obtained if one establishes the reasons for spontaneous resolution of enantiomers upon crystallisation or finds a procedure for their forced resolution. It is also probable that noncentrosymmetrical crystals just have received lesser attention and, in spite of a large body of data in the CSD, a sample of compounds in this case is not yet representative. Statistical studies confirmed that molecular association in crystals through hydrogen bonds plays a governing role in the formation of crystal packings. Some structural features of crystals whose packings contain stable synthons (dimers, chains or layers) were revealed. These are, first of all, a high probability of occurrence of polymorphic modifications, structures with $Z' > 1$ and with pseudosymmetry and cases of spontaneous resolution of isomers. These structures often possess (or can possess) useful physical properties. A procedure was developed for the search for new ferroelectrics and other materials exhibiting phase transitions.

Analysis of the results of the first systematic statistical studies of organic crystal structures with the use of the CSD allows one to draw up a plan of further investigations in this field. Thus the first stage of studies of the reasons for spontaneous resolution of enantiomers upon crystallisation should apparently involve the establishment of types and forms of molecules that can undergo spontaneous resolution and analysis of the role of molecular association in crystals (apparently, from the initial solution). In this respect, it is very advantageous to compare crystal packings of compounds having centro- and noncentrosymmetrical polymorphic modifications. A search for compounds exhibiting polymorphic transformations and compounds potentially possessing liquid-crystalline and nonlinear-optical properties in the CSD can be rather simple. These are only some applications of the CSD.

Donor – acceptor complexes and radical ionic salts based on fullerenes

D V Konarev, R N Lyubovskaya

Contents

I. Introduction	19
II. Fullerenes	20
III. Donor–acceptor complexes and radical ionic salts of fullerenes	21
IV. Structure and spectral characteristics of complexes and radical ionic salts of fullerenes	30
V. Conclusion	35

Abstract. The review generalises for the first time the published data on the synthesis and properties of donor-acceptor type of compounds based on fullerenes, various solvates and clathrates, inclusion compounds, molecular complexes and charge-transfer complexes both with inorganic donors and with organoelement donors of the tetrathiafulvalene, amine, metallocene and metalloporphyrin series. Radical ionic salts of fullerenes with bulky cations and alkali metals obtained by intercalation or by direct synthesis in solution are discussed. Results of studies of fullerene compounds by IR, optical, ESR, X-ray photoelectron and ^{13}C NMR spectroscopy, as well as their conducting (including superconducting), magnetic and optical properties are discussed. The bibliography includes 208 references.

I. Introduction

The discovery of fullerenes, a new allotropic modification of carbon, in the mid-80's¹ confirmed the prediction of theorists^{2,3} on the possible existence of polyhedral carbon molecules with icosahedral symmetry.

In the early 90's, a simple method to obtain fullerene C_{60} in gram amounts was found; this gave an impetus to more detailed studies of physical and chemical properties of the C_{60} clusters and compounds based on them.⁴ The number of works in this area grows steadily, and they cover an ever wider range of fundamental and applied branches of science and technology. In 1996, Kroto, Smalley and Curl were awarded the Nobel Prize in chemistry for

the discovery of fullerene and for their great contribution to the development of this area.

Generally, fullerenes display acceptor properties^{5–7} and can be regarded as π -acceptors. They can form various donor–acceptor (D–A) non-covalent compounds, similar to the well-known planar π -acceptors, *e.g.*, tetracyanoquinodimethane **1** (TCNQ), tetracyanoethylene **2** (TCNE), *p*-quinone, *etc.*^{5,8}

These D–A compounds are formed due to rather weak (in comparison with the standard covalent chemical bonds) van der Waals interactions and due to charge transfer from the donor to the acceptor.⁹ Charge transfer plays a very important role and results in qualitatively new physicochemical properties of these compounds. D–A compounds can be divided into several groups according to the degree of charge transfer (δ), although there is no distinct boundary between these groups. The compounds with δ close to zero can be attributed to molecular complexes. In the case of partial charge transfer from the donor to the acceptor ($0 < \delta < 1$), charge-transfer complexes (CTC) $\text{D}^{\delta+}\text{A}^{\delta-}$ are formed. For example, in the TTF–TCNQ complex, where TTF is tetrathiafulvalene, different estimates give $\delta = 0.48–0.67$.⁸ A characteristic feature of CTC is the appearance of a new band in the absorption spectrum of the complex in the visible and near IR regions due to the transfer of an electron from the donor to the acceptor when absorption of a light quantum occurs.⁹ In the extreme case, *i.e.*, in the complete charge transfer from the donor to the acceptor or in the formation of a compound from oppositely charged ions, radical ionic salts $\text{D}^{n+}\text{A}^{n-}$ are formed (in the case of radical ionic salts of fullerenes, n is an integer).

The charge-transfer complexes and radical ionic salts based on planar polyconjugated heterocyclic π -donors and acceptors are being intensely studied lately. Many of them, the so-called organic metals, have unique conduction and magnetic properties.^{10,11}

Radical cationic salts of tetrathiafulvalene derivatives draw special attention. The majority of organic metals and superconductors obtained to date correspond to this class of compounds.^{10,11}

The discovery of fullerene has given the researchers a new π -acceptor with a number of essential features that distinguish it from other acceptor molecules: larger size, spherical shape, unique electronic structure, high symmetry and polarisability. The resulting specific features of donor-acceptor interactions in compounds of the C_{60} fullerene enabled the design of materials with

Received 26 May 1998

Uspekhi Khimii **68** (1) 23–44 (1999); translated by S S Veselyi

unusual physical properties. For example, it was found that intercalation of C_{60} by alkali metals results in superconductors with composition M_3C_{60} ($M = K, Rb, Cs$) with rather high superconductivity transition temperatures (T_c) ($18 \leq T_c \leq 40$ K).^{12–14} The salt of C_{60} with an organic donor, tetrakis(dimethylamino)ethylene (TDAE), is a ferromagnetic with $T_c = 16.1$ K,¹⁵ and apparently has superconducting properties.¹⁶ Combination of conducting polymers with fullerene enables efficient phototransfer and separation of charges with long lifetime, which increases considerably the photoconductivity of polymers and can be utilised in xerography and energy phototransducers.¹⁷

By now, a considerable number of various D–A compounds of fullerenes have been obtained, including molecular complexes, CTC and radical ionic salts with different states of oxidation or reduction. The C_{60} fullerene molecule can accept up to 12 electrons^{13, 14, 18} and release one electron,⁷ *i.e.*, the charge of the C_{60} molecule can vary from +1 to –12. As a result, C_{60} compounds manifest a broad spectrum of properties.

The considerable interest of experts from different areas in fullerenes and compounds based on them is reflected in a number of books and reviews.^{19–28} In particular, the reviews are devoted to chemistry,²¹ spectroscopy^{22–26} and magnetic properties²⁷ of fullerenes and compounds based on them, as well as to intercalation of fullerenes with alkali and alkaline-earth metals.^{13, 14, 28}

The present review generalises for the first time the published data on the synthesis of D–A compounds based on fullerenes that are formed both through van der Waals interaction and charge transfer. These include solvate and clathrate compounds, inclusion compounds, molecular complexes, CTC and radical ionic salts of fullerenes with organic and organometallic donors and various metals. Data on IR, electronic, ESR, X-ray, photoelectron and ¹³C NMR spectroscopy are considered. The features of D–A complexes and radical ionic salts of fullerenes, including superconducting, magnetic and optical properties, are discussed.

II. Fullerenes

1. Features of fullerene structure

It is known that the molecule of the C_{60} fullerene has icosahedral symmetry (group I_h), and its surface consists of 20 six- and 12 five-membered rings.¹

The molecule of the C_{70} fullerene consists of 25 six-membered and 12 five-membered rings. It has an elongated shape and lower symmetry (D_{5h}). Higher fullerenes also represent polyhedral molecules and contain a larger number of hexagonal facets.²⁵

All 60 carbon atoms in the C_{60} molecule are equivalent, which is confirmed by the presence of a single signal in the ¹³C NMR spectrum.²⁹ The mean C–C distance in C_{60} (1.44 Å) is close to the C–C distance in graphite (1.42 Å). Each carbon atom in the C_{60} molecule is linked to three other carbon atoms by two longer 6–5 bonds in five-membered rings and by one shortened 6–6 bond, which is common to two fused six-membered rings. Thus, the carbon atoms in C_{60} have a near- sp^2 hybridisation.^{25, 30}

Usually, the symmetry axis of the π -orbital is orthogonal ($\theta_{\sigma\pi} = 90^\circ$) to the plane of the three σ -bonds in the sp^2 hybridisation. Because of the spherical shape of the C_{60} fullerene molecule, the four mutually linked carbon atoms do not lie in the same plane and the angle $\theta_{\sigma\pi}$ is 101.64° rather than 90° .³⁰ Thus, pyramidalisation of carbon atoms occurs in fullerenes, which results in significant strain in the fullerene molecule and changes the character of the π -orbitals; thus, there is certain contribution by a σ -orbital to the π -orbitals of all fullerenes. Pyramidalisation affects strongly the electronic properties of fullerenes and pre-determines their high electron affinity, as the strain in the molecule is partially eliminated upon reduction of fullerenes.³⁰

2. Donor – acceptor properties and polarisability of fullerenes

The ionisation potentials (IP),²⁵ electron affinities (EA)⁶ and the corresponding redox potentials (E_{Ox} , E_{Red})³¹ of the C_{60} , C_{70} and C_{76} fullerenes are listed in Table 1.

Table 1. Vertical electron affinity (EA),⁶ first and second reduction potentials of fullerenes (E_{Red}^1 and E_{Red}^2),³¹ ionisation potentials (IP)²⁵ and oxidation potentials of fullerenes (E_{Ox}).⁷

Fullerene	EA/eV	E_{Red}^1 /V ^a	E_{Red}^2 /V ^a	IP/eV	E_{Ox} /V ^b
C_{60}	2.67	–0.44	–0.82	7.58	+1.26
C_{70}	2.68	–0.41	–0.80		+1.20
C_{76}	2.86	–			+0.81

^a CH_2Cl_2 , SCE, 0.05 M $Bu_4^+NBF_4^-$; ^b relative to Fc/Fc^+ (Fc is ferrocene).

The first redox potentials of the C_{60} and C_{70} fullerenes in the polar solvents are close to each other. The redox potential of the C_{60}/C_{60}^- pair is –0.44 V in dichloromethane and acetonitrile^{5, 31} and –0.33 V in tetrahydrofuran³² relative to the saturated calomel electrode (SCE). These values are 0.6–0.7 V smaller than the corresponding redox potentials of TCNQ (+0.22 V) and TCNE (+0.28 V).⁵ Changing the polarity of the solvent shifts the redox potential of C_{60} insignificantly. For example, the redox potential in nonpolar benzene is –0.36 V relative to SCE.³²

The C_{60} fullerene is rather a weak acceptor. The EA of C_{60} in the gas phase is 2.67 eV.⁶ The adiabatic EA of C_{60} in solution (estimated from the energy of charge transfer and redox potentials) is much lower and equals 2.10–2.20 eV.⁵ These values are comparable with the EA of such weak acceptors as 3,6-dibromo-2,5-dimethylquinone (**3**) or 1,2,4,5-tetracyanobenzene (**4**) (2.1 eV) but are much lower than those of TCNQ (2.82 eV) and TCNE (2.90 eV).⁵

One possible way to increase the EA is the introduction of strong acceptor substituents in fullerenes. It has been shown^{33, 34} that halogenated fullerenes have stronger acceptor properties than C_{60} . For example, the theoretically calculated EA for $C_{60}Br_8$ is ~ 4.0 eV.³³ Fluorinated fullerenes, *viz.*, $C_{60}F_{36}$, $C_{60}F_{48}$ and $C_{70}F_{54}$, have considerably more positive first redox potentials than the corresponding fullerenes (–0.05, +0.51 and +0.76 V, respectively, relative to an Ag/Ag^+ reference electrode in dichloromethane).³⁴ The electron affinities of $C_{60}F_{36}$ and $C_{60}F_{48}$ are also higher than that of C_{60} (3.48 and 4.06 eV, respectively).³⁴ Functionalisation results in significant changes in the symmetry and electron structure of the C_{60} fullerene.³³

Fullerenes, especially C_{60} , have high oxidation potentials. The ESR method detected the formation of the C_{60} radical cation in solutions containing strong oxidants,³⁵ but individual compounds in which C_{60} is charged positively have not been isolated yet.

Higher fullerenes possess higher electron affinities, and thus they are stronger acceptors. The C_{76} fullerene and other higher fullerenes undergo oxidation a little more readily than C_{60} .⁷ For example, C_{76} is oxidised with hexabromocboranyltris(2,4-dibromophenyl)ammonium ($E_{Red} = +1.16$ V) to give a radical cationic salt with positive charge on the fullerene.⁷

The polarisability of the C_{60} fullerene molecule is high ($\alpha \sim 85$ Å)³⁶ and is several times higher than that of other π -acceptors. Therefore, polarisation van der Waals forces are essential in the formation of D–A complexes and radical ionic salts of fullerenes.

3. Features of the crystal structure of C₆₀ fullerene

At room temperature, C₆₀ has a face-centred cubic (FCC) lattice.³⁷ The shortest distance between the centres of the C₆₀ molecules in a crystal is 10.02 Å, which is smaller than the van der Waals diameter of the C₆₀ molecule, considering the size of its π -electron cloud (10.18 Å, Ref. 25), hence the π -orbitals of the C₆₀ molecules in a crystal overlap little. The weakness of interactions between the fullerene molecules in the solid state is the reason for the fast isotropic rotation of the C₆₀ molecules in the crystal. Below 255 K, C₆₀ crystals undergo a phase transition from the face-centred cubic lattice to a simple cubic lattice.³⁷ The rotation of the fullerene molecules in these crystals becomes anisotropic, it slows down, gets synchronised and occurs ratchet. In the case of such rotation, adjacent C₆₀ molecules can be present in two different orientations relative to each other, which have different energies. In the first orientation, the shortened 'double' bond of one C₆₀ molecule is located above the electron-deficient pentagonal facet, whereas in the second orientation, it is above the hexagonal facet of the C₆₀ molecule. As the temperature is decreased, the number of pairs of molecules in the first orientation increases and reaches 83% at 90 K. Below 90 K, the ratio of molecules in the first and second orientations remains constant, but ratchet rotation of the C₆₀ molecules occurs in such a manner that each of two orientations is transformed only to the equivalent one.²⁵ This results in ordering, in which the rotation of the C₆₀ molecules in a crystal is synchronised completely. This kind of ordering can also occur in D–A complexes and radical ionic salts of fullerenes provided that the distances between the C₆₀ molecules are short.^{38–40}

4. Conducting and magnetic properties of fullerenes

The upper unoccupied and lower occupied levels of the C₆₀ molecule are presented in Fig. 1. The highest occupied h_u level is five times degenerate and is completely filled with ten electrons. The lowest free t_{1u} and t_{1g} levels are three times degenerate.^{25, 36}

Figure 1. Highest occupied and lowest unoccupied molecular π -orbitals of the C₆₀ fullerene calculated by the Hückel method;³⁶ β is resonance integral.

Overlapping of π -orbitals of the adjacent C₆₀ molecules in a crystal results in the formation of a valence band and a conduction band. The energy gap between the valence band and the conduction band in C₆₀ is estimated as 1.5–1.8 eV,^{25, 36} hence crystalline fullerene is a semiconductor. The highest-energy edge of the valence band consists of the h_u levels, while the lowest-energy edge of the conduction band consists of the t_{1u} levels (see Fig. 1).

Magnetic measurements carried out with pure C₆₀ and C₇₀ fullerene specimens have shown that magnetic transitions are observed at 60 K.⁴⁰ This is due to the fact that the currents of π -electrons in the six- and five-membered fullerene rings are different and create a very small but distinct magnetic moment in the fullerene molecule [for C₆₀, $\mu = -0.35 \times 10^{-9}$ A m² (see Ref. 27)]. Cooling of specimens of pure C₆₀ below 90 K results in the transition to ratchet synchronised rotation of the fullerene molecules. In this transition, the positions of 83% of the magnetic moments of the C₆₀ molecules are frozen in an ordered fashion, but 17% of the magnetic moments are frozen in disorder. This results in a glassy magnetic state.⁴⁰

When C₆₀ specimens are placed in a magnetic field, the magnetic moments of the C₆₀ fullerene molecules are oriented along the external magnetic field. Therefore, cooling of C₆₀ specimens in a magnetic field below the temperature of transition to synchronised rotation of fullerene molecules results in freezing of the ordered positions of the magnetic moments of the C₆₀ molecules and formation of the frozen glassy magnetic state. Heating of the specimens above the temperature of this transition results in violation of the synchronised rotation of fullerene molecules, and ordering of the magnetic moments of the C₆₀ molecules disappears.⁴⁰

III. Donor – acceptor complexes and radical ionic salts of fullerenes

1. Methods of preparation

Fullerene compounds are prepared using various methods: slow concentration of solutions,^{41–43} diffusion methods,^{44–52} cooling of saturated solutions,^{53, 54} precipitation with a solvent^{48–50, 55} and an electrochemical method.^{56–61}

Concentration of solutions containing a fullerene and a donor is the basic method for the preparation of molecular fullerene complexes. The concentration is carried out in an inert atmosphere, as molecular oxygen can be absorbed on the surface of the fullerene molecule, which blocks the approach of the donor to the fullerene.⁶²

As a rule, those solvents are used in which fullerenes are well soluble: carbon disulfide (7.9 mg ml^{−1}), benzene (1.5 mg ml^{−1}), toluene (2.9 mg ml^{−1}) and chlorobenzene (5.7 mg ml^{−1}).^{63, 64} Fullerene forms solvates of the type C₆₀(Sol)_x with many of these solvents.^{65–74}

Two competing reactions occur upon concentration in a reaction system 'donor–C₆₀–solvent':

Sol is a solvent, D is a donor;

$n = 1–6$, $m = 1–3$, $l = 0–4$; $x = 0.4–4$.

Shifting of the reaction equilibrium towards the formation of a complex (as the solvent is present in a considerable excess in comparison with the donor) sometimes requires a great molar excess of the donor relative to the fullerene (up to 100 : 1).^{75–77} As the temperature is increased, the rate of displacement of the solvent by the donor from the solvent shell increases, thus the time of heating or refluxing of the reaction mixture is an essential factor. An increase in the temperature of concentration of fullerene solutions in benzene results in a decrease in the content of benzene in the crystal solvate [C₆₀–C₆H₆], and above 40 °C the solvate is decomposed completely and virtually pure fullerene is formed.⁴²

To avoid losses on the walls of the reaction vessel in the preparation of microquantities of complexes, special techniques for the concentration of the solvent in closed volume using a temperature gradient have been developed.^{41, 42}

Fullerene compounds can be isolated from solutions by precipitation or cooling of saturated solutions. For example, radical anionic salts of fullerenes are isolated from solutions in pyridine and benzonitrile by precipitation with non-polar solvents (pentane or hexane). However, this results in polycrystalline specimens.^{48–50, 55} Single crystals of the K₃C₆₀(THF)₁₄ salt can be prepared by slow gradient cooling of a solution obtained by treatment of the C₆₀ fullerene with potassium in tetramethylethylenediamine in the presence of tetrahydrofuran and diethyl ether.⁵³

The diffusion method (in which the vessels with solutions of a fullerene and an appropriate donor are connected by a tube filled with a solvent) is most suitable for the preparation of single crystals of poorly soluble C₆₀ compounds. Single crystals of the

complexes (DAN)C₆₀(C₆H₆)₃ (DAN is dianthracene),⁴⁴ the salt (TDAE)C₆₀ [TDAE is tetrakis(dimethylamino)ethylene]^{45,46} and others have been obtained using this procedure.⁴⁷

The diffusion method is also used in the synthesis of fullerene radical anionic salts by cationic metathesis. The reaction is carried out in two stages. In the first stage, C₆₀ is reduced with an excess of sodium in THF in the presence of dibenzo-18-crown-6^{48–50} or other crown ethers.⁵¹ The degree of reduction of the fullerene to the C₆₀^{n−} anion is controlled by the exact molar ratio of the fullerene and the crown ether (1 : *n*). The salt [Na⁺(18-crown-6)]C₆₀[−](THF)₃ is isolated from THF by precipitation with hexane.⁴⁹ Similar C₆₀^{2−}, C₆₀^{3−} and C₆₀^{4−} salts are poorly soluble in THF and spontaneously precipitate from solutions.^{49,51} In the second stage, the resulting sodium salts of C₆₀ are dissolved in acetonitrile and placed in a vessel. A compound with a bulky cation, for example, bis(triphenylphosphoranylidene)ammonium chloride **5** (PPNCl), is placed in the other vessel.^{50,51}

The vessels are connected by a tube containing the pure solvent. Single crystals of (PPN)₂C₆₀ have been obtained by this method.⁵⁰ Cationic metathesis of Rb₃C₆₀ with the salts Me₄NCl, Et₄NBr and Me₄PCl in liquid ammonia can also be used; the specimens were isolated as powders.⁵²

In the electrochemical method, the radical anions C₆₀^{−•} and C₇₀^{−•} were obtained by reduction of neutral fullerenes in an H-shaped cell on a platinum cathode. Compounds Ph₄PCl or PPNCl with bulky cations were used as the supporting electrolytes.^{56–60} 1,2-Dichlorobenzene or mixtures of dichloromethane with toluene and chlorobenzene with tetrahydrofuran served as the solvents. The fullerene salts crystallised on the cathode.^{56–60}

The salts M_xC₆₀(THF)_y with alkali metals (M = Li, Na, K, *x* ~ 0.4, *y* ~ 2.2) were obtained by electrochemical reduction of C₆₀ in the presence of a supporting electrolyte, *viz.*, the corresponding tetraphenylborate. A mixture of chlorobenzene with THF served as the solvent.⁶¹

2. Solvate and clathrate compounds. Inclusion compounds

Dissolution of C₆₀ in various solvents results in formation of donor–acceptor compounds.^{65,66} The interaction of the solvent with C₆₀ occurs basically through polarisation van der Waals forces. In fact, the solubility of fullerenes in solvents with high polarisability, especially in benzene (*α* ~ 10 Å³) and naphthalene derivatives (*α* ~ 20 Å³) is the highest.^{63,64} Most of the complexes with solvents are unstable, but in some cases C₆₀ solvates can be isolated as crystals by slow concentration of the solutions.^{67–74}

The interaction with the solvent molecules results in the orientational ordering of molecules compared to crystalline C₆₀; in certain cases, this allows one to perform X-ray diffraction studies of these compounds. Solvate compounds have diverse crystal structures: C₆₀(C₆H₆)CH₂I₂ has lamellar packing,⁶⁷ C₆₀(C₆H₆)₄ forms a cage with hexagonal channels,^{68,69} while C₆₀(C₆H₁₂)₂⁷⁰ and C₆₀(1,2-Me₂C₆H₄)₂⁷¹ have hexagonal layered packing. The crystal cells of the solvates have lower symmetry than that of pure C₆₀. However, the crystal structure could not be determined for many solvates, such as C₆₀(Cl₂C=CHCl),⁷² C₆₀(CS₂)⁷³ and C₆₀(CCl₄)₁₀,⁷⁴ because of significant orientational and structural disorder.

The solvent molecules in clathrate compounds are located in the cavities between the bulky fullerene molecules. Clathrate compounds of C₆₀ are obtained by precipitation of the fullerene from toluene with a large excess of the other solvent, *viz.*, *n*-pentane, 1,3-dibromopropane, butanone, diethyl ether, acetone,⁷⁸ *n*-heptane,⁷⁹ *etc.*^{80,81} The composition of the clathrates is C₆₀(Sol)_{*x*}. For solvents with small molecules, *x* = 1. As the size of solvent molecules increases, *x* decreases. Precipitation of fullerene with isobutane results in pure C₆₀.⁷⁸ Clathrate compounds have

been obtained basically with the solvents in which the solubility of fullerene is very small; this suggests that the interaction between the molecules of the solvent and fullerene is weak.^{78–81}

Solvate and clathrate compounds are characterised by phase transitions related to orientational ordering of the fullerene molecule. For instance, phase transitions for C₆₀(Me₂CO) occur at 240 K,⁷⁸ for C₆₀(CS₂)_{*x*} at 230 K,⁷⁸ for (TSeT)_{*x*}C₆₀(CS₂)_{*y*} (TSeT is tetraselenatetracene) at 203–240 K,⁸² for C₆₀(C₅H₁₂) at 190 K,⁷⁸ for C₆₀[Br(CH₂)₃Br] at 190 K⁷⁸ and for C₆₀(Cl₂C=CHCl), at 167 K.⁷² All these transitions are similar to the phase transition in pure C₆₀ at 255 K.³⁷

Compound (TSeT)_{*x*}C₆₀(CS₂)_{*y*} contains up to 26% of carbon disulfide and only traces of the donor.⁸² The high content of the solvent probably results in orientational disorder and separates the C₆₀ molecules from each other to such an extent that upon complete removal of carbon disulfide the fullerene is completely sublimed at ~ 520 °C, whereas the maximum sublimation rate of pure C₆₀ is reached only at 700 °C.⁸²

Inclusion compounds of fullerenes are obtained by refluxing aqueous solutions of γ-cyclodextrin (**6** (γ-CD)) with finely dispersed fullerene.^{83–85} There are two types of complexes of γ-CD with C₆₀: one C₆₀ molecule forms van der Waals contacts with two γ-CD molecules, or a van der Waals aggregate of several C₆₀ molecules forms short contacts with several γ-CD molecules.^{83–85} The unique property of these compounds is their solubility in water, therefore such complexes can be utilised in reactions that occur in the presence of water. In particular, complexes of fullerene with γ-CD can be used for medical purposes.⁹⁵ Similar compounds are formed upon dissolution of a mixture of fullerenes with *p*-tert-butylcalix[8]arene (**7**) in toluene.⁸⁶ Complexation with calixarenes has been proposed for efficient separation of fullerene mixtures.^{86,87} It is possible to isolate C₆₀ of 99.5% purity by multiple recrystallisation of a mixture containing 85% C₆₀ and 15% C₇₀.⁸⁶ It was shown that fullerene molecules are separated from each other in crystal structures of compounds C₆₀–*p*-iodocalix[4]arene⁸⁸ and C₆₀–*p*-iodocalix[5]arene.⁸⁹

3. Complexes with inorganic compounds

Complexes of fullerenes with S₈,^{41,90–92} P₄,⁹³ I₂,⁹⁴ S₄N₄,^{75,95} and a number of other small molecules have the composition C₆₀X₂ or C₆₀X(Sol). The crown-shaped S₈ molecule is very flexible, and molecular sulfur readily forms complexes with fullerenes. The structures of compounds C₆₀(S₈)₂ and C₆₀S₈(CS₂) are cage lattices of the fullerene molecules with channels filled with the sulfur molecules.^{90,91} In compounds C₇₀(S₈)₆ and C₇₆(S₈)₆, the fullerene molecules form loose corrugated hexagonal layers with distances between the fullerene molecules 10.2–10.5 Å.^{41,92} All S₈–fullerene compounds contain shortened S–C contacts [3.13–3.52 Å, which is shorter than the sum of the van der Waals radii of sulfur and carbon (3.7 Å)]. As a result of this strong interaction, the rotation of fullerene molecules ceases almost completely. This made it possible to establish the structure of the fullerenes C₇₀ (see Ref. 92) and C₇₆ (see Ref. 36) more precisely. The complex C₆₀(P₄)₂ has a laminar structure.⁹³ In compound C₆₀I₂(C₆H₅Me), iodine can act as an acceptor with respect to C₆₀, as its EA (3.06 eV) is higher than that of fullerene (2.65 eV). This compound has a donor–acceptor sandwich structure, in which the iodine molecules are located between the fullerene and toluene molecules.⁹⁴

Tetrasulfur tetranitride S₄N₄ (**8**), like S₈, has a crown shape and forms a number of molecular complexes with the C₆₀ fullerene.

The following compounds were isolated from toluene: $C_{60} \cdot S_4N_4$ and $C_{60}(S_4N_4)_2$.⁷⁵ The similarity of the sizes of the S_4N_4 and benzene molecules results in their mutual replacements in the crystal lattice of the complex. For this reason, compounds of the series $C_{60}(S_4N_4)_{2-x}(C_6H_6)_x$ were isolated from benzene, where $x < 2$.^{75,95} This replacement has a random character, and the use of an excess of the donor yields compounds with a higher content of S_4N_4 . In the crystal structure of the complex $C_{60}(S_4N_4)_{1.33}(C_6H_6)_{0.67}$, the densely packed layers of fullerene molecules alternate with layers of tetrasulfur tetranitride and benzene molecules.⁹⁵

The Pd_6Cl_{12} cluster and C_{60} form a complex $C_{60}(Pd_6Cl_{12})_2(C_6H_6)_3$ with cage structure, in which each fullerene molecule is surrounded by eight Pd_6Cl_{12} molecules.⁹⁶

4. Complexes with organic donors

The interest in complexes of fullerenes with donors of the tetrachalcogenafulvalene class (**9–17**) is primarily related to the fact that both tetrathiafulvalene and its derivatives are the main components in the production of organic metals and superconductors.¹⁰

It is known⁹⁷ that tetrachalcogenafulvalenes are strong donors with IPs ranging from 6.3 to 7.4 eV. The molecular polarisability of these donors is 15–38 Å.⁹⁷ Tetrathiafulvalenes have planar structures, sometimes with a small deviation of the terminal groups from the conjugation plane.¹⁰ This structure allows arrangement of their salts in regular stacks or layers. A partial charge transfer ($0.25 \leq \delta \leq 1$) from the donor to the acceptor is a prerequisite for the appearance of conductivity.⁸ Tetrathia(selenium,tellura)fulvalenes **9–17** are widely used as donors for the preparation of complexes with fullerenes.

(HM – TTeF)

(BDMT – TTeF)

(TMDTDM – TTF)

(C₁TET – TTF)

(TM – TSeF)

The (BEDT-TTF)₂C₆₀ complex was the first to be obtained.⁹⁸ Subsequently, about a dozen compounds of fullerenes with tetrachalcogenafulvalene derivatives have been synthesised (Table 2). It was found that the degree of charge transfer in these compounds is insignificant.^{5,98,103–106} This is due both to the weak acceptor properties of fullerene and the steric factors unfavourable for charge transfer from the π -orbitals of the initially flat donors to the spherical t_{1u} orbital of C₆₀.¹⁰⁶ The formation of complexes with spherical fullerene molecules results in strong distortion of the flat tetrachalcogenafulvalene molecules, which assume boat conformations: the dihedral angles between the flat central fragment E₄C₂ and the terminal groups of tetrachalcogenafulvalene derivatives are 20–30°,^{98,101,103,105,107} which results in some violation of π -conjugation in these molecules.¹⁰⁸

The packing of fullerene molecules in the crystals of these complexes can be diverse: dense^{5,89,100} or rather loose^{107,108} layers of C₆₀ molecules,^{98,100} double chains of C₆₀ molecules^{98,102,110} as well as island motifs with isolated C₆₀ mole-

cules.^{101, 105, 111} The donor-acceptor interaction of tetrathiafulvalene molecules with C₆₀ occurs both by the $n-\pi$ type (the n -orbitals of the sulfur atom of the central E₄C₂ donor fragment are directed to the centre of the six-membered ring of one C₆₀ molecule) and by the $\pi-\pi$ type (the central E₄C₂ donor fragment is almost parallel to the six-membered ring of the other C₆₀ molecule).^{98, 105} The distance between heteroatoms of the donor and atoms of the C₆₀ molecule is somewhat shorter than the sum of the van der Waals radii of the corresponding heteroatoms and carbon atoms.^{98–107}

Syntheses of tetrathiafulvalene complexes with halogenated fullerenes have been described. As halogenated fullerenes are stronger acceptors than the C₆₀ fullerene, the oxidation of tetrathiafulvalenes with the formation of radical cationic salts is possible.^{33, 119}

In addition to compounds of fullerenes with tetrachalcogenafulvalene derivatives, compounds with donor molecules of other classes (Table 3) have also been obtained.

The molecules of compounds **21** (CTV),¹¹⁴ **22** (BTX)^{54, 111} and **23** (DAN)⁴⁴ have three-dimensional shapes (BTX and DAN, of the 'double butterfly' type, and CTV, of the hemisphere type). The structures of these molecules match well the spherical surface of the C₆₀ molecule, which forms molecular complexes with them owing to numerous van der Waals contacts. DAN has a unique ability to undergo cocrystallisation with C₆₀ almost quantitatively even from dilute solutions in benzene; this can be utilised for the isolation of C₆₀ from various mixtures.⁴⁴ The C₇₀ fullerene matches less the spatial shape of such molecules as CTV and DAN and does not form complexes with these donors.^{44, 114} However, it forms complexes with composition 1 : 1 : 0.5 with BTX and CS₂.¹¹⁹ Isolated packing of C₆₀ molecules is characteristic of complexes with other donors, such as HMT,¹¹⁵ SbPh₃,¹¹⁶ Au(PPh₃)Cl¹¹⁷ and hydroquinone¹¹⁸ (see Table 3).

All of the complexes described above are dielectrics with a conductivity of $\sim 10^{-6}$ S cm⁻¹ and less.^{5, 100, 103, 104}

5. Composites of conducting polymers with the C₆₀ fullerene

The discovery of the photoinduced charge transfer in polyvinylcarbazole–C₆₀ composites¹⁷ stimulated the intense development of studies in this field. Composites with a dozen of different polymers have been studied by now.¹²⁰ Films of polymer–C₆₀ composites are prepared by concentration of solutions of a polymer and a small amount of a fullerene (from 1% to 3% of the polymer weight) in aromatic hydrocarbons on a substrate.^{17, 120–122}

Only weak charge transfer from the polymer to the fullerene is observed in these composites in the ground state.^{121, 122} For example, an ESR signal corresponding to an insignificant concentration of C₆₀^{•-} (2.3×10^{18} spins g⁻¹) was detected in a composite polyvinylpyrrolidone–C₆₀.¹²²

The polymer photoexcitation occurs at energies higher than the difference between the HOMO and LUMO levels of the polymer. This is accompanied by fast transfer of an electron

The possibility of using these composites in xerography, in solar energy phototransducers and in other devices is being studied.^{120, 121}

Saturated amines, such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) or triphenylamine (TPA) (see Table 4), possess weaker donor properties than the amine **25**, and form only weak charge-transfer complexes.^{76, 77, 129} These compounds are obtained by concentrating solutions of fullerenes in chlorobenzene with a large excess of the donor (100 : 1). The existence of charge transfer in compounds of C₆₀ with TMPD is confirmed by the presence of an absorption band of C₆₀^{•+} at 1070 nm in the optical spectrum and a shift of the absorption band of the T_{1u}(4) vibration of C₆₀, which is sensitive to charge transfer onto the fullerene molecule, in the IR spectrum.⁷⁶

$$\text{Am} + [\text{C}_{60}] \xrightarrow{k_1} [\text{Am}^+][\text{C}_{60}^-] \xrightarrow{k_2} [\text{Am}^+\text{C}_{60}^-]$$

salt zwitter-ion

If the first reaction step is sufficiently fast (k_1 is high) and the resulting salt is poorly soluble in the solvent (as in the case of TDAE), the reaction stops in the first step, and the salts $[\text{Am}^+][\text{C}_{60}^-]$ can be isolated. If k_1 is small and the formation of salts occurs slowly (as in the case of amines **29**, and, especially, **27** and **30**), and the resulting salts are rather soluble in the solvent, the amine adds to C_{60} in this stage to give diamagnetic zwitterions.^{123, 127, 128} These reactions are accompanied by recombination of radicals, which results in a gradual decrease in the signal of the radical anion C_{60}^- . The addition products that are precipitated from the solution contain a small amount of the radical anion C_{60}^- [4% and 2% for (DBU) C_{60} and (TMBI) C_{60} , respectively^{123, 128}]. Fullerene mixed addition and reduction products are perhaps formed in the reaction. If the salt is rapidly precipitated from benzene, the addition cannot go to completion. In this case, the reaction product, *viz.*, (DBN) C_{60} , contains a large percentage of reduced C_{60}^- (14%) and manifests strong magnetic fluctuations down to 80 K.¹²⁷ The addition of amines to C_{60} complicates the study of these compounds and results in significant differences in the estimation of their magnetic properties.

The compound (TDAE)C₆₀ has been studied by IR,¹³³ Raman,¹³⁴ ESR,¹³⁵⁻¹³⁷ NMR¹³⁸ and X-ray photoelectron¹³⁹ spectroscopies. The temperature of ferromagnetic transition in (TDAE)C₆₀ is 16.1 K. It has been shown^{39,43,135} that the onset of

the ferromagnetic state in (TDAE)C₆₀ specimens requires that they were kept for several days at 20–100 °C (constant temperature). Without this procedure, the (TDAE)C₆₀ specimens manifest only antiferromagnetic properties.^{39, 43, 135}

Several mechanisms for the origin of the ferromagnetic state in (TDAE)C₆₀ have been discussed.^{38, 140, 141} It has been shown by ESR^{137, 142} that in (TDAE)C₆₀ complete charge transfer from the donor to the fullerene occurs. It was assumed that ferromagnetism is due to the presence of the radical anion C₆₀^{•−}. However, other salts with the radical anion C₆₀^{•−} do not manifest any ferromagnetism.^{38, 141}

It was suggested^{38, 39} that ferromagnetism in (TDAE)C₆₀ is also determined by the presence of the radical cation TDAE^{•+}. The ESR spectrum of (TDAE)C₆₀ contains only one line with $g = 2.0008$, which is an average value between those for TDAE^{•+} ($g = 2.0035$) and C₆₀^{•−} ($g = 1.9960$).^{38, 142} This is probably due to the strong exchange interaction between TDAE^{•+} and C₆₀^{•−}. The C₆₀ molecules in crystalline (TDAE)C₆₀ are packed in one-dimensional chains along the crystallographic axis $\bar{c}$ with shortened distances between the centres (9.98 Å)^{15, 45} (Fig. 2). The presence of shortened contacts between the C₆₀ molecules allows the slowing down of the rotation of these molecules on cooling, with transition to synchronised ratchet rotation, as in crystals of pure C₆₀ cooled below 90 K. In fact, the rotation of the C₆₀ fullerene molecules in (TDAE)C₆₀ slows down at temperatures below 150 K, as confirmed by broadening of the ¹³C NMR signal.^{38, 138} According to theoretical calculations, the negative charge of the radical anion C₆₀^{•−} is mostly concentrated in the equatorial area of the fullerene sphere. Because of this, long-range magnetic order can be formed in this salt upon transition to synchronised rotation of C₆₀ molecules.^{38, 39} In this case, the spins of C₆₀^{•−} in the fullerene chain along the crystallographic axis $\bar{c}$ are ordered antiferromagnetically. The antiferromagnetic interaction can be transferred between the fullerene chains through the radical cation TDAE^{•+} (see Refs 38 and 39).

Figure 2. Scheme for formation of ferromagnetic order in the salt (TDAE)C₆₀ by the spin polarisation mechanism;^{38, 39} (1) is ferromagnetic interaction; (2) is antiferromagnetic interaction.

According to theory,³⁹ distortion of the radical cation TDAE^{•+} may result in inhomogeneous spin density distribution on TDAE^{•+} (Fig. 2). In fact, after keeping of the salt (TDAE)C₆₀ at constant temperature,³⁹ the ¹H NMR spectrum displays two sets of lines (A and B) from the methyl groups of TDAE^{•+} (see Ref. 138). This implies an asymmetrical spin density distribution in the radical cation TDAE^{•+}. Asymmetrical spin density distribution results in violation of the antiferromagnetic order of the C₆₀^{•−} spins (Fig. 2) and the onset of ferromagnetic transition

below 16.1 K. Ferromagnetic ordering of the C₆₀^{•−} spins is observed in the plane ab normal to the crystallographic axis $\bar{c}$ (Fig. 2).

Compound (TDAE)C₆₀ manifests only antiferromagnetic properties without preliminary keeping at constant temperature. In this case, the spin density is uniformly distributed on TDAE^{•+}, and the intensity ratio of lines A and B in the ¹H NMR spectrum of (TDAE)C₆₀ differs from that of the specimens kept at constant temperature.^{39, 138}

No ferromagnetic properties have been found for compounds of TDAE with higher fullerenes (C₇₀–C₉₆). This is apparently due to differences in the electronic structures of C₆₀^{•−} and radical anions of higher fullerenes, as the negative charge in the mono-anions of higher fullerenes was found to be delocalised over the entire anion surface rather than in the equatorial area of the sphere, as is the case in C₆₀^{•−} (see Ref. 143).

The conducting properties of some compounds of fullerenes with amines have been studied.^{45, 46, 123} The antiferromagnetic phase of the salt (TDAE)C₆₀ displays semiconductor properties with a conductivity of about 10^{−5} S cm^{−1} and an activation energy (E_a) of 0.4–0.8 eV.⁴⁶ The conductivity of the ferromagnetic phase of (TDAE)C₆₀ at room temperature is of the same order of magnitude (5 × 10^{−5} S cm^{−1}). It is also of activated character and is due to tunnelling of electrons between the fullerene molecules. Electron transfer is largely affected by the rotation of fullerene molecules; for this reason, the decrease in the activation energy at 150 K from 0.3 to 0.14 eV is explained by slowing down of the rotation of C₆₀ molecules in this salt.⁴⁵ It was shown¹²³ that the conductivity of (TMBI)C₆₀ is 5 × 10^{−4} S cm^{−1}.

Measurements on a SQUID magnetometer have shown that a superconducting phase with $T_c = 17.4$ K may be present in (TDAE)C₆₀.¹⁶ The volume of the superconducting phase increases if the sample is cooled very slowly at ~150 K, which temperature corresponds to the transition to hindered and synchronised rotation of the C₆₀ molecules.

7. Complexes and radical ionic salts of C₆₀ with metallocenes

Table 5 lists the compounds of C₆₀ with metallocenes. The donor properties of metallocenes vary over a wide range, and they can form compounds with different degrees of charge transfer with fullerenes (from molecular complexes to radical ionic salts containing C₆₀^{3−•}).^{50, 151} The cyclopentadienyl rings of metallocenes coordinated with fullerenes are parallel to the five-membered fullerene rings. For example, the deviation from this plane in the structure [(C₅Me₅)₂Ni]C₆₀(CS₂) is only 0.3° (see Ref. 149). Such a coordination ensures the maximum overlapping of the metallocene and fullerene π -orbitals and efficient charge transfer.

Two types of structures are characteristic of compounds of metallocenes with fullerenes. In compounds of C₆₀ with ferrocene and cobaltocene, dense layers of fullerene molecules alternate with layers of the metallocene molecules.^{47, 145} The layers of the fullerene molecules in compounds with substituted metallocenes are looser and also alternate with the layers of the donor.¹⁴⁹ The physical properties of these compounds are little studied. It is known that the ESR spectra of compounds of C₆₀ with nickelocene and decamethylferrocene contain a signal corresponding to C₆₀^{•−} (see Ref. 147). The complexes [(C₅H₅)₂Ni]C₆₀ and [(C₅H₅)₂Co]C₆₀ display magnetic properties with an S-shaped magnetisation curve which has a hysteresis. However, these properties disappear on exposure of the specimens to air,¹⁴⁰ which indicates that the radical anions C₆₀^{•−} in these complexes are sensitive to oxygen. It has been shown that the conductivity of [(C₅Me₅)₂Ni]C₆₀(CS₂) is rather high (10^{−2} S cm^{−1}).¹⁴⁹

8. Fullerene salts with bulky cations

Radical anionic salts of C₆₀^{•−} and C₇₀^{•−} with bulky cations, such as Ph₄P⁺, PPN⁺ and others,^{56–58, 152–154} are stable in air (Table 6). Each radical anion of C₆₀ in these ionic compounds is located in a highly symmetrical cationic environment. The phenyl substituents

of the cations are drawn together to the six-membered rings of the fullerene in such a manner that the phenyl groups surround completely the C₆₀[•] radical anion. In the salt C₆₀(PPN)₂,¹⁵⁵ one fullerene molecule is surrounded by 22 phenyl groups of the cations, which efficiently shield the charge of the C₆₀²⁻ anion. According to X-ray diffraction data, there are no shortened distances between the fullerene anions in the crystal; the shortest distance between the centres of fullerene molecules is $\sim 12.5 \text{ \AA}$.^{152, 153, 155}

A study of the magnetic susceptibility of these salts⁴⁹ showed that they are paramagnetic.^{49, 50} Apparently, the bulky cations surrounding the C₆₀ fullerene radical anions interfere with their magnetic interaction. The magnetic susceptibility is determined by the spin ground state of fullerene radical anions. The magnetic moment of salts containing the C₆₀[•] and C₆₀³⁻ anions is $1.8 \mu_B$ at room temperature, which corresponds to the singlet ground state with $S = 1/2$. At low temperatures, the magnetic susceptibility in C₆₀[•] salts decreases because of the weak antiferromagnetic interaction between the neighbouring fullerene molecules. The magnetic moment of C₆₀²⁻ salts at room temperature was found to be $2.5 \mu_B$.^{49, 50}

A study of the conductivity of these salts showed that all of them are semiconductors. The conductivity of the salt [Ru(bipy)₃](C₆₀)₂ (Table 6) is $10^{-2} \text{ S cm}^{-1}$, and this salt is a semiconductor with an activation energy of 0.15 eV .⁵⁹ It has been shown^{56, 153} that the conductivity of the salts of C₆₀[•] with the Ph₄P⁺ cation is from 10^{-7} to $10^{-4} \text{ S cm}^{-1}$. The low conductivity is apparently due to the large distances between the fullerene anions in these compounds.

9. Salts of the C₆₀ fullerene with metalloporphyrins

The redox properties of metalloporphyrins also make it possible to use them for the reduction of fullerenes. For example, compound Cr(II)(TPP), where TPP is tetraphenylporphyrin, has strong donor properties ($E_{Ox} = -0.86 \text{ V}$)¹⁵⁶ and reduces fullerene in tetrahydrofuran to C₆₀[•] to give the [Cr(TPP)]C₆₀(THF)₃ salt.¹⁵⁶ The reaction is reversible; the addition of toluene shifts the equilibrium towards the formation of neutral C₆₀. In pure toluene, the reduction of C₆₀ does not occur. The [Cr(TPP)]C₆₀(THF)₃ salt is a paramagnetic with $S = 1/2$.¹⁵⁶

The Sn(II)(TpTP) complex, where TpTP is tetra-*p*-tolylporphyrin ($E_{Ox} = -1.17 \text{ V}$), in the presence of *N*-methylimidazole (*N*-MeIm) forms a salt with C₆₀ with composition [Sn(TpTP)](*N*-MeIm)₂(C₆₀)₂. *N*-Methylimidazole stabilises the Sn(TpTP)²⁺ cation and hence facilitates the formation of the complex.⁴⁸

10. Metal salts of fullerenes

a. Conducting properties of fullerene salts. Superconductivity

Reduction of fullerene results in the population of the t_{1u} energy levels, which can be populated with up to six electrons.^{25, 36} Therefore, the compounds obtained can display conducting and superconducting properties if the degree of reduction x of the C₆₀ fullerene ranges from 0 to 6.^{13, 14, 25}

The character of conductivity in the salts M_{*x*}·C₆₀ varies strongly depending on the degree of the fullerene reduction. At the degree of reduction $x = 1$, the salts M·C₆₀ can display metallic conductivity.^{61, 157–159}

The compounds M₃C₆₀ have higher conductivity (*e.g.*, the conductivity of K₃C₆₀ at room temperature was shown to be

$2.5 \times 10^{-3} \text{ S cm}^{-1}$) than the compounds M_xC_{60} with different stoichiometry. At low temperatures, the salts M_3C_{60} display metallic conductivity and can pass into the superconducting state.

The density of energy states at the Fermi level $N(E_F)$ (number of states eV^{-1}) is an important parameter determining the superconductivity transition temperature (T_c). Because of the small overlapping of the π -molecular orbitals of the neighbouring C_{60} molecules in the compounds M_3C_{60} , the conduction band is half occupied and has a width of 0.2–0.3 eV. At a small band width, the density of states at the Fermi level is rather high (25 states eV^{-1} for K_3C_{60} and 35 states eV^{-1} for Rb_3C_{60} , see Ref. 25). It is this fact that explains higher T_c values in fullerene salts with alkali metals in comparison with other known organic superconductors.¹⁰

In the compounds M_3C_{60} with face-centred cubic (FCC) lattice, an increase in the size of the alkali metal atom results in an increase in the distance (d) between the fullerene molecules in the crystal cell and a linear increase in T_c . The explanation for the latter phenomenon is that the increase in $d(\text{C}_{60}-\text{C}_{60})$ in M_3C_{60} decreases the overlapping of the π -molecular orbitals of the neighbouring fullerene molecules and, accordingly, the width of the conduction band. The narrowing of the conduction band increases the density of states at the Fermi level (as the number of states at the Fermi level does not depend on the band width and is constant) and increases the temperature of superconductivity transition (T_c).^{13, 14, 28} However, if the distance between the centres of fullerene molecules in the crystal cell is more than 10.3 Å, the compound becomes a Mott dielectric.¹⁶¹

It was found that the M_2C_{60} and M_4C_{60} salts, in which the C_{60} molecule accepts two or four electrons, display only semiconductor properties with an activation energy of about 0.5 eV.¹⁶⁰ The significant difference of these phases from the M_3C_{60} phase may be due to a decrease in the symmetry of the fullerene molecule in these compounds. Partial removal of the degeneracy of the t_{1u} orbital and splitting of the conduction band into two bands (completely filled and vacant) with an energy difference between them of ~ 0.5 eV occurs in M_2C_{60} and M_4C_{60} .¹⁶⁰

At $x = 6$, the conduction band is filled completely, and M_6C_{60} compounds are dielectrics.¹³

If more than six electrons are introduced in a C_{60} molecule, filling of the t_{1g} level starts; this level can accept six electrons. Therefore, metallic conductivity is displayed again and transition to the superconducting condition is possible at a degree of reduction of fullerenes, x , in C_{60} compounds from 6 to 12.^{13, 18}

The conductivity of C_{70} fullerene salts is little studied. Calculations show that M_xC_{70} phases, where M is an alkali metal and $x = 4$, can have metallic conductivity, while at $x = 1.8$ they can be semiconductors. For example, the K_4C_{70} phase actually has metallic conductivity but is not a superconductor down to 1.35 K.¹³

b. Intercalation of fullerenes

The crystals of the C_{60} fullerene have a densely packed FCC lattice³⁷ with relatively weak intermolecular bonds between separate molecules. This lattice contains two tetrahedral and one octahedral cavities per molecule with radii 1.10 Å and 2.06 Å, respectively, hence fullerene is a convenient object for intercalation. If the cavities are completely filled with the metal atoms, the composition of the compounds obtained has the formula M_3C_{60} . As the dopant size or the number of its atoms are increased (to $n = 6$), the densely packed FCC-lattice is transformed to a less dense volume-centred cubic (VCC) lattice with six equivalent tetrahedral cavities per C_{60} molecule.^{13, 14, 28}

Diverse methods for the intercalation of fullerenes have been developed. In the most popular procedure for the synthesis of M_xC_{60} compounds, a fullerene and x equivalents of an alkali metal are placed in a quartz tube evacuated to 10^{-2} – 10^{-5} Torr, which is then sealed and heated at 200–500 °C.¹⁶² The intercalation of the C_{60} fullerene with alkali metal hydrides, borohydrides and azides and other reagents has also been described.^{13, 14}

The gas-phase intercalation of the C_{60} fullerene suffers certain drawbacks. In this case, it is difficult to control the degree of reduction of the fullerene; the formation of a mixture of M_xC_{60} phases with different content of the metal is possible (for example, M_3C_{60} contains the M_6C_{60} phase, which is a dielectric). An inevitable heterogeneity of the specimens formed complicates the study of the crystal and electronic structure of these materials.

Single crystals of these compounds are obtained by syntheses with $\text{C}_{60}^{\cdot-}$ and $\text{C}_{60}^{3-\cdot}$ radical anions in solutions.^{153, 154}

Refluxing a fullerene solution with a 90-fold excess of K or Rb in toluene results in a precipitate containing 1% of a superconducting K_3C_{60} phase and 7% of a superconducting Rb_3C_{60} phase.¹⁶³ The addition of 5%–30% of benzonitrile to toluene favours the electron transfer from the alkali metal to the fullerene and interferes with the precipitation of intermediate compounds with the $\text{C}_{60}^{\cdot-}$ and $\text{C}_{60}^{2-\cdot}$ anions, which allows one to obtain specimens with high content (up to $\sim 50\%$) of the superconducting M_3C_{60} phase. Reduction of fullerene with an alkali metal in pure benzonitrile results in M_xC_{60} compounds, where $x = 4, 5$ and 6.¹⁶² A drawback of the method is the presence of an unconsumed alkali metal among the reaction products.

Heating and stirring of a suspension of fullerene in *N*-methylimidazole with a high excess of a metal (Li, Na, Ba, Fe, Cu, Zn) resulted in the corresponding salts of $\text{C}_{60}^{\cdot-}$ and $\text{C}_{60}^{2-\cdot}$. The compounds have the formulas: $[\text{M}(\text{N-MeIm})_x]\text{C}_{60}$ and $[\text{M}(\text{N-MeIm})_x]_2\text{C}_{60}$, where $x = 4$ –6.¹⁴⁸

A series of compounds $\text{M}_x\text{C}_{60}(\text{THF})_y$, where $x = 0.4$ –3 and $y = 1$ –14, have been obtained by the reaction of C_{60} with alkali metals in THF in the presence of 1-methylnaphthalene,⁵⁵ by cooling a C_{60} solution reduced with potassium in tetramethylethylenediamine⁵⁵ or by the reaction of C_{60} with $\text{K}[\text{Mn}(\text{C}_5\text{Me}_5)_2]$ in THF.¹⁶⁴ Salts with small x (~ 0.4) and y (~ 2.2) values have been obtained by electrochemical reduction of fullerene in the presence of an alkali metal tetraphenylborate.⁶¹

The anions $\text{C}_{60}^{3-\cdot}$ in the structure of $\text{K}_3\text{C}_{60}(\text{THF})_{14}$ are packed in linear chains;⁵³ one of the K^+ ions is coordinated with a five-membered ring of C_{60} and serves as a bridge between two fullerene radical anions. The other two K^+ cations are located above and below the $\text{C}_{60}^{3-\cdot}$ anion, forming contacts with six-membered rings of C_{60} . The K^+ cations are also coordinated with THF molecules. Judging by the arrangement pattern of the $\text{C}_{60}^{3-\cdot}$ anions, the structure of $\text{K}_3\text{C}_{60}(\text{THF})_{14}$ is similar to that of M_3C_{60} superconductors with an FCC lattice. However, the distance between the $\text{C}_{60}^{3-\cdot}$ ions is large, and this compound does not display metallic properties.⁵³ A compound with a different stoichiometry, *viz.*, $\text{M}_x\text{C}_{60}(\text{THF})_y$, where $x \sim 0.4$ and $y \sim 2.2$, has a conductivity of 50 S cm^{-1} at room temperature, which increases with a decrease in temperature and is about 1000 S cm^{-1} at 100 K. This is probably due to incomplete charge transfer to the fullerene ($\delta = 0.4$) and the presence of small distances between C_{60} molecule centres along the crystallographic axis c (9.93 Å) in the crystal.⁶¹

After removal of tetrahydrofuran from the salt $\text{K}_3\text{C}_{60}(\text{THF})_7$ by evacuation, keeping at constant temperature at 300 °C for 12 h and subsequent cooling to 103 °C, heat evolution in the sample is observed, which is explained by a transition to a more stable phase with an FCC lattice. As a result, the sample becomes a superconductor containing 31% of the superconducting K_3C_{60} phase.¹⁶⁴

c. Fullerene polymerisation in MC_{60} and M_3C_{60} salts

The intercalation of C_{60} fullerene with alkali metals in stoichiometric ratio (1 : 1) gave the radical anionic salts KC_{60} , RbC_{60} and CsC_{60} .^{157–159} On slow cooling of the intercalation products, [2+2]-cycloaddition of the neighbouring fullerene molecules occurs, which results in the polymerisation of $\text{C}_{60}^{\cdot-}$ into linear chains. The distance between the centres of fullerene molecules decreases to 9.11–9.13 Å.¹⁵⁷ Polymeric compounds are stable in air,¹⁵⁷ insoluble in tetrahydrofuran and depolymerise only on heating above 320 °C. A study of the conductivity of the resulting

polymeric specimens showed that $[\text{KC}_{60}]_n$ is a three-dimensional metal the conductivity of which slowly increases on decreasing the temperature to 4 K.¹⁵⁸ Magnetic measurements also show¹⁵⁹ that $[\text{KC}_{60}]_n$ behaves as a three-dimensional metal down to liquid-helium temperatures. Unlike $[\text{KC}_{60}]_n$, the $[\text{RbC}_{60}]_n$ and $[\text{CsC}_{60}]_n$ polymers are one-dimensional metals and pass to the dielectric state at 50 K and 40 K, respectively. At 25 K, the $[\text{RbC}_{60}]_n$ and $[\text{CsC}_{60}]_n$ polymers undergo magnetic transition with antiferromagnetic ordering of spins in the polymeric chain. The interaction between antiferromagnetic polymeric chains occurs through alkali metal atoms, which results in three-dimensional magnetic ordering of spins.¹⁵⁹

The nature of conductivity in these compounds is not clear yet. It is possible that polymerisation of fullerenes results in π -conjugated bonds between the molecules and the conduction electrons can move through them along the fullerene chain. Another possible mechanism assumes that the carbon atoms that are not bound directly and correspond to the neighbouring fullerene skeletons approach each other with overlapping of the t_{1u} orbitals of these skeletons, and the conduction electrons move through these orbitals.¹³ The second variant is more likely, as it has been shown¹⁵⁸ that the decrease in the ionic radius of the metal on going from rubidium to potassium results in overlapping of the t_{1u} orbitals of fullerenes belonging to different polymeric chains and to a change from one-dimensional to three-dimensional conductivity.

If C_{60} doped by alkali metals is rapidly cooled by liquid nitrogen, polymerisation cannot occur and monomeric radical anionic salts are obtained, such as KC_{60} , RbC_{60} and CsC_{60} .¹⁵⁷ Heating of monomeric KC_{60} above 77 K, or RbC_{60} and CsC_{60} above 160 K, results in dimerisation; the dimeric phase $\text{K}_2(\text{C}_{60})_2$ is a dielectric.¹⁵⁷

It has been shown that the radical anion $\text{C}_{60}^{3-\cdot}$ in compounds M_3C_{60} can polymerise as well.¹⁶⁵ $\text{Na}_2\text{CsC}_{60}$ polymerises with transition to an orthorhombic phase at a pressure of 3 kbar; the resulting polymer maintains superconducting properties.¹⁶⁵

d. Superconducting compounds of C_{60}

To date, about thirty superconductors have been obtained based on C_{60} . Their superconducting transition temperatures range within 2–40 K (Fig. 3).

Compounds with composition M_3C_{60} , where $\text{M} = \text{K}, \text{Rb}$ or a combination of K, Rb and Cs , with an FCC lattice (Fig. 3, 1) have been studied in most detail.^{12–14, 28} It was found for this series of compounds that T_c increases linearly with the size of the alkali metal atom and the distance between the centres of fullerene molecules, $d(\text{C}_{60}-\text{C}_{60})$, in the crystal cell.^{13, 14, 28, 166} An increase in T_c is also observed in the reaction of the M_3C_{60} salts with ammonia. For example, the intercalation of $\text{Na}_2\text{CsC}_{60}$ with

Figure 3. Phase diagram for the salts M_3C_{60} . Dependence of T_c on the closest distance (d) between the centres of C_{60} molecules in crystalline state at room temperature:¹⁴ (1), experimental data for M_3C_{60} (K_3C_{60} , $\text{K}_2\text{RbC}_{60}$, $\text{K}_2\text{CsC}_{60}$, $\text{KRb}_2\text{C}_{60}$, Rb_3C_{60} , $\text{Rb}_2\text{CsC}_{60}$ and $\text{RbCs}_2\text{C}_{60}$) with FCC lattice; (2), experimental data for the series $\text{Na}_2(\text{Rb}_x\text{Cs}_{1-x})\text{C}_{60}$ with simple cubic lattice; (3), $\text{Li}_2\text{RbC}_{60}$; (4), $\text{Li}_2\text{CsC}_{60}$; (5), Cs_3C_{60} with A15 structure, which has superconductor properties under 15 kbar.

ammonia results in $(\text{NH}_3)_4\text{Na}_2\text{CsC}_{60}$ with a similar crystal lattice, while the distance between the $\text{C}_{60}^{3-\cdot}$ radical anions increases from 9.99 Å to 10.23 Å. This is accompanied by an increase in T_c from 10.5 K in $\text{Na}_2\text{CsC}_{60}$ to 29.6 K in $(\text{NH}_3)_4\text{Na}_2\text{CsC}_{60}$.¹⁶⁶ However, it was found¹⁶⁰ that the compound Cs_3C_{60} with the A15-type structure and distances between the fullerenes molecule ~ 10.35 Å is the Mott dielectric and becomes a superconductor with $T_c = 40$ K only at a pressure of 15 kbar.¹⁶⁰

The salts M_xC_{60} have the highest temperature of superconductivity transition for $x = 3$.²⁸ If the stoichiometry deviates from this value in either direction, T_c starts to decrease, and at $x \leq 2$ and $x \geq 4$ the compounds no longer pass into the superconducting state.

On transition from one crystal lattice type to the other, the character of interaction between the neighbouring fullerene molecules changes. Therefore, the compounds $\text{Na}_2\text{MC}_{60}$, where $\text{M} = \text{K}, \text{Rb}$ and Cs , with simple cubic lattice have a different dependence of T_c on the distance between the fullerene molecules than the compounds M_3C_{60} with FCC lattice. A minor increase in this distance in compounds with a simple cubic lattice strongly increases the T_c (Fig. 3, 2).¹⁴

A weak covalent interaction $\text{Li}-\text{C}$ in compounds $\text{Li}_2\text{MC}_{60}$ (Fig. 3, 3, 4) changes their electronic structure, and these compounds do not display superconducting properties.¹⁴

A group of superconductors A_xC_{60} obtained by intercalation of C_{60} with alkaline-earth metals, *i.e.*, Ca, Sr and Ba , is of interest.^{13, 18} Unlike M_3C_{60} ($\text{M} = \text{K}, \text{Rb}, \text{Cs}$), in which the population of the t_{1u} orbital occurs, the superconductivity in these compounds is due to the population of the t_{1g} orbital. The T_c of compounds A_xC_{60} ranges within 4–8.5 K and depends little on the distance between the fullerene ions.¹³ The superconducting state is observed at different populations of the conduction band, but it is rather difficult to determine the exact extent of charge transfer (δ) to the fullerene. In the series of compounds Ca_xC_{60} with $x = 3-6$, Ca_5C_{60} has the maximum conductivity (the degree of charge transfer to C_{60} δ equals 10) and passes in the superconducting state at 8.4 K.^{13, 18} The compounds Ca_3C_{60} ($\delta = 6$) and Ca_6C_{60} ($\delta = 12$) (the conduction band is completely populated) do not display metallic properties.^{13, 18} As opposed to Ca_3C_{60} and Ca_6C_{60} , a weak covalent interaction of Ba and Sr with fullerene in Ba_3C_{60} , Ba_6C_{60} , Sr_3C_{60} and Sr_6C_{60} is possible because of the larger ionic radii of these metals. This results in a decrease in the actual charge transfer to the fullerene and in only partial population of the conduction band at $x = 3$ and $x = 6$.¹⁸ Therefore, Ba_3C_{60} and Sr_3C_{60} display metallic properties, and Ba_4C_{60} , Sr_6C_{60} and Ba_6C_{60} have superconducting properties at $T_c = 4, 7$ and 4 K, respectively.^{13, 18}

It has been shown¹⁶⁶ that C_{60} fullerene intercalated with lanthanides can also be a superconductor (for example, $\text{Yb}_{2.75}\text{C}_{60}$ has $T_c = 6$ K).

e. Intercalation of molecular complexes of C_{60} with alkali metals

Structural diversity of organic molecules allows one to create C_{60} compounds with different packing of the C_{60} molecules in the crystal, *viz.*, one-dimensional chains, two-dimensional layers or three-dimensional arrangement of the C_{60} molecules. Fullerene compounds with one-dimensional and two-dimensional packing of the C_{60} molecules are of special interest for the study of conducting and superconducting properties. In addition, by using different donor molecules, it is possible to control the distance between the fullerene molecules in the crystal lattice in order to obtain materials with high T_c . This stimulated studies of the intercalation of C_{60} complexes with alkali metals. The intercalation of molecular complexes of C_{60} is accompanied by reduction of the fullerene according to the scheme:

Red is reducing agent.

The intercalation of C_{60} complexes with octamethylenetetra-thiafulvalene (**10**) $(OM-TTF)C_{60}(C_6H_6)$ or bis(ethylenedioxy)-tetrathiafulvalene $[(BEDO-TTF) \sim C_{60}]$ with potassium and rubidium is carried out at 10^{-4} – 10^{-5} Torr and 55 and 67 °C, respectively, as in the case of pure C_{60} .^{168, 169} The intercalation of $(OM-TTF)C_{60}(C_6H_6)$ gave compounds with composition $K_x(OM-TTF)C_{60}(C_6H_6)$, where $x \leq 1.8$. Apparently, the solvent is retained in the compound.¹⁶⁸ Because of their small radii, the alkali metal atoms occupy the cavities in the structure of the starting molecular complex; this increases somewhat the parameters of its crystal cell.¹⁶⁹ The intercalation of $(OM-TTF)C_{60}(C_6H_6)$ with potassium gives a superconducting phase with a transition temperature of 17–18.8 K, and that with rubidium gives a superconducting phase with $T_c = 23$ –26 K. The intercalation of $[(BEDO-TTF) \sim C_{60}]$ with potassium yields a superconducting phase with $T_c = 15$ K.^{168, 169}

f. Intercalation of fullerenes and their complexes with halogens

The intercalation of fullerenes with molecular iodine (I_2) and interhalides, *viz.*, IBr and ICl , gives the complexes $(Hal_2)_x C_{60}$. The reaction is carried out at 100–250 °C in evacuated tubes.^{40, 170, 171} The content (x) of the halogen in the sample can vary from 0.2 to 2,^{170–172} depending on the conditions and duration of intercalation. A study of the structure of the $(I_2)_2 C_{60}$ complex has shown that it has a layered structure; the C–I distances (3.6–4.0 Å) are smaller than the sum of the van der Waals radii of carbon and iodine.¹⁷⁰ There is no charge transfer from the fullerene to iodine in these compounds. Iodine is weakly bound to the fullerene and is removed from the compound at 200 °C.¹⁷⁰ $(I_2)_2 C_{60}$ is a dielectric the conductivity of which is less than 10^{-9} S cm⁻¹ (Ref. 170).

A study of the magnetic properties of C_{60} complexes obtained by intercalation of fullerene with I_2 , ICl and IBr revealed magnetic transitions^{40, 171} at 60 K, 30 K and 30 K, respectively. For pure C_{60} and C_{70} fullerenes, these are also observed at 60 K.³⁸ Apparently, these magnetic transitions, like those in the case of pure fullerenes, are due to transition of the specimens to the frozen glassy magnetic state,³⁸ because synchronisation of rotation of the C_{60} molecules is also possible in the presence of shortened contacts between the C_{60} molecules in the crystals of these molecular complexes at low temperatures. Cooling of these specimens in a magnetic field below this temperature results in freezing of a completely ordered orientation of the magnetic moments of the fullerene molecules.

The intercalation of the complexes $(DB-TTF)C_{60}(C_6H_6)$, $(TMDTDM-TTF)_2 C_{60}(CS_2)_3$ and $TPDP(C_{60})_2(CS_2)_4$ with iodine results in compounds with a high content of iodine, *viz.*, $(DB-TTF)C_{60}I_9$, $(TMDTDM-TTF)_2 C_{60}I_{7.5}$ and $TPDP \cdot (C_{60})_2 I_{10}$.^{173, 174}

The intercalation of C_{60} complexes with iodine is based on the solid-phase oxidation of the donor component of these complexes with the formation of a radical cation. The solvent, for example, CS_2 , is displaced by iodine.¹⁷⁴

Ox is oxidant.

The intercalation is accompanied by noticeable changes in the ESR spectra due to the oxidation of the donor.¹⁷³ The optical absorption spectra display a shift (up to 10 nm) of the absorption bands of the basic electron transition ϵ_0 at $\lambda = 260$ and 350 nm and an increase in absorption intensity in the region of 450–620 nm.¹⁷³ These changes can be due to the formation of a radical cation by the donor.¹⁷³ The position of the absorption band of the $T_{1u}(4)$ vibrations of C_{60} (1429 cm⁻¹) in the IR spectrum of intercalated specimens is not changed, which indicates the absence of charge transfer to the fullerene molecule. The starting complexes are dielectrics. Intercalation results in an insignificant increase in the conductivity of the complexes (by a

factor of less than 100), which is apparently due to the large distances between the donor molecules in these complexes.¹⁷⁴

IV. Structure and spectral characteristics of complexes and radical ionic salts of fullerenes

1. Specific features of the crystal structure

The position of the C_{60} molecules in a crystal and the number of direct van der Waals contacts between the fullerene molecules make it possible to distinguish several structural types of fullerene compounds.¹⁷⁵

1. Three-dimensional packing of the C_{60} fullerene molecules with distances between the centres of the molecules ranging from 9.8 to 10.3 Å is observed in fullerene salts $M_x C_{60}$ ($x = 1$ –6) with alkali and alkaline-earth metals. Simple cubic, cubic face-centred, cubic volume-centred and rhombic lattices with the number of closest neighbouring C_{60} molecules from 8 to 12 correspond to this type of packing.^{13, 14}

2. Layered packing, in which two-dimensional dense or loose hexagonal layers of C_{60} molecules are formed. The number of closest neighbouring fullerene molecules ranges from 4 to 6. The layers of donor molecules in these structures also alternate with layers of C_{60} molecules. In the donor layer, *e.g.*, in the $(TMDTDM-TTF)_2 C_{60}(CS_2)_3$ complex,¹⁰³ there are also shortened contacts between the TMDTDM–TTF molecules. A shift of hexagonal layers relative to each other with transition to simple hexagonal packing of layers can be observed in compounds with small donors. This refers to compounds of C_{60} with such molecules as I_2 ,¹⁷⁰ S_4N_4 ,⁹⁵ P_4 ,⁹³ TMPD,¹²⁹ OM–TTF,⁵ TPDP¹⁰⁹ or DAN.⁴⁴

The structure of the $(DAN)C_{60}(C_6H_6)_3$ complex with layered packing of C_{60} molecules is shown in Fig. 4. Each C_{60} molecule in this complex is surrounded by four fullerene molecules with a distance of 10.07 Å between the centres.

Figure 4. Projection of the crystal structure of the complex $(DAN)C_{60}(C_6H_6)_3$ (the positions of the fullerene molecules are indicated with grey spheres) along the crystallographic axis b ⁴⁴ (schematic representation). The solvate benzene molecules (not shown) are located in the dianthracene layer.⁴⁴

3. Cage packing: the fullerene molecules form various cavities or channels, in particular, hexagonal channels, which are filled with donor molecules. The number of the closest neighbouring fullerene molecules can vary from 4 to 8. This structure is represented by compounds of C_{60} with *twin*-TDAS,¹¹³ C_6H_6 ,^{68, 69} and S_8 .^{90, 91}

4. Chain packing: the fullerene molecules form densely packed chains (with two closest neighbouring fullerene molecules) or double chains (with three closest neighbouring fullerene

molecules). This structure is characteristic of complexes of fullerene with BEDT-TTF,^{98,99} *twin*-BEDT-TTF¹⁰² and C₁TET-TTF.¹¹⁰

5. Island mode of packing: in this case, there are no direct van der Waals contacts between the fullerene molecules, and all distances between the centres of C₆₀ molecules are ~12 Å. This type of packing is observed in compounds with large donor molecules (HMT,¹¹⁵ Ph₃Sb¹¹⁶) or cations (Ph₄P⁺ (see Refs 57, 136 and 153) and PPN⁺ (see Refs 58 and 155)).

The structures of some fullerene complexes, for example with such donors as DBTTF¹⁰⁵ and BTX, are intermediate between the cage and island structures.¹¹¹ Figure 5 presents the structure of the DBTTF·C₆₀·C₆H₆ complex. It is characterised by isolated packing of C₆₀ molecules, in which each of them is surrounded by six closest neighbouring fullerene molecules with a distance of 10.4–10.5 Å between the centres. This distance is larger than the van der Waals diameter of fullerene (10.18 Å) but smaller than the distance characteristic of island structures (~12 Å).

Figure 5. Crystal packing of the complex (DB-TTF)C₆₀·C₆H₆ (positions of fullerene molecules are indicated by grey spheres; crystallographic axes are shown by straight lines).¹⁰⁰

Table 7 lists the mean bond lengths of the C₆₀ fullerene molecule in its compounds. It is evident that the bond lengths in C₆₀ change with an increase in the degree of charge transfer to the fullerene molecule; in this case, the 6–5 bonds shorten while the 6–6 bonds elongate. The direction of changes in the bond lengths upon reduction of fullerene is due to the nature of the *t_{1u}* orbital, which is anti-bonding with respect to the 6–6 bonds and bonding with respect to the 6–5 bonds.¹³ This results in elongation of the fullerene molecule, and the C₆₀ sphere is distorted to become an ellipsoid.

Table 7. Lengths of 6–5 and 6–6 bonds for D–A complexes and radical ionic salts of C₆₀.

Compound	Charge on C ₆₀	6–5 Bond length/Å	6–6 Bond length/Å	Ref.
C ₆₀	0	1.467(2)	1.355(9)	176

K ₆ C ₆₀	–6	1.432(1)	1.445(3)	13

2. Stability

The stability of fullerenes with respect to atmospheric oxygen differs from the stability of their compounds. In solid state, fullerenes can adsorb oxygen on their surface.⁶² In solution, they can add oxygen under illumination to give epoxides C₆₀O_{*n*}, where *n* = 1, 2 and 3 (therefore, it is preferable to carry out reactions with fullerenes in the dark).¹⁹ Anionic fullerene compounds are particularly sensitive to oxygen because of the possible reaction

This reaction can also yield addition products C₆₀O₂^{·–} at the fullerene 6–6 or 6–5 bonds.¹⁷⁷

In aprotic media, the redox potential of the O₂/O₂^{·–} couple is –0.8 V,⁴⁸ while the first redox potential of fullerenes, C₆₀/C₆₀^{·–} and C₇₀/C₇₀^{·–}, is –0.4 V.³¹ With these values of redox potentials, oxidation of fullerene radical anions C₆₀^{·–} and C₇₀^{·–} is thermodynamically unfavourable, and hence radical monoanionic fullerene compounds should be stable when exposed to air. This is actually observed for salts containing the C₆₀^{·–} radical anion (KC₆₀, RbC₆₀, CsC₆₀) and salts with bulky cations.^{56–58, 152–154, 157} The instability of salts of C₆₀^{·–} with metalloporphyrins,⁴⁸ metallocenes^{48, 147} and amines^{15, 134} in the air can be due to the fact that protons or metal cations can stabilise the charge on O₂^{·–}. The redox potential of the O₂/O₂^{·–} couple becomes more positive due to stabilisation of the O₂^{·–} radical anion, which enables the oxidation of C₆₀^{·–}.

The second redox potential of fullerenes C₆₀^{·–}/C₆₀^{2–} and C₇₀^{·–}/C₇₀^{2–} is ~–0.8 V,³¹ hence the oxidation of fullerene dianions with oxygen is thermodynamically favourable. Therefore, radical anionic salts containing fullerene dianions or C₆₀^{n–} anions in higher degrees of reduction are very sensitive with respect to oxygen.⁸²

3. Thermogravimetry

Derivatography is generally used to study the thermal stability of both pure fullerene and its compounds.^{43, 44, 54, 75, 101, 104, 178} Heating in air causes complete combustion of fullerene at 650 °C. In nitrogen, fullerene starts to sublime at 600 °C, and the maximum sublimation rate is reached at 700–800 °C.¹⁷⁸

It is possible to determine the content and the strength of binding of a solvent in a complex from derivatograms of molecular complexes of fullerenes.^{43, 44, 54, 75, 101, 104} Thermogravimetric studies of fullerene complexes show that partial decomposition of donors occurs in these compounds. The decomposition temperatures of donors in complexes are close to those of the pure donors. In certain instances, the decomposition temperature of a donor increases owing to its stabilisation because of the donor-acceptor interaction with the fullerene.^{44, 54, 75} The presence of a large amount of a solvent in a molecular complex separates the fullerene molecules from each other. Therefore, the sublimation temperature of the fullerene in such complexes even after complete removal of the solvent is lower^{43, 50, 103} than that of pure C₆₀.¹⁷⁸

4. Spectroscopy of compounds based on fullerenes

A significant number of publications deal with the study of fullerenes and their compounds by spectroscopic methods (see, for example, Refs 5, 22–26, 36 and 179–195).

a. Electronic spectroscopy

Optical spectroscopy is a convenient method for the study of changes in the electronic structure of fullerenes upon formation of donor–acceptor compounds.^{5, 9, 181–185}

The optical absorption spectrum of the C₆₀ fullerene in solid state (Fig. 6) has been studied in detail.^{25, 66} In the ultra-violet region (250–400 nm), two intense bands corresponding to symmetry-allowed electronic transitions are observed. There is a rather strong band in the visible region (λ = 420–540 nm) with a maximum at λ = 450 nm (2.7 eV), the origin of which is not quite clear. This band is absent in the absorption spectra of C₆₀ solutions,²⁵ but appears, for example, upon aggregation of several

Figure 6. The absorption spectrum of C₆₀ in a KBr matrix.¹⁸¹

C₆₀ molecules in a complex with γ -cyclodextrin in aqueous solution.⁸⁴ Therefore, this band is sometimes¹⁷⁹ related to intermolecular transfer of an electron from the HOMO of the C₆₀ molecule to the LUMO of the neighbouring C₆₀ molecule. The absorption at $\lambda = 540\text{--}620\text{ nm}$ (2.2–2.0 eV) has low intensity and corresponds to the symmetry-forbidden $h_u \rightarrow t_{1u}$ transition from HOMO to LUMO of one C₆₀ molecule (see Fig. 1).²⁵ The manifestation of this forbidden transition both in liquid and in solid phase is explained by a deviation of the symmetry of C₆₀ molecules from I_h .²⁵ The absorption edge of fullerene in optical spectra is in the region of 1.95–1.75 eV, which corresponds to 640–700 nm, and it is basically related to exciton transitions.¹⁸⁰

The formation of molecular complexes does not induce considerable changes in the electronic system of fullerenes.¹⁸¹ Irrespective of the solvent, the absorption edge of fullerene in fullerene solvates shifts by 0.1 eV upfield in comparison with pure fullerene,¹⁸⁰ which is explained¹⁸⁵ by separation of fullerene molecules from each other by the solvent.

The spectra of complexes both in solution and in solid state display charge-transfer bands (CTB) from the donor to the fullerene. The process of charge transfer for complexes with an uncharged ground state upon absorption of a light quantum is described by the scheme:

The dependence of the charge transfer energy ($h\nu_{CT}$) on the donor IP for complexes of one acceptor with a series of donors is linear. This dependence is described by the equation:^{5,9}

$$h\nu_{CT} = \alpha(IP - EA) - E_C,$$

where α is a constant, IP is the ionisation potential of the donor, EA is the electron affinity of the acceptor, and E_C is the energy of electrostatic interaction between the donor and acceptor radical ions in the excited state of the complex.

Such a dependence for complexes of the C₆₀ fullerene with substituted anilines¹⁸² and naphthalenes¹⁸³ (IP = 7.2–8.13 eV) in toluene is shown in Fig. 7 and can be described by the expression: $h\nu_{CT} = 0.91IP - 4.34$ (eV).

Table 8 lists the energies corresponding to the maximum of the charge-transfer band for a number of C₆₀ complexes in the solid state. It is evident that $h\nu_{CT}$ decreases with a decrease in the redox potential ($E_{Red/Ox}$) of the donors.⁵

Irradiation of a crystalline complex (TMPD)C₆₀ with visible light (He–Ne laser) was found to cause a strong increase in the absorption at 1070 nm.⁷⁶ This is related to the formation of a long-lived radical anion C₆₀^{•−} upon transfer of an electron from TMPD to C₆₀. The lifetime of the C₆₀^{•−} radical anion in a crystal is about 1 h, which is several orders larger than the lifetime in the case of similar electron transfer in solution.⁷⁶

Figure 7. Dependence of charge transfer energy $h\nu_{CT}$ on ionisation potentials of donors in CTC of C₆₀ in toluene: (1), *N,N*-diethylaniline;¹⁸² (2), *N,N*-dimethylaniline;¹⁸² (3), *N*-methylaniline;¹⁸² (4), 1-methoxynaphthalene;¹⁸³ (5), 2,6-dimethylaniline;¹⁸² (6), *o*-toluidine;¹⁸² (7), 1-methylnaphthalene;¹⁸³ (8), aniline;¹⁸² (9), 1-chloronaphthalene.¹⁸³

^a The exact complex composition has not been determined.

Charge transfer from the donor to the fullerene in the ground state is related to the population of the t_{1u} orbital of the C₆₀ fullerene. This enables electronic transitions from the t_{1u} orbital to vacant molecular orbitals with higher energies (see Fig. 1), which results in the appearance of new absorption bands in the near IR region. Their position corresponds to definite charge of the fullerene molecule:

Fullerene	C ₆₀ ^{•−}	C ₆₀ ^{2−}	C ₆₀ ^{3−}	C ₆₀ ^{4−}	C ₇₀ ^{•−}	C ₇₀ ^{2−}
ν (nm)	1070	950	780	730	1370	1165
			1380	1195

b. IR spectroscopy

The change in the symmetry and redistribution of the electron density upon formation of D–A complexes and radical ionic salts of fullerenes is reflected in their IR spectra.^{9, 25, 26, 184–195}

Due to its high symmetry (I_h), the C₆₀ molecule has 46 characteristic normal vibrations. Four of these are active in the IR spectra [T_{1u} (1–4) vibrations with absorption bands at 527, 577, 1183 and 1429 cm^{−1}, respectively] and ten in Raman spectra; 32 normal vibrations in the C₆₀ molecule are symmetry-forbidden in the dipole approximation.^{25, 26, 186}

In the crystalline C₆₀ fullerene¹⁸⁶ and some of its crystal solvates,^{187, 188} violation of symmetry of the environment of the C₆₀ fullerene molecules is observed, which results in partial modification of symmetry-forbidden vibrations, hence they appear in the IR spectra. This is due to the presence of defects, dislocations, admixtures or solvent molecules in the crystal structure of C₆₀ and in crystal solvates.

At room temperature, the molecules of the C₆₀ fullerene in crystals rotate quickly and isotropically, occupying positions with the T_h symmetry.¹⁸⁸ The T_{1u} vibrations, which are active in IR

spectra of the C_{60} fullerene, are threefold degenerate and appear as single bands. Cooling C_{60} crystals below 255 K results in an orientational-type phase transfer with freezing of the rotation of the fullerene molecules and a decrease in its position symmetry to S_6 .¹⁸⁹ The degeneration of the $T_{1u}(4)$ vibration of C_{60} at 1429 cm^{-1} is eliminated, and at 8 K it is split into three bands with wave numbers 1424.5, 1427.9 and 1431.2 cm^{-1} . The $T_{1u}(3)$ vibration at 1183 cm^{-1} remains unsplit.¹⁸⁹ Similar splitting of the $T_{1u}(4)$ vibration of C_{60} into three bands (Table 9) has been reported in compounds of C_{60} with amines, viz., (TMPD) C_{60} and (TPA) C_{60} .¹⁹⁰ This splitting is due to freezing of rotation of the C_{60} molecules in the crystal of the complex due to the intermolecular interaction with molecules of the donor and a decrease in the positional symmetry of the C_{60} molecules (in comparison with pure fullerene above 255 K).¹⁹⁰

Table 9. Position of the $T_{1u}(4)$ vibration band of fullerene (ν) and degree of charge transfer (δ) estimated from Eqn (2) in donor-acceptor complexes and radical ionic salts of C_{60} .

^a Measured at 8 K; ^b splitting of the $T_{1u}(4)$ band of fullerene on freezing the rotation in the crystal; ^c measured at 293 K; ^d film.

The transfer of electron density from the donor to the C_{60} fullerene in the ground state results in a shift of some of its bands in the IR and Raman spectra.^{26, 191, 192} This is caused by the population of the t_{1u} orbital of the fullerene and interaction of the T_{1u} vibrations with virtual electronic transitions from the t_{1u} orbital to the higher t_{1g} orbital.¹⁹¹ Figure 8 shows the charge dependence of the position of absorption bands (ν) of C_{60} vibrations active in the IR spectrum.^{26, 191} The $T_{1u}(4)$ and $T_{1u}(2)$ vibrations are most sensitive to charge transfer: they are characterised by a linear increase in ν_p and an almost linear shift of ν . The $A_{1g}(2)$ vibration active at 1469 cm^{-1} in the Raman spectrum also has a linear dependence of ν on the degree of reduction of the fullerene molecule.^{26, 192} This relationship may be used for the determination of the degree of C_{60} reduction in salts,²⁶ including that occurring during intercalation. The plasma frequency (ω_p) (square root of the oscillator force) also changes linearly with the charge on the fullerene molecule (Fig. 9).

The change in frequency of absorption bands in the IR spectrum of C_{60} vibrations in D-A complexes makes it possible to estimate even a small degree of charge transfer ($0 < \delta < 1$). This method has already been used previously for the estimation of charge transfer in organic CTC.^{9, 193}

The $T_{1u}(4)$ vibration is most suitable for determination of the degree of charge transfer (δ), as the transition from C_{60} to the C_{60}^- radical anionic salts is accompanied by a strong shift of the absorption band of this vibration from 1429 cm^{-1} to $1390-1395\text{ cm}^{-1}$ (see Refs 26, 48, 184, 191 and 195) (Table 9).

Figure 8. Wave numbers (ν) for different degrees of reduction (x) of the C_{60} fullerene molecule.¹⁹¹ (1), $T_{1u}(1)$ vibrations; (2), $T_{1u}(2)$ vibrations; (3), $T_{1u}(3)$ vibrations; (4), $T_{1u}(4)$ vibrations; (5), $A_{1g}(2)$ vibrations.

Figure 9. Plasma frequency (ω_p) for different degrees of reduction (x) of the C_{60} fullerene molecule.¹⁹¹ (1), $T_{1u}(2)$ vibrations; (2), $T_{1u}(4)$ vibrations.

The change in the positions of absorption bands of three other T_{1u} vibrations active in the IR region on transition from C_{60} to C_{60}^- is less marked.^{26, 192}

Taking into account the linear dependence of the position of the absorption band of the $T_{1u}(4)$ vibrations on the degree of reduction of the fullerene molecule, it is possible to use Eqn (1) for the estimation of the degree of charge transfer in complexes:^{9, 193}

$$\delta = \frac{2\Delta\nu}{\nu_0(1 - \nu_1^2/\nu_0^2)}, \quad (1)$$

where ν_0 is the position of the absorption band of the $T_{1u}(4)$ vibration in neutral C_{60} (1429 cm^{-1}); ν_1 is its average position in C_{60}^- salts [$1392.5 \pm 2.5\text{ cm}^{-1}$, depending on the crystal structure (Table 9)], and $\Delta\nu$ is the difference between the positions of absorption bands of $T_{1u}(4)$ vibrations in neutral C_{60} and in the corresponding complex.

The use of these values in Eqn (1) gives Eqn (2):

$$\delta \approx 0.03 \Delta\nu. \quad (2)$$

The accuracy of estimation of charge transfer δ , which is ± 0.03 , depends on the accuracy of measurement of the positions of absorption bands in IR spectra ($\pm 1\text{ cm}^{-1}$).

One can see from Table 9, which lists the positions of the $T_{1u}(4)$ vibration bands and the degree of charge transfer in C_{60} compounds estimated from Eqn (2), that the degree of charge transfer is close to zero (molecular complexes) for the majority of C_{60} compounds with organic donors. In radical ionic salts, the

degree of charge transfer is close to unity. Only the complexes of C_{60} with TMPD,¹⁹⁰ cobaltocene^{47,48} and dibenzenechromium¹⁵⁰ have intermediate degrees of charge transfer.

c. ESR spectra

The g -factors and ΔH of ESR signals of fullerenes and their compounds are listed in Table 10. In a discussion of the ESR spectra of C_{60} compounds, it is necessary to emphasise the presence of two ESR signals at room temperature in specimens of the initial, 'pure' fullerene, one with $g = 2.0025$ – 2.0021 and $\Delta H = 2$ G^{196,197} and the other with $g = 2.0006$ – 2.0012 and $\Delta H = 0.5$ – 2 G;¹⁹⁶ their widths virtually do not change down to liquid-helium temperatures. These signals originate from defects, *i.e.*, paramagnetic admixtures formed upon oxidation of fullerene with oxygen.^{177,196} The intensity of the former signal increases by an order of magnitude on heating the specimen in air at 623 K for 2 h and by two orders on heating for 24 h.¹⁹⁶ The intensity of this signal changes considerably depending on the way the fullerene has been obtained or stored.

Unlike the signals related to the oxidation of fullerenes, the ESR signals of the $C_{60}^{\cdot-}$ anions have a considerably larger line width ($\Delta H = 20$ – 60 G), which depends strongly on temperature. The ground state of the radical anion $C_{60}^{\cdot-}$ is a singlet ($S = 1/2$) with $g = 1.997$ – 1.999 . This value is smaller than the g -factor of a free electron.^{56,56,61,153} Larger g -factors (2.0008) are observed only in salts of C_{60} with amines.^{38,142} The C_{60}^{2-} anion displays a signal with $g = 2.0010$ and $\Delta H = 10$ – 30 G at room temperature. This corresponds to the triplet state ($S = 1$) with forbidden splitting $D \cong 0$: two electrons with parallel spins are so distant from each other that they behave similarly to electrons with independent spins, therefore their interaction is not displayed in the ESR spectra.⁵⁰ The radical anion C_{60}^{3-} is in a singlet basic state ($S = 1/2$) at room temperature, and its g -factor equals 2.0012–2.0017, and $\Delta H = 10$ – 30 G.⁴⁹ In the compounds M_3C_{60} , the ESR parameters (the g -factor and ΔH) of the C_{60}^{3-} radical anion depend on the nature of the metal.^{13,14} The ESR signals of all of the $C_{60}^{\cdot-}$ anions become much narrower as the temperature is decreased.^{58,153,154}

Due to the Jahn–Teller effect, the presence of fullerene radical anions in C_{60} salts with bulky counter-ions results in violation of the I_h symmetry of C_{60} .^{48–50,149} The effect can be both dynamic

and static on the ESR time scale.¹⁹⁸ At room temperature, a dynamic effect with fast transition from one static Jahn–Teller configuration to the other is observed. Based on the ESR data, the frequency of this pseudo-rotation is estimated as $\sim 10^{12}$ Hz.¹⁹⁸ If the temperature is decreased, pseudo-rotation is hindered, the ESR signal narrows, and transition to the static Jahn–Teller effect is observed. In the salt $(Ph_4P)C_{60}(Ph_4PCl)_2$, this transition occurs when the temperature is decreased to 70 K;¹⁹⁹ this is accompanied by abrupt narrowing of the signal. On further decreasing the temperature, its width almost does not change. The static Jahn–Teller effect at low temperatures (4–70 K) results in transformation of the isotropic ESR signal to anisotropic. For instance, the $Na(18\text{-crown-6})C_{60}(\text{THF})_3$ salt displays an anisotropy of the g -factor: $g_{\perp} = 1.9968$, $g_{\parallel} = 2.0023$.⁴⁸

As the symmetry of the $C_{60}^{\cdot-}$ radical anion decreases from I_h to D_{5d} , the T_{1u} state splits into two states, *viz.*, E_{1u} and A_{2u} (Fig. 10). The difference between the energies of the E_{1u} and A_{2u} states is small and equals 1 kcal, therefore thermal population of the overlying A_{2u} state can occur, and an additional 'high-temperature' signal with $g = 2.000$ appears in the ESR spectrum of $C_{60}^{\cdot-}$.⁴⁸

Figure 10. Scheme of partial removal of degeneracy of the t_{1u} orbital in the $C_{60}^{\cdot-}$ radical anion upon lowering the symmetry from I_h to D_{5d} .⁴⁸

The radical anion $C_{70}^{\cdot-}$ in the $(Ph_4P)_2C_{70}I$ salt gives a broad ESR signal with $g = 2.047$,¹⁵⁴ as does that in the salt $(TDAE)C_{70}$, with $g = 2.0022$.^{136,137} Higher fullerenes display a narrow signal with $g = 2.0023$,¹⁴³ which is close to the g -factor for the free electron.

The ESR signal of the $C_{60}^{\cdot-}$ radical anion in some fullerene complexes has been used to determine the degree of charge

transfer from the donor to C_{60} (based on the number of $C_{60}^{\cdot-}$ spins per formula unit).^{123, 127, 128}

d. X-ray photoelectron spectroscopy

X-Ray photoelectron spectroscopy (XPS) is a sensitive method for the determination of the valence state of elements in thin (0.5–4.0 nm) surface layers. Based on the position of lines corresponding to internal electronic shells of heteroatoms of the donors contained in the complex and their shift relative to the lines of the individual donor, it is possible to estimate the redistribution of the electron density upon formation of a D–A compound and the atomic composition of the compound.^{200–205}

The C(1s) X-ray photoelectron spectrum of the C_{60} fullerene consists of the main singlet peak with an energy of 285 eV. The higher energy region contains a satellite shifted by 5.9 eV from the main C(1s) peak. It originates from excitation of a π -plasmon, *i.e.*, coordinated vibrations of π -electrons of the C_{60} molecules in a crystal.²⁰⁶ The density of valence electrons is determined from the electron energy loss spectra (EELS). The loss function has two peaks in the case of the C_{60} fullerene,^{203, 206} which correspond to the π -plasmon with a maximum at 5.8 eV originating from excitation of plasma vibrations of π -electrons and the $(\pi + \sigma)$ -plasmon with a maximum at 26.1 eV originating from excitation of all valence electrons in C_{60} .^{203, 206}

The position of the C(1s) peak in the XPS spectra of molecular complexes and salts of fullerenes remains unchanged, but some changes in its satellite structure occur.^{44, 205} The disappearance of $\pi - \pi^*$ transitions of phenyl substituents of the donors in the satellite structure of C_{60} compounds, *e.g.*, in (DAN) $C_{60}(C_6H_5)_3$ ⁴⁴ and in salts with bulky cations,²⁰⁵ has been reported. This is due to the strong interaction of the phenyl substituents of the donor with the fullerene or to the fact that, upon formation of a compound with fullerene, the $\pi - \pi^*$ transitions in the donor molecule become less favourable than the excitation of plasma vibrations of π -electrons of the fullerene itself.^{44, 205} In many compounds, a decrease in the energy of the $\pi + \sigma$ -plasmon is observed: 24.0 eV in $(S_8)_2C_{60}$,²⁰³ 25.2 eV in (BTX) $C_{60}(CS_2)$ ^{54, 119} and 25.5 eV in TPDP(C_{60}) $_2(CS_2)_4$.⁴³

The shift in the position of the S(2p), N(1s) and Te ($3d_{5/2}$) lines of the donor heteroatoms in various fullerene complexes by 0.1–1.0 eV towards higher energies can be caused^{200, 201, 204} by the electron density shift from the donor to the fullerene. However, in some cases a similar shift in fullerene complexes in comparison with the individual donors can also be due to the calibration of spectra of the complex and the donor with respect to the C(1s) line, as the exact position of this line in the spectra of the donor and C_{60} can differ.²⁰⁰ A shift in the position of the S(2p) peak in compound $(S_8)_2C_{60}$ towards lower energies by 0.4 eV has been reported.²⁰³

e. ^{13}C NMR spectroscopy

The ^{13}C NMR spectrum of crystalline C_{60} fullerene at room temperature contains a narrow singlet at δ 143.²⁹ This is caused by fast rotation of the C_{60} molecule and isotropic averaging of the signal. As the temperature is decreased, the rotation of fullerene molecules is hindered, and broadening of the signal is observed.²² The observed phase transitions in fullerene at 255 and 90 K result in stepwise changes in the line width. The formation of molecular complexes does not change the position of the ^{13}C NMR signal of the fullerene.^{93, 98, 114} The formation of fullerene anions, C_{60}^{n-} ($n = 1, 2, 3$), causes a shift of the ^{13}C NMR signal towards lower magnetic field, which can be due to the paramagnetic state of these ions.^{50, 207, 208} However, the salts containing the $C_{60}^{\cdot-}$ and C_{60}^{2-} anions have close chemical shifts of signals in the ^{13}C NMR spectra (δ 187 and 183, respectively), though their magnetic susceptibilities differ strongly.^{207, 208} A shift of the ^{13}C NMR signal to δ 156 is also observed in the diamagnetic state of the C_{60}^{6-} anion.²⁰⁸

V. Conclusion

Based on the survey of the most important results concerning the synthesis and properties of the D–A complexes and radical ionic salts of fullerenes obtained over the last years, one can distinguish the most important directions of the development in this field and evaluate some possibilities of using fullerene compounds, both for obtaining new materials and for solving fundamental problems.

The ability of molecules of the C_{60} fullerene, its molecular complexes and salts to synchronise their rotation in crystals results in the appearance of unusual magnetic properties in these compounds. The existence of the frozen glassy magnetic state of fullerenes and molecular complexes of fullerenes with halogens has been established; radical anionic salts of $C_{60}^{\cdot-}$ with unsaturated amines possess ferromagnetic properties with the highest T_c among organic materials; various magnetic properties are displayed by complexes of C_{60} with metallocenes. Obviously, synthesis of D–A complexes of fullerenes with strong organic and organometallic donors, *viz.*, unsaturated amines, metallocenes and metalloporphyrins, and the study of their structure and properties will lead to new interesting results.

Another important direction includes the synthesis of conducting and superconducting materials based on fullerene compounds. By now, several dozens of superconductors with $T_c \leq 40$ K have already been obtained based on C_{60} and some specific features of their superconductivity have been rationalised. Superconducting phases can exist in fullerene compounds with alkali or alkaline-earth metals, lanthanides, and in salts of C_{60} with strong organic donors: they can be obtained both by direct chemical synthesis and by intercalation in the gas phase.

Fullerenes are weak acceptors, and the range of donors capable of reducing them to radical anions is limited. In addition, the essential drawback of both superconducting and ferromagnetic compounds of fullerenes is their instability in air. This restricts considerably the possibilities of obtaining and applying the fullerene-based materials with specific conducting and magnetic properties.

One possible way to solve these problems is the synthesis of three-component systems. The systems ‘organic donor – fullerene radical anion – alkali metal cation’ include a wider range of ionic compounds of fullerenes. In some of them, the fullerene radical anion can be stabilised because the bulky organic donor sterically hinders the approach of oxygen molecules to the fullerene radical anion.

In the majority of fullerene complexes that have been obtained, in particular in the complexes with tetrathiafulvalenes, charge transfer is insignificant because of the weak acceptor properties of C_{60} and C_{70} . However, in a three-component system ‘donor radical cation – neutral fullerene – halide anion’, fullerene compounds with radical cations of the donors can be obtained. Similar compounds can also possess conducting and magnetic properties.

Three-component systems can be obtained by intercalation of fullerene complexes (with either alkali metals or halogens) or by direct synthesis in solution. In the latter case, it is probably possible to obtain single crystals of these compounds.

Synthesis of complexes of chemically modified fullerenes, in particular, brominated, chlorinated and fluorinated ones, seems to be a promising direction. Unlike the C_{60} and C_{70} molecules, these derivatives have strong acceptor properties and can apparently yield molecular complexes and radical ionic salts with strong organic donors (*e.g.*, tetrathiafulvalenes).

The significant delocalisation of electrons in C_{60} upon photo-induced electron transfer results in the formation of free charge carriers and high photoconductivity. In the near future, this phenomenon can find application for the development of energy phototransducers and other devices that use photoconductivity. Therefore, the study of electron photoconduction in fullerene compounds is an important direction. The most promising compounds for the development of materials with high photo-

conductivity can include both the composites 'C₆₀ – conducting polymer' and D–A complexes of fullerenes with organic donors, in which charge separation with significant life time is possible. The use of the combination 'organic donor – C₆₀ – conducting polymer' is also promising.

The authors thank Yu M Shul'ga for useful discussions. The work has been carried out with financial support of the Russian programme 'Fullerenes and Atomic Clusters'.

Recyclisation of carbo- and heterocyclic compounds involving malononitrile and its derivatives[†]

V P Litvinov

Contents

I. Introduction	39
II. Recyclisation of three- and four-membered rings	39
III. Recyclisation of five-membered rings	41
IV. Recyclisation of six-membered rings	45
V. Conclusion	50

Abstract. Published data on recyclisation reactions of carbo- and heterocycles with participation of malononitrile and recyclisation of compounds containing a malononitrile fragment or fragments with malononitrile as a synthon are surveyed, described systematically and analysed. The bibliography includes 206 references.

I. Introduction

Recyclisation of carbo- and especially heterocyclic compounds occupies an important place in organic chemistry. Recyclisation in the presence of various nucleophilic, electrophilic or dipolar reagents occurs as opening of the ring in the initial molecule and its subsequent closure. This process is often accompanied by ring expansion or contraction, introduction of a heteroatom in the ring or its replacement by another heteroatom, *etc.* Nevertheless, from the preparative viewpoint, all these complex transformations occur during a one-stage reaction, which makes possible relatively easy synthesis of compounds that are difficult to obtain by other methods or modification of heterocyclic fragments in complex, including natural, molecules. The latter is fairly important for the synthesis of new biologically active products. At present, a large number of transformations of this type are known; they include name reactions, for example, the Yur'ev, Zincke–Konig and Hafner reactions, the Dimroth, Boulton–Katritzky, Cornforth and Kost–Sagitullin rearrangements, *etc.* The problem of recyclisation is considered in numerous publications and reviews (see, for example, Refs 1–24).

Malononitrile **1**, containing highly reactive methylene and cyano groups,²⁵ is of special interest as a reagent for recyclisation of carbo- and heterocyclic compounds. In this review, we consider recyclisation reactions with participation of malononitrile and its derivatives including carbo- and heterocyclic compounds with vicinal cyano groups. Primary attention is paid to the synthetic potential of these reactions and less space is given to the reaction mechanisms, because the data on the mechanisms are quite limited and often contradictory.

II. Recyclisation of three- and four-membered rings

In 1983, a group of German scientists found that cyclopropene derivatives **2** react with the malononitrile anion, generated by treatment of malononitrile with sodium methoxide in methanol, to give functionally substituted cyclopentadienes **3**. Bicyclic derivatives **4** were postulated as intermediates in this reaction.²⁶

Cycloaddition of *N*-cyclohexenylpyrrolidine **5** to 2,2-dimethyl-1,1-cyclopropanedicarbonitrile **6** has been reported.²⁷ The reaction follows an S_N2 mechanism and yields adduct **7**. On partial hydrolysis, this product rearranges into spiro compound **8**, which is further hydrolysed to give 5-(4,4-dimethyl-2-oxocyclopentyl)pentanoic acid **9**.

The reactivity of substituted tetracyanocyclopropanes has attracted considerable attention of researchers in recent years. Thus it was found that treatment of 3,3-phthaloylcyclopropane-1,1,2,2-tetracyanitrile **10** with nucleophiles (alcohols or ketox-

[†] This review is dedicated to the memory of Professor Yu A Sharanin.

imes) induces recyclisation of the cyclopropane fragment in **10** and results in the formation of 2-alkoxy-2-(2-alkoxycarbonylphenyl)-5-amino-4-cyano-3-dicyanomethylene-2,3-dihydrofurans **11**.^{28,29}

R = Me, Et, (CH₂)₂OH, N = CMe₂, N =

Unlike the cyclopropane **10**, 3,3-diacetylcyclopropane-1,1,2,2-tetracyanonitrile **12** reacts with alcohols or ketoximes in the presence of catalytic amounts of the corresponding sodium alkoxides or oximates with retention of the cyclopropane ring to give substituted 3-oxabicyclo[3.1.0]hexane-1,6,6-tricyanonitriles **13**.^{28,30} However, when a twofold excess of the catalyst is used, 2,3-dihydrofuran derivatives **14** are formed under similar conditions.

R = Me, Et, N = CMe₂, N = CMeEt, N = CMeBu, (CH₂)₂OH,
N = , N =

The cyclopropane ring is also retained when substituted pyrazoline-4-spirocyclopropanetetracyanonitriles **15** are treated with alcohols and ketoximes under the same conditions; this reaction affords adducts **16**.³¹

R = Pri, Ph; R' = Me, Et, N = CMe₂, N = CMeEt, N = , N =

When ethyl pentacyanocyclopropanecarboxylate **17** is made to react with alcohols in the presence of an equimolar amount of the corresponding alkoxide, it undergoes recyclisation to give 5,5-dialkoxy-2-amino-4-dicyanomethylene-2-pyrroline-3-carbonitriles **18**. The formation of a stable intermediate, sodium pentacyanopropenide **19**, was noted.³²

R = Me, Et.

2*H*-Pyrazolo[3,4-*b*]pyridines **21** have been prepared by recyclisation of tetracyanocyclopropanes **20** involving phenylhydrazine.³³

R = Me, Et, Ph, 4-ClC₆H₄, 4-NO₂C₆H₄.

The reaction of 3-dicyanomethylene-1,2-diphenylcycloprop-1-ene **22** with 3,4-dihydroisoquinolines **23** in ethanol is accompanied by recyclisation giving rise to 4-dicyanomethylene-2,3-diphenyl-4*H*-2,3,6,7-tetrahydropyrido[2,1-*a*]isoquinolines **24** in 73%–78% yields.³⁴ Refluxing of the compound **22** with isonitriles **25** in acetonitrile results in the formation of 4-dicyanomethylene-4*H*-cyclopenta[2,3-*b*]imidazole derivatives **26** in 43%–58% yields.³⁵

R = H, Me, Ph.

R = Ph, CO₂Et.

Various three-membered heterocycles, oxiranes,^{1,36} thiiranes^{1,36–38} and aziridines,^{38,39} can also undergo recyclisation on treatment with nucleophiles. Thus it was found that the reaction of oxiranes **27** with malononitrile in the presence of sodium ethoxide in ethanol occurs as recyclisation yielding 2-amino-4,5-dihydrofuran-3-carbonitrile **28**.^{40–42}

R¹ = H, Me, Et, Ph; R², R³ = H, Me.

In the case of oxiranes **29**, recyclisation proceeds *via* acyclic intermediates **30**, which were treated with malononitrile after isolation. This afforded 2-amino-4-nitromethyl-4,5-dihydrofuran-3-carbonitrile **31** in yields of up to 60%.^{43–45}

R = H, Me.

2-Methoxy-2,3-diphenyloxirane **32** recyclises in the presence of sodium malononitrile giving rise to 2-amino-4,5-diphenylfuran-3-carbonitrile **33**.⁴⁶

The γ -iminolactone **35** has been synthesised by treatment of the oxirane **34** with potassium malononitrile in *tert*-butyl alcohol.⁴⁷

It has also been reported^{48,49} that recyclisation of 2,2-dicyano-oxiranes **36** in the presence of amidines **37** affords 4-aminoimidazole-5-carbonitriles **38**.

Thiiranes also enter into recyclisation reactions.^{1, 38, 42, 50–52} For example, thiiranes **39a–c** react with malononitrile in the presence of sodium hydride in DMSO giving 2-amino-4,5-dihydrothiophene-3-carbonitriles **40a–c** in 50%–62% yields. Note that in the case of the thiiranes **39a,b**, ring opening occurs in conformity with Krasuski's rule, while in the case of **39c**, the ring opens against this rule.^{38,50}

$R^1 = H$; $R^2 = H$ (**a**), Me (**b**), Ph (**c**).

Recyclisation reactions for three-membered nitrogen-containing heterocycles have been reported.^{42,52–54} The reaction of aziridines **41** with malononitrile in the presence of sodium hydride affords different products depending on the reaction conditions and the ratio of the reactants.⁴² When the compounds **1** and **41** are taken in equimolar amounts, 2-amino-1-(toluene-*p*-sulfonyl)-4,5-dihydropyrrole-3-carbonitrile **42** is formed. The reaction with a twofold excess of the initial aziridine **41** (Bu^tOK , 10 °C) yields spiro compound **43**, whereas the use of a twofold excess of malononitrile and an increase in the reaction temperature to 100 °C results in the formation of 2,3-dihydropyrrolo[2,3-*b*]pyridine **44**.

Recyclisation of four-membered heterocycles with participation of malononitrile is also known. Thus the reaction of 2-oxetanone **45** with malononitrile in the presence of sodium hydride affords 2-amino-3-cyano-6-methyl-4-pyrone **46**.⁵⁵

Treatment of 1-ethoxycarbonyl-5-oxo-4-oxaspiro[2.3]hexane **47** with malononitrile under similar conditions gives rise to a mixture of cyclopentenone **48** and 2-amino-4-pyrone **49** (yields 49% and 24%, respectively).⁵⁶ 1-Dimethoxyphosphoryl-1-methyl-5-oxo-4-oxaspiro[2.3]hexane **50** reacts with malononitrile under the same conditions to afford 2-amino-3-cyano-6-(2-dimethoxyphosphorylpropyl)-4-pyrone **51** in 58% yield.⁵⁶

III. Recyclisation of five-membered rings

Recyclisation of tetracyanocyclopentanes **52** has been reported.^{57,58} Depending on the reaction conditions, they are transformed into 2-dicyanomethylene-pyrrolidines **53** or tetracyanopiperidones **54**.

$R^1 = Me$; $R^2 = Me, Et$; $R^1 = Pr$, $R^2 = Me$.

A scheme for the transformation of 2-dicyanomethyleneindane-1,3-dione **55** into salts **56** has been proposed.⁵⁹ The transformation is attained by refluxing **55** in acetonitrile in the presence of lithium iodide or methyltriphenylphosphonium iodide or by stirring it in dry THF with finely divided sodium. The reaction scheme includes a single-electron transfer in the indanedione **55** resulting in symmetrical radical anion **57**, which cyclises to give spirocyclopropane intermediate **58**. The rearrangement of the compound **58**, accompanied by cyclopropane ring opening, and subsequent cyclisation result in the formation of cyclopropane intermediate **59**. This compound also recyclises to afford salts **56**. Treatment of the lithium or methyltriphenylphosphonium salt **56** with concentrated hydrochloric acid gives 2,3-dicyano-1,4-naphthoquinone **60** in 65% and 40% yields, respectively.⁵⁹

(a) M^+I^- , MeCN, Δ , $M = Li, Ph_3PMe$; (b) Na, THF, 20 °C, 48 h.

The review on molecular rearrangements of five-membered heterocycles¹¹ published in 1984 presents virtually no data on recyclisation with participation of malononitrile or recyclisation of heterocyclic systems containing malononitrile fragments. Meanwhile, an original pathway to aminoazulenes **61** consisting in recyclisation of lactones or iminolactones, 2*H*-cyclohepta[*b*]-furan derivatives **62**, on treatment with methylene active nitriles, including malononitrile, had been reported in the literature.^{36, 60–63}

X = O, NAc; R = CO₂Et, COMe.

2,5-Disubstituted pyrrolidine-3,3,4,4-tetracarboxitriles **63** react with aromatic amines to give 2-aminopyrrole-3,4-dicarbonitriles **64**.⁶⁴ Depending on the ratio of the reactants, the reactions of the compounds **63** with primary alcohols in the presence of KOH yield either 3,4-dicyanopyrroles **65** or substituted 3*H*-pyrrolo[2,3-*d*]pyrimidines **66**.^{65, 66}

R = Ph; R' = Ph, 3-MeC₆H₄.

R = Ph, 4-BrC₆H₄, 4-FC₆H₄, 4-MeC₆H₄, O-C₆H₄; R' = Me, Et, Pr.

4-Acetyl-2,5-dimethyloxazole **67** also reacts with malononitrile with recyclisation of the oxazole ring. This reaction results in the formation of 3-amino-6-dicyanomethyl-2,4-dimethylpyridine-5-carbonitrile **68** in 33% yield. 5-Acetyl-2,4-dimethyloxazole **69**, which is an isomer of the compound **67**, reacts with malononitrile

under similar conditions being thus converted into 2-acetyl-5-amino-3-methylcyclopentadiene-1,1,4-tricarbonitrile **70** in 60% yield.⁶⁷

It has been noted^{68–71} that isoxazoles **71** recyclise to give 2-amino-4*H*-pyran-3,5-dicarbonitriles **72**. Opening of the isoxazole ring in the compound **71** under the action of an aldehyde and EtONa in ethanol gives rise to substituted nitriles **73**. The subsequent nucleophilic attack on the compounds **73** by malononitrile followed by cyclisation of the Michael adducts **74** affords aminopyrans **72**.⁶⁹

R¹ = Me; R² = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, Bu^t;
R¹ = Ph; R² = Prⁱ, Bu^t, CH₂Et₂.

In turn, when fused isoxazoles **75** and **76** are made to react with malononitrile in the presence of triethylamine, the corresponding annelated 2-amino-3-cyanopyridine 1-oxides **77** and **78** are formed in high yields.^{70–72}

R¹ = H, Me; R² = H, NO₂; R³ = H, Cl, NO₂.

Recyclisation of 4-aminothiazolin-2-ylidenemalononitriles **79**, prepared from 4-aminothiazoline-2-thiones **80**, in the presence of sodium ethoxide in ethanol giving substituted 3,5-diaminothiophene-2,4-carbonitriles **81** has been described.⁷³

$\text{R}^1 = \text{OEt}, \text{NH}_2$; $\text{R}^2 = \text{Me}, \text{Ph}, \text{Bn}, \text{CH}_2\text{CH}=\text{CH}_2$.

Substituted 4-dicyanomethylenethiazolidin-5-ones **82** form complexes **83** with morpholine. Hydrolysis of these complexes with hydrochloric acid affords pyrrolo[3,4-*c*]pyridine derivatives **84**, whereas their interaction with NaOH followed by acidification gives rise to furo[3,4-*c*]pyridine derivatives **85**.⁷⁴

$\text{R}^1 = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$; $\text{R}^2 = \text{Ph}, 4\text{-MeC}_6\text{H}_4$.

It was also shown that 2-methylthio-5,7-diphenyl-1,3,4-oxadiazolo[3,2-*a*]pyridinium iodide **86** reacts with malononitrile in ethanol in the presence of triethylamine to give 2-amino-5,7-diphenylpyrazolo[1,5-*a*]pyridine-3-carbonitrile **87**.⁷⁵

2-Methylthio-5-phenyl-1,3,4-thiadiazolo[3,2-*c*]-4-quinazolinium iodide **88** reacts with malononitrile in a similar way, with elimination of one heteroatom from the five-membered ring. Thus it was shown that the salt **88** reacts with malononitrile in dry

acetonitrile in the presence of triethylamine to give 2-amino-3-cyanopyrazolo[1,5-*c*]quinazoline **89**.⁷⁶ When potassium triethylamine is replaced by potassium *tert*-butoxide, a mixture of the pyrazoloquinazoline **89** and 3,4-dihydroquinazoline **90** is formed.⁷⁶

Recyclisation of 1,3-oxathiolium salts **91** on treatment with malononitrile has been used successfully in the synthesis of functionally substituted thiophenes **92**.^{36, 77–81} In the general form, the mechanism of this reaction includes the attack on the 2-position of the salt **91** by the malononitrile anion to give adduct **93**. The subsequent cleavage of the ring at the C(2)–S(3) bond in the compound **93** gives intermediate **94**, which then cyclises according to the Thorpe reaction pathway to give imine **95**; this product isomerises into more stable 3-aminothiophene **92**.

$\text{R}^1 = \text{Ph}, 4\text{-BrC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4$,

$\text{R}^2 = \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-Me}_2\text{NC}_6\text{H}_4$.

1,3-Oxathiolidene-2-immonium salts recyclise in a similar way to give functionally substituted thiophenes.^{81,82}

The reaction of 3-methylthio-1,2-dithiolium iodides **96** with ylidenemalononitriles **97** in dichloromethane in the presence of triethylamine has been shown⁸³ to afford dithiolyldenemalononitriles **98** and recyclisation products — 2-iminothieno[3,2-*b*]thiopyran-3-carbonitriles **99**.

$\text{R}^1 = \text{Ph}, \text{SMe}, 4\text{-MeOC}_6\text{H}_4$; $\text{R}^2 = \text{H}, 4\text{-MeC}_6\text{H}_4$;
 $\text{R}^3 = \text{Ph}, 4\text{-MeOC}_6\text{H}_4$.

The reaction of iodide **100** with malononitrile in the presence of triethylamine in chloroform is also accompanied by recyclisation of the dithiole fragment. Simultaneously, ring expansion occurs and 2-imino-4-(*N*-methylanilino)-2*H*-[1,4]dithiapyrino-[2,3-*b*]indole-3-carbonitrile **101** is formed in 83% yield.⁸⁴

1,3,4-Dithiazolium perchlorates **102** react with malononitrile in the presence of a base (Et_3N , NaH, pyridine, γ -picoline) in EtOH, THF, CH_2Cl_2 or MeCN. Depending on the substituent at the C(5) atom, the base used and the ratio of the reactants, this gives 4-amino-2-(1-cyano-2-dialkylamino-2-sulfanylviny)-6-phenylpyrimidine-5-carbonitriles **103**, 2-dicyanomethylene-5-phenyl-1,3,4-dithiazole **104** or substituted 1,3-butadiene **105**.⁸⁵

B is a base.

The pathway of the reactions of 1,3-dithiolium perchlorates with malononitrile also depends substantially on the nature of the substituents in the heterocycle and the solvent used. For example, the reaction of 2-diethylamino-4-phenyl-1,3-dithiolium perchlorate **106a** with malononitrile in the presence of a weak base (γ -picoline) results in the formation of 2-dicyanomethylene-4-phenyl-1,3-dithiole **107**, whereas in the presence of a strong base (triethylamine), 3-amino-5-diethylamino-2-thiobenzoylthiophene-4-carbonitrile **108a** is formed.⁸⁵

R = NEt_2 (a), NMe_2 (b).

However, when 2-dimethylamino-derivative **106b** is used as the substrate, 1,3-dithiole **107** is formed in the presence of the strong base, triethylamine.

Similarly, the final products formed in the reaction of 4,5-diphenyl-1,3-dithiolium perchlorates **109** with malononitrile depend on the reaction conditions; this reaction can yield (in various proportions) 2-dicyanomethylene-4,5-diphenyl-1,3-dithiole **110**, 2-amino-5,6-diphenyl-1,4-dithiine-3-carbonitrile **111** and 4-amino-2-dicyanomethylene-5,6-diphenyl-2*H*-thiine-3-carbonitrile **112**.⁸⁵

$\text{NR}_2 = \text{NEt}_2, \text{N} \begin{array}{c} \diagup \diagdown \\ \text{O} \end{array}$.

The reaction of 3,5-diphenyl-1,2,4-dithiazolium perchlorate **113** with malononitrile on refluxing in THF in the presence of sodium hydride is accompanied by recyclisation and gives 2,6-diphenyl-4-sulfanylpurine-5-carbonitrile **114** in 92% yield.⁸⁶

2-(2-Hydroxyphenyl)-4-dicyanomethylene-4*H*-1,3-benzoxazine **116** and 5-imino-2-(2-hydroxyphenyl)-1-benzopyrano-[4,3-*d*]pyrimidine-4-thione **117** have been synthesised by recyclisation of 1,2,4-dithiazolidine **115** involving malononitrile in the presence of NaF (refluxing for 2 min in a 1:1 DMSO:Pr₂O mixture).⁸⁷

On fusion with malononitrile (15 min, 90 °C), 2-butylbenzimidazo[1,2-*d*][1,4]thiadiazol-3(2*H*)-one **118** undergoes recyclisation with elimination of isocyanate to give 3-imino-2,3-dihydrobenzimidazo[2,1-*b*][1,3]thiazole-2-carbonitrile **119**.^{88,89}

In a series of studies,^{90–93} it has been found that benzofuroxans recyclise on treatment with malononitrile giving rise to substituted 2-amino-3-cyanoquinoxaline *N,N*-dioxides. Recyclisation of benzofuroxan-15-crown-5 **120** during the reaction with malononitrile in DMF in the presence of triethylamine, resulting in the formation of 2-amino-3-cyanoquinoxaline *N,N*-dioxide **121**,⁹³ can be cited as an example.

IV. Recyclisation of six-membered rings

For six-membered carbocycles containing a malononitrile fragment, base-induced recyclisation of 1-amino-1,3-cyclohexadiene-2,6,6-tricarbonitriles **122**, resulting from dimerisation of alkylidenemalononitriles, has been reported. This reaction yields 2-dicyanomethylene-1,2-dihydropyridine-3-carbonitriles **123** and involves intermediate formation of *cis(trans)*-2-amino-1,3,5-hexatriene-1,1,3-tricarbonitriles **124**.^{94–101}

$\text{R}^1 = \text{Ph}, 4\text{-MeC}_6\text{H}_4$; $\text{R}^2 = \text{Ph}, 4\text{-FC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, \text{cyclo-C}_3\text{H}_5$.

The formation of acetylaminothiophene **125** in a low yield in the recyclisation of hexa-1,3-diene **126** upon refluxing with morpholine polysulfide in ethanol for 4 h has been described.¹⁰²

Recyclisation of six-membered heterocycles with participation of malononitrile possesses a substantially greater synthetic potential. First of all, mention should be made of recyclisation of heterocyclic compounds to carbocyclic compounds. For example, recyclisation of 2,4,6-triphenylpyrylium salt **127** during its reaction with malononitrile in *tert*-butyl alcohol in the presence of potassium *tert*-butoxide affords 2-amino-3-cyano-4,6-diphenylbenzophenone **128**, which is difficult to obtain by other methods, in a high yield.^{103–106}

Later, this reaction was used to prepare 2-amino-3-cyano-4-methyl(or phenyl)-6-piperidylaceto(or benzo)phenones **129**¹⁰⁷ and 2,4,6-triphenylbenzonitrile **130**¹⁰⁸ from pyrylium salts **131** and 2,4,6-triphenylthiapyrylium perchlorate **132**.

$\text{R} = \text{Me}, \text{Ph}$.

The synthesis of 4-amino-2-benzoyl-1-phenylfluorene-3-carbonitrile **133** in 89% yield by the reaction of 2,4-diphenyl-5*H*-indeno[2,1-*b*]pyrylium perchlorate **134** with malononitrile in acetonitrile in the presence of piperidine has been reported.¹⁰⁹

2-Benzopyrylium salt **135** undergoes similar recyclisation on treatment with malononitrile in the presence of sodium *tert*-butoxide in *tert*-butyl alcohol. This gives 2-amino-1-(3,4-dimethoxybenzoyl)-4-methyl-6,7-dimethoxynaphthalene-3-carbonitrile **136** in 33% yield.¹¹⁰

$\text{R} = 3,4\text{-(MeO)}_2\text{C}_6\text{H}_3$.

Of other examples of recyclisation of six-membered oxygen-containing heterocycles with malononitrile, the formation of (2-amino-3-cyano-4*H*-1-benzopyran-4-yl)acetamide **138** from coumarin **137** should be mentioned.¹¹¹

It has been reported¹¹² that 2-formyldimedone **139** reacts with malononitrile in the presence of piperidine in methanol or ethanol to give 2-amino-4-dicyanomethyl-7,7-dimethyl-5-oxo-5,6,7,8-tetrahydrobenzopyran-3-carbonitrile **140** in 78% yield and 3-cyano-7,7-dimethyl-5-oxo-5,6,7,8-tetrahydro-2(1*H*)-quinolone **141** in 20% yield.

A new method for the synthesis of compounds of the benzo[*h*]quinoline series **142** has been proposed.¹¹³ The method is based on the Michael addition of malononitrile to 2-arylidene-1-tetralones **143** in the presence of sodium methoxide in methanol. The reaction mechanism was confirmed by isolation of the reaction intermediate, 4*H*-naphtho[1,2-*b*]pyran **144**.

$\text{R} = \text{H}, \text{Me}, \text{Cl}, \text{OMe}, \text{NO}_2$; $\text{R}' = \text{Me}, \text{Et}$.

The condensation of pyrazolinone **145** with malononitrile in the presence of ammonium acetate and methyl ethyl ketone on refluxing in ethanol for 3 h gives rise to substituted nicotinonitrile **146**.^{114,115}

The reaction of 4*H*-pyrans **147**, incorporating a dicyanomethylene fragment, with amines is accompanied by recyclisation and results in the formation of 4-dicyanomethylene-1,4-dihydropyridines **148**.^{116–118}

R = Alk, Ar.

However, the reactions of 4-dicyanomethylene-2-phenyl-4*H*-benzo[*b*]pyran **149a** and the corresponding thiopyran **149b** with malononitrile in methanol in the presence of KOH gives 5-amino-4-cyano-2-phenylbenzo[*b*]pyrano[4,3,2-*de*][1,6]naphthiridine **150a** or the corresponding thiopyranonaphthiridine **150b**.¹¹⁹

X = O (a), S (b).

The benzopyran **149a** reacts with primary amines under mild conditions giving rise to 4-amino-5-*R*-imino-2-phenyl-4*H*-[1]benzopyrano[3,4-*c*]pyridines **151**.¹²⁰

R = Ph, Bn, PhNH.

In order to synthesise analogues of the antitumour antibiotic streptonigrin, recyclisation of 4-dicyanomethylene-2-(2-quinolyl)-4*H*-[1]benzopyran **152** in pyridine in the presence of NH₄OH has been studied. This reaction gave 4-amino-5-imino-2-(2-quinolyl)-4*H*-[1]benzopyrano[3,4-*c*]pyridine **153** in 91% yield.¹²¹

Recyclisation of 4-dicyanomethylene-2-(2-hydroxyphenyl)-4*H*-[1,3]benzoxazine **154** induced by various nucleophiles follows a similar pathway. Thus refluxing of the benzoxazine **154** in 2-methoxyethanol in the presence of ammonium acetate affords 2-(2-hydroxyphenyl)-4,5-diimino-3,4-dihydro-5*H*-[1]benzopyrano[4,3-*d*]pyrimidine **155a** in 91% yield.¹²² The thiazine **155b** was prepared by treatment of the benzoxazine **154** with hydrogen sulfide in the presence of triethylamine, and the 1,3-oxazine **155c** was synthesised by treatment of the compound **154** with hydrochloric acid in 2-methoxyethanol. It was noted that adducts **156a–c** are formed as intermediates in this reaction; in the case of the thiazine **155b** and oxazine **155c**, the Dimroth rearrangement occurs under the reaction conditions, yielding 2-(2-hydroxyphenyl)-5-imino-4-thio-3,4-dihydro-5*H*-[1]benzopyrano[4,3-*d*]pyrimidine **157** and 2-(2-hydroxyphenyl)-4,5-dioxo-3,4-dihydro-5*H*-[1]benzopyranopyrimidine **158**.¹²²

X = NH (a), S (b), O (c).

When isatic anhydride [2*H*-3,1-benzoxazine-2,4(1*H*)-dione] and its substituted derivatives **159** react with malononitrile in DMF in the presence of triethylamine and then the reaction mixture is hydrolysed with 48% HBr or 6*N* KOH, they are converted into 2-amino-4-hydroxyquinolines **160**.^{123,124} Compounds **161** and **162** were identified as reaction intermediates.

R = H, Cl, Me, OMe.

Recyclisation of pyrimidines involving malononitrile has been studied comprehensively.^{19, 125–136} For the reaction of 1,4,6-trimethylpyrimidin-2-yl iodide **163**, it was found that first the 4(6)-position of the pyrimidine nucleus in the compound **163** is attacked by the malononitrile anion, which gives adduct **164**. Then the pyrimidine ring in the compound **164** is cleaved at the N(3)–C(4) bond. Due to the presence of both nucleophilic [the N(1) atom] and electrophilic [the nitrile group carbon atom] reaction sites, the intermediates **165** and **166** thus formed cyclise to give pyridine **167**. The latter is stabilised by being converted into aminopyridine **168** upon abstraction of an aminomethylene fragment as methylamine and formic acid.¹²⁵

Recyclisation of 2,3-disubstituted 4(1*H*)-pyrimidinethiones **169** on treatment with malononitrile in ethanol in the presence of sodium ethoxide affords pyridinethiones **170** in 78%–93% yields.¹²⁸

R¹ = Ph; R² = Ph, 3-MeC₆H₄, 4-MeC₆H₄; R¹ = R² = 4-MeC₆H₄.

Recyclisation of 2(1*H*)-pyrimidinediones¹²⁹ and fused pyrimidines, such as quinazolines,¹³² 1*H*-pyrazolo[3,4-*d*]pyrimidines¹³¹ and their 3-oxides¹³⁰ occurs in a similar way. The scheme for the recyclisation of pyrimidinediones can be represented in relation to the interaction of 5-cyano-1,3-dimethyluracil **171** with malononitrile.^{134, 135}

Recyclisation of 1-thia-2*a*,5*a*-diazacacenaphthene system **172** on treatment with malononitrile in ethanol in the presence of sodium ethoxide giving fused tetracyclic heterocyclic compound **173** in 88% yield has been described.¹³⁶

The recyclisation of 1-phenylphthalazine 3-oxide **174** during its reaction with malononitrile in methanol in the presence of sodium methoxide is accompanied by the loss of two nitrogen atoms and gives 3-phenylindene-2-carbonitrile **175**.¹³⁷

The recyclisation of 2,3-diphenyl-5,6-dihydropyrazine **176** occurring on refluxing with malononitrile in ethanol over a period of 1 h follows a peculiar pathway and affords 2,6-diamino-4,10-diphenyl-1,7-diazatricyclo[5.2.1.0^{4,10}]deca-2,5-diene-3,5-dicarbonitrile **177** in 70% yield.¹³⁸

Recyclisation of 1,3,5-oxadiazinium salts **178** with participation of malononitrile carried out in acetonitrile in the presence of triethylamine has been reported. 2-Amino-6-aryl-4-carbamido-pyrimidines **179** were obtained in this way in 65%–83% yields.¹³⁹

$R^1 = \text{Ph}; R^2 = \text{Me}, R^3 = \text{Me}; R^2, R^3 = (\text{CH}_2)_5, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2.$

When reacting with malononitrile, 1,3,5-triazine undergoes recyclisation, similar to the transformation of pyrimidines into pyridines. This gives 4-aminopyrimidine-5-carbonitrile in 80% yield.^{140, 141} Recyclisation of 4*H*-1,2,4,6-thiatriazine 1,1-dioxide **180** yielding 3-amino-4-cyano-1,2,6-thiadiazine 1,1-dioxide **181** should be classified as the same type of reaction.¹⁴²

3-Cyanopyridin-2(1*H*)-ones, -thiones, -selenones and their derivatives represent an important class of heterocyclic compounds because of the diversity of their chemical transformations and the possible practical applications.^{36, 76, 143–154} These bifunctional compounds, which contain the nitrile and the oxo-hydroxy, thione–thiol or selenone–selenol functional groups in the vicinal positions, proved to be promising starting compounds in the preparation of annelated heterocyclic systems difficult to obtain by other methods.^{143, 144} The strategy of the synthesis of 3-cyano-2-pyridinones, -thiones and -selenones and their hydrogenated analogues is based, first of all, on cyclisation of functionally substituted carbonyl compounds or their derivatives with malononitrile or other derivatives of cyanoacetic acid.^{155–164} During these studies it was found that thio(seleno)pyrans **182a,b** are formed in the reactions of arylidenemalononitriles **183** with cyanothio(or seleno)acetamides **184a,b**, or in a one-step procedure involving aromatic aldehydes, malononitrile, and the amides **184a,b**, or in the reactions of arylidenecyanothio(or seleno)-

acetamides **185a,b** with malononitrile. The compounds **182a,b** readily recyclise to give the corresponding pyridinethiones (or selenones) **186a,b**.^{143, 144, 155, 157, 159, 161, 164–179}

$X = \text{S (a)}, \text{Se (b)}.$

According to the results of physicochemical studies, including X-ray diffraction analysis, the thio(or seleno)pyran ring in the compounds **182a,b** occurs in the flattened boat conformation in which the aryl substituent at the 4-position is equatorial.^{159, 168, 180–183} The steric overcrowding of the thio(or seleno)pyran molecules **182a,b** with bulky electron-withdrawing substituents hampers the bond inversion in the ring and inversion of the substituents and thus makes impossible the conformational transitions in the heterocycle at higher temperatures. Therefore, on heating, ring cleavage at the weakest bond occurs (it is denoted by a dashed line in the scheme) and the compounds **182a,b** are then converted into pyridinethiones(or selenones) **186a,b**. In some studies,^{165, 184–186} faulty data on the structures of the thiopyrans **182a** and the pyridinethiones **186a** are presented. The structure of the thiopyrans **182a** ($\text{Ar} = 4\text{-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$) was attributed to the corresponding pyridinethiones **186a**.^{165, 168} The structures of 5-acetyl-2-amino-4-(4-methoxyphenyl)-6-methyl-4*H*-thiopyran-3-carbonitrile and 2,4-diamino-5-cyano-3-(2-furyl)-methylene-3,6-dihydropyridine-6-thione reported in the literature^{185, 186} are also erroneous. In addition, it has been found that the thiopyrans **182a** recyclise on treatment with dimedone **187** to give 2-amino-4*H*-pyran-3-carbonitriles **188**, whereas on treatment with ketones, **182a** are converted into pyridinethiones **189**.¹⁸⁷

An original pathway to substituted pyridinethiones **190** has been proposed.¹⁸⁸ The reaction of β -enaminothioamides **191** with malononitrile under kinetically controlled conditions gives substituted thiopyrans **192**; on heating with a base under thermodynamically controlled conditions, these products are converted into pyridinethiones **190**, their yields being more than 80%.

$$\begin{array}{c}

 \quad \text{193} \qquad \qquad \qquad \text{194}$$

The ylidene-derivatives of 6-amino-2*H*-thiopyran-5-carbonitrile **195**, prepared from thiopyrylium salts, are converted into 2,6-dicyano-3-sulfanylanilines **196**; this reaction is similar to the reactions of pyrylium salts with nucleophiles.¹⁸⁷

the pyridimethionones **200** and **201**.

Reaction of **199** with $R^1 = R^2 = \text{Me}$ in MeOH at 20–25 °C yields **200**, while reaction in DMF at 150–160 °C yields **201**.

NC1=C(C#N)C(=S)SC1(C)C(R2)C(R1)C (**199**, $R^1 = R^2 = \text{Me}$)

 In MeOH, 20–25 °C → Cc1c(C)c(C#N)c(=S)n1C(=S)C2=CC=C(C)C=C2 (**200**)

 In DMF, 150–160 °C → CCc1c(C)cc(C#N)c(=S)n1C(=S)C2=CC=C(C)C=C2 (**201**) + **200**

R^1H_2C(R^2)S(=O)(=O)c1c(N)cc(C#N)c(Ar)c1 (**199**) $\rightarrow$ R^1H_2C(R^2)S(=O)(=O)c1c(N)cc(C#N)c(Ar)c1 (**202**) + NC(=O)C(R^2)=C(Ar) (**203**) $\rightarrow$ $\left[\text{Intermediate} \right] \xrightarrow{-H_2S}$ R^1C1=C(C#N)C(=S)N(C1)C2=CC(=CC=C2)Ar (**189**)

The mechanism of recyclisation of 4*H*-thiopyrans and 1,3-dithiacyclohex-4-enes **199** was confirmed by studying their cross-recyclisation with various CH acids, α -methylene ketones, 1,3-dicarbonyl compounds and their enamines, ethyl cyanoacetate and malononitrile.^{25, 143, 144, 181–183} Under thermodynamically controlled conditions, cycloelimination of heterocyclic compounds **182** and **199** occurs, yielding arylidenecyanothioacetamides **203** and either malononitrile or thioketones, respectively. The subsequent competing transformations of the amides **203** involving malononitrile or carbonyl compounds give rise to substituted pyridinethiones **204** or **186a**.

X = Alk, OAlk; Y = Alk.

To elucidate the mechanism and stereochemistry of transformations of the heterocyclic compounds **182a** and **199**, their reactions with pyridinium ylides have been studied.^{144, 156, 181, 182} It was found that in this case, too, arylidenecyanothioacetamides **203** are formed as intermediates; they react stereoselectively with pyridinium ylides to give 3,4-*trans*-1,2,3,4-tetrahydropyridine-2-thiolates **205**. The latter are converted into pyridinethiones **206** on heating with ammonium acetate in acetic acid.

The results obtained demonstrated that the stereochemistry and the electronic structures of heterocyclic compounds **182a** and **199** have similar features, namely, (1) both molecules contain a planar enamionitrile fragment with a well-developed system of p,π-conjugation; (2) they are partially hydrogenated; (3) they contain a nonplanar ring sterically overcrowded with alkyl and aryl substituents; (4) they contain one or several electron-withdrawing groups as substituents. Due to these features, when the enthalpy increases, the compounds **182a** and **199** cannot decrease their energy upon conformational transitions; instead, they undergo cycloelimination involving the weakest bonds.

The reactions of arylidenecyanothioacetamides **203** with dimedone afford substituted pyrans **207**, which recyclise in the presence of bases to give intermediates **208** and then quinoline-thiolates **209**.^{203–206}

V. Conclusion

The data on recyclisation of carbo- and heterocyclic compounds with participation of malononitrile and its derivatives considered here clearly demonstrate the high synthetic potential of these reactions and good prospects for using them in the syntheses of various compounds, including products that are difficult to obtain by other methods, which possess a broad spectrum of useful properties.

The review was written with the financial support of the Russian Foundation for Basic Research (Project No. 96-03-32012a).

Reductive amination of oxygen-containing organic compounds

V A Tarasevich, N G Kozlov

Contents

I. Introduction	55
II. Reductive amination of carbonyl compounds with ammonia and amines	55
III. Reductive amination of alcohols with ammonia and amines	60
IV. Reductive amination of aldehydes and ketones with nitro compounds and pyridine bases	62
V. Reductive amination of aldehydes, ketones and alcohols with nitriles and oximes	63
VI. Conclusion	69

Abstract. The data dealing with reductive amination of oxygen-containing organic compounds of different classes are systematised. New data on the amination agents and the catalysts used are presented. The dependence of the reactivity of reagents on their structures is considered. The bibliography includes 249 references.

I. Introduction

Reductive amination or hydroamination is widely used for the synthesis of amines. This method is based on the reaction between oxygen- and nitrogen-containing compounds on the surface of a catalyst under a hydrogen atmosphere or in solution in the presence of hydrogen donors.

In the literature, this reaction is often referred to as 'reductive alkylation', which does not reflect exactly its chemical essence.

It has been shown in numerous studies that during the reaction with oxygen-containing compounds in the presence of hydrogen donors, some nitrogen-containing compounds, namely, nitro and nitroso compounds, nitriles and oximes, are first reduced to amines, and then the latter react with oxygen-containing compounds. Thus, this reaction occurs successfully when an amino group is present; therefore, it is more correct to call this reaction 'reductive amination' or 'hydroamination' rather than 'reductive alkylation'.

This review deals with reductive amination reactions involving hydrogen or hydrogen donors; the reaction conditions and the catalysts used are discussed.

II. Reductive amination of carbonyl compounds with ammonia and amines

The ability of ammonia and amines to form imines with aldehydes and ketones and the fact that imines can be reduced relatively easily to the corresponding amines permitted the synthesis of amines by direct amination of carbonyl-containing compounds

with ammonia or amines. Hydrogen (in the presence of a catalyst) or formic acid and its derivatives are used most often as the reducing agents in this process. This reaction is widely employed to prepare amines from various aldehydes and ketones.

Mignonac^{1,2} was the first to carry out the reductive amination of aldehydes and ketones with ammonia. Mixtures of the corresponding primary, secondary and tertiary amines were obtained from aliphatic aldehydes and ammonia in the presence of nickel catalysts.

In the first stage of the reaction, ammonia adds to the carbonyl compound (Scheme 1, pathway *a*); this is followed by the reduction of either the product of nucleophilic addition itself, α -amino alcohol **1** (pathway *d*), or the product of its dehydration, imine **2** (pathways *b* and *c*).³ In some cases, the imines formed in the condensation of carbonyl compounds with ammonia can be isolated, whereas the α -amino alcohol **1** could not be isolated.⁴

As the primary amine is accumulated in the reaction mixture, it enters into reaction with the initial carbonyl compound similarly to ammonia (Scheme 1, pathway *e*). The imine **3**, which is formed upon dehydration of the condensation product, is converted into secondary amine (pathways *f* and *g*). In addition, primary amine can react with the imine **2** to give addition product **4**, the reduction of which also gives a secondary amine (pathways *h–j*). Secondary amines also can enter into this type of reactions (pathways *k–n*); this gives tertiary amines. Thus, the process occurs as a set of consecutive and parallel reactions yielding a mixture of primary, secondary and tertiary amines.

To suppress the formation of secondary and tertiary amines, the reductive amination of carbonyl compounds is carried out in the presence of ammonium salts.⁵ Under these conditions, only primary amines are formed. Apparently, an excess of ammonium salts shifts equilibrium towards primary amines; in addition, the formation of secondary amines is suppressed because primary amines lose their nucleophilic properties upon transformation into alkylammonium ions

For example, the introduction of ammonium chloride into the reaction mixture during hydroamination of 1-(2,5-dimethoxyphenyl)propan-2-one **5** with ammonia in methanol in the presence of Raney nickel permitted the synthesis of 2-amino-1-(2,5-dimethoxyphenyl)propane **6** in 95% yield.⁶

Scheme 1

Most often, hydroamination of carbonyl-containing compounds with ammonia is carried out in the presence of nickel catalysts.^{7–9} When metallic rhenium and rhodium supported on alumina are used as the catalysts, the total yield of primary and secondary amines reaches 93%–95%.¹⁰ In order to direct the process at the formation of secondary amines, catalysts are often modified by various oxides. Thus the reaction of cyclohexanone **7** with ammonia catalysed by the 0.35% PdO/SiO₂ catalyst modified by Ag, Mn, K, Na and Al oxides gives dicyclohexylamine **8** in 97% yield.¹¹

Synthesis of 2,2-disubstituted 1,5-diaminopentane derivatives by the reaction of the corresponding aldehydes containing a terminal nitrile group with excess ammonia over acid catalysts has been reported.^{12,13} The imino nitrile formed in the first stage is hydrogenated over catalysts based on Co, Ni, Ru and other noble metals at 60–150 °C and 5–15 MPa. The yields of diamines amount to 50%–72%.

The use of reduced promoted fused iron catalysts (RPFIC) in various reactions, most of all, in reductive amination of carbonyl-containing compounds, has been described in a review.¹⁴ Among other reactions, the reductive amination of octan-2-one with ammonia has been studied in detail.^{15–18} The kinetic isotope effect observed after replacement of H₂ by D₂ made it possible to propose a stepwise mechanism of reductive amination of carbonyl compounds, the addition of hydrogen to ketimine being the rate-determining step.

Hydroamination of 3,5,5-trimethylcyclohex-2-enone (isophorone, **9**) with ammonia in the presence of a copper–zinc–aluminium catalyst (SNM-1) and RPFIC at 160–230 °C has been reported.^{19,20} The yield of 3,3,5-trimethylcyclohexylamine **10** reaches 90%–95%.

3-Aminomethyl-3,5,5-trimethylcyclohexylamine **11** is prepared by reductive amination of 1,3,3-trimethyl-5-oxocyclohexanecarbonitrile **12** with simultaneous reduction of the cyano group at 50–150 °C on Raney nickel or cobalt using anhydrous Ni, Co, Y, and La halides as co-catalysts. The yield of the amine **11** was 83%.²¹

Transformation of aldehydes and ammonia into secondary amines was attained²² by using a three-component catalyst based on Cu, a metal of the series Cr, Mn, Fe and Zn and a platinum group metal (Pt, Pd, Ru, Rh). The predominant formation of either primary or secondary amines from ketones and ammonia can depend significantly on the procedure used to prepare the catalysts and on the catalyst composition, all other factors being the same. Study of hydroamination of cyclohexanone **7** with ammonia in the presence of various catalysts has demonstrated²³ that in the presence of a nickel catalyst, the primary amine, cyclohexylamine **13**, is formed predominantly, whereas the use of colloidal platinum results in the secondary amine **8** being formed as the major product.

However, later,²⁴ it was found that in the presence of platinumated silica gel, the ketone **7** is readily converted into the primary amine **13** rather than into the secondary amine **8**, as noted in the study²³ cited above. Thus, depending on the method for the preparation of the platinum catalyst, either secondary or primary amines can be synthesised. Hydroamination of alicyclic ketones with aromatic amines in the presence of catalysts containing Ru, Rh, Pd or Ni supported on γ -Al₂O₃ yields, depending on the temperature conditions, either cycloaliphatic or aromatic sec-

dary amines. For example, at 180 °C and $p_{H_2} = 5$ MPa,²⁵ dicyclohexylamine was obtained from cyclohexanone **7** and aniline **14a** over a nickel catalyst, whereas the reaction between the same compounds or their *para*-substituted derivatives at temperatures of dehydration of alicyclic compounds (above 300 °C) gives²⁶ only the corresponding diarylamines.

R, R' = H (**a**), Hal (**b**), Alk (**c**).

The reductive amination of arylaliphatic aldehydes and ketones with ammonia results in the formation of primary aliphatic-aromatic amines.^{9,27,28} The reaction is complicated by the reduction of the corresponding carbonyl compounds to hydrocarbons. The yield of the amination products is influenced by the location of the carbonyl group with respect to the aromatic ring of the initial aldehyde or ketone. The yields of amines produced from aromatic aldehydes or alkyl aryl ketones are much lower than the yields of amines formed upon hydroamination of ketones in which the carbonyl group is removed from the aromatic nucleus. Thus over a nickel catalyst at 150 °C and 8 MPa, acetophenone is converted into 1-phenylethylamine **16** in 50% yield.²⁸

Under the same conditions, benzylideneacetone **17** gives 2-amino-4-phenylbutane in 84% yield.²⁹

In this case, it should be borne in mind that the reaction starts with hydrogenation of the alkene double bond. This eliminates the conjugation between the carbonyl group and the aromatic nucleus. Thus it has been shown³⁰ that hydrogenation of 3-phenylacrolein **19** at 80 °C and $p_{H_2} = 2$ MPa gives initially aldehyde **20** and then alcohol **21**.

A method has been proposed^{31,32} for the synthesis of diamines **22** from aliphatic dialdehydes containing four to ten carbon atoms; according to this method, they are treated with excess ammonia and hydrogen in the presence of Ni, Co, Pd or Ru catalysts at 40–150 °C and a pressure of 10 MPa.

In order to prevent the formation of secondary amines and possible intramolecular cyclisation giving a heterocyclic deriva-

tive, excess ammonia is used (the ammonia : aldehyde molar ratio is 5 : 1). Conversely, an excess of the initial dicarbonyl compound is favourable for the formation of heterocyclic systems. Thus the reaction of acetonylacetone **23** with ammonia [the diketone : ammonia molar ratio is (2–3) : 1] in the presence of Raney nickel at $p_{H_2} = 15$ MPa resulted in the synthesis of a mixture of 2,5-dimethylpyrrole **24** and 2,5-dimethylpyrrolidine **25**, *i.e.* amination and cyclisation were accompanied by hydrogenation of the pyrrole ring.³³ Esters of 4-oxo acids behave in a similar way.

Hydroamination with primary amines, like hydroamination with ammonia, involves evidently the intermediate formation of addition product **26**, which is either hydrogenated to amine **27** or is converted initially into imine **28** and then into the amine.³⁴

A kinetic study of the catalytic reductive amination of acetone **29** with isopropylamine **30** in aqueous alcohol over a platinum catalyst at 29 °C has demonstrated³⁵ that the reaction consists of two steps: the formation of imine **31** and its subsequent hydrogenation, giving rise to diisopropylamine **32**.

This pathway to secondary amines, which includes the formation of imines, has also been confirmed in studies dealing with hydroamination of furfural **33** with aromatic amines. It was shown that the reaction over palladium catalysts includes the initial formation of the corresponding imines, which are then hydrogenated, in particular, in the furan ring.^{36–38} The yields of substituted *N*-(2-tetrahydrofurylmethyl)anilines **34** vary from 10% (for *o*-bromoaniline) to 85% (for aniline). When palladium immobilised in the polymeric matrix of the AB-17-8 or AN-1 anion exchanger is used, the yield of *N*-(2-tetrahydrofurylmethyl)aniline reaches 100%.

R = H, *m*-Me, *p*-Me, *o*-Me, *m*-Hal, *p*-Hal, *o*-Hal.

The reductive amination of furfural **33** with cyclohexylamine over the same catalysts at 20–60 °C and $p_{H_2} = 0.98-1.03$ MPa in a solvent (an alcohol or a hydrocarbon) affords *N*-(2-tetrahydrofurylmethyl)cyclohexylamine **35** in a high yield.

Palladium catalysts immobilised in an anion-exchanger polymeric matrix are inferior to Pd/C regarding the rate of formation of the amine **35** but are superior regarding the selectivity and the service stability. The rate of reductive amination of the aldehyde **33** was found³⁹ to be directly proportional to the dielectric constant of the solvent.

N,N-Diethylaminophenols are prepared⁴⁰ in high yields by reductive amination of acetaldehyde with *o*-, *m*- and *p*-aminophenols at 150 °C and $p_{H_2} = 2$ MPa in the presence of Pt, Pd or Ni catalysts in the medium of an aliphatic alcohol (MeOH, EtOH, Pr^nOH). For example, in the case of *m*-aminophenol, the yield of *N,N*-diethyl-*m*-aminophenol was 98.4%. In a study of reductive amination of aliphatic ketones with primary amines, it has been found^{41–43} that the product yield is substantially influenced by steric factors caused by the structures of both the ketone and the initial amine. Steric restrictions were considered⁴⁴ to be the only reason for the fact that the yields of amines upon the hydroamination of ketones with cyclohexylamine **13** decrease in the sequence acetone > methyl ethyl ketone > diethyl ketone. When ethanolamine is used instead of cyclohexylamine, steric hindrance markedly diminishes, and the yields of hydroamination products obtained from acetone and diethyl ketone **36** become almost identical. Study of the influence of steric factors on the reductive amination of acetone with aniline and 2,4,6-trimethylaniline **37**⁴⁵ has shown that the sterically hindered amine **37** is converted into secondary amine, *N*-isopropyl-2,4,6-trimethylaniline **38**, in 36% yield (when aniline is used, the yield of the corresponding secondary amine increases to 98%).

The yield of the product of reductive amination of benzylideneacetone **17** and benzylideneacetophenone **39** with toluidines⁴⁶

varies as a function of the position of the methyl substituent in the aromatic amine. The yields of secondary amines **40** in the hydroamination of the ketone **17** were 14.0, 35.0 and 52.4% for *o*-, *m*- and *p*-toluidine, respectively. Meanwhile, it was found that the yields of secondary amines formed from aliphatic amines increase with an increase in the basicity of the amine used.

$R = Me$ (**17**), Ph (**39**).

Secondary amines of the aliphatic series have been prepared in two stages from primary amines and aldehydes.⁴⁷ In the first stage, imines were synthesised; after isolation, they were hydrogenated over a platinum catalyst in anhydrous EtOH. The total yields of the imines **41** and the amines **42** were 40%–63%.⁴⁸

$R = R' = Et, Pr^n, Pr^i, Bu^n, Bu^i$.

Reductive amination of carbonyl compounds of the furan series has been studied only occasionally. Reductive amination of unsaturated ketones **43** with ammonia has been reported.^{49–51} The reaction was carried out in methanol saturated with ammonia over skeletal nickel–aluminium catalyst and under a hydrogen pressure of 12–14 MPa.⁵²

$n = 1, 2$; $R = Alk$.

The synthesis of pyrrole (**44**) and pyrrolidine (**45**) homologues from furan derivatives **46**, containing an amino group in the alkyl substituent, over platinum catalysts should be regarded as a peculiar intramolecular reductive amination reaction (Scheme 2). The reaction consists of two stages: hydrogenolysis of the furan ring at the O(1)–C(5) bond to give amino ketones **47** and amino alcohols **48** and their intramolecular hydroamination leading to the formation of a heterocycle.^{53–55} Selective hydrogenolysis at the O(1)–C(5) bond is possible only with platinum catalysts

Scheme 2

$R = R' = H, Me, Et$; $R'' = H, Me$.

(Pt/C, Pt/asbestos); in this case, the mixture of reaction products contains pyrrolidines and pyrroles with a propyl radical at the 5-position. Pyrrolidine homologues are formed at 200–220 °C, their yields being 85%–90%, whereas pyrrole homologues are produced at 300 °C in ~85% yield. The yields of *N*-methyl-substituted pyrrolidines and pyrroles are somewhat lower (70% and 73%–75%). High-boiling nitrogen-containing compounds (2%–3%) and the recovered amine (~23%) were also detected in the product mixture.⁵⁵

The structure of the pyrrolidines and pyrroles formed is determined by the structure of the aminoalkyl side chain.^{54,55} The influence of the structure of alkyl and aminoalkyl groups in the molecules of the furan derivatives **49** on the course of hydrogenolysis and the formation of pyrrole and pyrrolidine trialkyl derivatives was studied.⁵⁵

$R = R' = R'' = H$ (a); $R = Me, R' = R'' = H$ (b); $R = R' = R'' = Me$ (c).

When the substituents R and R' at the carbon atom attached directly to the furan ring in **49** are methyl groups, hydrogenolysis of the furan ring is more selective, due to the shielding effect, and involves the $O(1)–C(5)$ bond. In addition, in the presence of these substituents, the formation of the pyrrole ring is impossible. As a result, catalytic hydrogenation of 2-(3-amino-1,1-dimethylbutyl)-5-methylfuran **49c** over platinum catalysts at 250 °C resulted in the synthesis of 2-*n*-butyl-3,3,5-trimethylpyrrolidine **51**.⁵⁶

Whereas the reaction on platinum catalysts gives only one series of pyrrolidine homologues owing to the selective rupture of the $C(5)–O(1)$ bond at 200–220 °C, in the presence of skeletal nickel–aluminium catalysts, three series of pyrrolidine homologues containing methyl, ethyl or *n*-propyl groups at the 2-position can be obtained (Scheme 3).⁵⁷

Scheme 3

(a) rupture of the $O(1)–C(5)$ bond; (b) rupture of the $O(1)–C(5)$ and $C(4)–C(5)$ bonds; (c) rupture of the $O(1)–C(5)$ and $C(3)–C(4)$ bonds.

The yield of pyrrolidines in the hydrogenolysis products was, on the average, 70%–75% based on the consumed amine. The pyrrolidines formed contained 35% of 2-methyl-4-*R*-pyrrolidines, 20% of 2-ethyl-4-*R*-pyrrolidines and 45% of 2-*n*-propyl-4-*R*-pyrrolidines. The formation of a particular pyrrolidine homologue depends substantially on the reaction temperature. For example, when the temperature is raised to 270 °C, the proportion of 2-methyl-4-*R*-pyrrolidines increases to approximately 50%–60%; however, the overall content of pyrrolidines in the reaction products diminishes to 30%–40%. The synthesis of pyrrole homologues over skeletal nickel–aluminium catalyst is carried out at 300 °C;⁵⁸ in this case, the mixture of pyrroles contains 30% of 2-methyl-5-*R*-pyrroles, 25% of 2-ethyl-5-*R*-pyrroles and 45% of 2-*n*-propyl-5-*R*-pyrroles (Scheme 4).

Scheme 4

(a) rupture of the $O(1)–C(5)$ bonds; (b) rupture of the $O(1)–C(5)$ and $C(4)–C(5)$ bonds; (c) rupture of the $O(1)–C(5)$ and $C(3)–C(4)$ bonds.

Hydroamination of cyclohexanone **7** and cyclopentanone **52** was performed⁵⁹ using azobenzene **53**, 1,2-diphenylhydrazine **54** and cyclohexanone phenylhydrazone **55**. It is known that hydrazines are able to undergo hydrogenolysis over nickel–alumina or copper–alumina catalysts at 250 °C to give primary amines.⁶⁰ It was found that in all cases, hydrogenolysis of the $N–N$ bond and the formation of secondary cycloalkylamines (in 18% to 75% yields) is a typical reaction pathway. Since the $N=N$ bond in azobenzene **53** is relatively stable, it can undergo hydrogenolysis only after saturation; therefore, the use of the hydrazine **54** results in higher yields of the reductive amination products; for example, the yields of *N*-cyclohexylaniline **56** obtained upon hydroamination of cyclohexanone with azobenzene and 1,2-diphenylhydrazine are 45% and 75%, respectively.

Several studies,^{14,61–70} 'generically' related to hydroamination, deserve special attention. They describe the synthesis of various amines in the presence of RPFIC in the Fischer–Tropsch synthesis. These catalysts are used to prepare various hydrocarbons and oxygen-containing organic compounds from CO and H_2 .^{71,72} The use of the modified Fischer–Tropsch reaction for the synthesis of oxygen-containing compounds and their reductive amination with ammonia, alkylamines and piperidine **57** have led to the development of a number of one-step proce-

dures for the synthesis of various amines. Thus hydrogenation of CO at 169–195 °C, 10–12 MPa and at an H₂:CO ratio of (2–6):1 in the presence of HNMe₂ (1 vol. %–10 vol. %) over RPFIC gives rise to dimethylalkylamines.⁷⁰ The yield of liquid amines reaches 73%. The use of piperidine and RPFIC in the modified Fischer–Tropsch synthesis permitted the preparation of *N*-alkylpiperidines with alkyl substituents consisting of one to fifteen C atoms at the nitrogen atom (the selectivity of the reaction with respect to amines reaches 97%).^{64–69} The highest activity was found for RPFIC containing V₂O₅, Al₂O₃ or Cr₂O₃ and CuO.⁶⁸ Two pathways to *N*-alkyldimethylamines are possible: (1) hydroamination of a surface oxygen-containing intermediate, precursor of an aldehyde, ketone or alcohol; (2) direct hydroamination of alkanals or alkyl methyl ketones, primary components of the Fischer–Tropsch synthesis.

Synthesis of alkylamines from CO, H₂ and N₂ in the presence of RPFIC has been carried out. The process included two alternating reactions performed in one catalytic area: first NH₃ was obtained from H₂ and N₂ and then it was used to aminate the oxygen-containing or olefinic products of the Fischer–Tropsch synthesis, formed after the introduction of CO. Primary terminal C₄–C₉ amines were the major reaction products.^{73,74}

Reductive amination of aldehydes and ketones is usually carried out at high (up to 50 MPa) pressures of hydrogen.⁷⁵ Various solvents have been used in this process, MeOH, EtOH, PrⁱOH, BuⁱOH, THF and cyclohexanol.^{76–78} Nickel or cobalt catalysts^{34,77,79–81} and platinum group metals (Pt, Pd) supported on activated carbon^{79,82–85} are used most often. Some metals (Ni, Pt, Ru, Rh) supported on an active material, for example, on alumina or kieselguhr, are also employed.^{77,86–88} Catalysts based on copper and chromium oxide mixtures have been patented.⁸⁹ Rhenium and palladium sulfides (Re₂S₇, PdS) as well as Fe, Co, Ni, W and Mo sulfides supported on alumina proved to be highly active catalysts of reductive amination.^{90,91} In some studies, catalysts modified with sulfur or other organic or inorganic sulfur-containing compounds have been considered. Thus reductive amination of 4-methylpentan-2-one **58** with *N*-phenyl-1,4-phenylenediamine **59** over nickel supported on kieselguhr (63% Ni) at 165 °C and a hydrogen pressure of 5.2–7.0 MPa gave *N*-phenyl-*N'*-(1,3-dimethylbutyl)-1,4-phenylenediamine **60** in 58% yield. The addition of Bu₂S increased the yield of the diamine **60** to 97%.⁸⁸

Sulfoxides, thiols and sulfur-containing heterocycles have also been used to modify the catalysts.⁹² The influence of the nature of the catalyst on the yield of the final product can be followed in relation to the reductive amination of camphor **61** with methylamine **62**. Thus when Raney nickel is used as the catalyst, *N*-methylbornan-2-imine **63** (yield 82.8%) is formed predominantly, whereas the reaction over 5% Pd/C yields a mixture of the imine **63** and *N*-methylbornan-2-ylamine **64** (30.4% and 65.7%, respectively).

If platinum oxide is used as the catalyst, the yield of the amine **64** reaches 92.7%.⁸² High stereoselectivity of RPFIC, unusual for metallic heterogeneous catalysts, has been noted.^{93–95} Thus the

degree of transformation of *d,l*-camphor into *endo*- (**65**) and *exo*-bornan-2-ylamines (**64**) during hydroamination reaches 92%, the *endo* to *exo* ratio being (1.4–1.8):1. Apparently, this stereoselectivity is due to the 'imine–enamine' tautomerisation occurring on the acid–base sites of the catalyst.

R = H, Alk.

Highly effective and selective catalysts for hydroamination of aldehydes and ketones with ammonia, amines and nitro compounds have been developed. These catalysts, which make it possible to conduct this reaction under mild conditions (20–60 °C, and *p*_{H₂} = 0.1 MPa), are Pd, Pt, Rh, Co, Fe, Ni and Cu complexes with dimethyl- and dibenzylglyoximes and with polymeric macroligands such as polyacrylic acid, polyethyleneimine, copolymers, anion exchangers, cation exchangers, *etc.*^{96–106} The rate of hydroamination in the presence of these catalysts depends appreciably on the nature of the polymeric matrix. The major contribution to the activity is made by the rigidity of those sections of the macromolecule which bear the active metal sites. The activity and selectivity of these catalysts can be controlled by changing the 'local rigidity'; this can be attained by increasing the temperature, by using a different solvent or exchangeable ion, by varying the particle size of the support, by irradiating the polymeric matrix or by introducing microadditives of another solvent.^{99,106}

III. Reductive amination of alcohols with ammonia and amines

The reaction of ammonia with alcohols results in the formation of mixtures of primary, secondary and tertiary amines. In the vast majority of cases, alcohols react with ammonia or amines only in the presence of catalysts. Heterogeneous acidic catalysts have found wide application in industry. In the presence of these catalysts, the process is carried out in the gas phase at 350–450 °C. Their influence consists in the activation of the C–OH bond due to adsorption of the alcohol on the catalyst acid sites.

The reactions between ammonia and alcohols are carried out using dehydrating catalysts (copper, nickel and cobalt on alumina, fused iron, copper chromites)^{107–111} and hydrogen. In this case, the reaction follows a mechanism other than the acid–base one. First, the alcohol is dehydrogenated to give aldehyde, and then the aldehyde condenses with ammonia, and the imine thus formed undergoes hydrogenation coupled with dehydration.

The mechanism of dehydration of alcohols followed by amination has been comprehensively studied by Bashkirov *et al.*^{112–117} Secondary and tertiary amines are formed upon the reactions of primary and secondary amines with aldimines. RPFIC modified with various oxides have been successfully used in reactions with amines. For example, hydroamination of a number of alcohols (2-ethylhexan-1-ol, octan-1-ol, octan-2-ol, heptan-4-ol) with dimethylamine at 210–240 °C gave the corresponding *N,N*-dimethylalkylamines in ~80% yields. The highest yield of tertiary amine was observed in the presence of RPFIC promoted by 10% Al₂O₃ + 1% CuO.¹¹⁸ The same catalyst was used in the reductive amination of borneols **66** with ammonia, which afforded bornylamines **67** and **68**, mostly as *endo*-isomers.¹¹⁹

Copper-containing catalysts exhibit high activity in the amination of various alcohols with ammonia and amines. When bifunctional catalysts, $\text{Cu}/\text{Al}_2\text{O}_3$ or $\text{Ni}/\text{Al}_2\text{O}_3$, were used in hydroamination of alicyclic alcohols, the yields of primary amines reached 80%. To suppress cyclisation and isomerisation, lithium and potassium hydroxides were introduced into the alumina.¹²⁰ Hydroamination of cyclohex-2-enol **69** in the presence of $\text{Cu}/\text{Al}_2\text{O}_3$, $\text{Ni}/\text{Al}_2\text{O}_3$ and $\text{Pt}/\text{Al}_2\text{O}_3$ has been studied.¹²¹ In the case of the copper catalysts, cyclohexylamine is mostly formed (yield 65%), whereas the reaction carried out at 310 °C over active dehydrating Pt and Ni catalysts containing 10%, 15% and 20% of the metal gives aniline. In the presence of copper and nickel catalysts at 310 °C, pyridine bases are formed, mostly 2-methylpyridine (60%–62% of the total amount of pyridine bases). Presumably, in the latter case, the reaction passes through the formation of an unstable bicyclic compound resulting from insertion of the nitrogen atom of the amino group into the ring with the simultaneous rupture of the carbon–carbon bond.

When alkanols are hydroaminated with dimethylamine, 2-ethylhexylamine and cyclohexylamine over the industrial copper–zinc–aluminium oxide-type catalyst (SNM-1) and over RPFIC,^{122–125} the highest yields of non-symmetrical secondary and tertiary amines (up to 90%) are attained at 175–195 °C and at an amine:alcohol molar ratio of 0.2. Secondary amines containing an alkyl radical ($\text{C}_{10}\text{--C}_{22}$) are prepared by hydroamination of alcohols with primary amines at $p_{\text{H}_2} = 0.3\text{--}0.5$ MPa in the presence of the Ni or Ni–Cu catalyst containing some K_2CO_3 ; the yields of non-symmetrical secondary alkylamines can be as high as 85%.

$\text{R} = \text{C}_{10}\text{H}_{21}\text{--C}_{22}\text{H}_{45}$, $\text{R}' = \text{CH}_3\text{--C}_8\text{H}_{17}$.

When K_2CO_3 is not added, the content of secondary amine in the amination products is 17%, and the content of tertiary amine is 45%.¹²⁶

To increase the yield of amines, nickel catalysts are modified with various additives. Thus the activity of nickel oxides prepared by various methods and their mechanical mixtures with titanium dioxide, quartz and Aerosil has been studied in the vapour-phase amination of n-butanol in the presence of hydrogen under atmospheric pressure.¹²⁷ Synergism of nickel–titanium and nickel–silicon binary oxide catalysts in this reaction was found. It is noteworthy that in some cases, in order to attain higher yields of amines, two-stage synthetic procedures are used, which include a separate stage of dehydration of alcohols to aldehydes.¹¹¹

Non-symmetrical dialkylamines are prepared in 75%–90% yields¹¹² by the reaction of a primary amine with an alcohol in the presence of a catalyst containing copper chromite at 180–210 °C and $p_{\text{H}_2} = 4.0\text{--}12.0$ MPa. When copper catalysts are used, the reaction between ethanol and ammonia at $p_{\text{H}_2} = 15.0$ MPa affords triethylamine (yield 90%).¹²⁸

Unlike hydroamination of primary and secondary aliphatic alcohols with ammonia, which mainly yields primary amines, hydroamination of tetrahydrofurfuryl alcohol **70** gives rise to a

heterocyclic compound, piperidine **57**. This reaction, which is of interest from the practical viewpoint, has been studied in detail.^{129–135} Scheme 5 shows the possible pathways to the main products (**57**, **71–74**) formed from the alcohol **70**, ammonia and hydrogen. It was found that, irrespective of the catalyst used, the reaction products contain piperidine, tetrahydrofurfurylamine **71**, *N*-(n-pentyl)piperidine **72**, *N*-(tetrahydrofurfuryl)piperidine **73** and bis(tetrahydrofurfuryl)amine **74**.

Scheme 5

When this reaction is carried out in the presence of the SNM-1 catalyst, the yield of the amine **71** reaches 62% at a virtually complete conversion of tetrahydrofurfuryl alcohol. When Co- and Ni-based catalysts are used, the formation of piperidine is the predominant reaction route (its yield reaches 51%). The compounds **73** and **74** result from intermolecular amination of the alcohol **70** with piperidine and with the amine **71**, respectively. The presence of *N*-(n-pentyl)piperidine **72** among the reaction products was explained¹³⁵ by hydrogenolysis of the alcohol **70** at the intracyclic C–O bond with the intermediate formation of pentane-1,5-diol **75**, its partial hydrodeoxygenation to n-pentan-1-ol **76** and subsequent interaction of the alcohol **76** with piperidine.

Nitrogen-containing five-, six- and seven-membered heterocyclic compounds have been prepared by hydroamination of the corresponding diols with ammonia over the industrial SNM-1 catalysts and RPFIC.^{136–139} The formation of the heterocycle in the reaction of butane-1,4-diol **77** with a mixture of NH_3 and H_2 (Scheme 6) occurs in two stages. First, the initial diol **77** is aminated to give 4-aminobutan-1-ol **78**, and then this product undergoes intramolecular amination (cyclisation) to give pyrrolidine **79**.

Scheme 6

The yield of the compound **79** on the SNM-1 catalyst at 220 °C reaches 85.5%.¹³⁹ The appearance of *N*-4-aminobutylpyrrolidine **80** in the product mixture can be interpreted as being due to the reaction between 4-aminobutan-1-ol **78** and pyrrolidine. Partial hydrodeazotisation of the compound **80** affords *N*-(*n*-butyl)pyrrolidine **81**. 1,4-Dipyrrolidinobutane **82** is formed upon exhaustive amination of butanediol with pyrrolidine. The highest yield of the compound **82** (22.5%) was attained with RPFIC. Dehydrogenation of one heterocycle in the molecule of **82** gives rise to *N*-(4-pyrrolidinobutyl)pyrrole **83**.

The reaction of hexane-2,5-diol **84** with a mixture of NH₃ and H₂ is highly selective. The yield of 2,5-dimethylpyrrolidine **25** over RPFIC at 200 °C amounts to 93%.¹³⁹ The subsequent dehydrogenation of pyrrolidine **25** yields 2,5-dimethylpyrrole **24**.

Hydroamination of pentane-1,5-diol **75** and hexane-1,6-diol **85** with ammonia follows a similar route, resulting in the formation of piperidine **57** and perhydroazepine **86**, respectively.

$n = 5$ (**75**), 6 (**85**); $m = 1$ (**57**), 2 (**86**).

The main pathways of the catalytic transformations of the diol **75** during its interaction with NH₃ and H₂ can be illustrated by Scheme 7. The presence of *N*-(*n*-pentyl)piperidine **72** in the reaction products is due to the alkylation of piperidine **57** with the diol **75** involving the intermediate formation of *N*-(5-hydroxypentyl)piperidine **87** and its subsequent hydrodeoxygenation. Hydrogenolysis of the C–C bond in the alkyl substituent of the compound **72** accompanied by elimination of an *n*-butane molecule gives rise to *N*-methylpiperidine **88**.

A typical feature of the transformation of the diol **85**¹³⁹ (Scheme 8) is relatively high yields of *N*-alkyl-substituted perhydroazepines **89**–**91** and secondary and tertiary alkylamines **92**–**94**. For example, when the diol **85** is hydroaminated over the SNM-1 catalyst at 180°C, the total contents of perhydroazepines **89** and **91** in the reaction products reaches 22%.

Piperazine and 1-alkyl- and 1,4-dialkyl-piperazines have been synthesised by hydroamination of diethanolamine or *N*-alkyldiethanolamines in the presence of RPFIC.¹⁴⁰ Cyclisation of ethylenediamine **95** with propane-1,2-diol **96** giving 2-methylpyrazine **97** over a catalyst containing 1% of Pd supported on a mixture of zinc and chromium oxides (Zn : Cr = 3 : 1) has been studied.¹⁴¹ The highest selectivity of this process is observed at 38°C.

Scheme 8

IV. Reductive amination of aldehydes and ketones with nitro compounds and pyridine bases

Reduction of nitro compounds, which is carried out in a variety of ways (catalytic hydrogenation; reduction with iron in the presence of hydrochloric acid, with metal sulfides, zinc or iron in a strongly alkaline medium, lithium aluminium hydride and hydrazine; and electrochemical reduction) is among the methods used most widely for the synthesis of amines. These reactions occur *via* several intermediate stages; for most of the reducing agents listed above, they include the formation of nitroso compounds and hydroxylamines.

Catalytic hydrogenation has found wide application in industry. Most often, it is used to convert aromatic nitro compounds into the corresponding amines.^{142, 143}

The ability of nitro compounds to be reduced to amines under the conditions of reductive amination has permitted the use of this ample class of nitrogen-containing organic compounds for direct amination of aldehydes and ketones. This reaction was first performed by Emerson.¹⁴⁴ A mixture of acetone **29** and nitrobenzene **98** was reduced by hydrogen in an autoclave over platinum oxide; the yield of *N*-isopropylaniline **99** reached 59%.^{144–147}

Subsequently this reaction has been widely used to synthesise secondary amines. Hydroamination by nitro compounds is normally carried out in autoclaves over platinum catalysts under a pressure of hydrogen.^{86, 148} Thus reductive amination of acetone by 4-nitrodiphenylamine at 120 °C and $p_{H_2} = 2.0$ – 2.5 MPa on the Pt/C catalyst gave *N*-phenyl-*N'*-isopropyl-*p*-phenylenediamine in 95% yield.¹⁴⁹ To increase the yield of secondary amines the catalysts are modified by various additives. For example, the reaction catalysed by platinum supported on carbon containing phosphorous acid gives amines in preparative yields.⁷⁸ Other acids or acidic compounds — H₃BO₃, organic acids or anhydrides, CO₂

— are also used as modifying agents. Acidic additives form salts with primary amines and thus prevent side reactions.

Apart from platinum, nickel catalysts are also widely used in this reaction. The use of a catalyst containing 63% of Ni supported on kieselguhr permits preparation of secondary amines from nitro compounds and ketones in yields of up to 57%. Modification of this catalyst by sulfur-containing compounds (sulfides, disulfides, sulfoxides, thiols) made it possible to increase the yields of amines to 75%.⁸⁷ Hydroamination carried out with aromatic nitro compounds is accompanied in some cases by hydrogenation of the aromatic ring.^{150,151} To prevent this process, mixtures of ketones with aromatic nitro compounds are reduced over various catalysts containing Pt, Pd, Ni, Rh, Os, Sr or Co on silica or alumina in the presence of SO₂.¹⁵⁰ The same can be attained by using metal sulfides. Amines can be obtained in preparative yields by conducting the reaction at 250 °C at a pressure of hydrogen of up to 10.0 MPa in the presence of cobalt, nickel or molybdenum selenide or telluride as the catalyst.¹⁵²

Palladium-containing anion exchangers are efficient catalysts of hydroamination of aldehydes and ketones by nitro compounds (mostly, aromatic ones).^{99,106} A study of the influence of the substrate structure on the rates of hydroamination of oxygen-containing compounds by nitro compounds of the aromatic series has shown that the reaction rate decreases following an increase in the magnitude of the Hammett constant.¹⁵³

Several studies^{151, 154–156} have been devoted to hydroamination of alicyclic and heterocyclic ketones by nitro compounds of aliphatic and aromatic series over nickel- and copper–alumina catalysts. It was found¹⁵¹ that hydroamination of alicyclic ketones **99** with nitrobenzene at 250 °C and at $p_{H_2} = 2.0$ MPa over nickel catalysts gives rise to *N*-cycloalkylcyclohexylamines in yields of up to 82%. In the presence of copper catalysts, *N*-cycloalkylanilines are formed in this reaction (yields 40%–80%).

The capability of pyridine and its alkyl-substituted derivatives to be reduced to piperidines permits the use of these nitrogen-containing heterocycles in the reductive amination of ketones. Thus reductive amination of aliphatic and alicyclic ketones with pyridine and its monomethyl derivatives over nickel catalysts under a pressure of hydrogen has been studied.^{157, 158} The reactions of pyridine **100** and α -, β - and γ -picolines **101a–c** with ketones afford the corresponding *N*-substituted piperidines as the major products.

R = H (**100**), 2-Me (**101a**), 3-Me (**101b**), 4-Me (**101c**);
R' = Me, Et, Bu^t; R'' = Me, Et; $n = 2, 3$.

It was assumed^{157, 158} that this reaction can follow two pathways. One of them includes simultaneous reduction of the ketone to the corresponding secondary alcohol and hydrogenation of pyridine **100** to piperidine **57**. The subsequent interaction of the alcohol with piperidine accompanied by dehydration affords *N*-substituted piperidine derivatives. In the second pathway, pyridine is reduced to piperidine and the latter reacts directly with the ketone, without its intermediate transformation into the alcohol. This pathway, like the first one, affords *N*-substituted piperidine as the final product.

The use of α -picoline as the aminating agent demonstrated that the methyl group located in the vicinity of nitrogen has a substantial influence on the reaction route. For example, hydroamination of methyl ethyl ketone **102** with this compound, in addition to the expected product **103** (yield 4%), gave the products resulting from elimination of the methyl group from the pyridine ring (**104**, 9%) and elimination of the methyl group from the *N*-substituent (**105**, 5%).

The course of hydroamination of aliphatic ketones with pyridine bases depends substantially on the ketone structure. Thus the highest yield of the final reaction products is achieved when pyridine is made to react with alkyl methyl ketones; for example, the yield of *N*-butan-2-ylpiperidine in the reaction with methyl ethyl ketone amounts to 50%. When pyridine reacts with diethyl ketone **36** and propyl ethyl ketone **106**, the yields of the target reaction products sharply decrease (32%, for the ketone **36**) due to the substantial steric hindrance created by the two alkyl radicals attached to the carbonyl group. *tert*-Butyl methyl ketone does not enter into hydroamination at all.¹⁵⁸ The optimum conditions for the synthesis of *N*-alkylpiperidines are the following: temperature 220–230 °C, $p_{H_2} = 2.0$ MPa; $v = 0.3$ h^{−1}, catalyst — 20% Ni/Al₂O₃.¹⁵⁸

V. Reductive amination of aldehydes, ketones and alcohols with nitriles and oximes

1. Nitriles and oximes as aminating agents

Owing to the progress in the chemistry of nitrogen-containing organic compounds achieved in recent years, nitriles can be considered to be readily available starting compounds for the synthesis of diverse and valuable organic products.

Methods of catalytic ammonolysis occupy a special place in the synthesis of nitriles. They include, first of all, oxidative ammonolysis of saturated and unsaturated hydrocarbons, methylbenzenes, naphthalene and pyridine. Linear hydrocarbons, for example, butane and butenes, can be converted by ammonolysis into saturated and unsaturated mono- and dinitriles.^{159–167} Thus oxidative ammonolysis of butadiene gives rise to a mixture of nitriles of fumaric and maleic acids (total yield 67%).¹⁶⁸ Oxidative ammonolysis of toluene, xylenes, mesitylene or dimethylnaphthalenes can be used to synthesise nitriles of the corresponding mono-, di-, and tri-carboxylic acids, their yields being 70%–95%.^{169, 170} Halotoluenes, toluidines and cresols can also be introduced into ammonolysis; this gives rise to the corresponding benzonitrile. Methylpyridines are converted into the nitriles of pyridinecarboxylic acids in 70%–95% yields.^{171–175}

At present, ammonolysis is employed in industry to produce acrylonitrile, benzonitrile and nitriles of methacrylic, terephthalic, and nicotinic acids. These processes have been patented and considered in several reviews (see, for example, Refs 176–179).

Thus, the development of this line of research has extended substantially the range of raw materials used for the production of diverse amines.

Hydrogenation of carbonitriles has been studied in detail, because the products of their reduction are important for practical purposes. Nitriles are converted into primary amines upon the

addition of two hydrogen molecules. However, the first molecule is added faster than the second one. Therefore, the reduction intermediately gives aldimines, which are converted into primary amines during subsequent hydrogenation. In some cases aldimines can be isolated in a pure state. The general pattern of hydrogenation of nitriles can be written as follows:

Aldimines are highly reactive and are able to react with the resulting primary amines; this gives rise to secondary and tertiary amines. Therefore, hydrogenation of nitriles can yield different products, depending on the reaction conditions.¹⁸⁰

Catalytic reduction of nitriles with molecular hydrogen is the most interesting process. A fairly broad range of catalysts have found practical application in the nitrile hydrogenation — monometallic (Pt, Pd, Ni, Co, *etc.*) and bimetallic (Ni–Co, Co–Cr, *etc.*) catalysts; bifunctional metallic catalysts supported on various materials (Al₂O₃, TiO₂, SiO₂, MgO) modified with various additives (acids, alkalis); and metals (Pt, Pd, Ni, Co) immobilised on polymers. For example, synthesis of 3-amino-5-aminomethyl-2-methyl-4-methoxymethylpyridine by coupled hydrogenation and dehalogenation of 6-chloro-2-methyl-4-methoxymethyl-3-nitropyridine-5-carbonitrile over palladium-containing anion exchanger AB-17-8 has been described.¹⁸¹ The yield of the target product (20–60 °C, p_{H_2} = 0.98–1.03 MPa, EtOH as the solvent) reaches 99%. The catalyst proposed for this reaction proved to be much more stable and active than Pd/C.

Data on the liquid-phase hydrogenation of hexanenitrile to amines have been reported.¹⁸² Reduced metals (Ni, Co, Ru, Pd, Pt, Os, Cu) on γ -Al₂O₃ were used as the catalysts in this reaction. In terms of their activity in hydrogenation, the studied catalysts can be arranged in the sequence Ru > Ni > Os > Co > Pd > Pt > Cu; the selectivities of these catalysts were also dissimilar. Thus the cobalt catalyst exhibited the highest selectivity (91%) with respect to primary amine (hexylamine). The highest selectivity with respect to secondary amine was found for Ru and Pt catalysts (81%–89%). In the presence of the Pd catalyst, the yields of di- and tri-hexylamines are 65.4% and 34.6%, respectively. Hydrogenation of hexanenitrile over the industrial nickel–chromium catalyst at 120–140 °C and p_{H_2} = 5.0 MPa gave a mixture of amines containing 64% of the secondary amine and 36% of the primary and tertiary amines (the total yield). By varying the reaction temperature, the pressure of hydrogen and the chemical composition of the catalyst, the ratio of the reaction products can be controlled. Thus at 145 °C and p_{H_2} = 0.35–0.50 MPa, 100% conversion of acetonitrile was attained; the reaction products were found to contain 3.1% of primary amines, 45.4% of secondary amines and 51.5% of tertiary amines. At higher temperatures, the yield of secondary amines increases.¹⁸⁰ The use of Pd, Pt and Ru catalysts supported on lithium aluminium spinel in this reaction permits the preparation of an amine mixture containing 99.7% of tertiary amine.¹⁸³

Numerous studies dealing with hydrogenation of acetonitrile **107** and acrylonitrile **108** over a series of copper and copper–nickel catalysts with various metal contents (5% Cu; 8% Cu + 2% Ni; 15% Cu + 2% Ni, *etc.*) have been carried out. Gumbrin was used as the support. Some catalyst specimens were modified with NaOH (3%). Hydrogenation was carried out at 100–200 °C under atmospheric pressure. The reduction of the nitriles **107** and **108** affords mixtures of the corresponding primary, secondary and tertiary amines. The copper–nickel catalyst (8% Cu + 2% Ni) annealed at 900 °C proved to be the most active towards hydrogenation of acrylonitrile; the total yield of amines on this catalyst was 69.7%. The modification of the Cu–Ni catalyst with alkali increases its stability.¹⁸⁴ The nitrile **108** was converted into dipropylamine in two stages with a high yield.¹⁸⁵ In the first stage, acrylonitrile was hydrogenated to propionitrile **109** in the presence of a catalyst containing Pd, Bi and K on silica gel, and in the second stage, the resulting

propionitrile was converted into dipropylamine using 50%–56% Ni supported on kieselguhr at p_{H_2} = 0.1–2.0 MPa and 140–200 °C.

To increase the yield of primary amines, hydrogenation is carried out in the presence of ammonia. The role of ammonia or alkali is to retard the reaction of aldimines with amines and deamination.^{186–188} The addition of ammonia markedly increases the yields of higher primary amines (C₈–C₂₄) produced in the hydrogenation of the corresponding individual nitriles or their mixtures.^{189–191} The introduction of LiOH, NaOH, KOH or Na₂CO₃ (0.1 mass %–2.0 mass % relative to the catalyst) leads to higher yields of primary amines. Thus hydrogenation of phenylacetone nitrile **110** over Raney nickel gave 2-phenylethylamine **111** in 51.2% yield, the yield of the corresponding secondary amine **112** being 37.5%. When 2.0 mass % NaOH was introduced into the catalyst, the yield of the primary amine became 92.5%–95.5%.^{192, 193}

Since benzylamine **113** is a valuable compound for fine organic synthesis, a large number of studies dealing with catalytic hydrogenation of benzonitrile have been carried out. Hydrogenation of benzonitrile in dioxane in the presence of ammonia at 70–80 °C has been studied.¹⁹⁴ Nickel supported on kieselguhr was used as the catalyst. The benzene ring was not hydrogenated under these conditions; the yield of benzylamine was 76%–79% and the selectivity was 82.5%. Interesting results have been obtained in a study of hydrogenation of benzonitrile on the Pt/C, Pd/C and Ru/C catalysts.¹⁹⁵ The reaction rate was found to increase on increasing the pressure of hydrogen; however, the yield of toluene also increased (from 0.3%–3.0% to 8%–9%).

Hydrogenation of nitriles and dinitriles in methanol or cyclohexane¹⁹⁶ is carried out on cobalt catalysts supported on Fe, Co, Mn or Cr metal powders at 80–120 °C and p_{H_2} = 25.0–35.0 MPa in the presence of ammonia. The yields of the corresponding primary amines were 90%–95%. It was noted that the service life of metal-supported catalysts is longer than those of catalysts supported on oxides.

Dinitriles of the aliphatic and aromatic series are hydrogenated under the same conditions as mononitriles. For example, octamethylenediamine (yield 91%) is prepared by catalytic reduction of the dinitrile of the corresponding acid in the presence of a ruthenium catalyst in an inert solvent containing an additive of NH₃, at p_{H_2} = 3.0 MPa.¹⁹⁷ By varying the reaction conditions, the reduction of dinitriles can be terminated at the stage of formation of amino nitrile as the major reaction product. Thus the dinitriles CN(CH₂)_nCN (where n = 1–10) can be converted on a rhodium catalyst into the corresponding amino nitriles, formed in high yields.^{198, 199} Data on the conditions and the mechanism of this reaction and various factors that influence its course have been described systematically.²⁰⁰ The mechanisms of the formation of primary, secondary and tertiary amines were described in detail. In terms of their activity in this reaction, known catalysts can be arranged in the following sequence: Pt > Pd > Ni > Co > Fe > Cu. The reduction of aliphatic dinitriles containing CN groups at the 1,2-, 1,3- and 1,4-positions, in addition to the corresponding diamines, yields five-, six- and seven-membered saturated heterocyclic compounds, resulting from intramolecular heterocyclisa-

tion. For example, succinodinitrile **115** is converted into pyrrolidine **79**.

Data on the hydrogenation of nitriles in the presence of homogeneous or heterogeneous catalysts in the liquid phase have been described systematically.²⁰¹ The reaction mechanisms and the pathways to side products were considered. The effects of the solvent, temperature, the pressure of hydrogen and the nature of the catalyst on the course of this reaction carried out over heterogeneous catalysts were studied.

Oximes are also hydrogenated using nickel catalysts. Thus hydrogenation of acetone oxime gives a mixture of amines in which the secondary amine predominates.²⁰²

Hydrogenation of a number of alkylaromatic oximes has been studied.²⁰³ It was found that the formation of primary amines is preceded by the intermediate formation of imines **116**; in some cases, they can be isolated from the reaction mixture (Scheme 9). The reaction products contain primary, secondary and tertiary amines.^{204–207} Secondary amines result from interaction of the imine **116** with primary amines. They can also arise upon deamination of primary amines in the presence of a catalyst.²⁰⁸

Rosenmund *et al.*²⁰⁹ were the first to use an oxime acetate for preventing the formation of a secondary amine. Hydrogenation of the benzaldehyde oxime acetate **117** gave a primary amine (formed as acetate **118**) in 91% yield.

Primary amines are also prepared by hydrogenation of oximes in acetic anhydride. Thus hydrogenation of benzaldehyde oxime under these conditions resulted in the synthesis of *N*-benzylacetamide; hydrogenation of acetone oxime gave *N*-(1-phenylethyl)acetamide.²⁰⁴ Free amines are obtained by hydrolysis of these amides. Good yields of primary amines, formed as hydrochlorides, are attained when oximes are hydrogenated on a palladium catalyst in anhydrous ethanol with three equivalents of HCl.²¹⁰ Hydrogenation of oximes in the presence of ammonia,²¹¹ which increases the yield of primary amines, has found a wider practical application.

In the case of catalytic hydrogenation of oximes, nickel, cobalt and rhodium supported on alumina are used most often as the catalysts.²⁰⁴ In the reduction of oximes of α,β -unsaturated ketones, platinum dioxide is used as the catalyst and MeOH is used as the solvent.²⁰⁵ The solvent has a substantial influence on the composition of the products of oxime reduction in the liquid phase. For example, when a more polar solvent was used, aziridine was obtained from benzylideneacetone oxime, in addition to the corresponding amine.²¹² Study of hydrogenation of cyclohexa-

none oxime in various solvents in the presence of Pt, Pd, Rh and Ru supported on finely dispersed carbon made it possible to elucidate the influence of the solvent and the catalyst on the reaction rate and the product composition. The reaction does not occur in dioxane; the reaction in methanol proceeds in the presence of the rhodium catalyst, while in acetic acid, it proceeds over a platinum catalyst. When the reaction is carried out in water, cyclohexanol is produced as the major product.²¹²

Apart from the platinum Group metals listed above, cobalt is also used to catalyse hydrogenation of oximes. In some cases Raney cobalt is more active than the nickel catalyst.²¹³ Alumina is usually employed as the support.^{204, 214}

When oximes are reduced over copper catalysts, together with amines, side products are formed, in particular, the Beckmann rearrangement product, the corresponding ketones, aldehydes, nitriles and imines.²¹⁵

Apart from molecular hydrogen, the hydrazine–Raney nickel system is also widely used as the reducing agent in the hydrogenation of oximes.^{208, 216} This system permits easy and selective reduction of oximes to primary amines.

2. Reductive amination of oxygen-containing compounds with nitriles and oximes

Significant progress in the development of new methods for the synthesis of amines was associated with the use in the reductive amination of nitriles and oximes, which had not been used previously as direct aminating agents. Hydroamination of oxygen-containing compounds with nitriles extends still further the potential of this reaction.

The ability of nitriles to be reduced to amines under the conditions of catalytic hydrogenation made it possible to aminate various ketones and aldehydes in one stage.^{217–221} The reaction is carried out in the vapour phase over a heterogeneous catalyst in a flow-type setup operating under a pressure of hydrogen. The process of hydroamination of oxygen-containing compounds with nitriles includes several successive coupled reactions resulting in the formation of secondary amines. In the carbonyl compound–nitrile–hydrogen system, this reaction occurs in accordance with the following scheme:^{218, 219}

R, R' = H, Alk, Ar; R'' = Alk, Ar.

Under the reaction conditions, carbonyl compounds are partly reduced to the corresponding alcohols. The possibility of hydroamination of alcohols with nitriles, as shown below, also cannot be ruled out.

R = H, Alk, Ar; R' = H, Alk, Ar; R'' = Alk, Ar.

The reaction pathway depends on the structures of the reactants and on the rate of each particular stage. The above reactions might also occur simultaneously.

Hydroamination of cyclic ketones by aliphatic nitriles under a pressure of hydrogen has been studied.^{218, 219} Nickel–alumina and copper–alumina catalysts with a metal content of 15%–20%, both non-modified and modified by the addition of Li, Na

and K, were used. The main reaction pathway is the formation of alicyclic secondary amines **119**.

R = Me (**107**), CH=CH₂ (**108**), Et (**109**), Prⁿ (**120**); *n* = 3 (**7**, **8**), 2 (**52**, **121**).

The yields of the corresponding amines **119** with the 15% Cu/Al₂O₃ catalyst at 240 °C and *p*H₂ = 1.5 MPa reaches 75%. The introduction of alkaline additives (Li, Na, K) in the copper–alumina catalyst increases the total yield of amines by 5%–12%. The di(cycloalkyl)amines **8** and **121** are formed as side products. It was assumed²¹⁸ that the main reason for the formation of the amines **8** and **121** is the low stability of *N*-alkylcycloalkylamines **119** under the conditions employed. In fact, when *N*-ethylcyclohexylamine is passed over the catalyst under the conditions of hydroamination, it partly decomposes to give a mixture of cyclohexylamine **13** and dicyclohexylamine **8** (up to 30%). Study of the reductive amination of the alicyclic ketones **7** and **52** with aceto- (**107**), acrylo- (**108**), propio- (**109**) and butyro-nitriles (**120**) showed that the yield of *N*-alkylcycloalkylamines **119** decreases following an increase in the number of the carbon atoms in the nitrile molecule.

N-Alkylcyclohexylamines **123** have been prepared in good yields (up to 73%) by hydroamination of phenols **122** with nitriles on nickel–alumina catalysts. In this case, amination is accompanied by hydrogenation of the aromatic ring.²²²

R = Me, Et, Pr; R' = H, *o*-Me, *m*-Me, *p*-Me.

In order to synthesise aromatic amines which contain the amino group in the side chain and form a number of important biologically active compounds, hydroamination of acetophenone **15**, benzophenone **124** and benzyl methyl ketone **125** with nitriles has been carried out.²²³ In the presence of copper–alumina catalysts, the highest yields (31%–72%) of secondary amines were attained with 20% Cu/Al₂O₃ at 220 °C, *p*H₂ = 1.5–2.0 MPa. The reactivity of ketones in the amination by nitriles decreases in the order **125** > **15** > **124**.²²³ The conjugated system of bonds present in acetophenone results in a lower positive charge on the carbonyl carbon atom; this accounts for the decrease in the reactivity of the ketone **15**. In the case of hydroamination of benzophenone with acetonitrile, the yield of *N*-ethylbenzhydrylamine is influenced not only by conjugation but also by steric factors. Ethylbenzene and diphenylmethane were isolated as side products upon hydroamination of aceto- and benzophenone. Virtually no propylbenzene is formed on hydroamination of benzyl methyl ketone.

15, 124

R = Me, Ph; R' = Me, Et, Prⁿ.

125

R = Me, Et, Prⁿ.

Unsaturated ketones, aliphatic nitriles, phenylacetone, aliphatic and alicyclic ketones, benzonitrile and aldehydes have been used successfully for the synthesis of aliphatic-aromatic amines^{219, 223–227} (Table 1). *N*-Alkylbornan-2-ylamines were synthesized in 45%–55% yields by hydroamination of camphor **61** by aliphatic nitriles.²²⁸

Table 1. Synthesis of aliphatic-aromatic secondary amines by hydroamination of ketones and aldehydes with nitriles

Ketone, aldehyde	Nitrile	Catalyst	The resulting amine	Yield (%)	Ref.
<i>T</i> = 220 °C, <i>p</i> H ₂ = 1.5 MPa, <i>v</i> = 0.25 h ^{−1}

R = Me, Et, Prⁿ.

Systematic study of the reductive amination of carbonyl-containing compounds and secondary alcohols of the terpene series resulted in the development of preparative and selective methods for the synthesis of both unsaturated and completely hydrogenated amines with diverse structures (aliphatic; mono- bi- and tricyclic; containing three-, four, five- and six-membered rings)^{229–239} (Table 2).

A series of 3-(1-alkylaminoethyl)- and 3-(arylmethylaminoethyl)-pyridines have been synthesised in 50%–65% yields by hydroamination of 3-acetylpyridine **126** with aliphatic and aromatic nitriles.²⁴⁰

R = Me, Et, Prⁿ, Ar.

Hydroamination of an α,β -unsaturated heterocyclic ketone — 4-(2-furyl)but-3-en-2-one **127** — which has an additional reaction site, the oxygen atom of the furan ring, has been studied. This process can follow several alternative pathways depending on the catalyst used (Scheme 10). In the presence of a copper–magnesium catalyst, the reaction stops at the stage of formation of a

secondary amine of the furan series, namely, 2-(3-alkylaminobutyl)furan **128** (yield 45%–48%); the use of copper–alumina catalyst results in hydrogenolysis of the furan ring at the O(1)–C(5) bond and cyclisation of the intermediate amino ketone. In this case, *N*-alkyl-2-methyl-5-propylpyrrolidine **129** is the main product (yield 42%–46%).²⁴¹ In addition, the reaction products contain a small amount of pyrrole derivatives **130** (5%), which result from the direct replacement of the oxygen atom of the furan ring by an amino group accompanied by hydrogenation of the carbonyl group and the double bond in the side chain.

Scheme 10

^a The total yield is given.

Several studies have been devoted to the interaction of nitriles with bifunctional oxygen-containing compounds in which both reaction sites can be involved in hydroamination. In particular, reactions of hydroxy ketones, diketones and diols were investigated.^{242–244}

α -Diketones and α -glycols react with nitriles according to similar patterns. Thus the reaction of diacetyl with nitriles yields the same products as the reaction of ethylene glycol, namely, mono- and diamines.^{243, 244} Acetylacetone (β -diketone) **131** is unstable under the reaction conditions, products of its decomposition being involved in reductive amination. The reaction of the diketone **131** and benzonitrile **114** over the 15% Cu/MgO catalyst at 240 °C and $p_{\text{H}_2} = 1.5$ MPa gives rise to *N*-ethylbenzylamine **132** (yield 29%), *N*-isopropylbenzylamine **133** (yield 19%) and *N,N*-diethylbenzylamine (yield 18%) (Scheme 11).

Reactions of dinitriles with carbonyl compounds have been studied. It was found²²¹ that hydroamination of acetone and butanal with adiponitrile **135** can follow two pathways, one yielding a heterocycle and one yielding aliphatic amines. The nitrile groups in the adiponitrile molecule behave under the hydrogenation conditions as if they possessed different reactivities. This fact has been explained by the formation of unstable cyclic systems.²⁴⁵ A pseudo-ring forms upon interaction of nitrogen of one nitrile group with the hydrogen located at the α -position relative to the second nitrile group. Therefore, reductive amination occurs as preferential reduction of one nitrile group rather than simultaneous reduction of both of them and yields 6-aminohexanenitrile **136**.

The amino nitrile **136** can undergo two types of transformation. The first of them is hydrogenation of the second CN group to give hexamethylenediamine **137** and subsequent hydroamination of a carbonyl compound, for example, acetone **29**. The second route includes hydrogenation of the amino nitrile **136** accompanied by cyclisation and gives rise to perhydroazepine **86**.

The crucial factor which determines the reaction route is temperature. Thus at 190 °C, the yields of *N*-isopropylperhydroazepine **138** and *N,N'*-diisopropylhexamethylenediamine **139** are 25% and 84%, respectively, whereas at 240 °C they are 22% and 3%.

The good results attained in hydroamination of oxygen-containing compounds, together with the theoretical fundamentals and the published data concerning reduction of oximes to primary amines under conditions similar to those used in hydroamination, permitted oximes to be employed for the first time for reductive amination of various ketones and aldehydes.^{246–249} Analysis of the ability of oximes to be reduced over heterogeneous catalysts led to the conclusion that, in addition to the traditional catalysts used to reduce oximes to primary amines (platinum Group metals and nickel), copper catalysts are also active in this process.

Hydroamination of carbonyl compounds with various oximes includes several consecutive coupled reactions, resembling those involved in hydroamination of carbonyl compounds with nitriles. The necessity of a high degree of coupling between separate stages becomes evident if one examines the processes occurring in the 'oxime-carbonyl compound-hydrogen' ternary systems over a heterogeneous catalyst. Initially, the oxime is reduced on the hydrogenating sites of the catalyst to give a primary amine (Scheme 12).^{247, 248}

R = Alk, Ar; R' = H, Alk, Ar.

Scheme 12

The resulting primary amine can participate in many thermodynamically allowed reactions. Within the scope of our review, condensation of the primary amine with the carbonyl compound is of interest (Scheme 13).^{247, 248}

R, R'' = Alk, Ar; R', R''' = H, Alk, Ar.

Scheme 13

The reaction of the primary amine with the imine, resulting from incomplete reduction of the oxime, is a competing process (Scheme 14).^{247, 248}

Scheme 14

Thus, when there is no coupling between the formation of primary amine and its condensation with the carbonyl compound (see Schemes 12 and 13), the overall process can be substantially influenced by the reaction of the primary amine with the nitrogen analogue of the carbonyl compound, *i.e.* imine (see Scheme 14). The formation of symmetrical secondary amines markedly decreases the selectivity of the main reaction.^{247, 248}

The attainment of coupling depends appreciably on the catalyst. The carbonyl compound should be activated towards condensation (see Scheme 13) to an extent that its reactivity in

relation to the nucleophile be higher than that of the imine. This activation occurs on the acid sites of the catalyst.²⁴⁸ The condensation proceeds *via* intermediate formation of the addition product, which is converted into imine upon dehydration. This stage is followed by hydrogenation of the C=N double bond on the hydrogenating sites of the catalyst and by the formation of a secondary amine, which is the final reaction product. The data on the methods of synthesis of secondary amines from oximes, ketones, aldehydes and alcohols are presented in Table 3.

VI. Conclusion

The data considered in the review convincingly demonstrate the substantial progress achieved in the development of catalytic methods for the synthesis of amines based on reductive amination of various oxygen-containing organic compounds. The most significant achievements are the use of nitriles and oximes, which had not been used previously for these purposes, as aminating agents; elaboration and use of complex catalysts for reductive amination, which allow the processes to be conducted under mild conditions with high selectivity; and the use of reduced promoted fused iron catalysts in the synthesis of nitrogen-containing heterocycles.

The assimilation of new reactions of oxidative ammonolysis and oxo synthesis made it possible to synthesise numerous nitriles, carbonyl compounds and oximes, needed for the production of amines of various structures and compositions. Thus, there are strong grounds for believing that in the near future, the reaction in question would become one of the most significant methods for the preparation of amines.

VIII. Conclusion	82

Abstract. Data concerning the methods of synthesis, chemical transformations and application of levulinic acid are analysed and generalised. The wide synthetic potential of levulinic acid, particularly as a key compound in the synthesis of various heterocyclic systems, saturated and unsaturated ketones and diketones, difficultly accessible acids and other compounds is demonstrated. The accessibility of levulinic acid from hexose-containing wood-processing and agricultural wastes is noted. The bibliography includes 260 references.

I. Introduction

At present, the use of organic synthesis on an industrial scale is so extensive that the problem of limited natural resources, such as petroleum and gas employed in this process comes to the foreground.¹ This generates a need for timely measures aimed at elaboration of alternative strategies of fine organic synthesis on the basis of alternative sources of raw materials. In this context, the synthesis of key compounds from wood processing products holds great promise. The most common cellulose-derived products include glucose, xylose, ethanol, polyhydric alcohols and furfural. Their use in industrial organic synthesis has been documented in numerous publications. Much less attention has been given to such cellulose hydrolysis products as organic acids, first of all, 4-oxopentanoic or levulinic acid (LA). The molecule of LA contains two highly reactive functional groups providing a great number of synthetic transformations. LA has been used to obtain various heterocyclic compounds, saturated and unsaturated ketones and diketones, difficultly accessible acids, alcohols and so on. We have analysed publications devoted to LA and found that despite the great number of these studies, their results have virtually not been generalised. Some reviews on the subject (see Refs 2 and 3) are not sufficiently comprehensive and outdated.

In our opinion, the synthetic potentialities of LA are far from being exhausted, although the attention of investigators has now switched to starting compounds from other natural sources. Our desire to fill the information gap in this field, on the one hand, and to attract the attention of investigators and practitioners in synthetic chemistry to the high synthetic potentialities of LA manufactured from wood-processing and agricultural wastes on an industrial scale, on the other hand, was the incentive to write this review.

II. Physicochemical characteristics

Under normal conditions, LA is a colourless crystalline compound with a melting point of 37 °C, its boiling point (with decomposition) is 246 °C. The main physical constants for LA are as follows: d_4^{20} 1.140, d_4^{25} 1.1447; n_D^{20} 1.4796, n_D^{25} 1.441; surface tension 39.7 dyne cm⁻¹ (25 °C); heat of vaporisation (150 °C) 0.58 kJ mol⁻¹ and heat of fusion 79.8 J mol⁻¹ (see Ref. 4).

Levulinic acid is readily soluble in water, ethanol, diethyl ether, acetone and many other organic solvents. The temperature dependence of solubility of LA in water has been studied in detail.⁵ In water, LA is fairly well dissociated, its pK_a (25 °C) is 4.59, see Ref. 6. In other words, the acidity of LA is comparable with that of the majority of lower alkane carboxylic acids. For comparison of gas-phase acidity of LA with those of other carboxylic acids, see Ref. 7.

The analysis of ¹H and ¹³C NMR spectra of LA allowed a correct assignment of signals,² which demonstrated that the protons of the β-methylene group at position 3 are more 'acidic': (δ = 2.71 ppm) than those of the α-methylene group (δ = 2.47 ppm).

The rate of oxygen exchange of LA with water was studied using mass spectrometry. It was found⁸ that the exchange of the carbonyl group oxygen occurs 10 times faster than that of the carboxy group. The approximate values of the pseudo-first-order constants in excess of H₂¹⁸O are $k_{CO} = 7 \times 10^{-3}$ s⁻¹ and $k_{COOH} = 5 \times 10^{-4}$ s⁻¹, respectively. As expected, the carbon atom of the carbonyl group of LA is more susceptible to nucleophilic attack than that of the carboxy group.

The first ionisation potential of LA (9.7 eV according to photoelectron spectroscopic data⁸) corresponds to withdrawal of an electron from the orbital for which the main contribution is given by the unshared electron pair of the carbonyl oxygen atom.

The knowledge of the specific characteristics of the keto–enol equilibrium of LA is substantial for the understanding of mechanisms of its reactions; for the equilibrium constants of LA derivatives see Refs 9 and 10. It was found¹⁰ that the content of the enolic forms of LA, *viz.*, 4-hydroxypent-3-enoic (**1**) and 4-hydroxypent-4-enoic acids (**2**), in diethyl ether is as low as $1.9 \times 10^{-2}\%$. The concentration of the LA enolic forms **1** and **2** in D₂O solutions is negligible, which followed from the absence of deuterium exchange at C(3) and C(4) (¹³C NMR spectral data). A similar conclusion was made from the analysis of UV spectra of aqueous solutions of LA.¹¹ Apparently, the ease of intramolecular transfer of the proton from the carboxy group to the carbonyl atom of oxygen is the reason for the predominant formation of 5-hydroxy-γ-valerolactone (**3**) rather than the enolic forms.

On the other hand, in acidic media (D₂O with addition of D₂SO₄) rapid H/D exchange occurred² resulting in the formation of C(3)D₂, C(5)D₃-pentadeuteriolevulinic acid. Thus under conditions of acid catalysis the concentration of the enolic forms **1** and **2** increases substantially. Apparently, the structures **1** and **2** are the intermediates in the cyclisation of LA into the lactones **4** and **5** (Scheme 1).⁸

Thus, the generally accepted viewpoint that LA is at equilibrium with the unsaturated lactones **4** and **5** (see, *e.g.*, Ref. 12) is not quite correct, since an appreciable concentration of these lactones is observed only in the presence of strong mineral acids. As expected, removal of water shifts the reaction towards the formation of the cyclic product. Thus the lactone **4** can be easily prepared by boiling LA in the presence of sulfuric or phosphoric acids using a Dean–Stark trap.¹³ It should be noted that the lactone **5** is thermodynamically more stable and is formed from the lactone **4** upon heating or treatment of the latter with a base.¹⁴

Enolisation of the lactone **4** into 2-hydroxy-5-methylfuran is theoretically possible. However, compound **4** does not manifest any enolic properties and its O-alkylation cannot be carried out despite the evolution of 0.3 equiv. of methane in the determination of mobile hydrogen according to the Tservitinov procedure.¹⁵ The chemical behaviour of furanones is rather specific and its consideration is beyond the scope of this review. Different aspects of furanone chemistry have been described in a comprehensive review.¹⁶

This derivatives of LA manifest an even greater trend for intramolecular cyclisation. Thus the reaction of LA with P₂S₅ or H₂S gives only cyclic products, such as the dihydrothiophenones **6** and **7** containing traces of 5-mercapto-5-methyltetrahydrothiophen-2-one.^{17,18}

III. Preparation

On an industrial scale, LA is produced from wood-processing and agricultural wastes. The basis of industrial methods for the preparation of LA is transformation of hexoses in acidic media. This is usually considered as a combination of dehydration

resulting in the formation of 5-hydroxymethylfurfural (**8**) and its subsequent hydration resulting in LA. The formation of 5-hydroxymethylfurfural **8** occurs through a series of consecutive reactions, which has been established by numerous studies aimed at identification of intermediate products and analysis of pathways of their further transformations (Scheme 2).^{19,20} The enediol **12** obtained upon enolisation of D-glucose (**9**), D-mannose (**10**) or D-fructose (**11**) in acidic media is the key compound in the formation of 5-hydroxymethylfurfural **8**. Its dehydration results in compound **13**, which represents the enol form of 3-deoxyhexosulose (**14**). Compound **13** yields 3,4-dideoxyglycosulose-3 (**15**). The latter is readily converted into the dienediol **16**, which eventually results in 5-hydroxymethylfurfural *via* the intermediate cyclic compound (**17**). Humin compounds are the side products of this reaction.²⁰

Scheme 3

The conversion of 5-hydroxymethylfurfural **8** into LA is a result of addition of a molecule of water to the $\text{C}(2)=\text{C}(3)$ bond of the furan ring.^{19, 20} This leads to ring opening with formation of an unstable tricarbonyl intermediate **18**. The latter is decomposed into the final products, viz., LA and formic acid.

There are several assumptions about the nature of intermediates involved in the conversion of compound **8** into LA. The above scheme has been proposed in a recent study²¹ devoted to the analysis of this reaction (the formation of humin compounds is not shown). The sequence of transformations was proposed by Horvat *et al.*^{21, 22} on the basis of analysis of ^{13}C NMR spectra of the reaction mixture formed in the hydration of compound **8**.

Acid treatment of plant raw materials containing up to 75% of polysaccharides in the form of cellulose and hemicelluloses results in the hydrolysis of polysaccharides to monosaccharides.²³ The rate of wood pulp hydrolysis depends on the acid concentration, temperature, pressure and particle size.²⁴ Hydrolysis of cellulose to hexoses at atmospheric pressure is usually performed with strong acids (HCl , H_2SO_4) at 100°C . The resulting hydrolysate is heated up to 110°C with 20% HCl and kept at this temperature for 24–28 h. The reaction is accelerated by free halogens, transition metals, anion-exchange resins and other compounds.² After termination of the one-pot reaction, the reaction mixture is filtered to separate humin compounds and concentrated. LA is isolated from the mixture by distillation at reduced pressure or extraction with ether, ethyl acetate or ethyl methyl ketone. The yield of LA is about 40% with respect to the hexose content.² The reaction performed at 190°C under pressure gives a considerable gain in time.²⁵

Preparation of LA from hexoses in supercritical reactors (34.5 MPa, $200\text{--}385^\circ\text{C}$) has been described in many papers over the last decade.^{26, 27} In the absence of acidic or basic catalysts, the dehydration reaction is more selective. Currently, degradation of hexoses under hydrothermal conditions^{28, 29} or using alcohols in the presence of strong acids at $180\text{--}200^\circ\text{C}$ ³⁰ is being developed. This permits one to reduce the reaction time to several minutes at sufficiently high yields of LA. A search for new efficient catalysts is currently under way. Thus zeolites were found to

manifest high catalytic activity in the preparation of LA from glucose and fructose.³¹

Furfuryl alcohol (**19**), another product of wood pulp chemical processing, is an alternative source of LA. Its heating in aqueous organic acids ($K_a = 10^{-6}\text{--}10^{-4}$) in the presence of hydrochloric acid affords LA in more than 80% yield. When this reaction is performed in boiling ethyl methyl ketone in the presence of HCl , LA is formed in 90%–93% yield.^{33, 34} The hydroxy derivatives **20** and **21** were shown (^{13}C NMR) to be the key intermediates in this reaction.^{21, 22}

Levulinic acid is also formed upon oxidation of 5-methylfurfural (**22**) with 28% H_2O_2 at 60°C in the presence of HCOOH . This reaction gives a mixture of levulinic and 4-oxopent-2-enoic (**23**) acids (Scheme 3).^{35, 36}

It was shown³⁷ that LA is formed in high yield in the reaction of 4-(diphenylmethylsilyl)butyrolactone (**24**) with MeMgI .

LA can also be obtained in satisfactory yields³⁸ upon conjugate addition of nitroethane to acrolein in the presence of Al_2O_3 with subsequent oxidation of 4-nitropentanal (**25**) with an $\text{H}_2\text{O}_2\text{--K}_2\text{CO}_3$ system.

Despite the high yield of LA in the above reactions, they still cannot compete on an industrial scale with the simple and inexpensive procedures used in the preparation of LA from plant raw material.

IV. Reactions involving the carboxy group

Of reactions involving the carboxy group of LA, special mention should be made of esterification which yields useful levulinates. The reaction of LA with primary alcohols, which is a first-order reaction with respect to both reactants,³⁹ occurs in solutions of LA in respective alcohols even at room temperature.⁴⁰ In order to

obtain esters in nearly quantitative yields, the reaction is carried out in the presence of typical dehydrating agents, such as sulfuric,^{41,42} polyphosphoric⁴³ or *p*-toluenesulfonic acid.^{44,45} The use of anion-exchange resins⁴⁶ or 2-halogenopyridinium salts⁴⁷ also gives good results. The increase in the size of the hydrocarbon fragment of the primary alcohol does not impede its esterification.⁴⁸ Since primary alcohols are easily and selectively acylated under these conditions, LA is used as a protective group in the synthesis of oligonucleotides⁴⁹ and oligosaccharides.^{50–52} Deprotection can be achieved using sodium borohydride⁵³ or sulfite anion donors.⁵⁴ However, hydrazinolysis is the most efficient method for deprotection.^{55,56} Under mild conditions, LA esters quantitatively react with hydrazine and its derivatives, which results in the regeneration of the original alcohol and the formation of the corresponding dihydropyridazinone, as a result of which the acid is completely eliminated from subsequent reaction. The formation of dihydropyridazinones and their reactivities are discussed in Section V.

The synthesis of LA esters with tertiary alcohols in good yields usually involves other reactions than esterification. For example, *tert*-butyl levulinate is obtained by the reaction of LA with dimethylformamide *tert*-butyl acetal⁵⁷ or *tert*-butyltrichloroacetimidate.⁵⁸

Substituted benzyl and aryl esters of LA can be obtained using other classical methods for ester synthesis, e.g., acylation of alcoholates with levulinoyl chloride^{2,59–61} or alkylation of LA salts with alkyl halides under conditions of phase-transfer catalysis.⁶²

In addition to the methods described above, there are some other ways to obtain LA esters. Levulinates are formed by the reaction of LA with diazomethane derivatives,⁶³ upon photooxidation of cyclopentenone derivatives,⁶⁴ from the corresponding nitro compounds by the Nef reaction⁶⁵ or catalytic carbonylation of 4-alkoxybutan-2-one on rhodium catalysts.⁶⁶

LA thio esters are obtained in high yields by the reaction of thiols with a pyridinium salt of LA formed *in situ* from the free acid and 2-fluoro-1-methylpyridinium tosylate.⁶⁷

Decarboxylation of LA in the gaseous phase occurs with difficulty.⁶⁸ Attempts to perform this reaction in a flow of hydrogen over Ni- and Pd-catalysts at 180–330 °C or over zeolites containing group I, II and VIII metals were more successful.⁶⁹ Thus heating of the lactone **4** up to 570 °C in the presence of SiO_2 gave up to 80% of ethyl methyl ketone.⁷⁰ A method for decarboxylation proposed recently using xenon fluoride was applied successfully to LA. Such fluorodecarboxylation occurs at room temperature⁷¹ via intermediate fluoroxenon esters **26**.

Studies of anodic electrolytic decarboxylation of LA under conditions of the Kolbe reaction have established interesting synthetic possibilities. In methanol, at a potential difference of 80–129 V and 2–3 A in the presence of sodium methoxide, LA was converted into octane-2,7-dione (**27**).⁷² Cross-decarboxylation in the presence of other carboxylic acids results in unsaturated ketones **28**⁷³ and higher aliphatic oxo acid esters **29**.^{74,75}

(a) $\text{MeOH}, \text{MeONa}$; (b) $\text{Me}-\text{CH}=\text{CH}-\text{COOH}$; (c) $\text{HOOC}(\text{CH}_2)_n\text{COOMe}$, $n = 4, 8, 12$.

In addition to the above reactions involving the carboxy group of LA, of note is its nucleophilic addition to alkoxyacetylenes.⁷⁶ The addition product **30** is unstable and is easily rearranged into the lactone **31** which ultimately yields 3-methylhex-3-enedioic acid (**32**).

V. Reactions involving the carbonyl group

1. Reactions with N-nucleophiles

The presence of two highly reactive functional groups in the LA molecule determines its specific properties. Reactions of LA with nitrogen-containing nucleophiles provide an illustrative example. As a rule, reactions of LA with such nucleophiles are not terminated by their addition to the carbonyl group or the formation of the corresponding amide but result in heterocyclisation. For example, the carbonyl group of LA undergoes the Knoop–Oosterlin reductive amination.⁷⁷ This reaction is catalysed by Co, Ni and Pd and gives either the corresponding amino acids **33**,⁷⁸ or 5-methyl-2-pyrrolidone derivatives **34** as a result of cyclodehydration, depending on whether the carboxy group of LA is protected or not.^{79,80}

The amides formed by the reaction of LA with various amines are attractive not only because of their biological activity,⁸¹ but also because of their ability for cyclisation. Thus the amide **35** formed in the reaction of phenethylamine with α -angelicalactone (**4**) is unstable and is at equilibrium with the corresponding pyrrolidone **36** (the **35**:**36** ratio is 1:2).^{82, 83}

Reactions of anilines with LA or the lactone **4** in acidic media yield reactive benzoazepinone derivatives **37** rather than anilides.^{84, 85} The direction of their hydrogenation depends on the nature of the reagent used. Thus hydrogenation with hydrogen over PtO_2 results in saturation of the C(4)=C(5) bond of the azepine ring, whereas treatment of the benzoazepinones **37** with LiAlH_4 results in the reduction of the oxo group to the methylene group. Treatment of compound **37** with POCl_3 gives the chloro-substituted benzoazepine **38**.

The result of the reaction of LA with pyrrole derivatives containing the 2-aminoethyl group depends on its position in the ring. Thus the reaction of LA with 2-(2-aminoethyl)pyrrole gives the 1*H*-pyrrolo[3,2-*c*]pyridine derivatives **39**.⁸⁶ A similar reaction of LA with 3-(2-aminoethyl)indole (tryptamine) or *N*-(2-aminoethyl)indole leads to the formation of fused heterocyclic systems **40** and **41**, respectively.^{87, 88}

The reaction of LA with 5-aminopyrazoles gives substituted 4-methyl-6*H*-7,8-dihydropyrazole[3,4-*b*]azepin-7-ones.⁸⁹

The reaction of LA with *o*-phenylenediamine derivatives results in the formation of the benzoimidazole ring and yields isomeric pyrrolobenzoimidazolones **42** and **43**.⁹⁰

Substitution of an amide group for an amino group in the aromatic component of this reaction affords other types of heterocyclic derivatives. Thus anthranilic acid and its amides react with LA to give fused heterocyclic systems, *e.g.*, 2,3,3*a*,4-tetrahydropyrrole[1,2-*a*]quinazoline-1,5-diones **44** from anthranilamides.^{91, 92}

As noted above, LA and its esters readily react with hydrazine and its derivatives to give the corresponding hydrazones. Dihydropyridazinones^{93–96} possessing analgesic and diuretic activities are formed from hydrazine and its monosubstituted hydrazones upon cyclodehydration.⁹⁷

R = H, Alk, Ph, *p*-MeC₆H₄, *p*-EtOC₆H₄.

Dihydropyridazinones are highly reactive compounds and can be used in organic synthesis. Using compound **45** as an example, it was demonstrated that dihydropyridazinones are easily oxidised with bromine or SeO₂ to the corresponding pyridazinones^{93,94} and reduced with LiAlH₄ first to tetrahydropyridazines⁹⁵ and then to hexahydro derivatives.⁹⁸ Pyridazinones undergo alkylation, nitration and chlorination.⁹⁹ Compound **45** was also used to obtain glutamic acid *via* the intermediate pyridazinone-3-carboxylic acid.¹⁰⁰

The formation of the dihydropyridazinone ring upon treatment of levulinamide with hydrazine illustrates the possibility of nonenzymic hydrolysis of the peptide bond. This is exemplified by reaction of *N*-levulinoyl-L-phenylalanine (**46**) with hydrazine.¹⁰¹

LA reacts very easily with 2,4-dinitrophenylhydrazine. This circumstance was used in the development of a semi-quantitative colorimetric procedure for determination of hydrazones. This method is based on the ability of LA to serve as an acceptor of 2,4-dinitrophenylhydrazine and to regenerate the ketone from the corresponding hydrazone as a result of the exchange reaction.¹⁰² It was noted also that treatment of the oximes **47** with LA recovers carbonyl derivatives.¹⁰³

R¹ = Me, R² = Ph; R¹ = Ph, R² = H; R¹ = R² = Ph.

LA hydrazones manifest noticeable antibacterial activity.^{104–106} They also serve as a source of *N*-substituted pyrrolidones. The reaction between LA and hydrazides of nicotinic or isonicotinic acids demonstrates an approach to the synthesis of *N*-acyl pyrrolidones **48**.¹⁰⁷

R = 3-pyridyl, 4-pyridyl.

Unlike acylhydrazines, their thio analogues react with LA or its esters to give the 1,3,4-thiadiazole derivatives **49**.^{107, 108}

The hydrazones **50** prepared from LA and 3-aryl-2-hydrazinoquinazolinones are thermally unstable and undergo the Dimroth rearrangement at melting temperature with simultaneous cleavage of the imine bond, eventually resulting in 3-amino-2-anilinoquinazolinones **51**.¹⁰⁹

The role of LA arylhydrazones in the Fischer indole synthesis has been studied in most detail, since this reaction gives an access to not only heteroauxin analogues manifesting growth-regulating activity¹¹⁰ but also to a broad range of antiinflammatory drugs, such as indometacin [1-(4-chlorobenzoyl)-5-methoxy-2-methylindol-3-ylacetic acid].¹¹¹ Halogen-, alkyl- and alkoxy-substituted arylhydrazines,^{112,113} 1-naphthylhydrazine¹¹⁴ and various *N*-acyl-*N*-arylhydrazines enter into this reaction.^{115–120} Sodium arylhydrazinesulfonate can be used instead of phenylhydrazine hydrochloride which is unstable on storage.^{121, 122}

The mechanism of this reaction was studied with LA as an example. It was found that hydrazone rearrangement, which is probably similar to the Claisen rearrangement of allyl phenyl ethers, is the key stage. The key intermediate of the imine type, *viz.*, compound **52**, which gives the intermediate **53** upon heterocyclisation, was studied by ¹³C NMR spectroscopy.¹²³

2. Reactions with O- and S-nucleophiles

Under conditions of acid catalysis, LA esters react easily with alcohols and thiols to give the corresponding dialkylacetals and dialkyldithioacetals in more than 90% yields.¹²⁴ Special mention should be made of compound **54** formed in the reaction of LA with 3-mercaptopropionic acid, which can selectively extract some metal cations.¹²⁵

The reaction of LA with thiazolyl- and indolyethanols gives the fused tetrahydropyrans **55** and **56**.^{126, 127}

The reaction of LA or its esters with 1,2-diols or dithiols gives dioxolanes and dithiolanes.^{128, 129} As is known, the formation of such structures is often used to protect the carbonyl group. This approach is also used in multistage syntheses involving LA. Thus the 1,2-dioxolane (**57**) and 1,3-dioxolane (**58**) derivatives of LA were used to protect its carbonyl group in the syntheses of a natural pheromone,¹³⁰ Z-jasmone and dihydrojasmone.^{131–133}

The presence of an amino group in the α -position with respect to the hydroxy or the mercapto group in amino alcohols or amino thiols makes it possible to carry out heterocyclisation on their reactions with LA^{134, 135} to give the bicyclic lactams **59**.

R = COOH, CHMe₂; X = O, S.

3. Reactions with organoelement compounds

The carbonyl group is capable of nucleophilic addition of organometallic compounds. However, this reaction is often complicated due to involvement of the carboxy group. γ -Valerolactone derivatives^{136–140} are formed instead of the expected hydroxy acid derivatives even in reactions of organometallic derivatives of group I and II elements with levulinates with the protected carboxy group. Thus the reaction of LA with allylzinc bromide gives 5-allyl- γ -valerolactone (**60**) in 80% yield.¹³⁹

The allyl carbanion formed *in situ* as a result of hydrolysis and scission of the Si–C bond in allyltrimethylsilane under the action of tetrabutylammonium fluoride adds to LA to give the γ -valerolactone **60** following hydrolysis of the intermediate product.¹⁴¹

Nevertheless, allylation of LA and its esters to the corresponding derivatives of 4-hydroxyvaleric acid can be achieved with allyl bromide in the presence of metallic Zn, Sn and Al^{142, 143} as well as alkyl complexes of transition metals.¹⁴⁴ The pseudo-Barbier reaction involving ethyl levulinate and alkyl halides in the presence of samarium cyclopentadienyl complexes is also possible.¹⁴⁵

The reaction of LA with metal cyanides and hydrocyanic acid gives the cyanohydrin **61**.¹⁴⁶ The latter yields 5-cyano- γ -valerolactone (**62**) under the action of dehydrating reagents; its hydrolysis gives 2-hydroxy-2-methylglutaric acid (**63**). The lactone **62** can also be converted into 2-methylglutamic acid.¹⁴⁷

The reaction of the cyanohydrin **61** with hydrazine followed by oxidation gave the azo compound **64**, which is an initiator of radical reactions.^{148, 149}

The carbonyl group of LA or its esters reacts with phosphorus-substituted carbanions^{150, 151} in the Wittig and Horner–Emmons reactions to give compounds **65** and **66**.

Hydrides of group IV and V elements also easily add to the carbonyl group of LA. Hydrosilylation in the presence of rhodium complexes with chiral ligands occurs as enantioselective reduction.^{152, 153} However, unlike diethylsilane, which gives a stable silylation product,¹⁵⁴ hydride derivatives of arsenic and phosphorus yield unstable addition products that easily undergo intramolecular cyclisation.^{155, 156}

The result of the reaction of halides of group V elements with LA depends on the nature of the halide. As would be expected, bismuth and antimony halides yield predominantly acyl derivatives,^{157, 158} whereas the reaction with MeNbCl₄ results in the chlorination of the carbonyl group of LA.¹⁵⁹ The same result is observed in the interaction of LA with phosphorus pentachloride.¹⁶⁰ However, the reaction of PCl₅ with α -angelicalactone (4) leads to phosphorylation of the multiple bond.¹⁶¹

4. Condensation reactions

Aldol condensation of LA with aromatic and heterocyclic aldehydes under conditions of the Claisen reaction gives α,β -unsaturated carbonyl compounds and their derivatives. Benzaldehyde and its analogues easily enter into the condensation reaction to give 6-aryl-4-oxohex-5-enoic acid (67),^{162–164} while the reaction of LA esters with 2-hydroxyacetophenone yields the 2-substituted chromone 68.^{165–167} It is believed¹⁶⁸ that this reaction proceeds *via* the lactone intermediate by the Stobbe condensation.

Since the unsaturated acids 67 thus formed are γ -oxo acids, they retain ability to form pyridazinones on reaction with hydra-

zine. Pyridazinones can undergo bromination and yield pyridazines.¹⁶⁹

Condensation of LA with furfural offered even broader possibilities for the synthesis.^{170–175} This reaction can yield diverse furancarboxylic acids. 5-Furfurylidenelevulinic acid (69) is the main reaction product at room temperature. However, at a temperature above 50 °C, the proportion of 3-furfurylidene- (70) and 3,5-difurfurylidenelevulinic acids (71) increases.¹⁷³

Acid treatment of the acid 69, *i.e.*, the main reaction product, gives dilevulinic acid 72; its reduction on a Raney nickel catalyst yields sebacic acid,¹⁷¹ and its cyclisation results in the dicarboxylic acid 73, which served as the starting compound in the synthesis of prostaglandins.¹⁷⁴

Condensation of LA or its esters with cyanoacetic acid under conditions of the Knoevenagel reaction yields the nitriles 74. The latter were used to obtain 3-methyladipic acid by reduction of the double bond and acid hydrolysis.¹⁷⁶

$\text{R} = \text{H, Me, Et, CH}_2\text{Ph.}$

Like aldehydes and ketones, LA undergoes acid-catalysed condensation with phenols and naphthols to give the 4,4-diaryl-substituted valeric acids 75.^{177–180}

$\text{R} = \text{H, Me.}$

Furan and its derivatives react analogously.^{181–183} Conjugate condensation of furan with acetone and LA or its esters makes it possible to obtain macrocycles of the type **76**, which can selectively extract metal ions similarly to crown ethers.

The reaction of LA with resorcinol occurs in a different way and gives the arylated γ -valerolactone **77**.¹⁸⁴

In the reaction of LA esters with enol silyl ethers in the presence of equivalent quantities of TiCl_4 , cross-aldol condensation occurs smoothly to yield esters of 4-hydroxy-4,5-dimethyl-6-oxocarboxylic acids **78**.¹⁸⁵

R = Alk.

A similar reaction takes place in the condensation of LA with chlorodifluoromethyl ketones.¹⁸⁶

VI. Reactions involving the methyl and the methylene groups

The carbonyl and the carboxy groups of LA activate the neighbouring carbon atoms. Therefore, LA undergoes easy chlorination and bromination. These reactions yield organic halides which represent valuable 'building blocks'.

Chlorination of LA with chlorine at moderate temperatures results in 3,5-dichlorolevulinic acid (**79**).¹⁸⁷ With a rise in temperature or in the presence of Lewis acids, more profound chlorination takes place to give 2,3,5,5,5-pentachloro-4-oxopentenoic acid (**80**),^{188–191} which can be used as defoliant.

The result of bromination of LA strongly depends on the medium in which the reaction is performed. By varying the solvent, one can obtain different bromo derivatives of LA with sufficiently high selectivity. Thus bromination in the presence of concentrated HCl gives predominantly 2-bromolevulinic acid (**81**),¹⁹¹ whereas in acetic acid 3,5-dibromo-derivative **82** is obtained.¹⁹² In methanol, the reaction results in regioselective bromination of LA at the methyl group to give 5-bromolevulinic acid (**83**).¹⁹³

Combination of halogenation and dehydrohalogenation of LA affords halogen-containing hydroxyfuranones **84a,b**.^{194, 195}

X = Cl (**a**), Br (**b**).

Sulfur tetrafluoride^{196–198} and its derivatives¹⁹⁹ are the most effective fluorinating agents for LA. However, this does not involve the methyl and the methylene groups. It was shown that the lactone **3**, which is always present in a solution of LA, is the first to undergo fluorination. The latter is converted into 1,1,1,4,4-pentafluoropentane through the intermediate **85**.

Ethyl levulinate undergoes fluorination only at the carbon atom of the carbonyl group under these conditions.²⁰⁰

The methyl group of LA is active in the metallation reaction. Thus treatment of LA with lithium diisopropylamide gives the organolithium compound **86** which, in turn, yields 6-phenyl-4,6-dioxohexanoic acid (**87**) in the reaction with benzoyl chloride.²⁰¹

VII. Oxidation and reduction reactions

The result of oxidation of LA strongly depends on the type of the oxidant. High-temperature oxidation of LA with oxygen over V_2O_5 gives succinic acid²⁰² and oxidation of LA with selenium dioxide under conditions of the Riley reaction results in 2-oxoglutaric acid.²⁰³

Oxidation of LA and its derivatives with peroxy compounds in the Baeyer–Williger reaction has been studied.^{204–207} The first step of this reaction yields hydroxyperoxyvaleric acid derivatives **88**, which rapidly cyclise to peroxyvalero- γ -lactones **89**. If the carboxy group is protected, succinates are formed.

Reduction of LA can be carried out by various methods. First, mention should be made of catalytic hydrogenation of LA and its esters on Raney nickel. The free acid is quantitatively converted into γ -valerolactone,²⁰⁸ while its esters are reduced to 4-hydroxyvaleroates.²⁰⁹ Analogous products are obtained upon hydrogenation of LA and its esters on a copper–chromium catalyst (CuO, 80%; Cr₂O₃, 20%).²¹⁰ Modification of hydrogenation catalysts with optically active substances (L-alanine, L-phenylalanine, L-glutamic acid, D-tartaric acid) allowed one to accomplish asymmetric synthesis of γ -valerolactone from LA.^{211–213}

Under conditions of reductive cyclisation, LA and its esters serve as starting compounds in the synthesis of different saturated lactones, e.g., 5-substituted butyrolactones.^{214–216} Thus the optically active γ -valerolactone is obtained in good yield by reduction of LA with silanes in the presence of rhodium catalysts with chiral ligands.²¹⁷

The reaction of LA with SOCl₂ gives the saturated lactone **90** in addition to levulinoyl chloride. This reaction is believed to occur according to the mechanism depicted in the scheme given below.²¹⁸ The yield of compound **90** can reach 100%.²¹⁹ Apparently, the formation of 5-methoxy- γ -valerolactone in the reaction of LA with methyl chloroformate occurs in a similar way.²²⁰ The halogen atom in compound **90** is rather mobile. Thus the reaction of the lactone **90** with equimolar amount of 90% *tert*-butyl hydroxypoxide gives compound **89** (R¹ = Bu¹).²²¹

The reaction of LA with sodium dithionite in boiling aqueous dioxane also gives γ -valerolactone. It is believed²²² that this reaction occurs through the formation of α -hydroxysulfonates. For catalytic hydrogenation of the oxo group of LA catalysed by ruthenium and rhodium complexes see Refs 223 and 224.

More profound reduction of LA derivatives to diol or valeric acid is also possible. Thus reduction of LA with lithium aluminium hydride gives racemic pentane-1,4-diol,²²⁵ while electrochemical reduction of LA under conditions of catholyte recirculation and membrane separation of anolyte gives valeric acid.²²⁶ Bakers yeast reduce LA esters to 4-hydroxyvalerates in good yields and then to (*R*)- γ -valerolactone and (*S*)-pentane-1,4-diol.²²⁷

VIII. Conclusion

Thus, easy access to LA from natural renewable raw materials makes this acid a readily available starting compound for the synthesis of 1,4-dicarbonyl systems the synthetic approaches to which are limited.²²⁸

On the one hand, LA enter into miscellaneous reactions of nucleophilic addition of N-, O-, S- and C-centred nucleophiles at the oxo group; on the other hand, it undergoes classical transformations characteristic of carboxylic acids. Moreover, LA as a typical representative of γ -oxo carboxylic acids reacts with involvement of both functional groups at once. This permits the

synthesis of various types of heterocyclic compounds on the basis of LA, e.g., pyrrolidone, benzoazepinone, indole and chromone derivatives.

It is noteworthy that the presence of an electron-acceptor carbonyl group in the LA molecule strongly increases the acidity of the protons at C(3). Their mobility favours the alkylation and halogenation of the LA molecule as well as its lactonisation.

Owing to the accessibility of LA, the methods for synthesis of various compounds based on it efficiently compete with alternative synthetic approaches.

In addition, both LA and its derivatives possess various useful properties which significantly expand the range of their ever increasing synthetic applications. Thus levulinic acid is used to control plant growth.²²⁹ Being an inhibitor of choline photolysis,²³⁰ LA can inhibit or stimulate chlorophyll synthesis.²³¹ It is used as a modifying additive to resins based on furfuryl alcohol,²³² modifies the surface of aminoaerosols,²³³ confers radiation-protective properties to polymers²³⁴ and is used for scheelite flotation.²³⁵ Its esters and salts are used in the food industry^{236–240} as preservatives, stabilising and flavouring agents as well as in the manufacture of cosmetics^{241–246} and in medicinal practice.^{247–250} LA esters as additives increase thermal stability of poly(vinyl chloride)²⁵¹ and improve the characteristics of motor fuels,²⁵² while glycol esters are perfect plasticisers.^{41, 61, 253} Compounds synthesised from LA are used as corrosion inhibitors,²⁵⁴ initiators of radical polymerisation,^{148, 149, 255–257} cross-linking reagents²⁵⁸ and components of liquid crystals.^{259, 260}

There is no doubt that LA may be used as one of the components in the elaboration of an alternative source of raw materials in organic synthesis.

Abstract. Chemistry is on the threshold of a new flight; new ideas and lines of research are originating now; new directions arise, which form a new face of chemistry. The bibliography includes 79 references.

I. Introduction

Chemistry ultimately formed as a fundamental science only in the early XXth century when it got a reliable and solid physical basis made of three main concepts of quantum mechanics, namely

- the Schrödinger equation, which is the quantum successor of the classical mechanics equations (Hamilton–Jacobi equations);
- Pauli's exclusion principle, which governs the distribution of electrons among spin states and energy levels and
- wave function, which carries information on the charge and spin distribution.

It is these concepts that have imparted physical meaning to the D. I. Mendeleev Periodic Table, an outstanding discovery of the XIX century the significance of which goes far beyond chemistry. From the viewpoint of these three concepts, a chemical reaction should be regarded as a physical process involving rearrangement of electron shells and nuclei.

The understanding and realisation of the significance of these quantum-mechanics principles for chemistry makes chemical science clear and predictable as regards its main features; they give rise to the diversity and richness as well as to the elegant logic and beauty of chemistry.

In the XX century chemistry became an exact science; many quantitative regularities and precise laws have been established (including the 'electron periodicity' of the Mendeleev law); a very high metrological level of determination of atomic, molecular,

thermodynamic and kinetic constants, characterising both substances and chemical processes, has been attained.

During this century, chemistry has developed into a branched science. Nowadays, many fields of chemistry exist as separate branches of science — inorganic, organic and physical chemistry; radiochemistry, biochemistry, analytical chemistry, geochemistry, *etc.* Each of them has its own subject and the scope of investigations as well as its own problems and experimental techniques. However, by the 80s, the professional separation of the chemistry branches has started to be replaced by attempts to tackle jointly the general fundamental problems of chemical science.

The first attempt to identify the most important 'integration' lines in chemistry was made in a paper by Legasov and Buchachenko,¹ in which chemistry was classified at a new level. The chemical science was structured according to the targets and problems rather than according to the names of various 'chemistries,' which now number more than four dozen. This classification follows the logic inherent in chemistry, which does not separate chemistry into 'chemical counties' but instead organises it as a unified science and also unites chemists as a community.

Nowadays, at the end of the XXth century, the classification proposed in the publication mentioned above¹ has not changed much, and the hierarchy of general problems of chemistry can be presented as follows.

- the art of chemical synthesis;
- chemical structure and function;
- control of chemical processes;
- chemical materials science;
- chemical technology;
- chemical energetics;
- chemical analytics and diagnostics;
- chemistry of living matter.

These are the main 'arterial roads' which direct the development of modern chemistry and reflect its achievements and progress.

Uspekhi Khimii 68 (2) 99–118 (1999); translated by Z P Bobkova

[†] This paper is an extended version of the report presented by the author at the General Meeting of the Division of General and Technical Chemistry of the Russian Academy of Sciences and at the XVIth Mendeleev Congress on General and Applied Chemistry (St. Petersburg, 1998).

Chemical synthesis is the key direction in the development of chemistry and the source of all its treasures. This route makes chemistry the most constructive branch of science. Chemistry provides other branches of science and industry with materials; in this sense, one can say that it stands in the middle of natural sciences. It is especially intriguing that, despite the existence of theoretical principles of chemical synthesis, there still remains scope for the freak of imagination and intuition. This brings chemical synthesis closer to an art.

The atomic and molecular architecture and the electronic structures of newly synthesised compounds are infinitely diverse, so are their physical and chemical properties and, therefore, functions. The relationship between the structure and functional behaviour of a substance is the subject of the second line of research.

The control of chemical processes and their molecular mechanisms and the use of chemical factors (complex formation, solvation, molecular organisation, catalysis) and physical treatment (ranging from light to mechanical treatment) for controlling chemical processes constitute the essence of the third line.

A substance is not a material yet but only the precursor of a material. People have to 'teach' substances to work as materials and to estimate their operation characteristics and ranges of applicability. These are the tasks of the *chemical materials science*.

The aim of *chemical technology* is to design, optimise and scale a technological process as well as to ensure its low energy expenditures and safety and to make it environmentally clean.

The development of efficient ways of transformation of chemical energy into other kinds of energy, accumulation of energy in energy-storing substances and materials (including lasers with chemical and solar pumping), transformation of solar energy, chemical cells and coupling of energy-producing and energy-consuming processes constitute the subject of *chemical energetics*.

The progress in chemical materials science and chemical technology would be impossible without reliable *chemical analytics and diagnostics*. This is a vigorously developing line of research (which includes chemical sensors and the chemistry of odour) having links to lots of branches, ranging from technical monitoring systems to medicine or ecology.

There is no question that all these lines of research are related not only logically. They are intrinsically connected by the methodology of chemical research itself — elements of several lines can be found in a good scientific article. The remarkable combination of differentiation and integration makes up the efficient and creative style of modern chemistry.

Finally, the *chemistry of living matter* is an enormous chemical galaxy, which is still to be explored. It assimilates the results of biochemistry, chemistry of natural products, phytochemistry, enzyme science, medical and pharmaceutical chemistry, genetic engineering, biotechnology and many other fields of chemistry. This line of research is associated with great expectations; it undoubtedly possesses an exceptionally high potential, indisputable prospects and a highly promising future. Even today, its outlines and significance can be traced by looking at the transgene technology.

II. Novel chemical structures and materials

Each arterial road of chemistry has its own events and discoveries, which can be both regular and unexpected. However, the most significant events still occur in the first, key arterial road. Development of methods for the synthesis and design of new substances and materials are the main goals of chemistry. It should be noted that the number of compounds that have been created chemically (artificially and skilfully) is permanently increasing. The molecular architecture of newly formed compounds is infinitely variable and fabulously abundant. For example, the following unusual structures have been obtained: rhombic molecules — structural units of one-dimensional metals; proton

'sponges' and 'tubes' (molecularly organised proton-carrying reservoirs and channels); toroidal molecules; polymetal rotaxanes; catenanes; crowns and anticrowns, capable of separating cations and anions; hypervalent radicals such as NH_4 , CH_5 , H_3O , some of which are long-lived species, for example, $(\text{CH}_3)_2\text{NH}_2$ (lifetime $\sim 3 \mu\text{s}$);² high-spin molecules containing tens of unpaired electrons within a single species [for example, the complex $\text{Mn}_6^{2+}(\text{R}_2\text{NO})_6$ has 36 unpaired electrons]; multi-deck polyaromatic molecules; molecules with large numbers of chiral centres, etc. Some of the compounds obtained artificially may remain exotic species for good, but some others would trigger new lines of research.

The adoption of new principles of radial synthesis in which molecules unite according to the fractal pattern to give an enormous molecule, *dendrimer*, has been an important event in chemistry. Nature has used this principle to produce glycogen, amylopectin and some other polysaccharides and proteins. Many remarkable discoveries have been made in the chemistry of dendrimers, especially in the polymer chemistry.³ The architectures of dendrimer structures are virtually infinite; the same is true for their functions and applications. In particular, it has been predicted that dendrimers based on polyconjugated molecules could serve as energetic antennas collecting the energy of optical (including solar) excitation and transforming it into photoelectric current.

Impressive results have been attained in the synthesis of organometallic polymers. The preparation of ladder, tape and rod-like organometallic polymers can be formally classified as 'one-dimensional' or 'two-dimensional' radial synthesis. Thus Fig. 1 shows two projections of an unusual organometallic ladder polymer $[(\text{CuL}_2)\text{PF}_6]_\infty$, prepared by polymerisation of 2,7-diazapyrene (L) and $[\text{Cu}(\text{MeCN})_4]\text{PF}_6$ in the MeCN–PhCN system.⁴ It can be seen from the Figure that a monomer unit of this polymer is

Figure 1. Two projections of the organometallic ladder-type polymer $[(\text{CuL}_2)\text{PF}_6]_\infty$ (L = 2,7-pyrene) with polycatenane and adamantane structural units.⁴

formed by three interpenetrating adamantane networks arranged at angles of 90° relative to one another. Examples of three-dimensional organometallic dendrimers have been reported (see below).

The discovery of *superconducting ceramics* has stirred up not only physicists and engineers but also chemists. These compounds had been prepared well before their superconducting properties were discovered, but it was this intriguing and unexpected feature of ceramics that aroused most enthusiasm and hope. The achievements in this field proved to be modest compared to the expectations; although the progress along this line has now substantially slowed, some pleasant surprises are still possible (note the startling publication⁵ dealing with superconductivity of inorganic compounds at room temperature, the value of which is still unclear). It is about this type of situation that Niels Bohr said that problems are more important than solutions. In fact, solutions can become obsolete to leave the problems, which stimulate the search for new solutions.

After a great number of paramagnetic organic compounds (stable radicals and high-spin molecules) had been synthesised, attempts to prepare *molecular ferromagnets* were undertaken. The principle of design of organic ferromagnets had been formulated long before they were discovered in 1989.^{6,7} The exchange interaction of the unpaired electrons in paramagnetic organic molecules is known to be negative; it accounts for the antiparallel arrangement of the magnetic moments of the electrons. It has been suggested that macroscopic ferromagnetism in ferromagnets is attained *via* pairwise antiferromagnetic interactions. This hypothesis immediately received experimental support.⁸

Figure 2 shows the crystal structure of 2-(4-nitrophenyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-*N'*-oxyl *N*-oxide.

Figure 2. Two-dimensional representation of the crystal lattice of 2-(4-nitrophenyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-*N'*-oxyl *N*-oxide.

The NO[•] groups (areas with high spin density) are coloured black, while the NO₂ groups (areas with small negative spin density) are designated by crosses.⁸

It can be seen that the nitroxides are arranged in the crystal in such a way that fragments with high spin density (NO[•] groups) are located close to fragments where the spin density is low and negative (NO₂ groups). Owing to the pairwise exchange interaction of the neighbouring spins with positive and negative electron density, spins with positive density align in one direction, while those with negative density align in the opposite direction; this creates macroscopic ferromagnetism in the crystal. This is only one of the numerous examples of organic ferromagnets.⁹

One should not, however, create illusions about this class of compound. The specific spin density and the degree of magnetisation in these substances are very low; correspondingly, the temperatures of ferromagnetic phase transitions are also very low (~ 1 K). Mixed organometallic ferromagnets are more promising (and therefore more attractive). Figure 3 presents the structure of an organometallic ferromagnet, $\{[\text{FeCr}(\text{ox})_3] \cdot (\text{NBu}_4)\}_\infty$ (ox is oxalate anion). The structure consists of the Cr(ox)₃ fragments being joined together by the Fe ions to form a huge ferromagnetic molecule. In the crystal, the compound $\{[\text{FeCr}(\text{ox})_3](\text{NBu}_4)\}_\infty$ has a layered structure.^{10,11}

Figure 3. Structure of the organometallic ferromagnet $\{[\text{FeCr}(\text{ox})_3](\text{NBu}_4)\}_\infty$ ($T_c = 12$ K). For the sake of simplicity, the tetra-butylammonium cation is not shown.¹⁰

Fullerenes have become a real treasure for chemistry. The most daring and optimistic forecasts are associated with fullerenes. Fullerenes C₆₀, C₇₀, etc. can be prepared in macroscopic quantities by the arc method. However, the mechanism of their formation still remains obscure. The perception of this fact stimulates experimental and theoretical (molecular dynamics) studies of the formation of fullerenes from atoms, pairs of atoms and clusters under the conditions of gas discharge, plasma, electric arc, etc. The main goal of these studies is to understand the mechanism of polyhedral clustering and the arrangement of atoms to give a fullerene structure (see, for example, Ref. 12). The search for catalysts of this process is also perfectly reasonable. It is beyond doubt that this route would bring both predicted discoveries and godsend.

At present, in addition to traditional chemistry, targeted chemistry of these compounds is in progress. In particular, it is of interest to perform polymerisation of fullerenes with retention of the spherical cage units (*via* cross-linking). According to predictions, these polymers would possess high electron 'capacity,' which would permit them to be used in chemical and storage cells. Thermal polymerisation of the most readily available C₆₀ fullerene is known to be forbidden from the symmetry viewpoint. Therefore, it requires some sort of treatment which would stimulate distortion of the icosahedral symmetry of C₆₀ and

eliminate the prohibition (high pressure,[‡] shear deformations, shock waves, *etc.*). This is a key problem.

Among other lines of research in the targeted chemistry of fullerenes, mention should be made of fullerene modification aimed at producing materials for microelectronics (the easy construction of integral circuits, simple and clean nano-technologies and other advantages) and synthesis of fullerene-based organometallic and organic complexes to be used as superconductors.

Thus it was found that M_3C_{60} and $M_2M'C_{60}$ fullerides ($M, M' = K, Na, Rb, Cs$) exhibit superconducting properties. The compound $RbCs_2C_{60}$ still remains the record holder, $T_c = 33$ K. A remarkable feature of the superconducting fullerides is the dependence of the temperature of superconductivity transition T_c on the crystal lattice parameter (Fig. 4).¹³ This dependence proved to be opposite to that observed for organic superconductors based on tetrathiafulvalene and its derivatives, which were famous in the 60s–70s (for details, see Ref. 1). In the latter case, compression of the crystal lattice by external pressure results in higher T_c values; conversely, in the case of fullerides, compression decreases T_c . This unusual behaviour has stimulated the search for new superconducting fullerides based on the expansion of the fullerene crystal lattice (by intercalation by NaN_3 and NaH , introduction of NH_3 , *etc.*). In particular, the compound $(NaH)_4C_{60}$ obtained by intercalation of C_{60} by NaH exists as two crystal phases, cubic and orthorhombic. The cubic β -phase conducts electricity, while the orthorhombic α -phase does not.¹⁴ Within the framework of the same idea (crystal lattice expansion), synthesis of charge transfer complexes based of fullerenes and tetrathiafulvalene and its derivatives (the latter served as 'bricks' in the construction of organic superconductors) is being developed.

Figure 4. Dependence of the superconductivity transition temperature T_c on the crystal lattice parameter a in the series of fullerides M_3C_{60} with a face-centered cubic structure.¹³

The mechanism of superconductivity still remains an intriguing question. Does the consideration of this problem go beyond the canonical electron pair theory, according to which the movement of electron pairs is governed by the lattice phonon spectrum (the Bardeen, Cooper, Shrieffer — BCS — theory)? This question has stimulated the synthesis of $^{13}C_{60}$ fullerene (with 99% replacement of ^{12}C by ^{13}C) and the corresponding fullerides, $K_3^{12}C_{60}$ and $K_3^{13}C_{60}$.¹⁵ In qualitative agreement with the BCS theory, the superconduction point decreased from 19.2 to 18.8 K on passing from $K_3^{12}C_{60}$ to $K_3^{13}C_{60}$. This important result confirms partic-

ipation of phonons in the formation and movement of the Cooper pairs.

According to the canonical BCS theory, the superconduction point $T_c \propto M^{-\alpha}$, where M is the mass of the particle responsible for the phonon spectrum (in this particular case, $^{12}C_{60}$ and $^{13}C_{60}$), and α is a characteristic parameter, equal to 0.5. Taking account of the isotope effect and proceeding from the value $T_c = 18.8$ K, one can easily find that $\alpha = 0.3$ (rather than 0.5 as predicted by the BCS theory) for the fulleride $K_3^{12}C_{60}$. This could prompt the conclusion that the BCS theory requires modification. However, this conclusion is not ultimate. In particular, there are no grounds for claiming that the phonons responsible for the Cooper pairing are generated by vibrations of C_{60} as a whole; the pairing might be due to the part of the phonon spectrum created by internal vibrations of C_{60} (for example, the breathing vibration of the sphere). In this case, a mass smaller than the mass of C_{60} should be substituted into the expression $T_c \propto M^{-\alpha}$ and thus the resulting α would move towards 0.5. These conclusions are consistent with the results obtained for Rb_3C_{60} with partial substitution of ^{13}C atoms for ^{12}C . The α value found for this fullerene (0.37) is closer to 0.5.

Endofullerenes constitute one of the most exotic and remarkable classes of chemical compounds created by chemistry. They are formed upon insertion and capture of atoms or ions inside the fullerene sphere. However, it is not the insertion into the fullerene sphere itself that makes these compounds unique but rather the fact that capture of these species by fullerenes is a virtually irreversible process (unlike, for example, the capture of species by cyclodextrins, which is reversible).

A great number of endofullerenes have already been synthesised: $T@C_{60}$ (tritium atoms are formed from ^6Li ions on irradiation with neutrons in the presence of C_{60}), $(^3He, ^4He)@C_{60}$, $K@C_{59}B$, $La@(C_{60}, C_{70}, C_{74}, C_{82})$, *etc.*; endofullerenes with two or even three captured atoms have been obtained, for example, $He_2@C_{70}$, $La_2@(C_{72}, C_{74}, C_{80})$, $(Gd_2, Y_2)@C_{90}$, $(Sc_2, Er_2)@C_{82}$, $Sc_3@C_{82}$, *etc.*¹⁶ It should be noted that in the synthesis of $La_2@(C_{72}, C_{74})$ in the arc of graphite implanted with La_2O_3 , only endofullerenes $La_2@C_{72}$ and $La_2@C_{74}$ are intensively formed, no 'empty' C_{72} and C_{74} being observed. This fact may prove significant from the viewpoint of catalysis of fullerene synthesis.

Some answers to the question of what is the mechanism of the endofullerene synthesis have already been found. As was to be expected, the early idea that the carbon shell is permeable for high-energy atoms proved to be naive. This idea might (although not for sure) be valid in the case of hydrogen atoms; however, even for He direct insertion into C_{60} (without violation of the cage structure) would require ~ 10 eV, and He^+ would be able to penetrate through a six-membered ring upon an orthogonal collision only if it has an energy of 35–45 eV. This is much larger than the energy required for dissociation of the C–C bonds in the fullerene shell (70–80 kcal mol^{−1}). It is clear that rupture of the C–C bonds to open a 'window' in the shell followed by insertion of the guest atom and closure of the 'window' upon restoration of the C–C bonds is energetically much cheaper than direct insertion.

This mechanism is not at variance with the experimental results. Thus helium slowly (over a period of several weeks) enters the C_{60} sphere at a pressure of ~ 3000 atm and a temperature of 600–650 °C.¹⁷ The endofullerene $Ne_2@C_{70}$ is obtained by heating C_{70} under a high pressure of neon, the $C_{70} : Ne@C_{70} : Ne_2@C_{70}$ ratio being dependent on the number of the synthesis cycles and reaching a limiting value of 1000 : 1 : 0.02.¹⁸ These findings led to the important conclusion that there exists a promoter or catalyst which facilitates the insertion of He atoms into C_{70} . This might be a radical, which adds to fullerene and thus weakens the adjacent chemical bonds and promotes the opening of a 'window'. Certainly, discovery of a catalyst able to reversibly open and close a 'window' in the fullerene sphere would ensure a breakthrough into this new class of compound.

[‡] The report that at high pressures and temperatures the hardness of the fullerene polymerisation product exceeds that of diamond has not been supported.

Probably, a reversibly appearing 'window' as a capture mechanism is important for small neutral atoms (such as He and Ne). In the case of large atoms (*e.g.*, lanthanides), trapping of atoms (or ions) during the formation of the carbon sphere is apparently more significant. The search for appropriate catalysts which would facilitate this process is also worth efforts.

Both mechanisms can act simultaneously; apparently, this is the case for trapping of an N atom by C_{60} (when C_{60} is heated in a nitrogen plasma).¹⁹ In the $N@C_{60}$ molecule, the nitrogen atom with three unpaired electrons (one electron in each *p* orbital) is chemically inert (this is also true for hydrogen in $H@C_{60}$ and for phosphorus in $P@C_{60}$). The unique chemical inertness of an inner π -electron shell in fullerenes is in sharp contrast with the high reactivity of the outer π shell. Thus reactions involving the outer shell (Fig. 5) barely affect the inner nitrogen atom; only slight distortion of its EPR spectrum is observed, which is manifested as weak satellite lines, indicating that the spherical symmetry of C_{60} has been somewhat distorted. This makes the nitrogen *p* orbitals energetically slightly non-equivalent (by ~ 0.003 eV) and stimulates dipole spin splitting of the Zeeman levels.

Figure 5. Scheme of the $N@C_{60}$ molecule and the product of its cyclopropanation. The corresponding EPR spectra are shown below.

Yet another feature of endofullerenes, which is of fundamental importance, is noteworthy, namely, contraction of the electron shell inside the fullerene sphere. The constant of hyperfine (electron–nucleus) coupling in a free N atom is 3.7 G, that in the KN_3 crystal is 5.0 G and the same value for $N@C_{60}$ is 5.7 G. This indicates that atoms inside the fullerene sphere experience substantial pressure, which results in contraction of the *p* orbitals of valence electrons. In terms of quantum chemistry, this means perturbation of the wave function resulting in an increase in the contribution of the *s* orbital to the superposition of atomic orbitals. Contraction of the electron shell of the inner atom has also been found in the endofullerenes (Sc,La,Y) $@C_{60}$. In these compounds, anisotropy of the *g*-factor of the unpaired electron was observed,²⁰ which points unambiguously to hindered rotation of the atoms inside the sphere.

It is not difficult to find a relationship between the electron shell contraction and the behaviour of 'onion' fullerenes such as $C_{60}@C_{240}@C_{540}$..., which consist of several spherical molecules arranged one inside the other, the distance between the sphere surfaces being ≥ 0.34 nm. This is a new class of endofullerenes. The inner spheres experience enormous pressure of the outer spheres, and this accounts for the fact that the inner spheres are converted into diamond even upon weak photo or radiation treatment.

Synthesis of *cylindrical carbon nanotubes* (~ 100 Å in diameter), which are formed according to the same principle as fullerenes, has become a prominent event in modern chemistry. They can be doped with metals (both on the inside and on the outside)

and are characterised by high solubility of hydrogen (owing to capillary condensation); therefore, they can be used in chemical cells. Young's moduli of carbon nanotubes are close to that of graphite (in one plane). The first experimental data on the use of nanotubes as probing tips in scanning force tunnelling microscopy were reported. Development of methods for the preparation of oriented nanotubes on thin metallic films using laser etching is in progress. Polymerisation of nanotubes opens up ways to new porous materials such as organic zeolites. Multilayer nanotubes consisting of molecular cylinders enclosed one into another have been obtained.

Technologies that enable manipulation of nanotubes by virtue of atomic force tunnelling microscopy are being developed.²¹ One can lay, bend, cut, straighten, cross and move nanotubes thus arranging molecular electronic devices. Thus, it becomes possible to pass from fine words to impressive deeds.

Preparation of *metallic hydrogen* represents one more important achievement of recent years. It can be debated whether it was done by chemists or physicists; however, the transformation of hydrogen into metallic hydrogen is undoubtedly a chemical process, resulting in a rearrangement of the electron shells of hydrogen molecules. Metallic hydrogen is obtained by shock compression of a 0.5-mm thick liquid film of molecular hydrogen placed between single-crystal Al_2O_3 anvils at a pressure of 2 Mbar.²² The electrical conductivity of this material ($\sim 2000 \Omega^{-1} \text{ cm}^{-1}$) is close to those of molten cesium and rubidium; in this sense, metallic hydrogen resembles liquid alkali metals. The mechanism of its formation is unknown; it involves either immediate complete release of the electrons from a hydrogen molecule or dissociation of the molecule into atoms followed by the discharge of electrons to the conduction band. In order to decide between these variants, non-stationary reaction regimes need to be studied.

III. Chemistry in micro- and macro-reactors

It should be admitted that the chemistry created by the mind and hands of Man is only a minor fraction of chemistry created by Nature. The vast majority of reactions implemented by humans are 'non-organised' reactions in which species (molecules, ions, atoms or radicals) react when they meet by chance (in space and time). Meanwhile, the 'natural' chemistry is highly organised, *i.e.* almost all the chemical transformations occur in systems with molecular or supermolecular order. Large sets of biochemical reactions are organised both in space and in time. Thus, during photoreception each light quantum absorbed by the retina of an eye triggers a cascade of reactions yielding ultimately cyclic guanosine monophosphate (quantum yield 10^4), which induces an electric potential on the membrane. This signal is then recorded in the brain as the signal for light reception (other examples can be found in a review¹). It is owing to the high degree of organisation that the selectivity and productivity of biochemical reactions reach very high levels, which are yet inaccessible in conventional chemistry.

The realisation of this fact and the turning of chemistry as a science to molecular and supermolecular organisation of reactants started in the second half of this century; now this is a leading line in the intrinsic self-organisation of chemistry directed towards the future.

The simplest microreactor in which reactants can be organised in space is a van der Waals molecule. A large number of micro-reactors of various natures and sizes and various degrees of molecular ordering exist. They include complexes, crystal solvates, gas (for example, methane) hydrates, inclusion compounds (in which 'hosts', represented by cyclodextrins, semispherands, calixarenes, *etc.*, organise reactions of 'guest' molecules), macromolecules, (helices or rigid zigzag-like rods), the cavities of zeolites and other porous media, micelles and vesicles. Microreactors change the molecular dynamics of reactants, mechanisms and rates of chemical transformations, the *pK* values of acids and

bases, local charges and charge distributions, ionisation potentials, electron affinities, conformations and reactivities. Reactions in microreactors follow new 'forced' pathways, and other anomalous features can also be observed.

Two-dimensional microreactors are represented by the electric double layer, monomolecular layers (of the Langmuir–Blodgett type), membranes (both biological and artificial), interfaces (they are used in phase transfer catalysis, especially in reactions involving ordered and directed exchange by substances and electric charges between the phases), adsorption layers of reactants on solids ('two-dimensional' zone reactions) and so on.

A classical two-dimensional microreactor — electric double layer — has now a new lease on life, associated with high time resolution regimes ($\sim 10^{-12}$ – 10^{-9} s), which are brought about by the laser-induced chemistry at solid–liquid interfaces. The main character in such a microreactor is an electron, either solvated or free. Its chemical behaviour is the subject of special interest regarding generation of electric potentials and modelling of the potentials existing in 'natural' chemistry. Potentials at a liquid–liquid interface also deserve attention.

The interest in 2D monolayers on solids is due not only to their use as heterogeneous catalysts (this topic is already out of date) but also to the new opportunities offered by synthetic chemistry on the surface. For example, 1,5-cyclooctadiene, which binds to the surface of an Si(001) single crystal upon rupture of one C=C bond, forms a two-dimensional molecular lattice.²³ The highly ordered monolayer consisting of grafted molecules exhibits high reactivity and can participate in further chemical functionalisation leading to any chemical architecture.

Cluster microreactors are highly diverse. They can be atomic, molecular, ionic, ion-molecular and organometallic, either charged or neutral. Clusters are formed in gases (for example, in expanding supersonic atomic-molecular beams), in zeolite channels (for example, the In_8 clusters), in liquids, on solid surfaces, in solid matrices (such as solid argon or xenon), *etc.* They play an important role in the chemical materials science (cluster materials with unusual physics and mechanics), in chemical analytics and diagnostics (detectors and sensors) and in other fields of applied chemistry.

The main, fundamental problem in the chemistry of clusters is associated with dimension effects. This is an intriguing question — how do the properties of separate species evolve on their combination into the properties of a new phase; how are the bridges between the world of a separate molecule and the world of macroscopic matter being built? The dimension effects are so diverse and unexpected that no general solution of this problem exists. Quantum chemistry and molecular dynamics methods provide partial answers only to some questions.

Clusters still remain enigmatic objects (for unusual properties of clusters, see for example, Ref. 24). Thus Re atom is inert towards CH_4 , whereas the Re_3 cluster is active; the linear clusters Cu_3 and Ni_3 do not react with H_2 or CH_4 , whereas triangular clusters react readily and rapidly; the Co_n clusters are reactive towards H_2 at $n = 3, 10$ and 12 and are inert at any other n ; the Nb_n clusters with $n = 3, 4$ and 5 react with H_2 , whereas other Nb clusters are relatively inert; Nb clusters with $n = 5, 6$ and 11 are active in dehydrogenation of benzene; the Ag_n clusters exhibit metallic properties starting from $n = 6$, whereas Na_n do not exhibit any signs of a metal phase even at $n = 14$. The $\text{I}_2(\text{C}_6\text{H}_6)_m$ cluster is polyhedral and $\text{V}_n(\text{C}_6\text{H}_6)_m$ has a multi-deck sandwich structure.

The MoO^+ cation does not react with NH_3 , whereas the Mo_3O_8^+ and Mo_3O_9^+ clusters dehydrogenate NH_3 to give complexes with the nitrogen formed upon dehydrogenation. The same clusters oxidise CO to CO_2 . The V_3O_7^+ and $\text{V}_3\text{O}_{12}^+$ clusters are efficient in dehydrogenation of butadiene and destruction of butane, while V_3O_6^+ and $\text{V}_3\text{O}_{11}^+$ are inert in these reactions but they are active in the addition and oxidative cyclisation reactions.²⁵

In the cluster of α -naphthol with $(\text{H}_2\text{O})_n$ (these compounds are called crystal hydrates), proton transfer from excited α -naphthol to water has been detected only for $n \geq 20$; in the case of α -naphthol clusters with $(\text{NH}_3)_n$ this process occurs even at $n \geq 4$. In the clusters of univalent magnesium (or calcium) with $(\text{H}_2\text{O})_n$ and $(\text{CH}_3\text{OH})_n$, the electron transfer and hydrogen reduction

occur for $6 \leq n \leq 15$; at any other n the reaction does not occur, and hydrogen elimination is not observed.²⁶

The rate of photoinduced isomerisation of *trans*-stilbene placed in the $(\text{hexane})_n$ cluster was measured in molecular beams by picosecond spectroscopy.²⁷ The rate constant for this process decreases in the sequence 9.7×10^9 ($n = 0$, free molecule), 3×10^9 ($n = 1$), 1×10^9 ($n = 2$), 0.8×10^9 ($n = 3$), $0.5 \times 10^9 \text{ s}^{-1}$ ($n = 4$). Unexpectedly, all these constants proved to be smaller than the observed isomerisation constant of *trans*-stilbene in pure liquid hexane at the same temperatures and energies ($11.5 \times 10^9 \text{ s}^{-1}$); *i.e.* immersion of *trans*-stilbene into the $(\text{hexane})_n$ cluster decreases its reactivity. The cluster shell fixes the molecule even more strongly than a 'liquid-phase' shell; it abnormally increases the kinetic (Kramers) friction, which accompanies the movement of the reacting molecule along the reaction coordinate.

Special interest is aroused by the dimension effects in semi-conducting nanocrystals the size of which is smaller than the Bohr radius of an exciton. Quantum capture of an electron and a hole (generated by photochemical or radiation-chemical treatment) in the confined space of these nanoclusters (called quantum dots) results in an increase of the band gap following a decrease in the cluster size; hence, recombination luminescence shifts to the blue region (to higher energies). A striking example is provided by nanocrystals of CdSe 'coated' by one or two ZnS monolayers. When the diameter of the inner CdSe nucleus increases stepwise from 23 to 55 Å, the bright blue luminescence passes into green, yellow, orange and, finally, bright red luminescence.²⁸

In addition, cluster chemistry opens up the way to a new strategy in heterogeneous catalysis, especially when combined with scanning tunnelling microscopy. The tip of the microscope is able to apply any number of any atoms on the faces, edges or terraces of any crystal, thus creating diverse catalytic microreactors and providing conditions for testing various reactions on them. This is a new wind in the fundamental science of catalysis and its future.

Clusters are much more widespread and, hence, much more significant than it has been believed until recently. Thus it has been found experimentally (by cold-neutron and X-ray scattering) that liquid ammonia is clustered — it consists of the $(\text{NH}_3)_7$ clusters containing one molecule in the centre and six molecules at the periphery.²⁹ The cluster structure of liquid water is well known: water molecules are united into hexa-, penta- and tetramers, having close energies and forming prismatic, cage, 'open-book' and adamantane structures, and also into dodecahedra and other big clusters. Liquid aqueous solutions of ethanol are also non-uniform; they consist of water and ethanol clusters.³⁰ It is noteworthy that when the content of the alcohol in water is $\sim 40\%$, the proportions of ethanol and water clusters are equal. Perhaps, this accounts for the special receptive-gustatory properties of the well-known and popular water-ethanolic drink. Indications of clustering have also been found in liquid benzene. This might prove to be a general phenomenon; if this is really so, all liquid-phase reactions should be interpreted as occurring in microreactors.

Furthermore, a chemical reaction can itself stimulate molecular organisation of a microreactor. Thus a colourless molecule of spiropyran having a long hydrocarbon 'tail' is converted upon photochemical treatment into a coloured bipolar form with separated charges; it is in this form that spiropyran molecules

unite to form micelles. Here photochemical reaction acts as the trigger for micelle formation.

Brain is a macroreactor of enormous complexity. There occur a tremendous number of chemical reactions, responsible for the synthesis of the memorising molecular structures, which form memory and the whole control system of a living organism. Brain is of key importance in the entire chemistry of living matter; chemistry of brain is the chemistry of the XXI century.

The main purpose of brain is to transform chemical energy into electric energy; this task is accomplished by neuromediators. They stimulate enzymic synthesis in synaptic membranes and ensure communication between neurons, formation of electric potentials and transfer of electric signals *via* recharge of the membrane. They control a cobweb of impulses and potentials, which govern all functions of a living organism. Neuroprotectors act *via* chemical mechanisms.

Many neuromediators have long been known. Thus dopamine and its chemical functions have been studied comprehensively; however, only recently it has been found that its deficiency in an organism is responsible for dotage. One reason for the reduction of the dopamine level with advance in age is that it is destroyed under the action of the enzyme monoamino oxidase B. Another reason is that the number of dopamine-receiving neurons in an organism decreases with time (a low level of these neurons is also characteristic of those who suffer from parkinsonism). In addition, it has been found that some narcotics trap neurons and remove them from the functioning of brain. It is clear that the understanding of the chemical mechanisms of the operation of neuromediators opens up ways for eliminating disorders in the work of the brain macroreactor.

Other neuromediators are also known; among these, mention should be made of versatile nitrogen oxide with a broad spectrum of chemical and physiological action and Semaks – a neuropeptide consisting of seven amino acids.

Study of a macroreactor such as the human brain requires delicacy, which sharply restricts the range of possible direct experiments. Nevertheless, these studies are carried out within the framework of neurophysiology in combination with medicine and clinical surgery. The studies widely use microelectrode equipment, which permits estimation of the behaviour of the electric potentials formed and their response to chemotherapy and physiological treatment. Enormous opportunities are also provided by positron-emission tomography, in which the ^{11}C isotope and ^{11}C -labelled chemical compounds being tested are used as the positron sources. At present, researchers have realised that wide use of experimental modelling of brain elements can help in the understanding of the operation of this macroreactor. The main goal of modelling is to answer the question how does the brain perform its primary task, *i.e.* how does it transform chemical energy into electric energy. By the way, as a 'side result' of this modelling, one could expect design of molecular devices characterised by high coefficients of conversion of chemical energy into electric energy (within the framework of chemical energetics).

The Earth is a huge *geochemical macroreactor*. This mechanochemical reactor is the source of earthquakes. It covers the whole of mechanochemistry and its consequences: chemical bond rupture induced by mechanical treatment, formation and migration of dislocations, generation and multiplication of cracks, shears and shear waves, generation of electric potentials and their gradients, radio waves, magnetic fields and chemical emission. Now scientists have understood that the key to the diagnostics and prediction of earthquakes lies in mechanochemistry. All events that take place in the geochemical macroreactor echo in the ionosphere as electric field gradients and are detected there as forerunners of earthquakes. Mechanochemistry, a field of science in which chemistry occupies a prominent place, is directed towards the XXI century.

IV. Coherent chemistry

Coherent chemistry is a 'new face' of chemistry. Coherence is the ability of chemical systems to generate oscillation regimes of reactions. The coherence (time synchronisation) of a chemical reaction is manifested as cyclic variations of the reaction rate and can be detected as oscillating product yields, luminescence emission, electrochemical currents or potentials, *etc.*

Chemical coherence exists at two levels, quantum and macroscopic levels. In the former case, the coherence refers to the reactivity of an assembly of reacting particles generated by a laser pulse. Such an assembly oscillates between states with different reactivities, these oscillations modulating the yields of the reaction products. The vibrational and spin types of coherence are of the quantum origin. In the case of macroscopic coherence, the concentrations of active reagents (or intermediates) periodically change. The best known example of macroscopic coherence is the Belousov–Zhabotinsky reaction.

The coherence introduces new notions into chemistry, such as wave packet, phase, loss of phase coherence (dephasing), interference, bifurcation and bifurcation diagrams, phase portrait, strange attractor and phase turbulence. This is not simply a new language of chemistry; this reflects a new level of thinking and a new level of chemical research practice. In the coherent chemistry, the random, statistical behaviour of molecules is replaced by organised, ordered and synchronous behaviour; thus, chaos turns into order.

A short (10^{-14} – 10^{-13} s) laser pulse (with a duration shorter than the period of vibrations of atoms) 'excites' a molecule and 'throws' it onto a new potential. In this new potential, an assembly of molecules prepared by the laser pulse behaves coherently, *i.e.* vibrations of atoms of all of the members of the assembly are synchronised, the whole assembly being a wave packet.

When moving on the potential surface, a wave packet can disperse into several smaller packets (with different vibration amplitudes and phases); some of them can go out of phase (lose the coherence) and disappear, while some other can interfere to restore partially the initial packet, *etc.*

A classical illustration of the coherent behaviour of a wave packet is provided by an assembly of NaI molecules (Fig. 6).³¹ Molecules of NaI excited by a short (~ 50 fs) pulse are 'transferred' from the surface of the ground (ionic) state to the surface of an excited 'covalent' state; this creates a wave packet localised on a potential surface. This wave packet slides in an adiabatic potential (Fig. 6a, the upper curve), in which it oscillates between the covalent and ionic states and crosses at some intervals the point of intersection of the ionic and covalent terms (when the interatomic distance is 6.93 Å). Due to the non-adiabatic connection of these two terms, there is a finite probability of penetration of the packet from the upper curve to the lower one. As this takes place, a part of the penetrated packet dissipates to generate Na atoms (they can be detected experimentally) and the rest becomes a new wave packet, which moves coherently in the lower valley.

The point of intersection of the ionic and covalent terms (where the upper and the lower potential curves contact with each other) is the bifurcation point in which the wave packet splits into two packets, one of which is partially irreversibly destroyed. In principle, it is clear that the packet situated in the lower potential curve can return to the upper potential curve *via* the same bifurcation point and restore the initial packet (interference), although in this particular case, the probability of this event is low. For other systems characterised by a different configuration of the potential energy surface, this probability can be substantial and the packet interference can be manifested fairly clearly.

These qualitative considerations can be converted into a quantitative picture by calculating the probabilities of dissipation of the packet at the bifurcation point (according to Landau–Zener). Fig. 6b shows the pattern of the packet movement on the time and space coordinates. It can be readily seen that the coherent movement of the packet in the upper valley generates a stream of

Figure 6. Femtosecond dynamics of photodissociation of NaI; (a) potential curves for the covalent and ionic states; (b) dynamics of the ionic and covalent wave packets; (c) experimental dynamics of wave packets detected based on the activated complex NaI^* and from the yield of free sodium atoms (the upper curve).³¹

Na atoms (reaction product) at the bifurcation point. The density of this stream oscillates with time, the oscillation frequency being equal to the frequency of packet oscillation in the upper valley; the density amplitude attenuates due to the packet dissipation, dephasing and falling into the deep lower valley (Fig. 6c).

The coherence created initially is retained during the reactions and is transferred to the products. This indicates that the molecular assembly undergoes a collective, synchronous and phase coherent chemical transformation.

This coherence can be found not only in simple reactions such as dissociation of the NaI, I_2 , HgI_2 , etc. molecules but also in complex systems. Thus phototransformation of rhodopsin and its analogues occurs in parallel *via* a coherent and a non-coherent[§] channel over a wide spectral range (400–1100 nm).³² The key process in the phototransformation of rhodopsin — a molecular system consisting of an apoprotein (opsin) and 11-*cis*-retinene attached to it — is the *cis*–*trans*-isomerisation of retinene around the C(11)=C(12) bond. The direct coherent formation of the first intermediate (bathorhodopsin from rhodopsin and hR_K from halorhodopsin hR) occurs over a period of ~200 fs, the coherence being retained in the reaction product. The fact that even in a complex molecular system such as rhodopsin, the degree of

coherence remains remarkably high (~20%) merits attention. When the hydrogen atoms at C(11) and C(12) are replaced by deuterium, the isotope effect is not observed over a short period of time (up to 110 fs); it appears only in the range 110–170 fs, when rocking around the C(11)=C(12) bond is characterised by a large amplitude and leads to full rotation. This means that the coherence of the whole process (it takes ~200 fs) is a stable characteristic, which is retained at any amplitude along the coordinate of isomerisation.³³

Vibrational coherence can also be detected in the chemical transformations of such a bulky molecular system as the bacterial photosynthetic centre.³⁴ Moreover, coherence has been found in the antennae of photosynthesising centres, its degree and ‘length’ (*i.e.* the length of the ‘coherent’ accumulation of energy) being dependent on the molecular order and spatial arrangement of the light-collecting complexes near the the energy-collecting photosynthesising centre.

It is not the coherence itself that is the most remarkable feature of the coherent chemistry but rather new and non-traditional methods for controlling chemical reactivity. When the first pulse throws a wave packet onto a potential surface, the second pulse can influence its evolution: either throw it further onto a new surface or bring it back onto the initial surface (the Raman process). This can be done either before or after the wave packet has passed the bifurcation point by changing the delay between the first (pump) pulse and the second (probe) control pulse. In

[§]Phototransformation *via* a non-coherent channel implies statistical thermalisation of the excited state followed by slow (2–4 ps) statistical formation of the product.

other words, the dynamics of wave packets and their chemical fate can be controlled; the ratio of the channels of their transformation and the yields of the reaction products can be altered. Thus a new tool for controlling a chemical reaction appears, *i.e.* the phase of a coherent assembly. By affecting a wave packet in various phases of its evolution, one can change its chemistry.

For example, in the electronically coherent assembly of HD^+ molecules, prepared from HD by a short ionising laser pulse (pump pulse), the electron oscillates between the H and D atoms. Using the second (control) pulse, one can attain the coherent control of the HD^+ dissociation, which gives either $\text{H} + \text{D}^+$ or $\text{H}^+ + \text{D}$, depending on the instant when the second pulse acts. To induce the former dissociation pathway, the second pulse should be switched on when the electron resides on the hydrogen atom, whereas for the latter pathway, it should occur when the electron is on deuterium. This is the highest level of coherence in chemistry, the prospects of which are being discussed even now.³⁵

An even finer and a more elegant way of controlling the chemical fate of a wave packet is embodied in the phase relationship between the packet and the probe pulse. The current state of optics makes it possible to control the frequency-dependent phase of laser pulses. The delay $\tau(\omega)$ of the group velocity of a particular frequency component of the optical spectrum is known to depend on the phase of this component Φ by the relation $\tau(\omega) = \partial\Phi(\omega)/\partial\omega$. For a pulse with a given spectrum, all the frequency components should be in phase and should arrive simultaneously at the destination point, *i.e.* $\tau(\omega)$ does not depend on frequency. In this case, $\Phi(\omega)$ includes no frequency-dependent quadratic terms (or terms with higher exponents). However, one can change $\Phi(\omega)$ in a specified way (by virtue of optical grids and prisms) in order to introduce frequency-dependent quadratic terms (they are called chirps). In these chirped pulses, phase velocities become frequency dependent. Thus when the chirps are negative, the red component of the pulse lags behind and arrives at the destination point (*e.g.*, at a wave packet) later than the high-energy blue component. Conversely, in the case of positive chirps, the red light is ahead of the blue one. It is clear that by changing the chirp of an optical pulse, one can control the relationship between the phases of the wave packet and the control pulse and thus 'catch' the packet in various positions on the potential surface by either red, or blue, or another appropriate light.

Certainly, this is a simplified picture illustrating in a clear form the main principles and chemical effects of the vibrational quantum coherence. The main idea is that the coherent chemistry brings about a new factor controlling chemical reactions, namely, the phase. By changing the phase (this can be attained by delaying the control pulse relative to the generating pulse or by chirping), one can manipulate the chemical behaviour of assemblies of reacting species without changing the energy or angular momentum.

The next level of coherence is quantum periodicity in a system consisting of two species, each carrying an electron spin (for example, a pair of radicals). Such a spin pair can exist in two states — singlet (reactive) and triplet (chemically inert). An assembly of these pairs, prepared by a pulsed method (photolysis or radiolysis) in a specified spin state (*e.g.*, in the triplet state), oscillates synchronously between the two states. The driving force of this oscillation is the difference between the Zeeman energies of the two partner spins or the hyperfine electron – nuclear coupling (if the radicals contain magnetic nuclei). The magnitude of these interactions is of the order of several megahertz (it is with this frequency that the assembly oscillates between the singlet and triplet states). It is clear that the yield of the products of a chemical reaction (which are formed only when the species occur in the singlet state) is time-modulated at the same frequency (Fig. 7). The periodicity in the product formation is a consequence of the coherence of the behaviour of spin pairs; this is an example of electron-spin quantum beats in chemical reactions (as opposed to the vibrational quantum beats, considered in the previous Section).

Figure 7. Quantum beats in the recombination of the (diphenyl sulfide)⁺/(*p*-terphenyl-*d*₁₄)[−] radical-ion pair in *cis*-decalin at $H = 1200$ (a, b) and 3000 G (c, d). The product of recombination of *p*-terphenyl-*d*₁₄ was detected by fluorescence.

(a, c) Experimental data, (b, d) theoretical calculations; $I(t)$ is the fluorescence intensity, $\rho_{ss}(t)$ is the content of the singlet state in the radical-ion pair.

The electron-spin coherence has been found in photochemical and radiation-induced chemical reactions of radical pairs³⁶ and in the primary photochemical event of charge (and electron spin) separation in the photosynthetic reaction centres. In these systems coherence originates due to the synchronous oscillation of spin pairs between the singlet and triplet states. Moreover, in addition to the electron-spin coherence, nuclear-spin coherence has been found in these systems (ordered in-phase precession of the system of polarised nuclei occurs).³⁷

The advantage of spin coherence is that it provides new methods of investigation and identification of fine and accurate details of the structure and dynamics of chemically generated spin systems. Furthermore, even when the chemical reaction producing spin systems occurs statistically (non-coherently), spin coherence exists in these systems, which opens up a way to the new field of science, chemical radiophysics (see Section V).

The oscillating regimes of chemical reactions were first observed rather long ago. At that time, oscillations were considered to be an exotic rather than a regular feature. Nowadays the Belousov–Zhabotinsky reaction and oscillations of pH and electrochemical potentials in heterogeneous systems such as oil–water systems, Liesegang rings and wave combustion, have become classical examples. However, the fact that macroscopic coherence is a fundamental property has been realised only recently. The science of chemical oscillators has been revived owing to two important facts.

Firstly, it became clear that coherent regimes could increase the yields of reaction products and the process selectivity and could lead to self-cleaning of surfaces from catalytic poisons, *etc.* These expectations have been confirmed, especially for chemical oscillators with forced oscillations.³⁸

Secondly, the interest in chemical oscillators has been aroused again owing to biochemical oscillating processes occurring in nerve cells, muscles, and mitochondria. This resulted in active assimilation of new systems of oscillators, *i.e.* in combination of several chemical oscillators into a common unified system. It is believed that such a system would be a prototype (although yet primitive) of the future models of neuron networks.³⁹ However, even now, studies are in progress on the oscillator excitation thresholds in such a combined system and on the influence of the

Figure 8. Periodic potential oscillations during the reduction of bromate ions in a solution of NaOH at a silver electrode and at the current 1.5 (a), 2.5 (b) and 3.0 mA (c).⁴²

number of oscillators, the way of their connection (a linear or a circulating system) and the connection parameters (mass exchange, control of electrochemical potential and currents) on the excitation of collective oscillations, *etc.*

New chemical oscillators have been discovered. Thus the potential of a platinum electrode in the $\text{ClO}_2\text{--I}_2\text{--CH}_3\text{C(O)CH}_3$ system varies as a periodic function of time. When formaldehyde and methanol are oxidised under galvanostatic conditions, the oscillation frequency repeatedly doubles, resulting in the break-down to chaos at the bifurcation points.⁴⁰ This type of behaviour resembles that observed in some enzymic reactions and biological systems.⁴¹ Oxidation of bromate ions in alkaline solutions is also an oscillating process (Fig. 8). Oscillations are due to the concentration effects at the electrode surface and, therefore, they vary as a function of the surface geometry (roughness, presence of islets, *etc.*).⁴² Another bromate oscillator catalysed by tris(bipyridine)-ruthenium is, in addition, a photo-controlled system displaying different bifurcation diagrams in the light and in the dark. A strange bifurcation behaviour of the order and chaos regimes and doubling of frequency are also observed in the peroxidase-catalysed oxidation of dihydro(nicotinamide)adenine dinucleotide (NADN).⁴³

In heterogeneous catalytic oscillators, oscillations may arise due to a non-linear relationship between the rates of chemical reaction and heat exchange, concentration gradients, periodic modulations of the composition of a 'two-dimensional' reactant, 'breathing' of the surface (when atoms go down and up, similarly to waves in a two-dimensional lattice), *etc.* Examples of chemically oscillating processes are provided by the reduction of NO with hydrogen (when the pressure of H_2 decreases, the period of oscillations repeatedly doubles until break-down to chaos occurs), oxidation of CO with oxygen on platinum, accompanied by generation of time-and-space helical waves (Fig. 9)⁴⁴ and some other processes.

The brain is a striking and a unique example of a system self-organised in space and time. The chemical activity of enzymes and, as a consequence, the electric potentials in the system of synaptic membranes and neurons in brain are remarkably

Figure 9. Helical wave on the Pt(110) surface which develops during oxidation of CO with oxygen (434 K). The light sections are areas occupied by CO; the dark sections are areas occupied by oxygen. The photographs were taken consecutively at times 0 (a), 10 (b), 21 (c), 39 (d), 56 (e) and 74 s (f) on a $0.2 \times 0.2 \text{ mm}^2$ area.⁴⁴

synchronised (coherent). It is also clear that the scales of coherence (*i.e.* the sizes of synchronised areas in brain) are different for different levels of brain functioning. In other words, the brain consists of biochemical oscillators of various sizes connected to one another and combined into a unified control system.

Order is the normal state of this system, while chaos implies severe pathologies (such as Alzheimer's disease). Perfect order is the property of a brilliant genius brain (this idea is only hypothetical but looks like being true).

V. Spin chemistry and chemical radiophysics

Yet another new field of modern chemistry is spin chemistry concerned with the behaviour of angular momenta (spins) of electrons and nuclei during chemical reactions. Spin chemistry is based on the fundamental law: in adiabatic chemical reactions the electron and nuclear spins are strictly retained. Only those reactions are allowed which do not require spin change. In other words, all the chemical reactions are spin-selective, *i.e.* they are allowed only for those spin states of reactants the total spin of which is equal to the total spin of products, and they are completely forbidden when the reactant spin is not equal to the product spin.

A simple example is provided by a radical pair comprising methyl and hydroxyl radicals. Recombination of these radicals to give methanol occurs only in the singlet state, because this ensures that the electron spin of the pair ($S = 0$) is identical to that of CH_3OH . However, disproportionation of the same radicals in the singlet state to yield H_2O and triplet methylene (the total spin of the products $S = 1$) is forbidden for spin reasons. For the triplet radical pair ($S = 1$), on the contrary, recombination is forbidden, whereas disproportionation is allowed, although its activation energy is relatively high, $\sim 6 \text{ kcal mol}^{-1}$.

One should be conscious of the fact that chemistry is governed by two fundamental factors — energy and spin (as shown in the previous Section, one more factor, phase, appears in the coherent chemistry).

Unlike the prohibition for energy reasons (it appears when the energy of reactants is lower than the energy barrier to the

reaction), which can be overcome *via* tunnelling under the barrier, the spin prohibition is insurmountable.

Spin can be changed upon non-chemical magnetic interactions; only they can transform spin-forbidden (non-reactive) states of reactants (*e.g.*, radical pairs) into spin-allowed (reactive) states. Magnetic interactions, the energy of which is negligibly small, switch reaction channels — they can open closed channels and, conversely, close the open (allowed) ones, depending on the initial state of the reactants. Actually, they write a new, magnetic script of a chemical reaction.

The spin selectivity and, hence, the magnetic sensitivity of chemical reactions has served as the source of three generations of magnetic effects discovered during the last two decades.⁴⁵ Fig. 10 illustrates the origin of these effects in relation to a particular example, which is, however, frequently encountered in chemistry, namely, a radical pair able to exist in either the singlet or the triplet spin state. In the case where triplet–singlet transitions are induced by static magnetic fields (external fields or internal fields of magnetic nuclei), first-generation magnetic effects arise. Magnetic effects of the second generation appear when the spin conversion of pairs occurs on exposure to microwave fields. Finally, when the conversion is induced by the influence of a third paramagnetic species, a remarkable phenomenon, spin catalysis, can be observed, which represents the third generation of magnetic effects. The third species (a radical or a paramagnetic ion) acts as a spin catalyst.

First-generation magnetic effects. An external magnetic field exerts two types of influence on the spin conversion of radical pairs and, hence, on the chemical reactivity. Firstly, the field switches off two of the three channels of spin conversion, namely, $S-T_+$ and $S-T_-$, so that only the $S-T_0$ channel is left (T_+ , T_0 and T_- are triplet states which differ in the projection of the total spin). Secondly, it accelerates the $S-T_0$ conversion if the partners of the pair have different Zeeman energies. Depending on the initial spin state and magnetic parameters (hyperfine coupling energy, *g*-factors, dipole interaction) of the reactants, chemical reactions can be accelerated or decelerated by an external magnetic field.

Magnetic field effects have been found in a great number of chemical and biochemical reactions, their range constantly extending. A reliable theory capable of predicting the significance

Figure 11. Molecular mass of the polymer obtained by emulsion polymerisation of styrene (dibenzyl ketone as a photoinitiator; sodium dodecyl-sulfate as an emulsifier; constant polymerisation time) *vs* magnetic field intensity.⁴⁶

and behaviour of magnetic effects has been developed. The magnitudes of these effects are often quite large. Thus the rate of photoinduced aqueous-emulsion polymerisation of styrene and the molecular mass of the resulting polymer increase 6–8-fold even in weak magnetic fields, ~ 100 G (Fig. 11).⁴⁶ An even more pronounced effect (20–25-fold increase) is attained in the light scattering by colloidal particles subjected to photochemical cross-linking.⁴⁷ This strong effect can be used for visualisation of magnetic fields and their gradients.

Being selective regarding the electron spin, chemical reactions between spin carriers (radicals, paramagnetic ions and molecules, carbenes, *etc.*) are also selective as regards the nuclear spin. If the two spin subsystems (electronic and nuclear) are related by the Fermi hyperfine coupling (FHC), the nuclear subsystem can affect the behaviour of the electronic subsystem *via* the FHC and thus modify the chemical reactivity of spin carriers. The nuclear-spin selectivity is manifested as different rates of spin-selective reactions of radicals (or other spin carriers) with magnetic and non-magnetic nuclei. This is a new phenomenon referred to as magnetic isotope effect (MIE), which differs fundamentally from the classical isotope effect (CIE), resulting from nuclear-mass selectivity of reactions. Both effects sort the isotope nuclei: the CIE selects nuclei according to their weights, while the MIE selects them according to their spins and magnetic moments.

The discovery of the magnetic isotope effect is a prominent event of the last quarter of the XX century, its significance being comparable with that of the discovery of the classical isotope effect. In addition, the magnitude of this effect substantially exceeds that of the CIE (Fig. 12) and, unlike the magnitude of the CIE, it depends on the magnetic field, temperature, molecular and chemical dynamics and the spin state of the reactants. The magnetic isotope effect results in fractionation of magnetic and non-magnetic isotopes in chemical, biochemical, geochemical and interstellar processes.⁴⁸

The third effect belonging to the group of first-generation magnetic effects is chemically induced dynamic nuclear polarisation (CIDNP). Unlike the MIE, in this case the nuclei are sorted not only according to their magnetic moments but also according to their orientations. During a chemical reaction, nuclei with different orientations are sent into different products and this creates non-equilibrium populations of the Zeeman nuclear levels in these products. An excessive population of the lower Zeeman level corresponds to the positive nuclear polarisation, whereas overpopulation of the upper level implies negative polarisation. The latter case is especially remarkable: when the overpopulation of the upper level exceeds some permissible limit, the populations are inverted; this provides the basis for chemical radiophysics.

An assembly of product molecules with inverted populations accumulates energy in the Zeeman storage reservoir; the energy can either be consumed as heat (*via* spin–lattice magnetic relaxation) or be converted into stimulated emission at a Zeeman

SPIN CHEMISTRY

Figure 10. Spin evolution of radical pairs. The following designations are used: MFE is magnetic-field effect, MIE is magnetic isotope effect, CIDNP and CIESP are chemically induced dynamic nuclear polarisation and electron spin polarisation, RYDMR is reaction yield detected magnetic resonance, RIMIE is radio-induced magnetic isotope effect and SNP is stimulated nuclear polarisation.

Figure 12. Comparison of the magnitudes of the magnetic (white areas) and classical isotope effects (black areas) in the separation of the $^{13}\text{C}/^{12}\text{C}$, $^{17}\text{O}/^{16}\text{O}$, $^{29}\text{Si}/^{28}\text{Si}$, $^{33}\text{S}/^{32}\text{S}$, $^{73}\text{Ge}/^{72}\text{Ge}$ and $^{235}\text{U}/^{238}\text{U}$ isotope pairs. The coefficient α of one-stage isotope separation (a universal measure of isotope effect) is plotted as the abscissa.

nuclear frequency. In this case, the reaction becomes a radio-frequency emitter, *i.e.* a quantum generator with chemical pumping (similar to chemical lasers). This new phenomenon — radio-frequency emission of chemical reactions — was first predicted theoretically and later found experimentally.⁴⁹ It appears when the energy stored in the Zeeman storage reservoir exceeds the generation threshold, the movement of nuclear spins spontaneously becomes coherent, and this coherent set of nuclei functions as a quantum generator.

Chemically induced electron spin polarisation (CIESP) is the fourth effect. It arises due to the electron-spin selection during the reaction and results in non-equilibrium population of the Zeeman electron levels in radicals and paramagnetic molecules (in this respect, CIESP resembles CIDNP).

The two latter effects are widely used in chemistry and biochemistry as new investigation methods (diagnostics of reaction mechanisms, detection of radicals, and chemical kinetics and chemical physics techniques).

Second-generation magnetic effects. The microwave emission of chemical reactions is only one aspect of chemical radiophysics. A chemical reaction can be not only a generator but also a receiver of microwaves. The reception at the chemical level follows from the principles of spin chemistry: the resonance microwave radiation stimulates the triplet–singlet conversion of radical pairs (or pairs of other spin carriers) and changes the yields of chemical products, which can be detected by chromatography, luminescence, electrical conductivity, *etc.* Thus, owing to the second-generation magnetic-spin effects, a reaction becomes a chemical receiver of microwave radiation.⁵⁰ Moreover, this expedient can be performed selectively. If the microwave pumping affects all the radical pairs, the final outcome reduces to the change in the product yield at resonance frequencies. This effect has been called reaction yield detected magnetic resonance (RYDMR). Selective pumping involving only radical pairs with magnetic nuclei brings about a remarkable phenomenon, radio-induced magnetic isotope effect (RIMIE). Finally, when the microwave pumping is also selective regarding the orientation of nuclear spins (involves only assemblies of radical pairs with selected orientations of nuclear spins), stimulated nuclear polarisation (SNP) appears.

Third-generation magnetic effects. Spin catalysis is the first example of purely physical catalysis.⁴¹ This phenomenon is notable because the spin conversion of reactants is induced by a

paramagnetic species, a spin catalyst. Conversion occurs as a result of exchange interaction of the catalyst with the reactants. Spin catalysis accelerates radical recombination, *cis–trans* isomerisation of compounds with double bonds (by seven to eight orders of magnitude), recombination of spin-polarised atoms, *etc.* Spin catalysis might also be effective in biochemical processes.

The spin chemistry and the chemical radiophysics are based on electron- and nuclear-spin manipulation. When manipulation is accomplished by the chemical reaction itself, interesting first-generation magnetic-spin effects arise; they include microwave generation, which transforms a chemical reaction into a molecular radio station. When spin manipulation is induced by microwaves, even more elegant second-generation magnetic effects originate. They serve as an indicator of microwave reception.

The spin chemistry and the chemical radiophysics are tightly connected; nevertheless, each of them solves independent problems. The former develops new principles of the control of chemical reactions (including that by virtue of microwaves), while the latter is significant practically for biomedical purposes.

VI. Chemistry under extreme and exotic conditions

Nowadays, the scope of chemistry is expanding, modern chemistry is actively encroaching upon fields that have not been of interest or have been inaccessible for classical chemistry. Transition from the ‘explored’ reaction conditions to extreme, non-classical and even exotic conditions occurs more and more swiftly. These conditions include intense electric and magnetic fields, superhigh pressures, shear deformations, light fields with intensities comparable with those of the electric fields inside the molecules, supercritical conditions, powerful gravitation, sonic and microwave fields, *etc.*⁵²

Ultrashort laser pulses (duration 10 fs or shorter) carry enormously powerful optical radiation and electric fields. This immediately gave impetus to the search for new possible effects. In fact, the interaction of optical and electric fields with the electron shells of molecules gives rise to lots of unusual effects.

Picosecond pulses with a power of up to 10^9 W cm^{-2} induce ‘orbital’ excitations in molecules, which lead mainly to the molecule fragmentation. However, when the power is higher (about $10^{14}–10^{15} \text{ W cm}^{-2}$), multielectron ionisation of molecules occurs, which is followed by Coulomb explosion of the atomic-nuclear core. This type of behaviour is observed, for example, for clusters: an intense laser pulse (120 fs, $10^{15} \text{ W cm}^{-2}$) induces efficient ionisation of the NH_3 molecular clusters, which is accompanied by Coulomb explosion, yielding charged nitrogen atoms (N^{2+} , N^{3+} , N^{4+}).⁵³ Fullerene C_{60} is also ionised by an intense laser beam (100 fs, $10^{16} \text{ W cm}^{-2}$) to give C_{60}^{4+} , which is split into fragment ions *via* Coulomb explosion.⁵⁴

The Lorentz forces, which accompany the passage of a laser pulse through a substance, induce several other effects. Thus they ensure the formation of microparticles in polymer solutions. The photon pressure of the Lorentz forces in a concentrated beam captures polymer chains and condenses them into microparticles with diameters of $\sim 10 \text{ nm}$ or larger.⁵⁵ In addition, laser beams cause ablation of atoms and atomic-molecular clusters from solid surfaces, thus performing molecular etching. Each of these effects can provide the basis for not only new chemical research methods but also new high-end chemical technologies.

High-power laser pulses are an excellent means for generating powerful short shock waves (in particular, they are used in physics for laser compression of deuterium aimed at attaining controlled nuclear fusion). In chemistry, laser shock waves are employed to study the behaviour of substances under extreme conditions (high temperatures, high pressures, shear deformations). Thus laser-induced shock waves ensure a pressure of up to 5 GPa in the front; the duration of the leading front can reach several hundred picoseconds for reversible compression and $\sim 20–25 \text{ ps}$ for irreversible compression. The temperature drop behind the shock front occurs at enormous rates (about 10^{11} K s^{-1}).

Laser-stimulated shock waves provide great scope for ‘extreme’ chemistry; they actually give rise to a ‘new wave’ in the use of shock waves. Onion fullerenes and the transformation of fullerene spheres into diamond have been already mentioned. The same occurs with multilayer nanotubes: at pressures of ~ 50 GPa, their outer shells are torn and twisted to give graphite structures (diamond nanocrystals have also been detected).⁵⁷ The synthesis of diamond according to the known explosion technology might occur (at least, partly) *via* onion fullerenes and nanotubes, which are then converted into diamond under the action of a shock wave.

The supercritical state of matter is a source of unexpected and, hence, ‘anomalous’ effects. For example, near the critical point, highly developed density fluctuations are observed, which implies fast reversible clustering of the substance. Perhaps, it is this feature that accounts for the considerable technological advantages of the supercritical state for extraction and other processes.⁵⁸

Synthesis of metallic hydrogen (which has been mentioned above) and the reaction of tritium with hydrogen and deuterium in normal liquid helium and in superfluid quantum helium should be noted as the latest achievements of the ‘extreme’ chemistry.⁵⁹ It was found that the exceptionally large isotope effects observed in this reaction (this is predictable) are different for normal and quantum helium (this is unexpected). If this finding is confirmed, new and unusual evidence for chemical coherence will be thus obtained.

Magnetic-field effects in chemistry have been already discussed within the framework of spin chemistry. All the effects observed in spin chemistry arise as a response of the electron and nuclear magnetic moments to magnetic treatment (a magneto-static field or the magnetic component of a microwave field). In a system of moving electric charges (solvated electrons or ions), the magnetic fields create Lorentz forces, which, in turn, induce a number of other effects. Therefore, the range of magnetic-field effects may prove to be even broader than predicted by pure spin chemistry.

Magnetic fields have considerable influence on the rate of migration of dislocations in ionic and atomic crystals such as NaCl and Si (the rate increases 3–6-fold in 4–5 T magnetic fields),⁶⁰ on the plastic deformation rate and on the strength of ionic crystals⁶¹ (Fig. 13). These effects are of interest for chemistry and solid-state mechanics. Despite the fact that they can find a reasonable and non-contradictory explanation in terms of the concepts of spin chemistry (spin-dependent recombination of dislocations on paramagnetic stoppers, affecting the rate of migration of dislocations), a contribution of Lorentz forces also

cannot be ruled out, even more so because the effects themselves depend on low-frequency (about hundreds of hertz) electric fields.

The influence of magnetic fields on the electrodeposition of silver on copper is apparently also associated with Lorentz forces (the yield of the reaction in a ~ 80 T field at a field gradient of 4×10^3 kT m⁻¹ increases to 45%; in addition the density of the dendrites of the deposited metal increases and their quality improves).⁶² In this case, the magnetic field influences the microdynamics and microturbulence of the electric double layer at the electrode–solution interface *via* the Lorentz force. (It would be pertinent to evaluate the prospects of this new phenomenon).

Unlike chemical radiophysics, based on the magnetic component of a microwave field, *microwave chemistry* utilises the electric component of this field. In microheterogeneous systems with localised polar and non-polar regions (*e.g.* when polar reagents are concentrated in microreactors), microwaves are absorbed by polar and polarisable areas. Actually, these areas function as miniature microwave ovens with addressed supply of heating energy; therefore, reactions which occur in these reactors are highly selective.⁶³

Chemical reactions initiated by ultrasound also occur in microreactors (cavitations). Although the chemical effects in them are specific, they largely resemble those induced by low-temperature plasma and shock waves. Both microwave and ultrasound chemistry are regarded (for good reason) as providing new means for synthetic chemistry.

Finally, the chemistry in intense gravitation fields (as well as the chemistry in the state of weightlessness) undoubtedly belongs to the ‘extreme’ chemistry. A sharp increase in the gravitational force of molecules, clusters and associates in these fields should generate new effects; the magnitudes and signs of the concentration gradients change, equilibria shift, the arrangement of phases in accordance with density is inverted and the rates and competition of processes alter.⁶⁴ The opportunities provided by these effects are virtually unlimited; the problem lies only in the availability of technical means needed to implement them in practice. Of course, this would be possible only for high-end technology rather than for large-scale chemical production.

The *low-temperature region* (near 4 K) was assimilated by chemistry relatively long ago. The most outstanding result is the discovery of the quantum mechanism of chemical reactions, *i.e.* tunnelling through the barrier, and its consequences (enormous isotope effects, temperature-independent limiting rates of reactions). Certainly, this also can be classified as ‘extreme’ chemistry.

The chemistry dealing with temperatures of 10^{-4} – 10^{-6} K should be regarded as ‘exotic’. The preparation of ultracold atoms is based on the fact that the velocity of their movement changes upon the absorption of an optical quantum (laser cooling of atoms). If atoms and laser photons are selected in such a way that the absorption occurs in the low-frequency region of the spectrum (‘red’ edge), then the resonance absorption by an atom moving towards the photons shifts to the line centre and is enhanced, due to the Doppler shift. In the case of ‘accompanying’ atoms, the Doppler effect shifts the resonance away from the centre and attenuates the absorption; consequently, the atoms experience a decelerating force directed along the photon stream. Atoms placed in orthogonal laser beams are decelerated in all the three directions; this creates an optically viscous medium in which the movement of atoms stops, their kinetic temperature being 10^{-4} – 10^{-6} K (even temperatures of 10^{-10} K can be attained).

From ultracold ⁸⁵Rb atoms, a crystal lattice has been constructed (it proved to be a body-centred cubic lattice), the lattice parameters were measured by optical diffraction and the frequencies of collective lattice vibrations were determined.⁶⁵ In other words, scientists succeeded in creating a new state of matter — crystalline gas.

Ultracold atoms, devoid of kinetic energy, are of interest for precise spectroscopy and metrology, for probing the atom – atom and atom – surface potentials, for experimental verification of the postulates of quantum electrodynamics of a single-atomic maser.

Figure 13. Rate of plastic deformation of a single crystal of NaCl $\dot{\epsilon}_f$ in a 0.7 T magnetic field (in relation to the rate of deformation $\dot{\epsilon}_0$ in a zero field) as a function of deformation ϵ (a), and deformation ϵ as a function of stress σ (b) (the up arrow shows the instant when the magnetic field is switched on, and the down arrow shows the instant of switching off the field).

Optical excitation of atoms in the crystalline gas affords electronically excited atoms, which react with other atoms to give excimer molecules implanted into the crystalline gas. The first steps in the chemistry of the energy-free cold atoms and molecules have already been made; its future starts today. Furthermore, the possibility of laser cooling of molecules in liquids is being discussed.⁶⁶

VII. Once again about cold fusion

In the late 80s of the outgoing century, the scientific world was overwrought by a dramatic event — discovery of nuclear reactions accompanying electrochemical synthesis. The brilliant horizons of the cold nuclear fusion immediately became visible; indirect evidence supporting this finding (neutrons, γ -radiation, excess thermal effects) was even obtained. However, the euphoria has soon come to an end; experimental mistakes and non-reproducibility of the observed effects were found. Consequently, ‘cold fusion’ was wittily renamed to ‘confusion’. At present, both experimental research and debates concerning cold nuclear fusion have transformed into sluggish processes continued by a small group of enthusiasts.

However, the curiosity of this ‘discovery’ has not disappeared. The questions of whether a chemical reaction can induce nuclear fusion and whether transformations of the electron shell can stimulate nuclear transformations still remain open.

Probably, the answer is that generation of neutrons can accompany a chemical process; however, neutrons do not result directly from this process but are formed as a secondary product. They can arise upon nuclear decay induced by γ - and X-radiation emitted by the electron shell, *i.e.* they have a chemical nature.

Although direct chemonuclear fusion was not accomplished, it has given rise to a new strategy of chemical energetics — coupling of a mechanochemical reaction with a non-branched (or slightly branched) chain photonuclear reaction.

This strategy is based on the following idea: mechanically stimulated reactions result in excited electron shells and give rise to γ - and X-rays, which are captured by nuclei (photonuclear reaction); the nuclei excited in this way decay to generate new γ -quanta and/or neutrons. A chain (or partially branched) chemonuclear reaction with energy evolution can occur. The problem is that the mechanical treatment must excite inner electrons; only in this case, conversion of outer electrons to inner vacancies (such as the Auger process) would generate hard X-rays or γ -rays. It is clear that shock waves would be the most suitable type of mechanochemical treatment for this purpose. It is also necessary to elucidate theoretically the appropriate type of electron shell compression (this has already been mentioned in relation to endofullerenes and diamond synthesis) that would enable excitation of high-lying electronic levels of inner electrons (excitation of the outer electrons followed by ionisation would imply escape and inefficient consumption of the mechanical energy).

Another problem is to choose an atomic composition of molecules (or mixtures of molecules) that would permit complete capture of γ - and X-rays by the nuclei. The capture cross-section in photonuclear reactions is known to be relatively large, its spectrum being fairly broad. This provides grounds for believing that the second problem could be solved more easily than the first one (effective mechanochemical generation of hard radiation).

Obviously, this is a strategic goal; on the way to its solution, one can face insurmountable and yet unpredictable obstacles. However, the aim deserves development (at least theoretically, to start with).

VIII. Physics of chemical reactions

Chemistry, like any other highly developed branch of science, has become a high-risk science. This means that the problems of chemistry are complicated and it is not always possible to solve

them by existing methods; therefore, the probability of failures and wasted labour, time and resources becomes fairly high. The risks can be reduced only on the basis of deep insight into the physical aspect of chemical reactions, which is the most important and elitist part of chemical physics.

The physics of chemical reactions is based on four types of dynamics:

- molecular dynamics and molecular organisation;
- energy dynamics (energy dynamics in gases, energy migration in clusters, energy transformation in liquids, energy relaxation in solids);
- chemical dynamics (potential energy surfaces, energetics in the chemical dynamics, theory of chemical reactions);
- angular momentum dynamics and spin dynamics.

The physics of chemical reactions is a field of science involving both experimental and theoretical research; its advances are natural and the problems are traditionally clear (they are analysed in Ref. 24). The main point in this field of science is chemical dynamics, the most important aspect of which is the theory of chemical reactions.

Chemical dynamics have grown out of chemical kinetics; the latter include a general knowledge that has penetrated into all the branches of chemistry and has promoted the development of universal chemical criteria for reaction mechanisms.

However, chemical kinetics deal with the number of chemical events (*i.e.* the interval between the events), whereas chemical dynamics are concerned with the course of the events themselves (movement of the reactants over the potential energy surface). This is the central event in the circle of which the whole chemistry moves and which lies at the heart of a chemical reaction. Chemical dynamics are the ‘cardiogram’ of this ‘chemical’ heart.

The advances in the theory of chemical reactions constitute an individual and broad subject.^{67,68} Actually, two large problems need to be solved: the construction of potential energy surfaces and the calculation of the movement of the reactant nucleus in the calculated potential fields (the proper dynamics of a chemical event).

Both problems can be solved in various modifications, with several levels of approximation and with different degrees to which the quantum nature of the movement is taken into account. In principle, it is now possible to construct a potential surface for any reaction with any degree of accuracy (taking account of the capabilities of modern computers, one has to be able to reduce a reaction of any desired complexity to a simple one without losing its physical or chemical contents). Reliable methods for the calculation of the dynamic trajectories of the reactant movement over the potential surfaces have now been developed. They include methods of classical trajectories (based on the Hamilton–Newton–Lagrange laws of classical mechanics), semiclassical trajectories (taking account of quantum effects *via* superposition of the initial quantum states of the reactants) and purely quantum trajectories (based on the solution of the Schrödinger equation, which presents the probabilities of reactant transformations *via* all reaction channels as an *S*-matrix or scattering matrix). The resulting set of trajectories is used to calculate the canonical $k(T)$ and microcanonical $k(E)$ rate constants (T and E are temperature and energy). Two examples of such calculations are presented in Figs 14 and 15.

General methods for the solution of the dynamic problem have been developed: the method of the reaction path Hamiltonian, the method of the trajectory curvature, multidimensional quantum dynamics and quantum transition state theory. The main idea of the dynamical methods is to distinguish the movement of the reactants along the reaction coordinate and to take into account the influence of all the other types of movement (both ‘assisting’ and retarding). The interaction of all the types of movement (both those directed along the coordinate and others) is considered to be ‘dynamic friction’ and, among other tasks, the modern theory should provide calculation of its value.

Figure 14. Potential energy surface for the reaction $\text{Br} + \text{I}_2 \rightarrow \text{BrI} + \text{I}$ (a) and one of the trajectories on this surface (b) with a duration of 17.6 ps; v are vibrational states, J is the rotation moment and E_T is the kinetic energy.

However, the great theoretical power of chemistry has an unpleasant aspect. Owing to the broad and successful application of quantum chemistry and molecular dynamics methods, researchers tend to avoid science-dependent and expensive experiments, this tendency becoming more and more pronounced. This is objective reality and the general trend of development of world's chemistry (perhaps, not only chemistry).

The theory of chemical reactions is closely related to the theory of nuclear reactions (this is true not only for the diffusion regime in which the kinetic equations and their solutions are absolutely identical). A system that undergoes a chemical reaction in a liquid or in a solid is similar to the reacting nucleons surrounded by the medium, *i.e.* other nucleons in a nucleus. In this case, too, chemistry occupies an advantageous position: it is simple in the sense that only one type of interaction operates, namely, the Coulomb interaction with a known energy–distance relationship. This is a fundamental statement, which follows from quantum mechanics (the accuracy of its laws is beyond controversy, like that of the laws of classical mechanics). However, there is also direct experimental evidence supporting this statement. The case in point is the experimental probing of atomic wave functions, which are the basis for the entire chemistry.

Figure 15. Free energy surfaces for the reaction $\text{Cu}^{2+} \rightarrow \text{Cu}^+$ at an electrode for adiabatic (a) and nonadiabatic (b) transformation; z is the distance of the ion from the electrode, E is the energy of solvent reorganisation.

This experiment is very simple: an atomic (Ca or Cu) beam is excited by polarised light to the p_z or d_{z^2} state; after that, this beam with spatially oriented p_z or d_{z^2} orbitals is exposed to a crossed beam of He atoms; scattering of the He beam is detected, the scattering pattern being used to reconstruct the scattering potential. The result proved to be very vivid: the scattering profile exactly reproduced the shapes of the atomic orbitals.

One can argue that this result is trivial (in the sense that no other result was to be expected); however, it leads to the understanding of the fact that only the Coulomb potential operates in chemistry (a part of it, the exchange interaction, is spin-dependent). Moreover, if we recall the fact that the atomic wave functions have originated on the tip of a pen from the quantum-mechanics postulates and the Schrödinger equation with a centrosymmetrical Coulomb potential, we can feel the triumph of the human mind.

The magic and fascination of chemistry are due to the fact that the Coulomb potential gives rise to a variety of chemical bonds (ionic, covalent, donor–acceptor, dative, hydrogen and van der Waals bonds), chemical species (atoms, carbenes, ions, molecules, exciplexes, Rydbergs, excimers, van der Waals molecules, complexes, radicals, *etc.*), states (ground, excited, charge, spin, orbital, differing in symmetry, *etc.*), mechanisms of chemical transformations and controlling factors (energy, spin, phase, orbital symmetry). With this diversity and wealth, chemistry is always new. The discovery of new states of hydrogen molecules can serve as an example (Fig. 16). They are matched by adiabatic potential minima located in the vicinity of the points of intersection of the binding term $\text{H}^+ + \text{H}^-(1s^2)$ and the repulsive terms $\text{H}(1s) + \text{H}(np)$, where $n = 1, 2, 3, \dots$. These species are not Rydberg molecules having ‘plump’ electron shells with principal quantum numbers reaching hundreds but ‘normal’ molecules with

Figure 16. Terms of metastable hydrogen molecules with interatomic distances 6, 13 and 106 Å. They are located in adiabatic valleys at the intersection of the ionic term (H^+ , H) with the terms corresponding to the orbitally excited states $H(1p)$, $H(2p)$ and $H(3p)$.

equilibrium interatomic distances of 6, 13, 106 Å, *etc.* characterised by their own vibrational-rotational spectra. Similar molecules can also exist for other atoms. They can be detected in low-temperature or rarefied plasma or in the huge interstellar chemical reactor.

IX. Atomic-resolution spectroscopy and chemistry

This field of modern chemistry is being vigorously developed; it assumes detection of chemical reactions with high time resolution (about ≤ 10 fs, which is shorter than the period of vibrations of an atom in a molecule) or with high space resolution (~ 1 –5 Å, which is about the size of a single atom or a molecule). Both values correspond to atomic resolution.

The adoption of short laser pulses has extended the scope of chemistry and introduced into chemistry new ideas, which have been embodied in *femtochemistry*.⁶⁹

Firstly, the time periods of 10–100 fs are so short in relation to the period of nuclear vibrations that the nuclei remain virtually fixed at their positions during this period. For example, the interatomic distances in a iodine molecule in the ground state oscillate between 2.5 Å (contracted bond) and 5 Å (stretched bond). A femtosecond pulse ‘catches’ a molecular assembly with a particular interatomic distance and a particular motion phase and throws it almost instantly onto a new potential surface. On this potential, atoms start a new movement, which is now synchronous (coherent). Thus the femtosecond pulse has created a wave packet — an assembly of molecular oscillators with a fixed vibration phase, a given interatomic distance and a definite energy. In other words, femtochemistry opens up the way for production of coherent wave packets.

Secondly, a time resolution of 1–100 fs corresponds to a coordinate resolution of 0.1–0.01 Å. This means that the movement of the nuclei over the potential surface, including that on the top of the barrier and near it, is monitored with this coordinate resolution. It is clear that we are dealing with spectroscopy and chemistry of the transition state, which has always been an object for investigation by theorists but now has become the subject of experimental research. Femtochemistry deals with the time of movement of reaction systems on the potential surface and introduces into chemistry the experimental chemical dynamics.

Thirdly, by monitoring the movement of nuclei over the potential surface, one can interfere in the dynamics of the transition state by its energy or phase pumping and thus change the transformation pathways of the transition state itself. In this sense, one can say that femtochemistry is the chemistry of the transition state.

As an example of the control of chemical reaction channels, let us consider decomposition of a chlorine dioxide molecule $OCIO$. When the pumping energy is $\sim 0.3 \times 10^{12} \text{ W cm}^{-2}$, decomposition follows predominantly the $O + ClO$ pathway; when the energy exceeds $0.8 \times 10^{12} \text{ W cm}^{-2}$, the second channel leading to $O_2 + Cl$, starts to predominate and at an energy of $1.4 \times 10^{12} \text{ W cm}^{-2}$, the rate of decomposition *via* the second channel is 12 times greater than that according to the first channel.⁷⁰ Chemical approaches also permit complete switching of the reaction from the first channel to the second one, for example, this can be attained by adding a water molecule to chlorine dioxide or by placing chlorine dioxide in an $(H_2O)_n$ cluster.⁷¹ Although the chemical method leads to the same result as femtochemistry, this result is achieved by an absolutely different mechanism. In fact, when the initial state of the reactants changes, the reaction switches to a new potential surface; thus, the chemical approaches represent a classical example of changing the reactivity upon complex formation or solvation.

Fourthly, femtochemistry has opened a new chapter in the structural analysis of short-lived species including transition states. Instruments which permit ultrafast diffraction of electrons on these species have been designed. The first femtosecond pulse from a photocathode generates an ultrashort electron beam accelerated by an intense electric field ($\sim 30 \text{ kW cm}^{-1}$). After that, the second femtosecond pulse (with a controlled delay) generates a wave packet or a transition state for a chemical system under study. After that, electron beam diffraction on the transition state or on the reaction product is recorded.

In the future, this remarkable equipment would permit probing of the transition state geometry.⁷² A resolving power of ~ 1 ps with respect to the electron beam (which is the factor limiting the capability of the instruments) has already been attained, and this limit can undoubtedly be overcome. This would enable not only time (spectroscopic) but also geometrical monitoring of the transition state (based on the electron diffraction).

Finally, fifthly, femtochemistry provides great possibilities for investigating ultrafast reactions such as proton (electron) transfer in acid–base (donor–acceptor) pairs; tautomerisation; *cis–trans*-isomerisation with detection of *twist*-conformations; photo-generation and relaxation of an electron–hole pair in semiconductors; elementary steps of photosynthesis; decomposition of molecules (*e.g.*, decomposition of iodine in clusters near the gas–liquid phase transition or under supercritical conditions, *etc.*).

Femtochemistry reveals important new facts concerning heterogeneous processes, in particular, desorption of molecules and desorption mechanism. A femtosecond pulse heats an electron gas to a temperature of several thousand degrees but leaves phonons in metal almost cold (heated to a temperature of only several hundred degrees). The low phonon temperature cannot account for either the high rates of desorption or the high vibrational temperature ($\sim 2000 \text{ K}$) of diatomic molecules. It is clear that the fast desorption of molecules (not more than 10 vibrations on the surface after a femtosecond pulse) is stimulated by the hot electron gas (apparently, *via* generation of an electron–hole pair followed by its fast annihilation at the adsorption site).⁷³ Independent experiments with generation of a surface electromagnetic wave, which probes the surface and its adsorption coverage, has confirmed that, after a femtosecond pulse has been initiated, a molecule remains on the surface only for 3–5 vibrations.

Apparently, femtochemistry would enable detection of fast electronic events such as electron exchange between the protons in the H_2^+ cation (these events take ~ 2 fs), π -electron migration in the Kekule structures of benzene, electron revolution round the nucleus, electron transfer to upper orbitals upon excitation, *etc.* However, this would require lasers of the next generation with a resolving power in the attosecond range (1 attosecond = 10^{-18} s).

The progress in the design of photodetectors and scanning optical microscopes has given access to *observation of single*

molecules (such as rhodamine 6G, and terrylenediimine). By exciting and monitoring stationary luminescence of single molecules (molecular ‘fireflies’), one can study lateral diffusion of molecules on solid surfaces and bulk diffusion in solids (such as polymers). When polarised light is used for excitation and polarised luminescence is recorded, it becomes possible to measure reorientation of molecules and monitor their trajectories. The first wonderful phenomena have already been discovered. Thus an unusual type of behaviour of rhodamine 6G molecules deposited on glass was found; some of the molecules remain still, some other move without rotating and some other rotate without moving.⁷⁴ The behaviour of terrylenediimine on an SiO₂ surface proved to be even more surprising: luminescence of some molecules was found twice modulated by a low frequency (10 and 100 Hz), the luminescence bands of ‘modulated’ molecules being shifted to higher frequency.⁷⁵ Even these two examples demonstrate that probing of a surface by molecular ‘fireflies’ promises a lot of new discoveries.

The capability of optical detection using single molecules is not limited to investigations of molecular dynamics. A ‘flickering’ (non-statistical) behaviour of single molecules associated with spectral diffusion has been found; it is also possible to measure directly the rate of energy transfer to neighbouring molecules and to elucidate the dependence of the energy on the distance (by changing the number of ‘fireflies’ per unit surface; normally several molecules are located on one square micron).⁷⁶

It is obvious that the potentialities of detection using single molecules are substantially increased by using pulse excitation. This brings about new opportunities in the investigation of ergodicity and new methods for direct measurement of quantum yields in the photodecay of single molecules, etc.

The discovery of *tunnelling vibrational spectroscopy* of single molecules is a new great breakthrough in chemistry.⁷⁷ The tunnelling current, which flows between the tip of a tunnelling scanning microscope and a solid surface on which an adsorbed molecule ‘sits’ under the tip, has a clear-cut resonance character. The resonance always occurs in the case where the tip potential (and, hence, the energy of tunnelling electrons) corresponds to the vibronic levels of an adsorbed molecule. Examples of vibrational spectra for several single molecules are shown in Fig. 17.

Vibrational spectroscopy of a single molecule exactly reproduces its portrait and permits one to follow its dynamics (rest time) and chemical fate.⁷⁸ This opens up new prospects for the science of

catalysis. The ways for detecting electron paramagnetic resonance of a single spin are clear and have already been theoretically substantiated.⁷⁹ A great number of new ideas are originating in *atomic-resolution chemistry*.

X. Conclusion

Chemistry as a fundamental science has no limits; it is impossible to represent even its outline within one paper. The face of chemistry is being permanently renewed; new beautiful features appear, which include coherence, atomic resolution (in time and in space), magnetic script of chemical reactions, chemical radio-physics, new ideas in molecular architecture and new molecular assemblies. A special part in the modern chemistry is assigned to the coherent chemistry, which introduces a third controlling factor, the phase (in addition to the energy and spin). In this review, we have discussed the quantum vibrational coherence, the quantum spin coherence and the macroscopic coherence with characteristic times of 10^{-15} – 10^{-13} , 10^{-9} – 10^{-7} and 10^{-1} – 10^{-3} s, respectively. A new level of this field of science would be associated with the generation of electron coherence, *i.e.* creation of electronically coherent wave packets with characteristic times of 10^{-18} – 10^{-15} s.

The intrinsic order and the structure of chemistry and also everything created by chemistry display the charm of strict logic, substantiation and perfection. This is yet another feature of chemistry, which makes it a fundamental science. The scope of chemical research is constantly expanding; it is possible (and useful) to make predictions only regarding the tendencies of development. We cannot foresee the particular events in science; this is clearly demonstrated by the achievements of the last three decades (fullerenes, telomerase, superconducting ceramics, etc.). However, we can make use of our scientific intuition, foresight and professional sense of understanding of the general movement of science and thought.

Abstract. Data on the electronic and chemical structure of a new quasi-one-dimensional form of matter, *viz.*, nanotubulenes, are generalised and systematised. Methods and approaches used in modern quantum chemistry for the simulation of the composition, structure, and properties of isolated tubulenes based on layered phases (graphite, boron nitride, boron carbide and boron carbonitride), nanotubular composites and nanotube crystals are described. The role of quantum theory in the development of the concepts of fundamental properties of substances in the nanotubular form and methods of their targeted modification is discussed. Prognostic potentials of theoretical models in solving material science problems are considered. The bibliography includes 197 references.

I. Introduction

The study of nanomaterials (NM) is one of the leading areas of investigation in modern chemistry. Nanomaterials that are currently produced in the form of isolated clusters, powders, films, and consolidated systems with a characteristic size of crystallites not more than 100 nm possess many unusual properties that are promising for the development of high technologies.^{1–8} In addition, they form a unique class of objects used for studying fundamental problems of the metastable state of matter and the prospects of producing its new forms that have no analogues in nature.^{2,6,8}

The greatest progress in this area has been achieved in the field of synthesis and comprehensive studies of a new allotropic modification of carbon, fullerenes, and first of all, ‘classical’ spheroidal carbon clusters (C₆₀ and C₇₀), endohedral complexes, as well as film and crystalline materials based on these substances (fullerites).^{1,2,8}

The topology and physicochemical properties of nonspherical carbon clusters built of a large number of atoms (the so-called giant fullerenes C_n, *n* > 70) have become the subject of numerous

recent studies in which different types of closed carbon structures (capsulenes, torrenes, barrellenes, *etc.*) were discussed.^{1,2}

Iijima⁹ has discovered quasi-one-dimensional (quasi-1D) hollow tubular carbon fibres, *viz.*, nanoscale carbon tubes (nanotubulenes), which are extended cylinders whose walls are formed by rolled graphite sheets. Carbon nanotubes with diameters ranging from five to several tens of nanometres and consisting of 2 to 50 coaxial graphite cylinders [the so-called multilayered nanotubes (MNT)] were detected⁹ by transmission electron microscopy (TEM) in the soot obtained in arc-discharge experiments using graphite electrodes. More recently, both multilayered and single-layered nanotubes (SNT) were obtained.^{10–16}

It was suggested^{8,10} to consider nanoscale tubular structures as a new, quasi-1D form of carbon that occupies a ‘vacant’ position in the series of the known forms of carbon of different topological dimension 3D (diamond), 2D (graphite), and 0D (fullerene).

Almost simultaneously with the first reports on the syntheses of carbon NT,^{10–16} several studies devoted to simulation of their electronic structure were carried out,^{17–24} and unexpected and extremely interesting results were obtained. It was established that, depending on the NT diameter and the type of helical ordering of carbon atoms constituting the cylinder walls, tubulenes can possess both metallic and semiconducting properties.

The predicted possibilities of targeted modification of carbon NT conductivity have at once become the subject of daring hypotheses for their use in diverse exotic devices and elements of electronic circuits of uniquely small sizes (nanocoils, nanowires, *etc.*).^{10,16} The list of possible ‘nanoscale devices’ in which electronic, optical, catalytic, capillary, and other properties of NT can be used, is increasing rapidly.^{25–31}

In the first stage of experimental studies, methods of production of carbon NT and a number of nanotubular composites were developed. The results of these studies were generalised in a monograph.⁸

Recently, stable nanotubular structures based on several layered compounds, *viz.*, BN,^{32–36} BC₃,³⁷ BC₂N,^{37,38} and MoS₂^{39,40} have been synthesised and it was suggested that nanotubular forms of silicon^{41,42} and boron⁴³ as well as consolidated nanotubular materials^{44,45} can be obtained.

Research in the field of the synthesis and study of the properties of nanotubular forms of substances is intimately associated with the development of quantum chemistry of tubulenes, which is caused by several reasons. The interest of investigators in quasi-1D carbon NT and initiation of large-scale projects in the field of

synthesis, physical chemistry, and material science of NT is to a great extent due to predicted unusual electronic properties of these objects.^{17–24}

Nanotubulenes are obtained by vapour deposition in various media (see, *e.g.*, Refs 6, 8). For instance, carbon tubulenes are synthesised in arc-discharge apparatus in the presence of catalysts. As a rule, the final product is a mixture of NT and other carbon-containing species (*e.g.*, metal carbides), which hampers substantially the studies of the properties of NT themselves. Suffice it to say that the isolation of NT possessing semiconducting and metallic properties predicted in 1992^{17–24} was reported only recently.^{46, 47}

Theoretical simulation of NT plays an extremely important role in the solution of the problem of obtaining the nanotubular substances 'in pure form': almost all the known substances in the nanotubular form and many of their properties were predicted from the results of calculations.

In the present review, the main stages of the development of ideas of the electronic properties of substances in the nanotubular form calculated first of all using modern quantum-chemical methods are considered. Particular attention is paid to the application of theory to the simulation of the structure and description of physicochemical properties of non-ideal nanotubulenes, nanotubular composites, and nanotubular crystals that are most interesting from the viewpoint of their practical use.

II. Theoretical models of electronic properties of ideal carbon nanotubulenes

The principles of theoretical description of ideal carbon single-layered NT were developed in 1992.^{17–24} Schemes of NT classification were proposed and fundamental dependences between the atomic structure of cylindrical nanostructures and their electronic properties were established.

Saito *et al.*¹⁸ considered the principles of the formation of two types of NT taking closed tubulenes as an example. Fullerene C₆₀ hemispheres were taken as the end groups; they can be obtained as a result of dissecting the C₆₀ framework in such a manner that the section plane contained 9 or 10 carbon atoms (Fig. 1). This respectively corresponds to the so-called 'arm-chair' or 'zigzag' cross sections. Since the type of ordering of the atoms constituting the cylinder walls closed by the above-mentioned end groups will be determined uniquely, the corresponding terminology is also used for the description of the NT obtained, and 'arm-chair' or 'zigzag' NT are considered (Fig. 2).

'Open' NT can also be constructed by rolling a planar atomic graphite sheet. In this case each cylinder is characterised by its diameter and the type of helical atomic ordering (chirality).^{18, 19}

Figure 1. 'Arm-chair' (a) and 'zigzag' (b) cross sections of fullerene C₆₀.

Figure 2. Structure of 'arm-chair' (a) and 'zigzag' (b) tubulenes.

Using the basis vectors of the graphite sheet **a**₁ and **a**₂ (Fig. 3), the diameter (*d*), and the pitch angle (*θ*), the vector

$$\mathbf{c}_n = n\mathbf{a}_1 + m\mathbf{a}_2$$

is given [the so-called (*n*, *m*)-NT]. The parameters *d* and *θ* are defined by the following relationships:

$$d = \frac{|\mathbf{c}_n|}{\pi} = \frac{a\sqrt{3(n^2 + m^2 + nm)}}{\pi},$$

where *a* is the interatomic distance in the planar sheet, and

$$\theta = \arctan\left(-\frac{\sqrt{3}m}{2n + m}\right).$$

Figure 3. The method for selecting the vector **c**_{*n*} that defines the diameter and the pitch angle *θ* for an 'open' nanotube that can be constructed by rolling a graphite sheet (by matching the points *A* and *A'*).

Depending on the indices *n* and *m*, chiral (*n*, *m*) and achiral (*n*, 0) nanotubes are distinguished.

Calculations of electronic properties for a large number of SNT with variable indices *n* and *m* were performed.^{17–24} In Fig. 4, the distributions of the density of states (DOS) calculated by the tight-binding (TB) method for the (10, 0) and (9, 0) 'zigzag' carbon NT¹⁹ are shown as an example. The energy bands are formed by mixed $\pi(2p_z)$ and $\sigma(2s, 2p_{x,y})$ carbon states. Depending on the radius of curvature, carbon nanotubulenes can possess either metallic or semiconducting properties.

According to calculations,^{17–24} there is a clear dependence between the structural indices (*n*, *m*) and conducting properties of ideal cylindrical single-layered tubulenes. All carbon (*n*, *n*)-NT possess a metallic type of conductivity. If *m* ≠ 0 and *n* = *m* + 3*q*, where *q* is an integer, then the corresponding tubulenes are semiconductors with narrow band gaps, for which the band gap (ΔE_g) depends on the NT radius

$$\Delta E_g \simeq R^{-2}.$$

All other NT possess properties of semiconductors with wide band gaps, for which

$$\Delta E_g \simeq R^{-1}.$$

Figure 4. The total density of states (TDOS) for the ‘zigzag’ (10, 0)- (a) and (9, 0)-carbon nanotubes (b).¹⁹ The TDOS for a planar graphite sheet is shown by dashed lines. Calculations by the TB method.

It is natural that the relationships listed above are valid for the tubes of relatively small diameters, whereas at $d \rightarrow \infty$ the band structure of NT is transformed into that of a planar graphite sheet. This fundamental dependence of electronic properties of NT on their structure^{17–24} was confirmed experimentally.^{46,47} Two groups of NT with varied chirality were isolated and their current *vs.* voltage characteristics were measured. In accordance with theoretical predictions, a metallic or semiconducting type of conductivity was observed for these groups of NT depending on their structure.

Refinement of the details of electronic structure of carbon SNT was reported.^{48–64} For instance, it was pointed out that σ - π -hybridisation should be taken into account in the case of semiconducting tubulenes of small radius.⁵⁰ A detailed study of this effect for NT with wide band gaps in the framework of the TB method made it possible to suggest an analytical dependence of ΔE_g on the tube radius.³⁴ The results of some calculations of (n, m) -NT with wide band gaps are listed in Table 1.

Table 1. Dependence of ΔE_g for carbon (n, m) -NT with wide band gaps on their radii.^{26, 54}

Figure 5. Dispersion of the energy bands (a, b) and the density of p (solid line) and s (dashed line) states of NT, (c) and (d), respectively; (a) and (c) (10, 5)-tubulene; (b) and (d) (9, 0)-tubulene. The δ -shaped DOS resonances near the Fermi level are shown by arrows.

The dependence of the DOS distributions on the NT radii and pitch angles was considered taking a group of metallic NT as an example.⁵⁰ The presence of a DOS ‘plateau’ near the Fermi level between the δ -shaped peaks (Fig. 5) separated by the E interval is a characteristic feature of carbon nanotubes with metallic (and quasi-metallic) types of conductivity [e.g., the (10, 5) and (9, 0)-NT, respectively]. A general relation describing the $E(\theta, R)$ dependence was derived and numerical calculations of this spectral parameter were performed (Fig. 6). As can be seen, the E value (the width of the DOS ‘plateau’ near the Fermi level) is determined by the tube size, *viz.*, E decreases substantially as R increases. For this reason, the parameters of the electronic states of tubulenes possessing metallic and semiconducting properties depend explicitly on their geometric indices.

Figure 6. Dependence of the energy interval (E/V_{p-p}) between the δ -shaped DOS resonances near the Fermi level (see Fig. 5) for NT with metallic (1), (2) and quasi-metallic (3), (4) types of conductivity on their radii (R) referred to the C–C interatomic distance (d_0); V_{p-p} is the energy parameter used in TB calculations and determining the interaction between p - p orbitals; (1), (2) $\theta = 30^\circ$; (3), (4) $0 \leq \theta \leq 30^\circ$.

The Peierls type of instability effects for metallic 1D-tubulenes was considered.^{17–19} Based on the results of *ab initio* self-consistent calculations, it was shown¹⁷ that, unlike, e.g., *trans*-polyacetylene,⁵⁸ the temperature of the Peierls transition for the metal-like NT should be much higher than room temperature.⁵⁹

The dependence of the stability of carbon tubulenes on their sizes was evaluated⁶⁰ and compared to similar data for other carbon nanoscale structures and macrostructures. The analysis was based on calculations of carbon atom binding energies (E_b) in NT. The calculations were carried out using two empirical potentials^{61,62} for a total of 169 nanotubes with $R < 9$ Å and pitch angles in the range $0^\circ < \theta < 30^\circ$ (the C–C distances were assumed to be equal to 1.44 Å). Several highly symmetric (n, n)-NT ($n = 3, 4, 5, 6, 7, 9$) were also calculated in the framework of the *ab initio* local electron density functional (LEDF) method.^{63,64} Figure 7 illustrates a clear dependence of the E_b of carbon atom on the NT geometric size ($E_b \sim R^{-2}$), according to which the binding energy of a carbon atom in NT approaches that of a carbon atom in graphite as the NT radius increases. As can also be seen, the E_b values of carbon atoms in fullerenes C_{60} , C_{180} , and C_{240} are higher than those of carbon atoms in the NT of corresponding radii. It was concluded that the formation of tubular or spheroidal nanoscale forms of carbon will be controlled not only by the energy state of a system, but also by the kinetics for the conditions of growth.

Figure 7. Binding energies of carbon atoms for nanotubes of various radii; (1) LDA calculations; (2) and (3) calculations by the pseudopotential method using data taken from Refs 27 and 28, respectively. The dashed line corresponds to the binding energy of carbon atoms in graphite. The binding energies of carbon atoms in fullerenes C_{60} , C_{180} , and C_{240} are also shown [the data were taken from Refs 27 (4) and 28 (5)].

The electron energy spectra (EES) of multilayered NT are much less studied than those of SNT. A double-layered NT (the radii of the ‘outer’ and ‘inner’ cylinders were 3.4 and 6.8 Å, respectively) was considered using the approximate density-functional computational scheme.⁶⁶ The calculations were carried out assuming a uniform surface electron density distribution without taking into account specific features of individual atomic geometry of the cylinders. It was found that the total density of states (TDOS) distribution for the double-layered NT was similar to that of SNT with characteristic oscillations reflecting the van Hove DOS singularities for 1D systems (Fig. 8). It is believed⁶⁶ that an

Figure 8. Decomposition of the TDOS for a double-layered NT into partial *s*- (1), (2), *p*- (3), (4), and *d*-components (5), (6) for the inner (1), (3), (5) and outer (2), (4), (6) nanotubes.²⁹

increase in the number of layers will lead to the DOS of MNT approaching that of graphite.

On the whole, the results of quantum-chemical simulation of ideal cylindrical SNT made it possible to obtain a detailed description of their electronic properties and establish clear correlations between the parameters of the electron energy spectra, topology, and NT size. These results have become the basis for further calculations and predictions of some physicochemical properties of NT.

III. Defect structure of carbon nanotubulenes. Nanotubular composites

Investigation of defect NT is a certain stage of the development of the quantum chemistry of nanotubular forms of carbon. Both ‘intrinsic’ structural defects of tubulenes and various heterostructures involving NT (the so-called nanotubular composites) are considered.^{6,8} Three main types of ‘intrinsic’ defects of NT are distinguished, *viz.*, topological defects, rehybridisation defects, and defects of unsaturated (or ‘dangling’) bonds. In the first case, it is assumed that the rolled graphite sheet contains pentagons and heptagons (or their combinations). Rehybridisation defects are associated with the possibility of changing the standard sp^2 hybridisation of carbon atoms (*e.g.*, $sp^2 \rightleftharpoons sp^3$). The third type of defects is due to vacancies, impurities, dislocations, and to the structure of the end groups (open or closed) of NT.

1. Structural defects and relaxation processes

The effects of quasi-1D structural relaxation capable of distorting the ideal cylindrical geometry of model NT were assessed⁶⁷ by the molecular-dynamics (MD) Car–Parrinello method⁶⁸ for a number of chiral and achiral NT. The ‘optimised’ structure of the (10, 0)- and (11, 5)-tubulenes considered⁶⁷ virtually coincides with the initial structure of the model rolled graphite sheet (the difference in the interatomic distances does not exceed ~ 0.01 Å). A possible explanation⁶⁷ is that the substance in the tubular form retains the main types of interatomic interactions characteristic of graphitic sheets.

Donor (nitrogen) or acceptor (boron) substitutional impurities⁶⁷ cause perturbations of the electron density and can affect the conducting properties of carbon NT. Local relaxation rearrangements upon $N \rightarrow C$ substitution are insignificant. When NT are doped with boron, the carbon atoms closest to the boron atoms are shifted along the bond axis by ~ 0.11 Å.

Charge distributions in the presence of substitutional impurities (individual B, N, and Si atoms, anions, and cations) were investigated⁵⁷ in the framework of embedded cyclic cluster model⁶⁹ by the MNDO/PM3 method taking a (6, 6)-NT as an example. It was pointed out that discrete donor or acceptor levels appear in the band gap of the tubulene. Defect-induced perturbations are propagated along the NT axis to a larger number of neighbouring spheres than those propagated along the circumference of the cylinder. Charged defects produce larger perturbation areas than neutral ones.

A topological type of defect associated with the formation of a carbon vacancy was considered.⁷⁰ Taking a metal-like (4, 4)-NT as an example, it was found that the number of conductivity channels (according to terminology^{71,72}) decreases in the presence of carbon vacancies, which leads to suppression of conducting properties of the NT.

2. Radial deformations of nanotubulenes

Charlier *et al.*⁷³ discussed the effect of change in the curvature of atomic layers along the circumference of the carbon cylinder on the electronic properties of NT. The possibility for non-cylindrical carbon NT with pronounced ‘cut’ of the walls to be formed was confirmed by three-dimensional holographic TEM images.^{74–76}

It should be noted that the nature of microdeformations of carbon NT walls (the ‘ripples’ observed on the NT surface⁷⁷) is associated with the rehybridisation effect, *i.e.*, with the change in

the effective hybridisation of the carbon atom from sp^2 to sp^3 (diamond). In this case, local protrusions of the surface that form ‘structural waves’ (folds) with variable curvature will be characterised by averaged $sp^{2+\alpha}$ carbon hybridisation, where the parameter α depends on the curvature of the microarea of the NT surface.

The edges of prismatic NT can be considered as visual lines of rehybridisation that occurs upon the change in the atomic configurations from sp^2 to sp^3 , or as lines of hybridisation defects.⁷⁷

Tight-binding DOS calculations for a cylindrical (10, 0)-tube and (10, 0)⁵-tubes with n -gonal cross sections showed that in the latter case there is a number of peculiarities on the DOS profile such as clearly seen effects of $\sigma^* - \pi^*$ hybridisation and appreciable changes in the energy band structure. These peculiarities are characteristic of small-diameter NT.

In Fig. 9, the energy band structures of the (10, 0)- and (10, 0)⁵-NT are shown as an example. The π^* -band energy of the (10, 0)⁵-NT decreases substantially (the so-called NT ‘metallisation’). The nature of this phenomenon becomes clear from comparing the charge density distributions (ρ) in the cross-sectional planes of cylindrical (10, 0)- and pentagonal (10, 0)⁵-NT for the Γ -states near the Fermi level. The clearly seen ρ anisotropy at the vertices of the pentagon, partial outward shift of the charge density (the formation of σ -like states), and the reduction of the symmetry of the system lead to a substantial decrease in the band gap and to a change in the type of conductivity from semiconducting for the (10, 0)-NT to metallic for the (10, 0)⁵-NT.

Figure 9. The energy band structures of (10, 0)- (a) and (10, 0)⁵-NT (c), and a tubulene with ‘intermediate’ type of cross section (b).

Changes in the energy band structure of metal-like NT upon ‘polygonisation’ of their cross sections were considered taking (12, 0)ⁿ-NT ($n = 6, 4, 3$) as examples.⁷³ It was established that the conducting properties of the NT change in the following order: metallic [(12, 0)-NT] → semiconducting [(12, 0)⁶-NT with a band gap of about 0.5 eV] → metallic [(12, 0)⁴- and (12, 0)³-NT], which is mainly determined by the energies of the $\pi - \pi^*$ bands.

3. Uniaxial compression (tension) of nanotubes

Along with radial deformations in the cross-sectional plane, nanotubes can undergo longitudinal compressions (in particular, axial ones). This type of effect becomes of particular interest in connection with the investigation of mechanical properties of NT.^{6, 8, 78, 79}

The effect of uniaxial stress on the density of states and type of conductivity of SNT was studied by the TB method taking ‘zigzag’

($n, 0$) and ‘arm-chair’ (n, m) carbon nanotubulenes as examples.⁸⁰ A homogeneous uniaxial compression ($\sigma < 0$) and tension ($\sigma > 0$) was simulated by displacements of carbon atoms. Uniaxial stress will lead to the change in the NT chirality, which determines the energy characteristics of the cylindrical structures. It was found⁸⁰ that, depending on the index n and considering it as $(3q - 1)$, $3q$, or $(3q + 1)$, where q is an integer, the ($n, 0$)-NT can be arbitrarily classed into three groups. The band gaps of $(3q + 1)$ -NT will increase while those of $(3q - 1)$ -NT will decrease upon compression of ($n, 0$)-NT. The type of conductivity of the $(3q, 0)$ -NT changes from metallic to a semiconducting one; for this reason, these NT are the most convenient objects for experimental testing of the dependence predicted.⁸⁰

For all ($n, 0$)-NT considered,⁸⁰ the band gaps depend linearly on the modulus of compression (σ). According to the estimates⁸⁰ the band gap sensitivity to stress, $|dE_g/d\sigma|$, is about $10.7 \text{ meV GPa}^{-1}$ in the range $|\sigma| < 10 \text{ GPa}$. All metal-like ‘arm-chair’ (n, m)-NT retain their properties upon uniaxial stress.

The effect of compression on the electronic characteristics and other properties (in particular, on chiral currents) of nanotubulenes was studied by the self-consistent electron density functional method taking a group of carbon NT as an example (Table 2).⁸¹ It was found that the major effect of compression of (9, 7)-NT consists in an appreciable increase in the band gap due to a decrease in the dispersity of π and π^* bands near the Fermi level. It is possible to make the system conducting by introducing hole or electron carriers. This can be done by doping NT with atoms of alkali metals (AM) or halogens. Miyamoto⁸¹ simulated this effect by fixed shift of E_F . By solving the Boltzmann equation the components of the conductivity tensors of NT were found and the pitch angles for charge carrier currents were determined (see Table 2). It was stated⁸¹ that violation of the symmetry of the hexagonal atomic ordering of the cylinder walls upon its compression can cause chiral currents to flow. This effect is most pronounced for the ‘arm-chair’ NT.

Table 2. Geometric parameters of compressed (n, m)-NT and pitch angles of chiral currents (θ') in the case of doping with electrons (e) and holes (h).

Geometric parameters of (n, m)-NT				θ' / deg (see ^a)
(n, m)	$d / \text{\AA}$	θ / deg	degree of compression (%)	
(13, 1)	10.78	4.1	10	1.6(h) 8.8(e)
(11, 4)	10.60	15.5	10	0.5(h) 12.4(e)
(9, 7)	10.97	24.9	5	4.2(h)

^a The calculations were carried out assuming that E_F is shifted by 50 meV from the bottom of the conduction band and from the top of the valence band upon doping of NT with electrons and holes, respectively.

TEM images^{82–84} indicate that carbon NT can undergo diverse changes in their shapes and spatial configurations and that the types of NT deformations considered (radial and uniaxial) are a particular case of such changes. Studies of arbitrarily deformed NT are scarce due to the complexity of the description of their electronic properties.

4. Deformations of carbon nanotubulenes

As a rule, the problems of deformational behaviour of NT are studied in the context of the development of ‘nanomechanics’. Most of experimental studies in this line^{6, 8, 78, 79, 85–90} have been devoted to investigation of the brittle–elastic properties of NT under different conditions of external strain.

The microscopic simulation of the energy characteristics of mechanically deformed NT was performed by MD methods^{88, 91}

Figure 10. Dependence of the strain energy (E) and its derivative ($dE/d\phi$) on the bending angle (ϕ) for the (13, 0)-NT (a) and the NT shape upon 'kink' (b).

using many-body interatomic potentials^{61,62} and energy parameters obtained in band structure calculations of 'slightly deformed' NT.^{60,92,93}

Typical of this investigation line are MD calculations of the brittle–elastic properties of NT exposed to classical types of deformation (compression, bending, and torsion).^{88,91} Figure 10 illustrates the results obtained from MD calculations of the strain energy dependence of a (13, 0)-NT, 8 nm in length and 1 nm in diameter, on the tube bending angle. External strain was applied to both tube ends. The strain energy smoothly increased before the tube 'kink' (or inelastic bending) and sharply decreased afterwards.

The results of calculations^{88,91} reproduce the observed singularities on the strain–stress curves of NT of different dimensionality and are in good agreement with the experimental results.^{8,85–89} This makes it possible to point to the development of theoretical foundations of the nanomechanics of nanotubular objects.

Quantum-chemical calculations of electron states were carried out only for certain possible configurations of deformed NT, *e.g.*, for uniform and non-uniform tubular helices (Fig. 11)⁹⁴ both predicted theoretically⁹⁵ and observed using the TEM technique.^{96,97} In addition to hexagons, the walls of helices include various heptagon/pentagon combinations. Helical NT are an extensive class of objects related to toroidal carbon nanostructures.^{8,20,98–102} The topology of helical NT is

Figure 11. Models of helically deformed uniform (C_{360}) (a) and non-uniform (C_{540}) (b) tubular structures.⁹⁴

described^{96,103} using the Kekule structures and the concept of 'phason lines'.¹⁰⁴ Tight-binding calculations⁹⁴ showed that the energy band structure (in particular, the change in the band gap ΔE_g) depends strongly on the topology of the NT helices: an interrelation has been found between the arrangement of the 'phason lines' in the helices and the type of their conductivity.

5. Connection of nanotubulenes

Targeted introduction of topological defects into an NT, *i.e.*, replacement of a part of hexagons in the rolled graphite sheet that forms tubulene walls by other polygons (heptagons or pentagons) can change substantially its electronic properties. In this case, the theoretically predicted possibility of the formation of heterojunctions based on NT^{6,8} opens wide prospects for using carbon NT as the elements of integrated circuits of uniquely small size.

This situation can be considered from the viewpoint of longitudinal connection of two different tubulenes in which heptagons, pentagons, and their various combinations play a determining role in the formation of matched structures of NT (Fig. 12), thus opening new possibilities of producing electronic n – p transitions.

Figure 12. Variants of longitudinal connection of 'zigzag' carbon tubulenes; (a) (12, 0)/(9, 0)- and (b) (12, 0)/(8, 0)-tubulenes. Carbon atoms participating in the formation of heptagons and pentagons in the structure of intertubular connectors are shown as bold solid circles.

It should be noted that the above-mentioned polygons (pentagons and heptagons) can be constituents of the ends of 'open' nanotubes and impart to them a conical shape of variable conicity, which can become of great importance for the development of nanoscale electron-emitting devices based on NT.¹⁰⁵

Different types of matching and the properties of carbon NT of different diameter involving a heptagon–pentagon pair were simulated by the TB method taking (12, 0)/(9, 0)- and (12, 0)/(8, 0)-tubulenes as examples (see Fig. 12).¹⁰⁶ According to calculations performed taking into account only π -states, there are delocalised states for each of the tubulenes and localised states corresponding to open ends of NT ('dangling' bonds) in the spectrum of the entire system. The estimates¹⁰⁶ of the dependence of conducting properties on the voltage applied (U) showed that the current I increases as U increases for matched (12, 0)/(9, 0)-nanotubes with metallic type of conductivity and that oscillations corresponding to resonances of tunnelling probability between the two NT are observed on the current *vs.* voltage plot. The conductivity of the system of connected metallic (12, 0)- and semiconducting (8, 0)-nanotubes will be determined by the contribution from the (12, 0)-tubulene to the region near the Fermi level in the spectrum of the entire system.

A more detailed consideration of the EES of carbon NT with variable number of topological defects (pentagon–heptagon pairs, or 5/7-defects) of the wall surfaces of 'zigzag' (n , 0)-tubu-

lenes was carried out.¹⁰⁷ A system of (12, 0), (11, 0), and (9, 0)-nanotubulenes matched in pairs using one, two, and three pentagon–heptagon pairs arranged either along the cylindrical axis or along the cylinder circumference was calculated. The data listed in Table 3 illustrate the change in the energy of NT with topological defects (relative to that of ‘perfect’ tubulenes). As can be seen, in the general case, an axial arrangement of the 5/7-defect is the most energetically favourable. Even more energetically favourable is the formation of a specific type of defect in which a pentagon and a heptagon are separated by rings of hexagons (the 5/6/7-defect, see Table 3).

Table 3. Energy changes (relative to the energies of ‘perfect’ tubulenes) for different types of nanotube connection depending on the type of the arrangement of topological defects.

NT system	Number of defects	$\Delta E / \text{eV atom}^{-1}$		
		5/7 defects along the circumference	axial 5/7 defects	specific defect ^a
(12, 0)/(11, 0)	one 5/7	0.132	—	—
(12, 0)/(11, 0)	two 5/7	0.258	0.249	0.208
(12, 0)/(9, 0)	three 5/7	0.405	0.291	—

^a 5/6/7-Defect, see text.

Regularities of the rearrangement of electron states near the Fermi level in the region of hetero-junction can be traced taking a matched (12, 0)/(11, 0) metallic–semiconducting NT with optimised geometry as an example (Fig. 13). On going from the last segment of the (12, 0)-NT to the first segment of the connection structure, the DOS oscillations relative to the DOS ‘plateau’ of isolated (12, 0)-NT are observed near E_F . Similar DOS oscillations of gradually decreasing amplitude are observed when moving further along the connection structure toward the first segment of the (11, 0)-NT. The first segment of the (11, 0)-NT is gapless, which manifests itself as a smooth metal to semiconductor transition. The DOS of the hetero-junction structure approaches those of individual nanotubulenes at a distance of $\pm 20 \text{ \AA}$ from the connection structure on each side of the cylinders.

Figure 13. The electron density of π states (a) and the cross sections (1)–(18) of the intertubular connector structure for the (12, 0)/(11, 0)-NT (b).

6. Nanotubular composites: intercalation of carbon nanotubulenes

Intercalation of NT with atoms of various elements makes it possible to obtain quasi-1D nanomaterials with varied properties. For instance, it is possible to obtain composites by incorporating metal wires into NT. These can be used as nanowires of uniquely small cross section in which the tubulene simultaneously acts as both an insulator and a protective shell (*e.g.*, in oxidation processes). The properties of the components can change substantially upon interaction between the metal nanowire and NT (*e.g.*, new phases of a metal ‘encapsulated’ into the NT can be formed). This interaction can also cause a non-trivial modification of the properties of the entire hetero-system. For instance, its electron-phonon spectra and superconducting properties can be changed appreciably by intercalating the NT with alkali metals (AM), as is observed for fullerenes doped with AM or for intercalated graphite (see, *e.g.*, Ref. 8).

In most of experiments on NT intercalation, multilayered tubulenes of large diameter ($> 100 \text{ \AA}$) were obtained, which were filled (either directly in the synthesis or using the capillary effect) with Mg, Bi, Pb, several transition metals, lanthanides, and their carbides.^{108–117}

These systems are considered in the framework of several computational schemes. Semiempirical MNDO calculations⁵⁷ of ($n, 0$)-tubulenes ($n = 6, 8$) with one or two encapsulated monatomic potassium wires oriented along the cylinder axis were performed using the embedded cyclic cluster model. It was found that the band gaps characteristic of initial NT disappear in the intercalated systems because of the appearance of new $K 4p$ states. As a result, the $K@(n, 0)$ systems are 1D conductors.

A quasi-1D hetero-structure consisting of a carbon nanotube ($R = 3.4 \text{ \AA}$) filled with a Pb nanowire ($r = 2.4 \text{ \AA}$) was considered.⁶⁶ Taking into account the approximations used in the calculations (a numerical method¹¹⁸ was employed), Östling *et al.*⁶⁶ could only suggest that the electron states of the Pb nanowire will hybridise mainly with the near-the-Fermi-level π -states of the tubulene.

More rigorous calculations of (4, 4)-NT intercalated with 1D potassium and aluminum wires were carried out by the *ab initio* pseudopotential method.^{119, 120} It was assumed that the metal wires and the (4, 4)-NT constitute commensurate ‘phases’ and that the interatomic distances in the wires are the same along the whole tube length. For the $K@(n, n)$ -NT system, the energy effect of intercalation (heat of formation) was also calculated depending on the tubulene diameter ($\sim 1 \text{ eV atom}^{-1} \text{ K}^{-1}$).¹¹⁹ The corresponding value for the $Al@(4, 4)$ -NT system was found to be negative¹²⁰ and it was assumed that intercalation of Al into the (4, 4)-NT can occur only in the gas phase under high pressure. Under normal conditions, only carbon nanotubes of large diameter can be intercalated with aluminum.

The results obtained^{119, 120} show that quantum-chemical methods can be effectively used for solving important problems related to search for compositions of nanotubular composites and conditions of their production. Taking into account promising technological applications of these materials, one can expect the development of the material science of this class of substances.

IV. Electronic properties of several non-metal compounds in the nanotubular form

The progress in the synthesis and the study of the properties of carbon NT has initiated investigations on the search for tubular nanostructures of other substances. Hexagonal boron nitride (h-BN), an isoelectronic and isostructural graphite analogue, was proposed^{121, 122} as the first candidate. It should be noted that the syntheses of the nanotubular form of BN and some other boron compounds^{32–38} were performed on the basis of predictions made in the first theoretical studies on their structure and properties.^{121–124}

Based on similarity in the structural and electronic properties of the known 2D boron compounds (h-BN, BC_3 , and BC_2N ^{125, 126}) and graphite, the theoretical approaches successful in calculations on the tubular forms of carbon were used.^{121–124}

1. Boron nitride-based nanotubulenes

Electronic properties of nanotubes based on h-BN were considered.^{121, 122, 127} The dependence of the EES of chiral and achiral (n, m)-NT on their diameters was studied using a simple s, p TB model.¹²² It was found that all the boron nitride nanotubulenes (BNT) considered are semiconductors in which the band gap (ΔE_g) decreases as the tube radius decreases. Chiral (n, m)-NT are less sensitive to variations of the tube radius than ($n, 0$)-NT. In addition, ($n, 0$)-NT are semiconductors with direct gaps ($\Gamma-\Gamma$), whereas (n, m)-NT have indirect band gaps ($\Delta-\Gamma$). Changes in ΔE_g upon varying pitch angles θ are most pronounced for the tubes of small diameter. Nanotubes with $d > 12 \text{ \AA}$ have wide band gaps which depend slightly on θ . The following qualitative explanation can be proposed: in NT of small radii, the number of nonadjacent atoms is larger, and the distances between them appear to be comparable with interlayer separations in h-BN.

MNDO calculations of the electronic properties of ($n, 0$)- and (n, n)-BNT ($n = 6, 7, 10, 12$) were performed.⁵⁷ All NT were referred to dielectrics ($\Delta E_g \approx 4.8 \text{ eV}$). The position of the bottom of the conduction band is determined mainly by boron s, p states, whereas that of the top of the valence band is determined by nitrogen states.

More rigorous LDA calculations¹²¹ of ($n, 0$)- and (n, n)-BNT with diameters in the range from 4.0 to 12.0 $\text{\AA}$ indicate that they are semiconductors with wide band gaps ($\Delta E_g \approx 5.5 \text{ eV}$). Because of this, the dependence of the electronic properties of BNT on their size and structure is less pronounced than in the case of graphite-based tubes. This fact is of importance for the preparation of nanomaterials with preset parameters.

When analysing the bands near the Fermi level, it was found that the states of the bottom of the conduction band are similar to those of ‘quasi-free’ electrons.¹²¹ These states are concentrated in the inner part of the tube (Fig. 14). This peculiarity may have important technological applications in the doping of BNT with electron carriers, which would make it possible to vary their electrophysical properties over a wide range.

Figure 14. The total charge density distribution in the longitudinal section (including nitrogen atoms) (a) and in the cross section (b) of the (6, 6) BNT (LDA calculations).

Interesting results were obtained in the optimisation of the geometry of BNT.¹²¹ It was shown that this tubular structure can be considered as a ‘double-layered’ structure consisting of oppositely charged coaxial cylinders that form a specific quasi-1D dipole. The boron ions constitute the ‘outer’ cylinder, while the nitrogen ions constitute the ‘inner’ one. The ‘intercylinder’ distance depends slightly on the tube chirality and decreases as its diameter increases. The total energy (E_{tot}) of BNT appeared to be lower than that of carbon NT of the corresponding diameter (Fig. 15). Comparison of the total energies of a BNT and an h-BN ‘strip’ obtained upon the ‘development’ of the corresponding cylinder showed that the ‘strip’ form of h-BN is much less stable than its tubular form.

It was established that if the distance between the tube walls in double-layered BNT [e.g., a (4, 4)@(9, 9)-NT] is comparable with

Figure 15. Dependence of the total energy (E_{tot}) on the diameter (d) for carbon (1) and BN (2) nanotubes. The E_{tot} value for a ‘strip’ obtained by ‘developing’ the (6, 0)-BN nanotube (the point 3) is shown.

the interlayer separation in crystalline h-BN, the intertubular interaction has virtually no effect on the structure of electron states of individual NT. Single-layered and multilayered BN tubulenes are stable semiconductors with wide band gaps.¹²¹

Simulation of hetero-structures based on boron nitride tubulenes was first performed by Rubio *et al.*¹²⁸ who considered (4, 4)-BN-tubulenes intercalated with K and Al. It was assumed that, taking into account the peculiarities of the electronic structure of BNT,^{121, 122} the interaction between the metal atoms and the NT walls will be appreciably weaker than for carbon tubulenes. The estimated intercalation energies (the difference between the total energies of the composite and its components, *viz.*, the tubulene and the metallic wire) of these hetero-structures appeared to be much lower than those of analogous systems based on carbon NT. The K 4s states of the K@ (4, 4)-BNT were found to interact with the tubulene band near the Fermi level (Fig. 16). For an Al@ (4, 4)-BNT, it was found that additional Al s and p_z levels

Figure 16. Energy band structures (a)–(d) and charge distributions (e)–(h) for the (4, 4)-BNT and for the composite K@ (4, 4)-BNT and Al@ (4, 4)-BNT.

The energy bands: (a) K@ (4, 4)-BNT; (b) and (c) (4, 4)-BNT for single and double unit cells, respectively; and (d) Al@ (4, 4)-BNT. Charge distributions for the states near the Fermi level are shown for longitudinal sections of the tubes. For the composite Al@ (4, 4)-BNT, the contributions from Al s states are shown by solid lines.

appear in the band gap. The EES of the $\text{Al}@ (4, 4)\text{-BNT}$ appeared to be close to a simple superposition of the spectra of a monatomic Al wire and a (4, 4)-tubulene, which indicates a weak interaction between them. The plots of the charge density distributions for the near-the-Fermi level states in the $\text{K}(\text{Al})@ (4, 4)\text{-BNT}$ (see Fig. 16) show that the density of electron carriers that control the conductivity of intercalated BNT is localised inside the cylinder. This differs these systems from composites based on carbon NT in which the contribution to the conductivity from the tubulene walls dominates. For this reason, BNT can be preferred (as compared to carbon tubulenes) for production of the nanowires with preset properties. The possibility of intercalation of BNT with Ag and Au atoms for production of continuous nanowires¹²⁷ cannot also be ruled out.

2. Boron carbide-based nanotubulenes

Electronic characteristics of some hypothetical $(n, 0)\text{-NT}$ based on layered BC_3 were considered.¹²⁴ The conductivity type changes from metallic to semiconducting as the NT diameter increases. This effect is associated with noticeable deviations of the bond angles (for NT of small diameter) from 120° . With an increase in the NT diameter, the bond angles approach the ideal value for planar sheets (120°), and ΔE_g for NT approaches the band gap of single BC_3 sheets (see, e.g., Refs 125 and 126). The analysis of the DOS distribution for a $\text{BC}_3\text{-tubulene}$ shows that the lowest unfilled bands are composed of π - and π^* -states and the highest filled bands are composed of σ -states. Near the Fermi level, the density of σ -states is considerably higher than that of π -states. It is assumed that the conductivity of a $\text{BC}_3\text{-NT}$ of a fixed diameter can be varied over a wide range upon doping by varying the degree of filling of the energy bands. In this case, ‘metallisation’ of the σ -band, i.e., a decrease in the concentration of electrons, will be a more efficient way of increasing the NT conductivity. Additional holes can appear upon partial replacement of carbon atoms by ‘superstoichiometric’ boron atoms. Atoms of halogens (Cl, Br, I) can also act as hole donors, as is the case for, e.g., intercalated graphite-based compounds.¹²⁴

Strain energies of BC_3 nanotubes were calculated.¹²⁴ The total energies of these tubulenes appeared to be lower than those of graphite-based NT. Further studies of $\text{BC}_3\text{-nanotubes}$ should be carried out taking into account not only single-, but also multi-layered nanotubes, since it is known that the interlayer interaction plays a decisive role in the formation of conducting properties of crystalline BC_3 .¹²⁵

3. Boron carbonitride-based nanotubulenes

Depending on the ordering type of atoms (B, C, N) constituting the layers and on the type of layer-by-layer packing, graphite-like boron carbonitrides can possess either metallic or semiconducting properties.^{125, 126} In addition, the strong ‘intralayer’ anisotropy of charge distributions suggests that circular chiral currents can arise upon rolling the single layers into cylinders. In this case the NT can be considered as nanoscale solenoids.

The geometry of several $(n, n)\text{-BC}_2\text{N}$ nanotubes was calculated by the TB method.¹²³ Nanotubulenes of small diameters ($n = 2$) retain the conductivity type intrinsic in the initial BC_2N single layers.¹²⁵ However, for $(n, m)\text{-NT}$ the change in the conductivity type from metallic to semiconducting is possible depending on their diameters and chirality (like for graphite-based NT). It is assumed that $(n, n)\text{-NT}$ should be the most stable, since their atomic configuration provides the maximum number of the strongest C–C and B–N bonds.

According to Miyamoto *et al.*,¹²³ partial replacement of carbon atoms by ‘extra’ B or N atoms leads to the appearance of donor or acceptor impurity levels, respectively, in the band energy spectrum of carbonitride NT. This occurs due to the increase in the concentration of electrons or holes in $\text{B}_{1-x}\text{C}_{2+x}\text{N}$ or $\text{BC}_{2+x}\text{N}_{1-x}$ nanotubes, respectively. Calculations of chiral currents for doped BC_2N -tubulenes were carried out and the magnitude of induced magnetic field was evaluated.¹²⁹

4. ‘Mixed’ boron carbonitride-based nanotubulenes

Hypothetical ‘mixed’ single-layered NT built of segments of carbon and BN hexagons that alternate either along the tube circumference or along the tube axis are considered as an example of possible quasi-1D systems possessing interesting quantum properties. They were studied by the MNDO method.⁵⁷ The following combinations of packing of carbon and BN hexagons were considered: alternation of C_6 and B_3N_3 ‘belts’[†] along the circumference of a (6, 6)-NT ($k\text{B}_3\text{N}_3 + l\text{C}_6$; $k = 3, 2, 1$; and $l = 1, 2, 3$, respectively) and alternation of strips[†] of hexagons along the tube axis ($k\text{B}_3\text{N}_3 + l\text{C}_6$; $k = 1, 2, 3, 4, 5$; and $l = 5, 4, 3, 2, 1$, respectively). We present here only the most important conclusions.⁵⁷ The introduction of a ‘belt’ or a strip of carbon hexagons substantially reduces ΔE_g of the boron nitride NT. An increase in the number of carbon fragments is accompanied by further decrease in the ΔE_g value. The introduction of ‘belts’ or strips of carbon hexagons between dielectric B_3N_3 ‘belts’ or strips leads to the appearance of additional states in the band gap of the (6, 6)-BN tubulene, with the major contribution from the ‘frontier’ atoms of contacting different strips or ‘belts’. For a ‘belt’ structure of mixed tubulenes, the contribution of carbon states to the bands near the Fermi level dominates, thus controlling the conducting and magnetic properties of the C_6 ‘belts’.

5. On the possible existence of nanotubular forms of boron

The results of calculations^{43, 130–134} of elemental boron clusters have led to unexpected and non-trivial conclusions about possible directions of structural evolution of isolated boron microparticles upon their aggregation into larger associates.

Calculations^{43, 130–134} were carried out using the Hartree–Fock methods with different basis sets (STO-3G, 3-21G, and SCF/DZ) and the local electron density functional method. The energy band structure was calculated for boron clusters with optimised geometry. A large number of topologically different B_n forms (starting from B_7) was designed. Three main possible types of their structural evolution were revealed, which lead to the formation of stable forms of boron clusters: (1) three-dimensional (3D) due to the growth of individual fragments of the structure of crystalline boron; (2) convex clusters (segments of a sphere or a cylinder); and (3) quasi-planar clusters.¹²⁶

Nanotubes can also be formed in the bulk of α -boron quasi-crystals.^{132, 133} This follows from calculations of possible local structural transformations in the bulk of an α -boron quasi-crystal with a ‘compressed’ rhombohedral unit cell for one of its fragments, viz., joined B_{12} icosahedra, lying on the minor diagonal of the rhombohedron. The structure of the B_{24} group changes substantially in the course of optimisation. The stages of structural evolution of the B_{24} fragment are illustrated in Fig. 17. ‘Diffusion’ of the boron atoms located between the B_{12} icosahedra leads to the formation of a closed pseudotubular group (see

Figure 17. Structural evolution of the B_{24} fragment in the bulk of rhombohedral α -boron quasi-crystal in the course of geometry optimisation.

[†] According to terminology used in Ref. 57, a ‘belt’ is a tube segment ‘cut’ perpendicular to the tube axis, whereas a ‘strip’ is ‘cut’ along the tube axis.

Fig. 17 *c*), which can become a ‘protoform’ of extended nanotubular boron structures.

It was emphasised^{43, 132–134} that the structure and properties of proposed nanostructural forms of elemental boron (including a nanotubular form of boron) can differ fundamentally in the presence of impurities of other elements (*e.g.*, carbon, nitrogen, silicon, *etc.*). However, neither detailed studies along this line nor calculations of the electronic structure of the nanotubular form of boron have been carried out so far.

V. Theoretical models of the growth and morphology of nanotubes

One of the fundamental challenges of theoretical investigations is to describe the nature, the kinetics of nucleation and growth, and the morphology of nanotubular structures on the microscopic level.

Thermodynamic aspects of the formation of tubular and spheroidal carbon structures have been discussed.^{8, 11, 14} It was emphasised^{135, 136} that a symmetry axis determining the direction of the structure growth is required in the reaction zone in order to form tubulenes. In the synthesis of cylindrical structures, such a direction can be specified, *e.g.*, by a beam of accelerated carbon ions^{135, 136} or catalysts.⁸

The most widely used method for the NT synthesis is their growth in an electric arc discharge apparatus between graphite electrodes in the presence of various catalysts. It is not possible, in the present state-of-the-art in the field of NT synthesis, to control their size and chirality exactly. Along with NT (or NT bundles whose diameters vary over a wide range), the end product contains fullerenes, other nanoparticles, and soot.^{8, 11, 14, 135–138}

The nature and mechanism of NT growth became the subject of discussion in the first studies in which the preparation of NT was reported.⁸ Fullerene hemispheres were considered to be precursors,^{18, 19, 139, 140} and the growth of tube walls was explained by successive addition of C₂ dimers to the carbon atoms at the hemisphere circumference.

Yet another type of mechanism of SNT growth involving cyclic structures as precursors was proposed.¹⁴¹ These structures were found in the studies of laser ablation of graphite.^{142–144} The most typical structures of C_n species (10 ≤ *n* ≤ 40) are planar cyclic structures,^{143–145} whereas spheroidal structures are formed at *n* > 40. Two mechanisms of growth of the structures built of carbon rings were suggested,¹⁴¹ *viz.*, the formation of either a fullerene or an NT. According to the model proposed by Kiang and Goddard,¹⁴¹ tubular structures are formed due to the presence of catalysts that activate the process.¹³⁸

The model of NT growth from a nucleus (a carbon ring) is illustrated in Fig. 18. In the first stage, a planar ring is distorted in arc plasma in the presence of a catalyst (*e.g.*, cobalt carbide, Co_mC_n) to adopt a *cis*- or a *trans*-form analogously to crystalline carbyne rings.¹⁴⁶ The *cis*-form of the ring can act as a precursor in the synthesis of achiral NT by addition of C₂ dimers. The *trans*-form of the carbon ring may give rise to a larger number of cylindrical structures. The formation of the NT geometry occurs without involving the catalyst species.¹⁴¹

In other models of NT growth, the primary emphasis is placed on the role of the substrate and the catalyst. A phenomenological model of mechanism of SNT growth on diamond-like crystallites was proposed.¹⁴⁷ The (111) type of the surface was considered and it was found that the prerequisite for the beginning of the process is the presence of a nanoscale surface defect, *e.g.*, an atom of another element that ‘shades’ one of the carbon atoms of the upper monatomic layer. A ‘nanoisland’ that formed is surrounded along its circumference by carbon atoms that have free bonds oriented normal to the surface and interact with the ions in the vapour phase. The ions that precipitate form a ring, an NT ‘root’ capable of further independent growth. The formation of the first layer according to the model proposed by Chernozatonskii¹⁴⁷ is

Figure 18. A model of the formation of seeds of nanotubular structures based on cyclic structures: (a) initial planar ring; (b) local deformation involving the planar ring with the formation of *cis*- and *trans*-forms; (c) nucleation of an achiral nanotube based on the *cis*-form; (d) nucleation of an achiral nanotube based on the *trans*-form; and (e), (f) nucleation of chiral nanotubes based on the *trans*-form.

depicted schematically in Fig. 19 taking a (6, 0)-NT as an example.

The above-mentioned model¹⁴⁷ is versatile and provides a qualitative explanation for the NT growth under any conditions of their synthesis. An important point is that the size of the nucleus (a surface defect) or that of metal particles (catalysts) should be smaller than the characteristic diameter of the SNT. Then, taking into account that each preceding carbon atom interacts with the ‘surface’ states of the nanostructure to form its own ‘free’ bond and becomes an active adsorption centre for the succeeding atom, the process can be interpreted simply.¹⁴⁸

In the case of metal particles whose size is larger than the characteristic SNT diameter, a carbon (carbide) layer is formed on the surface in the first stage of precipitation, which is then followed by growth of the SNT nuclei (roots). For several metals (*e.g.*, lanthanides) it was found^{8, 149, 150} that, depending on the surface morphology, SNT can grow in the form of compact bundles radiating from the nucleus. In this case it is assumed that nanoscale inhomogeneities (protrusions) of the surface of metal grains play the role of ‘active nuclei’ in the formation of SNT roots.

Figure 19. A scheme of the formation of the (6, 0)-NT on the diamond (111) surface. The substrate atoms (1), the tube ‘root’ atoms (2) surrounding the surface atom (3) ‘shaded’ by a univalent ion (4), and the atoms of tubulene walls (5) are shown. The surface (A) and near-surface (B), (C) atomic layers are shown.

A microscopic model of growth of carbon NT on the surface of a metal catalyst was developed.¹⁵¹ The process on a planar metal surface covered with a hexagonal network of carbon atoms formed upon primary precipitation was considered. Special emphasis was placed on the energy effects upon the rearrangement of the initial layer geometry in the region of curving the elementary polygons that form the SNT base (Fig. 20). It was shown that such a rearrangement results in the formation of pentagons and heptagons. The carbon atoms that precipitated successively on the metal carbide surface migrate toward the SNT base to form 'belts' of hexagons constituting the SNT stem. This provides the possibility for the tube wall surrounding the protrusion on the substrate surface to grow. The model¹⁵¹ makes it also possible to explain why multilayered NT do not grow.

Figure 20. A scheme of growth of single-layered carbon nanotube on a protrusion (1) of a surface layer (2) of a metal catalyst. (A)–(E) are characteristic positions of carbon atoms migrating from the SNT base toward its stem (according to the model by Maiti *et al.*¹⁵¹).

Starting from the first study by Iijima,⁹ the MNT were considered as a system of ideal coaxial cylinders formed by rolled graphitic sheets. The conditions of the MNT growth depending on the substrate (diamond) structure were considered.¹⁴⁷ It was argued that the presence of the (111) crystallite terraces is a prerequisite for the MNT growth. In this case, 'nucleation ring seeds' consisting of the atoms separated from one another by a distance of several Angström can be distinguished. It has been pointed out that the MNT growth can give rise to intercylindrical interactions and narrowing of the walls of individual NT. As a result, the MNT can be 'shrunk' into cones,¹⁵² thus forming a peculiar kind of 'graphite caps' that close the protrusions of diamond crystallites.

Mention may be made of yet another structural model of a 'quasi-tubular' form of carbon. The conditions under which 'hangars' (multilayer 'arches' of graphene sheets 'resting' on the substrate surface) are formed have been discussed.¹⁴⁷ There are open 'hangars' and those closed at the ends with truncated spheroidal structures.

A growth model of conical multilayered tubular structures was proposed¹⁵³ and the possibility of the formation of a helical MNT structure was considered.^{154,155} Successive stages of the growth of helical MNT are shown in Fig. 21. The NT nucleus was assumed to consist of a fullerene hemisphere formed at the substrate surface. Depending on the type of the hemisphere cross section, the 'primary' tube stem can grow in different ways. Ideally, this is a right circular cylinder;¹⁵³ however, if the tube base contains pentagons (a 'zigzag' C₆₀ cross section), the NT walls can be tilted with respect to the normal to the surface. The first tube type and the corresponding energy of interaction between the pair of graphitic sheets clearly defines the nucleation template (achiral or chiral) of the graphite layer of the next tube walls. The structure of the third sheet (the outer one with respect to the first and second sheets) is not unambiguously defined. This allows mutual reorientations of the system of coaxial tubes (*e.g.*, rotations about a common axis). Effects of NT sliding over one another in MNT have been discussed.⁸

Figure 21. The major stages of growth of helical NT (a)–(f).¹⁵³ (1)–(3) graphitic layers in the cross sections of corresponding structures; the edges of dislocations are shown. Arrows indicate the direction of MNT growth.

The increase in the number of graphitic sheets (see Fig. 21) can lead to the formation of lateral dislocations that are considered as energy stabiliser of the system.¹⁵³ As a result, the MNT structure is transformed into a helical one and the MNT grows by building up a helix rather than by nucleating the next graphitic sheet. It is of importance that a pair of lateral dislocations of opposite signs should be present in each helical nanotube.

The presence of dislocations will lead to some increase in the tube volume. The MNT growth is terminated when dislocations become oriented parallel to the tube axis.¹⁵³

The authors of the above-mentioned models of MNT growth used qualitative ideas of a specific type of interatomic interactions in the systems in question. Kwon *et al.*¹⁵⁶ studied growth conditions, morphology, and stability of achiral double-layered (5, 5)@(10, 10)- and (9, 0)@(18, 0)-tubulenes consisting of coaxial cylinders with respectively 'arm-chair' and 'zigzag' edges by performing rigorous *ab initio* calculations in the framework of the electron density functional formalism (a cluster model with geometry optimisation according to the DMol version).

During the NT growth process, adatoms can either build up the open end of either tube or connect these ends to become bridging atoms (see respectively configurations 1 and 2, 3 in Fig. 22). For each of the configurations considered, *ab initio* calculations of energy parameters and electronic structure were carried out. The tube growth was analysed with an increment of 10 extra atoms arranged as described above. Relaxation effects were taken into account by the MD method.

Let us illustrate the results of calculations¹⁵⁶ taking a double-layered (5, 5)@(10, 10)-MNT as an example. Placing extra carbon atoms exactly on the tube edges leads to the formation of a system of 'dangling' bonds. However, in this case the cohesive energies of MNT remain virtually unchanged. For bridging atoms, the

Figure 22. Cross (a) and longitudinal (b) section of possible growth structures (1)–(3) of a two-layer (5, 5)@(10, 10)-NT.¹⁵⁶

situation is markedly different. For a fully optimised structure, the energy gain per each extra atom is rather large ($\Delta E \simeq 0.42$ eV), which confirms the assumption¹⁵⁸ of stabilising contribution of ‘lip-lip’ interactions between the walls of neighbouring tubes to the total energy of the system. The stabilising effect of bridging atoms depends on their distance from the tube interior and on the type of the polygons formed by these bridging atoms and the atoms of tube walls in the NT cross section. Thus, the configuration 3 in Fig. 22 is unstable ($\Delta E \simeq -3.52$ eV). Analogous conclusions can be drawn from the analysis of the (9, 0)@(18, 0)-MNT. The optimum NT morphology is determined by a combination of the above-mentioned factors.

Ab initio studies of MNT growth and termination depending on the number of extra atoms have also been carried out.¹⁵⁶ The main parameter used in the case of a growing cylindrical MNT was the degree of the edge coverage

$$\varepsilon = \frac{N}{N_a},$$

where N is the total number of carbon atoms on the tube edge and N_a is the number of added (extra) atoms. Then the energy parameter was calculated as a function of ε

$$E_c = \frac{E_{\text{tot}}(C_N) - NE_{\text{tot}}(C_\infty)}{N_a},$$

where $E_{\text{tot}}(C_N)$ is the total energy of the truncated NT of a given length and $E_{\text{tot}}(C_\infty)$ is the total energy of an infinite tube.[‡] It was assumed that NT growth is favoured to the greatest extent at a minimum E_c value that can be achieved at a certain concentration and for particular configurations of adatoms on the tube edge when the ‘growing’ tube has a minimum energy as compared to the ‘end reaction product’, a perfect infinite MNT.

The results of calculations for a (5, 5)@(10, 10)-NT are shown in Fig. 23. Stabilisation of the structure is at $\varepsilon = 2/3$. The ‘lip-lip’ interactions play an important role in the structure stabilisation. Stable structures of MNT growth contain carbon hexagons and pentagons, but no squares or triangles. In the range $0 < \varepsilon \leq 2$, the initial tube growth is simulated. The interval $2 < \varepsilon \leq 4.5$ corresponds to an ‘intense edge coverage’ of the tubulene. Changes in the relative energies of dome closure, which terminates the process of nanotube growth, are also shown. The simplest types of the domes for closing the inner and outer tubes of the (5, 5)@(10, 10)-NT are hemispheres of the C_{60} and C_{240} fullerenes, respectively. To form closed noninteracting domes, the degree of the edge coverage should lie in the range $8/3 < \varepsilon < 14/3$.

Figure 23. Dependence of the energy (E) of edge groups of the (5, 5)@(10, 10)-NT on the number of adatoms ε (see text). The interval $0 < \varepsilon \leq 2$ corresponds to the MNT growth; curves (1)–(3) in the region $2 < \varepsilon \leq 4.6$ describe how E changes for continuous NT growth (1) and for the dome closure of the nanotube without (2) and with (3) account of ‘lip-lip’ interactions.¹⁵⁶

The mechanism of double-layered NT growth and conditions of its termination¹⁵⁶ can be extended to MNT with any number of layers. However, problems can arise in the case of odd-walled

MNT. It is much more difficult to determine optimum conditions of the saturation of ‘dangling bonds’ in this case. Probably, MNT with an odd number of layers are less stable. This is indirectly confirmed by larger abundance of MNT with an even number of layers.¹⁵⁸ At the same time, the proposed growth mechanism can be corrected to a certain extent for the presence of ‘passivating’ elements as impurities (‘covalent spot welds’) capable of saturating one or several free (‘dangling’) bonds of the carbon atoms of outer cylinders.

VI. Nanotube crystals

Nanotube crystals (NTC) are regular 3D structures formed by individual NT.

To date, theoretical models of crystalline nanotubular forms of matter and predictions of their characteristics have been reported only for certain possible crystalline forms of nanotubular carbon. It was suggested that NTC be considered as a new phase of crystalline carbon with quasi-one-dimensional, strongly anisotropic properties.

Progress in the synthesis of single-layered NT and, in particular, the possibility of producing NT of most plausible diameters^{6,8} under specified conditions of plasmachemical process provides an experimental basis for performing theoretical studies. Production of compact nanotubular associates, e.g., NT bundles and ropes, as well as nanotube films with regular arrangement of individual cylinders has been reported.^{6,8,159–169}

Let us consider the main lines of theoretical investigations of nanotube crystals.

1. Intertubular interactions in nanotube crystals

In the studies of NT packed into regular 3D structures, the problem arises of establishing the form of their packing and the nature of interaction between individual NT, and of determining the energy effect of this process. It is assumed^{166,167} that the intertubular bonding is due to the van der Waals interactions (as is the case, e.g., for fullerenes⁸).

Optimum ways of packing individual NT into a periodic 3D structure were studied.¹⁶⁸ Nanotube crystals formed by (6, 6)-nanotubulenes with parallel cylindrical axes were calculated. Depending on the type of mutual arrangement of individual NT in the nanotube crystal, a tetragonal and a hexagonal unit cell was investigated. In the latter case, calculations were performed for two types of packing of single-layered NT, which correspond to the hypothetical graphite *AAA...* stacking and to the conventional graphite *ABAB...* stacking.

It was found that the system in which carbon atoms of neighbouring tubes are packed similarly to graphite *ABAB...* stacks is the most stable (Fig. 24). In addition, the ‘intertubular’

Figure 24. Dependence of the cohesive energy of an NTC formed by (6, 0)-NT on the distance (l) between individual NT for tetragonal (1) and hexagonal (2), (3) unit cells. Type of the NT packing in hexagonal unit cells: (*AAA...*) (2), and (*ABAB...*) (3).

[‡] An idealised model of a quasi-1D structure is an infinite tube.

cohesive energy E_{coh} in NTC ($9.76 \text{ meV atom}^{-1}$) is lower than the interlayer energy in graphite (20 meV atom^{-1})¹⁷⁰ and comparable with the energies of intercluster interactions in condensed fullerenes ($\sim 10 \text{ meV atom}^{-1}$). It can be assumed that the conditions of the formation of 3D NTC from tubes of different diameters control the degree of close packing of individual NT and the possibility of the *AB* type of packing of the carbon atoms in neighbouring tubes. Any violation of the optimum combination of these factors will lead to destruction of crystal structure and to orientational disorder in the NT arrangement.

The energy band structure of a hexagonal carbon NTC is characteristic of a mixed 1D–3D electronic system.¹⁶⁸ The main dispersive effects are due to ‘intratubular’ interactions; at the same time, intertubular interactions also make a noticeable contribution. The NTC analysed possess a metallic type of conductivity, which means that packing of individual (6, 6)-NT into a crystal does not change the nature of their conductivity.

2. Radial deformations of nanotubulenes in crystals

Charlier *et al.*¹⁶⁸ considered an NTC in which the shape of NT constituting the crystal was assumed to be preset and unchanged upon packing into the 3D structure. The problem of possible deformations of SNT in the interaction was posed.^{8, 166, 167}

The original concepts of the effect of the interaction between two NT on their cross section geometry were developed by Ruoff *et al.*¹⁶⁶ who calculated structural deformations for a pair of nanotubes using a many-body interaction model. It was established that, first, the walls of neighbouring NT become ‘flattened’ so that the respective regions of NT reproduce the geometry of planar graphite sheets (which corresponds to a maximum interaction energy) and, second, the intertubular volume is decreased (Fig. 25). It was also pointed out¹⁶⁶ that the degree of deformation depends strongly on the NT diameter and increases as the diameter increases.

Figure 25. Radial deformations of a pair of contacting NT upon their interaction (a) and the charge density ρ distribution (b).

The above-mentioned peculiarities of deformation of two individual cylinders upon their packing into a 3D structure are clearly illustrated in Fig. 26. The principles of calculations of structural distortions for a pair of contacting cylinders¹⁶⁶ were extended to 3D NTC.¹⁶⁷ In Fig. 26, one can clearly see the formation of a ‘honeycomb’ structure of the NTC cross section with gradual transformation of the cross sections of cylindrical NT into those of hexagonal prisms as the tube diameter increases. In the framework of the model used,¹⁶⁷ the ‘flattening’ effects of NT walls are detected starting from $d \approx 15 \text{ \AA}$.

These structural deformations will play an important role in the formation of cohesive and elastic properties of NTC. In the general case, one can expect that the increase in the NT diameter

Figure 26. NT deformations in the NTC as a function of tubulene diameter; (a) $d = 10 \text{ \AA}$; (b) $d = 40 \text{ \AA}$; and (c) hexagonal distortions of a nanotube cross section in the crystal with an increase in the NT diameter (for an NT with $d = 10, 15, 20, 30$, and $40 \text{ \AA}$). The points correspond to the carbon atoms in the NT cross section.

will be accompanied by weakening of interparticle interactions (in the *XY* plane of the NTC) and reduction of its 2D cohesive characteristics. According to calculations,¹⁶⁷ the dependence of the cohesive energy and the modulus of elasticity on the NT diameter is noticeably nonmonotonic (Fig. 27). The formation of a ‘honeycomb’ structure imparts an anomalous hardness to the NTC that is maintained upon further increase in the diameter (starting from $d \approx 25 \text{ \AA}$) of NT constituting the crystal. It is suggested that NTC be divided arbitrarily into two groups with ‘small’ (or ‘large’) diameters of NT constituting the crystal, possessing respectively a nonmonotonic and a monotonic dependence of the cohesive energy on the NT diameter. Presumably, these groups of NTC will have substantially different physicochemical properties and will respond differently to the effects of doping (*e.g.*, upon introduction of alkali metal ions into intertubular channels) upon the formation of composites, *etc.*

Figure 27. Dependence of the cohesive energy (E_{coh}) (a) and the modulus of elasticity (M) (b) for a nanotube crystal on the diameter (d) of nanotubes constituting the NTC. Filled circles correspond to analytical extrapolation of the results of calculations of NTC consisting of nanotubes of small diameter.

3. Hetero-junctions in nanotube crystals

In the formation of 3D structures of regularly packed NT it may happen that the geometric and electronic parameters of a pair of neighbouring NT are different or an NTC contains the domains consisting of different NT. It is obvious that in this case one can suggest the existence of ‘interphase domains’ (or ‘interface domains’) between nanotube ‘polycrystals’. Chico *et al.*⁷⁰ considered hetero-junctions in pairs of (12, 0)/(6, 6)- and (9, 0)/(6, 3)-NT and possible differences in electronic properties between the ‘interphase domain’ and the NT constituents using Green’s functions formalism. This study can be considered as the first attempt to describe the above-mentioned systems by semiempirical quantum-chemical methods.

The development of the ideas of condensed regular nanotubular forms of matter as 3D periodic structures, *viz.*, nanotube crystals, makes it possible to consider these solids taking into account all factors determining the ‘composition–structure–properties’ interrelations inherent in all ‘conventional’ solids.

Assuming that isolated nanotubes whose properties can be varied over a wide range can be considered as ‘structural elements’

of NTC, one can accept the idea of a defect (impurity, vacancy) structure of NTC and consider the order–disorder problem therein. Such an approach makes it possible to consider NTC in the context of general problems of the description of specific properties of crystals (including electronic ones) and to pose the problems of surface states of NTC, interfaces between nanotube polycrystals, etc.

The above-mentioned lines of the development of the ideas concerning fundamental properties of NTC are still in a primitive state even for carbon NTC. One can expect that they will be useful for the development of the problems of quantum materials science and their application to NTC forms of other substances including those considered in this review.

VII. Conclusion

The discovery of the nanotubular form of matter was one of the major achievements of physical chemistry in the last decade. Unique properties of nanotubulenes offer extremely attractive prospects of their use in technology and are of considerable interest for fundamental research.

Only the principal results of the studies of electronic structure of NT by methods of solid state quantum chemistry have been covered in this review. The most considerable progress has been achieved in the studies of single-layered isolated nanotubes and prediction of their properties.

Recent studies on the synthesis of NT and nanotubular materials^{171–174} are intimately associated with the development of theoretical models. One of the most important theoretical problems is to describe the ‘life cycle’ of tubulenes (nucleation–growth–disintegration). Currently, considerable interest is demonstrated in ‘intermediate’ nanoscale forms (barrellenes,^{175–177} onions,¹⁷⁸ calabashes,¹⁷⁹ and other nanoscale structures and mesostructures^{180,181}) which can act as intermediates in the formation or disintegration of NT.¹⁸²

Topical are investigations of various nanotubular structures (tori,^{183–185} cones,¹⁸⁶ nanotubes with negative Gaussian curvature,¹⁸⁷ quasi-2D NT associates, and nanotubular layers and films^{188–191}), nanotubular superstructures,^{191–194} and ‘mixed’ nanoscale forms and composites (e.g., NT-fullerene,¹⁹⁵ amorphous nanotubular carbon¹⁹⁶) which can possess unusual properties.

The theory of adsorptive, capillary, electromagnetic, catalytic, mechanical, and other properties of NT that are of interest for researchers in the field of materials science is in the early stage.

The problem of whether the nanotubular form of matter is a universal form for the whole known diversity of inorganic substances or are there certain physical or chemical criteria clearly reducing the number of potential objects whose nanotubular forms can be obtained under certain (which?) conditions, is a basic problem which remains open so far.

The solution of the above-mentioned problems is one of the priorities in the quantum chemistry of nanotubulenes. It provides a basis for the development of the tubulene materials science, thus favouring their effective use in nanoscale electronics, in instruments and chemical engineering, and in other areas.

Abstract. The review surveys data on over 200 crystal and molecular structures of metal halide complexes with oxygen-containing crown ethers. The major types of the complexes are distinguished. The characteristic features of formation of these complexes and their coordination fragments are discussed. The bibliography includes 143 references.

I. Introduction

Structural aspects of the chemistry of macrocyclic polyether complexes with metal salts have been discussed in several reviews and monographs (see, for example, Refs 1–3). These data were most completely surveyed in the monograph² containing a bibliography up to 1989. In succeeding years, a large number of publications have been devoted to structural studies of crown compounds with metal halides prepared from organic media, including those devoid of water molecules, along with studies of salts of alkali and alkaline-earth metals (which comprise the major body of structural data throughout the period of studies of these compounds). The results obtained confirmed on the whole the existence of several structural types of crown complexes, which were suggested for the first time by Dalley⁴ and more recently by Poonia.⁵ The first group comprises complexes in which all the oxygen atoms of the crown ether (CE) molecule are coordinated to the metal atom, which is located within or outside the CE cavity (type A). The second group includes complexes in which only some of the oxygen atoms are involved in the coordination sphere of the metal atom (type B). The third group contains complexes in which the metal atom is located outside the cavity of the crown ether and is not directly bound to the oxygen atoms of the CE molecule (type C). Finally, complexes of the ‘half-sandwich’ type in which the metal atom deviates substantially from the mean

plane through the oxygen atoms of the CE molecule (type D) are documented.

The structural classification of crown compounds has been based on CE as such.^{2,3} At that time, this was quite reasonable because the data on structurally characterised crown ethers were scarce in the literature. Presently, it seems difficult to use this classification. In the present review, we consider structural features and compositions of crown compounds with metals in the order of increasing atomic numbers. We deliberately exclude CE complexes with sodium halides and with halides of the heaviest alkali metals from consideration since their structures are rather trivial and have been reported many times.

II. Systems with halides of the first-row elements

1. Lithium halides

The reaction of anhydrous lithium chloride with 12-crown-4 (12C4) afforded a molecular complex with composition $[(\text{LiCl}) \cdot (12\text{C}4)]$ (**1**).⁶ The lithium atom is coordinated by the chlorine atom ($\text{Li}-\text{Cl} = 2.290 \text{ \AA}$) and four oxygen atoms ($\text{Li}-\text{O} = 2.128 \text{ \AA}$) and deviates from the mean plane through the oxygen atoms by $0.929 \text{ \AA}$ (Fig. 1).

Received 22 May 1998

Uspekhi Khimii **68** (2) 136–153 (1999); translated by T N Safonova

The reaction of lithium chloride dihydrate with 18-crown-6 (18C6) in dry diethyl ether gave a molecular binuclear complex with composition $[(\text{H}_2\text{O})_2 \cdot (\text{LiCl})_2 \cdot (18\text{C}6)]$ (**2**).⁷ Therefore, the CE molecule with a large inner cavity serves as a ‘host’ simultaneously for two lithium atoms. The coordination environment about each lithium atom is a strongly distorted tetrahedron formed by two oxygen atoms of the polyether, one oxygen atom of the water molecule and one chlorine atom. This coordination

results in small five-membered rings with the following distances: $\text{Li}-\text{O}_{\text{cr}} = 1.980$ and $2.065 \text{ \AA}$, $\text{Li}-\text{O}_{\text{w}} = 1.865 \text{ \AA}$ and $\text{Li}-\text{Cl} = 2.277 \text{ \AA}$ (Fig. 2). The five-membered metallocycles in complex **2** adopt an envelope conformation.

Figure 2. Structure of the complex **2**.

By contrast, this reaction in a typical solvent, which have not been dehydrated,⁸ gave structurally different ionic complexes with compositions $\{[(\text{Li})_2 \cdot (\text{H}_2\text{O})_4 \cdot (18\text{C}6)]^{2+} + 2\text{X}^-\}$, where $\text{X} = \text{Cl}$ (**3**) or Br (**4**), with a unique structure. In these compounds, two lithium atoms are also 'guests' but they are arranged nonsymmetrically with respect to the centre of the CE molecule. Both cations have a trigonal-bipyramidal environment (Fig. 3), one of them being coordinated by three oxygen atoms of the ether molecule and two oxygen atoms of water molecules, while the second cation, on the contrary, being coordinated by two oxygen atoms of the ether molecule and three oxygen atoms of water molecules. The bipyramids are linked to each other through a shared vertex formed by the bridging oxygen atoms. The $\text{Li}-\text{O}_{\text{cr}}$ bond lengths vary from 1.88 to $2.12 \text{ \AA}$ and the $\text{Li}-\text{O}_{\text{w}}$ bond lengths are in the range 1.90 to $2.00 \text{ \AA}$. In the crystal structure, an extensive three-dimensional network of $\text{OH} \cdots \text{O}$ and $\text{OH} \cdots \text{X}$ intermolecular hydrogen bonds exists.

Figure 3. Structure of the cation in the complex **3**.

2. Beryllium chloride

Only one complex of BeCl_2 with crown ethers, *viz.*, $[(\text{BeCl}_2) \cdot (15\text{C}5)]$ (**5**), which was prepared by the reaction of anhydrous beryllium chloride with the polyether in anhydrous diethyl ether, was structurally characterised.⁹ In this complex, the beryllium atom retains the typical tetrahedral coordination formed by two oxygen atoms of the crown ether molecule

Figure 4. Structure of the complex **5**.

($\text{Be}-\text{O}_{\text{cr}} = 1.64$ and $1.73 \text{ \AA}$) and two chlorine atoms ($\text{Be}-\text{Cl} = 1.88$ and $2.0 \text{ \AA}$) (Fig. 4). Therefore, complex **5** is a typical representative of type B compounds. The bond angles in the O_2BeCl_2 tetrahedron vary from 90 to 118° , which is associated with steric hindrances due to coordination of two closely arranged oxygen atoms of the polyether.

3. Boron trifluoride

Presently, two complexes of BF_3 with 18C6, which have been prepared by the reaction of boron trifluoride etherate with the polyether, are known, *viz.*, the complex with composition $\{[(\text{BF}_3) \cdot (\text{OH}_2)] + (18\text{C}6)\}$ (**6**) solvated with toluene¹⁰ and the complex $\{2[(\text{BF}_3) \cdot (\text{H}_2\text{O})] + (18\text{C}6) + (\text{H}_2\text{O})_2\}$ (**7**) obtained when BF_3 and CE were taken in a 2 : 1 ratio.¹¹ Both compounds belong to type C complexes because the tetrahedral boron-containing fragments interact with the CE molecule through hydrogen bonds between the coordinated water molecules and the oxygen atoms of the crown ether molecule. In structure **6**, only two oxygen atoms of the ether molecule are involved in 'guest–host' interactions, while in structure **7** all six oxygen atoms of the ether molecule participate in these interactions.

The reaction of the complex $\text{BF}_3 \cdot \text{Et}_2\text{O}$ with dicyclohexyl-18-crown-6 (DCHex18C6) in the presence of atmospheric moisture¹¹ afforded a product with composition $\{[(\text{BF}_3) \cdot (\text{H}_2\text{O})_2] + (\text{DCHex}18\text{C}6)\}$ with intramolecular H-bonds analogous to those observed in structure **7**.

III. Systems with halides of the second-row elements

1. Magnesium chlorides

In the compound $\{[(\text{Mg}) \cdot (\text{H}_2\text{O})_6]^{2+} + (12\text{C}4) + 2\text{Cl}^-\}$ (**8**) (Fig. 5), which was prepared by the reaction of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ with 12C4, the metal atom is not involved in direct bonding with the oxygen atoms of the CE molecule.¹² Hence, this complex should be assigned to type C. In the crystal structure of **8**, the $[(\text{Mg}) \cdot (\text{H}_2\text{O})_6]$ octahedra, the CE molecules and the chloride ions are linked to each other through a complex system of $\text{OH} \cdots \text{O}$ and $\text{OH} \cdots \text{Cl}$ hydrogen bonds. The $\text{Mg}-\text{O}_{\text{w}}$ distances in the cation vary from 2.052 to $2.082 \text{ \AA}$.

Figure 5. Structure of the complex **8**.

The reactions of slightly hydrated magnesium chloride with 15C5 in acetonitrile or chloroform gave related compounds with compositions $\{[(\text{H}_2\text{O}) \cdot (\text{MgCl}) \cdot (15\text{C}5)]^+ + \text{Cl}^-\} \cdot (\text{L})$, where $\text{L} = \text{CH}_3\text{CN}$ (**9**) or CHCl_3 (**10**), respectively. The magnesium atom is located in the cavity of the CE molecule (type A complex) and has a pentagonal-bipyramidal coordination.¹³ Five oxygen atoms of the crown ether molecule occupy the equatorial plane of the polyhedron ($\text{Mg}-\text{O}_{\text{cr}} = 2.11$ – $2.23 \text{ \AA}$). The water molecules ($\text{Mg}-\text{O}_{\text{w}} = 2.05$ and $2.06 \text{ \AA}$) and the chlorine atoms ($\text{Mg}-\text{Cl} = 2.42$ and $2.44 \text{ \AA}$) are located in the apical positions (Fig. 6). The coordinated water molecule forms intermolecular hydrogen bonds with the chloride ions ($\text{OH} \cdots \text{Cl}^- = 3.10$ – $3.11 \text{ \AA}$).

Figure 6. Structure of the complex **9**.

In the case of complete hydration of the above-described complexes, which is achieved by keeping these complexes in an atmosphere with 100% humidity,¹⁴ the apical chlorine atom is replaced by the second water molecule and the composition of the complex corresponds to the formula $\{[(\text{Mg}) \cdot (\text{H}_2\text{O})_2 \cdot (\text{15C5})]^{2+} + 2\text{Cl}^- + (\text{H}_2\text{O})\}$ (**11**). The $\text{Mg}-\text{O}_{\text{cr}}$ distances vary from 2.086 to 2.225 Å and $\text{Mg}-\text{O}_{\text{w}} = 2.045$ Å. In this crystal, the system of $\text{O}_{\text{w}}\text{H} \cdots \text{O}_{\text{w}}$ and $\text{OH} \cdots \text{Cl}$ hydrogen bonds is more complex than those observed in crystals of **9** and **10**.

The reaction of anhydrous magnesium chloride with 18C6 in anhydrous tetrahydrofuran¹⁵ afforded a molecular complex $[(\text{MgCl}_2) \cdot (\text{18C6})]$ (**12**) (Fig. 7). The coordination polyhedron

Figure 7. Structure of the complex **12**.

about the magnesium atom is a pentagonal pyramid. The coordination number of the Mg atom is 7, which is very untypical of this metal. The $\text{Mg}-\text{O}$ distances in complex **12** vary from 2.220 to 2.331 Å. The CE molecule also adopts an unusual conformation due to coordination of the metal atom by only five out of the six oxygen atoms. The magnesium atom has analogous coordination in the complex $\{[(\text{MgCl}_2) \cdot (\text{18C6})] \cdot (\text{HCl})_2\}$ (**13**) (Fig. 8),¹⁶ which was prepared by the reaction of MgCl_2 with the clathrate of composition $\{[(\text{H}_3\text{O}) \cdot (\text{18C6})]^+ + [\text{HCl}_2]^- \}$. This complex is considered¹⁶ as a purely ionic compound with composition $\{[(\text{Mg}) \cdot (\text{18C6})]^{2+} + 2[\text{HCl}_2]^- \}$. However, the $\text{Mg}-\text{Cl}$ distances in **13** (2.428 and 2.454 Å) and in **12** (2.429 Å) are close to the sum of the covalent radii of both elements and, in our opinion, it is more reasonable to describe both compounds as molecular complexes.

Figure 8. Structure of the complex **13**.

2. Aluminium chloride

A complex with composition $\{[(\text{AlCl}_2) \cdot (\text{15C5})]^+ + [\text{AlCl}_4]^- \}$ (**14**) was produced by the reaction of anhydrous AlCl_3 with 15C5 in anhydrous ether.¹⁷ The coordination number of the aluminium atom in the cation is 7. The coordination polyhedron about the metal atom is a pentagonal bipyramid with the oxygen atoms of the crown ether molecule in the equatorial plane and the chlorine atoms in the axial positions. This type of the polyhedron and the coordination number are untypical of aluminium compounds. The $\text{Al}-\text{O}$ distances vary from 2.081 to 2.142 Å and the $\text{Al}-\text{Cl}$ distances are 2.188 and 2.210 Å. The statistically disordered crown ether molecule in **14** is located on the mirror plane (Fig. 9). The complex of AlEtCl_2 with benzo-15-crown-5 (**15**) has an analogous structure.¹⁸

Figure 9. Structure of the complex **14**.

Complete hydration of complex **14** gave a compound with composition $\{[(\text{Al}) \cdot (\text{H}_2\text{O})_6]^{3+} + (\text{15C5}) + 3\text{Cl}^- + (\text{H}_2\text{O})_4\}$ (**16**)⁷ in which the metal atom is not coordinated by the oxygen atoms of the crown ether molecule and the individual structural units are linked to each other through a complex network of $\text{OH} \cdots \text{O}$ and $\text{OH} \cdots \text{Cl}$ hydrogen bonds.

3. Silicon tetrafluoride

The only silicon-containing complex with CE known to date was prepared by the reaction of SiF_4 with 18C6.¹⁹ The compound has the composition $\{[(\text{SiF}_4) \cdot (\text{H}_2\text{O})_2] + (\text{18C6}) + (\text{H}_2\text{O})_2\}$ (**17**) and belongs to type C complexes. The silicon atom is in an octahedral environment. The isolated structural fragments are linked to each other through intermolecular $\text{OH} \cdots \text{O}$ hydrogen bonds with the participation of water and CE molecules.

IV. Systems with halides of the third-row elements

1. Calcium chloride

The reaction of crown ether 12C4 with an aqueous solution of calcium chloride afforded a compound with composition $\{[(\text{Ca}) \cdot (\text{12C4}) \cdot (\text{H}_2\text{O})_4]^{2+} + 2\text{Cl}^- + (\text{H}_2\text{O})_2\}$ (**18**).²⁰ The calcium atom is located above the mean plane of the macrocycle and is coordinated by all the four oxygen atoms of CE and the four water molecules (Fig. 10). The $\text{Ca}-\text{O}$ distances vary from 2.380 to

Figure 10. Structure of the complex **18**.

2.540 Å. In the crystal structure of **18**, a complex network of OH...O and OH...Cl intermolecular hydrogen bonds with the participation of all water molecules is realised.

The reaction of molten CaCl₂ with 18C6 in acetone yielded ⁷ a complex with composition $\{[(\text{Ca}) \cdot (18\text{C}6) \cdot (\text{H}_2\text{O})_2]^{2+} + 2\text{Cl}^- + (\text{H}_2\text{O})_2\}$ (**19**), which is a typical representative of type A crown compounds. The calcium atom is located exactly in the centre of the cavity of the CE molecule ($\text{Ca}-\text{O}_{\text{cr}} = 2.555\text{--}2.604$ Å) and is additionally coordinated by two water molecules ($\text{Ca}-\text{O}_{\text{w}} = 2.29$ Å) which are located above and below the mean plane of the macrocycle.

2. Scandium chloride

Data on homometallic complexes of scandium halides with CE molecules are unavailable in the literature. The structures of heterometallic halides have been studied.^{21–23} These complexes were prepared by the following reactions:

In compounds **20–23**, the scandium atom is located in the centre of the cavity of the CE molecule and has a bipyramidal coordination. The Sc–O distances vary from 2.09 to 2.30 Å.

3. Titanium chlorides

The compositions and structures of complexes of TiCl₄ with various CE reflect the general tendency of interactions between metal halides in the highest oxidation states and polyethers, which is associated with destruction of the latter and the formation of various reactive oxygen-containing fragments.

Only one complex of TiCl₄ with 12C4, which was prepared by the reaction of a mixture of TiCl₄ and SbCl₅ in acetonitrile, was reported in the literature.²⁴ This reaction yielded a complex with composition $\{[(\text{TiCl}_3) \cdot (\text{CH}_3\text{CN})_3]^+ + [\text{SbCl}_6]^{-}\}$ as an intermediate. Treatment of the latter with 12C4 in dichloromethane afforded a compound with composition $\{[(\text{TiCl})_2(\mu_2\text{-O}) \cdot (12\text{C}4)]_2^+ + [\text{SbCl}_6]^{-} + (\text{CH}_2\text{Cl}_2)\}$ (**24**). The bridging oxygen atoms in this structure occur apparently due to destruction of a portion of CE molecules. The structure of the Ti-containing fragment is shown in Fig. 11. The Ti–O_μ distances (1.81 and 1.82 Å) are intermediate between the length of the double bond in titanyl chloride and the coordination bond. The Ti–O_{cr} distances vary from 2.12 to 2.38 Å, *i.e.*, these bonds are nonequivalent. The coordination number of the Ti atom is 7. The coordination polyhedron about the metal atom is a distorted pentagonal

Figure 11. Structure of the $[(\text{TiCl})(\mu_2\text{-O}) \cdot (12\text{C}4)]_2^+$ fragment in the complex **24**.

bipyramid with the oxygen and chlorine atoms in the apical positions.

Apparently, analogous destruction of CE to form titanyl chloride as an intermediate occurs in the reaction of TiCl₄ with 15C5 in acetonitrile.²⁵ The resulting complex has the composition $[(\text{TiCl}) \cdot (15\text{C}5) \cdot (\mu_2\text{-O})(\text{TiCl}_3)]$ (**25**) (Fig. 12). Unlike the above-described compound, the Ti–O distances in **25** are essentially nonequivalent (1.691 and 2.014 Å), which is indicative of the predominant formation of the Ti(1)–O double bond and the Ti(2)–O coordination interaction due to the lone electron pair of the bridging oxygen atom. The Ti–O_{cr} distances vary from 2.073 to 2.140 Å. The coordination polyhedra about the Ti(1) and Ti(2) atoms are a pentagonal bipyramid and a typical octahedron, respectively.

Figure 12. Structure of the complex **25**.

It was demonstrated²⁵ that destruction of CE is suppressed upon introduction of metal halides with readily ionisable M–X bonds which are not prone to autocomplexation. Thus the reaction of TiCl₄ with 15C5 in the presence of MgCl₂ in acetonitrile afforded the complex $\{[(\text{Mg}) \cdot (\text{CH}_3\text{CN})_2 \cdot (15\text{C}5)]^{2+} + [\text{TiCl}_6]^{2-}\}$ (**26**) in virtually quantitative yield. As in the compounds **9–11**, the magnesium atom in the complex **26** has a pentagonal-bipyramidal environment. The anion has a usual octahedral structure with the Ti–Cl distances varying from 2.324 to 2.354 Å. The reaction of TiCl₃ and AlCl₃ with 15C5 in tetrahydrofuran²⁵ gave a complex with composition $\{[(\text{TiCl}_2) \cdot (15\text{C}5)]^+ + [\text{AlCl}_4]^{-}\}$ (**27**). In **27**, the titanium atom is located in the centre of the cavity of the CE molecule. The Ti–O distances vary from 2.12 to 2.20 Å and Ti–Cl = 2.38 Å. The structure of the anion is analogous to that of the anion in the complex **14**.

According to the published data, the reaction of TiCl₄ with 18C6 did not lead to destruction of the CE molecule. Thus a distinct type B complex with composition $[(\text{TiCl}_4) \cdot (18\text{C}6)]$ (**28**) was prepared.²⁶ The coordination polyhedron about the titanium atom in this compound is an octahedron formed by four chlorine atoms and two oxygen atoms of the CE molecule (Ti–O = 2.125 and 2.145 Å). The CE molecule is strongly distorted (Fig. 13). The reaction of TiCl₄ with 18C6 in ethanol²⁷ afforded a type C

Figure 13. Structure of the complex **28**.

complex with composition $[(\text{TiCl}_3) \cdot (\text{OC}_2\text{H}_5) \cdot (\text{C}_2\text{H}_5\text{OH})_2 \cdot (18\text{C}6)_2]$ (**29**). The environment about the titanium atom is an octahedron (Fig. 14) formed by three chlorine atoms ($\text{Ti}-\text{Cl} = 2.337\text{--}2.387\text{ \AA}$), the oxygen atom of the ethoxy group ($\text{Ti}-\text{O} = 1.726\text{ \AA}$) and two coordinated ethanol molecules ($\text{Ti}-\text{O} = 2.030\text{ and }2.033\text{ \AA}$). The coordinated ethanol molecules interact with the macrocycle molecules through $\text{OH} \cdots \text{O}$ hydrogen bonds ($2.63\text{ and }2.64\text{ \AA}$).

Figure 14. Structure of the complex **29**.

4. Vanadium chlorides

The reaction of VCl_4 with **15C5** in acetonitrile in the presence of water was accompanied by disproportionation of the halide to form a complex with composition $\{[(\text{V}^{\text{III}}\text{Cl}_2) \cdot (15\text{C}5)]^+ + [\text{V}^{\text{VO}}\text{Cl}_4]^- \}$ (**30**).²⁸ The coordination polyhedron about the vanadium atom in the cation is a pentagonal bipyramid formed by the five oxygen atoms of the macrocycle ($\text{V}-\text{O} = 2.08\text{--}2.11\text{ \AA}$) and the two apical chlorine atoms ($\text{V}-\text{Cl} = 2.34\text{ and }2.35\text{ \AA}$). The coordination environment about the vanadium atom in the anion is a tetragonal pyramid formed by four chlorine atoms ($\text{V}-\text{Cl} = 2.23\text{--}2.26\text{ \AA}$) and one oxygen atom ($\text{V}-\text{O} = 1.548\text{ \AA}$).

The structure of the complex prepared by the reaction of VOCl_2 with **18C6** in aqueous ethanol was reported^{29,30} to belong to type C and it is described by the formula $\{[(\text{VOCl}_2) \cdot (\text{H}_2\text{O})_2] + [(18\text{C}6) \cdot (\text{H}_2\text{O})]\}$ (**31**). The coordination polyhedron about the vanadium atom is a slightly distorted tetragonal pyramid ($\text{V}-\text{O} = 1.573\text{ \AA}$, $\text{V}-\text{O}_w = 1.964\text{ and }2.024\text{ \AA}$ and $\text{V}-\text{Cl} = 2.215\text{ and }2.362\text{ \AA}$). Both fragments of the structure are linked to each other through $\text{OH} \cdots \text{O}$ intermolecular hydrogen bonds with the participation of water and CE molecules.

5. Chromium trichloride

Presently, only one structure of the chromium-containing complex with composition $[(\text{CrCl}_3) \cdot (\text{H}_2\text{O}) \cdot (15\text{C}5)]$ (**32**) (Fig. 15) is known.³¹ This complex was prepared by the reaction of CrCl_3 with **15C5** in aqueous acetonitrile. In the monomolecular complex of type B, the coordination environment about the chromium

Figure 15. Structure of the complex **32**.

atom is an octahedron formed by three chlorine atoms, one oxygen atom of the water molecule and two (of five) oxygen atoms of the CE molecule ($\text{Cr}-\text{O}_{\text{cr}} = 2.05\text{--}2.10\text{ \AA}$).

6. Manganese halides

The reaction of manganese bis(tribromide) with **12C4** gave the sandwich complex $\{[(\text{Mn}) \cdot (12\text{C}4)_2]^{2+} + 2[\text{Br}_3]^- \}$ (**33**) (Fig. 16).³² The $\text{Mn}-\text{O}$ distances vary from $2.241\text{ to }2.369\text{ \AA}$.

Figure 16. Structure of the $[(\text{Mn}) \cdot (12\text{C}4)_2]^{2+}$ cation in the complex **33**.

One product of the reaction of MnCl_2 with **18C6** in tetrahydrofuran is a compound with composition $\{2[(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+ + [\text{MnCl}_4]^{2-} \}$ (**34**). Its formation can only be attributed to partial hydrolysis in the solution or to the use of the reagents containing water.³³ The oxonium ion in **34** is located in the centre of the cavity of the CE molecule. In the nearly regular tetrahedral anion, the $\text{Mn}-\text{Cl}$ distances vary from $2.35\text{ to }2.37\text{ \AA}$. Interestingly, hydrolysis products were not detected in the analogous reaction performed in the presence of an excess of water. In this case, the salt underwent complete ionisation and the cation was hydrated.^{34,35} The structure of the Mn-containing fragment is more complex and the CE molecule is located in the second coordination sphere.

Individual fragments of the structure **35** (Fig. 17) are linked to each other through a complex system of $\text{OH} \cdots \text{O}$ and $\text{OH} \cdots \text{Cl}$ hydrogen bonds.

Figure 17. Structure of the $[(\text{H}_2\text{O})_4 \cdot \text{Mn}(\mu\text{-Cl}_2)\text{Mn} \cdot (\text{H}_2\text{O})_4]^{2+}$ cation in the complex **35**.

7. Iron halides

The reaction of FeBr_2 with **15C5** in dry dichloromethane afforded a complex of type A with composition $\{[(\text{FeBr}_2) \cdot (15\text{C}5)] + (\text{CH}_2\text{Cl}_2)\}$ (**36**) with the iron atom in the pentagonal-bipyramidal

environment. The Fe–O distances in the equatorial plane vary from 2.18 to 2.26 Å and the Fe–Br distances (the Br atoms are located in the apical positions) are in the range of 2.623–2.628 Å.³⁶

The reaction of FeCl₃ with 15C5 in dry tetrahydrofuran proceeded analogously to the reaction of aluminium chloride with this CE (see the preparation of **14**). The process yielded an ionic complex with composition $\{[(\text{FeCl}_2) \cdot (15\text{C}5)]^+ + [\text{FeCl}_4]^- \}$ (**37**) as the final product.³⁷ The Fe–O_{cr} distances in the cation vary from 2.112 to 2.192 Å.

The reaction of FeCl₃ or FeBr₃ with 18C6 in ordinary tetrahydrofuran containing water resembles the above-considered reaction of MnCl₂ with 18C6, *i.e.*, this reaction proceeded as hydrolysis to form type C complexes with composition $\{[\text{FeX}_4]^- + [(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+ \}$ [X = Cl (**38**) or Br (**39**)]. In the resulting complexes, the oxonium ion is a ‘guest.’ The cations have a flattened tetrahedral structure.^{38,39} An analogous reaction performed in a mixture of dry tetrahydrofuran and diethyl ether afforded an unusual sandwich complex of type B with composition $\{[(\text{FeCl}) \cdot (18\text{C}6)_2]^{2+} + 2[\text{FeCl}_4]^- \}$ (**40**) (Fig. 18).⁴⁰ Crystals of this complex contain the dications $[(\text{FeCl}) \cdot (18\text{C}6)_2]^{2+}$ in which the five-coordinate iron atom exists in two equally probable orientations. The coordination environment about the iron atom in the cation is a distorted octahedron formed by two chlorine atoms [statistically disordered positions (50%)] and four of the six oxygen atoms of the CE molecule (the Fe–O_{cr} distances vary from 2.156 to 2.209 Å). The anion has a flattened tetrahedral structure.

Figure 18. Structure of the $[(\text{FeCl}) \cdot (18\text{C}6)_2]^{2+}$ cation in the complex **40**.

The reaction of an equimolar mixture of FeCl₂ and FeCl₃ with 18C6 in tetrahydrofuran gave a product with an interesting structure.⁴¹ In the complex of type B, the Fe^{II} atoms form complex cations $\{2[(\text{Fe}) \cdot (\text{H}_2\text{O}) \cdot (\text{C}_4\text{H}_8\text{O}) \cdot (18\text{C}6)](\mu_2\text{-Cl}_2)\}^{2+}$ (**41**) (Fig. 19). The coordination polyhedron about the metal atom is an octahedron. The equatorial plane is formed by two chlorine atoms (Fe–Cl = 2.43–2.47 Å) and two oxygen atoms of the CE molecule (Fe–O_{cr} = 2.14–2.18 Å). The apical positions are

Figure 19. Structure of the cation $\{2[(\text{FeCl}) \cdot (\text{H}_2\text{O}) \cdot (\text{C}_4\text{H}_8\text{O}) \cdot (18\text{C}6) (\mu\text{-Cl}_2)]\}^{2+}$ in the complex **41**.

occupied by the oxygen atom of the water molecule (2.06 Å) and the oxygen atom of the tetrahydrofuran molecule (2.13 Å). The Fe^{III} atoms form tetrahedral anions $[\text{FeCl}_4]^-$.

8. Cobalt chlorides

The reactions of CoCl₂ with 15C5 were studied in a series of works.^{42–47} This reaction in acetonitrile always afforded the inner-cavity cation $[(\text{Co}) \cdot (\text{CH}_3\text{CN})_2 \cdot (15\text{C}5)]^{2+}$ but the composition of the anion in the complex varied from $[(\text{CoCl}_3) \cdot (\text{CH}_3\text{CN})]^-$ (**42**) and $[\text{CoCl}_4]^{2-}$ (**43**) (mononuclear tetrahedral) to $[\text{Co}_2\text{Cl}_6]^{2-}$ (**44**) (binuclear bridging) depending on the concentration of CoCl₂. The presence of water in organic solvents resulted only in hydration of the complex rather than in hydrolysis of the salt. In this case, the acetonitrile molecules located in the apical positions of the pentagonal bipyramid (the coordination polyhedron about the cobalt atom) were replaced by water molecules with retention of the structural type of the cation $[(\text{Co}) \cdot (\text{H}_2\text{O})_2 \cdot (15\text{C}5)]^{2+}$ (see Ref. 44). Only free Cl[–] ions (**45**) or tetrahedral anions $[\text{CoCl}_4]^{2-}$ (**46**) act as anions. In all the structures under consideration, the coordination polyhedron about the cobalt atom is a pentagonal bipyramid. The Co–O_{cr} distances vary from 2.07 to 2.40 Å.

The reaction of anhydrous CoCl₂ with 15C5 in ethanol yielded a complex of type A with composition $\{[(\text{Co}) \cdot (\text{EtOH})_2 \cdot (15\text{C}5)]^{2+} + [\text{CoCl}_4]^{2-} \}$ (**47**).⁴⁵ The Co–O_{Et} distances vary from 2.11 to 2.13 Å.

The reaction of CoCl₂ with 15C5 in the presence of an equimolar amount of MgCl₂ in acetonitrile afforded an inner-cavity magnesium complex with CE with composition $\{[(\text{Mg}) \cdot (\text{CH}_3\text{CN})_2 \cdot (15\text{C}5)]^{2+} + [\text{CoCl}_4]^{2-} + (\text{CH}_3\text{CN})\}$ (**48**).⁴² One product of hydration of this compound is a homometallic complex with composition $\{[(\text{Co}) \cdot (\text{H}_2\text{O})_2 \cdot (15\text{C}5)]^{2+} + 2\text{Cl}^- + (\text{H}_2\text{O})_{2.5}\}$ (**49**). The cobalt atom is in the typical pentagonal-bipyramidal coordination. The structural fragments are linked to each other through a system of OH⋯O and OH⋯Cl intermolecular hydrogen bonds.⁴²

The reaction of a mixture of cobalt chloride and copper chloride with 15C5 in acetonitrile gave a complex with composition $\{[(\text{Co}) \cdot (\text{CH}_3\text{CN})_2 \cdot (15\text{C}5)]^{2+} + [\text{Cu}_2\text{Cl}_6]^{2-} \}$ (**50**). The Co–O_{cr} distances in this compound vary from 2.103 to 2.269 Å, Co–N = 2.097 Å. Complete hydration of this complex led to changes in the composition of the cation and in the structure of the anion. The resulting compound has the composition $\{[(\text{Co}) \cdot (\text{H}_2\text{O})_2 \cdot (15\text{C}5)]^{2+} + [\text{CuCl}_4]^{2-} \}$ (**51**).

The reaction of anhydrous CoCl₂ with 18C6 in acetonitrile yielded a compound with composition $\{[(\text{Co}) \cdot (\text{CH}_3\text{CN}) \cdot (18\text{C}6)]^{2+} + [\text{CoCl}_4]^{2-} \}$ (**52**). In this complex, the cobalt atom has a rather untypical hexagonal-pyramidal coordination (the coordination number is 7). The metal atom is coordinated to all the six oxygen atoms of the CE molecule (Co–O_{cr} = 2.26 Å) and to the nitrogen atom (Co–N = 1.83 Å) and deviates from the mean plane through the oxygen atoms by 0.5 Å. The values of the torsion angles indicate that the CE molecule is highly strained.⁴⁵

The reaction of CoCl₂ · 6H₂O with 18C6 in acetone afforded a complex with composition $\{[(\text{Co}) \cdot (\text{H}_2\text{O})_6]^{2+} + [\text{CoCl}_4]^{2-} + (18\text{C}6) + [(\text{CH}_3)_2\text{CO}]\}$ (**53**). All structural units of this complex are linked to each other through a branched system of OH⋯O and OH⋯Cl hydrogen bonds.⁴⁸

The reaction of a mixture of CoCl₂ and BaCl₂ with 18C6 gave a compound $\{[(\text{Ba}) \cdot (\text{H}_2\text{O})_2 \cdot (18\text{C}6)]^{2+} + [\text{CoCl}_4]^{2-} \}$ (**54**).⁴⁹

9. Nickel chloride

The reaction of anhydrous NiCl₂ and NaCl with 15C5 gave a complex with composition $\{2[(\text{Na}) \cdot (15\text{C}5)]^+ + [\text{NiCl}_4]^{2-} \}$ (**55**) in which the tetrahedral anion and the complex cation are linked through an Na⋯Cl interaction (2.65 Å).⁵⁰

The reaction of nickel chloride dihydrate with 18C6 in methanol afforded a compound $\{[(\text{H}_2\text{O})_4 \cdot \text{Ni}(\mu\text{-Cl}_2)\text{Ni}(\text{H}_2\text{O})_4]^{2+} + (18\text{C}6) + 2\text{Cl}^- \}$ (**56**) the structure and composition of which are analogous to those of the manganese complex **35**.⁵¹

10. Copper halides

The products of reactions of a mixture of monovalent copper iodide and KI with various CE in acetone were studied by Rath and Holt.⁵² Complexes containing potassium cations, CE molecules (dibenzo-24-crown-8, DB24C8, or dibenzo-18-crown-6, DB18C6) and $[\text{Cu}_x\text{I}_y]^{n-}$ anions of different compositions were prepared according to the following reactions:

The reaction of CuI with DB18C6 in acetonitrile gave a molecular complex of composition $\{[(\text{Cu}_4\text{I}_4) \cdot (\text{CH}_3\text{CN})_4] + (\text{DB18C6})\}$ (**60**) with fragments that are not linked to each other.⁵³

Only one structure of a monomolecular complex of CuCl_2 with 12C4 (**61**) (Fig. 20) has been reported.⁵⁴ In this complex, the copper atom has an octahedral coordination formed by four oxygen atoms of the CE molecule and two chlorine atoms ($\text{Cu}-\text{O}_{\text{cr}} = 2.113\text{--}2.403\text{ \AA}$ and $\text{Cu}-\text{Cl} = 2.214\text{--}2.228\text{ \AA}$).

Figure 20. Structure of the complex **61**.

The reaction of CuCl_2 with 15C5 in acetonitrile was studied in several works.^{55–57} Ionic complexes of the type $\{[(\text{Cu}) \cdot (\text{CH}_3\text{CN})_{2-x} \cdot \text{Cl}_x \cdot (\text{15C5})] + \text{A}\}$, where $x = 0$ or 1 and A is an anion in which the coordination environment about the copper atom is a pentagonal bipyramid, were synthesised. The following complexes were obtained depending on the halide : CE : solvent ratio:

The $\text{Cu}-\text{O}$ distances in these compounds vary from 2.16 to 2.34 Å and the $\text{Cu}-\text{N}$ distances are in the range of 1.95–1.99 Å. In the complex **63**, the anion exists as an infinite chain of alternating tetragonal-bipyramidal and tetragonal-pyramidal fragments linked through bridging chlorine atoms (Fig. 21). The $\text{Cu}-\text{Cl}$ distances are in the range of 2.255–2.787 Å. Hydration of compounds **62** and **63** with water vapour resulted in the removal of the CE molecules from the coordination sphere of the metal atom and in the change in the type of the complex from A to C.⁵⁷ In this case, compounds with compositions $\{[(\text{Cu}) \cdot (\text{H}_2\text{O})_4]^{2+} + [(\text{Cu}_3\text{Cl}_8) \cdot (\text{H}_2\text{O})_2]^{2-} + (\text{15C5})_2\}$ (**64**) and $\{2[(\text{CuCl}_2) \cdot (\text{H}_2\text{O})_2] + (\text{15C5})\}$ (**65**) were formed along with $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$. Separate fragments in **64** and **65** are linked to each other through $\text{OH}_w \cdots \text{O}_{\text{cr}}$ hydrogen bonds (Figs 22 and 23, respectively).

Figure 21. Structure of the $[\text{Cu}_3\text{Cl}_8]^{2-}$ anion in the complex **63**.

Figure 22. Structure of the complex **64**.

Figure 23. Structure of the complex **65**.

The reaction of anhydrous CuCl_2 with 15C5 in aqueous methanol gave a complex of type C with composition $\{[(\text{CuCl}_2) \cdot (\text{H}_2\text{O})_2 \cdot (\text{CH}_3\text{OH})] + (\text{15C5})\}$ (**66**).⁵⁸ The coordination environment about the copper atom is a square pyramid. In the crystal structure of the complex, $\text{OH} \cdots \text{O}$ intermolecular hydrogen bonds with the participation of water, methanol and CE molecules are realised. The reaction of CuBr_2 with 15C5 yielded a complex with composition $\{[(\text{H}_2\text{O})_2 \cdot (\text{CuBr}_2)] + (\text{15C5})\}$ (**67**). The coordination polyhedron about the copper atom is a strongly flattened tetrahedron.⁵⁹

The structures of a number of products which were formed in the reactions of a mixture of CuCl_2 and MgCl_2 with 15C5 in acetonitrile where the reagents were taken in different ratios and at various concentrations were reported.⁶⁰

The structure **68** consists of monomolecular fragments (Fig. 24), while structures **69** and **70** are ionic. In all the three compounds, the magnesium atom is located in the centre of the cavity of the CE molecule and has a pentagonal-bipyramidal

Figure 24. Structure of the complex 68.

coordination. In compound **70**, the chain anion is analogous to that observed in the structure **63**. Hydration of compounds **68–70** with water vapour gave complexes with compositions $\{[(\text{H}_2\text{O})_2 \cdot (\text{Mg}) \cdot (15\text{C}5)]^{2+} + [\text{CuCl}_4]^{2-}\}$ (**71**) and $\{[(\text{Cu}_3\text{Cl}_8) \cdot (\text{H}_2\text{O})_2]^{2-} + [(\text{Mg}) \cdot (\text{H}_2\text{O})_6]^{2+} + (15\text{C}5)_2\}$ (**72**). The structure of the cation in **71** is analogous to that in **11**. The metal atom in the cation of **72** has an octahedral coordination. The central copper atom in the anion has an octahedral coordination formed by two oxygen atoms of the water molecules and four chlorine atoms. The terminal copper atoms have a tetrahedral environment. The fragments are linked to each other through $\text{OH}_w \cdots \text{O}_{\text{cr}}$ and $\text{OH}_w \cdots \text{Cl}$ hydrogen bonds.

The reactions of copper chloride with 18C6 in the presence of halides of alkali or alkaline-earth metals gave complexes in which the metal atoms are coordinated by CE molecules and the copper atoms form the $[\text{Cu}_2\text{Cl}_6]^{2-}$ anions.⁶¹

The product of the reaction of CuCl_2 with benzo-15-crown-5 (B15C5) in chloroform was also structurally characterised.⁶² The product has the composition $\{[(\text{CuCl}_2) \cdot (\text{B15C5})] + (\text{CHCl}_3)\}$ (**75**). The copper atom is located in the centre of the cavity of the CE molecule and has a pentagonal-bipyramidal coordination. This reaction in acetonitrile in the presence of NaCl gave a complex $\{2[(\text{Na}) \cdot (\text{B15C5})]^+ + [\text{Cu}_2\text{Cl}_6]^{2-}\}$ (**76**).⁶³ An analogous product with composition $\{2[(\text{Na}) \cdot (\text{DB18C6})]^+ + [\text{Cu}_2\text{Cl}_6]^{2-}\}$ (**77**) was formed when DB18C6 was used as a polyether.⁶³ The reaction with KCl and naphtho-15-crown-5 (N15C5) yielded a compound with a similar composition, $\{2[(\text{K}) \cdot (\text{N15C5})]^+ + [\text{Cu}_2\text{Cl}_6]^{2-} + (\text{H}_2\text{O})\}$ (**78**), containing a water molecule of crystallisation.⁶⁴

11. Zinc halides

The reactions of anhydrous ZnCl_2 with 15C5 in different solvents gave complexes of type A of the general formula $\{[(\text{Zn}) \cdot (\text{L}_1) \cdot (\text{L}_2) \cdot (15\text{C}5)]^{2+} + [\text{Zn}_2\text{Cl}_6]^{2-}\}$, where $\text{L}_1 = \text{Cl}$ and $\text{L}_2 = (\text{CH}_3)_2\text{CO}$ (**79**), $\text{L}_1 = \text{Cl}$ and $\text{L}_2 = \text{H}_2\text{O}$ (**80**) (both prepared in acetone), $\text{L}_1 = \text{L}_2 = \text{C}_4\text{H}_8\text{O}$ (**81**) (in tetrahydrofuran) and $\text{L}_1 = \text{L}_2 = \text{CH}_3\text{CN}$ (**82**) (in acetonitrile).^{65,66} In all the structures under consideration, the zinc atom is located in the cavity of the CE molecule and has a pentagonal-bipyramidal coordination. The $\text{Zn}-\text{O}_{\text{cr}}$ distances vary from 2.13 to 2.27 Å.

The reaction of zinc chloride dihydrate with 15C5 in methanol yielded a typical complex of type C with composition $\{[(\text{H}_2\text{O})_2 \cdot (\text{ZnCl}_2)] + (15\text{C}5)\}$ (**83**).⁶⁷ In this complex, the zinc atom has a tetrahedral coordination. The structural fragments are linked to each other through $\text{OH} \cdots \text{O}$ hydrogen bonds.

In going from 15C5 to 18C6, the compositions and structures of zinc chloride complexes become more diversified. Thus the reaction in tetrahydrofuran^{66,68} gave a complex of type B with composition $[(\text{H}_2\text{O}) \cdot (\text{ZnCl}_2) \cdot (18\text{C6})]$ (**84**). The coordination poly-

hedron about the zinc atom is a tetrahedron formed by two chlorine atoms ($\text{Zn}-\text{Cl} = 2.20$ and 2.23 Å), one water molecule ($\text{Zn}-\text{O}_w = 1.97$ Å) and one oxygen atom of the CE molecule ($\text{Zn}-\text{O}_{\text{cr}} = 2.08$ Å). The water molecule, in turn, forms an intramolecular hydrogen bond with another O_{cr} atom (2.77 Å) resulting in strong distortion of the macrocycle (Fig. 25).

Figure 25. Structure of the complex 84.

The reaction of ZnCl_2 with 18C6 in diethyl ether afforded a complex of type B with composition $\{2(\text{H}_2\text{O})_2 \cdot (\text{ZnCl}) \cdot (18\text{C6})\}^+ + [\text{Zn}_2\text{Cl}_6]^{2-}$ (**85**).⁶⁹ The zinc atom is coordinated by one chlorine atom, one oxygen atom of the water molecule and three (of six) oxygen atoms of the CE molecule. Recrystallisation of this compound from a mixture of acetone and CCl_4 gave a complex of type C with composition $\{[(\text{Zn}) \cdot (\text{H}_2\text{O})_6]^{2+} + 2[(\text{ZnCl}_3) \cdot (\text{H}_2\text{O})]^- + (18\text{C6}) + [(\text{CH}_3)_2\text{CO}]\}$ (**86**). In the crystal structure of this complex, an extensive system of intermolecular hydrogen bonds exists. The reaction of ZnCl_2 with 18C6 in tetrahydrofuran yielded a product with composition $\{[\text{ZnCl}_4]^{2-} + 2[(\text{H}_3\text{O}) \cdot (18\text{C6})]^- \}$ (**87**) with the oxonium ion occupying the centre of the cavity of the CE molecule.³² Under analogous conditions, the reaction of ZnI_2 with 18C6 afforded the compound $\{[(\text{H}_2\text{O})_2 \cdot (\text{ZnI}_2)] + (18\text{C6})_2 + (\text{H}_2\text{O})\}$ (**88**) in which the tetrahedral zinc-containing fragments are located between two CE molecules and are bound to the CE molecules through $\text{OH} \cdots \text{O}$ hydrogen bonds (Fig. 26).

Figure 26. Structure of the complex 88.

12. Gallium halides

It was shown⁷⁰ that the complexes prepared by reactions of gallium halides with 15C5 have the composition $\{[(\text{GaX}_2) \cdot (15\text{C}5)]^+ + [\text{GaX}_4]^- \}$, where $\text{X} = \text{Cl}$ (**89**) or Br (**90**). These complexes are isostructural to the aluminium complex **14**.

The reaction of GaCl_3 with 18C6 in acetonitrile afforded the compounds $\{[\text{GaCl}_4]^- + [(\text{H}_3\text{O}) \cdot (18\text{C6})]^+ \}$ (**91**) with the oxonium ion occupying the centre of the CE molecule. The structure of this complex is analogous to that of the above-described manganese complex **34**.

13. Arsenic halides

The structures of the molecular complexes $[(\text{AsCl}_3) \cdot (12\text{C}4)]$ (**92**) (Fig. 27) and $[(\text{AsCl}_3) \cdot (15\text{C}5)]$ (**93**) were reported.⁷¹ The $\text{As} \cdots \text{O}_{\text{cr}}$ distances in these compounds vary from 2.776 to 2.915 Å and from 2.944 to 3.156 Å, respectively, which are only slightly smaller than the sum of the van der Waals radii. In general, a complex of arsenic bromide with 15C5 has an analogous structure.⁷² However, the $\text{As} \cdots \text{O}$ bonds in the latter complex are nonequivalent: four bonds vary from 3.12 to 3.29 Å and the fifth bond is substantially longer (3.85 Å).

Figure 27. Structure of the complex **92**.

V. Systems with halides of the fourth-row elements

1. Zirconium tetrachloride

The reactions of metal halides in the highest oxidation states with CE were accompanied by destruction of the latter. The reaction of ZrCl_4 with 18C6 in tetrahydrofuran is a typical example.⁷³ The resulting product (Fig. 28) has the composition $\{[(\text{ZrCl}_5) \cdot (\text{C}_4\text{H}_8\text{O})]^- + [(\text{ZrCl}_2) \cdot (\text{O}_4\text{C}_8\text{H}_{16}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{Cl})]^+\}$ (**94**). The $\text{Zr} \cdots \text{O}$ distances (1.93 and 2.24–2.33 Å) in the cation indicate that both covalent and coordination interactions exist between the zirconium and oxygen atoms.

Figure 28. Structure of $[(\text{ZrCl}_2) \cdot (\text{O}_4\text{C}_8\text{H}_{16}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{Cl})]^+$ cation in the complex **94**.

2. Molybdenum halides

The reaction of MoCl_5 with 15C5 in 1,2-dimethoxyethane (L) in the presence of sodium silicide was accompanied by reduction of Mo^{V} to Mo^{IV} (see Ref. 74). The resulting complex of type C has the composition $\{[(\text{MoCl}_4) \cdot (\text{L})]^- + (15\text{C}5)\}$ (**95**). The coordination polyhedron about the molybdenum atom is a distorted octahedron. The $\text{Mo} \cdots \text{O}_{\text{cr}}$ distances vary from 2.14 to 2.18 Å.

The reaction of MoCl_5 with 15C5 in acetonitrile in the presence of AlCl_3 gave the compound $\{[(\text{MoOCl}_4) \cdot (\text{CH}_3\text{CN})]^- + [(\text{AlCl}_2) \cdot (15\text{C}5)]^+ + (\text{CH}_3\text{CN})\}$ (**96**). It was assumed⁷⁵ that the oxychloride was formed as a result of decomposition of the CE molecule under the action of the strong Lewis acid, *viz.*, MoCl_5 . The coordination polyhedron about the molybdenum atom in the

anion of **96** is an octahedron. The structure of the cation of **96** is analogous to that of the complex **14**.

The reactions of molybdenum oxychloride $\text{Mo}^{\text{V}}\text{OCl}_3$ with 12C4 or 18C6 yielded complexes containing the octahedral cations $[(\text{MoOCl}_4) \cdot (\text{H}_2\text{O})]^-$ and the oxonium-containing cations of the type $[(\text{H}_3\text{O}) \cdot (\text{CE})]^+$, *viz.*, $\{[(\text{MoOCl}_4) \cdot (\text{H}_2\text{O})]^- + [(\text{H}_3\text{O}) \cdot (12\text{C}4)]^+\}$ (**97**) and $\{[(\text{MoOCl}_4) \cdot (\text{H}_2\text{O})]^- + [(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+\}$ (**98**), respectively.^{76,77} The $\text{Mo} \cdots \text{O}$ and $\text{Mo} \cdots \text{O}_{\text{w}}$ distances in these complexes are 1.641 (1.654) and 2.285 (2.355) Å, respectively. Separate structural fragments are linked to each other through a system of $\text{OH} \cdots \text{O}$ and $\text{OH} \cdots \text{Cl}$ hydrogen bonds. The reaction with MoOBr_3 gave a complex with an analogous structure $\{[(\text{MoOBr}_3) \cdot (\text{H}_2\text{O})]^- + [(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+\}$ (**99**).⁷⁸

3. Palladium chloride

The reaction of PdCl_2 with 18C6 in a tetrahydrofuran solution of hydrochloric acid afforded a binuclear complex $\{[\text{Pd}_2\text{Cl}_6]^{2-} + 2[(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+\}$ (**100**) of type C.³⁸ The palladium atoms in the planar anion have a square coordination. The $\text{Pd} \cdots \text{Cl}$ distances are 2.326 Å (for the terminal bond) and 2.668 Å (for the bridging bond).

4. Silver halides

The reactions of silver halides with DB18C6 in dimethylformamide in the presence of alkali metal halides were studied by Helgesson and Jagner.⁷⁹

In all cases, complexes containing planar anions of silver halides were detected (Fig. 29).

Figure 29. Structure of the complex **102**.

5. Cadmium halides

The reactions of cadmium halides with 18C6 gave typical complexes of type A with composition $[(\text{CdCl}_2) \cdot (18\text{C}6)]$ (**105**), $[(\text{CdBr}_2) \cdot (18\text{C}6)]$ (**106**) and $[(\text{CdI}_2) \cdot (18\text{C}6)]$ (**107**) in which the cadmium atom is located in the centre of the cavity of the CE molecule and has a hexagonal-bipyramidal coordination.^{80,81} The Cd–O_{cr} distances in the complexes vary from 2.36 to 2.75 Å.

6. Indium halides

The reactions of indium(III) halide hydrates with 15C5 or 18C6 always yielded complexes of type C in which direct In–O_{cr} contacts were absent. Thus the reaction of $\text{InCl}_3 \cdot 4\text{H}_2\text{O}$ with 15C5 gave the complex $\{[(\text{InCl}_3) \cdot (\text{H}_2\text{O})_2] + (15\text{C}5)\}$ (**108**).⁸² The coordination environment about the indium atom in this complex is a slightly distorted trigonal bipyramid. The In–O_w distances are in the range of 2.201–2.218 Å. The fragments are linked to each other through O_wH···O_{cr} hydrogen bonds. An analogous reaction with 18C6 afforded the complex $\{[(\text{InCl}_3) \cdot (\text{H}_2\text{O})_3] + (18\text{C}6)\}$ (**109**). In this compound, the indium atom has an octahedral environment. The In–O_w distances vary from 2.23 to 2.25 Å.

The reaction of InCl_3 with 18C6 in tetrahydrofuran afforded the compound $\{[\text{InCl}_4]^- + [(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+\}$ (**110**) isostructural to the complex **38**.³⁸ The formation of the tetrahedral anions of the same type was also observed in the reactions of indium mixed halides with alkali metal halides and alkyl derivatives.^{83–85}

7. Tin chlorides

Only one example of complexation of SnCl_2 with CE (18C6) in methanol saturated with hydrogen chloride is documented.⁸⁶ This reaction gave the complex $\{[(\text{SnCl}) \cdot (18\text{C}6)]^+ + [\text{SnCl}_3]^- \}$ (**114**) with a very unusual structure (Fig. 30). The tin atom in the cation has a nontypical hexagonal-pyramidal coordination with the Sn–O distances varying from 2.59 to 2.88 Å. The tin atom in the anion has a pyramidal coordination and is located in the mean plane of the base of the pyramid. Oxidation of SnCl_2 in aqueous methanol containing 15C5 with atmospheric oxygen at 120 K yielded the complex of type C with composition $\{[(\text{Sn}^{\text{IV}}\text{Cl}_4) \cdot (\text{H}_2\text{O})_2] + [15\text{C}5]\}$ (**115**).⁸⁶ The coordination polyhedron about the tin atom is an octahedron. The Sn–O_w distances vary from 2.107 to 2.125 Å. The fragments in this compound are linked to each other through O_wH···O_{cr} hydrogen bonds.

The reaction of SnCl_4 with 15C5 in acetonitrile resulted in decomposition of the CE molecule.⁸⁸ In this case, two C–O bonds were cleaved, one –CH₂–CH₂– unit was eliminated in the form of dichloroethane and two tin atoms were μ_2 -coordinated by two

Figure 30. Structure of the complex **114**.

Figure 31. Structure of the complex **116**.

terminal oxygen atoms (Fig. 31). The resulting complex has the composition $\{[(\text{SnCl}_4) \cdot (\text{O}_5\text{C}_8\text{H}_{16}\text{SnCl}_2)] + (\text{CH}_3\text{CN})\}$ (**116**). The coordination environment about the Sn(1) atom is a pentagonal bipyramid. The Sn(1)–O_{cr} coordination bonds are in the range of 2.237–2.239 Å. The Sn(1)–O_μ covalent bond is 2.074 Å. The Sn(2) atom has an octahedral coordination with the Sn(2)–O_μ distances of 2.149 Å.

The reaction of SnCl_4 with 18C6 in chloroform gave a complex of type C with composition $\{[(\text{SnCl}_4) \cdot (\text{H}_2\text{O})_2] + (18\text{C}6) + (\text{CHCl}_3) + (\text{H}_2\text{O})\}$ (**117**).^{89,90} The octahedral tin-containing fragment is linked to the CE molecule through O_wH···O_{cr} hydrogen bonds. In addition, there are H-bonds between the coordinated water molecules and the water molecules of crystallisation.

8. Antimony halides

The complex $[(\text{SbCl}_3) \cdot (12\text{C}4)]$ (**118**)^{71,91} has a structure analogous to that of the complex **92**. The reaction of a mixture of SbCl_3 and SbCl_5 with 12C4 in acetonitrile gave a compound with composition $\{[(\text{Sb}^{\text{III}}) \cdot (12\text{C}4)_2]^{3+} + 3[\text{Sb}^{\text{V}}\text{Cl}_6]^- + (\text{CH}_3\text{CN})\}$ (**119**).⁹² The Sb–O_{cr} distances in the sandwich cation vary from 2.325 to 2.530 Å.

The reaction of SbCl_3 with 15C5 afforded the monomolecular complex $[(\text{SbCl}_3) \cdot (15\text{C}5)]$ (**120**).⁹³ The pyramidal SbCl_3 molecule is hanging over the mean plane of the CE molecule and the lone electron pair of the antimony atom is directed toward the polyether molecule. The Sb–O_{cr} distances vary from 2.787 to 2.997 Å. The reaction of SbBr_3 with 15C5 and the reaction of SbCl_3 with DB18C6 in chloroform afforded analogous structures [**121**⁹⁴ and **122** (Fig. 32), respectively].[†]

Figure 32. Structure of the complex **122**.

The reaction of a mixture of tri- and pentavalent antimony chlorides with 18C6 in acetonitrile afforded a compound with composition $\{[(\text{Sb}^{\text{III}}\text{Cl}_2) \cdot (18\text{C}6)]^+ + [\text{SbCl}_6]^- \}$ (**123**)⁹⁵ in which the antimony(III) atom is coordinated by two chlorine atoms and only two oxygen atoms of the CE molecule. The coordination polyhedron about this atom (taking into account the lone electron pair) is a trigonal bipyramid. The anion in the complex **123** has the typical octahedral structure.

[†] V K Belsky. Unpublished data.

9. Tellurium tetrachloride

The reaction of TeCl_4 with a mixture of SbCl_5 and 15C5 gave a bimetallic ionic complex with composition $\{[(\text{TeCl}_3) \cdot (15\text{C}5)]^+ + [\text{SbCl}_6]^- \}$ (**124**). The $\text{Te}-\text{O}_{\text{cr}}$ distances vary from 2.66 to 2.79 Å.⁹⁶

VI. Systems with halides of the fifth-row elements

1. Barium bromide

Only one structure of the complex formed by the reaction of barium bromide hydrate with 15C5 was reported in the literature.⁹⁷ The resulting compound has the composition $\{[(\text{Ba}) \cdot (15\text{C}5)_2]^{2+} + 2\text{Br}^- + (\text{H}_2\text{O})_2\}$ (**125**). The barium ion is located in the centre of the sandwich formed by CE molecules. The $\text{Ba} \cdots \text{O}$ distances are in the range of 2.749–2.880 Å. In the crystal, the Br^- anions and the water molecules are involved in the formation of a network of $\text{OH} \cdots \text{Br}$ intermolecular hydrogen bonds (3.326–3.493 Å).

2. Lanthanide and yttrium halides

The structures of complexes of lanthanide halide hydrates with 12C4, which were crystallised from a mixture of methanol with acetonitrile, are known.^{98,99} Compounds of three different structural types were obtained depending on the nature of the metal atom and the reaction temperature. In the case of lanthanide and yttrium chlorides, the compositions and structures of the resulting complexes are similar, viz., $\{[(\text{Ln}) \cdot (\text{H}_2\text{O})_5 \cdot (12\text{C}4)]^{3+} + 3\text{Cl}^- + (\text{H}_2\text{O})_2\}$, where $\text{Ln} = \text{Ce}$ (**126**) (Fig. 33), Nd (**127**), Sm (**128**), Eu (**129**), Gd (**130**), Dy (**131**), Y (**132**), Ho (**133**), Er (**134**) or Yb (**135**). In these complexes, the coordination environment about the metal atom is a monocapped tetragonal antiprism formed by four oxygen atoms of the CE molecule and five oxygen atoms of the water molecules ($\text{Ln}-\text{O}_{\text{cr}} = 2.42\text{--}2.63$ Å and $\text{Ln}-\text{O}_{\text{w}} = 2.23\text{--}2.51$ Å). All water molecules (both coordinated and of crystallisation) and chloride ions are involved in the formation of a complex system of $\text{OH} \cdots \text{Cl}$ intermolecular hydrogen bonds.

Figure 33. Structure of the complex **126**.

In complexes with composition $\{[(\text{H}_2\text{O})_2 \cdot (\text{LnCl}_2) \cdot (12\text{C}4)]^+ + \text{Cl}^-\}$, where $\text{Ln} = \text{Ho}$ (**136**), Er (**137**), Tm (**138**), Yb (**139**) or Lu (**140**) (Fig. 34), the coordination environment about the metal atom is a bicapped trigonal prism formed by four oxygen atoms of the CE molecule, two oxygen atoms of the water molecules and two chlorine atoms. The structural fragments are linked to each other through a system of $\text{OH} \cdots \text{Cl}$ hydrogen bonds.

The reaction of yttrium chloride with 12C4 afforded a complex with composition $\{[(\text{H}_2\text{O}) \cdot (\text{YCl}_2) \cdot (\text{CH}_3\text{OH}) \cdot (12\text{C}4)]^+ + \text{Cl}^-\}$ (**141**) in which one water molecule is replaced by the methanol molecule. Though the yttrium atom retains the coordination number of 8, it has a different coordination environment (a square antiprism, Fig. 35).

The praseodymium complexes with compositions $\{[(\text{H}_2\text{O}) \cdot (\text{PrCl}_3) \cdot (12\text{C}4)] + (12\text{C}4) + (\text{CH}_3\text{OH})\}$ (**142**) and $\{[(\text{CH}_3\text{OH}) \cdot (\text{PrCl}_3) \cdot (12\text{C}4)]\}$ (**143**) were also described in the literature.¹⁰⁰ In both structures, the coordination environment

Figure 34. Structure of the complex **136**.

Figure 35. Structure of the complex **141**.

about the metal atom is a tetragonal antiprism with $\text{Pr}-\text{O}_{\text{cr}} = 2.56\text{--}2.63$ Å, $\text{Pr}-\text{OCH}_3\text{OH} = 2.51$ Å and $\text{Pr}-\text{O}_{\text{w}} = 2.48$ Å. In the complex **142**, the structural fragments are linked to each other through $\text{O}_{\text{w}}\text{H} \cdots \text{O}_{\text{cr}}$ hydrogen bonds (Fig. 36).

Figure 36. Structure of the complex **142**.

Complete hydration of complexes of lutetium chloride with 12C4 gave eight-coordinate (square antiprism) octa-aqualutetium ions.^{101, 102}

The reactions of LnCl_3 with 15C5 generally gave complexes of two types. The complexes of the first type, viz., $\{[(\text{LnCl}_3) \cdot (15\text{C}5)]\}$, were formed when anhydrous chlorides of praseodymium (**146**), neodymium (**147**) or samarium (**148**) were used.^{103, 104} The structures of these complexes are analogous to those of trihalides of Group V elements (see, for example, structure **93**). The pyramidal LnCl_3 molecule is located above the mean plane of the CE molecule. The $\text{Ln}-\text{O}_{\text{cr}}$ distances vary from 2.50 to 2.75 Å. The stabilities of these complexes were calculated by the INDO method.¹⁰⁵

Complexes of the second type have the composition $\{[(Ln) \cdot (H_2O)_8]^{3+} + (15C5) + 3Cl^- + (H_2O)_n\}$. These compounds were obtained by the reactions with metal chloride hydrates in aqueous solvents or by hydration of lanthanide salts with water vapour. The complexes with $Ln = Y$ (**149**), Gd (**150**) and Lu (**151**) were prepared.^{106–109} In all cases, the coordination polyhedron about the metal atom is a distorted dodecahedron. Complex systems of $OH \cdots O$ and $OH \cdots Cl$ hydrogen bonds are observed in all the structures under consideration.

Products of complexation of chlorides of rare-earth elements with 18C6 are characterised by different types of crystal structures.^{110,111} The reactions performed in a 1 : 3 mixture of methanol and acetonitrile afforded complexes with compositions $\{[(H_2O)_2 \cdot (LnCl) \cdot (18C6)]^{2+} + 2Cl^- + (H_2O)_2\}$, where $Ln = Nd$ (**152**), Sm (**153**), Gd (**154**), Tb (**155**), Pr (**156**) or Eu (**157**). The metal atom is coordinated by six oxygen atoms of the CE molecule, one chlorine atom (located 'above' the mean plane of CE) and two water molecules (located 'below' the mean plane of CE) (Fig. 37).

Figure 37. Structure of the complex **155**.

The $Ln-O_{cr}$ and $Ln-O_w$ distances are in the ranges of 2.53–2.55 and 2.36–2.45 Å, respectively. In all cases, the coordination polyhedron about the lanthanide atom is a tricapped trigonal prism. The lanthanide atoms have the same coordination in another type of complexes in which one coordinated water molecule is replaced by the chlorine atom or the methanol molecule:¹¹¹ $\{[(CH_3OH) \cdot (LaCl_2) \cdot (18C6)]^+ + Cl^- + (H_2O)_{1.5}\}$ (**158**), $\{[(H_2O) \cdot (LaCl_2) \cdot (18C6)]^+ + Cl^-\}$ (**159**) and $\{[(H_2O) \cdot (CeCl_2) \cdot (18C6)]^+ + Cl^- + (H_2O)_2\}$ (**160**).

An anhydrous lanthanum complex $[(LaCl_3) \cdot (18C6)]$ (**161**) was prepared by crystallisation at 70 °C.¹¹¹ The coordination polyhedron in the complex **161** is also similar to a tricapped trigonal prism (formed by six oxygen atoms of the CE molecule and three chlorine atoms).

The addition of the salting-out reagent, $LiCl$, to a solution of $[(GdCl_3) \cdot (H_2O)_6 + (18C6)]$ in methanol afforded a compound with a more complex composition, $\{[GdCl_6]^{3-} + 3[(H_2O) \cdot (GdCl_2) \cdot (18C6)]^+ + 2[CH_3OH]\}$ (**162**).¹¹¹ The chlorine atoms and water molecules in the cation are statistically disordered. The structure of the complex **162** is analogous to those of compounds **159** and **160**.

The reactions of lanthanide chloride hexahydrates $LnCl_3 \cdot 6H_2O$ with 18C6 in a methanol:acetonitrile mixture under argon¹¹² gave complexes with composition $\{[(H_2O)_7 \cdot (Ln) \cdot (CH_3OH)]^{3+} + 2[(H_2O)_2 \cdot (LnCl) \cdot (18C6)]^{2+} + 7Cl^- + (H_2O)_2\}$, where $Ln = Y$ (**163**) or Dy (**164**) (X-ray data were collected at –150 °C). The structures of the double-charged cations are analogous to those observed in the complexes **152**–**157**. The trivalent cation has an octahedral environment. All the water and methanol molecules and noncoordinated chloride ions are involved in intermolecular hydrogen bonding.

In addition, two more types of complexes of $DyCl_3$ with 18C6 were reported. One of them was formed in acetonitrile and has the

composition $\{[(Dy) \cdot (H_2O)_8]^{3+} + (18C6) + 3Cl^-\}$ (**165**).¹¹³ The coordination polyhedron about the dysprosium atom is a bicapped trigonal prism. In a complex with triethylene glycol (L) with composition $\{[(DyCl_3) \cdot (L)] + (18C6)\}$ (**166**), the dysprosium atom has a pentagonal-bipyramidal environment.¹¹⁴

3. Tantalum chlorides

As mentioned above, the reaction of CE with strong Lewis acids (halides of metals in the highest oxidation states) are often accompanied by opening and decomposition of the macrocycle to produce large amounts of water, hydrogen chloride (due to hydrolysis), $-O-CH_2-CH_2-O-$ fragments and products of their interactions. The products of the reaction of anhydrous $TaCl_5$ with 15C5 have been studied most thoroughly.¹¹⁵ The reaction in dry acetonitrile afforded a mixture of several compounds. Thus crystals of an ionic complex with composition $\{[(TaCl_2) \cdot (C_8H_{16}O_5)]^+ + [TaCl_6]^- \}$ (**167**) were isolated at room temperature. The structure of the cation of this compound (Fig. 38) is analogous to that of the complex **116**. The Ta(1) is located in the centre of the mean plane formed by five oxygen atoms of the CE molecule. However, as in the case of the complex **116**, the metal atom is bound to three oxygen atoms [O(1), O(4) and O(4a)] through donor-acceptor bonds ($Ta-O = 2.24-2.27$ Å) and to two oxygen atoms [O(7) and O(7a)] through covalent bonds ($Ta-O = 1.89$ Å).

Figure 38. Structure of the complex **167**.

The coordination polyhedron about the tantalum atom is a slightly distorted pentagonal bipyramid. The $Cl-Ta-Cl$ angle is 162°.

Heating of the reaction mixture to 35–40 °C afforded a complex with composition $\{[TaCl_6]^- + [(H_3O) \cdot (18C6)]^+\}$ (**168**).¹¹⁵ The structure of the cation in this compound is analogous to those, for example, of the complexes **34**, **87** and **91**. The appearance of a new CE (18C6) in the $TaCl_5-15C5-CH_3CN$ system was attributed to processes of profound destruction of 15C5, chain extension of the open-chain polyether and closure of the latter. Apparently, these processes are accompanied by the formation of water molecules and hydrolysis of $TaCl_5$ as follows from the presence of the oxonium ion in the complex **168** and the concurrent formation of complexes with compositions $\{[(H_2Cl) \cdot (15C5)_2]^+ + [TaCl_6]^- \}$ (**169**) and $\{[(15C5) \cdot (CH_3C(Cl)=NH_2)]^+ + [TaCl_6]^- \}$ (**170**). The fragments in the cation of the last-mentioned compound are linked to each other through $NH \cdots O$ hydrogen bonds (Fig. 39).

Figure 39. Structure of the complex **170**.

Introduction of an additional component, namely, a tertiary amine or a quaternary ammonium salt, into the TaCl_5 –15C5–acetonitrile system afforded the complex $\{[(\text{C}_2\text{H}_5)_3\text{NH} \cdot (15\text{C}5)]^+ + [\text{TaCl}_6]^- \}$ (**171**) in which the fragments of the cation interact through $\text{NH} \cdots \text{O}$ hydrogen bonds and a complex tantalum oxychloride with composition $\{[\text{Ta}_3\text{O}_3\text{Cl}_{12}]^{3-} + 3[\text{N}(\text{CH}_3)_4]^+ + (\text{CH}_3\text{CN})\}$ (**172**), which contains no CE molecules. The structure of the cation in the complex **172** is shown in Fig. 40.

Figure 40. Structure of the $\text{Ta}_3\text{O}_3\text{Cl}_{12}$ fragment in the complex **172**.

The reaction of TaCl_5 with 15C5 in acetonitrile in the presence of LiCl gave complexes in which the lithium atom is a 'guest' for the CE molecule and the tantalum atom forms anions of different compositions depending on the ratio of halide molecules.¹¹⁶ Two products with compositions $\{[(\text{TaCl}_5)_2\text{O}]^{2-} + 2[(\text{Li}) \cdot (\text{CH}_3\text{CN}) \cdot (15\text{C}5)]^+ \}$ (**173**) (Fig. 41) and $\{[\text{TaCl}_6]^- + [(\text{Li}) \cdot (\text{CH}_3\text{CN}) \cdot (15\text{C}5)]^+ \}$ (**174**) were identified. The structures of the cations in both compounds are identical. The lithium atom has a pentagonal-pyramidal coordination and deviates from the mean plane through the oxygen atoms of the CE molecule by 0.45 Å. The $\text{Li} - \text{O}_{\text{cr}}$ distances vary from 2.08 to 2.39 Å. The $\text{Li} - \text{N}$ distance is 2.11 Å.

Figure 41. Structure of the complex **173**.

4. Rhenium halides

The reactions of ReOCl_3 and ReOBr_3 with 12C4 and 18C6 in the presence of water gave complexes with compositions $\{[(\text{ReOX}_4) \cdot (\text{H}_2\text{O})]^- + [(\text{H}_3\text{O}) \cdot (12\text{C}4)]^+ \}$, where $\text{X} = \text{Cl}$ (**175**) and Br (**176**), respectively. The reaction of ReOCl_2 with 18C6 yielded the complex $\{[(\text{ReOCl}_4) \cdot (\text{H}_2\text{O})]^- + [(\text{H}_3\text{O}) \cdot (18\text{C}6)]^+ \}$ (**177**).^{76,117} The structures of the anions in the compounds **175**–**177** are analogous to that in the complex **98**.

The reaction of a mixture of ReCl_4 and LiCl with 12C4 in acetonitrile afforded a product with composition $\{(\text{ReCl}_5) \cdot (\text{CH}_3\text{CN})\}^- + [(\text{Li}) \cdot (12\text{C}4)_2]^+ + [(\text{CH}_3\text{CN})]$ (**178**) containing the octahedral anion.¹¹⁷

5. Gold trichloride

The reaction of a mixture of gold trichloride and potassium chloride with 15C5 yielded a compound with composition $\{[(\text{K}) \cdot (15\text{C}5)_2]^+ + [\text{AuCl}_4]^- \}$ (**178**) containing the tetrahedral anion $[\text{AuCl}_4]^-$.

6. Mercury halides

The reactions of HgCl_2 and HgBr_2 with 18C6 gave typical complexes of type A with composition $[(\text{HgX}_2) \cdot (18\text{C}6)]$, where $\text{X} = \text{Cl}$ (**180**) and Br (**181**), respectively. The mercury atom is located in the cavity of the CE molecule and has a hexagonal-bipyramidal coordination. The $\text{Hg} - \text{O}_{\text{cr}}$ distances vary from 2.31 to 2.86 Å.^{81,118}

7. Thallium halides

The reaction of a mixture of TlCl and SbCl_5 with 12C4 afforded a bimolecular complex with composition $\{[\text{SbCl}_6]^- + [(\text{Tl}) \cdot (12\text{C}4)_2]^+ \}$ (**182**).¹¹⁹ The thallium atom in the sandwich cation is located between two CE molecules. The $\text{Tl} - \text{O}_{\text{cr}}$ distances vary from 2.865 to 2.904 Å. The reaction of an equimolar mixture of TlBr_3 and RbBr with 15C5 yielded a complex with composition $\{[\text{TlBr}_4]^- + [(\text{Rb}) \cdot (15\text{C}5)_2]^+ \}$ (**183**) with the thallium atom in the tetrahedral anion and the rubidium atom in the sandwich cation.⁴⁹

The reactions of mixtures of TiX and TiX_3 with 18C6 in the presence of copper or manganese dihalides gave complexes with the analogous composition $\{4[(\text{Ti}^{\text{I}}) \cdot (18\text{C}6)]^+ + 2[\text{Ti}^{\text{III}}\text{X}_4]^- + [\text{MX}_4]^{2-} \}$, where $\text{M} = \text{Cu}$ and $\text{X} = \text{Cl}$ (**184**) or Br (**185**); or $\text{M} = \text{Mn}$, $\text{X} = \text{Cl}$ (**186**).^{49,61,120} In all the structures, the thallium(I) atom deviates from the mean plane through the oxygen atoms of the CE molecule by ~ 0.9 Å. The $\text{Tl} - \text{O}_{\text{cr}}$ distances vary from 2.93 to 3.01 Å.

8. Lead halides

The reaction of lead dibromide with 18C6 in a hot aqueous solution gave a complex of type A with composition $\{[(\text{PbBr}_2) \cdot (18\text{C}6)] + (\text{H}_2\text{O})\}$ (**187**). The coordination number of the lead atom is 8 (the $\text{Pb} - \text{O}_{\text{cr}}$ distances with the six oxygen atoms of the CE molecule vary from 2.77 to 2.80 Å; $\text{Pb} - \text{Br} = 2.924$ and 2.927 Å).¹²¹ In the crystal, the complex molecules are linked to each other through $\text{OH} \cdots \text{Br}$ intermolecular hydrogen bonds (3.37 Å) with the participation of water molecules. The complexes $[(\text{PbI}_2) \cdot (18\text{C}6)]$ (**188**)¹²² and $[(\text{PbCl}_2) \cdot (\text{DCHex}18\text{C}6)]$, where $\text{DCHex}18\text{C}6$ is dicyclohexyl-18-crown-6, (**189**)¹²³ have analogous structures. The reaction of a 1 : 2 mixture of PbCl_2 and SbCl_5 with 18C6 in acetonitrile afforded a compound with composition $\{[(\text{CH}_3\text{CN})_3 \cdot (\text{Pb}) \cdot (18\text{C}6)]^{2+} + 2[\text{SbCl}_6]^- \}$ (**190**) in which the lead atom is also located in the centre of the CE cavity and is additionally coordinated by three acetonitrile molecules (one molecule is located 'above' the mean plane of the macrocycle and two molecules are located 'below' this plane).¹²⁴

9. Bismuth halides

Complexes of BiCl_3 with 12C4 (**191**) and of BiBr_3 with 12C4 (**192**) are structurally similar to the corresponding arsenic complex (**92**).^{125,126} A 1 : 1 mixture of BiCl_3 and SbCl_3 reacted with 12C4 in acetonitrile to yield a product with composition $\{[(\text{Bi}) \cdot (12\text{C}4)_2]^{3+} + 3[\text{SbCl}_6]^- + [\text{CH}_3\text{CN}]\}$ (**193**),⁹² which is isostructural to the antimony complex **119**.

The reaction of a 1 : 1 mixture of BiCl_3 and SbCl_5 with 15C5 in acetonitrile afforded the complex $\{[(\text{CH}_3\text{CN}) \cdot (\text{BiCl}_2) \cdot (15\text{C}5)]^+ + [\text{SbCl}_6]^- \}$ (**194**) in which the $[(\text{BiCl}_2) \cdot (\text{CH}_3\text{CN})]$ fragment is located above the mean plane through the oxygen atoms of the CE molecule.¹²⁷ The analogous reaction of a 1 : 2 mixture of tri- and pentachlorides of bismuth and antimony with 18C6 gave a product with composition $\{[(\text{CH}_3\text{CN})_2 \cdot (\text{BiCl}) \cdot (18\text{C}6)]^{2+} + 2[\text{SbCl}_6]^- \}$ (**195**) in which the bismuth atom is coordinated by one chlorine atom, two nitrogen atoms and four (of six) oxygen atoms of the CE molecule.¹²⁷

VII. Systems with actinide halides

The reaction of uranium(VI) oxychloride with 12C4 in tetrahydrofuran containing water yielded a compound with composition $\{[(\text{H}_2\text{O})_2 \cdot (\text{UO}_2\text{Cl}_2) \cdot (12\text{C}4)] + [12\text{C}4]\}$ (**196**).^{128,129} The coordination environment about the uranium atom is a pentagonal bipyramid formed by two oxygen atoms of the water molecules

(U–O_w = 2.41 Å), two chlorine atoms (U–Cl = 2.68–2.71 Å), two oxygen atoms of the uranyl fragment (U–O = 1.76 Å) and one oxygen atom of the CE molecule (U–O_{cr} = 2.55 Å) (Fig. 42).

Figure 42. Structure of the complex **196**.

The reaction of uranyl chloride with 12C4 in the presence of NaCl afforded the complex $\{[\text{UO}_2\text{Cl}_4]^{2-} + 2[(\text{Na}) \cdot (12\text{C}4)]^+\}$ (**197**) containing the octahedral anion.^{130, 131} The reaction of uranyl chloride with benzo-15-crown-5 (B15C5) proceeded analogously to form a complex with composition $\{[\text{UO}_2\text{Cl}_4]^{2-} + 2[(\text{Na}) \cdot (\text{B}15\text{C}5)]^+\}$ (**198**).¹³²

Thorium tetrachlorides reacted with various CE in solvents containing water to produce complexes of type C in which the thorium atom is not directly bound to oxygen atoms of the CE molecules.^{133–135}

The coordination polyhedron about the thorium atom in the complexes **199**, **200** and **201** is a tricapped trigonal prism, a square antiprism and a distorted dodecahedron, respectively.

The reactions of UCl_4 with crown ethers 15C5, DB18C6 and DCHex18C6 in air proceeded with oxidation of U^{4+} to U^{6+} (see Refs 131 and 136–138).

In the absence of air, the reaction of UCl_4 with B15C5 in the presence of NH_4Cl afforded the octahedral anion $[\text{UCl}_6]^{2-}$ and the cation $[(\text{NH}_4) \cdot (\text{B}15\text{C}5)]^+$ (**206**).¹³¹ The reaction of uranium tetrachloride with DCHex18C6 gave compounds with compositions $\{[\text{UCl}_6]^{2-} + 2[(\text{H}_3\text{O}) \cdot (\text{DCHex}18\text{C}6)]^+\}$ (**207**)¹³⁷ and $\{[\text{UCl}_6]^{2-} + 2[(\text{UCl}_3) \cdot (\text{DCHex}18\text{C}6)]^+\}$ (**208**)¹³⁹ depending on the reaction conditions. The coordination number of the uranium

atom in the cation of **208** is equal to 9. The metal atom is coordinated by three chlorine atoms and all the six oxygen atoms of the CE molecule.

The reaction of a 1 : 1 mixture of UCl_4 and NH_4Cl with 18C6 in acetonitrile yielded a compound with composition $\{[\text{UCl}_6]^{2-} + 2[(\text{NH}_4) \cdot (18\text{C}6)]^+ + (\text{CH}_3\text{CN})_2\}$ (**209**).¹⁴⁰

An interesting example of a redox process that occurred in the reaction of UCl_4 with 18C6 in tetrahydrofuran was reported.¹⁴¹ The reaction product contained the uranium(IV) and uranium(VI) atoms.

The uranium(VI) atom in the anion has a pentagonal-bipyramidal environment and the uranium(IV) atom in the cation is coordinated by all the six oxygen atoms of the CE molecule (U–O_{cr} = 2.48–2.61 Å) and three chlorine atoms.

VIII. Conclusions

To date, crown compounds of the majority of metal and semi-metal halides in the highest oxidation states have been prepared and structurally characterised. However, data on the structures of this class of compounds with metal halides in the lowest oxidation states are virtually unavailable. As has been mentioned in the Introduction, the structures of the great majority of crown compounds can be actually classed into three major types, *viz.*, A, B and C, and their variations. Homonuclear molecular complexes of crown ethers with halides of semimetals, such as As, Sb and Bi, as well as complexes, the nature of bonding in which is still not clearly understood, should be assigned to exceptions or to the individual type D.

The geometrical correspondence between the dimension of the metal atom (d_m) and the dimension of the cavity (d_c) of the crown ether molecule is a necessary but not nearly sufficient condition for the formation of inner-cavity crown compounds. The principle of this correspondence virtually forbids the synthesis of these compounds only if $d_m > d_c$. Moderate-sized metal atoms in the cavity are displaced toward two or three oxygen atoms or find alternative possibilities for the formation of complexes (see, for example, complexation of halides of lithium, beryllium, metals of the arsenic subgroup and lanthanides).^{142, 143} In these cases, the metal atoms are generally located outside the cavity of the CE molecule. It should be noted that unusual and nontypical coordination numbers of metal atoms located in the cavity of the CE molecule (for example, of the aluminium atom in the complex with the crown ether 15C5) should not be regarded as a violation of the well-known structural principles because the above-mentioned deviations of the metal atoms are induced by the macrocyclic nature of the polyethers.

Apparently, the possibility of ionisation and/or autocomplexation of a salt in a solution should be regarded as a prerequisite for the preparation of crown-ether compounds containing the metal atom in the cavity. All the above-considered inner-cavity crown compounds were prepared in solvents of the donor type. Since the processes of ionisation and autocomplexation in these solvents occur with difficulty, complexes with metal halides in the lowest oxidation states are very poorly studied. It should be noted that these metals generally form rather stable polymeric structures.

Acceptors of halide ions are introduced into salt solutions in order to direct the reactions toward inner-cavity complexes. However, in these cases the reactions always afford hetero- or homonuclear different-valence ionic complexes in which the inner-cavity cation is formed by the metal ion with the lower affinity for the halogen atom (a weaker Lewis acid). In this respect, the conversion of the complexes based on SbX_3 from type D to type A in the presence of SbX_5 is a prominent example.

The introduction of a versatile solvent, *viz.*, water, into the reaction system prevents, as a rule, the formation of inner-cavity

crown compounds or causes their destruction, *i.e.*, leads to the passage from type A to type B or C in which the fragments are linked to each other through a system of hydrogen bonds. We are aware of only three examples where the metal atoms remain in the cavity of the macrocycle in the presence of water, *viz.*, the complexes prepared by the reactions of 15C5 with CoCl_2 (see Ref. 42) and with MgCl_2 (See Ref. 14) and by the reaction of CaCl_2 with 18C6.⁷

The presence of water in a salt–CE–organic solvent system sharply changes the character of interactions between the components. In this case, the process involves either hydration of the cation accompanied by displacement of molecules of the organic solvent from the coordination sphere of this cation or hydrolysis accompanied by the appearance of hydrogen halide, oxonium ions, oxides, hydroxides and a number of other products in the solution. However, the reasons for the appearance of water in the reaction zone have not been a matter of discussion in the majority of works. Undoubtedly, the experiments performed with the use of crystal hydrates or ordinary (not dehydrated) solvents are quite understandable the more so that hydrated compounds are formed under these conditions in rather high yields.

The instances where the reactions which were carried out with the use of anhydrous solvents and thoroughly dehydrated salts afforded single crystals of hydrated complexes are not so unambiguous. Since the yields of these salts were no more than 5%–8% (see, for example, Refs 7, 14 and 41), hydration of salts may be attributed to residual traces of moisture in the initial compounds and in solvents as well as to the anomalous hydrophilicity of salts of some divalent metals.

Finally, the appearance of water in reactions of crown ethers with some anhydrous metal halides in the highest oxidation states, for example, with MoCl_5 ⁷⁵ and TaCl_5 ,^{115, 116} is still unclear. The complexes prepared by these reactions never have and apparently cannot have the structures of classical intra-cavity crown compounds because these structures can be formed only if the charge of the cation is no less than $3+$, which is observed in none of the above-described structures. However, these reactions always afforded a wide range of various compounds, including hydrolysis products in yields of up to 20%–30%. These yields are substantially larger than those calculated taking into account all possible sources of residual moisture that could exist in the reaction zone. In this connection, we believe that hydrolysis can be explained only by profound decomposition of the polyether molecule accompanied by the formation of large amounts of water. In this case, residual moisture, which is introduced into the reaction zone with the initial compounds and the solvent, can act as an initiator of cleavage of the macrocycle. Taking into account the above-mentioned characteristic features of the salt behaviour, not only the results of experiments on extraction and separation of metal halides (and, apparently, compounds of other types as well) with the use of crown ethers but also the ideology of these studies are highly questionable.

Reactions of solvation and complexation are the major subject matter of coordination chemistry. However, these reactions are explicitly and implicitly involved in many processes which are far from this field of chemistry. In this respect, the chemistry of macrocyclic compounds (in particular its structural aspect) is undeniably helpful in developing general model concepts of interactions between components of complex systems which can be used in various divisions of chemistry.

For example, products of intercalation of salts of the acceptor type (generally, metal halides, Lewis acids) into the interlayer space of graphite (the so-called intercalation graphite compounds, IGC) are known. Most of these products are compounds formed by metal halides MX_n which are intercalated into graphite only in the presence of free halogen or metal halides in the highest oxidation states M^*X_m (hetero-IGC). If the graphite network is considered as a polyligand, this behaviour of salts MX_n is readily explained from the standpoint of formation of heterocrown compounds, *i.e.*, on the assumption that ionisation, autocomplex-

ation and, finally, intercalation of ionic salts of the type $\{[\text{M}^*\text{X}_{m-1}]^+[\text{MX}_{n+1}]^-\}$ or $\{[\text{X}^+[\text{MX}_{n+1}]^-\}$ into the interlayer space occur.

Yet another example is associated with the chemistry of Ziegler–Natta catalytic systems applied onto mineral supports whose surface layers, in principle, can be considered as polyligands. It is known that introduction of magnesium salts, for example, of MgCl_2 , into catalysts $\text{AlRR}'\text{R}''\text{--TiXX}'\text{X}''$, where $\text{R} = \text{Alk}$, $\text{R}' = \text{H}$, $\text{R}'' = \text{Hal}$; $\text{X} = \text{Hal}$, $\text{X}' = \text{Alk}$, $\text{X}'' = \text{C}_5\text{H}_5$, *etc.*, increases their activity in polymerisation of alkenes by several orders of magnitude. Aluminium and titanium salts can form both cationic and anionic components of complexes, while magnesium is involved only in cations of CE complexes. Therefore, magnesium efficiently competes with the first two metals in formation of cations thus causing them to form anions. One would expect that, like MgCl_2 , salts of other metals which can undergo ionisation and are not prone to autocomplexation (for example, ScCl_3), are efficient promoters of polymerisation.

Abstract. The data on the synthesis and properties of furazan derivatives fused with pyridine, pyran, thiopyran, azepine and thiepine rings are surveyed and described systematically. The bibliography includes 85 references.

I. Introduction

Furazan (1,2,5-oxadiazole) derivatives are heterocyclic compounds of a non-natural origin. The first representatives of furazans were synthesised more than a hundred years ago. The subsequent development of the chemistry of this class of compound has been stimulated both by the diversity of their chemical transformations and by a number of their interesting properties, which provide the possibility of using them in medicine, agriculture and some fields of engineering.

In this decade alone, the peculiar behaviour of furazans and their *N*-oxides (furoxans) and the large body of information, which permanently extends as a result of studies of numerous groups of researchers, have led to the publication of several reviews^{1–10} and monographs.^{11,12}

Fused systems consisting of two or more heterocycles, of which at least one heterocycle is a furazan ring, deserve close attention both from the theoretical viewpoint and due to the possible application of these compounds as intermediates in synthesis. Some derivatives of this class have been proposed as herbicides, rubber modifiers, liquid crystals, luminescent dyes and explosives.

Systems in which a furazan ring is fused to a five-membered heterocycle have been considered in a review.⁶ The present review is devoted to the least studied derivatives, furazans fused to six- and seven-membered heterocycles with one heteroatom.

II. Furazan ring as a fragment of a bicyclic system

Furazan can be regarded as a hetero-analogue of cyclopentadiene. On passing from electron-releasing cyclopentadiene to electron-withdrawing furazan, chemical properties are virtually reversed. One can say that furazan is a sort of antipode of cyclopentadiene.

Successive replacement of carbon atoms by heteroatoms results in redistribution of electron density and in enhancement of π -acceptor properties of the system in the following series: cyclopentadiene, furan, isoxazole, furazan.

In all of these rings, electronic effects of substituents are transferred solely through the (hetero)diene system of bonds.¹³ The CH_2 group (in cyclopentadiene) and oxygen atoms (in the other three rings) act as a sort of insulator for this transfer. As a consequence, the degrees of aromaticity of these four cyclic systems are approximately equal.

Compound				
Aromaticity index (<i>I</i>) ¹⁴	45	43	47	43

It should be noted that the degree of bond order fixation in the heterodiene system of furazan is extremely high; derivatives of this heterocycles are not susceptible to annular-group tautomerism.

The chain consisting of three heteroatoms, present in the furazan molecule, accounts for the substantial electron-withdrawing properties of this heterocycle.^{15–17} The Taft induction constants σ^* of 4-*R*-furazanyl groups (as substituents) fall in the range 2.55–2.88 (these values correspond to *R* = NH_2 and *R* = NO_2 , respectively).¹⁸ For comparison, the σ^* value of the 3-furyl group is 0.62. The well-known electron-withdrawing picryl group, 2,4,6-(NO_2)₃ C_6H_2 has a σ^* value of only 1.62. The following substituents are characterised by σ^* constants close to that of furazan: $\text{CH} = \text{C}(\text{CN})_2$ ($\sigma^* = 2.56$), CF_3 ($\sigma^* = 2.6$); $\text{CBr}(\text{NO}_2)_2$ ($\sigma^* = 2.8$); 5-tetrazolyl group ($\sigma^* = 2.82$); nitrile group ($\sigma^* = 3.25$).¹⁹

The reactivity of annelated furazan derivatives is also significantly affected by the nature of the second ring — its size, the number of heteroatoms and their type and positions. A typical feature of annelated furazans is bond order fixation over the whole contour of the bicyclic system. It is known that the degree of delocalisation of π electrons in benzoannelated heterocycles can be estimated using the Gunther method²⁰ based on the ratio of spin-spin coupling constants, J_{bc}/J_{ab} . When the bonds are fully

Received 23 September 1998

Uspekhi Khimii 68 (2) 154–166 (1999); translated by Z P Bobkova

equivalent, as in benzene, this ratio is equal to unity, whereas completely localised bonds correspond to a ratio of 0.5. According to ^1H NMR spectroscopy, the J_{bc}/J_{ab} ratio for benzofurazan is 0.706; in other words the bonds are substantially localised.²¹

The replacement of one $=\text{CH}-$ unit in the benzene molecule by an isoelectronic fragment, $=\text{N}-$, is known to result in a less uniform distribution of electron density and more pronounced localisation.¹⁴ In fact, on passing from benzofurazan to furazano[3,4-*b*]pyridine, the spin-spin coupling constant for protons a, b changes only slightly ($J = 9.34$ Hz for benzofurazan²² and $J = 9.00$ Hz for furazanopyridine²³), whereas the constant for protons b, c changes more significantly ($J = 6.50$ and 3.70 Hz, respectively). Evidently, this points to a decrease in the order of the b-c bond and, hence, to an increase in the degree of localisation upon the replacement of the $=\text{CH}-$ fragment by $=\text{N}-$.

On passing from benzene to pyridine and then from benzofurazan²² to furazanopyridine,²³ the ^1H NMR signal shifts downfield, which is also due to a decrease in the electron density in this series. However, it should be mentioned that the influence of the furazan ring is still weaker than that of two *ortho*-nitro groups.

Compound					
δ , ppm	7.27	7.46	7.96	8.25	8.92

The *N*-oxide fragment acts as a resonance electron-releasing group of medium strength;¹⁴ therefore, on passing to the *N*-oxide, furoxanopyridine, the electron-withdrawing influence of the furazan ring becomes weaker. In particular, the signals of the protons at C(7) in the ^1H NMR spectra of both isomers of furoxanopyridine are shifted upfield in relation to corresponding signal in the spectrum of furazanopyridine.²³

Theoretical calculations²⁴ and polarographic studies^{25–29} have also been used to describe the influence of the furazan ring on the properties of molecules incorporating it. Acid–base properties of some annelated furazan derivatives have also been studied.³⁰

III. Furazanopyridines

Derivatives of all three possible types of bicyclic systems based on furazan and pyridine rings — furazano[3,4-*b*]pyridine (**A**), furazano[3,4-*c*]pyridine (**B**) and furazano[3,4-*a*]pyridine (**C**) — have been described in the literature.

1. Furazano[3,4-*b*]pyridine

The heterocyclic system of furazano[3,4-*b*]pyridine (**A**) is also referred to as 1,2,5-oxadiazolo[3,4-*b*]pyridine and the correspond-

ing 1(3)-oxides are also called furoxano[3,4-*b*]pyridines and pyridofuroxans.

Derivatives of the bicyclic system **A** can be obtained from both furazan and pyridine synthons. Thus the reaction of 3-amino-furazan-4-carbonitrile **1** with β -dicarbonyl compounds in the presence of a catalytic amount of nickel acetylacetonate gives rise to labile enamines **2a–e**. On heating with acetic acid in ethanol, they undergo intramolecular condensation to give the corresponding amino-derivatives **3a–e**. The overall yields of the compounds **3a–e** are 80%–95%.^{31, 32}

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**a**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Ph}$ (**b**); $\text{R}^1 = \text{R}^2 = \text{Ph}$ (**c**);
 $\text{R}^1 = \text{OEt}$, $\text{R}^2 = \text{Me}$ (**d**); $\text{R}^1 = \text{OEt}$, $\text{R}^2 = \text{Ph}$ (**e**).

Even in the case where $\text{R}^1 \neq \text{R}^2$, as in the compound **2b**, the reaction occurs regioselectively giving only one product **3b** in which the more bulky substituent is attached directly to the pyridine ring.

The reaction of the nitrile **1** with dimedone in the presence of nickel acetate affords tricyclic compound **4** in 67% yield. In this case, the intermediate enamine was not isolated.³²

Dehydration of 1,2-dioximes (glyoximes) is used most widely for the synthesis of furazans.^{1, 6} An unusual version of dehydration has been employed in order to prepare furazan **5**. 2,3-Dihydroxyiminopyridine **6** adsorbed on silica gel undergoes spontaneous dehydration over a period of 12 h to give the compound **5** in 14% yield.³³

Readily available furoxanopyridine **7a** can be reduced to the corresponding furazan **8** by a short-term heating to 100 °C in trimethyl phosphite.²³ Benzo-annelated derivative **9** can be obtained in a similar way from the furoxan **10**.³⁴

The above furazanopyridines have been synthesised only recently. Meanwhile, the 1(3)-oxides of furazanopyridines of type **A** (furoxans) were first prepared more than 40 years ago.³⁵ The synthesis of these compounds is based on the ability of *o*-azido nitro aromatic compounds to undergo thermally induced intramolecular cyclocondensation. The mechanism of this transformation has been studied comprehensively by measuring the kinetics of this reaction for benzene derivatives.¹¹ It is believed that an oxygen atom of the nitro group attacks a nitrogen atom of the azide group. Cyclisation can be represented as electron transfer occurring synchronously with elimination of a nitrogen molecule.

Thus heating of tetrazolopyridine **11a**, which is formed upon treatment of chloropyridine **12a** with sodium azide, in dichlorobenzene leads to elimination of a nitrogen molecule from the intermediate azide **13a** and closure of the furoxan ring yielding the bicyclic compound **7a**.³⁵ Later it has been shown that the compound **7a** is formed in approximately the same yield when thermolysis is carried out in some other solvents or without a solvent (Table 1).

Table 1. Synthesis of furoxano[3,4-*b*]pyridines **7a–i** by thermolysis of the corresponding tetrazolopyridines **11a–i**.

11i	NH ₂	NO ₂	C ₆ H ₆	80	1.5	95	42, 43

This reaction is general. The presence of any substituents, especially electron-withdrawing ones, in the initial nitrotetrazolopyridines **11a–i** facilitates their transformation into tautomeric 2-azido-3-nitropyridines and is thus favourable for the formation of the furoxan ring upon thermolysis (see Table 1).

It should be noted that furoxanopyridine **7f** exists as the more stable tricyclic tautomer **14**.³⁷

A particular modification of this method is the reaction of 2-chloro-3,5-dinitropyridine with sodium azide in the presence of phase transfer catalysts in dichloroethane followed by keeping the reaction mixture at 60 °C. The furoxanopyridine **7e** is prepared in this way in 92% yield without isolation of the intermediate azide or tetrazolopyridine.⁴⁴

The thermolysis of azide **15**, isomeric to azide **13a**, gives the furoxanopyridine **7a**, which is thermodynamically more stable than isomer **16**.^{45, 46} It is noteworthy that for the azide **15**, azido-tetrazole tautomerism is impossible, and in this case, the solvent determines not only the yield of the bicyclic compound **7a** but also the reaction pathway itself. A similar situation is observed in the transformation of *o*-azidonitrobenzenes into benzofuroxans.¹¹ Thus at 87 °C in decalin, the yield of the compound **7a** is 94%, while in ethanol, it is equal to 80%. Thermolysis of the azide **15** in *o*-dichlorobenzene or acetic anhydride does not give a furoxan derivative but yields instead azo compound **17**.⁴⁶

An attempt to synthesise isoquinolinofuroxan **18** by thermolysis of azide **19** failed.⁴⁷

Yet another method for the synthesis of furoxano-[3,4-*b*]pyridines consists in oxidative condensation of 2(3)-amino-3(2)-nitropyridines. The most widely used oxidant which permits successful preparation of this bicyclic system is diacetoxy-λ³-iodanylbenzene.^{34, 36, 39, 48, 49} In fact, when amines **20a–e** or isomeric amines **21a–e**, or bicyclic amines **22** and **23** are merely stirred with this reagent in acetic acid, acetone or benzene at room temperature or at 50–60 °C, the corresponding furoxans **7** or **10a,b** are formed in 70%–90% yields.

The use of sodium hypochlorite as the oxidant in the synthesis of furoxano[3,4-*b*]pyridine derivatives usually does not lead to the desired products, unlike its use in the synthesis of benzofuroxans¹¹ from the corresponding *o*-amino nitro compounds.³⁶ Only one example of successful employment of this oxidant in the reaction in question is known. On treatment with sodium hypochlorite in a methanolic solution of KOH, the amine **23** undergoes

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{H}$ (**a**); $\text{R}^1 = \text{R}^3 = \text{H}$, $\text{R}^2 = \text{Me}$ (**b**); $\text{R}^1 = \text{R}^2 = \text{H}$, $\text{R}^3 = \text{Me}$ (**20c**, **21c**, **7j**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{R}^3 = \text{H}$ (**20d**, **21d**, **7k**); $\text{R}^1 = \text{R}^3 = \text{Me}$, $\text{R}^2 = \text{H}$ (**20e**, **21e**, **7l**).

$\text{R} = \text{Me}$ (**22**, **10a**), $\text{OC}_6\text{H}_4\text{Cl-}p$ (**23**, **10b**).

oxidative condensation with simultaneous replacement of the *p*-chlorophenoxy group by a methoxy group to give tricyclic compound **24** in 64% yield.³⁴

Furazano[3,4-*b*]pyridines enter into two types of reactions. The first type comprises transformations that do not affect the bicyclic cage of the initial molecule. Reactions in which this cage is destroyed belong to the second type. The first type of reactions includes transformations of the functional groups present in the pyridine moiety of the molecule. Thus refluxing of the tetrazole **14** in ethanol in the presence of triphenylphosphine results in the formation of the iminophosphorane **11g** in 90% yield. Hydrolysis of this product occurs quantitatively and affords amine **25**, which is readily acylated with acetic anhydride to give amide **26**.³⁷

Refluxing of the tricyclic compounds **9** ($n = 0$) or **10** ($n = 1$) with selenium dioxide in dioxane is accompanied by oxidation of the methyl group. This gives aldehydes **27** and **28** in 56% and 75% yields, respectively.³⁴ Further oxidation of these products with bromine in a solution of sodium bicarbonate in aqueous butanol

gives rise to the corresponding acids **29** (yield 72%) and **30** (yield 65%). The acid **30** was converted into amide **31**.³⁴

(a) Et_3N , BuOCOCl ; (b) $\text{H}_2\text{N}(\text{CH}_2)_2\text{NMe}_2$; (c) HClO_4 ; $n = 0$ (**9**, **27**, **29**), $n = 1$ (**10**, **28**, **30**).

Interestingly, when sodium chlorite is employed as the oxidant in this reaction, the acid is not formed but instead the aldehyde group is eliminated and the C(5) atom in the ring is oxidised. The corresponding isoquinolinones **32** and **33** are produced in 75% – 79% yields. The compound **33** (yield 54%) can also be obtained by alkaline hydrolysis of the methoxy-derivative **24**.

$n = 0$ (**27**, **32**), 1 (**28**, **33**).

Treatment of the *N*-oxide **23** with excess (*N,N*-dimethylamino)ethylamine at 75 °C leads to substitution of the *p*-chlorophenoxy group. The resulting amine **34** was isolated as the corresponding perchlorate in 42% yield.³⁴

The second type of reaction typical of furazano[3,4-*b*]pyridine derivatives is transformation of the furoxan ring. For example, when the bicyclic derivatives **7a,e** are heated in dimethyl sulfoxide, retro-cleavage of the furoxan ring at the *N*–*O* bond occurs giving rise to a nitro group and a nitrene. The nitrene reacts with the solvent yielding sulfimine *S*-oxides **35a,e**.³⁸ Irradiation of the *N*-oxide **7a** with a UV lamp in aqueous acetonitrile for 30 h affords nitropyridone **36** in 18% yield.³³ The furoxan **7a** is not oxidised with *m*-chloroperbenzoic acid. However, treatment of **7a** with concentrated hydrogen peroxide in oleum results in oxidation of the furoxan ring giving 2,3-dinitropyridine **37** in 60% yield. No products resulting from the oxidation of the pyridine nitrogen

atom were detected. An additional nitro group present in the initial furoxan, for example in **7e**, makes the furoxan ring resistant to oxidation.³⁷

R = H (**a**), NO₂ (**e**).

Diamine **38** has been obtained in 17% yield on treatment of the furoxan **7a** with sodium sulfide. It was suggested that the furazan **8a** could also arise in this reaction; however, it was not isolated in this study.³⁵

On treatment with sodium borohydride at 50 °C in methanol, the furoxanisoquinoline **10** is reduced to give glyoxime **39** in a low yield.³⁴ The reduction of a furoxan ring giving two oxime groups occurs more efficiently under the action of hydroxylamine. Thus the reaction of the *N*-oxide **7b** with hydroxylamine affords glyoxime **40** in 54% yield. It should be noted that in addition to the reduction of the furoxan moiety, this reaction involves amination of the pyridine ring.⁴⁰

Photolysis of the compound **7a** ($\lambda = 254$ nm) carried out for 15 h in dichloromethane in the presence of morpholine under argon at room temperature gives a series of morpholine-containing products such as the glyoxime **6** (5%), the furazan **5** (9%), monomorpholypyridine **41a** (0.3%) and bis(morpholyl)pyridine **42** (0.3%).³³

Mor is morpholin-1-yl.

However, the compound **41** as well as a large number of its analogues can be prepared in a higher yield by conventional nucleophilic substitution. Treatment of the compound **7a** with *N*- and *O*-nucleophiles in water or ethanol at 18–25 °C induces opening of the furoxan ring accompanied by nucleophilic substitution of the hydrogen atom at C(6) in the pyridine ring.

This reaction has been used to prepare a group of diverse 3-amino-2-nitropyridines **41** and **43**. The yields of the products are 70%–80%.^{45,50}

$R^1 - R^2 = (CH_2)_2O(CH_2)_2, (CH_2)_2NH(CH_2)_2, (CH_2)_4$;

$R^1 = R^2 = H, Me, Et$; $R^1 = H$; $R^2 = Me, Et, Bu$; $R^3 = H, Me, Et$.

It is noteworthy that aminonitropyridines such as **41** and **43** as well as some other products of transformation of furoxanopyridines are potential precursors of polyfunctional derivatives of the same bicyclic system (which can be synthesised, for example, by oxidation). Unfortunately, this line of research is not represented in original publications.

The reaction of furoxanopyridines and amines in the presence of carbonyl compounds having an α -methylene unit follows a totally different pathway. In this case, the so-called Beirut reaction occurs,¹¹ in which enamine formed in the reaction medium functions as the active nucleophile, attacking the furoxan ring rather than the C(6) atom of the pyridine ring. The amine merely catalyses this transformation and is not incorporated in the reaction products, which are azaquinoxaline bis-*N,N'*-oxides **44**.^{39,51,52} The mechanism proposed for this process is presented below.

R^1	Me	Me	H	Pr ⁱ	Me
R^2	Me	H	Me	H	CO ₂ Me
R^1	CO ₂ Me	Me	Me	H	CH(OMe) ₂
R^2	Me	CONMe ₂	CH ₂ CO ₂ Me	CH(OMe) ₂	H

Unlike benzofuroxans, the furoxanopyridine **7a** gives rise to the Beirut reaction products in low yields (20%–30%). The standard procedure is very simple and consists in stirring the furoxan **7a** with excess carbonyl compound in ethanol in the presence of an amine (ammonia, morpholine, pyrrolidine, *etc.*) or sodium acetate. The resulting azaquinoxaline bis-*N,N'*-oxides **44** are of interest for pharmacology.

Detailed analysis of the ^1H and ^{13}C NMR spectra has provided full assignment of all the ^{13}C and ^1H signals for furazano[3,4-*b*]pyridine derivatives.^{23,31,37} NMR spectroscopy is especially useful for the investigation of isomeric *N*-oxides of this bicyclic system.^{23,49} The acid–base properties of the compound **7h** have been estimated based on the data of potentiometric titration in various solvents.⁴¹ X-Ray diffraction analysis of the bicyclic furazan **3a**³¹ and the tricyclic furoxan **14**³⁷ has shown that the bond lengths and bond angles in these compounds are close to the standard values. Kinetic studies led to the assumption that the initial events in the thermal decomposition of the compounds **7e** and **7i** and benzofuroxan and pyridine *N*-oxide derivatives are similar. These reactions were assumed to involve the formation of three-membered activated intermediates of the oxaziridine type.^{53–55}

The furoxan **7a** has been patented as a modifier (vulcaniser) for unsaturated polymers.^{56–59} Nitro-derivatives of this bicyclic system are thermally stable explosives.^{42,53,54} Biological studies have shown that some furazanoquinoxalines exert moderate inhibitory effect on c-AMP-dependent protein kinase.⁶⁰

2. Furazano[3,4-*c*]pyridines

Derivatives of furazano[3,4-*c*]pyridine (**B**) are also referred to as 1,2,5-oxadiazolo[3,4-*c*]pyridines, and the corresponding *N*-oxides are also called furoxano[3,4-*c*]pyridines.

The methods used to synthesise this class of compounds are more diverse, while the procedures employed to prepare the *N*-oxides largely resemble those outlined above.

The first representative of furazano[3,4-*c*]pyridines — cage furazan **47** — was prepared 100 years ago by treatment of α,α' -dihydroxyiminotropinone hydrochloride **45** with an alkaline solution of hydroxylamine. Obviously, the reaction starts with oximation of the free carbonyl group, which is followed by dehydration of two neighbouring oxime groups in the trioxime **46** thus formed. Compound **47** was isolated in 90% yield.⁶¹

A series of fused furazan derivatives **48** have been obtained in high yields from 2,2,6,6-tetrasubstituted⁶² and 2,6-disubstituted⁶³ piperazin-4-ones **49**.

Compounds 48 and 49	R ¹	R ²	R ³	R ⁴
a	Me	Me	Me	H
b	Me	Me	Me	OH
c	H	Me	Me	Me
d	H	Me	Me	H
e	H	Me	Me	Bu ^t
f	H	Ph	Ph	Me
g	H	Ph	Me	Me
h	H	Me	Me	OMe
i	H	H		Ph

Compounds 48 and 49	R ¹	R ²	R ³	R ⁴
j	H	H	H	Bu ^t
k	H	H	H	H

When asymmetrical initial compounds are used, for example **49g,i**, mixtures of isomers are produced.

Nitrosation of quinolinizinium salt **50** with sodium nitrite in 2 M hydrochloric acid affords *o*-amino nitroso compound **51**, which was reported⁶⁴ to be converted into tricyclic derivative **52** during recrystallisation from ethanol.

Furazano[3,4-*c*]pyridine derivatives have also been synthesised from furazan precursors. Thus condensation of 3,4-dibenzoylfurazan **53** with benzylamine in boiling toluene catalysed by diazabicycloundecene (DBU) results in the formation of compound **54a** in 13% yield.⁶⁵ However, condensation of dibenzoylfurazan with salts of amines having electron-withdrawing substituents at the α -carbon atom is more efficient and gives derivatives **54b–e** in higher yields.⁶⁶

Compound	R	X	Yield (%)
54b	CO ₂ Et	Cl	41
54c	CO ₂ Me	Cl	45
54d	CN	HSO ₄	73
54e	COPh	Cl	44

The reaction of trioxime **55a** with potassium ferricyanide occurs as oxidative cyclocondensation of two neighbouring oxime groups yielding furoxan **56a**. A similar treatment of the trioxime **55b** is accompanied by oxidation of the hydroxylamine function and gives rise to the furoxan nitroxide **57** stable under ambient conditions.⁶²

R = H (**a**), OH (**b**).

Oxidation of an alkaline solution of cyclic glyoxime **58** with sodium hypochlorite involves closure of the furoxan ring and gives lactam **59** in 87% yield.⁶⁷ On heating in toluene, this product partly rearranges to the isomeric 3-oxide **60**. The rearrangement gives a mixture of the isomers **59** and **60** in 1 : 4 ratio.

Benzoannulated analogues of the lactams **59** and **60**, for example **61**, have been synthesised by thermolysis of 4-azido-3-nitroquinolones **62** in boiling bromobenzene. The compounds **61** exist as unseparable mixtures of 3-oxides (**61a**) and 1-oxides (**61b**); this is clearly manifested in the ¹H NMR spectra.⁶⁸

Thermolysis of 4-azido-3-nitropyridine **63** in boiling ethanol or decalin at 80 °C gives furoxan **64** in 74% and 95% yields, respectively.⁴⁶ It is worth noting that the earlier attempts to perform this reaction in boiling toluene have failed.⁶⁹

When amine **65** is oxidised with diacetoxy- λ^3 -iodanylbenzene, only traces of the *N*-oxide **64** are detected; when sodium hypochlorite is used as the oxidant, the product **64** is not formed at all.³⁶

The attempts to annelate a furoxan ring to pyridine *N*-oxides have been unsuccessful. Thus thermolysis of *N*-oxides **66** and **67** gave only high-melting compounds, the structures of which were not identified.⁶⁹

An additional nitro group present in the initial azidonitropyridine facilitates the formation of the furoxan ring. In this case, an unusual solvent effect is manifested. Thermolysis of compound **68** in decalin gives furoxan **69** in 97% yield.⁴⁶ When the process is carried out in benzene, the yield becomes 45% to 70%, the reaction product being produced as a complex with the solvent. The same reaction performed in acetic acid gives rise to hydrated compound **70**.⁶⁹

Being an analogue of dinitrobenzofuroxan,¹¹ the compound **69** might also exhibit superelectrophilic properties. However, no studies considering its reactivity from this viewpoint have been reported to date.

On heating in decalin, 4-azido-3-nitroquinoline **71** is smoothly converted into furoxan **72** in 94% yield.^{46,47} The same compound is formed as a minor product, together with 3-nitroquinoline, when quinoline is treated with nitrogen oxides.⁷⁰

Since the electron-withdrawing furazan ring in furazano[3,4-*c*]pyridines is separated from the pyridine nitrogen, the N atom exhibits basic properties; hence, these compounds can form salts with acids.⁶⁹ Compounds in which the pyridine ring is hydrogenated show the highest basicity.⁶¹ Conversely, the nitro derivative **69** is an acid; it forms salts with bases, hydrazine and transition metal cations and charge transfer complexes with naphthalene derivatives and pyrene (no data about the structure of complexes formed by **69** are presented in the study cited).⁶⁹ The oximes **47** and **48** can be acylated on treatment with acyl chlorides in the presence of bases according to a conventional procedure.^{61,63} Deoxygenation of the nitroxide **57** is accompanied by simultaneous migration of the *N*-oxide oxygen atom in the furoxan ring to give ketone **73**.⁶²

Oxidation of hydroxylamino oxime **48b** is accompanied by deoxygenation with generation of a radical site.⁶² The furazan nitroxide **74** thus formed is stable under ambient conditions.

Treatment of the oximes **48c–i** with sodium hypochlorite in alkaline solutions affords nitro derivatives of dihydrogenated bicyclic compounds **75c–i**. However, the yields of these products are normally relatively low (12%–43%). The oximes **48c–i** are chlorinated with nitrosyl chloride in organic solvents to give chloro nitroso compounds, which have been isolated as salts **76c–h** in 60%–70% yields. The reaction of the compound **48i** with nitrosyl chloride affords the chloro nitroso derivative **76i**, its yield being only 7%, due to the side reactions caused by the presence of the thienyl substituent.⁶³

Nitration of the bicyclic compounds **48k** ($R^1 = R^2 = R^3 = H$) and **48j** ($R^1 = R^2 = H, R^3 = Bu^t$) with N_2O_4 , N_2O_5 , BF_4NO_2 or a mixture of HNO_3 with sulfuric or trifluoroacetic acid either gives trinitro derivative **77** or involves aromatisation giving rise to mono (**78a**) or di-nitro compound (**78b**). The reaction can be directed at the predominant formation of either of the products, their yields reaching 80%.⁶³

$R^1 = H$ (**48k**), Bu^t (**48j**); $R^2 = H$ (**78a**), NO_2 (**78b**).

The reduction of the compound **54b** with sodium borohydride involves three reaction sites — the ester group (to give hydroxymethyl derivative **79**), the pyridine ring (with the formation of dihydro derivative **80**) and the N–O bond (this leads to cleavage of the furazan ring resulting in the formation of diamines **81** and **82**). Depending on the reaction conditions (ratio of the reactants, temperature, reaction duration), a mixture of compounds enriched in a particular reduction product can be obtained.⁷¹ The yields of individual compounds are rather low. When $LiAlH_4$ is used as the reducing agent, the reaction carried out at room temperature affords alcohol **79** in 62% yield.

Only two types of products can be formed in a similar reaction of the cyano derivative **54d**. Stirring this compound with sodium borohydride in ethanol for 1 h at 20 °C gives furazan **83** in 65% yield and diamine **84** in a yield of only 4%. If the reaction mixture is refluxed for 10 min, the diamine **84** becomes the sole reaction product (yield 79%).⁷¹

Treatment of the dihydro derivatives **80** and **83** with NaOH in ethanol (1.5 h, 20 °C) or with DBU in benzene (4 h) induces oxidative aromatisation giving rise to the compounds **54b,d** in good yields.⁷¹

The structures of furazano[3,4-*c*] pyridine derivatives have been studied by mass spectrometry,^{72,73} IR⁷¹ and NMR⁶⁷ spectroscopy and UV spectrometry.⁷¹

The compound **54d** has been patented as a luminescent dye.⁷⁴

3. Furazano[2,3-*a*]pyridines

Furazano[2,3-*a*]pyridines (**C**) are also referred to as 1,2,5-oxadiazolo[2,3-*a*]pyridines.

The only method for the synthesis of these compounds known to date is based on pyridine precursors. The reaction of the *E*-oxime of 2-acetylpyridine *N*-oxide **85a** with toluene-*p*-sulfonyl chloride in the presence of alkali leads on closure to a furazan ring and gives the bicyclic derivative **87** in 67% yield.⁷⁵

Presumably, this transformation involves the intermediate formation of the tosylate **86a**. A similar reaction of the corresponding *Z*-isomer **85b** does not give a bicyclic product but stops at the stage of formation of the tosylate **86b**.

Treatment of the *E*- and *Z*-isomers of the methylquinolyl and methylisoquinolyl ketoxime *N*-oxides did not result in closure to give a furazan ring.⁷⁶

Heating of the *E*-isomer **85a** in acetic anhydride at 130 °C for 2 h affords furazan derivative **88** in 88% yield. At temperatures below 100 °C, the reaction stops at the stage of formation of acetyl derivative **89**. The *Z*-isomer **85b** is not converted into a furazan derivative even at high temperatures. The compound **88** is formed by a radical mechanism. This was confirmed experimentally by conducting the reaction in the presence of radical sources or radical traps. The course of the reaction can be described by a scheme with intermediates **90–92** (Scheme 1).⁷⁷

The compound **88** remains unchanged when refluxed with 20% hydrochloric acid or alkali. However, it is readily brominated in chloroform to give a mixture of di- (**93**) and tetra-brominated (**94**) compounds in 52% and 33% yields, respectively. On refluxing in ether for 4 h, the compound **94** eliminates a bromine molecule, being quantitatively converted into the dibromide **93**.⁷⁷ The dimer **88** is stable against catalytic hydrogenation (H₂, Raney nickel).⁷⁷

The tosylate **87** is reduced with hydrogen over Pd to give, depending on the reaction conditions, either hydrogenated bicyclic compound **95** (in a yield of up to 25%) or monocyclic furazan **96** (in a yield of up to 89%).⁷⁵

The structure of these derivatives, which are unusual for the furazan series, was established based on thorough analysis of their

¹H NMR, ¹³C NMR, UV, IR and mass spectra; 2D NMR techniques have also been used for this purpose.^{75,77}

IV. Furazanopyrans

Of the two theoretically possible types of bicyclic compounds comprising furazan and pyran rings (**D** and **E**), only furazano-[3,4-*c*]pyran derivatives (type **E**) are known.

Furazano[3,4-*c*]pyran derivatives can be obtained both from furazan and pyran synthons. Thus treatment of furazan-3-carboxylic acid **97** with acetic anhydride or dicyclohexylcarbodiimide (DCC) induces intramolecular esterification. This gives lactone **98** in 80%–85% yield.⁷⁸

Dehydration of glyoxime **99** is accompanied by the formation of a furazan ring. This reaction gives cage furazan compound **100**.⁷⁹

Refluxing of the pyridinium salt **101**, containing a carbohydrate fragment, with sodium nitrite in the presence of pyridine in aqueous THF leads to furoxan **103**, which is formed in 58% yield, apparently, *via* the intermediate formation of nitro derivative **102**.⁸⁰

The isomeric furoxan **105** can be prepared by successive treatment of 2-keto-D-glucopyranoside **104** with hydroxylamine in aqueous pyridine and with a solution of sodium nitrite in aqueous dioxane followed by keeping the reaction mixture for 3 h at 90 °C. The yield of the furoxan **105** is 40%.⁸⁰

Data on the reactivity of furazano[3,4-*c*]pyran derivatives are very scarce. It is only known that the lactone ring in the compound **98** can be opened by amines to give amides of furazan-3-carboxylic acid **106**.⁷⁸

R = R' = Me (**a**), Et (**b**); R = H, R' = Ph (**c**).

Spirocyclic lactone **107** is cleaved on treatment with methanol, being thus converted into monocyclic furazan derivative **108**.⁸¹

Compounds of this group have been characterised by the data of IR and UV spectroscopy and mass spectrometry.⁸⁰

V. Furazanothiopyrans

Two types of furazanothiopyrans can be conceived, furazano[3,4-*b*]thiopyrans (**F**) and furazano[3,4-*c*]thiopyrans (**G**). However, no derivatives of structure **F** are known.

Only one study concerning furazano[3,4-*c*]thiopyran derivatives has been published.⁶³ The dehydration of trioximes **109a-d** induced by heating with alkali or DCC is accompanied by closure to give a furazan ring, resulting in the formation of oximes **109a-d** in 67%–85% yields. The formation of a furazan ring with simultaneous acylation of the third oxime group was observed when trioximes **109b** and **109d** were treated with acetic anhydride. The acetates of bicyclic oximes **110d** and **110e** were isolated in 88%–93% yields.⁶³

R¹ = R² = H (**a**); R¹ = Ph, R² = H (**b**); R¹ = Me, R² = H (**c**); R¹ = 2-furyl, R² = H (**109d**), Ac (**110d**); R¹ = Ph, R² = Ac (**110e**).

No data concerning the reactivity of this bicyclic system can be found in the literature.

VI. Furazanoazepines

Four types of annelation of furazan and azepine rings (**H**, **I**, **J** and **K**) are possible.

Only few derivatives of furazano[3,4-*c*]azepine (**I**) have now been described.

The heterocyclic system of furazano[3,4-*c*]azepine has been mentioned in the literature as 1,2,5-oxadiazolo[3,4-*c*]azepine.

The Beckmann rearrangement of *Z*-oxime **111** in the presence of PCl_5 in ether at 20 °C gives rise to azepin-4-one **112** (yield 29%). Treatment of *E*-oxime **113** under similar conditions gives the same product **112** in a yield of only 5%. The main bulk of the initial compound is converted into a polymer rather than into the expected isomeric azepine **114**.⁸²

Azepine **112** is also formed upon the Curtius rearrangement of ketone **115**, induced by treatment with sodium azide in a mixture of chloroform and sulfuric acid. Note that the Curtius rearrangement gives the azepine **112** in a higher yield (55%) than the Beckmann rearrangement.⁸³

The reaction of **112** with acetyl chloride in the presence of sodium hydride in toluene gives the corresponding N-acetylation product in 67% yield.⁸²

The structure of this azepine has been confirmed by the data of its IR, ¹H NMR and mass spectra.

The azepine **112** exhibits moderate antimicrobial activity.⁸³

VII. Furazanothiepinines

Of the three types of annelation of a furazan ring to a thiopine ring possible theoretically (**L**, **M** and **N**), only type **N** derivatives, furazano[3,4-*d*]thiepinines, have been synthesised.

Heating of a benzene solution of bis-*N,N*-oxide **117**, prepared by treatment of dioxime **116** with an alkaline solution of sodium hypochlorite, affords furoxan **118** in 90% yield.⁸⁴

Thieno-annelated compounds **119a,b** have been synthesised in a similar way.⁸⁵ However, the replacement of a benzene ring in the initial molecule by a thiophene ring results in somewhat lower yields of the corresponding tetracyclic compounds **119a,b** (72%–74% yield).

R = H (**a**), Me (**b**).

Furoxans **119a,b** exist as unseparable mixtures of isomers.

VIII. Conclusion

The data presented in this review demonstrate on the one hand, the great synthetic potential of the class of compounds considered and, on the other hand, the scarcity of investigations along this line. The latter is apparently due to the facts that the required initial compounds are relatively difficult to obtain and that the methods for their transformations are not adequately developed. Meanwhile, some existing efficient methods for the construction of the title bicyclic systems have not yet found wide use. We hope that systematisation of the published data presented in this review will serve as the basis for the further development of this field of chemistry.

IV. Reactions with oxazadienes	161
V. Conclusion	161

Abstract. Data on reactions of halophosphines $\text{P}(\text{H})\text{X}_3$, $-\text{P}(\text{H})\text{X}_2$, and $>\text{P}(\text{H})\text{X}$ with hetero-1,3-dienes resulting mostly in the formation of phosphorus-containing heterocycles are generalised and systematised. The influence of the nature, the number and positions of heteroatoms (O, N) in the heterodiene system, and of the nature of the substituents at the phosphorus atom on the reaction pathways and mechanisms is analysed. The bibliography includes 155 references.

I. Introduction

Reactions of tricoordinate phosphorus derivatives with diene systems is an important route to cyclic phosphorus-containing compounds, first of all following the $[4+1]$ -cycloaddition mechanism. In this regard, reactions of halophosphines (HP) $\text{P}(\text{H})\text{X}_3$, $-\text{P}(\text{H})\text{X}_2$, and $>\text{P}(\text{H})\text{X}$ are most numerous. Their reactions with 1,3-dienes containing no heteroatoms are well studied. The reaction of $[4+1]$ -cycloaddition of HP to 1,3-dienes was discovered by McCormack in 1953^{1,2} and most intensively studied in the 1960's and early 1970's simultaneously by several groups of investigators. Reactions of HP with conjugated dienes have been adequately covered in reviews^{3,4} and monographs.^{5–7} Despite a wide variety of compounds obtained, they all belong to phosphol-2(3)-enes ($[4+1]$ -cycloaddition reaction), to polymers or oligomers containing a phosphorus atom in the chain (1,4-addition reaction), or to the products of cyclisation occurring with retention of the system of conjugated bonds. The studies in this field^{8,9} reported after publication of a book by Quin⁶ in 1981 contain no radically new data, except for a series of studies dedicated to investigation of reactions of 1,3-dienes with HP of the X_2CHPX_2 ($\text{X} = \text{Cl}, \text{Br}, \text{I}$) type in the presence of triethylamine.^{10–16} Under the action of excess triethylamine, this type of HP undergo dehydrohalogenation to form unstable phosphathenes $\text{XP}=\text{CX}_2$. The latter enter *in situ* into the Diels–Alder reaction with dienes following the $[4+2]$ -cycloaddition mechanism to give aromatic compounds, viz., 2-halophosphorinines containing a

dicoordinate phosphorus atom, *via* intermediate six-membered 1,2,2-trihalo-1,2,3,6-tetrahydrophosphorinines.

The study of reactions of HP addition to hetero-1,3-dienes was begun by Conant¹⁷ in 1917 taking unsaturated carbonyl compounds as an example and is being developed successfully at present. These reactions are very diverse and result in the formation of not only five-, but also six-membered rings, and open-chain structures as well. Recently, the range of heterodienes under study has been considerably extended, which has led, in particular, to obtaining of novel classes of phosphorus-containing heterocycles, which are not only of theoretical, but also of considerable practical interest.

The aim of the present review is to systematise the available information on the reactions of HP with heterodienes and to reveal peculiarities of the influence of heteroatoms in the diene system on the direction and mechanisms of these reactions. We do not discuss here the reactions of compounds that formally contain a heterodiene system, if one or both double bonds of a diene are fragments of arene or heteroarene systems.

II. Reactions with oxadienes

1. Reactions with α -dicarbonyl compounds

Investigation of the reactions of P(III) derivatives with α -dicarbonyl compounds was carried out almost simultaneously with the study of analogous reactions of dienic hydrocarbons. However, it should be noted that in most cases it was phosphites that have been used as dienophiles, whereas reactions with HP have been the subject of an insignificant number of publications; moreover, all of them involved α -diketones only.

Like dienic hydrocarbons, α -diketones **1** react with dialkylphosphorochloridites by the $[4+1]$ -cycloaddition mechanism to form adducts **2** containing a pentacoordinate phosphorus atom. Further elimination of alkyl chloride from the adducts **2** according to the mechanism of the second stage of the Arbuzov reaction (see Refs 18, 19) gives 2-alkoxy-2-oxo-1,3,2-dioxaphospholes **3**.^{20,21}

$\text{R}^1 = \text{Me}, \text{Ph}; \text{R}^2 = \text{Et}, \text{Pr}^n, \text{Bu}^i, \text{Bu}^n.$

Received 29 April 1998

Uspekhi Khimii 68 (2) 167–183 (1999); translated by A M Raevsky

Dialkyl phosphorochloridites are less reactive than trialkyl phosphites and phosphoramidites.^{20–22} It is believed²² that the closure of the dioxaphosphole ring occurs as a result of a concerted or almost concerted passage of the lone electron pair of the phosphorus atom to the conjugated π -system of the α -diketone and transfer of the π -electrons of this system to orbitals of the phosphorus atom.

The reaction of 2-chloro-1,3,2-dioxaphospholane (**4**) with biacetyl occurs to give initially spiroposphorane **5** containing a P(V)–Cl bond and is followed by its conversion into 4,5-dimethyl-2-oxo-2-(2-chloroethoxy)-1,3,2-dioxaphosphole (**6**) by the mechanism of the second stage of the Arbuzov reaction.²³

Biacetyl reacts with dichlorophosphines in a different way, viz., with the formation of 4-chloro-3*H*-5-methyl-2-oxo-1,2-oxaphosphole **7**, following a mechanism involving recyclisation.^{24,25}

R = Me, Et, Ph.

A phosphorane-type product of [4 + 1]-cycloaddition is obtained in the reaction of phosphorus trichloride with 3,5-di-*tert*-butyl-*o*-quinone (**8**).²⁶ Based on detection of signals in the EPR spectra recorded during this reaction, it was argued²⁶ that its mechanism involves a stage of one-electron transfer.

Similar signals in the EPR spectra were also observed in the reactions of PCl₃ with *o*-chloranil, *o*-naphthoquinone, and 9,10-phenanthrenequinone; however, the final products have not been isolated.²⁶ It should be noted that the appearance of paramagnetic intermediates, detected by the EPR technique, in the reaction mixture is not the unambiguous evidence for the formation of the final phosphorane as a result of one-electron transfer.

Phosphenium salts, which are closest analogues of HP, react with *o*-quinone **8** similarly to HP, following the [4 + 1]-cycloaddition mechanism to form 1,3,2-dioxaphospholenium salts **9**.²⁷

R¹ = Pr₂N; R² = Cl, N = PPh₃; R¹, R² = Alk;
R¹–R² = MeN(CH₂)₂NMe; X = AlCl₄, CF₃SO₃.

In the reactions with phosphenium salts the *o*-quinone **8** behaves analogously to 1,3-dienes.^{28–30} At the same time, (Pr₂N)₂PCl in which the phosphorus atom is less electrophilic than in the phosphenium cation, does not enter into this reaction.²⁷

Thus, as in the case of dienic hydrocarbons, symmetric heterodiene systems of diketones and *o*-quinone add a phosphorus-containing dienophile at positions 1 and 4 with the formation of a cycloadduct containing a pentacoordinate phosphorus atom in the first stage. The final reaction products are derivatives of 1,3,2-dioxaphospholes or 3*H*-1,2-oxaphospholes. No indications of the existence of intermediate bipolar ions were found. The intermediate **2** was detected by ³¹P NMR spectroscopy.²²

2. Reactions with α,β -unsaturated carbonyl compounds

Mesityl oxide and benzylideneacetophenone were the first 1,3-heterodienes used to study the reactions with HP taking PCl₃ and PBr₃ as an example.¹⁸ The assumption that the reactions with phosphorus trihalides follow the [4 + 1]-cycloaddition mechanism with the formation of five-membered cycles, viz., 3*H*-1,2-oxaphospholes,¹⁷ was confirmed in further studies. A brief summary of the results obtained in these earlier studies has been reviewed,³ so we do not discuss them here. After the review³ was published, it was established that passage of hydrogen sulfide through a mixture of phosphorus trihalide and α,β -unsaturated ketones **10–12** afforded 3*H*-1,2-oxaphosphole sulfides **13–15** in good yields.^{31,32} This is evidence in favour of [4 + 1]-cycloaddition.

R¹, R², R³ = H, Me.

X = Cl, Br.

It was also shown later that heating phosphorus trichloride and mesityl oxide in a sealed tube in the absence of a solvent gave 2-chloro-3,3,5-trimethyl-2-oxo-3*H*-1,2-oxaphosphole.³³ We believe that the formation of this compound can be explained by the replacement of two chlorine atoms in the intermediate [4 + 1]-cycloaddition product by the carbonyl oxygen atom of the second mesityl oxide molecule.

The reactions of methyl phosphorodichloridite with ketones **10** also follow the Diels–Alder reaction mechanism, subsequent elimination of methyl chloride from the adduct **16** results in 2-chloro-2-oxo-3*H*-1,2-oxaphospholes **17**.³⁴

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Me}$.

Reactions of dichlorophosphines with α,β -unsaturated ketones **10** in acetic anhydride give first the adducts of the type **16** and then 3*H*-1,2-oxaphospholes **18**.^{35–37}

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Me}; \text{R}^4 = \text{Et}, \text{Ph}, 2\text{-thienyl}$.

Benzylideneacetone and phenyl(dichloro)phosphine do not enter into this reaction in acetic anhydride.³⁵

However, the reactions of dichlorophosphines and phenyl phosphorodichloridites with mesityl oxide (heating in sealed tubes in the absence of a solvent) afford acyclic β,γ -unsaturated phosphorus acid chlorides **19** in which the coordination number of P atom is 4. The latter result from a ring–chain isomerisation of the adducts of the type **16** initially formed in the Diels–Alder reaction.³³

$\text{R} = \text{Me}, \text{Et}, \text{Ph}, \text{PhO}$.

Analogous products are obtained in the reaction of dichlorophosphines with α,β -unsaturated aldehydes **20**. In this case the reaction occurs under milder conditions (in solution).³⁸

$\text{R}^1 = \text{Me}, \text{H}; \text{R}^2 = \text{Et}, \text{Ph}$.

Aldehydes **20** react with phenyl(dichloro)phosphine or PCl_3 in acetic acid to give α -hydroxy- β,γ -unsaturated phosphorus acid dichlorides **21** in which the coordination number of the P atom is 4.³⁸

$\text{R}^1 = \text{Et}, \text{Ph}; \text{R}^2 = \text{Ph}, \text{Cl}$.

Compounds **4**, **22** and **23** react with α,β -unsaturated ketones **10** (heterodienes) by mechanisms involving cycloaddition followed by dealkylation, which is analogous to the second stage of the Arbuzov rearrangement. This results in the formation of 3*H*-1,2-oxaphosphole derivatives,^{39,40} as is shown below taking the reaction with benzylideneacetone as an example.

4: $\text{R} = \text{H}, n = 1$; **22**: $\text{R} = \text{Me}, n = 1$; **23**: $\text{R} = \text{H}, \text{Me}, n = 2$.

As was mentioned in Section II.1, biacetyl reacts with phospholane **4** following a conventional mechanism of cycloaddition to the $\text{O}=\text{C}-\text{C}=\text{O}$ bond system. However, it was reported⁴¹ that the reactions of biacetyl with compounds **4**, **22** and **23** under virtually the same conditions resulted in the formation of quite different products, viz., 1,2-oxaphospholan-4-ones **24**. This was rationalised by a [4 + 1]-cycloaddition of compounds **4**, **22** and **23** to the enol form of biacetyl as the heterodiene.

Condensation of ketones **10** with 2-chloro-1,3,2-oxathiaphospholane occurs analogously to the reaction with compound **4**. The second stage of the Arbuzov rearrangement of the intermediate adduct occurs with the cleavage of the C–O bond (not the C–S bond, as in the reaction with butadiene) to give derivatives of 2-oxo-3*H*-1,2-oxaphospholes **25** containing the P–S bond.⁴²

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Me}$.

The structure of the final product of reaction between 2-chloro-1,3,2-dithiaphospholane (**26**) and ketones **10** ($\text{R}^1 = \text{H}, \text{Me}; \text{R}^2 = \text{R}^3 = \text{H}$) is determined by the nature of the substituent R^1 . 2-Thioxo-3*H*-1,2-oxaphosphole **27** and 2-oxo-3*H*-1,2-thiaphosphole **28** are respectively formed at $\text{R}^1 = \text{Me}$ and H .⁴³

The reaction of compound **26** with ketone **10** ($\text{R}^1 = \text{H}$) occurs either with the rearrangement of an intermediate adduct or with the initial formation of thioxo derivative of the type **27**, which after the Pishchimuka rearrangement⁴⁴ is converted into the phosphoryl compound **28**.

$R^1 = \text{H, Me}; R^2 = R^3 = \text{H}.$

Alkylphosphonochloridothioites **30** react with ketones **10** in a similar way; however, in this case, alkyl halide is eliminated from the intermediate [4 + 1]-cycloaddition product **29** to give 2-ethyl(-phenyl)-2-thioxo-3*H*-1,2-oxaphospholes **31** (Scheme 1, route *a*).⁴⁵ In the presence of proton-donor reagents (acetic acid or water) this reaction results in the formation of *S*-alkyl phosphinothioates **32**⁴⁶ (Scheme 1, route *b*). The formation of products **32** is explained as follows.⁴⁶ The ambident ion **33** formed in the first reaction stage as a result of nucleophilic C-addition of alkylphosphonochloridothioite **30** to the unsaturated ketone **10** reacts with acetic acid⁴⁶ to give an intermediate acyclic adduct **34**. The latter undergoes the Arbuzov rearrangement with the elimination of acyl chloride and the formation of the final product **32**. If the reaction is performed in the presence of water, alkylphosphonochloridothioite **30** is initially hydrolysed into the corresponding acid **35**, which then is added to the ketone **10** to give the ester **32** (Scheme 1, route *c*).

We believe that it is possible to combine the routes *a*, *b* and *c* into a unified scheme assuming that betaine **33** can be a common intermediate to routes *a* and *b* and that in the presence of water the process can follow not only route *c*, but also route *b* (the latter can be considered as a route common to any proton-donor reagents). Under the action of proton-donor reagents, the halogen atom in the phosphorane **29** can be replaced by an OX group to form a product **36**. The latter adds hydrogen halide to give an ion **34**,

which is in equilibrium with an ion **37**, and then the final product **32**.

Heating of diethylchlorophosphine and mesityl oxide in a sealed tube in the absence of a solvent resulted in a crystalline adduct **38**, which was converted into phosphine oxide **39** upon treatment with alcohols following the scheme shown below:⁴⁷

$R = \text{Me, Bu}.$

Apparently, the intermediates **3**, **40** and **41** are the analogues of intermediates **29**, **36** and **34**, respectively, while the product **39** is an analogue of the products **32**. It is quite possible that both products **39** and **32** are formed *via* intermediates **33**. Thus, a conclusion can be drawn that the reactions of P(III) acid monochlorides with unsaturated ketones in the presence of proton-donor reagents follow a common mechanism irrespective of the reaction conditions.

A peculiar type of reaction is that of HP with β -diketones in the presence of organic base. It is believed that β -diketones **42** enter into reaction in the enol form, *i.e.*, that they can be considered as a particular case of α,β -unsaturated ketones **10** ($R^2 = \text{Me}, R^3 = \text{OH}$). Reactions of P(III) dichlorides with β -diketones give 4-methylene-4*H*-1,3,2-dioxaphosphorinines **43** with a semicyclic homodiene system of bonds.^{48–51}

Scheme 1

$R^1, R^2, R^3 = \text{H, Me}; R^1 = R^2 = \text{H}, R^3 = \text{Ph}; R^4 = \text{Et, Ph}; R^5 = \text{Et, Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i; \text{X} = \text{H, Ac}.$

$\text{R}^1 = \text{H, Et, Cl, Ac; R}^2 = \text{Et, Ph, MeO, EtO, Pr}^n\text{O, Pr}^i\text{O, Me}_2\text{N, Et}_2\text{N, EtS.}$

The reaction proceeds *via* intermediate heterodienes, *viz.*, α,β -unsaturated ketones **44**, which are formed upon O-phosphorylation of the hydroxyl group of the ketones **42**, which leaves the diene system intact. Subsequent intramolecular O-phosphorylation leads to the closure of the six-membered ring and the formation of dioxaphosphorinines **43** containing an exocyclic methylene group.^{49–51}

If P(III) monochlorides are used instead of P(III) dichlorides in the reaction with ketones **42**, in most cases the process is completed by the formation of acyclic products **45**, *viz.*, O-phosphorylated derivatives of the ketones **42**, which are analogous to the ketones **44**.^{51–55}

Thus, unlike all reactions considered above, this reaction occurs without involvement of the system of conjugated bonds of the heterodiene at all.

$\text{R}^1 = \text{H, Ac, Cl; R}^2 = \text{EtO, Pr}^n\text{O, Me}_2\text{N, Et}_2\text{N; R}^3 = \text{Me, MeO, EtO, Pr}^i\text{O, Bu}^i\text{O, Ph, Et}_2\text{N; R}^2\text{--R}^3 = \text{O}(\text{CH}_2)_2\text{O, OCH}_2\text{CH}(\text{Me})\text{O, o-O}_2\text{C}_6\text{H}_4.$

In the case of acetylacetone, it was established that the reaction product **45** is a mixture of *Z*- and *E*-isomers with a considerable predominance of the *E*-isomer.^{51, 54}

If P(III) monochlorides containing a dialkylamino group are introduced into the reaction with acetylacetone (**42**, $\text{R}^1 = \text{H}$), the linear heterodienes **45** formed initially undergo cyclisation into dioxaphosphorinines **43** with the elimination of dialkylamine. Dioxaphosphorinines **43** are isolated as final products after distillation. The reaction occurs successfully in the presence of acidic admixtures, which behave as catalysts and favour the conversion of the dialkylamino group into a good leaving group. Cyclisation occurs with particular ease if the intermediate linear heterodienes **45** contain two dialkylamino groups at the phosphorus atom. An interesting peculiarity was observed in those cases where it was possible to isolate the intermediates **45** or to obtain them by independent synthesis, *viz.*, the yields of the cyclisation products **43** were higher than the portion of *Z*-isomer in the intermediates **45**. This indicates that *Z,E*-isomerisation of heterodienes **45** occurs under the cyclisation conditions.^{51, 54}

$\text{R}^1 = \text{H; R}^2 = \text{EtO, Pr}^n\text{O, Pr}^i\text{O, Et}_2\text{N; R}^3 = \text{Me}_2\text{N, Et}_2\text{N.}$

Metal complexes of phenyl(dichloro)phosphine react with acetylacetone in the presence of triethylamine analogously to uncoordinated dichlorophosphines, leaving the metal-containing groups intact.^{56, 57}

This type of reactions was studied in more detail taking the reaction of pentacarbonylchromium complex **46** with acetylacetone as an example.⁵⁷

Finally, it should be noted that ethyl(dichloro)phosphine reacts in acetic acid with acetylacetone in its diketone form rather than in its enol form.⁵⁸

Reactions of enamino ketones **47** (nitrogen analogues of the diketones **42**) with alkyl phosphorodichloridites yield azaanalogues of dioxaphosphorinines **43**, *viz.*, 4-alkylidene-4*H*-1,3,2-oxazaphosphorinines **48**.^{51, 59}

$\text{R}^1 = \text{H, Me; R}^2 = \text{R}^3 = \text{H; R}^4 = \text{Me, Ph; R}^1\text{--R}^2 = (\text{CH}_2)_3;$
 $\text{R}^2\text{--R}^3 = (\text{CH}_2)_2; \text{R}^5 = \text{Me, Et, Pr, Bu.}$

The reaction of enamino ketones **47** with dialkyl phosphorochloridites halts in the stage of N-phosphorylation of the amino group and the formation of acyclic dialkyl phosphoramidites **49**.^{51, 60}

$\text{R}^1 = \text{H, Me; R}^2 = \text{R}^3 = \text{H; R}^4 = \text{Me; R}^5 = \text{Et, Pr.}$

However, as in the case of diketones **42**, the reaction of enamino ketone **47** ($\text{R}^1 = \text{R}^4 = \text{Me; R}^2 = \text{R}^3 = \text{H}$) with bis(diethyl)phosphorodiamidochloridite occurs in a more complex way. Observation of weak signals along with other signals in the ³¹P NMR spectrum indicates that the reaction mixture contains 4-methylene-4*H*-1,3,2-oxazaphosphorinene **50** and/or isomeric 6-methylenephosphorinene **51**.

However, only 5-methylene-2-oxo-5H-1,2-azaphosphole **52** was isolated after distillation^{51, 59} due to the vinyl phosphite–vinylphosphonate rearrangement.^{50, 51, 53}

Reactions of phosphorochloridites and crotonaldehyde in the presence of triethylamine occur with proton abstraction from the methyl group at the double bond and the formation of butadienyl phosphites.⁶¹ We believe that the initial attack of phosphorochloridite on the oxygen atom of the carbonyl group is followed by proton abstraction from the methyl group.

R = Et, Ph; (OR)₂ = O(CH₂)₂O.

2-Chloro-1,3,2-dioxaphospholane (**4**) reacts with α,β -unsaturated aldehydes only on the carbonyl group to form phosphorus-containing oligomers **53** with retention of the C=C bond.³⁹

R = H, Me.

The distinction between the reactions of functionalised ketones **42** and **47** with HP and those of aldehydes **20** with phosphoromonochloridites from the reactions of other heterodienes with HP is that these α,β -unsaturated carbonyl compounds react analogously to saturated carbonyl compounds,⁶² i.e., they enter into O-phosphorylation reactions rather than into the [4 + 1]-cycloaddition reactions. In turn, HP act simply as the corresponding acid chlorides rather than as P(III) derivatives, the coordination number of the phosphorus atom in which is increased immediately in the reaction with (hetero)dienes (as in the case of [4 + 1]-cycloaddition reaction). It should be noted that in the formation of oligomers **53** the coordination number of the phosphorus atom increases to four only upon subsequent dioxaphospholane ring opening.

The system of the C=C–C=O bonds can be a fragment of a more extended conjugated cyclic system, e.g., *p*-benzoquinone and its anthraquinone type analogues. A few reactions of these compounds with HP have been documented; however, since they occur with involvement of the entire quinone system, we do not discuss them here and restrict ourselves to referring to the corresponding reviews.^{63, 64}

Numerous studies have been dedicated to reactions of HP with α,β -unsaturated acids and their derivatives. Several early studies have been reviewed.³

Reactions of HP with acids **54** can follow several pathways. Dihalides most often add to the acids **54** to form β -phosphinocarboxylic acid dichlorides **55**.^{65–77}

R¹, R² = H, Me; R³ = Me, Et, Ph, *p*-MeC₆H₄, 2-thienyl, EtO, Me₂(CCl₃)CO, CH₂Cl.

Two different mechanisms of this reaction have been proposed. According to the first of them, HP react with unsaturated acids **54** following the [4 + 1]-cycloaddition pathway, which most often is considered as stepwise, to give linear phosphoranes, which undergo the intramolecular Arbuzov rearrangement resulting in the final products **55** (Scheme 2).^{65, 66, 68, 71, 73, 76}

Scheme 2

Here the P(III) atom acts as a nucleophile, since the higher the nucleophilicity of the R³ substituent the more readily the reaction proceeds.⁷⁶ However, this is also consistent with an alternative scheme involving no [4 + 1]-cycloaddition.

According to the alternative scheme,^{73, 75–79} (Scheme 3) the chlorine atom in the HP molecule and the hydroxyl group in the molecule of acid **54** exchange in the initial step. Then the hydrophosphoryl compound **56** that formed is added to the unsaturated acid chloride **57** according to the Pudovik reaction.^{80, 81}

Scheme 3

It is believed⁸² that this scheme involves a preliminary stage of P-protonation of HP by the unsaturated acid **54**.

The presence of the hydrophosphoryl compound **56** and unsaturated acid chloride **57** in the reaction mixture is detected by NMR spectroscopy; sometimes it is possible to isolate these compounds. Moreover, compounds **56** and **57** do add to each other to give the final product **55**, which has been proved in a model reaction.^{77, 82} Scheme 3 is also consistent with increase in the reaction rate with the increase in the electron-donor ability of the substituents at the phosphorus atom. Finally, which is also proved by kinetic studies,⁷⁸ hydrogen chloride, which is always present in the reaction mixture, plays an important role in these reactions. In this connection it is noteworthy that diethyl acryloyl phosphite (**58**) protonated under the action of HCl rearranges into β -diethoxyphosphorylpropionyl chloride (**59**) in good yield. It is most likely that in this case the reaction follows the same sequence of stages as that discussed for the preceding scheme.⁸²

Thus, it can be considered as proved that P(III) acid dichlorides react with unsaturated acids **54** according to Scheme 3. However, this does not imply that the [4 + 1]-cycloaddition scheme is wrong and makes no contribution to the reaction under consideration.

The rate of the reaction of the α,β -unsaturated acids **54** with HP decreases if acids **54** contain α - and/or β -substituents.^{71, 76, 79} Moreover, only acid chlorides **57** can be isolated as the reaction products of ethyl(dichloro)phosphine with several β -substituted α,β -unsaturated acids.^{76, 83, 84}

$\text{R}^1 = \text{Ph}, \text{HOOC}, \text{trans-Cl}, 2\text{-furyl}; \text{R}^2 = \text{H}.$

This fact is consistent with both reaction schemes proposed. According to Scheme 2, the phosphorus atom attack on the β -carbon atom of the acid **54** is the key reaction step. β -Substituents in the acid molecule produce steric hindrances, which only results in the formation of acid chlorides **57** from the carboxylic acid **54**. In the framework of Scheme 3, the attack on the carboxylic group in all cases is the initial and necessary stage. Obviously, if acid chlorides **57** contain substituents indicated in the scheme, the addition of ethyl(dichloro)phosphine to compounds **57** occurs very slowly due to both spatial shielding of the β -carbon atom and delocalisation of the electron density on the β -substituent and only these compounds can be isolated from the reaction mixtures.⁸²

The reaction of dibutyl phosphorochloridite with acrylic acid at a reduced pressure gave only acryloyl chloride.⁷⁷

The acids **54** react with methyl phosphorodichloridite to give unsaturated carboxylic acid chlorides **57** and oligomers **60**.³⁴

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}.$

Only oligomeric products were isolated in the reactions of acids **54** with compounds **4**, **22** and **23**.^{39, 85}

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Me}; n = 1, 2.$

It was assumed^{34, 39, 85} that the reactions of the acids **54** and other (hetero)dienes with HP occur according to the [4 + 1]-cycloaddition mechanism and are followed by the Arbuzov rearrangement of the adduct containing a pentacoordinate phosphorus atom with the formation of oligomers. However, it was shown later that no adduct containing a P(V) atom is formed in the reaction of ethyl phosphorodichloridite with acrylic acid without heating the reaction mixture at very high temperatures. Therefore, the formation of oligomeric products in the reactions of HP with α,β -unsaturated acids was explained by thermal conversions of acid dichlorides **55** that were formed.⁷⁷ It should be noted that the formation of oligomers together with distillable addition products^{65, 68, 79} was also considered as a result of thermolysis of primary reaction products upon distillation.

2,5-Dioxo-1,2-oxaphospholanes **61** are occasionally isolated along with the products **55** in the reactions of P(III) acid dichlorides with acids **54**.^{86–89} These originate from mixed anhydrides formed as byproducts from acid dichlorides **55** and acids **54** and are produced on heating during distillation.^{71, 86}

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}; \text{R}^3 = \text{ClCH}_2, 2\text{-thienyl}, 5\text{-chlorothieryl-2}, \text{Et}, p\text{-MeC}_6\text{H}_4.$

Oxaphospholanes **61** were also obtained in the reactions of phosphorochloridites and phosphonochloridites with the acids **54**. Their formation (as a result of elimination of alkyl chloride from intermediate addition products) competes with the formation of acyclic compounds **62** analogous to acid dichlorides **55**.^{75, 79, 82, 90–92} Either or both linear acid chlorides **62** and oxaphospholanes **61** were isolated under different conditions. Since cyclisation of acid chlorides **62** in the course of distillation can also result in the formation of the phospholanes **61**, it is unclear whether the latter are formed as a result of either or both direct reaction of HP with the acids **54** and thermolysis of the products **62**.

$\text{R}^1 = \text{H}; \text{R}^2 = \text{H}, \text{Me}; \text{R}^3 = \text{Et}, \text{Me}_2(\text{CCl}_3)\text{C}, (\text{ClCH}_2)_2\text{CH}, \text{ClCH}_2\text{CH}_2,$
 $\text{Cyclopentyl-CCl}_3; \text{R}^4 = \text{Et}, \text{Ph}, \text{MeO}, \text{PhO}, \text{Me}_2(\text{CCl}_3)\text{CO}, \text{MeEt}(\text{CCl}_3)\text{CO}.$

Only linear products analogous to compounds **62** are formed in the reactions of alkyl phosphorochloridites with acrylic acid.⁹³ This is associated with the lesser tendency of the $\text{AlkS}-\text{P}$ group to undergo dealkylation as compared to the $\text{AlkO}-\text{P}$ group (see monograph⁹⁴).

$\text{R} = \text{Et}, \text{Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i.$

Reaction of dichlorophosphines with *cis*- β -chloroacrylic acid (**63**) occurs with elimination of HCl from intermediate compounds **64** to give unsaturated acid dichlorides **65**.⁷⁶

R = Me, Et, Ph.

The products of reactions of dialkyl(chloro)phosphines with α,β -unsaturated acids and their derivatives were not isolated and characterised after treatment with alcohols. For instance, diethyl(chloro)phosphine reacts with α,β -unsaturated acids or their chlorides to form crystalline adducts **66**, the structure of which is not established. Treatment of these adducts with alcohols gave phosphine oxides **67**.^{47, 73, 76, 95–97}

R¹, R², R³ = H, Me; R⁴ = Me, Et, Pr, Bu, C₅H₁₁; X = OH, Cl.

Treatment of the adducts **66** formed from acids (X = OH) and acid chlorides (X = Cl) with ethanethiol instead of alcohols gives phosphine oxides **68** containing a thioester group and phosphine sulfides **69**, respectively.⁹⁶

R¹, R² = H, Me; X = OH, Cl.

Reactions of alkyl acrylates **70** with diethyl(chloro)phosphine result in different products depending on the reaction conditions. For instance, polymers or oligomers **71** containing a quaternary phosphonium unit in the main chain are formed quantitatively in a hexane solution after 30 h. However, monomeric phosphine sulfides **72** can be isolated in high yields from the reaction mixtures after 7 h following treatment with butanethiol. The adducts formed in the reaction conducted in ethyl bromide (or in hexane, in the presence of HCl) and then treated with methanol decompose to give phosphine oxides **73**.⁹⁸ These contradictory results require additional proof.

R = Me, Et, Bu.

It is believed that the mechanisms of reactions of unsaturated acids and their derivatives with diethyl(chloro)phosphine are the same or similar to those of their reactions with P(III) acid dichlorides.^{47, 73, 76, 95–97} However, it is likely that higher nucleophilicity of the phosphorus atom in diethyl(chloro)phosphine than in P(III) acid dichlorides favours [1 + 4]-cycloaddition. This assumption is confirmed by the fact that methyl acrylate readily reacts with diethyl(chloro)phosphine⁹⁸ where the formation of an intermediate hydrophosphoryl compound is impossible.

A similar mechanism was proposed⁹⁷ for the reaction of diethyl(chloro)phosphine with acryloyl chloride.

It is confirmed by preparative isolation of 5-chloro-2-ethoxy-2-oxo-3H-1,2-oxaphosphole from the reaction of diethylphosphorochloridite with acryloyl chloride.⁹⁷

Other monochlorophosphines react with the acids **54** analogously to diethyl(chloro)phosphine. Treatment of initially formed adducts of unknown structure with alcohols results in their decomposition and the formation of phosphine oxides **74**.^{99, 100}

R¹ = H, Ph; R² = H, Me; R³ = (CH₂)₂CN, CH₂CH(Me)CN, CH₂CH=CH₂, 2-thienyl; R⁴ = Me, Et.

Acrylamide and methacrylamide (compounds **75a** and **75b**, respectively) react with various HP analogously to the corresponding acids. Nitriles **76a,b** resulting from dehydrochlorination of imidoil chlorides **77a,b** are the major reaction products.^{76, 99, 101–110}

R¹, R² = Me, Et, Ph, Buⁱ, (CH₂)₂CN, CH₂CH(Me)CN, CH₂CH=CH₂,

OC(CCl₃)Me₂, OBU, OCH(CH₂Cl)₂, *p*-MeC₆H₄, CH₂Cl, Cl, 

R³ = H (**a**), Me (**b**).

In the presence of acetic acid, HP react with primary and tertiary acrylamides to form compounds **78** with the amide group remaining intact.^{99, 100, 111, 112}

$R^1 = \text{Me, Et, Ph, } p\text{-MeC}_6\text{H}_4$; $R^2 = \text{Cl, Et, 2-thienyl, EtOOC(CH}_2)_2$, $\text{Me}_2(\text{CCl}_3)\text{CO}$; $R^3 = \text{H, Me}$; $R^4, R^5 = \text{H, Et, Pr}^i$.

In some instances, distillation of products **78** is accompanied by elimination of hydrogen chloride (probably, due to thermolysis) and the formation of 2,5-dioxo-1,2-azaphospholanes **79**.¹¹²

$R^1 = \text{Et, Ph}$; $R^2 = \text{Cl}$; $R^3 = \text{H, Me}$; $R^4 = \text{H, Bu, CH}_2=\text{CHCH}_2$; $R^5 = \text{H}$.

Halophosphines react with several other functional derivatives of acids in a somewhat different pathway. Reactions of dialkyl(chloro)phosphines with alkyl perfluoromethacrylates **80** occur with a characteristic replacement of a fluorine atom at the C=C bond to form an intermediate **81**. Then, the chlorine atom and a fluorine atom in compound **81** are exchanged. The reaction results in the formation of phosphines, which usually undergo cyclisation into 5-oxo-5*H*-1,2-oxaphospholes **82** in the isolation.¹¹³

$R^1 = \text{Et, Me}$; $R^2 = \text{Me}$; $R^1 = \text{Pr}^i$, $R^2 = \text{Et}$.

β -Hydroxy derivatives **83**⁵² and β -amino derivatives^{51,60,114} of esters of α,β -unsaturated carboxylic acids **84** (enol tautomers of acetoacetic esters and β -aminocrotonates, respectively) react with P(III) monochlorides in the presence of triethylamine to undergo O- or N-phosphorylation without affecting the double bonds. The reaction occurs due to the presence of an acidic proton of the hydroxyl or amino group in the heterodiene and results in unsaturated phosphites **85** and **86**, respectively.

$R^1, R^2 = \text{EtO, Et}_2\text{N}$.

$R^1 = \text{Et, Pr}$; $R^2, R^3 = \text{H, Me}$; $R^4 = \text{H, CN}$.

Acrylates and methacrylates react with dialkyl phosphorochloridites in a similar way, *i.e.*, without affecting the heterodiene system. The reactions result in mixed anhydrides **87**, which are the products of O-phosphorylation.¹¹⁵

$R^1 = \text{Et, Pr, Bu}$; $R^2 = \text{H, Me}$.

α,β -Acetylenic acids also react with HP analogously to α,β -unsaturated acids. For instance, propiolic acid (**88**)^{70,76,116–118} reacts with dichlorophosphines to form unsaturated acid dichlorides **89** similar to the acid dichlorides **55**.

$R = \text{Et, ClCH}_2, \text{Ph}$.

When alkylphosphonochloridites were used in this reaction instead of dichlorophosphines, the products **90** were not isolated but rather were directly converted into diesters **91** by treatment with ethanol or into thioesters **92** by treatment with butanethiol. An attempt at distilling compound **90** [$R^1 = \text{Ph}$, $R^2 = \text{Me}_2(\text{CCl}_3)\text{C}$] resulted in isolation of a product of its cyclisation, *viz.*, 2,5-dioxo-5*H*-1,2-oxaphosphole **93**, which is an unsaturated analogue of phospholane **61**.¹¹⁹

$R^1 = \text{Et, Ph, } p\text{-MeC}_6\text{H}_4$; $R^2 = \text{Me}_2(\text{CCl}_3)\text{C}$,  CCl_3 .

$R^1 = \text{Ph}$, $R^2 = \text{Me}_2(\text{CCl}_3)\text{C}$.

Treatment of an intermediate product **94**, obtained in the reaction of tetrolic acid (**95**) with ethyl(dichloro)phosphine, with acetic anhydride resulted in the 5*H*-1,2-oxaphosphole **96**.¹²⁰

III. Reactions with azadienes

Investigation of reactions of HP with dienes containing one or several nitrogen atoms in the conjugation chain was begun recently. Most studies in this field were carried out in the late 1980's and the early 1990's. Currently, it is azadienes (among different types of heterodienes that react with HP) that attract the greatest attention of researchers. However, whereas the reactions of azadienes with dienophiles containing no phosphorus atom have long been studied and are well known (see, *e.g.*, a review¹²¹), almost no overview information concerning their reactions with phosphorus-containing dienophiles is available.

1. Reactions with α -diimines

Characteristic of α -diimines capable of adopting *s-cis*-conformation¹²² are [4 + 1]-cycloaddition reactions.^{121,123}

Diimines **97a,b** react with ethyl(dichloro)phosphine to form cyclic diaminophosphonium salts **98a,b**. It is convenient to isolate

them as the corresponding tetrafluoroborates **99a**¹²⁴ or phosphine oxides **100a,b**.^{125, 126}

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bu}$ (**a**); $\text{R}^1 - \text{R}^1 = (\text{CH}_2)_4$ (**b**).

Reactions of HP with *N,N'*-dibutylbiacetyldiimine **97a** occur to give 1,3-dihydro-1,3,2-diazaphospholes **101**.¹²⁷ The reaction occurs with dealkylation, as in the case of dienic hydrocarbons and α -dicarbonyl compounds.

$\text{R} = \text{Cl}$, EtO , Et_2N .

Reaction of 2-chlorobenzo-1,3,2-dioxaphosphole **102** with the diimine **97a** resulted in the phosphorane **103**.¹²⁸ An analogous product was obtained in the reactions of compound **102** with 1,3-dienes.

The reaction of the diimine **97a** with phosphorus trichloride results in resinification only.¹²⁸ However, its reaction with phosphorus tribromide in the presence of an organic base follows the [4+1]-cycloaddition pathway, and the reaction product is a tricoordinate phosphorus derivative, *viz.*, 2-bromo-1,3-dihydro-1,3,2-diazaphosphole **104**.¹²⁸

2,3-Diphenyl-5,6-dihydropyrazine (**105**) reacts with PBr_3 in an analogous manner to give a bridged product **106**.¹²⁹

Reactions of glyoxal diimines **107** with PCl_3 in the presence of a base also follow the [4+1]-cycloaddition pathway to form tricoordinate phosphorus derivatives, *viz.*, 2,4-dichloro-1,3-dihydro-1,3,2-diazaphospholes **108** as the reactions products. Their formation can be rationalised by elimination of HCl from an intermediate cyclic adduct.^{128, 130, 131}

$\text{R} = \text{cyclo-C}_6\text{H}_{11}$, Bu^t .

Diimine **97a** reacts with tetraethylphosphorodiamidochloride in the presence of triethylamine¹³² to give a mixture of two 1,3-dienes, *viz.*, 1,3,2-diazaphospholane **109** with an exocyclic system of conjugated double bonds and bicyclic compound **110**.

It was assumed¹³² that N-phosphorylation of both imino groups followed by dehydrochlorination results in an intermediate diene **111** as a mixture of *s-cis*- (**111a**) and *s-trans*-conformers (**111b**) (analogously to the formation of phosphorylated enamines from imines of saturated aldehydes^{128, 133}). Then, the reactions of *cis*- and *trans*-forms of compound **111** follow different pathways. Elimination of tris(diethylamino)phosphine from the *s-cis*-form **111a** results in monocyclic diazaphospholane **109**. *s-trans*-Isomer **111b** is converted into diazadiphosphabicyclooctadiene **110** as a result of elimination of two molecules of diethylamine. The bicyclic compound **110** was isolated in an individual form, while the formation of phospholane **109** was proved by spectroscopic methods.¹³²

Reactions of PCl_3 and phosphorodichloridites with diimines containing an exocyclic system of double bonds in the presence of a base result in bicyclic 1,3,2-diazaphospholane derivatives containing a cyclohexadiene fragment. These reaction products are bicyclic analogues of the phospholanes **109**.¹²⁶

$\text{R}^2 = \text{Cl}$, AlkO , Alk_2N .

Reaction of 2,3-dimethyl-5,6-dihydropyrazine (**112**, a cyclic analogue of diimine **97**) with dialkyl(chloro)phosphines (alkyls were not specified) in the presence of a base occurs with the formation of monophosphorylated tetrahydropyrazine **113** containing one exocyclic methylene group,¹²⁹ which means that the reaction proceeded only on one $\text{C}=\text{N}$ bond.

R = Alk.

Reactions of dialkylloxalimides **114** with dichlorophosphines and phosphorodichloridites occur with elimination of two mobile protons to form derivatives of 1,3,2-diazaphospholes **115**,¹³⁴ i.e., compounds **114** undergo cyclisation without participation of the heterodiene system as such.

R¹ = Me, Et; R² = Bu, Ph, *p*-MeC₆H₄, *p*-ClC₆H₄, PhO, *p*-MeC₆H₄O, *p*-ClC₆H₄O.

2. Reactions with azines

It was argued^{39, 135} that the reactions of cyclic phosphorochloridites with azines and with other conjugated systems proceed as [4 + 1]-cycloadditions; the 1,3,2-dioxaphospholane that forms undergoes ring opening according to the second stage of the Arbuzov reaction to give 3,5-dihydro-1,2,4-diazaphospholes. However, it was established later that dioxaphospholanes **4** and benzodioxaphospholes **102** react with acetoneazine (**116**) in the presence of triethylamine to form 3,5,5-trimethyl-4,5-dihydropyrazolophosphites **117**. Initially, electrophilic attack of the phosphorus atom on the nitrogen atom of ketazine **116** occurs, as in reactions of HP with imines.^{128, 133} The immonium salt **118** that forms undergoes the pyrazoline condensation to give the final product **117**.¹³⁶

R = (CH₂)₂ (**4**), *o*-C₆H₄ (**102**).

Reaction of diethyl phosphorochloridite with acetoneazine **116** in the presence of triethyl phosphite only resulted in compound **119**, the product of addition of diethyl phosphite to one of the C=N bonds. The formation of pyrazolinophosphite **117** was detected only by spectroscopic methods.¹³⁷

Reactions of asymmetrical azines **120** with the phosphite **102** occur with symmetrisation of the azine in the initial step.¹³⁸ This process is accelerated by diethyl phosphorochloridite (a Lewis acid) present in the reaction mixture. The symmetrical azine **121** that forms then reacts with phosphite **102** analogously to acetoneazine **116** to form pyrazolinophosphites **122**.¹³⁷

R¹, R² = H, Me.

3. Reactions with α-enimines

It was postulated¹³⁵ that α-enimines, as well as other 1,3-dienes and heterodienes, react with 1,3,2-dioxaphospholanes according to the [4 + 1]-cycloaddition pathway. However, the absence of any specific information on the products of these reactions makes one treat such an argument with precaution.

Reactions of enimes **123** with phosphorus trichloride or ethyl(dichloro)phosphine in the presence of an organic base^{139–141} result in 1,2-dihydro-1,2-azaphosphorinines **124**.

R¹ = Et, R² = Buⁿ, R³ = Cl, Et; R¹ = H, R² = Bu^t, R³ = Cl.

The reaction begins with electrophilic attack of the phosphorus trichloride or ethyl(dichloro)phosphine on the lone electron pair of the nitrogen atom of enime **123**, which results in an immonium salt **125** containing a P–N bond and a positive charge delocalised over the system of conjugated bonds. Then the first triethylamine molecule eliminates an acidic proton from the δ-carbon atom of the salt **125** to give an intermediate adduct **126**. This reaction is analogous to that leading to phosphorylated enamines from imines of saturated aldehydes and is similar to reactions resulting in the formation of heterodienes **111** and **118**.^{128, 133} Then, the closure of the six-membered ring containing the P–C bond occurs to form the intermediate **127** as a result of the intramolecular interaction of the phosphorus atom with the δ-carbon atom on which partial negative charge is localised due to conjugation with the lone electron pair of the nitrogen atom. The second molecule of the base eliminates hydrogen chloride from the intermediate **127**, which results in 1,2-dihydro-1,2-azaphosphorinine **124** as the final product.

It was assumed¹⁴¹ that in this case the [4 + 1]-cycloaddition reaction cannot compete with the attack on the nitrogen atom due to kinetic control because of asymmetry of the enime molecule. In addition, the nitrogen atom in α-enimines is more nucleophilic than that in α-diimines, since two electronegative azomethine groups in the latter interact with each other to weaken the nucleophilicity of the nitrogen atom in each of them.

Butadienylamine **123'**, the possible existence of which has been discussed,¹²¹ is the minor tautomer of the enimine **123** and can also contribute to the formation of azaphosphorinine **124**.

The similarity of behaviour of the enimes **123** and their oxygen analogue, crotonaldehyde, in reactions with HP in the presence of an organic base is obvious. These asymmetrical heterodienes can be represented by a general formula $\text{RCH}_2\text{CH}=\text{CRCH}=\text{Y}$ ($\text{Y} = \text{O}, \text{NAlk}$). In contrast to their symmetrical analogues, α -diimines and α -diketones, the above-mentioned heterodienes undergo phosphorylation at the nucleophilic centre Y rather than enter into [4 + 1]-cycloaddition reactions leading to the increase in the coordination number of the phosphorus atom.

However, reactions of functionalised enimes, *e.g.*, cinnamaldehyde *o*-hydroxyanils **128**, with P(III) chlorides proceed by [4 + 1]-cycloaddition, which precedes O-phosphorylation of the hydroxyl group or follows it. This reaction results in fused five-membered heterocyclic compounds **129** containing the pentacoordinate phosphorus atom.¹⁴²

$\text{R}^1 = \text{Me}$; $\text{R}^2-\text{R}^3 = \text{MeN}(\text{CH}_2)_2\text{NMe}$; $\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2 = \text{R}^3 = \text{Me}$, Ph, OMe ; $\text{R}^2-\text{R}^3 = \text{O}(\text{CH}_2)_2\text{O}, o\text{-C}_6\text{H}_4\text{O}_2$.

As in the case of reactions of dienes with HP,⁴⁻⁷ tricyclophosphoranes **129** can have structural isomers as a result of the double bond migration in azaphosphole (prototropism), and geometric isomers due to pseudorotation.¹⁴³ For instance, if amino groups are bonded to the phosphorus atom, the primary reaction product **129** undergoes partial [for $\text{R}^2-\text{R}^3 = \text{MeN}(\text{CH}_2)_2\text{NMe}$] or complete (for $\text{R}^2 = \text{R}^3 = \text{NMe}_2$) rearrangement into a thermodynamically more stable isomer **130**. The latter is isolated as the final reaction product of compounds **128** with bis(dimethylamino)-chlorophosphine.

$\text{R}^1 = \text{Me}$; $\text{R}^2-\text{R}^3 = \text{MeN}(\text{CH}_2)_2\text{NMe}$, $\text{R}^2 = \text{R}^3 = \text{NMe}_2$.

Reaction of diisopropylamino(chloro)phosphonium tetrachloroaluminate with crotonaldehyde dimethylhydrazone (**131**)¹⁴⁴ proceeds as a classical [4 + 1]-cycloaddition and is analogous to reactions with 1,3-dienes²⁸⁻³⁰ and α -dicarbonyl compounds;²⁷ this results in cyclic phosphonium salt **132**, which is hydrolysed to give 2-oxo-1,2-dihydro-3*H*-1,2-azaphosphole **133**.

Aminoenimes **134** react with P(III) chlorides in the presence of triethylamine. Their cyclisation occurring with elimination of two HCl molecules results in 1,2-dihydro-1,3,2-diazaphosphorinines **135**,¹⁴⁵ like the reaction of dialkylloxalimides with dichlorophosphines leading to derivatives of 1,3,2-diazaphospholes (see Section III.3).

$\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2, \text{R}^4 = \text{Ph}, p\text{-MeC}_6\text{H}_4, \text{cyclo-C}_6\text{H}_{11}$; $\text{R}^3 = \text{H}, \text{Ph}$; $\text{R}^5 = \text{Ph}, \text{Cl}$.

This is an example of synthetic procedures used for the preparation of nitrogen heterocycles based on azadienes, which has been discussed in detail.¹⁴⁶⁻¹⁴⁸

Reactions of HP with enamino ketones **47**, which are nitrogen analogues of β -diketones, were considered in Section II.2.a; however, these can also be discussed in this Section. Indeed, compounds **47** can also exist in the imine form **136**.¹⁴⁹

Tautomers **47** and **136** can react with HP concurrently to give the same final products.

Finally, reactions of HP with heteroenyne $\text{C}=\text{C}-\text{C}\equiv\text{N}$ systems are formally similar to the reactions of HP with enimine $\text{C}=\text{C}-\text{C}=\text{N}$ systems considered in this Section. Acrylo- and methacrylonitriles **137** react with alkylphosphonochloridothioites in the presence of proton donors according to the scheme:⁴⁶

$\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2 = \text{Et}, \text{Ph}$; $\text{R}^3 = \text{Et}, \text{Pr}, \text{Bu}$; $\text{X} = \text{O}, \text{S}$; $\text{Y} = \text{H}, \text{Ac}$.

These reactions are analogous to those of compounds **30** with α, β -unsaturated ketones in the presence of proton donors and follow the same mechanism (see Section II.2.a).

4. Reactions with azoalkenes

Dichlorophosphines react with azoalkenes **138** to give [1 + 4]-cycloaddition products, *viz.*, cyclic phosphonium salts **139**. Hydrolysis of compounds **139** results in a mixture of stereoisomers, *viz.*, 3-oxo-2,3-dihydro-4*H*-1,2,3-diazaphospholes **140**.^{143, 150}

$\text{R}^1 = \text{Me}, \text{Ph}, \text{Bn}$; $\text{R}^2 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^3 = \text{Me}, \text{Ph}$; $\text{R}^4 = \text{Me}, \text{Ph}, \text{Bu}^t, \text{Bn}, o\text{-ClC}_6\text{H}_4, p\text{-MeC}_6\text{H}_4, p\text{-MeOC}_6\text{H}_4$.

Reaction of the azoalkene **138** ($\text{R}^1 = \text{R}^3 = \text{Me}, \text{R}^2 = \text{H}$) with PhPCl_2 results in a mixture of products with different position of

the double bond, *viz.*, 2,3-dihydro-4*H*- and 1*H*-1,2,3-diazaphospholes (**141** and **142**), as is observed for isomerisation of phosphoranes **129** into phosphoranes **130**.

An analogous double bond migration in the ring is also often observed for phospholes formed in reactions of HP with dienic hydrocarbons.^{5,6}

The azoalkenes **138** react with PCl_3 to give diazaphosphole intermediates; treatment of the latter with alcohols causes elimination of a hydrazine fragment to form β -oxo phosphonates **143**.¹⁵¹

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{Me, Ph; R}^4 = \text{Me, Et, Ph; R}^1\text{--R}^2 = (\text{CH}_2)_4$;
 $\text{R}^3 = \text{R}^4 = \text{Me}$.

IV. Reactions with oxazadienes

Reactions of HP with 1,3-oxaza-1,3-dienes (*N*-acylketimines) **144** follow the [4+1]-cycloaddition pathway to give 5-oxo-4,5-dihydro-1,3,5-oxazaphospholes **145**.¹⁵²

$\text{R}^1 = \text{CF}_3, \text{OEt; R}^2 = \text{Me, OEt}$.

The reaction proceeds only in the presence of acetic anhydride or sulfur dioxide. Trialkyl phosphites¹⁵³ react according to the same scheme without these additives.

Halophosphines can be added to 1,4-oxaza-1,3-dienes (monimines of α -diketones) as has been exemplified in benzyl *o*-hydroxyanil (**146**).^{154,155} The latter reacts with different HP with the formation of intermediate compounds **147** and **148**, which are then transformed into polycyclic phosphoranes **149** or diphosphethanes **150** and **151**.

The key stage of this reaction is [4+1]-cycloaddition, which precedes phosphorylation of the hydroxyl group and/or follows it.

$\text{R}^1, \text{R}^2 = \text{Me, Ph, OMe, OPh, OCH}_2\text{Ph, NMe}_2$; $\text{R}^1\text{--R}^2 = \text{O}(\text{CH}_2)_2\text{O, O}(\text{CH}_2)_3\text{O, S}(\text{CH}_2)_3\text{S, } o\text{-C}_6\text{H}_4\text{O}_2, \text{MeN}(\text{CH}_2)_2\text{NMe}$.

Biacetyl acylmonohydrazones **152** react analogously. As in the case of oxazadiene **146**, the final bicyclic dioxadiazaphosphoranes **153** result from [4+1]-cycloaddition and O-phosphorylation.¹⁵⁴

$\text{R}^1 = \text{Me, Ph, Bn; R}^2 = \text{Me, Ph}$.

V. Conclusion

Though certain judgements on the mechanisms of the reactions considered in this review cannot be called indisputable, summing up the above information makes it possible to state that, despite the variety of types of HP, heterodienes, and the products that formed, the initial steps of these reactions belong to three types:

- (1) 1,4-addition reaction, in particular, [4+1]-cycloaddition reaction (concerted or stepwise);
- (2) reaction involving one of the multiple bonds of a heterodiene; and
- (3) reaction without participation of multiple bonds.

Differences in the structure of the final products formed in each of these three types of reactions are determined by further transformations of the primary reaction products.

Most often the reactions under consideration follow the [4+1]-cycloaddition pathway to give usually cycloadducts containing the pentacoordinate phosphorus atom. In some instances, it is possible to isolate them or to detect them by spectroscopic methods. However, [4+1]-cycloaddition reactions of HP with α -diketones, their diimines and mono-*o*-hydroxyanils, α,β -unsaturated ketones, azoalkenes and 1,2-oxazadienes result in various five-membered phosphole-type heterocycles containing P(III), P(IV) or P(V) atoms as the final products. α,β -Unsaturated carboxylic acids and their derivatives also react with HP according

to this scheme (not always) to give acyclic compounds. In some instances, linear products are also formed from unsaturated carbonyl compounds.

If only one of two double bonds of the heterodiene system is involved in the reaction with HP in the initial stage, the second double bond can be either involved in further transformations or left intact. This occurs in the reactions of HP with different types of heterodienes in the presence of organic bases, *e.g.*, in the reactions with crotonaldehyde and enamines, which are nitrogen analogues of α,β -unsaturated aldehydes. Unlike their symmetrical analogues (α -diketones, α -diimines), enamines do not enter into [4 + 1]-cycloaddition reactions, which result in an increase in the coordination number of the phosphorus atom, since HP react with their nucleophilic centre (the oxygen or nitrogen atom) thus phosphorylating it. Reactions of several cyclic α -diimines (dihydropyrazines) and azines proceed analogously involving one C=N bond. The same occurs in the reaction of tetraethylphosphorodiamidochloridite with acyclic α -diimine: each of the C=N bonds reacts independently. Usually, the alkyl group adjacent to the double bond is inert and left intact in the first reaction stage; the involvement of such a group in the reaction is one of the peculiarities of the reactions of HP with heterodienes in the presence of an organic base. Under the action of a base, proton abstraction from these groups occurs, which results in the formation of a new double bond and/or in the closure of phosphorus-containing rings. Reactions involving one of the double bonds can also occur in the absence of a base and, correspondingly, without dehydrohalogenation. For instance, unsaturated aldehydes react with 2-chloro-1,3,2-dioxaphospholane at the C=O bond, which results in the formation of phosphorus-containing oligomers. Perfluoromethacrylates react with dichlorophosphines only at the C=C bond leaving the ester group intact. It is possible to consider the reactions of α,β -unsaturated acids with HP as those occurring at the C=C bond if they proceed *via* exchange of the chlorine atom by the hydroxyl of the carboxy group followed by reaction between hydrophosphoryl compound and unsaturated acid chloride that formed according to the Pudovik reaction. Alkylphosphonochloridothioites react analogously with α,β -unsaturated ketones in the presence of proton donors.

Finally, reactions of several heterodienes (capable of eliminating one or two protons in the presence of an organic base) and salts of α,β -unsaturated carboxylic acids with HP proceed without participation of conjugated bonds at all. These reactions result in the formation of phosphorylation products. In these cases, HP behave as ordinary acid halides. If the phosphorus atom carries appropriate substituents, the phosphorylated heterodiene that formed can enter into further intramolecular reactions. These involve the diene system and result in its cyclisation. Acyclic P(III) derivatives initially obtained from HP and enol tautomers of β -diketones or their nitrogen analogues react in such a manner.

V. Conclusion	170

Abstract. Principles of the operation of the magnetic force microscope are considered. The main areas of application of magnetic force microscopy are characterised. The prospects are shown of using this method for solving problems of materials science, including the most topical problem, *viz.*, the creation of magnetic recording media with ultrahigh recording density. Unique potentials for investigation of nanostructures using a combination of magnetic force microscopy with electron spin resonance and nuclear magnetic resonance are pointed out. Primary attention is focused on the description of experimental techniques. The bibliography includes 27 references.

I. Introduction

The interest in magnetic force microscopy is due to its unique potential, which makes it possible to solve the problems of both basic and applied investigation, *e.g.*, the development of modern nanotechnologies. In chemistry, magnetic force microscopy is indispensable in the studies of the morphology, structure and properties of nanocomposites with magnetic inclusions. Magnetic force microscopy is of particular significance in the studies of magnetic properties of nanostructures, in particular, in the search for size and quantum effects. Magnetic force microscopy combines a modern technique of magnetic measurements with the unique potentials of probe microscopy.

The first probe microscopes, *viz.*, scanning tunnelling microscope, made it possible to investigate conducting surfaces and to perform their targeted modification on an atomic and molecular level.¹ This type of microscope has become an ancestor of a family of probe microscopes, among which the atomic force microscope² and its modifications³ are most often used.

In a scanning probe microscope there is a microprobe (a tip) with the help of which the precision mechanical system scans the surface. Simultaneously, the control unit of the microscope detects specified characteristics of the interaction between the probe and the surface under study. This can be the tunnelling

current between the metal tip and the surface of a conductor in the case of the tunnelling microscope and the force of the interaction between the sharpened tip made of a hard material and the surface of the sample for an atomic force microscope. The atomic force microscope is in essence a sensitive profilometer, *i.e.*, an instrument for measuring the roughness and topography of the surface, and in a sense it can be considered as a 'distant relative' of a phonograph with a diamond tip.

Tunnelling and atomic force microscopes have a spatial resolution better than 1 Å, *i.e.*, these make it possible to observe individual atoms and molecules on the surface of various materials. The images of different surfaces obtained using scanning tunnelling and atomic force microscopes⁴ are shown in Figs 1 and 2 as examples.

Figure 1. The surface of pyrolytic graphite.

The size of the area scanned is $2 \times 2 \text{ nm}^2$; a 'Scan-8' scanning tunnelling microscope developed by the 'Advanced Technologies Centre' (Moscow, Russian Federation) was used.

Figure 2. The surface of mica.

An NanoScope atomic force microscope (Digital Instruments, USA) was used.

Martin and Wickramasinghe⁵ have improved the atomic force microscope in order to investigate magnetic properties of the surface with submicron spatial resolution. It was proposed to use a microneedle made of ferromagnetic material as a probing tip for measuring the magnetic force experienced by this micro-magnet in the vicinity of the surface of a magnetic specimen. This modification of the atomic force microscope is called the magnetic force microscope. Further stages in the development of magnetic force microscopy have been repeatedly documented (see, e.g., Grütter *et al.*⁶).

Let us consider specific features of the operation of the atomic force and magnetic force microscopes in detail. The highest (atomic or molecular) spatial resolution is achieved if the atomic force microscope operates in the contact mode where the tip contacts the surface of the specimen under study. The resolution achieved in different 'tapping' modes is, as a rule, somewhat worse than in the preceding case. However, stable atomic resolution can also be achieved in the 'tapping' mode, *viz.*, in ultrahigh vacuum.⁷ In the 'tapping' mode, a springy microconsole (a cantilever) on which the tip is mounted oscillates at a resonant frequency in the vicinity of the surface of the specimen. A cantilever is a mechanical resonator similar to a miniature tuning-fork. As the cantilever approaches the surface, the force action of the surface can cause additional damping of the oscillations of the cantilever. Under conventional laboratory conditions, the viscosity of air and the presence of adsorbed water film on the surface negatively affect the accuracy of measurements. Measurements *in vacuo* are free of these perturbing factors, which makes it possible to maintain the force of the interaction between the probe and the sample at a minimum level and thus to improve the spatial resolution up to the atomic level.⁸

In the contact-free mode, the forces acting on the tip of the atomic force microscope are due to the van der Waals interaction.

In the magnetic force microscope, the tip experiences an additional action of magnetic forces. As the tip is raised above the surface to a height of 10 to 50 nm, the universal van der Waals attraction almost completely vanishes and the tip is mainly affected by magnetic forces. In this case, it is the magnetic interaction that causes the deviation of the tip from rectilinear motion (Fig. 3). Because of its small size, the tip of the magnetic force microscope can be approximated by a magnetic dipole. The force F acting on the tip is determined by the following relationship

$$F = m_0 \text{grad} H, \quad (1)$$

where m_0 is the magnetic moment of the tip and H is the magnetic field strength.

A magnetic microinclusion in the specimen will produce a magnetic field, the strength of which at a distance R is

$$H(R) = \frac{3r(\mathbf{r}m) - m}{R^3}, \quad (2)$$

Figure 3. A diagram illustrating the action of a magnetic force on the microtip of the magnetic force microscope. The orientation of magnetic domains on the surface of the sample is shown by arrows in the bottom part.

where $\mathbf{r}$ is the unit radius-vector along the specified direction and m is the magnetic moment of the microinclusion.

Taking into account Eqns (1) and (2), the force of the interaction between the microscope tip and the magnetic microinclusion is

$$F = \text{grad} \left[\frac{3(\mathbf{r}m)^2 - mm_0}{R^3} \right]. \quad (3)$$

Relation (3) can be used for approximate calculations. Let us assume that both dipole moments have the same vertical orientation along the direction of the z axis. Then the force of the interaction between them is

$$F_z = -\frac{6m_0m}{z^4},$$

and the force field gradient is

$$\frac{dF_z}{dz} = \frac{24m_0m}{z^5}.$$

For instance, for two iron microparticles with diameters 10 nm ($m_0 = m \simeq 9 \times 10^{-29}$ A m²) located at a distance of 10 nm, the magnetic force of the interaction is $\sim 4.9 \times 10^{-11}$ N and the force gradient is $\sim 1.9 \times 10^{-2}$ N m⁻¹. It is this order of magnitude of the values that are detected by the magnetic force microscope.

Comparative analysis of different methods used to study magnetic properties of the surface shows that magnetic force microscopy is highly sensitive to the magnetic flux (at a level of 10^{-4} T) and makes it possible to achieve a unique spatial resolution as compared to that obtained by other methods of magnetic measurements.⁹ The sensitivity of the magnetic force microscope to the magnetic flux is only slightly lower than that of the SQUID-based scanning microscope.¹⁰

II. The principle of operation of magnetic force microscope

A block diagram of the mechanical part of a magnetic force microscope is shown in Fig. 4a. The specimen is mounted on a piezoscanner, which provides spatial movement of the specimen along the three coordinate axes. Usually, the piezoscanner is a thin-walled tube made of piezoceramics coated with a system of metal electrodes. The electric voltage applied to the electrodes changes the geometric size of the tube because of the inverse piezoelectric effect. The piezoscanner is characterised by a high

Figure 4. A block diagram of the mechanical system of a magnetic force microscope (a), the cantilever tip coated with a ferromagnetic material (b) and the trajectory of the motion of the microtip (c); (a): (1) small displacement; (2) photodetector; (3) laser; (4) cantilever; (5) specimen; and (6) piezoscanner; (c): (1) trajectory in the course of recording the surface profile; (2) trajectory in the course of recording the magnetic profile; and (3) deviations from the selected trajectory caused by the interaction between the microtip and a magnetic domain in the specimen.

mechanical rigidity and, hence, it is insensitive to seismic and acoustic interferences, simple to control and has a long lifetime. It is these advantages that have determined wide use of this design of the piezoscanner in actual microscopes. Errors of movements, which are due to, *e.g.*, nonlinearity of the properties of the material of the piezoscanners are the drawbacks of this type of piezoscanner. However, the errors of the movement of the object under study can be reduced by software control, *viz.*, by applying a controlling voltage to the electrodes of the piezoscanner in accordance with special correcting algorithms. In metrological systems, additional capacitive or optical transducers are used; they provide the linear movement of the specimen in the range from 1 to 250 μm in the plane of the specimen (along the x and y coordinates) and from 1 to 15 μm normal to this plane (along the z coordinate) for different piezoscanners.

In a magnetic force microscope, the cantilever is above the specimen. The magnetic force F acting on the tip causes a bending of the cantilever and a vertical movement of the tip (Fig. 4*b*). According to Hooke's law, this movement is determined by the mechanical rigidity of the cantilever (by the spring constant) lying typically in the range from 0.1 to 10 N m^{-1} .

Bending of the cantilever is detected using a small displacement transducer. Among different transducers (capacitive, inductive, tunnelling, *etc.*), optical sensors have found the widest practical use. They detect angular deflection of the light beam reflected from the surface of the cantilever. A laser beam is focused on the reflecting surface of the free (unfastened) end of the cantilever and the changed position of the reflected beam, indicating a bending of the cantilever, is determined by a split photodiode.

When scanning the specimens under actual experimental conditions (the relative displacement of the probe and the surface under study), the probe successively scans each surface area and the electronics detects the total force of the interaction in the probe-sample system. The results of measurements, displayed after processing of the data, are three-dimensional (3D) images of the surface. If the bending of the cantilever is maintained constant during the scanning process, the images obtained correspond to the surfaces of constant force. This mode is called a 'constant force' mode. In the 'deflection mode' the cantilever moves in the horizontal plane above the specimen and the bending of the cantilever is detected, which is proportional to the force acting on the tip.

When scanning a rough surface, the contribution from the topography should be separated from that of the magnetic forces. To this end, the tip scans the same surface area twice. For the first pass, it moves contacting the surface of the specimen and the trajectory of the movement of the tip, which corresponds to the profile of the surface under study, is stored in a computer. The magnetic properties of the specimen (neglecting the surface deformations, which are small, as a rule) have no effect on the observed trajectory. For the second pass, the microconsole moves along the known trajectory above the same surface area without contacting the specimen. In this case, the tip is affected by long-range forces rather than by contact forces, as in the first case. The deviation of the tip from the specified trajectory depends on the magnetic properties of the specimen (Fig. 4*c*). In actual experiments, to achieve the maximum sensitivity, oscillations are induced of the cantilever at a natural resonant frequency and the tip also scans the specimen twice, *viz.*, first in the 'tapping' mode and then in the free oscillations mode at some distance from the surface. Recording the amplitude, phase or frequency of the oscillations provides more precise information on the magnetic inclusions (domains, clusters) in the specimen under study.

III. Areas of application of magnetic force microscopy

Magnetic force microscopy is used in the creation of materials for magnetic recording media [magnetic tapes, hard ('Winchester')

disks, magneto-optical disks,^{11, 12 *etc.* 13}], in the optimisation of the recording modes of magnetic heads,¹⁴ in the studies of the structure and properties of nanoparticles, alloys,¹⁵ nanocomposites and thin films,¹⁶ in the development of the methods for magnetic recording with ultrahigh density,¹⁷ in the studies of superconductors as well as in biological and geophysical studies. This makes it possible to observe single magnetic domains whose sizes vary from several nanometres to several tens of nanometres.

For instance, the formation of Ni particles on a quartz glass (silicon dioxide) resulting from autocatalysis of an 'island' Ni film upon annealing (at 800 °C) in an atmosphere of hydrogen was studied.¹⁸ Using magnetic force microscopy, it was shown that particles with sizes from 40 to 100 nm are single domain particles (Fig. 5), which agrees well with theoretical estimates.

Figure 5. A microtopographical (*a*) and the corresponding magnetic (*b*) image of Ni particles.

Magnetic force microscopy has found an important application in the development of novel methods for magnetic recording with ultrahigh density: the leading manufacturers of magnetic recording media make wide use of commercial magnetic force microscopes in the steps of design and quality control of finished products.

In Fig. 6, a topographical profile of a fragment of a surface of a magneto-optical disk (the dark lines seen are rectilinear micro-recesses, Fig. 6*a*) and a magnetic image of the microstructure of magnetised domains on the surface are shown. Elongated islands of dimensions $2 \times 1 \mu\text{m}^2$ corresponding to recording of one data bit (Fig. 6*b*) are fairly clearly seen. The domain structure of the magnetic film in the area of recesses (light longitudinal strips) is also visible. Magnetic force microscopy makes it possible to distinguish single grains of size 50 nm. The magnetic structure of the surface is intensively studied in research laboratories of the leading manufacturers of recording media in order to minimise the surface area corresponding to one data bit and to solve the problems of noise immunity, noise reduction during the recording and reproduction of the data. The results of these investigations are used in the development of novel principles and devices for magnetic and magneto-optical recording. We note that it is the use

Figure 6. The surface of a disk of size $5 \times 5 \mu\text{m}^2$ consisting of microtracks separated by longitudinal recesses (*a*) and the magnetic structure of the same surface (*b*).

of modern methods of investigation such as magnetic force microscopy that made it possible to provide a virtually exponential increase in the magnetic recording density on magnetic and magneto-optical disks in recent years. Currently, the storage capacity of hard disks can be as high as 20 Gbytes and even more.

In Fig. 7, a magnetic 'image' is shown of lithographically patterned Co metal particles.¹⁹ The procedure of patterning of metal 'islands' is used in the technology of production of magnetic media with digital type of data recording. Using a magnetic force microscope, it is possible to 'see' the domain structure of individual clusters (Fig. 7a). Smaller magnetic clusters (Fig. 7b) look like single magnetic dipoles.

Figure 7. Image of metallic Co 'islets' obtained using a magnetic force microscope.

The 'islet' area: (a) $200 \times 400 \text{ nm}^2$; (b) $1.7 \times 1.7 \text{ }\mu\text{m}^2$.

The magnetic force microscope can be used not only for the observation (mapping) of the magnetic field, but also for magnetic recording with ultrahigh density. In Fig. 8, the projections correspond to the magnetic domains formed on the surface of a TbFeCo film using the microscope tip. These domains are formed at an instant when a certain threshold value of the strength of the magnetic field produced by an external magnet and the tip is achieved. The threshold magnetic field strength is determined by the coercivity of the magnetic film. The magnetised domains decrease in size and gradually disappear as the net magnetic field decreases successively. In this case the recording density is 10 Gbit cm^{-2} , which is substantially higher than that achieved for hard ('Winchester') disks and magneto-optical disks used in modern computers.

In Figs 9a and 9b, a magnetic image of a hard disk and the result of averaging of the magnetic image in the central surface area of the disk (between the dashed lines in Fig. 9a) over a large number of cross-sections are shown, respectively. Figure 9c represents a signal in the reading magnetic head that had scanned the same surface area of the disk. The curves shown in Figs 9b and

Figure 8. Single magnetic domains (a bit array) formed on the surface of TbFeCo carrier with the aid of the tip of a magnetic force microscope in the presence of external magnetic field. The same tip was used to obtain the magnetic image. The surface area scanned is $12 \times 12 \text{ }\mu\text{m}^2$.

Figure 9. Image of a track of a magnetic disk obtained using a magnetic force microscope (a), averaged cross-section of the magnetic profile in the area between the dashed lines (b) and the signal in the reading magnetic head detected in the same area of the track (c).

9c are identical even in minor details, which indicates that the signals detected by the magnetic force microscope and conventional magnetic head coincide. The magnetic force microscope provides a much higher spatial resolution, which makes it possible to use this instrument in the detailed analysis and optimisation of read–write modes of standard magnetic heads.

The use of magnetic force microscopy in the studies of magnetic properties of biological objects is also promising. Micro-magnets play a significant role not only in artificial systems, but also in nature. For instance, bacteria *Aquaspirillum magnetotacticum* can move along the magnetic field lines. These bacteria contain specific organelles, viz, magnetosomes. The magnetosomes are chains of 10 to 25 permanent magnets, viz., iron oxide crystals of size $\sim 50 \text{ nm}$. Single crystals are clearly seen in nonstained cells using transmission electron microscopy. Magnets inside the cells determine the specified direction of motion of the bacteria in sea-water: to the north in the Northern hemisphere and to the south in the South hemisphere. It has been possible to measure the magnetic moment of a single bacterium *Aquaspirillum magnetotacticum* using a magnetic force microscope.²⁰ The length of the bacterium was $2 \text{ }\mu\text{m}$ and the measured magnetic moment was negligibly small, viz., 10^{-16} A m^2 .

Currently, 'Digital Instruments' and 'Park Scientific Instruments' companies (both from USA) produce magnetic force microscopes for use both in industry and scientific research. In the 'Centre of advanced technologies' (Moscow, Russian Federation), a promising model of scanning probe microscope, 'Femto-Scan' has been developed, which permits measurements of magnetic properties of the surface.

Cantilevers for both magnetic force microscopy and atomic force microscopy are fabricated by microlithography using a silicon technology, which means that one or several cantilevers at a time are formed at the edges of a silicon plate. Then the surface of the tip is coated with a thin layer of a ferromagnetic material. A scheme of the components for the probe of a magnetic force microscope made by Park Scientific Instruments (USA) is shown in Fig. 10.

A problem of calibrating the magnetic force microscope appears in relation to metrological measurements of magnetic forces. This problem has successfully been solved by Kong and

Figure 10. Scheme of manufacture of a cantilever with a tip (*a–c*) and the image of the tip mounted on a microconsole obtained using an electron microscope (*d*); (*a*) silicon plate holder with two cantilevers (*b*); (*c*) tip.

Chou,^{21,22} who have used metal microrings. The calibrating rings with diameters of 1 and 5 μm (Fig. 11) were made using electron-beam lithography (metal strips on a silicon surface). The magnetic tip moved at variable distances above the rings and its magnetic moment was evaluated from the electric current induced in the rings. The axial magnetisation of the silicon tip coated with a 65-nm thick cobalt film measured using this procedure was $3.8 \times 10^{-22} \text{ A m}^2$. Considerable attention is given to the procedure for fabrication of the tips, since it is the tips that largely determine the quality of the magnetic image of the surface.²³

Figure 11. Microrings used for calibration of a magnetic force microscope.

IV. Magnetic-resonance force microscopy

In the year 1991, it was suggested that a magnetic force microscope can be used to obtain three-dimensional images of individual biomolecules.²⁴ To this end, it was proposed to combine the existing methods of nuclear magnetic resonance and magnetic force microscopy. The novel method has been called magnetic-resonance force microscopy.^{25,26} Its major advantages are safety for the object under study (*i.e.*, it is a nondestructive method), a subnanometre spatial resolution and the possibility of studying individual biomolecules.

At present, magnetic-resonance force microscopic experiments are carried out as follows. A specimen under study of negligible mass ($\sim 10^{-11} \text{ kg}$) is mounted on a springy cantilever analogous to that used in atomic force microscopy (Fig. 12). A constant magnetic field in the specimen is produced by a magnet placed near the cantilever. The magnetic force from the side on which the tip is mounted, acting on the surface atoms of the specimen, is proportional to the spin of the unpaired electrons or to the magnetic moment of the nuclei. In an alternating magnetic

field, a quantum transition occurs between the energy sublevels of the electron or nucleus under the conditions of resonance, which causes a change in the orientation of the magnetic moment of the system. By periodically changing the frequency of the alternating magnetic field produced by an additional coil, one can modulate the magnetisation of the sample. The modulation frequency is chosen to be equal to the resonant frequency of the cantilever. The amplitude of the forced oscillations of the cantilever is measured with a small displacement transducer (*e.g.*, a fiber interferometer). For a chosen geometry of experiment, the conditions of nuclear and electron spin resonances in the system are held in the region of a specimen of subnanometre size.

The method of magnetic-resonance force microscopy has nontrivial possibilities for the structure determination of proteins and viruses. The results of the first successful experiments on the observation of electron paramagnetic resonance are documented.²⁷ Spin resonance in a sample of diphenylpicrylhydrazyl of mass 30 ng was detected. The force acting on the cantilever was 10^{-14} N . According to an assessment made, the observation of resonance from a single molecule requires the enhancement of sensitivity to force at least by 4 orders of magnitude. Recently, the construction of a microcantilever of length 230 μm and thickness of only 60 nm with a micromagnet mounted atop was reported.[†] The magnetic field of the micromagnet interacts with the magnetic moments of the atoms of a specimen. The magnetisation of the specimen is varied periodically (as in the preceding case) to achieve the conditions of electron (paramagnetic) or nuclear magnetic resonance. The force measured was $6 \times 10^{-18} \text{ N}$.

A description of early successful experiments on the observation of electron spin resonance using the magnetic force microscope is given in Ref. 27. The strength of the constant magnetic field is modulated, which changes the magnetisation of the specimen under conditions of spin resonance (Fig. 13). During the modulation period, the system will be at resonance twice and, in the case of sufficient strength of the alternating magnetic field, the absorption of energy reaches its maximum. This leads to the levelling of the populations of magnetic energy sublevels corresponding to the quantum numbers lying in the range from $-m$ to $+m$ and to the decrease in the magnetisation down to zero. To eliminate interference, the signal is detected at a frequency of the second-harmonic component of the modulation signal. The calculated and experimental spectra (Fig. 14) virtually coincide.

In early experiments on the observation of 3D images, a 2- μm particle of diphenylpicrylhydrazyl was mounted on a cantilever in a constant nonuniform magnetic field produced by a conical tip made of NdFeB. The magnetic field gradients were 4.3 and 0.94 $\text{G } \mu\text{m}^{-1}$ normal to the specimen and in the longitudinal direction, respectively. The transverse and longitudinal spatial resolutions were 1.2 and 5.3 μm , respectively. A 3D image of the sample with a resolution of $\sim 3 \mu\text{m}$ was obtained in the observa-

tion of NMR in ammonium nitrate at a field gradient of $22 \text{ G } \mu\text{m}^{-1}$.

Production of a constant magnetic field with the highest uniformity in the bulk of the entire specimen is the principal condition that should be met in the classical ESR and NMR methods. On the contrary, in the case of magnetic-resonance force microscopy the higher the nonuniformity of the constant magnetic field, the smaller the spatial region in which the resonance condition holds and, hence, the higher the spatial resolution obtained when constructing 3D images.

V. Conclusion

The material presented in this review shows that the investigations in the field of magnetic force microscopy are being intensively developed in the last decade. This method is used in both fundamental science and industry. Of particular interest and fruitfulness are the results of application of the magnetic force microscopy in the creation of magnetic media that make it possible to perform magnetic recording with ultrahigh density.

The latest studies have shown that combination of magnetic force microscopy and traditional methods of electron paramagnetic resonance and nuclear magnetic resonance opens unique potentials for the investigation of nanostructures including biomolecules.

Abstract. The time-resolved IR chemiluminescence method based on the study of the chemiluminescence of vibrationally excited molecules formed in chemical reactions is discussed. The approaches used in the study of elementary reactions and complex processes are systematised. The technique is compared with other methods for the study of gas-phase chemical kinetics. The bibliography includes 76 references.

I. Introduction

In modern gas-phase chemical kinetics, methods that enable the real-time detection of chemically active species in an excited state are used in studies of elementary reactions. These methods include laser-induced fluorescence, intra-cavity laser spectroscopy, laser magnetic resonance, resonance-amplified multiphoton ionisation and the IR chemiluminescence method (IR-CL) based on the study of the luminescence of vibrationally excited molecules formed in reactions.

The energy evolved in an elementary exothermic chemical process manifests itself most commonly as vibrational excitation of the reaction products.¹ The practical application of this kind of reaction for the pumping of chemical lasers is well known.^{2,3}

The works devoted to the IR-CL study of the vibrationally excited products of chemical reactions may be divided in two groups. The first one includes those where a steady-state IR-CL spectrum with rather a high spectral resolution is the quantity determined experimentally. This spectrum contains information on the distribution of the reaction products over the vibrational and rotational states. Many reactions resulting in the formation of vibrationally excited molecules, such as HF,^{4–9} HCl,¹⁰ HBr,¹¹ CO,¹² OH¹³ and H₂O,¹⁴ have been studied by this method. The study of the reactions is complicated by the disturbing effect of fast vibration and rotation relaxation processes. To reduce the

effect of relaxation processes, the experiments are carried out at low pressure using fast gas flow.

In another group of works, the kinetic approach is used. In these experiments, the dependence of the IR-CL intensity on the time elapsed after the pulse initiation of the chemical reaction is determined. The radiation is recorded in rather a wide spectral band. Based on this dependence, it is possible to determine the rate constants for reactions resulting in excited molecules and those of other reactions accompanying this process, as well as to find the rates of vibrational relaxation. From the methodical viewpoint, these works may be considered as a contribution to the development of the method of studying the vibrational relaxation of molecules based on their IR luminescence, which has been extremely fruitful in studies of the relaxation of polyatomic molecules.¹⁵

This review analyses the publications where the kinetic approach has been used. The main attention is given to methodical problems related to the use of kinetic IR-CL for the study of non-chain and chain reactions. A method for the measurement of the rate constants for reactions involving atoms and free radicals is discussed, in which a chain reaction resulting in the formation of vibrationally excited products manifests itself as an original 'probe' which makes it possible to trace the changes in the concentration of reactive species with time.

II. Processes resulting in IR chemiluminescence of vibrationally excited products of chemical reactions

Extensive studies on the processes of the formation of vibrationally excited molecules in exothermic reactions were linked with the research aiming at the development of chemical lasers and the optimisation of their operation. To date, the formation of diatomic vibrationally excited molecules in atom abstraction reactions have been studied rather thoroughly. Table 1 presents some typical exothermic reactions producing vibrationally excited molecules. Based on the analysis of the published data, one can state with a high degree of certainty that, if the energy liberated in the abstraction of an atom exceeds the energy of the quantum of the vibration energy of the molecule formed, this reaction should result in vibrationally excited molecules. The fraction of the vibrational energy is ten percent of the exothermicity of a reaction.

The study of the formation of polyatomic vibrationally excited molecules in chemical reactions is only beginning. However, the data available in the literature are consistent with the qualitative concept that in this case, too, a considerable fraction of energy produced in the reaction is transformed into the vibrational energy of the product containing the newly formed chemical bond.

The vibrationally excited molecules resulting from an exothermic reaction can lose energy either through spontaneous emission of IR radiation quanta or by relaxation of the vibrational energy in collisions. These processes are schematically shown in Fig. 1.

**Figure 1.** Scheme of the processes forming an IR chemiluminescence spectrum;

(a) vibrational bands of the corresponding transitions with unresolved rotational structure; (b) scheme of radiation transitive and vibration-translation (V-T) relaxation processes; (c) IR luminescence spectrum of an HCl molecule with well resolved rotational structure.

The characteristic probabilities of spontaneous radiative transitions in unit time (W) for the vibrationally excited molecules are listed in Table 2. The transitions that change the vibration quantum number v by one unit have the highest probability. It is in rare cases that W exceeds 100 s⁻¹ for the vibrations resolved in an IR spectrum.

As a rule, the probability of transitions that change v by two units (overtone luminescence) is one or two orders lower. Accordingly, the intensity of the overtone luminescence turns out to be lower. On the other hand, it has to be noted that overtone transitions play a more significant role in the IR luminescence

Table 2. Energy and probability of spontaneous radiative transitions for vibrationally excited molecules.

Molecule	Transition	E/cm^{-1}	W/s^{-1}	Ref.
HF	$(v = 1) \rightarrow (v = 0)$	3961	189.0	26
	$(v = 2) \rightarrow (v = 1)$	3788	320.0	
HCl	$(v = 1) \rightarrow (v = 0)$	2886	35.0	26
	$(v = 2) \rightarrow (v = 1)$	2782	59.0	
	$(v = 2) \rightarrow (v = 0)$	5668	3.5	
	$(v = 3) \rightarrow (v = 0)$	8347	0.037	
OH	$(v = 1) \rightarrow (v = 0)$	3568	20.0	27
	$(v = 2) \rightarrow (v = 1)$	3398	25.0	
	$(v = 2) \rightarrow (v = 0)$	6966	14.0	
	$(v = 3) \rightarrow (v = 0)$	10 194	0.9	
CO	$(v = 1) \rightarrow (v = 0)$	2170	30.0	28
	$(v = 2) \rightarrow (v = 1)$	2144	59	
CO_2	$(0^001) \rightarrow (0^000)^a$	2349	400.0	29
SiH_4	$(v_3 = 1) \rightarrow (v_3 = 0)^a$	2189	180.0	30

Note. The table presents data for molecules with vibration frequencies $> 2000 \text{ cm}^{-1}$ (the molecules with lower vibration frequencies are not interesting due to the low probability of spontaneous transitions).

^a The linear three-atomic CO_2 molecule has four vibrational degrees of freedom and three different frequencies. The five-atomic SiH_4 molecule has even more frequencies. In both cases, the parameters of only one possible vibrational transition are presented.

spectra than in IR absorption spectroscopy. A reason for this is that the overtone luminescence occurs in the region of shorter wavelengths (with respect to the fundamental luminescence), and hence more sensitive detectors can be used to record it.

Let us consider the energy loss by vibrationally excited molecules in collisional relaxation. The rate constants for the vibration-translation relaxation vary over a very broad range for various colliding partners. For example, the probability of vibrational relaxation of excited HCl molecules equals 10^{-7} in collisions with He atoms, 10^{-4} in collisions with HCl, 10^{-3} in collisions with CH_4 , and 2×10^{-3} in collisions with SiH_2Cl_2 . In a gas mixture prepared for studying a chemiluminescent reaction, vibrational relaxation occurs upon collisions with the molecules of the starting substances. The probabilities of vibrational relaxation upon collisions with polyatomic molecules usually vary from 10^{-2} to 10^{-3} , which corresponds to the time of vibrational relaxation $10^{-4} - 10^{-3} \text{ s}$ at a pressure of 1 Torr.

The above estimates show that the radiative path plays an insignificant role in the energy loss by vibrationally excited molecules. The quantum yield of IR-CL at a pressure of several Torr usually does not exceed 10^{-2} and decreases with an increase in the pressure. Such a dependence determines the upper limit of the pressure range used in experiments on IR-CL; this value is about 30 Torr.

The necessity of using low pressures and the relative simplicity of the luminescing molecules, whose IR spectra display well resolved rotational structure, results in a specific IR-CL spectrum. At low pressures, the width of an individual rotation line is mainly determined by the Doppler effect and does not exceed 10^{-2} cm^{-1} . The distance between the adjacent rotational lines is several units or even several tens of inverse centimetres. Therefore, the IR-CL spectrum is a set of very narrow lines far separated from each other.

If a reaction produces excited molecules in different vibrational states, the bands in their spectra are shifted relative to each other owing to vibrational anharmonicity. The anharmonic shift is usually smaller than the width of a separate band, therefore overlapping of bands occurs. Figure 1 schematically shows the luminescent spectrum of HCl molecules excited in the states $v = 1$,

$\nu = 2$, and $\nu = 3$. There is no actual superposition of the lines in the spectrum, because the width of a separate line is much smaller than the distance between the neighbouring lines. However, high spectral resolution is required to detect the luminescence corresponding to a particular vibrational state in such a spectrum. The spectral resolution in kinetic experiments on the study of IR-CL is small, hence it is helpful to use the so-called 'cold gas filter'. This is a cell filled with the gas whose luminescence is being studied. As the molecules in the gas filter are in the ground vibrational state, the gas filter enables blocking of the radiation of the $1 \rightarrow 0$ transition without affecting the radiation of the other transitions.

III. The sensitivity limit of the IR chemiluminescence method

A typical experimental set-up for the evaluation of the sensitivity of the IR-CL method includes a pulse laser (its radiation initiates the chemical reaction), a system for the preparation and injection of the gas mixture, and a system for the time-resolved recording of IR-CL.^{31–39} The initiation of a reaction most commonly occurs due to the dissociation of molecules under the action of laser radiation in the UV range (excimer lasers, neodymium laser with frequency multiplication, the second harmonic of the ruby laser, the second harmonic of dye lasers). In addition, pulse CO₂ lasers are used, whose IR irradiation causes the dissociation due to multi-photon absorption. The experiments are carried out at pressures from fractions of Torr to several tens of Torr. The repetition frequency of laser pulses is usually several Hertz, less commonly tens of Hertz.

Figure 2 shows the scheme of a typical experimental set-up for recording the luminescence. Luminescence is recorded in a direction perpendicular to the laser beam. Since the signal is usually insufficient for the use of a monochromator, interference filters combined with various absorption filters are used. Often a gas filter is used, which has the form of a gas cell several centimetres long containing an absorbing gas under a pressure of several tens of Torr. Semi-conductor photoresistors or photo diodes cooled to low temperatures are used as IR radiation detectors. Photo-detectors based on InSb are most commonly used for the mid IR region (3–5 μm). These detectors have high sensitivity and are convenient because they do not require cooling below 77 K. The time constant of these detectors is somewhat smaller than 1 μs in the case of photodiodes and several microseconds in the case of photoresistors. A very important requirement for a detector is its large area. This is caused by the fact that an IR-CL source has

considerable geometrical dimensions, hence its radiation cannot be effectively focused on the small area of a detector. In the optimum variant, the size of the detector should match the size of the area in which the reaction occurs (~ 1 cm). Smaller detectors are commonly used.

One can estimate the minimum concentration of vibrationally excited molecules detectable by this method as follows. The noise of a theoretical IR radiation detector is determined by fluctuations of the thermal background radiation reaching this detector. A signal of the excited molecules can be detected if the number of IR luminescence photons (I_{lum}) that have reached the radiation detector during the resolution time of the detecting system (τ_{reg}) exceeds the number of photons from the thermal radiation fluctuation (I_{therm})

$$I_{\text{lum}}\tau_{\text{reg}} > \sqrt{I_{\text{therm}}\tau_{\text{reg}}} \quad (1)$$

For the flux of thermal radiation photons we have

$$I_{\text{therm}} = \frac{2\pi c S \Delta\lambda}{\lambda^4 [\exp(hc/\lambda kT) - 1]} \left(\frac{D}{2l}\right)^2, \quad (2)$$

where c is the speed of light; S is the photodetector area; $\Delta\lambda$ is the wavelength range in which luminescence is recorded; λ is the irradiation wavelength; D and l are geometrical parameters (see Fig. 2b).

The flux of luminescence photons can easily be found if the geometrical dimensions of the experimental set-up are known. Based on the formula (1), the following expression for the minimum detectable concentration of excited molecules was obtained:

$$n_{\text{min}} = 2\sqrt{2\pi} \left(\frac{2l}{D}\right) \frac{\tau_{\text{rad}}}{r\sqrt{S\tau_{\text{reg}}[\exp(hc/\lambda kT) - 1]}} \frac{\sqrt{c\Delta\lambda}}{\lambda^2}, \quad (3)$$

where τ_{rad} is the radiative life time of a vibrationally excited molecule.

For an estimation of n_{min} , let us use the following parameters of a vibrationally excited HCl molecule: $\lambda = 3.6$ μm , $\tau_{\text{rad}} = 3 \times 10^{-2}$ s.²⁶ The typical geometrical parameters are as follows: $S = 10^{-2}$ cm², $r = 0.5$ cm, $2l/D = 5$; the resolution time of the detecting system τ_{reg} is assumed to equal 10^{-6} s, and $\Delta\lambda \approx \lambda$. After substituting these parameters in the formula (3), we obtain $n_{\text{min}} = 10^{11}$ cm⁻³.

Analysis of formula (3) shows that the sensitivity can be increased by using radiation detectors with large area and focusing lenses with large aperture (D/l ratio). The sensitivity can also be increased by narrowing the wavelength range $\Delta\lambda$ of the radiation that reaches the detector to a value equal to the width of the luminescent spectrum with the use of spectral filters. However, the maximum difference in the estimate obtained above due to all of these factors is one order of magnitude. Therefore, the value of $n_{\text{min}} = 10^{11}$ cm⁻³ should be considered as the sensitivity limit of the IR-CL method.

It should be noted that this estimate was obtained under the assumption that the sensitivity is limited by the noise that originates from fluctuations of the thermal radiation reaching the detector. This is true in the standard experiment, in which the gas to be studied is placed in a cell whose walls and the surrounding objects are at room temperature, and hence it is impossible to avoid the effect of thermal irradiation on the detector. The sensitivity is usually increased by accumulation of periodically repeated signals.

A comparison of the IR-CL method with other kinetic methods³² leads to the following conclusions. The sensitivity of IR-CL is inferior to that of laser-induced fluorescence (LIF) and resonance-enhanced multiphoton ionisation (REMPI) and is comparable to the sensitivity of the time-resolved laser magnetic resonance (LMR) and intra-cavity laser spectroscopy (ICLS). The response time of the method is within 10^{-7} to 10^{-6} s. This time is

Figure 2. Scheme of set-up for the observation of the IR-CL kinetics (a); part of the set-up with indication of geometrical parameters required for sensitivity estimation (b); (1) interference filter; (2) gas filter; (3) pressure gauge.

smaller than the response time of time-resolved LMR and somewhat larger than the response time of LIF, ICLS and REMPI. An important characteristic of the methods used in the study of gas-phase reactions is the product of the sensitivity and the response time. This value equals $1/(n_{\min}\tau_{\text{reg}}) \approx 10^{-8} \text{ cm}^3 \text{ s}^{-1}$ for IR-CL, which is much more than the maximum rate constants for bimolecular reactions. Hence, the fastest gas phase reactions can be studied by this method.

The main drawback of the IR luminescence method is its low spectral resolution. It does not exceed $20-50 \text{ cm}^{-1}$ if interference filters are used. The use of a monochromator decreases the sensitivity. The low spectral resolution restricts the scope of the method considered. It can be used when one type of excited molecules is formed in the reaction or the spectra of different excited molecules are separated considerably.

Thus, time-resolved IR-CL is an experimentally simple kinetic method with high sensitivity and fast response. The scope of this method is limited to systems which produce vibrationally excited molecules with simple spectra.

IV. Measurement of rate constants for non-chain reactions

The IR-CL method has been first used for the measurement of the rate constants for chemical reactions by Wodarczyk and Moore.³³ The following processes were studied:

The reactions were initiated by the action of a pulse of radiation of the second harmonic of the ruby laser on a mixture of Cl_2 with a small amount of HBr or HI diluted with a noble gas. The action of a laser pulse on a Cl_2 molecule resulted in its dissociation into two chlorine atoms. The IR luminescence of the excited HCl molecules formed in the reactions was recorded. The $\text{Br}^\bullet$ and $\text{I}^\bullet$ atoms have small reactivities, hence the set of kinetic processes can be represented by the following scheme

where $\text{X}^\bullet = \text{Br}^\bullet, \text{I}^\bullet$; $\text{M} = \text{He}, \text{Cl}_2$.

If a small fraction of Cl_2 molecules dissociates under laser irradiation ($[\text{Cl}^\bullet] \ll [\text{Cl}_2], [\text{HX}]$), the pseudo-first order condition is obeyed for the processes (4) and (5), and the solution of the corresponding kinetic equations can be found easily. It has the form

$$[\text{HCl}^\bullet](t) = A[\exp(-k_2[\text{M}]t) - \exp(-k_1[\text{HX}]t)]. \quad (6)$$

The experimentally observed time dependences of the luminescence intensity are well described by the formula (6). Under the experimental conditions used in Ref. 33, the time of vibrational relaxation was much greater than the reaction time. Therefore, the region of increase in the signal intensity was determined by the reaction time, and after passing a maximum, the signal intensity decreased according to vibrational relaxation. Analysis of the region of increase in the signal made it possible to determine the product $k_1[\text{HX}]$ and hence the reaction constant k_1 .

In another study,³⁴ more accurate measurements of rate constants for reactions of chlorine atoms with hydrogen bromide and hydrogen iodide were carried out; in addition, the isotope effect of the reaction rate was studied. The accuracy was increased by more careful determination of the concentration of the reagent, HBr or HI. The rate constants for the reactions at ambient temperature were 7.4×10^{-12} and $1.64 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$, and the isotope effects ($k_{\text{H}}/k_{\text{D}}$) were 1.50 and 1.84, respectively. The measured temperature dependences (in the range from 220 to 400 K) of the rate constants for the same reactions were found to be of non-Arrhenius type.³⁵

The reactions of $\text{F}^\bullet$ with HCl, HBr and HI molecules were studied.^{37,38} The fluorine atoms were formed upon dissociation of F_2 molecules under the irradiation by the fourth harmonic of a Nd-laser. The processes considered are strongly exothermic; the HF molecules were excited to $v = 3$ (for the reaction with HCl), $v = 4$ (for the reaction with HBr), and $v = 6$ (for the reaction with HI). This made it possible to detect the excited HF molecules using luminescence at the second overtone frequency. The maximum of the band of the $(3 \rightarrow 0)$ transition in HF is at 879 nm, therefore a photomultiplier was used to detect the radiation. The band corresponding to this transition could easily be separated from the other HF luminescence bands using an interference filter for 880 nm with a band pass of 10 nm. In addition to the rate constants for the reactions of the fluorine atom with HCl, HBr and HI, which are 7.0×10^{-12} , 6.2×10^{-11} and $5.6 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$, respectively, the rate constants for vibrational relaxation of HF molecules from the state $v = 3$ in collisions with HCl, CO_2 , N_2O , CO, N_2 and O_2 were measured.

The interpretation of various stages of the IR-CL signal was simple.³³⁻³⁷ As a rule, the region of the signal increase determined the reaction time, and the region of the signal decay determined the time of vibrational relaxation. Such a simple interpretation was possible because the atoms formed in the reaction were less reactive than the starting atoms. Therefore, secondary chemical reactions did not contribute to the observed time dependence of the signal. If species with high reactivity were formed in the reaction, a simple interpretation of the kinetic IR-CL curves was impossible because of secondary reactions. In this case, the role of secondary reactions as a photochemical source of atoms can be diminished by using sufficiently stable molecules which do not react with the newly formed radicals. This approach was used³⁸ for the reaction

The CCl_3F molecule dissociating under the action of radiation of a pulse CO_2 laser served as a source of the chlorine atoms. It was shown that the multiphoton dissociation of CCl_3F did not result in the formation of fluorine atoms. The CCl_3F molecules are sufficiently inert and do not react with the $\text{HCO}^\bullet$ radical. The rate constant for the reaction was $7.4 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$.

Multiphoton dissociation of SF_6 was found to be a convenient source of $\text{F}^\bullet$. This is explained by the high probability of SF_6 dissociation under the action of the radiation of CO_2 lasers and relative chemical inertness of SF_6 . The time-resolved IR-CL method was used to study the reaction of fluorine atoms that formed due to multiphoton dissociation of SF_6 , with various molecules. For example, the rate constants of reactions of fluorine with H_2 and D_2 were measured at ambient temperature.³⁹⁻⁴¹ To diminish warming of the gas by the radiation of pulse CO_2 lasers, the measurements were carried out in mixtures strongly diluted with a noble gas.

The numerical simulation of chemical HF- and DF-lasers requires the knowledge of the temperature dependences of the reaction rate constants for fluorine atoms with H_2 and D_2 . The most reliable experimental data for these dependences have been obtained by time-resolved IR-CL.^{42,43} It has been found for the temperature range 190–373 K:⁴³

$$k_{\text{H}_2} = 1 \times 10^{-10} \exp\left(-\frac{860}{RT}\right),$$

$$k_{\text{D}_2} = 9.1 \times 10^{-11} \exp\left(-\frac{1100}{RT}\right).$$

For the temperature range 290–765 K:⁴³

$$k_{\text{H}_2} = 2.1 \times 10^{-10} \exp\left(-\frac{1180}{RT}\right),$$

$$k_{\text{D}_2} = 1.1 \times 10^{-11} \exp\left(-\frac{1200}{RT}\right).$$

In the range of overlapping temperature ranges, the results differ by no more than 30% for the reaction with hydrogen and by much less for the reaction with deuterium. Deviation of the experimental data from the Arrhenius-type dependence over a wide temperature range was reported.

The reactions of the fluorine atom with HCl, HBr, HI, DBr, DCl and DI molecules at room temperature were studied.⁵ The temperature dependences of the rate constants were measured in the range 195–373 K for the first four processes.⁴⁴ It was found that these dependences at temperatures below the room temperature deviate from the Arrhenius-type dependence. The experimental dependence can approximately be described by a sum of two terms, one of which does not depend on temperature and the other has an Arrhenius-type dependence with $E_a = 2-3$ kcal mol⁻¹. The explanation of this temperature dependence is that the reaction occurs by two pathways: first, direct elimination upon the attack by a fluorine atom towards the hydrogen atom in a hydrogen halide molecule, and second, formation of a complex upon the attack of a fluorine atom towards the halogen atom. It is considered that the first pathway does not require an activation energy, whereas the reaction according to the second pathway is supposed to overcome an activation barrier to the reorganisation of the complex

which precedes its decomposition.

A study of the multiphoton dissociation of CF₃Cl by the time-resolved IR-CL method was reported.⁴⁵ Observation of the kinetics of IR-CL of HCl and HF molecules formed in reactions with HBr as a trap for atoms showed that dissociation occurs by two pathways to give F[•] and Cl[•]. When HBr was replaced by H₂, only the formation of excited HF molecules was observed. The rate constants for reactions of fluorine atoms with H₂ and HBr and chlorine atoms with HBr were measured.

The possibility of using the time-resolved IR-CL for the study of a particular reaction is determined to a considerable extent by the existence of a suitable pulse source of atoms. The photolysis of S₂Cl₂ is a convenient photochemical source of the chlorine atoms that makes it possible to avoid or diminish the role of secondary reactions (see Ref. 46).

The photolysis of S₂Cl₂ was carried out under irradiation by the second harmonic of a dye laser ($\lambda = 300$ nm)⁴⁶ and the fourth harmonic of a Nd-laser. The rate constants for chlorine reactions with H₂S (see Ref. 44), CH₃SH (see Ref. 47), and SiH₄ (see Ref. 48) were measured with the use of S₂Cl₂ as a source of chlorine atoms. Yet another photochemical source of chlorine atoms is the photolysis of COCl₂ by irradiation with an excimer KrF-laser. This source was used in a study of the reaction of chlorine with SiH₄ and SiH₃[•] (see Ref. 49).

V. Modification of the time-resolved IR chemiluminescence method

In all of the works considered above, the time-resolved IR-CL method was used for the study of reactions of atoms resulting in the formation of vibrationally excited molecules, whose IR luminescence could be recorded. An approach has been suggested which expands the scope of reactions that can be studied by the IR-CL method.⁵⁰ The essence of this approach is that reactive species underwent an auxiliary reaction, in parallel with the 'nonluminous' reaction being studied, which resulted in the formation of vibrationally excited luminescing molecules. By studying the kinetic characteristics of the luminescence signal from the auxiliary reaction, one can obtain information on the rate constant for the 'nonluminous' reaction.

This method was tested⁵¹ for the reaction of fluorine with CH₄. The reaction of fluorine with D₂ was used as the auxiliary reaction. The fluorine atoms were formed by IR multiphoton

dissociation of SF₆. The main processes can be presented by the following scheme:

Let us designate the rate constants for the basic reaction, the auxiliary reaction and vibrational relaxation as k_1 , k_0 and k_2 , respectively. If the concentration of the fluorine atoms is much smaller than that of any of the stable components of the gas mixture, the pseudo-first order condition is obeyed for bimolecular processes, and the following expression is valid for the luminescence intensity of vibrationally excited molecules DF^{*}

$$I_{DF}(t) = \frac{Ck_0[D_2][F]_0}{w' - w'} [\exp(-w't) - \exp(-w't)], \quad (7)$$

where C is a proportionality factor, $[F]_0$ is the initial concentration of the fluorine atoms, w' is the inverse time of the signal growth

$$w' = k_0[D_2] + k_1[CH_4], \quad (7a)$$

and $w'' = k_2[M]$ is the inverse time of the signal decay.

The inverse time of growth of the luminescence signal of DF^{*} molecules depends both on the rate constant for the reaction $F^{\bullet} + D_2$ and on the rate constant for the parallel process $F^{\bullet} + CH_4$. According to equation (7a), the plot of w' versus the CH₄ concentration is a straight line, whose slope determines the required rate constant k_1 , and the intercept with the ordinate axis determines the rate constant k_0 . Thus, the luminescence signal from the products of the 'auxiliary' reaction contains the same kinetic information as that obtained from observation of the luminescence of the reaction of interest.

As the reaction being studied, $F^{\bullet} + CH_4$, also results in the formation of vibrationally excited HF molecules, it was possible to check the equivalence of kinetic information obtained from the auxiliary reaction and by observation of the luminescence of the reaction products.⁵⁰ Experiments were carried out in which the signals of the HF^{*} and DF^{*} luminescence were recorded under identical conditions. It was found that the time of the growth of these signals coincided within the experimental error, as would be expected according to the kinetic scheme considered above.

The same approach was used⁵¹ to study the reaction

The fluorine atoms were obtained by multiphoton dissociation of SF₆. The process

was used as an auxiliary reaction producing vibrationally excited molecules. The dependence of the rate constant for the reaction of fluorine with NO₂ on pressure in the range 1–200 Torr was measured; based on this dependence, the ratio of the isomers FNO₂ and FONO formed in the reaction was determined.

VI. Study of the kinetics of chain reactions by the IR chemiluminescence method

The time-resolved IR-CL method combined with pulse initiation of the reaction by laser irradiation was found to be very convenient for the study of the kinetics of chain reactions. This method made it possible to observe in real time a number of features of chain reactions, for example, the induction period of a reaction with very slow chain growth.⁵² Using the data on the luminescence of the chain reaction products, it became possible to develop new kinetic approaches that enable quantitative information on the rate constants for the elementary reactions to be obtained.

For a non-branched chain reaction (or for a reaction with infrequent branchings) one can distinguish several stages that occur at different times after the pulse initiation of the reaction. The first one is the induction period, during which quasi-steady-state equilibrium between the concentrations of various active centres is established. The duration of the induction period approximately equals the time required for one step of a chain reaction to occur. Then the quasi-steady-state stage ensues. The concentration of active centres in this stage is approximately constant, and the accumulation of chain reaction products occurs. The third stage is the termination of the chain reaction, which occurs when the concentration of the active centres has decreased essentially owing to termination reactions. Let us consider how each of these stages manifests itself in the IR luminescence of the chain reaction products.

The induction period. The induction periods of the chain reactions were studied for the chlorination of H_2S .⁵² The following processes occur in a mixture $\text{Cl}_2 + \text{H}_2\text{S}$ after a pulse of UV irradiation:

In this case, excited molecules are formed in the first stage of the chain reaction. Let us designate the starting concentration of the chlorine atoms formed owing to the photolysis of Cl_2 as $[\text{Cl}^*]_0$. Only a small fraction of the Cl_2 molecules underwent dissociation, hence $[\text{Cl}^*]_0 \ll [\text{Cl}_2]$ and $[\text{Cl}^*]_0 \ll [\text{H}_2\text{S}]$. In the initial stage, it is possible to neglect the chain termination and to neglect the vibrational relaxation of the HCl molecules, therefore the following expression can be written for the concentration of the chlorine atoms:

$$[\text{Cl}^*](t) = [\text{Cl}^*]_0[\theta_2 + \theta_1 \exp(-\varphi t)], \quad (10)$$

where t is time, $\theta_1 = k_1[\text{H}_2\text{S}]/\varphi$, $\theta_2 = k_2[\text{Cl}_2]/\varphi$ and $\varphi = k_1[\text{H}_2\text{S}] + k_2[\text{Cl}_2]$. The following expression is obtained for the concentration of vibrationally excited HCl molecules:

$$[\text{HCl}^*](t) = \alpha k_1 [\text{Cl}^*]_0 [\text{H}_2\text{S}] \left[\theta_2 t + \theta_1 \frac{1 - \exp(-\varphi t)}{\varphi} \right], \quad (11)$$

where α is the probability of the formation of vibrationally excited molecules in reaction (8). During the initial period, the concentration of the chlorine atoms decreases from the starting value $[\text{Cl}^*]_0$ to $\theta_2[\text{Cl}^*]_0$. According to formula (11), the rate of formation of HCl molecules should also decrease during this period.

Thus, in this example the initial period of the chain reaction should manifest itself in the luminescence signal of HCl as a 'kink' segment. During the time corresponding to the initial region, the rate of formation of excited molecules decreases from the initial value to that corresponding to a quasi-steady-state process.

Figure 3a shows a luminescence signal of HCl observed after the irradiation of a $\text{Cl}_2 + \text{H}_2\text{S}$ mixture with a pulse of a UV laser. In the initial region of the signal, the rate of the product formation during the establishment of a quasi-steady-state equilibrium between the active centres decreases. After an equilibrium has established, the increase in the concentration of vibrationally excited HCl molecules continued. The deviation of this increase from the linear dependence is due to the vibrational relaxation of HCl molecules.

If the vibrationally excited molecules are formed in the second stage of the chain process, the induction period of a chain reaction manifests itself in the luminescence signals in a different way. An example of such a process is the reaction of chlorination of hydrogen¹⁹

Figure 3. Initial parts of signals of the luminescence of HCl^* molecules formed in chain reactions of H_2S (a) and H_2 (b) chlorination. Partial pressure, Torr: (a) 0.183 (H_2S), 2.20 (Cl_2), 8.48 (Ar); (b) 9.59 (H_2), 0.026 (Cl_2).

In this case, the formula describing the increase in the concentration of vibrationally excited HCl molecules after a laser pulse has the form

$$[\text{HCl}^*](t) = \alpha k_1 [\text{Cl}^*]_0 [\text{H}_2] \left[\theta_1 t - \theta_2 \frac{1 - \exp(-\varphi t)}{\varphi} \right], \quad (14)$$

where $\theta_1 = k_1[\text{H}_2]/\varphi$, $\theta_2 = k_2[\text{Cl}_2]/\varphi$ and $\varphi = k_1[\text{H}_2] + k_2[\text{Cl}_2]$. This formula shows that the rate of formation of the vibrationally excited product increases in the initial region from zero to a certain constant value.

Figure 3b displays an example of an IR-CL signal observed in a $\text{Cl}_2 + \text{H}_2$ mixture (see Ref. 52). It is evident that the rate of formation of excited HCl molecules in the initial region increases (the curve is concave, unlike the curve in Fig. 3a).

The initial region contains complete information on the rate constants for both stages of the chain growth. Using the formulas (11) or (14), it is possible to retrieve this information from the experimental signal. For approximation of the experimental curve, for example by formula (11), only three independent parameters have to be found, i.e., the signal amplitude, the reaction rate constant k_1 and one of the values θ_1 or θ_2 related by $\theta_1 + \theta_2 = 1$. These parameters are sufficient for finding the rate constants. However, this kind of analysis of the shape of the initial region of the luminescence signal has not been carried out.⁵²

Quasi-steady-state chain reaction. After the end of the induction period of the chain reaction, a quasi-steady-state equilibrium is established between the concentrations of the active centres. The concentration of vibrationally excited products increases in this stage at a rate that depends on a combination of the rate constants for the elementary steps of chain growth. It is convenient to consider this using the same reaction of H_2S chlorination as an example. The reaction rate is determined [taking the formula (11) into account] by the derivative

$$w = \frac{d[\text{HCl}^*](t)}{dt} = \alpha \frac{k_1 k_2 [\text{Cl}^*]_0 [\text{H}_2\text{S}] [\text{Cl}_2]}{k_1 [\text{H}_2\text{S}] + k_2 [\text{Cl}_2]}. \quad (15)$$

It is difficult to find w from the luminescence signal, as precise calibration of the absolute sensitivity of the radiation detector is required. Therefore, formula (15) cannot be used to obtain kinetic

information. However, measurement of w even in relative units can give such a kinetic information. Taking into account that the initial concentration of the chlorine atoms $[\text{Cl}^*]_0$ is proportional to the energy of the laser pulse E and the concentration of molecular chlorine, formula (15) can be rewritten as

$$\frac{[\text{Cl}^*]_0[\text{H}_2\text{S}]}{w} = \frac{1}{\alpha k_1} \left(1 + k_1 \frac{[\text{H}_2\text{S}]}{k_2[\text{Cl}_2]} \right). \quad (16)$$

Expression (16) means that the rate of the quasi-steady-state stage of the chain reaction normalised per pulse energy and the product of the concentrations of the starting substances depend only on the ratio of the rates of the stages of the chain growth. It follows from this formula that $E[\text{Cl}_2][\text{H}_2\text{S}]/w$ should depend linearly on the concentration ratio $[\text{H}_2\text{S}]/[\text{Cl}_2]$. Figure 4 demonstrates a plot of this dependence. Analysis of formula (16) shows that the simple graphical method can be used to determine the ratio of rate constants for the elementary steps of chain growth. One has to determine the slope of the straight line and its intercept with the ordinate axis. The ratio of these parameters equals k_1/k_2 .

Figure 4. Dependence of inverse normalised rate of a chain reaction on the ratio of reagent concentrations.⁵²

It should be noted that an account of the vibrational relaxation complicates the determination of w from the observed luminescence signal. The formulas containing the necessary corrections are presented in Ref. 52.

Using the technique described above, the ratio of the rate constants for the chain growth stages in the chlorination of H_2S [reactions (8) and (9)] was determined: $k_1/k_2 = 16$.⁵² The chain reaction of the SiH_4 chlorination was studied using this method.⁵³ The ratio of rate constants for the reactions

was found to be 4.6. The chain reaction of the SiHCl_3 chlorination was studied.⁵⁴ The ratio of rate constants for the reactions

was found to equal 1.3. The same technique was applied to the study of the chain chlorination of butane and ethane.

Certainly, this procedure does not correspond to direct methods for the determination of rate constants. However, it provides rather reliable information, which is difficult to obtain by other methods. The advantage of using the time-resolved luminescence technique is that it is possible to avoid the complicating effect of chain termination reactions.

A method for the measurement of rate constants based on the study of chain reaction termination stages. The IR-CL signal of chain reaction products recorded after a sufficiently long period

since its initiation contains information on the rate of decay of active centres in chain termination reactions. If the elementary reaction the rate constant of which has to be determined can serve as the chain reaction termination stage, it becomes possible to measure its rate. In this approach, the chain reaction resulting in the formation of vibrationally excited molecules plays the role of a probe for tracing the time dependence of the concentration of atoms or radicals. This allows one to study reactions that do not produce vibrationally excited molecules by the IR-CL technique. A similar approach for non-chain reactions has been developed.^{50,51} The use of a chain reaction gives two additional benefits. First, the sensitivity of the method increases as the total number of vibrationally excited molecules formed in a chain reaction can be many times greater than the number of active centres. Second, this expands the range of reactive species whose reactions can be studied by this method.

A detailed analysis of the IR-CL kinetics of chain reaction products at various inhibitor concentration was carried out by Chesnokov.⁵⁵ The exact solution of this problem is rather cumbersome, but the results for reactions with a long chain are simple enough and have a simple qualitative interpretation.

A chain reaction in a mixture of compounds $\text{A} + \text{B}$ with active centres X^* and Y^* involves the following elementary steps:

In the initial instant of time, a pulse of laser irradiation creates a certain concentration of active centres X^* equal to x_0 . The active centres Y^* are absent in the initial instant, $[\text{Y}^*] = 0$. Then, during the chain reaction induction period, a quasi-steady-state equilibrium between the concentrations of X^* and Y^* is established; the X^* concentration decreases, while the Y^* concentration increases (Fig 5a). The overall concentration of the active centres $[\text{X}^*] + [\text{Y}^*]$ remains approximately equal to x_0 .

After a quasi-equilibrium has been established, the overall concentration of the active centres decreases owing to their decay in chain termination reactions. The fractions of X^* and Y^* in the overall concentration of active centres remain constant. The fraction of X^* in the overall concentration of active centres equals

$$\theta_2 = \frac{k_2[\text{B}]}{k_1[\text{A}] + k_2[\text{B}]}, \quad (20)$$

while the fraction of active centres Y^* equals

$$\theta_1 = \frac{k_1[\text{A}]}{k_1[\text{A}] + k_2[\text{B}]}. \quad (21)$$

The decay of active centres occurs with an weighted average rate constant

$$\kappa = \theta_1 k_4 + \theta_2 k_3. \quad (22)$$

If the active centres X^* disappear in a reaction with substance C added to the reaction mixture:

then the rate of decay of the active centres increases:

$$\kappa = \theta_1 k_4 + \theta_2 (k_3 + k[\text{C}]), \quad (24)$$

where k is the rate constant for reaction (23).

The formula (24) underlies the method discussed for the determination of rate constants. If the life time of active centres of a chain reaction τ is measured at various concentrations of reagent C, then the reciprocal value $\kappa = \tau^{-1}$ should linearly depend on the reagent concentration. The factors θ_1 and θ_2 depend

Figure 5. Theoretical luminescence signal of chain reaction products. (a) establishment of quasi-steady-state equilibrium between the concentrations of X' (1) and Y' (2); (b) luminescence intensity at quasi-steady-state equilibrium between X' and Y' .

on the ratio of the starting concentrations of the original compounds A and B. If concentration B is chosen large enough, it is possible to reach the conditions where $\theta_2 \approx 1$ and $\theta_1 \approx 0$. If the reaction rate constant for the active centre Y' has to be measured, then, on the contrary, it is necessary to choose such conditions that $\theta_2 \approx 0$ and $\theta_1 \approx 1$.

The procedure for the determination of the life time of active centres from the luminescence signal of the reaction products remains the same. The curve $I(t)$ is described by a sum of exponential terms, which allow one to determine the time of vibrational relaxation and the life time of the active centres. One only has to exclude from consideration the initial period of the reaction, when the quasi-equilibrium between the concentrations of the active centres has not yet been established (see Fig. 5).

This method has been used for the measurement of the rate constants for a number of reactions.⁵⁵ Let us consider the measurement of the rate constants for the reactions $Cl' + NOCl$ with the use of this method.

First, one has to choose the chain reaction. Many chain reactions involving the chlorine atom and accompanied by the formation of vibrationally excited products are known. The reactions of chlorination of SiH_4 and its halogen derivatives are very convenient. These reactions give vibrationally excited hydrogen chloride molecules.^{23, 54} The stages of continuation in such reactions are fast,⁵⁶ hence the chain length can be significant even at low pressures. The inconvenience of the reaction of SiH_4 chlorination is that self-inflammation of its mixtures with Cl_2 occurs in the absence of an inhibitor. The reactions of SiH_2Cl_2 and $SiHCl_3$ chlorination are devoid of this drawback. Let us choose the faster reaction of SiH_2Cl_2 chlorination.

The chlorination of SiH_2Cl_2 involves the following chain growth steps:

The rate constant for reaction (25) is $1 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$,⁵⁶ The rate constant for reaction (26) is $2 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$.²³ Reaction (25) gives HCl^* molecules in the states $v = 0$ and $v = 1$ with probabilities of 0.67 and 0.33, respectively.²³

Figure 6. Examples of kinetic curves of luminescence of HCl^* molecules formed upon chlorination of SiH_2Cl_2 . Concentrations: SiH_2Cl_2 8×10^{14} ; Cl_2 2×10^{16} ; He $1.3 \times 10^{17} \text{ cm}^{-3}$; NOCl concentration/ cm^{-3} : (1) 2.2×10^{13} ; (2) 5.9×10^{13} ; (3) 15×10^{13} .

Figure 6 shows examples of IR-CL signals of excited hydrogen chloride molecules observed after reaction initiation in a $SiH_2Cl_2 + Cl_2$ mixture with addition of NOCl. An increase in the NOCl concentration decreases the amplitude of the luminescence signal. Such a dependence indicates that, under the conditions of the experiments, the time of vibrational relaxation exceeds the life time of active centres of the chain reaction. Figure 7 shows the dependence of the times of growth and decay of experimental curves on the NOCl concentration. It is evident that one of the characteristic times does not depend on the concentration of NOCl, while the other one varies over a wide range. The first time coincides with the time of vibrational relaxation and does not vary with the change in the NOCl concentration, since the concentrations of the other components of the mixture are much higher. The second time is the life time of the active centres of the chain reaction. At the concentrations $[NOCl] > 3 \times 10^{13} \text{ cm}^{-3}$, the life time of the active centres is smaller than the time of vibrational relaxation; at concentrations $[NOCl] < 3 \times 10^{13} \text{ cm}^{-3}$, the life time of the active centres becomes longer than the vibrational relaxation time. The inverse life time of active centres linearly depends on the NOCl concentration. The ratio of the projections of any segment of this linear dependence on the coordinate axes equals $(6.0 \pm 0.5) \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$.

In view of the above values of the rate constants for the steps of propagation of chain reaction under the conditions of the experiment, we obtain $\theta_2 = 0.85 - 0.9$; $\theta_1 = 0.1 - 0.15$. The parameter θ_1 cannot be regarded as negligibly small, hence it is necessary to take into account reactions of the active centres of both types

$$\kappa_2 = (\theta_2 k_3 + \theta_1 k_4)[NOCl] + \text{const}, \quad (27)$$

where k_3 and k_4 are the rate constants for the reactions

Figure 7. Dependences of reciprocal times of signal growth and decay on NOCl concentration; (1) life time of active centres; (2) vibrational relaxation time.

Thus, taking into account the slope of the straight line in Fig. 7, we obtain

$$\theta_2 k_3 + \theta_1 k_4 = (6.0 \pm 0.5) \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}. \quad (28)$$

A mixture with a larger fraction of SiH_2Cl_2 was studied to estimate the contribution of the term $\theta_1 k_4$; in this case, $\theta_1 = 0.3-0.4$. It was found that the contribution of the second term in formula (28) did not exceed 10%–15%. The resulting rate constant k_3 equals $(6.5 \pm 0.5) \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$.

This method was used^{57,58} for measuring the rate constants for a number of reactions of the chlorine atom with silicon-containing radicals. The results of these studies and the available published data obtained by other methods are listed in Table 3. The prospects of this method for the measurement of the rate constants for a certain reactive particle are determined by whether a fast chain reaction accompanied by formation of vibrationally excited molecules can be found for this particle. The analysis carried out by Chesnokov⁵⁵ shows that is possible to expect a gain in sensitivity only in the case where the rates of the chain propagation steps of the chain reaction exceed the rate of vibrational relaxation. This condition is similar to that demanded for the chain reaction for a chemical laser.²

Table 3. Rate constants for some reactions of the chlorine atom with silicon-containing radicals.

Reaction studied	Auxiliary reaction	$10^{11} k / \text{cm}^3 \text{ s}^{-1}$	Ref.

$\text{SiCl}_3^\bullet + \text{Br}_2 \rightarrow \text{SiCl}_3\text{Br}^\bullet + \text{Br}^\bullet$	$\text{Cl}_2 + \text{SiHCl}_3$	10.5 ± 1.7	57
$\text{SiHCl}_2^\bullet + \text{Br}_2 \rightarrow \text{SiHCl}_2\text{Br}^\bullet + \text{Br}^\bullet$	$\text{Cl}_2 + \text{SiH}_2\text{Cl}_2$	6.0 ± 0.9	57
$\text{Cl}^\bullet + \text{I}_2 \rightarrow \text{ICl}^\bullet + \text{I}^\bullet$	$\text{Cl}_2 + \text{SiHCl}_3$	$(2.5 \pm 0.7) \times 10$	58
$\text{SiCl}_3^\bullet + \text{I}_2 \rightarrow \text{SiCl}_3\text{I}^\bullet + \text{I}^\bullet$	$\text{Cl}_2 + \text{SiHCl}_3$	$(5.8 \pm 1.8) \times 10$	58

It should be noted that the idea of increasing the sensitivity by using a chain reaction as a ‘probe’ has been suggested and implemented by Orkin and Chaikin⁶⁴ for the thermometric detection of atoms. With the use of IR-CL, it was found possible to implement the same idea in a time-resolved version.

VII. The time-resolved Fourier-transform spectroscopy of IR chemiluminescence

In the last decade, time-resolved Fourier-transform spectroscopy is being used ever more frequently for the study of the IR luminescence of the products of gas phase reactions. This method makes it possible to obtain the luminescence intensity as functions of both frequency and time after the reaction initiation. In exceptional cases, it was also possible to obtain time-resolved IR-CL spectra by ordinary methods.⁶⁵

For the first time, the time-resolved version of Fourier-transform IR spectroscopy was used for the study of chemiluminescence in the gas phase by Aker and Sloan,⁶⁶ who studied the initial distribution over vibrational states of the $\text{OH}^\bullet$ radical formed in the reaction

A normal Fourier-transform spectrometer was used. The time resolution was achieved in these measurements by synchronisation of the pulse laser initiating the reaction under study with the instants of time when the spectrometer measures the values of the IR radiation interferogram.

Figure 8 illustrates the operation principle of a Fourier-transform IR spectrometer in the time-resolved mode. The directly measured characteristic is an interferogram, *i.e.*, dependence of intensity of IR radiation at the interferometer output on the difference between the ray paths in the two arms of the interferometer. The spectrum is obtained by Fourier transformation of the interferogram by a computer included in the set-up. The orientation of the moving mirror of the interferometer is determined using a helium–neon laser whose radiation passes through the auxiliary interferometer of the spectrometer combined with the main one. The controlling computer analyses the intensity of the ray of the helium–neon laser passed through the auxiliary interferometer and issues the commands for the measurement of the interferogram value. The moving mirror of the interferometer moves at a constant rate S , and the instants of time when the commands are issued are separated by identical time intervals T_0 (Fig. 8, curve 1)

$$T_0 = \frac{\lambda}{2S}, \quad (30)$$

Figure 8. Diagram clarifying the operation of a Fourier-transform IR spectrometer in time-resolved mode;

(1) sequence of time instants of interferogram measurement; (2, 5) laser pulses; (3) IR radiation at interferometer output; (4) interferogram with discarded region *a*; (6) IR radiation in the next cycle of spectrometer operation.

where $\lambda = 0.6328 \times 10^{-4}$ cm is the wavelength of the helium-neon laser. To synchronise the pulse laser, the computer command for performing the measurements is used for starting the pulse generator, which after the time Δt triggers the pulse laser (Fig. 8, curve 2). If the delay Δt is equal to the duration of the measurement recurrence period T_0 or slightly smaller, the pulse laser will act immediately before the instant of the interferogram measurement. By decreasing the delay, one can obtain a luminescence spectrum for some definite time instant after the laser pulse.

A difficulty in the implementation of such a scheme arises due to the fact that the usual measurement frequency of an interferogram by a Fourier-transform spectrometer is several kHz or several tens kHz. The lasers used for reaction initiation cannot work with such a pulse repetition rate. This means that only a part of the interferogram measurements contain the signal, while the major part of the measurements, which do not contain the signal, should not be taken into account (see region *a* of curve 4). The missing points in the interferogram can be obtained in the subsequent cycles of mirror scanning; however special measures should be taken so that the interferogram contains no gaps. The measurements in Refs 66, 67 were carried out according to such a scheme. The gaps in the measurement of an interferogram can be avoided at high pulse frequency of the laser or at very small movement speed of the spectrometer mirror. An excimer laser with a repetition frequency of 316 Hz was used,^{68–70} and the interferometer mirror was moved very slowly (0.01 cm s^{-1}). At this movement speed of the mirror, the time interval between the interferogram measurements [formula (30)] is equal to the recurrence period of the laser pulses, and rejecting a part of the measurements is no longer necessary.

In the studies mentioned above,^{66–70} the Fourier-transform IR spectrometer was used without updating the IR radiation intensity measurement system. In later studies,^{71,72} advanced equipment was used that made it possible to make a measurement of the interferogram at several different delay times after each laser pulse, instead of one delay time as before. This required alteration of the standard measuring part of the spectrometer, which was replaced with a digital signal recorder connected to a computer with a sufficiently large memory size capable of simultaneous accumulation of interferograms for all time instants. This updating increases considerably the speed of recording spectra.

Additional specific noise appears in the time-resolved mode; this may result, e.g., from the power instability of the pulse laser. It was suggested⁷³ that this noise be decreased by normalising the measurement results in each pulse using the pulse power.

Let us consider several examples of studies carried out by time-resolved Fourier-transform IR spectroscopy.

The reaction of the electron-excited $\text{O}^*(^1\text{D})$ atom with the hydrogen molecule was studied.⁶⁶ The distribution of the radical $\text{OH}^\bullet$ formed in reaction (29) over vibration levels was determined and found to be as follows: $P(v = 1 : 2 : 3 : 4) = 0.29 : 0.32 : 0.25 : 0.13$. The time-resolved Fourier-transform IR spectroscopy made it possible to study the distribution undisturbed by relaxation processes. The distribution obtained is of intermediate type between that characteristic of reactions occurring through an intermediate complex and that characteristic of direct cleavage reactions. It was thus assumed that the reaction dynamics includes a stage of a very strongly excited water molecule, which decays after the time corresponding to several vibration periods.

The reaction of the $\text{CHF}^\bullet$ radical with the NO molecule was studied.⁷² The radical was obtained by multiphoton IR dissociation of CH_2FCl or CH_2F_2 . The luminescence of vibrationally excited HF molecules formed in the reaction was recorded. The addition of D_2 to the reaction mixture resulted in the excited DF molecules, which allowed the determination of the ratio of the pathways yielding HF and $\text{F}^\bullet$ for the reaction studied; this ratio was found to be 0.6 : 0.4.

Vibration relaxation of NO molecules excited to high vibration levels was studied.⁷⁴ The photolysis of N_2O (irradiation with a wavelength of 193 nm) gives $\text{O}^*(^1\text{D})$, which reacts with N_2O to

give the highly excited NO molecule. Twenty IR luminescence interferograms corresponding to various instants of time (step 30 μs) were obtained. Based on the interferograms, the spectra were reconstructed in the range from 2500 to 1500 cm^{-1} with a resolution of 4 cm^{-1} . By plotting the spectra calculated in this way, a time dependence of the population of vibration levels from $v = 1$ to $v = 11$ was obtained. The results were interpreted using a system of eleven kinetic equations that described the vibrational relaxation. The rate constants for the vibrational relaxation of separate vibration levels were determined. The relaxation constant for the level $v = 11$ is 40 times greater than that for the level $v = 1$.

In several publications, the initial distribution of photodissociation products of various molecules over vibration levels was studied using time-resolved Fourier-transform IR spectroscopy. For example, one of them⁶⁹ is devoted to the study of excitation processes of HF molecules formed upon the photodissociation of CH_2CClF (irradiation at the wavelength of 193 nm), while another one⁶⁷ deals with a study of distribution of the $\text{NH}_2^\bullet$ radical formed upon the photodissociation of NH_3 (irradiation with a wavelength of 193 nm) over vibration levels.

The studies using time-resolved IR chemiluminescence cannot be classified as purely kinetic ones, or to those where only the energy distribution in the reaction products is studied. The basic purpose of these works is to establish the distribution of products over vibration states. However, this can also provide quantitative information on the rates of vibrational relaxation processes and chemical reactions.

VIII. Conclusion

The time-resolved IR-CL method is used in gas-phase chemical kinetics in order to obtain quantitative information regarding the rates of elementary reactions. The application of this method for studying chain processes was found to be particularly fruitful.

However, it should be noted that the method is limited to a narrow range of molecules the luminescence of which can be observed. In fact, the luminescence of either HCl or HF was used in all of the studies. Attempts to overcome this restriction were undertaken. Reactions were found that gave polyatomic vibrationally excited molecules yielding intense luminescence. For example, luminescence of SiH_3Cl ⁷⁵ and of products of butane and ethane chlorination⁷⁶ was observed. The luminescence kinetics of SiH_3Cl was studied in detail;⁷⁵ this process is mostly determined by the transfer of vibration energy and vibrational relaxation. It was found of little use for obtaining information on the rates of chemical reactions. The difficulties are basically caused by the fast vibrational relaxation of highly excited polyatomic molecules.

Further prospects of the IR-CL method are related to the use of the time-resolved Fourier-transform spectroscopy.

Abstract. The influence of steric and electronic factors on the reactivity and the stereochemical outcome of epoxidation of cycloalkenes and prochiral alkenes by alkyl hydroperoxides, peroxy acids, oxaziridines, dioxiranes and dimethyl- α -peroxy lactone is analysed comparatively and generalised. The distinctive features of the directing influence of functional groups on the stereochemistry of the epoxide ring closure in the series of ionic, radical and molecular reactions are demonstrated. Some variants alternative to known reaction mechanisms are proposed. The bibliography includes 114 references.

I. Introduction

Stereochemical regularities of the epoxidation of alkenes by peroxide reagents have been the subject of detailed studies,^{1–8} because reactions of this type are widely used in asymmetric synthesis and for the preparation of a number of polyfunctional compounds of specified structures. In the last two decades, the knowledge of the stereochemistry of epoxidation has become much deeper due to the understanding of the role of stereo-electronic microeffects in the transition state^{2,5–9} and long-range macrostereochemical effects at the stage of coming together and coordination of reactants.^{10–13}

Thus it was found that the rate of epoxidation of aliphatic compounds by peroxy acids depends on the length and conformation of the hydrocarbon chain of the molecule.^{1,2} The dependence of the rate constants for epoxidation (k_{epox}) on the number of carbon atoms in the molecule of the peroxy acid RCO_3H or alkene is a broken curve (alternation effect).¹⁰ When the size of the peroxy acid molecule increases, the rate and contribution of epoxidation decrease; simultaneously, the loss of active oxygen in the alkene-induced decomposition of the peroxy acid becomes more significant.^{2,11,12} The rate of epoxidation of the first double bond in the diallyl dicarboxylates $\text{H}_2\text{C}=\text{CHCH}_2\text{OCO} \cdot (\text{CH}_2)_n\text{COOCH}_2\text{CH}=\text{CH}_2$ markedly decreases at $n > 2$,

although the electron-withdrawing influence of the ester group rapidly decays with an increase in n .¹³

The k_{epox} is substantially influenced by the solvation of functional groups far removed from the reaction centre. This solvation, like the increase in the size of the molecule, results in the loss of rotational degrees of freedom of reactant molecules and thus decreases the probability of their efficient collision.^{2,13}

The requirements for the spatial compatibility of reactants become more rigorous with an increase in the size of the substituents surrounding the CO_3H group up to the point when the steric factor becomes more significant than the electronic factor. *cis*-Alkenes better fit in the ‘niche’ of the shielded peroxy-acid site. As a consequence, the $k_{\text{cis}}:k_{\text{trans}}$ value becomes relatively high. An increase in the number of alkyl substituents at the double bond decreases the reaction rate.¹⁴

The stereo- and regioselectivity of epoxidation are largely associated with the influence of alkyl substituents and functional groups in the alkene (OH , COOH , CONH_2 , $\text{C}=\text{O}$, SiR_3 , etc.) on the epoxidising reagent and with the geometry of the reactant molecules.^{2,6–8,15} However, the features of the stereochemical influence of substituents and the stages responsible for this influence are still not quite clear. In particular, they have not yet been identified for the set of epoxidising reagents presented below.^{1,2,4,5,16}

In this review, we attempt to generalise the accumulated data and to reveal new aspects concerning the mechanism of influence of the geometry of reactant molecules and the nature of functional groups on the rate, route and stereochemical outcome of epoxidation of alkenes with the above reagents. Using epoxidation by peroxy acids as an example, we describe systematically the general features of the behaviour of cycloalkenes and methylenecycloalkanes as functions of the strain and the degree of shielding of the double bond.

II. Epoxidation of alkenes with alkyl hydroperoxides

Epoxidation is normally carried out using alkyl hydroperoxide derivatives of types **1–3** shown below

M is a transition metal in the highest oxidation state (Mo^{6+} , V^{5+} , Ti^{4+} , etc.).

Alkylperoxide anions **1**, like the hydroperoxide anion, oxidise polar $\text{C}=\text{C}$ double bonds conjugated with a carbonyl group in chalcones, quinones, naphthoquinones,^{17,18} α,β -unsaturated esters, sulfones, sulfoximines and amides^{19–22} at moderate temperatures (-20 to 0°C) with relatively high diastereoselectivity (20%–100%). These reactions are catalysed by bases (NaOH , Na_2CO_3). The use of salts (ROOK and ROOLi), which are formed on treatment of ROOH with the corresponding metal hydrides or alkylmetals, is also efficient. It is of interest that the use of the $\text{Bu}^t\text{OOH}-\text{RLi}$ oxidative system results in a side reaction, transfer of active oxygen to the carbanion, occurring in parallel with epoxidation.¹⁹

The regularities of the process have been studied most comprehensively in relation to epoxidation of α,β -unsaturated esters. This reaction is highly sensitive to steric restrictions, especially when the α - and β -positions in the substrate are substituted. The oxidation of *cis*-isomers is slower than that of *trans*-isomers. The reaction is completely stereospecific, except for oxidation of some sterically hindered esters of maleic acid. Di(*tert*-butyl) maleate is converted into the epoxide of di(*tert*-butyl) fumarate under the oxidation conditions.¹⁹

It is significant that epoxidation of α,β -unsaturated esters occurs diastereoselectively (the content of one isomer reaches 74%) only when lithium *tert*-butyl peroxide is used. When potassium *tert*-butyl peroxide is employed, the stereospecificity is lost. Apparently, the lithium cation, which has the most intense electromagnetic field among alkali metal cations, forms a stronger associative bond with the carbonyl oxygen atom in the substrate and thus stipulates the formation of cyclic transition state **4**. One of the two possible orientations of the unsaturated compound results in a more stable conformation of the transition state (TS) (with equatorial R^2); this ensures the predominant formation of one isomer.

The reaction is accompanied by several side processes, in particular, transesterification and a rearrangement of the α,β -epoxy ester. Thus epoxycinnamate can rearrange to give the ester of an oxo acid, which then undergoes the Claisen cleavage.

Di(*tert*-butyl) maleate does not undergo stereocontrolled epoxidation.¹⁹ *N,N*-Dialkylamides of α,β -unsaturated acids undergo epoxidation with Bu^tOOLi with complete regio- and

stereo-control and a small extent of side reactions. This method is relatively ineffective for secondary amides and totally ineffective for primary amides. As in the case of esters, oxidation of *cis*-amides occurs more slowly than that of the corresponding *trans*-isomers. The reaction rate depends appreciably on the size of the substituent at the β -position.

Phenyl *cis*-styryl sulfone is epoxidised according to the same rules as α,β -unsaturated esters. Epoxidation with potassium *tert*-butyl peroxide is not stereospecific (the ratio of *cis*- and *trans*-epoxides is 2:3), whereas treatment with lithium *tert*-butyl peroxide under the same conditions gives *cis*-epoxide as the only product in a high yield. The *trans*-isomer of this sulfone is epoxidised in a similar way. Asymmetric α,β -unsaturated sulfoximines **5** undergo epoxidation with 100% diastereoselectivity.

In this case, unlike the reactions described above,¹⁹ the use of potassium *tert*-butyl peroxide in a $\text{THF}-\text{NH}_3$ mixture permits stereoselective epoxidation of unsaturated compounds **6**.²⁰ The ratio of *syn*- and *anti*-diastereoisomers amounts to 95:5.

α,β -Unsaturated sulfones **7** undergo stereoselective epoxidation by Bu^tOOLi ,²¹ and analogous alkenyl sulfones **8** can be stereoselectively epoxidised by an alkaline solution of potassium *tert*-butyl peroxide.²² In the latter case, the product of addition of alkyl hydroperoxide at the double bond was isolated, apart from the corresponding epoxide.

Intramolecular epoxidation of compound **9** simulates a stage of the biological oxidation of vitamin K.²³

The alkaline intramolecular epoxidation of cyclic α,β -unsaturated ketones **10** and **11** occurs in a similar way, yielding *cis*-epoxy alcohols.^{24,25}

It can be easily understood that a coplanar arrangement of the p electrons of the peroxide anion and the π^* (antibonding) orbital of the double bond in the substrate is a necessary stereochemical condition for epoxide ring closure in the ketones **9–11** (stereoelectronic factor). This is also true for a large number of other heterolytic and radical reactions involving not only π^* orbitals^{23–26} but also $\sigma^*_{\text{O}-\text{O}}$,²⁷ and $\sigma^*_{\text{H}-\text{O}}$ ²⁸ type orbitals. In particular, this can be clearly seen in the case of photo or thermal isomerisation of *endo*-peroxides formed during oxygenation of cyclic 1,3-dienes by singlet oxygen.²⁶

Similar stereoelectronic effects are involved in the deoxygenation of *endo*-peroxides with triphenylphosphine.²⁶

The scheme of epoxidation of alkenes with alkylperoxy radicals with the intermediate formation of β -peroxyalkyl radicals^{1,27} is shown in Fig. 1.

Figure 1. Epoxidation of alkenes with alkylperoxy radicals: **A** is the donor–acceptor complex; **B** is the β -peroxyalkyl radical; (1) the $\sigma_{\text{O}-\text{O}}^*$ orbital; (2) the $\pi_{\text{C}-\text{C}}^*$ orbital; (3) the $\sigma_{\text{antibond O}-\text{O}}^*$ orbital.

β -Hydroxy radicals **12** are generated during decarboxylation of β -hydroxy acids in the presence of lead tetraacetate and during oxidation of β -oxo esters **13** with manganese triacetate.²⁸

The epoxide ring closure occurring upon the oxidation of β -hydroxyl radicals by transition metal salts can be represented as follows:

Isomerisation of α -hydroxy epoxide **14** in an alkaline medium occurs in a similar way.²⁹

The generalisations made here can be invoked to interpret the mechanisms of some known reactions. Thus oxidation of alkenes with atmospheric oxygen on a vanadium catalyst^{5,30} gives allyl hydroperoxides, which undergo intramolecular epoxidation. This affords epoxy alcohols only as *cis*-isomers, which has been confirmed by simulation of the stage of self-oxidation of cyclo-alkenyl hydroperoxides.³¹ It is obvious that intramolecular *cis*-epoxidation rules out the possibility of the coplanar attack by the alkene π bond on the $\sigma_{\text{O}-\text{O}}^*$ orbital and the mechanism typical of epoxidation of inorganic acids by peroxy esters.^{5,7} Meanwhile, the structure of the substrate **15** is favourable for the nucleophilic attack by the outer peroxide oxygen atom on the π^* orbital of the alkene activated by the catalyst.

Yet another example of reaction the course of which can be predicted based on the above stereochemical regularity is oxidation of a biological antioxidant, vitamin E (D- α -tocopherol **16**).^{32,33} It was reported³² that the *tert*-butylperoxyl radical oxidises tocopherol **16** to give epoxy hydroperoxide **18** via the intermediate formation of hydroperoxide **17**.

When tocopherol **16** is oxidised by the radicals formed upon thermolysis of azobis-2,4-dimethylvaleronitrile in oxygen-saturated acetonitrile, the hydroperoxide **17** is formed in only small amounts and, judging by kinetic data, it is not an intermediate compound.³³ It was suggested that the reaction follows the scheme shown below:

With allowance for the above-discussed stereoelectronic conditions for the closure of an epoxide ring, two ring formation mechanisms operating during the transformation of the radical **19**

into **20** and then into the epoxide **21** can be conceived. In the case of direct attack by the alkylperoxyl radical $R'OO^\bullet$ on the π bond, the following transformations occur:

In the case where the radical **19** captures a triplet oxygen molecule, a different sequence of transformations is possible.

The epoxidation mechanism assuming the formation of the alkenylperoxyl radical **22** is possible in the case of either disproportionation of radicals or exchange interaction

One can expect that an equilibrium of this type in the reaction in question would be shifted towards the more stable hydroperoxide **21** having an intramolecular hydrogen bond.

It has been found that radicals formed from the superoxide ion ($O_2^{\bullet-}$) and polyhaloalkanes (CCl_4 , $CHCl_3$, F_3CCl_3 , $PhCCl_3$, $Cl_2C=CCl_2$, etc.)^{34,35} containing a halogen atom which can be homolytically eliminated possess epoxidising ability under mild conditions. For example, when CCl_4 is treated with potassium superoxide in acetonitrile in the presence of a phase transfer catalyst, the trichloromethylperoxyl radical $Cl_3COO^\bullet$ **23** acts as a species of this type.

In our opinion, the mechanism of generation of this radical includes radical decomposition of polyhaloalkanes initiated by the superoxide ion to give singlet oxygen.

The fact that the yield of the epoxide does not depend on the concentration of $^3O_2$ indicates that the radical **23** is formed only from the initial compounds in a solvent cage.

The radical character of the process is confirmed by the loss of stereospecificity — *cis*-stilbene is mostly converted under these conditions into *trans*-stilbene oxide. Additives able to transform $Cl_3COO^\bullet$ into the anion inhibit the epoxidation.

Oxidation of alkenes by radicals of the type **23** is a good model for the study of general, including stereochemical, regularities of the set of consecutive and competing transformations involved in epoxidation by alkylperoxyl radicals, oxometal complexes and triplet oxygen, which is usually accompanied by extensive oxidation of substrates with complete cleavage of the alkene double bond.^{2,5,36}

In particular, attention is attracted by the fact that in addition to oxirane (yield 73%), epoxidation of cyclohexene in the CCl_4-KO_2 system gives cyclohex-2-enone (yield 9%), whereas 1-methylcyclohexene is oxidised only to the corresponding oxirane. This difference is undoubtedly due to the higher nucleophilicity of the double bond in the latter compound. However, the steric factor also cannot be ignored; indeed, the methyl group introduced in the cyclohexene molecule decreases its conformational mobility. The stereochemistry of radical oxidation of cyclohexene at the α -C-H bonds requires that the $Cl_3COO^\bullet$ radical **23** be inserted into the axial position; this should be followed (at the stage of formation of the carbonyl group) by ring inversion and migration of the substituents to the equatorial position.

In addition to epoxides, the reaction affords products of complete cleavage of alkenes at the double bond (which are formed *via* a parallel route rather than in subsequent transformations). For example, acetophenone (19%) is formed in the oxidation of α -methylstyrene apart from the epoxide (73%). The highest yield of acetophenone is attained much earlier than that of the epoxide. It was found in special experiments that epoxide itself is not converted into acetophenone under the reaction conditions. It is also noteworthy that α -methylstyrene is oxidised more readily when taken as an equimolar mixture with styrene rather than in a pure state, although it is more nucleophilic.

The character of the observed transformations implies that in addition to the classical epoxidation of the alkene *via* β -peroxyalkyl radical **24** (pathway *a*),^{2,36} transformations in this system include more extensive oxidation involving a second KO_2 molecule, yielding intermediate **25** and resulting in complete rupture of the alkene bond. This brings about the fundamentally important question of what is the route leading to the oxo compound. Indeed, this product could be formed either *via* the ozonide and then the Criegee intermediate (pathway *b*) or *via* dioxetane (pathway *c*).

Pathway *b* is a result of the transfer of oxygen from the peroxide group $R-O-O-R'$ to the peroxyalkyl anion, by analogy with self-oxidation of peroxide compounds.² This seems more likely than pathway *c*, which assumes reversible nucleophilic substitution giving a strained dioxetane ring at an initial stage.

Pathway *b* involving the formation of a carbonyl oxide accounts for the fact that during oxidation of styrene, benzoic acid, formed in parallel with benzaldehyde, is accumulated in the reaction mixture.³⁵

However, in the presence of KO_2 , oxidation of aldehydes, in particular benzaldehyde, is also possible; this gives rise to the benzoylperoxide anion, the oxidative capacity of which exceeds that of the radical **23**. It is this fact that accounts for the promotory influence of styrene on the epoxidation of α -methylstyrene. The $\text{Cl}_3\text{CO}^\bullet$ radical formed in epoxidation is neutralised apparently by excess KO_2 . The epoxidising radical **23** can be consumed in a similar way.

If the polyhalide molecule contains a double bond, cyclisation of the intermediate peroxy radical **26** during the reaction becomes possible.³⁴

Epoxidation of alkenes by peroxy esters of inorganic peroxy acids has been studied fairly comprehensively.^{1, 2, 5, 7, 37, 38}

A peculiar feature of the ROOH –Cat epoxidising system (Cat is a transition metal complex) is that the hydroperoxide molecule enters the coordination sphere of the central atom as a nucleophile; this is accompanied by displacement of one ligand (acetylacetonate, OR, RCO_2 , CO, *etc.*). Apparently, the alkene also participates in the ligand exchange. The rate of these reactions can be comparable with the epoxidation rate. Consequently, the overall rate of the process is controlled by the rate of diffusion and exhibits self-acceleration or, conversely, self-deceleration effects.^{2, 39}

When the alkene contains a nucleophilic functional group (for example, an allylic hydroxy group), both the alkylperoxide fragment and this functional group get into the coordination sphere of the catalyst.^{5, 7} Thus, the stereodirecting influence of the hydroxy group in alkenes on the attack by alkyl hydroperoxide is exerted at the stage of construction of a highly ordered multiligand donor–acceptor complex. It has been found that the stereoselectivity of formation of the corresponding oxiranes in the epoxidation of allylic alcohols decreases upon an increase in the degree of shielding of the hydroxy group.⁴⁰

Compound				
ee (%)	> 95	85	25	5
Yield (%)	52	43	77	75

The geometry of the chiral environment of the catalytic center, which has a sort of matrix effect on the orientation of the prochiral double bond, is a crucial factor for the occurrence of stereocontrolled synthesis in the presence of the ROOH –Cat system. In

particular, the Sharpless reagent ensures not only high diastereoselectivity but also enantiofacial selection caused by the ligand configuration (D- or L-tartrate). The strict spatial orientation of the molecular orbitals participating in the construction of the intermediate complex also makes a certain contribution to the matrix effect (stereoelectronic factor).

The extent to which a hydroxy group is involved in the epoxidation of cyclic alkenes and alkadienes is determined not only by its position relative to the double bond but also by the conformation of the molecule as a whole. This can be judged by examining the relative rates of epoxidation of the double bonds [$\text{Bu}^\text{t}\text{OOH}$, $\text{VO}(\text{acac})_2$, C_6H_6 , 40 °C] in the following sequence of substrates:⁴¹

Compound					
k_{rel}	100	2.1	0.09	40	19

The introduction of a bulky trimethylsilyl group (*e.g.* at the 3-position) in the unsaturated alcohol molecule increases the stereoselectivity of epoxidation.⁴²

The higher stereoselectivity observed in the presence of alkyl hydroperoxides and the greater versatility of these reagents compared to peroxy acids is due to the formation of a fairly strong donor–acceptor bond between the hydroxy group of alkenol and the central metal atom.

Detailed investigation of the $\text{Bu}^\text{t}\text{OOH}$ –diethyl tartrate–Ti(IV) epoxidising system permitted the researchers^{7, 39} to conclude that epoxidation occurs in binuclear complex **27** with six-coordinate titanium.

$\text{R} = \text{Pr}^\text{i}$, $\text{R}' = \text{Et}$.

Change in the ligand nature, in particular, the use of titanium complexes containing chloride ions or amides of tartaric acid results in inverted stereoselectivity.⁴³

It has been shown⁴⁴ that opposite enantiofacial selectivities are observed for allylic and homoallylic alcohols. This finding might suggest a synergistic effect of the two hydroxy groups in the optically active (1*R*,2*R*)-1,2-divinylethylene glycol **28**. However, epoxidation of this compound by $\text{Bu}^\text{t}\text{OOH}$ led to an unexpected result,⁴⁰ namely, the inversion of enantioselectivity and enantiofacial selectivity was observed. Depending on the amount of the oxidant used, this reaction yielded either mono- (**29**) or di-epoxide (**30**).

DIPT is diisopropyl tartrate

Diisopropyl L-(+)-tartrate [L-(+)-DIPT], which should have been used according to the empirical rule formulated by Rossiter and Sharpless,⁴⁴ proved to be inapplicable. However, epoxidation of the monobenzyl ether of glycol **28** occurred in conformity with this rule.⁴⁵ The *meso*-form of 1,2-divinylethylene glycol **31** was epoxidised in a similar way.

The result of the asymmetric epoxidation of the stereoisomeric glycols **28** and **31** was interpreted by assuming that the (*R,R*)-substrate **28** reacted as a monomeric (**32**) or dimeric (**33**) complex, in which the peroxide oxygen atoms are arranged as in the complex **27**, whereas the *meso*-form reacted in complex **34**, in which the oxygen atoms are arranged horizontally.

III. Specific features of epoxidation of cycloalkenes and methylenecycloalkanes with peroxy acids

Cycloalkene molecules are characterised by various types of strain: cisoid stretching or compression strain and out-of-plane, one-sided, torsional and transannular strain.^{12, 46–48} The three last mentioned types of strain are most typical of methylenecycloalkanes.^{47, 48} The real contributions of the components to the total strain can be estimated based on thermochemical data and quantum-chemical calculations.^{12, 46–49} Qualitative estimates can be made by comparing the relative rates of epoxidation (ω) of several cycloalkenes under conditions A and B.

A. Reaction conditions for cycloalkenes **35–40**: AcOOH, AcOEt, 25 °C.⁴⁷

B. Reaction conditions for cycloalkenes **39**, **41** and **42**: PhCOOOH, THF, 20 °C.⁴⁶

It can be seen that the reactivity of five- and six-membered rings increases in the sequence **39** < **38** < **35**. This was attributed to the increase in the cisoid compression strain and out-of-plane strain.^{47, 49}

The higher reactivity of the double bond of the norbornene fragment compared to that in the cyclopentene fragment is manifested when dicyclopentadiene is oxidised with peracetic and monoperoxyphthalic acids⁵⁰ and with geminal hydroxyalkyl hydroperoxides.⁵¹

The reaction of norbornene **35** is characterised, in addition to the typical *exo*-selectivity of the attack on the double bond, by a high rate of electrophilic addition, observed irrespective of the reagent used or the reaction mechanism. A certain contribution to the relatively high reactivity of norbornene is made by the out-of-plane deformation and hyperconjugation.⁵² PMX calculations showed that the =C–H bonds in norbornene **35**, unlike those in cyclohexene **39** and bicyclo[2.2.2]octene **36**, are bent by 4.2° to the *endo*-region. In view of this result, which has been confirmed by *ab initio*⁵³ calculations, the preferred *exo*-attack by the electrophile is explained by the fact that in the *exo*-region, the π orbital of norbornene is turned outwards due to the repulsion from the occupied orbitals of the methylene bridge,^{53, 54} whereas in the *endo*-region, the orbital is shielded by the carbon skeleton of the molecule. In cyclopentene, this effect is less pronounced.⁵²

The replacement of the *endo*-methylene bridge in norbornene **35** by an *endo*-ethylene bridge relieves the cisoid compression strain and, apparently, enhances shielding of the double bond, which results in a markedly lower reactivity of bicyclo[2.2.2]octene **36**.

Upon replacement of the six-membered ring by an eight-membered ring, the system becomes more flexible and the reaction rate increases. Unlike other cycloalkenes, *cis*-cyclooctene **41** is readily converted into the epoxide on treatment with various oxidants including molecular oxygen. This leads to the conclusion that both the intermediate states and species and the epoxide formed from the cycloalkene **41** are highly conformationally stable.

trans-Cyclooctene **42** occupies a special place in the series of cycloalkenes.^{46, 55} It typically exists in a *twist*-conformation with highly pronounced out-of-plane torsional strain, favourable for *syn*-addition reactions. The electrophilic attack is directed only at one face of the double bond, which is rotated outwards due to twisting of the molecule.

The general pattern of the electrophilic addition to double bonds in cycloalkanes is as follows: as the substrate becomes more strained, the formation of a cyclic transition state is facilitated, because this releases strain.^{46, 47, 56} The more atoms incorporated in the transition state, the greater the decrease in the strain of the system; consequently, the reaction rates can differ by 2–3 orders of magnitude.⁵⁶ The fact that the rates of epoxidation of norbornene and cyclohexene differ by a factor of less than three attests to the formation of three-membered transition states in both cases.

It should be noted that in the case of typical 1,3-dipolar addition of phenyl azide (in CCl₄ at 25 °C) to *trans*-cyclooctene **42**, norbornene **35** and cyclohexene **39**, the relative reaction rates are 2.1×10^5 , 5.7×10^3 and 1.0.

Apparently, the rate of epoxidation depends on the strain not only in the initial alkene but also in the final product, oxirane. It is the high conformational distortions in the latter in combination with steric shielding that account for the facts that 3,5-dibromocyclopentene and 3,6-dibromocyclohexene are much more difficult to epoxidise than their open-chain analogue, 1,4-dibromobut-

2-ene, and that cyclobutene **37** is much less reactive than cyclopentene **38**.²

An important factor governing the stereochemistry of epoxidation of cycloalkenes is the principle of the least conformational strain formulated by Toromanoff.⁵⁷ By means of dynamic conformational analysis of the probable transition states with allowance for the Curtin–Hammett principle, the researcher showed that insertion of the epoxide oxygen during the epoxidation of mono- and bicyclic alkenes follows predominantly the direction that ensures the least conformational distortions (thermodynamic control). However, the notion of conformational distortion is ambiguous and can comprise several components. The concepts of torsional,^{10,58} hyperconjugative⁵⁹ and electrostatic⁶⁰ effects controlling the stereochemistry of epoxidation are being debated in the literature. It has been reported^{57,61} that bicyclononene **43** reacts with peroxy acids to give exclusively *endo*-epoxide **44**.

This reaction route is apparently facilitated by shielding of the double bond by the axial H¹ and H⁴ atoms at the stage when the reactants approach each other, by the torsional strain in the transition state, which would have been generated by an attack by the peroxy acid from the side of these atoms and, finally, by stabilisation of the transition state formed in the case of the *anti*-attack by RCO₃H due to the interaction of the C–H¹ and C–H⁴ σ bonds with the electron-deficient sites arising in the bicyclononene complex **43**. The latter type of interaction is involved in initial stages of classical rearrangements of carbenium ions of the type **45** and in the isomerisation of oxiranes **46** to oxo compounds,⁶² associated with hydride shifts.

The combined action of all these factors in the reaction of bicyclononene **43** results ultimately in the generation of a conformationally more stable (see Section V) and, hence, energetically more favourable transition state. The (σ–δ⁺) type interaction (in the σ–σ* variant) has been invoked⁶³ to explain the stereochemical outcome of epoxidation of the bicyclo[2.2.2]octene derivative **47** by *m*-chloroperbenzoic acid (MCPBA).

It was found that the proportions of the *syn*-isomer obtained with X = OMe, H, F and NO₂ are 48%, 50%, 58% and 77%, respectively. In other words, the introduction of an electron-withdrawing substituent (F, NO₂) decreases the σ-donor capacity

of the C(1)–C(6) and C(4)–C(5) bonds and thus makes the *syn*-attack by the peroxy acid more favourable.

The presence of an alkyl substituent in the five-membered ring and in polycyclic molecules^{6,50} can hamper the attack on the double bond from one side.

The presence of an axial methyl group at C(3) in 3,3,5-trimethyl-1-methylenecyclohexane decreases the proportion of the axial attack by RCO₃H on the double bond to 17% (compared to 64% observed for 3,5-dimethyl-1-methylenecyclohexane).¹⁵

However, in flexible systems, for example, in cyclohexene derivatives direct steric shielding can be removed or minimised due to the conformational mobility of the molecule,²⁹ because the most substantial steric restrictions are created by an axial substituent.

Alkene **48**, having a rigid alkenyl system, forms epoxide **49** with high diastereospecificity (93%–99%),¹⁸ in this case, the *anti*-attack by the oxidant predominates.

R = H, Br, CN, OMe.

Conformational analysis of diastereoisomeric transition states (**A** and **B**, Fig. 2) permits the conclusion that *gauche*-structure **A**, leading to the *anti*-epoxide, is more favourable than eclipsed

Figure 2. Newman projections of the transition state formed in the oxidation of the alkene **48** with *m*-chloroperbenzoic acid: **A** is the *gauche*-conformation; **B** is the eclipsed conformation.

structure **B**, in which the orientation of the benzamide group in one direction with the peroxy-acid fragment increases the torsional strain in the transition state. In the Newman projections, the line of sight of the observer is directed along the peroxide bond from the side of the attack of the alkene, the π bond passing through one of the two lone pairs of the active oxygen atom; this is a necessary condition for the occurrence of dative interaction at the stage of the epoxide ring formation.²

The composition of the products of epoxidation of two series of compounds, alicyclic compounds **50–54** with conformationally fixed styrene fragments, and more flexible structures, cyclohexene derivatives **55–58** and cyclopentene derivative **59**, by peroxy acids shows that high diastereofacial selectivity is manifested only in the series of compounds **50–54** (the ratio of *syn*- to *anti*-epoxides is given in parentheses). This may be explained by the conformational stability of the transition state with allowance for all factors which ensure this stability.

The regularities of epoxidation of methylene- and alkylidenecycloalkanes have been briefly considered.⁶⁴ The relative rates of epoxidation of monocyclic compounds with *exo*-double bonds by peracetic acid in ethyl acetate at 40 °C were determined.¹²

Terminal double bonds in aliphatic compounds are known to be substantially less reactive than symmetrically dialkyl-substituted bonds.^{2,14} In the series of alicyclic compounds, the relative reactivities of *exo*- and *endo*-double bonds are substantially affected by cyclic strain. This is indicated by kinetic and activation parameters. As noted above, more strained cycloalkenes are more reactive. However, methylenecyclobutane, which has the most strained molecule in the series of its analogues, is the least reactive compound. It may be expected that the rate of epoxidation would be correlated with the HOMO energy of the alkene, calculated by a quantum-chemical method: the higher this energy, the easier the interaction between the π orbital and the σ_{O-O}^* orbital of the peroxy acid. In the case of cycloalkenes, this correlation actually holds.⁴⁷ In fact, E_{HOMO} increases in parallel with the decrease in the ring size and with the enhancement of strain. In the series of methylenecycloalkanes, the opposite dependence is manifested.¹⁰ Methylenecyclohexane is epoxidised at a lower rate and with a higher activation energy than more strained methylenecyclopentane, although the data of photoelectron spectra indicate that they have close π -ionisation potentials. However, the low reactivity of methylenecyclobutane correlates with the fact that it has the highest ionisation potential in the series of compounds under study.¹⁰

Nevertheless, the differences in the reactivity found in the series of medium rings ($C_4–C_7$) are relatively small, because in all these cases, a strained three-membered transition state is formed.

Methylenecyclododecane occupies a special place in this series. Its low reactivity is inconsistent with the views on the ring strain and leads to the conclusion that the reaction rate is also influenced by the probability of effective collision of the reactant molecules, which varies depending on the size of the molecules.^{2,10,13}

Epoxidation of alicyclic compound **60** presents interest because this compound contains both norbornene and ethylidene fragments. The reaction with monoperoxyphthalic acid affords nearly equal amounts of compounds **61–63**, i.e. only the exocyclic double bond is involved in the reaction.⁵⁰

The ratio of the epoxide **61** to the epoxide **62** is 1.9 after 1 h, and 0.9 after 2 h. When peracetic acid is used, this ratio does not change during the reaction and lies in the range 1.6–1.7.

It was found in special experiments that the ketone **63** is formed only from the oxirane **61** during oxidation by monoperoxyphthalic acid. When peracetic acid is used, this isomerisation does not occur. This might be due to the lower acidity of the medium.

Study of epoxidation of substituted methylenecyclohexanes **64–68** revealed fine stereochemical features of this reaction.^{15,64–67}

The addition of an oxygen atom to an alkene can be directed at either axial (*a*) or equatorial (*e*) positions. Epoxide **69a** in which the methylene group is equatorial is 0.6–1.1 kJ mol^{–1} thermodynamically more favourable than the product **69b**.

The compositions of the isomeric epoxide mixtures formed from the alkenes **64–68** were determined using low-temperature ¹H NMR spectroscopy or stereochemical analysis of the alcohols formed upon hydride reduction of the epoxides.

In the majority of cases, when peracetic, *m*-chloroperbenzoic and peroxyphthalic acids are used, the axial attack proved to be preferred. The inversion of the epoxidation stereochemistry was observed in the case of the alkene **68**, due to the shielding of the double bond by the methyl group, and in the case where the methylenecycloalkanes **64–68** were epoxidised with peroxybenzimidic acid ($C_6H_5CN + H_2O_2 + KHCO_3$). It has been reported⁶¹

that the change in the predominant direction of the attack in the latter case is due to the larger size of the peroxy-carboimide group compared to the CO_3H group. It should also be noted that the presence of an active proton and a basic imide nitrogen atom in the peroxyimide acid molecule changes significantly the solvation conditions and may be the reason for the change in the optimum spatial orientation of the reactants.

The predominance of the axial attack^{66, 68} in the epoxidation of methylenecycloalkanes is mainly explained by hyperconjugation effects. The axial attack is facilitated by some stabilisation of the transition state attained due to interaction of the $\alpha\text{-C-H}$ bond electrons with electron-deficient sites, similar to what has been observed in the epoxidation of the bicycloalkene **43**.

The axial attack of the oxidant predominates in the epoxidation of methylenenorbornane **70**.^{64, 69}

The introduction of a *syn*-7-methyl group in methylenenorbornane (compound **71**) results in inverted stereoselectivity. The selectivity of epoxidation of methylenenorbornane **70** is lower than that for norbornene (98%) because the double bond is further removed from the methylene bridge.

The increase in the size of the exocyclic group in the series $=\text{CH}_2 < =\text{CHMe} < =\text{CMe}_2$ increases the rate of epoxidation by a large factor.

Meanwhile, the rate of oxidation of the exocyclic double bond depends on the ring size and decreases in the order cyclohexane > cycloheptane > cyclopentane.

Electrophilic addition to alicyclic alkenes is typically accompanied by participation of neighbouring atoms and groups, in particular, by migration of C-C and C-H σ bonds.^{70, 71} From the theoretical viewpoint, it is significant to distinguish the few cases in which the neighbouring nucleophilic groups directly participate in the transfer of active oxygen to the substrate.

The nucleophilic assistance of the *endo*- CONH_2 and *endo*- CH_2OH groups to the epoxidation of norbornene has been considered in a review.² Participation of this type of hydroxy group in the reaction has been noted in other studies.^{1, 70, 71} In particular, 5-hydroxymethylbicyclo[2.2.1]hept-2-ene reacts with perbenzoic acid 30 times faster than its methyl ether and 40 times faster than the corresponding acetate.⁷⁰ Most often, however, the formation and opening of an epoxide ring in cycloalkenes occur as consecutive reactions.

It is noteworthy that epoxy alcohol acetate **72** proved to be unstable on silica gel, its epoxide ring being cleaved, apparently due to participation of the neighbouring acetoxy group.

As noted above, the corresponding alcohol **14** exists in an alkaline solution of methanol in an equilibrium with its isomer. The exceptional instability of *trans*-2,3-epoxycyclohexanol acetate under conditions of epoxidation of cyclohex-2-enol with hexafluoro-2-hydroperoxypropan-2-ol has also been noted.⁷² Epoxycyclohexane containing a *trans*-benzamide group in the α -position behaves in a similar way.⁴

Epoxidation of 1,5-dimethylcyclooct-4-en-1-ol is accompanied by partial transannular cyclisation.⁷³

The hydroxy group at the 5-position of the compound **73** has no influence on the course of epoxidation.⁷⁴ However, cycloheptene derivatives **74** are epoxidised by *m*-chloroperbenzoic acid to give products of the transannular cleavage of the epoxide ring.

R = CH_2OH , COOH .

Epoxidation of the acid **75** of the norbornene series also affords initially the epoxy acid; however, due to the fast isomerisation to hydroxy lactone, the acid has not been isolated. Kinetic data rule out the possibility of participation of the carboxy group in the rate-determining step of transfer of the active oxygen to the alkene,⁶⁹ because the hydroxy group is more nucleophilic than the carboxy group.⁷⁶ In the case of lactone **76**, the cleavage of the epoxide ring during hydrolysis involves the hydroxy group rather than the carboxy group, because the latter is less nucleophilic.⁷⁶

Unlike norbornene, bicyclo[2.2.2]octene derivatives are epoxidised without *exo*-stereospecificity, which is due to the lower strain and the higher conformational mobility of the cage.

endo-Acids and esters of the bicyclo[2.2.2]octene series **77** form *endo*- and *exo*-epoxides together with the lactones derived from the *exo*-isomer.⁷⁶

Oxidation of bicyclic imide **78** is accompanied by intramolecular cyclisation involving the oxygen atom of the carbonyl group,⁷⁷ as has been observed for *endo*-amides of the norbornene series.² In the oxidation of amide **79**, the structure of the intermediate epoxide is favourable for the intramolecular cyclisation involving the nitrogen atom to give an azaadamantane derivative.⁷⁸

Epoxidation of diene **80** occurs chemoselectivity according to the following scheme:⁷⁹

During epoxidation by monoperoxyphthalic acid, tricyclic diene **81** partially isomerises, diepoxides **82a,b** being formed in a ratio of 65 : 35.⁸⁰

Sterically hindered cumulenes, which are converted into cyclopropanes upon a rearrangement of intermediate oxiranes, represent a peculiar system as regards epoxidation by peroxy acids.⁸¹ A probable mechanism for this reaction is shown below:

The formation of the intermediate epoxide **83** was not detected; therefore, the isomeric ketone **84** might also arise upon disproportionation of the alkene-RCO₃H complex in the transition state.

IV. Mechanism of the directing influence of functional groups during epoxidation of alkenes with peroxy acids

The stereodirecting influence of the hydroxy group in 2-, 3- and 4-alkenols on the attack by RCO₃H has been discussed in numerous publications.^{1,2,6,82,83} Possible variants of the transition state geometry have been discussed. Stereochemical features of the epoxidation of cyclohex-2-enols have been considered.²⁹ It was found that the directing influence is exerted by a pseudo-equatorial (compound **85**) rather than axial hydroxy group.²⁹

The relationship between the rate and the route of epoxidation and the structure of cyclohexenols is clearly illustrated by the scheme given below, in which $k_{\text{epox}} \times 10^3$ (perbenzoic acid, benzene, 5 °C) is resolved into components, k_{cis} and k_{trans} , with respect to the hydroxy group.

It is significant that in the epoxidation of C₆–C₉ cycloalkenols with *m*-chloroperbenzoic acid, the direction of the attack by the reagent changes on passing from seven- to eight-membered ring; the yields of *cis*-epoxides from the above cycloalkenols are 95.0%, 61.0%, 0.2% and 0.2%, respectively.⁴¹ When an alkyl hydroperoxide and a vanadium catalyst are used in this reaction, the coordination of the hydroxy group to the metal is so strong that it leads to a change in the conformation and ensures the *cis*-attack in the two latter cases.

It is notable that not only *cis*-cyclooct-2-enol **86** but also its methyl ether are epoxidised by RCO₃H stereospecifically into the *trans*-position. However, the difference in the reaction rates (perbenzoic acid, benzene, 5 °C) implies active assistance from the hydroxy group of the cyclooctenol **86**.²⁹

When cyclooctenol **86** occurs in a pseudo-chair conformation, electrophilic assistance to the peroxy acid comes, as in the case of cyclohexenol **85**, from the pseudo-equatorial OH group; however, in epoxycyclooctanol, unlike epoxycyclohexanol, this group gets into *trans*-position with respect to the oxirane ring. It was suggested that the rear attack by the peroxy acid is hampered by the hydrogen atoms at C(5) and C(8), similarly to the situation observed in the epoxidation of the bicycloalkene **43** and methylenecyclohexane.

The mechanism of interaction of the directing hydroxy group with a peroxy acid is not so unambiguous as that for alkyl hydroperoxides. It is clear that a peroxy acid is capable of forming hydrogen bonds with basic groups, including the hydroxy group. However, it is significant to elucidate not only the nature of these bonds but also the stage at which their role is manifested. On the one hand, a hydroxy group can be involved at the stage when the reactants approach each other and are coordinated; on the other hand, this group can stabilise the leaving RCO₂[−] anion at the stage of decomposition of the alkene-peroxy acid activated complex.

Several schemes have been proposed describing the hydrogen bonds formed between allylic alcohols and peroxy acids, in particular, **87**,^{2,6} **88**⁷³ and **89**.^{2,78}

Evaluation of the relative strengths of the hydrogen bonds and stereoelectronic analysis of the structures **87**–**89** lead to several conclusions. In conformity with the views on the acid–base properties of the reaction participants, the strength of the hydrogen bond must substantially decrease in the sequence **89** > **88** > **87**. Moreover, the formation of a hydrogen bond between an allylic hydroxy group and an RCO_3H molecule in the ground state according to the associate **87** pattern is relatively unlikely, because the p electrons of the $\text{O}(2)$ atom are involved in conjugation and are difficult to displace. In addition, the corresponding n orbitals are arranged at an angle relative to the $\text{O}–\text{H}$ bond of the alcohol. When the associates **88** and **89** are formed, the reaction sites ($\pi_{\text{bonding}} \text{C}–\text{C}$ and $\sigma_{\text{antibonding}}^* \text{O}–\text{O}$) are too far removed from each other for the epoxidation proper to occur. This rules out participation of the hydroxy group directly in the step of transfer of the active oxygen to the alkene.

The problem of efficiency of the directing action of the hydroxy group at the stage when the reactants approach each other was solved based on the data on epoxidation of cyclohexene containing an axial OR group ($\text{R} = \text{Me}, \text{Bz}$) in the allylic position.⁷⁴

It was found that when *m*-chloroperbenzoic acid is used as the oxidant, the hydrogen bond formed between the acid and the OR group, similar to that in **89**, is not sufficiently strong to exert a *syn*-directing influence; steric effects of the OR groups induce predominantly *anti*-epoxidation. Only replacement of *m*-chloroperbenzoic acid by CF_3COOOH , which is the strongest peroxy acid having a relatively high $\text{p}K_a$ value, results in *syn*-epoxidation. This mechanism for the assistance by the OR group is supported by the fact that replacement of the inert solvent (CH_2Cl_2) by a basic solvent (THF) capable of solvating CF_3COOOH changes the stereochemical outcome of epoxidation, which yields predominantly the *anti*-isomer. The hypothesis that the reactants approach each other through the formation of species like **87** and **88** seems even less likely.

Figure 3. Activated complex **90** formed in the oxidation of allylic alcohols by peroxy acids; (*a*, *b*, *c*, *d*) are the Newman projections.

Orbital consideration and quantum-chemical calculations^{2,84} allow the conclusion that the directing influence of a hydroxy group is due to the interaction of the leaving anion of the acid with the hydrogen atom of the hydroxy group during decomposition of the activated complex **90** (Fig. 3).

It can be seen from Fig. 3 that in this case we are dealing not with a classical hydrogen bond, formed as a hydrogen bridge between two proton acceptors, but with interaction of the proton with a delocalised negative charge in a fairly polarised intermediate complex. When constructing Newman projections *a*–*d* for the transition state **90**, we assumed that any of the two p -electron pairs of the active oxygen atom can participate in the formation of the oxirane ring.

Analysis of projections *a*–*d* with allowance for the Curtin–Hammett principle demonstrates that structures *b* and *d* are the most favourable. The actual occurrence of structure *b* is confirmed by a comparison of the epoxidation mechanism with the closely related mechanism of aziridination of cyclohex-2-enol by 3-acetoxyamino-2-ethylquinazoline.⁸⁵ The latter reacts more stereoselectively than peroxy acids. In our opinion, this is due to the more rigorous steric requirements imposed on the transition state. Unlike the peroxide oxygen atom in RCO_3H , nitrogen carries two substituents. This appreciably hampers the electrophilic attack on the alkene and makes it more strictly directed. In addition, the nitrogen atom has only one pair of p electrons. As a result, the optimum orientation of the reactants is attained only in structure **91** (Fig. 4), in which the bulkiest substituents occupy transoid positions and the NH group proton deflects from the plane of the $\text{O}–\text{C}=\text{O}$ fragment.

Figure 4. Activated complex **91** and its Newman projection for aziridination of cyclohex-2-enol with 3-acetoxyamino-2-ethylquinazoline

The transoid species *d*, which is energetically even more favourable, is sterically less strained than structure *b*; its active proton participates in the stabilisation of the leaving RCO_2^- anion through interaction with both p -electron pairs of the $\text{O}(2)$ atom. In structures *b* and *d* (Fig. 3) and **91** (Fig. 4), the allylic hydroxy group and the carboxy group are optimally removed from each other.

The close arrangement of the hydroxy and carboxy groups in the energetically unfavourable eclipsed conformation *a* diminishes or even completely rules out the possibility for assistance of the hydroxy group to the leaving RCO_2^- anion; in the case of planar structure *c*, the allylic hydroxy group is removed too far from the leaving anion.

The *syn*-directing effect is manifested in epoxidation of not only alkenols but also unsaturated carboxylic acids,^{86,87} amides,^{88,89} urethanes, urea derivatives,^{6,90} acetals, sulfones, sulfoxides,⁶ sulfamides⁹¹ and ketones of the aliphatic and aromatic series.⁹² In some cases, concerted or competing action of two groups has been observed.^{6,89,90}

Several variants have been considered for the mechanism of the directing influence of some groups, for example, those involving the formation of structures **92**,⁸⁹ **93**⁹⁰ and **94–96**.⁶

Kocovsky and Stary,⁶ who studied a broad range of unsaturated (allylic and homoallylic) carbamates, amides, urethanes and esters, in particular, cyclohexene (**97**, **98**) and cyclopentene (**99**) derivatives and steroid type compounds **100–105**, including those differing in the position of the double bond, concluded that the stereodirecting influence exerted by the functional groups present in these substrates is due to involvement of the carbonyl oxygen atom, which carries the highest electron density into the hydrogen bond (see structure **95**).

$R^1 = \text{H, Me; } R^2 = \text{Me, CH}_2\text{Ph}$ (**97**); $R^3 = \text{Alk, NH}_2, \text{EtO}$ (**98**).

$R = \text{PhCH}_2\text{NHCO}$ (**100a**, **101**, **102**); $R = \text{Me}_2\text{NCO}$ (**100b**, **103**, **104**).

The lower basicity of the carbonyl oxygen atom in esters compared to that in amides or carbamates accounts for the lower stereoselectivity of their epoxidation; however, *syn*-epoxidation of dimethyl *trans*-1,2-dihydrophthalate occurs to more than 90%.⁹³ The assumption that it is the carbonyl group that participates in the reaction was confirmed by the IR spectroscopy data obtained for *trans*- (**106**) and *cis*-hydroxy amides (**107**) used as model compounds. In the latter case, it was found that no intramolecular hydrogen bond is formed.

The directing influence of the carbonyl oxygen atom in the type **95** transition state, unlike that of the hydroxy group in the transition state **90**, appears most likely at the stage of coordination of the reactants. The two mechanisms acting through the transition states **90** and **95** are based on the formation of a hydrogen bond; however, they differ significantly regarding the stereochemical features and, hence, the general substrate selectivity. Thus allylic alcohol **101** ($R = \text{H}$) is converted into a mixture of *cis*- and *trans*-epoxy alcohols in a ratio of 3 : 1, whereas in the case of the corresponding *N*-benzylcarbamate, *cis*-epoxidation is prevented by the spatial shielding of the β -side, *trans*-epoxide **102** and compound **105**, resulting from intramolecular opening of the epoxide ring, being isolated as the major reaction products.

Carbamates **103** and **104**, like the corresponding alcohols ($R = \text{H}$), are mainly converted into *trans*-epoxides. The mere replacement of the benzyl group in the structure **100** by a phenyl group or the introduction of an additional substituent, for example, a methoxy group, into the carbamate **104** can result in the reversed stereoselectivity.⁹⁴ The *N*-ethylacetamide prevents epoxidation of amide **108**, which is consistent with the data reported in another publication.⁹⁵

However, the acetamide group in the molecule **109** exerts a *syn*-directing influence exceeding that of a hydroxy group.⁶

The competition of the acetamide and hydroxy groups⁷⁸ in amide **110** also results in the predominance of the stereodirecting influence of the former.⁸⁷

The distant acetamide and allylic hydroxy groups in the molecule of acid **111** exert a concerted influence.⁹⁶

The trialkylsilyloxy group in *cis*-cyclohexylcarbamate **112** stipulates the *trans*-attack by a peroxy acid. The reaction product undergoes partial intramolecular cyclisation.⁹⁷

Acyclic allyl *Z*-amides **113** are epoxidised by peroxy acids and *tert*-butyl hydroperoxide in the presence of $\text{Mo}(\text{CO})_6$ with a high *threo*-selectivity (75%–95%).⁸⁷ The corresponding *E*-isomers are less sensitive to this reagent and to the influence of the amide group, the yield of the *threo*-isomer amounting to 60%–78%. The general regularity is violated in the case of amides **114**. The low stereoselectivity of the reaction, in which the *erythro*-isomers slightly predominate in the reaction products, is apparently due to the unfavourable structure of the major conformation, which is fixed by an intramolecular hydrogen bond. In the case of amide **115**, participation of the carbonyl group in the orienting influence is relatively unlikely; nevertheless, the stereoselectivity of epoxidation is fairly high. This is apparently accounted for by the directing influence of the NH group, which has been postulated by Davies and Whitham.⁸⁷ This type of electrophilic assistance to the epoxidising agent is also preferable for the toluenesulfamide group.⁸⁸

R = CCl_3 , Ph, OMe, NHPh.

An α -carboxy group exerts a strong orienting influence on the attack by RCO_3H . Oxidation of both *trans*-1,2-dihydrophthalic acid and dimethyl *trans*-1,2-dihydrophthalate affords only mono- and diepoxides with *cis*-arrangement of the neighbouring epoxy and carboxy groups even in a basic solvent (ethyl acetate),⁸⁶ capable of solvating carboxy groups. It still remains unclear how the carboxy groups affect the course of the process, either similarly to a homoallylic hydroxy group or in accordance with the transition state **95**.

The *syn*-stereoselectivity of epoxidation of *trans*-5-*tert*-butylcyclohex-2-enecarboxylic acid in inert solvents is not very high (54%–79%). Meanwhile, the epoxidation of the corresponding methyl ester affords predominantly the *trans*-isomer irrespective of the solvent used.⁹⁸ Apparently, the *tert*-butyl substituent diminishes the coordination mobility of the ring and hampers the formation of the conformation optimum for the carbonyl group to be involved in the active oxygen transfer.

It has been reported⁹² that the carbonyl group in α,β -unsaturated steroid ketones **116**–**119** and dienone **120** influences the rate and regioselectivity of their epoxidation by MCPBA *via* the formation of a hydrogen bond.

The mere fact that these compounds do undergo epoxidation seems quite unexpected, because the double bond conjugated with a carbonyl group is usually inert to peroxy acids. Moreover, when the dienone **120** is oxidised in a non-polar solvent (benzene), the epoxidation involves the α,β -double bond rather than the remote double bond. In a polar solvent (acetonitrile), the efficiency of participation of the carbonyl group of the ketone **120** in the formation of the hydrogen bond decreases, the yields of the isomeric monoepoxides **121** and **122** becoming comparable. The *S*-*cis*-ketones **116** and **117** react with an oxidant faster and give the oxiranes in higher yields (63% and 51%) than the *S*-*trans*-isomers **118** and **119** (the yields of the corresponding oxiranes are 8% and 27%).

In this connection, it is pertinent to consider the possible epoxidation mechanisms. Stereoelectronic analysis shows that in this reaction, there are no stereochemical prerequisites for the mechanism based on the transition state **95**. The RCO_3H molecule, associated with the carbonyl group through a hydrogen bond, is unable to attack the π electrons of the alkenyl fragment. Therefore, if the classical epoxidation mechanism is realised, the carbonyl group of a cycloenone can render assistance only at the stage when the reactants approach each other, thus increasing the probability of their efficient collision. However, epoxidation of the ketone **116** affords α - and β -oxiranes in comparable amounts, although, by analogy with the epoxidation of the methylenecycloalkane **68** and alkyl-substituted cycloalkenes,^{6,15} one could have expected that the methyl substituent would shield the β -side and promote the formation of the α -isomer.

The geometry of the molecules of the cycloenones **116**, **117** and **120** and the whole set of the available experimental data suggest that the process follows a mechanism including a nucleophilic attack on the antibonding $\pi_{\text{C}=\text{O}}$ orbital and 1,4-addition of RCO_3H .

The structure of the *S*-*trans*-isomers **118** and **119** excludes the possibility of a similar synchronous nucleophilic addition of RCO_3H . In addition, the formation of only α -oxirane (27%) from the ketone **119** is evidence supporting the ordinary epoxidation mechanism, which assumes the electrophilic attack by the peroxy acid on the less shielded side of the double bond.

A fairly unusual effect of the nature of the solvent on the stereochemistry of epoxidation of 2-hydroxycyclopent-4-enylacetolactone has been observed.⁹⁹

The ratio of the *cis* to *trans* isomers in the resulting epoxides changes from 8.1 in acetic acid and 4.0 in hexane to 0.89 in benzene and 0.67 in CCl_4 . Since the carbonyl oxygen atom in the lactone is far removed from the double bond, its association with the peroxy acid molecule cannot influence significantly the epoxidation route. Apparently, solvation of the ester group, which determines the character of shielding of the double bond and the conformational stability of the diastereoisomeric transition states, is the

crucial factor governing the stereochemical outcome of the reaction. The pronounced difference between the reaction outcomes in inert solvents, for example, in hexane and benzene, indicates that the process stereochemistry depends substantially on the structural features of the solvent cage.

A similar type of dependence of the enantioselectivity on the solvent nature is displayed in the epoxidation of a number of cyclohexene derivatives by dimethyldioxirane.⁴ It might be this factor that is responsible for the enantioselectivity of some enzyme-catalysed reactions⁹⁸ and for the difference between the yields of glycols in epoxidation of diallyl dicarboxylates¹³ and phenylcyclohexene⁶² in solvents with close basicities — tetrahydrofuran and diethyl ether.

V. Complementarity of reactants as a factor of stereodirected epoxidation

As shown above, the presence in the alkene of a functional group capable of association with an epoxidising agent (ROOH, RCO₃H) is not always a sufficient condition for an efficient directing influence. Spatial compatibility of the reactants favourable for the reaction is also needed. This is ensured, on the one hand, by an appropriate molecular geometry and the environment of the reaction sites and, on the other hand, by a coplanar arrangement of the vacant and occupied orbitals which overlap during the reaction (stereoelectronic factor).

In cycloalkenes and, especially, in polycycloalkenes, the optimum direction of the attack by the oxidant is provided by the rigidly fixed structure of the carbon framework.^{8, 64}

In alkenes, which are normally characterised by relatively low barriers to the rotation around σ bonds, stereodirected epoxidation can be attained in those cases where the two diastereoisomeric transition states of the reaction have substantially different energies. According to the Curtin–Hammett principle, the reaction proceeds *via* the more favourable transition state. This transition state often arises upon transformation of the most stable conformation with a transoid arrangement of the bulkiest substituents.

The simultaneous influence of bulky groups such as SiR₃ or OSiR₃ and the corresponding functional group results in a single diastereoisomer being formed in an almost quantitative yield.^{42, 100} Only one diastereoisomer is produced, for example, in the epoxidation of amide **123**,¹⁰¹ which contains a bulky sulfonyl group in addition to the directing amide group.

In some cases, the stereoselectivity of the reaction can be ensured without the formation of a hydrogen bond with the peroxy acid but only due to the ordinary spatial shielding of one side of the π bond by bulky groups such as SiR₃ in a fixed conformation of the alkene.⁴² This can account for the *erythro*-selectivity of epoxidation of alkenylphosphonates.¹⁰² The bulky phosphonate group and the peroxy acid occupy transoid positions in the transition state **124** formed in this reaction.

The factors that govern the mutual arrangement of the reactants in space can be judged from a comparison of the stereochemical outcome of epoxidation of alkenes by peroxy acids and by hexafluoro-2-hydroperoxypropan-2-ol **125**.⁷² Whereas cyclohex-2-en-1-ol reacts with *m*-chloroperbenzoic acid to give *cis*- and *trans*-epoxycyclohexanols in 93 : 7 ratio, the reaction

with hydroperoxide **125** yields only the *cis*-isomer. Furthermore, on treatment with the hydroperoxide **125**, cyclohex-2-en-1-ol acetate is converted into the corresponding *cis*-epoxide by 80%, whereas the use of *m*-chloroperbenzoic acid results in a mixture of *cis*- and *trans*-isomers of epoxycyclohexyl acetate in a ratio of 2 : 3. Hexafluoro-2-hydroperoxypropan-2-ol oxidises bicyclic diene **126** to give only one monoepoxide. Other oxidants, namely, peroxy acids, ROOH–Cat and singlet oxygen combined with trimethyl phosphite, react with the diene **126** to give all four isomers of monooxirane.

The specific behaviour of the hydroperoxide **125** can be explained by the fact that its molecule, unlike RCO₃H, is tetrahedral, the hydroperoxide group occupying a vertex of the tetrahedron which has two bulky trifluoromethyl groups at the base (Fig. 5). Shielding of the peroxide site restricts the sphere of the attack on the alkene and imposes stringent steric requirements on the transition state caused by the torsional strain between the substituents in the hydroperoxide and the alkene.

Figure 5. Newman projections of the transition state formed in the oxidation of alkenols with hexafluoro-2-hydroperoxypropan-2-ol (**125**); (a) spiro structure; (b) eclipsed conformation.

Of the two transition state structures *a* and *b* (see Fig. 5), possible due to the presence of two lone electron pairs at the active oxygen atom, spiro structure *a* is preferred, in which the pseudo-axial electron pair in relation to the five-membered chelate ring of the hydroperoxide participates in ring formation.

Epoxidation of the cycloalkene **126** involves the double bond removed further from the benzyloxymethyl substituent. The *syn*-orientation of the oxidant with respect to the substituent ensures the formation of the most favourable transoid conformation of the transition state (Fig. 6*a*). The *anti*-orientation would result in *gauche*-conformation (Fig. 6*b*).

Figure 6. Newman projections of the transition state formed in the oxidation of the diene **126** by hexafluoro-2-hydroperoxypropan-2-ol (**125**); (a) transoid conformation; (b) *gauche* conformation.

Figure 7. Newman projections (*a* and *b*) of the transition state formed in the oxidation of cyclohex-2-enol acetate with hexafluoro-2-hydroperoxypropan-2-ol (**125**).

From this standpoint, it becomes clear why acylated cyclohex-2-enol is converted into the *syn*-epoxide. Evidently, conformation *a* is more stable than conformation *b* (Fig. 7).

Epoxidation of the same alkene by a peroxy acid affords mostly the *anti*-epoxide. When cyclohex-2-enol is epoxidised by hexafluoro-2-hydroperoxypropan-2-ol, the role of complementarity is enhanced by the directing influence of the hydroxy group, thus making this reagent more selective than peroxy acids.

The stereochemistry of the epoxidation of alkenes by α -hydroperoxides **127** and α -hydroperoxy nitriles **128** has been described in reviews.^{1,2}

R¹ = Me, R² = Ph; X = OR³, NR³, Alk.

The hydroxy group in cyclohex-2-enol has a *syn*-directing influence on epoxidation. However, unlike peroxy acids, the hydroperoxide **127** (X = OR) oxidises *trans*-stilbene more easily than *cis*-stilbene and oxidises *trans*- β -methylstyrene more easily than cyclohexene.

Interpretation of the *trans*-selectivity should be sought in a comparison of the electronic and steric features of the transfer of active oxygen from the hydroperoxide **127** to the alkene with those for peroxy acids. The latter are known to be characterised by low energies of the O–O bond and high mobility of the OOH-group proton. The RCO₃H–alkene transition state is extended along the reaction coordinate, and, in conformity with the Bell–Evans–Polanyi principle, its structure is closer to the final products than to the initial compounds. This means that loosening of the peroxide bond in RCO₃H starts at an early stage of insertion of the alkene π orbital into the antibonding $\sigma_{\text{O–O}}^*$ orbital before the O–H bond is cleaved. The proton transfer does not limit the overall rate of the process.^{1,2} In addition, in the case of peroxy acids, there is no torsional strain, involved in the transition state with hexafluoro-2-hydroperoxypropan-2-ol and the hydroperoxides **127**. This accounts for the low sensitivity of the RCO₃H molecule to the alkene structure; the *cis*-alkene is epoxidised slightly more readily than the *trans*-isomer,¹⁴ which can be easily explained by the higher thermodynamic stability of the latter isomer.

Regarding the α -hydroperoxides **127**, it should be noted that they are several orders of magnitude weaker oxidants than peroxy acids.² The peroxide proton in the hydroperoxides **127** is substantially less active than that in RCO₃H. Therefore, the α -hydroperoxide–alkene transition state **129** is compact and the intramolecular proton transfer on the leaving alkoxy anion is necessarily included in the step determining the overall rate of the process (Fig. 8). This, in turn, places certain steric demands on the orientation of the OH group in the hydroperoxide **127**. On the one hand, this group tends to be coplanar with the axial lone electron pair of the neighbouring peroxide oxygen atom and, on the other hand, it tends to escape the eclipsed position with respect to the

Figure 8. Transition state **129** formed in the oxidation of alkenes by the hydroperoxide **127** and its Newman projection: (1) equatorial lone pair of the oxygen atom; (2) axial lone pair of the oxygen atom.

bulky substituents at the alkene double bond. These requirements are satisfied in the case where the coplanar alkene π bond and chelated hydroperoxide molecule approach each other with the R³ substituent of the alkene being removed from the eclipsed position with respect to the OH group (under the π -bond plane) and the R⁴ substituent being located above the plane. This determines the *trans*-selectivity of the reaction.

In the case of *cis*-alkene, the substituents R³ and R⁴ should be directed below the plane of the chelated hydroperoxide; this increases the strain in the transition state due to the interaction of these groups with R². If the transition state had a spiro structure in which the alkene π plane passed through the n_{O} orbital of the active oxygen atom, the shift of the proton into the axial position and its interaction with the leaving alkoxy anion would be hampered. In this connection, it is noteworthy that the transition state formed in the epoxidation of alkenes by hexafluoro-2-hydroperoxypropan-2-ol **125** has a spiro structure (see Fig. 6*a*). In this case, the problem of the proton transfer to the leaving alkoxy anion is eliminated because the process is synchronous.

The complementarity factor, which determines the direction of the attack on the electrophilic site of the alkene, becomes significant when substituted oxaziridines are used as epoxidising agents.^{103–107} Diastereoisomeric 2-sulfonyloxaziridines **130–132** epoxidise alkenes containing no directing functional groups with higher enantioselectivity (*ee* 12%–65%) than chiral peroxy acids and hydroperoxides (*ee* 0%–8%).

Based on kinetic and thermodynamic parameters, correlation analysis of the effects of substituents present in the phenyl groups of oxaziridines, a synchronous mechanism of epoxidation of alkenes including transition state **133** has been proposed. In accordance with this mechanism, the oxaziridine ring and the π bond are coplanar, the process stereochemistry being controlled by the configuration of substituents.^{104–107}

Similar conclusions have been drawn from quantum-chemical calculations.¹⁰⁸ Experimental data cited above^{103–107} can be interpreted in a different way by invoking general theoretical views on the stereoelectronic features of reactions of this type, in particular, epoxidation of alkenes by hydroperoxides^{1,2,5} and dioxiranes.^{4, 109, 110}

The oxidising capacity of oxaziridines is due most of all to the N–O bond, which is similar to the peroxide bond. The nitrogen atom is less electronegative than oxygen but the $E_{\text{N–O}}$ value in the oxaziridines **130–132** decreases owing to the strong electron-

withdrawing influence of the SO_2 group. The difference between the O–N and O–C bond energies results in the loosening and rupture of the O–N bond at the stage of oxygen transfer to the substrate occurring somewhat ahead of the O–C bond cleavage. The asynchronous cleavage of bonds is apparently a general feature of small rings similar to oxaziridine, in particular, dioxirane and dioxetane.

The nucleophilic attack by the alkene π electrons on the oxygen atom of the oxaziridine ring is directed at the antibonding orbital of the O–N bond along its axis (transition state **134**, Fig. 9). In the initial interaction event, transfer of the π -electron density on the oxygen atom loosens the N–O bond and, simultaneously, the axial lone electron pair of oxygen n_a interacts with the π^* orbital of the alkene. As in the case of hydroperoxides, the combination of two types of interaction — donor-acceptor and dative interaction — is a necessary condition for the synchronous formation of the C–O bonds in the oxirane ring.

Figure 9. Transition state **134** formed in the epoxidation of alkenes with oxaziridines and its Newman projection; (1) $\sigma_{\text{N-O}}^*$; (2) equatorial lone pair of the oxygen atom (n_e); (3) $\sigma_{\text{N-O}}^*$; (4) π^* ; (5) $\sigma_{\text{C-O}}^*$; (6) axial lone pair of the oxygen atom (n_a).

The localisation of excess electron density at the nitrogen atom creates conditions for the overlap of the partially occupied $\sigma_{\text{N-O}}^*$ orbital (or the nitrogen n orbital) with the vacant $\sigma_{\text{C-O}}^*$ orbital, which, in turn, induces loosening of the C–O bond.

It is clear that the angle between the attack on the alkene π bond and the plane of the oxaziridine ring is about $180^\circ - 109^\circ = 71^\circ$, the most significant restrictions hampering the approach of the reactants and construction of the transition state being caused by the carbon atom and its substituents rather than by the substituents at the nitrogen atom in the epoxidising agent. Therefore, the epoxidation transition state **134** in which the ring formation involves the *cis*-alkene and the axial lone electron pair of oxygen seems to be the least sterically hindered.

Figure 10. Newman projections (*a–d*) of the transition state of epoxidation of *trans*-alkenes with sulfonyloxaziridines.

The best transition state for the epoxidation of *trans*-alkenes should be chosen out of the four possible structures *a–d* (Fig. 10) (in the Newman projections, the observer looks along the O–N bond from the side of the alkene attack).

Analysis of the stereochemical outcome of epoxidation of *trans*-stilbene with (*R,R*)-(+)-sulfonyloxaziridines **135a–d** shows that the (*R,R*)-(+)-oxirane is formed with *ee* 34.9%. Hence, the reaction occurs mainly *via* transition state *a*. Indeed, transition state *b* is sterically much more strained and transition states *c* and *d* would lead to the (*S,S*)-oxirane.

R = Me (**a**), Buⁿ (**b**), Buⁱ (**c**), Bu^t (**d**).

Our conclusions are also consistent with other experimental data.^{105–108} Thus epoxidation of (*R*)-(+)-limonene by sterically shielded oxaziridine **135a** is 20.7 times slower than that by oxaziridine **136**.¹⁰⁴ This reaction is fairly *cis*-selective (60%–74%), the selectivity increasing with an increase in the size of the group R.

Note for comparison that oxidation of limonene by *m*-chloroperbenzoic acid yields the isomers in 1:1 ratio. It is also noteworthy that the rates of limonene epoxidation by the oxaziridines **135a–c** are related as 1:0.93:0.3, and the compound **135d** barely enters into this reaction.

The replacement of the oxaziridine **136** by its analogue containing a nitro group in the *ortho*-position rather than in the *para*-position decreases the rate of epoxidation of 1-methylcyclohexene by a factor of more than 6.¹⁰⁷

To summarise the foregoing, we can conclude that the reaction in question occurs by an S_{N} -type mechanism assuming the formation of a spiro transition state. The fact that the bonds in the oxaziridine ring are cleaved asynchronously induces some charge separation. The negative charge on the nitrogen atom is highly delocalised due to the electron-withdrawing influence of the SO_2 group. The buffer function of this group markedly decreases the sensitivity of the reaction to the polar influence of the substituent X in the $\text{XC}_6\text{H}_4\text{SO}_2$ group. Hence, the Hammett constants of the reaction (ρ) found upon variation of substituents in the benzene nucleus at the carbon atom and in the sulfamide moiety of the sulfoxaziridine molecule are nearly equal and amount to 1.07 and 1.09, respectively.

Dioxiranes are very close to oxaziridines regarding the character of their reactions with alkenes.^{4, 109, 110} In the case of dimethyldioxirane, the reaction is highly sensitive to steric restrictions caused by the interaction of the methyl groups with the substituents at the double bond. Branched alkenes, *trans*-4,4-dimethylpent-2-ene and *trans*-2,2,5,5-tetramethylhex-3-ene, are epoxidised much more slowly than *trans*-hex-3-ene. In the series of ordinary dialkyl-substituted alkenes, *cis*-isomers are an order of magnitude more reactive than the corresponding *trans*-alkenes.

Based on the kinetic and thermodynamic parameters, it was concluded that the reaction proceeds *via* a bimolecular complex having a spiro structure.¹¹⁰

By analogy with the transition state **134**, it can be assumed that the attack by the alkene is directed at the antibonding $\sigma_{\text{O-O}}^*$ orbital of the dioxirane along the peroxide bond, the π -electron plane passing through the pseudo-axial non-bonding orbital of oxygen as has been shown in the structure **137** (Fig. 11).

Figure 11. Transition state **137** formed in the epoxidation of alkenes with dioxiranes and its Newman projection; (1) n_e of oxygen, (2) σ_{O-N}^* .

The loosening and rupture of the O–O bond in dioxirane at an initial stage of its reaction with the alkene occurs ahead of the C–O bond cleavage, a partial negative charge being created on the leaving oxygen atom. Unlike oxaziridine, dioxirane is unable to delocalise the excess charge and in the transition state **137**, the leaving anion is solvated, which is typical of the S_N -type reactions. It is due to this fact that the allylic hydroxy group has a directing influence on the oxidant during epoxidation of cyclohex-2-enol.⁴ It has also been found that admixtures of water in acetone catalyse the process.¹⁰⁹ The decrease in the effect of water admixtures in the case of epoxidation of low-reactivity alkenes by dioxiranes is, apparently, due, as in the case of epoxidation by peroxy acids,^{1,2} to the ability of the oxidant to undergo self-oxidation to give singlet oxygen in media favourable for the formation of hydrogen bonds. Reactive alkenes normally suppress decomposition of the epoxidising agent thus increasing the rate of formation and the yield of oxiranes. Chiral dioxiranes, prepared from chiral ketones and oxone ($KHSO_5$), epoxidise alkenes with a substantial asymmetric induction (up to 87%).¹¹¹

Correlation analysis and thermodynamic parameters point to a common character of electron density distribution in the transition states formed when dioxiranes, oxaziridines and peroxy acids are used as epoxidising agents.

Epoxidation of di-, tri- and tetrasubstituted alkenes by dimethyl- α -peroxy lactone **138**, the structure of which is similar to that of dimethyldioxirane, is controlled by absolutely different stereochemical factors.

First, attention is attracted by the high *trans*-selectivity of epoxidation by peroxy lactone **138**. *cis*-But-2-ene is virtually not epoxidised; instead, it is converted into cycloaddition product **139**. However, *trans*-but-2-ene is transformed only into the epoxide. As the number of alkyl substituents at the double bond increases, the overall rate of the process increases, indicating that the alkene acts in this reaction as a nucleophile. Simultaneously, the contribution of cycloaddition, which is known to be highly sensitive to steric restrictions, diminishes. In the case of tetraalkyl-substituted alkenes, cycloaddition hardly occurs. Yet another characteristic feature of this process is the relatively high polarity of the intermediate complex. This is indicated by the fact that it can be efficiently neutralised by methanol, acting as a carbocation trap.

The formation of the oxirane ring implies a concerted mechanism for the electron density redistribution in transition state **140**, which, judging from experimental data, is conformationally stable only for *trans*-alkene, as in the epoxidation of α,β -unsaturated carbonyl compounds **4**.¹¹²

(a) Cycloaddition; (b) ene reaction, $R^1 = \text{Me}$.

It turns out that the *cis*-orientation of substituents in the alkene, which is favourable for the reactants to come together, prevents the formation of a planar, conformationally stable transition state **140** with delocalised charges. In this case, zwitter-ionic transition state **141** with sterically non-hindered rotation around the σ -bonds, needed for 1,4-dioxane ring closure, becomes more preferable.

The principle of complementarity of reactants underlies the asymmetric epoxidation of simple, non-functionalised alkenes by oxometal complexes containing Schiff's bases, porphyrins or other oxygen- and nitrogen-containing compounds as ligands.^{112–114} The geometry of the environment of the reaction site determines the predominant orientation of the prochiral alkene at the stage when the reactants approach each other. For example, epoxidation of a number of alkenes with an oxygenated manganese complex gives the corresponding oxiranes in very high optical yields (92%–98%).¹¹² However, detailed consideration of reactions of this type is beyond the scope of our review.

VI. Conclusion

Conformational analysis of the diastereoisomeric transition states (TS) with allowance for the stereochemical conditions for the closure to give an oxirane ring is an efficient method for substantiation and prediction of the route and the stereochemical outcome of epoxidation of alkenes with various peroxide reagents. The integral stereocontrolling factor in these reactions is the conformational stability of the TS, which is determined, in its turn, by the spatial compatibility (complementarity) of the reactants, torsional strain, influence of the neighbouring functional groups, hyperconjugation and other effects.

The directing influence of allylic and homoallylic hydroxy groups in the case of alkyl hydroperoxides, which require metal complex catalysis, is attained at the stage of construction of a multiligand complex and the formation of a donor-acceptor bond between the OH group and the central atom. When epoxidation is carried out by an epoxy acid, the role of these groups is to stabilise the carboxylate anion, which is eliminated at the stage of decomposition of the transition state, whereas carbonyl groups in alkenyl-containing amides, esters, carbamates and urethanes exert a similar stereoeffect due to the formation of a hydrogen bond with RCO_3H at the stage of coming together and coordination of the reactants.

Epoxidation of α,β -unsaturated *S-cis*-ketones of the steroid type occurs apparently by a non-classical mechanism assuming 1,4-addition of the peroxy acid.

The stereochemistry of the non-catalysed epoxidation involving active alkyl hydroperoxides is largely determined by the formation of more compact transition states than those in the case of peroxy acids and by the substituents attached to the sp^3 hybridised carbon atom of the C–OOH group.

Some general regularities of the formation of planar transition states and spiro structures were established. The spiro type TS, which are less sterically strained, are formed in the epoxidation of alkenes with RCO_3H and $(\text{CF}_3)_2\text{C}(\text{OH})\text{OOH}$. Under these conditions, the stage of transfer of the active oxygen to the substrate does not depend on the rate of proton transfer. Meanwhile, the epoxidation of alkenes with α -hydroperoxy-derivatives of esters is controlled by the transfer of the OOH group proton on the axial pair of p electrons of the neighbouring oxygen atom. The orientation of molecular orbitals participating in this process induces the formation of a planar transition state and requires a transoid configuration of the alkene molecule.

trans-Selectivity is also typical of other epoxidation reactions involving the formation of planar TS, in particular, those using dimethyl- α -peroxy lactone as the epoxidising reagent and in the alkaline alkyl-peroxide oxidation of α,β -unsaturated esters. In the latter case, the reaction occurs stereoselectively because of the two possible conformations of the cyclic transition state, the more stable conformation with an equatorial orientation of the bulkiest substituent in the alkene molecule is formed preferentially.

cis-Selectivity is an indication of a spiro configuration of the compact transition states formed in epoxidation of alkenes with oxaziridines and dimethyldioxirane. The process stereochemistry is controlled by the substituents at the carbon atom in these heterocycles; in the case of oxaziridines, this ensures a fairly high enantioselectivity.

The overall effect of various types of strain in cycloalkenes and methylenecycloalkanes stipulates the predominance of the epoxidation pathway that relieves the strain in cycloalkene and results in the formation of the transition state and the oxirane with the least conformation distortion.

VIII. Conclusion	213

Abstract. The review surveys the data on the synthesis, tautomerism, electronic structures and chemical transformations of 4-polyfluoroalkyl- and 4-pentafluorophenyl-2,4-dioxo acids and their derivatives. The reactions yielding fluorinated heterocyclic compounds and their further conversions are considered. The bibliography includes 86 references.

I. Introduction

Fluorine-containing α -oxo esters,¹⁵ α -diketones,¹ β -oxo esters^{4–6} and β -diketones^{7–9} are used in studies of tautomerism, carbonotropy, stereoisomerism and reactivity of dicarbonyl compounds (DCC). Fluorinated DCC often serve as building blocks for the preparation of various heterocyclic compounds.^{1, 6, 7, 10} Particularly impressive progress has been achieved in the design of drugs of the fluoroquinolone series with unique antibacterial activity, which are analogues of nalidixic acid.^{11–16} These antibiotics contain a fluorobenzoylacetic acid structural fragment; for a number of these compounds, fluorinated β -DCC serve as starting compounds.^{11–16}

The use of fluorinated DCC is not confined to their application as biologically active compounds. Certain fluorine-containing DCC and their derivatives can be used as catalysts of various reactions, surfactants, shift reagents, analytical reagents, including those used for the determination and separation of a number of metals by gas chromatography, extractive agents for various metals, dyes and oil and composite additives.^{1, 6, 7, 17} Therefore, further progress in the chemistry and practical application of fluorinated dicarbonyl compounds seems to be very promising.

Polyfluorinated 2,4-dioxo acids and their derivatives containing simultaneously α - and β -dicarbonyl fragments are convenient starting compounds for the preparation of fluorinated heterocycles. Therefore, the development of procedures for the synthesis

of these compounds and investigation of their reactivity are topical problems. Although the chemistry of nonfluorinated 2,4-dioxo acids has been well studied (see, for example, Refs 18–21), this class of fluorine-containing compounds was not known until our first publications.^{22–25}

II. Synthesis and structures of esters of polyfluorinated 2,4-dioxo acids

Nonfluorinated 2,4-dioxo acids and their esters had been first prepared at the end of the 19th century. Esters of 4-polyfluoroalkyl- (**1a–d**)²² and 4-pentafluorophenyl-2,4-dioxo acids (**1e,f**)^{23–25} were first synthesised by the Claisen condensation starting from fluoroalkyl- and pentafluorophenyl ketones, respectively, and dialkyl oxalates. Lithium hydride was used as a condensing reagent. The target compounds were isolated *via* copper chelates **2a–f** (Scheme 1).

Copper chelates of esters **2a–d** are quite stable compounds.²² However, chelates of pentafluorobenzoylpyruvates **2e,f** undergo cyclisation in DMSO or DMF to 2-alkoxycarbonyl-5,6,7,8-tetrafluorochromones **3a,b**.^{23–25} Chromones **3a,b** are also formed upon heating of pentafluorobenzoylpyruvates **1e,f** above 25 °C.^{23–25} Cyclisation occurs through intramolecular replacement of the *ortho*-fluorine atom of the pentafluorophenyl group.

In the design of syntheses on the basis of polyfluoroacyl(pentafluorobenzoyl)pyruvates, it is necessary to have an idea of keto–enol tautomerism, charge distribution on atoms and frontier-orbital electron density in these compounds.

As for enolisation, the tautomerism of nonfluorinated analogues of dioxo esters **1** has been reported in a series of publications. Thus ¹H NMR spectral studies demonstrated²⁸ that aroylpyruvates exist mainly as enols. It was also concluded²⁸ that the intramolecular hydrogen bond in the β -dicarbonyl fragment of the molecule is strengthened as the electron-accepting ability of substituents increases. On the basis of the ¹H and ¹³C NMR spectral data, it was concluded that there was no tautomerism between two possible enol forms.^{28, 29} The proton is delocalised between two potential wells due to tunnelling. This agrees with the results of quantum-chemical SCF MO LCAO calculations by the CNDO/2 method.³⁰ In going from one substituent to another, ¹³C chemical shifts are changed due to

[†] Dedicated to the memory of our teacher Academician I Ya Postovskii on the occasion of his 100th birthday.

the electron density redistribution in the dicarbonyl fragment.³¹ It was attempted to determine the position of the proton in a series of β-DCC (including the acetylpyruvate molecule) by comparing the ¹³C chemical shifts for β-DCC and their BF₂ chelates.^{32,33} Presumably,^{32,33} insignificant changes in the chemical shifts on going from β-DCC to their BF₂ chelates indicate that the structures are nearly quasi-symmetrical and that the proton is delocalised between the two oxygen atoms to approximately the same extent.

It was established by X-ray diffraction analysis that ethyl acetylpyruvate is enolised at the C(2) atom.³⁴ A comparative analysis of the ¹³C NMR spectra of ethyl acetylpyruvate and ethyl trifluoroacetylpyruvate (**1b**) demonstrated that compound **1b** is also enolised at the C(2) atom.³⁵ It was found that polyfluoroacyl(pentafluorobenzoyl)pyruvates **1** are completely enolised.^{22,23}

It is remarkable that, unlike fluoroacyl(aroyl)pyruvates under consideration, fluorinated β-diketones and β-oxo esters are only partially enolised.^{6,7} The degree of enolisation reaches 100% only in fluorine-rich β-DCC. In this case, enolisation occurs at the carbonyl group bound to the fluorinated substituent.^{6,7}

With the aim of discussing the reactivity of fluoroacyl(aroyl)pyruvates **1**, quantum-chemical SCF MO LCAO calculations of charges and Fukui indices were performed for (fluoro)acylpyruvates³⁵ by the CNDO/2 method and for pentafluorobenzoylpyruvic acid and methyl pentafluorobenzoylpyruvate[†] by the AM-1 method³⁷ using the MNDO-89 program.³⁶ The calculations demonstrated that the largest positive charge in fluoroacyl(aroyl)pyruvates is localised on the C(1) atom. The Fukui indices for the lowest unoccupied molecular orbitals (LUMO) in fluoroacylpyruvates and methyl pentafluorobenzoylpyruvate have the maximum values for the C(2) and C(4) atoms, respectively. In pentafluorobenzoylpyruvic acid, the values of the Fukui indices for LUMO of the C(2) and C(4) atoms have close values. Therefore, under kinetically controlled conditions the attack of a nucleophilic reagent occurs preferentially on the C(1) atom according to the charge control. According to the orbital control, the reactions of fluoroacylpyruvates should occur at the C(2) atom, while the reactions of methyl pentafluorobenzoylpyruvate should occur at the C(4) atom. In the case of pentafluorobenzoylpyruvic acid, the orbital-controlled process is approximately equally probable for the C(2) and C(4) reaction centres (Table 1).

III. Transesterification reactions

Esters are prone to transesterification. This property substantially enhances the synthetic potential of fluoroacyl(aroyl)pyruvates when using them as the starting compounds for constructing various heterocyclic systems.

Copper chelates of ethyl(methyl) acylpyruvates **2a,c** can be readily transesterified with a higher alcohol (borneol) even in the absence of catalysts.³⁸

R¹ = CF₃, R³ = Born (**2g**, **1k**), where Born = 
R¹ = C₄F₉, R³ = Born (**2h**, **1l**).

Boiling the copper chelate of ethyl pentafluorobenzoylpyruvate **2e** in methanol also results in transesterification to form the chelate of methyl pentafluorobenzoylpyruvate **2f**.³⁹ Thereafter methyl pentafluorobenzoylpyruvate (**1f**) can be readily prepared from the copper chelate **2f**.

It should be noted that this reaction is common to copper chelates of β-oxo esters because the chelates of esters of both aceto- and trifluoroacetoacetic acids enter into this reaction.³⁸ However, the time required to achieve high degrees of conversion of the latter compounds is an order of magnitude larger than in the

case of copper chelates of acylpyruvates **2a,c**. Apparently, this is associated with the involvement of the ester group of β -oxo ester in intrachelate conjugation. Free ligands can also undergo transesterification; however, the selectivity of the reaction decreases sharply and substantial resinification of the reaction mixture occurs. Apparently, copper(II) ions favour the reaction by orienting an alcohol molecule through coordination and suppress side processes.

IV. Reactions with amines

The reaction of methyl acetopyruvate with ammonia affords an enamine at the carbonyl C(2) atom.⁴⁰ The reaction of methyl trifluoroacetopyruvate (**1a**) with ammonia yields [methyl (trifluoroacetopyruvato)]ammonium (**4**), which remains unchanged on boiling in toluene.^{41, 42} However, compound **1a** reacts with a softer base (aniline) at the C(2) centre to form an enamine, *viz.*, methyl 2-anilino-5,5,5-trifluoro-4-oxopent-2-enoate (**5**),^{41, 42} according to orbital control over the reaction.

Treatment of pentafluorobenzoylpyruvate **1a** with gaseous or aqueous ammonia affords chromone **3a**. Apparently, the corresponding ammonium salt is initially formed, which is followed by intramolecular substitution of the aromatic *ortho*-fluorine atom.^{42, 43}

The reaction of pentafluorobenzoylpyruvate **1e** with cyclohexylamine proceeds analogously. However, in this case cyclisation is accompanied by the orbital-controlled replacement of the fluorine atom at position 7 of chromone to form 7-cyclohexylamino-2-ethoxycarbonyl-5,6,8-trifluorochromone (**6**).^{42, 43}

Thus, in the reactions of compound **1e** with ammonia or cyclohexylamine, intramolecular cyclisation dominates over addition of the nucleophile at the C(2) centre regardless of the solvent.

Pentafluorobenzoylpyruvic acid (**1j**) prepared by hydrolysis of ester **1e** reacts with anhydrous ammonia in dioxane or with tertiary amines (triethylamine) to form 2-carboxy-5,6,7,8-tetrafluorochromone (**3c**).^{41, 42} The reaction of acid **1j** with ammonium hydroxide affords 2-amino-3-(3,4,5,6-tetrafluoro-2-hydroxybenzoyl)acrylic acid (**7**), which exists as a zwitterion.^{41, 42} When heated in an acidic medium, the amino acid **7** is hydrolysed to the acid **1j** or undergoes cyclisation to form the chromone **3c**.

When treated with aqueous ammonia followed by acidification, the latter, in turn, gives the amino acid **7**.^{41, 42} Consequently, in these cases intramolecular cyclisation also prevails.

The reactions of the acid **1j** with primary amines (aniline, isopropylamine or cyclohexylamine) yield addition-elimination products at the C(2) centre, *viz.*, 2-alkylamino(anilino)-2-pentafluorobenzoylacrylic acids **8a-c**, which indicates that this reaction is an orbital-controlled process. In an alkaline medium, compounds **8a,b** undergo cyclisation and nucleophilic replacement of the fluorine atom at the C(7) atom by the hydroxy group, which is typical of these fluorine-containing systems, to form 5,6,8-trifluoro-7-hydroxy-1-R-4-quinolone-2-carboxylic acids **9a,b**.^{41, 42} The fact that it was the fluorine atom at position 7 of quinolone that has been replaced was established by X-ray diffraction analysis of a complex of compound **9a** with DMSO.^{44, 45} Cyclisation of compound **8a** in the presence of morpholine affords 1-cyclohexyl-5,6,8-trifluoro-7-morpholino-4-quinolone-2-carboxylic acid (**10**).^{41, 42}

$\text{R} = \text{cyclo-C}_6\text{H}_{11}$ (**8a**, **9a**), Pr^i (**8b**, **9b**), Ph (**8c**).

V. Reactions with dinucleophiles

Various heterocyclic systems can be constructed by reactions of 2,4-dioxo esters with bifunctional nucleophiles. The reactions of acyl(aroyl)pyruvates can involve both the α -dicarbonyl and β -dicarbonyl fragments depending on the nature of the nucleophile.

1. Reactions with hydrazines and hydroxylamine

The reactions of acetyl(aryl)pyruvates with hydrazines give 3-alkoxycarbonyl-5-methyl(aryl)pyrazoles.^{26, 27, 46–48} The reactions of ethyl acetylpyruvates with hydroxylamine yield 3-ethoxycarbonyl-5-methylisoxazole, isomeric 5-ethoxycarbonyl-3-methylisoxazole or a mixture of isoxazoles depending on conditions.^{26, 49} Ethyl benzoylpyruvate reacts with hydroxylamine to afford 3-ethoxycarbonyl-5-phenylisoxazole, the reaction proceeds *via* intermediate α -oxime.^{27, 50}

Ethyl(methyl) fluoroacetylpyruvates **1a,c,d** react with hydrazine hydrate and phenylhydrazine at the β -dicarbonyl fragment like hydrocarbon analogues and fluorine-containing β -oxo esters⁶ and β -diketones.⁷ However, unlike the latter compounds, the reactions with **1a,c,d** give stable 3-alkoxycarbonyl-5-fluoroalkyl-5-hydroxy- Δ^2 -pyrazolines **11a–d** (Scheme 2). The position of the hydroxy group in the pyrazoline ring was established by ¹³C NMR spectral study of compound **11b**.³⁵

11: R¹ = CF₃, R² = Me; R³ = H (**a**), Ph (**b**);
R¹ = C₄F₉, R² = Et, R³ = H (**c**); R¹ = HCF₂, R² = Et, R³ = H (**d**).

Unlike methyl(ethyl) fluoroacetylpyruvates **1a,c,d**, the reactions of bornyl esters **1k,l** with hydrazine hydrate give 3-bornyloxycarbonyl-5-fluoroalkylpyrazoles **12a,b**.³⁸

12: R¹ = CF₃ (**a**), C₄F₉ (**b**).

The reactions of chelates **2b,c** with hydrazine and phenylhydrazine hydrochlorides in water or methanol afford pyrazoles **13a–c** rather than hydroxypyrazolines (Scheme 3).⁵¹

R¹ = C₄F₉, R² = H (**2c**, **13a**); R¹ = CF₃, R² = H (**2b**, **13b**), Ph (**13c**).

The reactions of copper chelates of trifluoroacetylacetone and ethyl trifluoroacetylacetate with hydrazine hydrochloride in DMF, which were studied for comparison, yielded 3-methyl-5-trifluoromethylpyrazole and 5-hydroxy-3-trifluoromethylpyrazole, respectively.⁵²

Pentafluorobenzoylpyruvate **1e** and its copper chelate **2e** react with hydrazine hydrate to give 3-ethoxycarbonyl-5-pentafluorophenylpyrazole **13d**, which can be readily hydrolysed in an acidic medium to 5(3)-pentafluorophenylpyrazole-5(3)-carboxylic acid (**14**).⁵¹

Pentafluorobenzoylpyruvate **1e** reacts with phenylhydrazine and copper chelate **2e** reacts with phenylhydrazine hydrochloride to form pyrazole **13e**.⁵³ The reactions of hydroxylamine hydrochloride with compounds **1e** and **2e** afford 5-pentafluorophenylisoxazole-3-carboxylic acid (**15**).⁵³

The formation of pyrazole and isoxazole derivatives in the reactions with hydrazines and hydroxylamine is typical also of both pentafluorobenzoylacetate ester⁵⁴ and derivatives of non-fluorinated aroylpyruvic acids.⁵⁵

2. Reactions of 2,4-dioxo esters with aliphatic and aromatic 1,2-dinucleophiles

Acyl(aryl)pyruvates react with 1,2-dinucleophiles at the α -oxo ester fragment. The reactions with ethylenediamine, *o*-phenylenediamine or *o*-aminophenol as dinucleophiles give piperazinone derivatives,⁵⁶ substituted quinoxalinones^{57–63} or benzoxazinones, respectively.^{63–65}

The reactions of polyfluoroacetylpyruvates **1b–d** with ethylenediamine and *o*-phenylenediamine give 3-(2-oxofluoroalkylidene)piperazin-2-ones **16a–c** and 3-(2-oxofluoroalkylidene)-1,2,3,4-tetrahydroquinoxalin-2-ones **17a–c**, respectively.³⁵ Copper chelates **2b–d** react with *o*-phenylenediamine hydrochloride in a similar fashion.⁵¹

16: R = CF₃ (**a**), C₄F₉ (**b**), HCF₂ (**c**), C₆F₅ (**d**).

17: R = CF₃ (**a**), C₄F₉ (**b**), HCF₂ (**c**), C₆F₅ (**d**).

Under mild conditions, pentafluorobenzoylpyruvate **1e** reacts with ethylenediamine to form piperazinone **16d**. However, heating of the reaction mixture affords piperazinone **16e** containing the tetrafluoro-2-hydroxyphenyl substituent.⁵³ The mechanism of formation of the latter is discussed below. The reactions of compound **1e** and its copper chelate **2e** with *o*-phenylenediamine or its hydrochloride yield quinoxalone **17d**.^{51, 53}

The reaction of pentafluorobenzoylpyruvic acid (**1j**) with ethanolamine yields 3-pentafluorobenzoylmethylidenemorpholin-2-one (**18**).^{41,42} When refluxed in DMSO, the morpholinone **18** undergoes cyclisation to form 7,8,9,10-tetrafluoro-4-oxo-1,2,4,6-tetrahydro[1,4]oxazino[4,3-*a*]-4-quinolone (**19**). Treatment of compound **19** with an aqueous KOH solution affords potassium 5,6,7,8-tetrafluoro-1-(2-hydroxyethyl)-4-quinolone-2-carboxylate (**20**).^{41,42} This procedure is one of a few methods for the synthesis of fluorine-containing 2-carboxyquinolones.

Pentafluorobenzoylpyruvate **1e** and its chelate **2e** react with *o*-aminophenol and its hydrochloride under mild conditions to form 3-pentafluorobenzoylmethylidene-2*H*-1,4-benzoxazin-2-one (**21a**). Under more severe conditions, this reaction, like the reaction of compound **1e** with ethylenediamine,⁵³ yields 3-(3,4,5,6-tetrafluoro-2-hydroxybenzoylmethylidene)-2*H*-benzoxazin-2-one (**21b**) containing the tetrafluoro-2-hydroxyphenyl substituent as a minor product in addition to compound **21a**.^{53,66} Apparently, the product **21b** is formed either from 2-ethoxycarbonyl- (**3a**) or from 2-carboxy-5,6,7,8-tetrafluorochromone (**3c**), which are generated under the reaction conditions. This suggestion was confirmed by the synthesis of compound **21b** directly from the chromones **3a** or **3c**.^{53,66}

R = Me, Et, Prⁱ.

The reactions of pentafluorobenzoylpyruvate **1f** and its copper chelate **2f** with *o*-aminobenzenethiol were studied. It was demonstrated that the chelate **2f** reacted with 2-aminobenzene-thiol hydrochloride at the α -oxo-ester fragment to form 3-pentafluorobenzoylmethylidene-2*H*-1,4-benzothiazin-2-one (**22**). In the reaction with *o*-aminobenzenethiol under mild conditions, the ester **1f**, unlike the chelate **2f**, undergoes acid scission accompanied by nucleophilic replacement of the fluorine atom in the pentafluorobenzoyl fragment of the molecule by the 2-aminophenylthio group to form 2-[4-(2-aminophenylthio)-2,3,5,6-tetrafluorophenyl]benzothiazole (**23**).³⁹

Thus, polyfluoroacylpyruvates react with hydrazines at the β -dicarbonyl fragment, while their reactions with ethylenediamine and *o*-phenylenediamine proceed at the α -oxo-ester fragment. Apparently, the first stage of the reactions with HN-dinucleophiles, as in the case of aniline, involves the attack of one amino group on the electrophilic C(2) centre according to the orbital control over the reaction. Subsequent attack of the second amino group can occur on two centres, *viz.*, either on the electrophilic C(1) centre or on the C(4) atom. Apparently, the nucleophilic attack on the C(4) centre to form five-membered rings in the case of hydrazines and on the C(1) centre to form six-membered rings in the case of ethylenediamine and *o*-phenylenediamine is governed by thermodynamic factors.

In the reactions of pentafluorobenzoylpyruvate **1e** with amines, intramolecular cyclisation to 2-ethoxycarbonylchromone **3a** is the dominant reaction route. Reactions at the β -dicarbonyl fragment are typical of the reactions of pentafluorobenzoylpyruvates with hydrazines and hydroxylamine, while reactions at the α -oxo-ester fragment are characteristic of the reactions with ethylenediamine, *o*-phenylenediamine and *o*-aminophenol. It is believed that the main regularities manifested in these reactions are similar to those observed in the case of polyfluoroacylpyruvates.

The use of copper chelates of β -di- and tricarbonyl compounds instead of free ligands in the reactions with nucleophiles does not necessarily lead to the formation of identical products. Thus the reactions of copper acylpyruvates **2b,c** with hydrazines afford pyrazoles **13a–c** rather than hydroxypyrazolines **11** (see Schemes 2 and 3). Apparently, this is due to the template role of the copper cation. In some instances, for example, in the reactions of β -DCC chelates with hydrazine hydrochlorides as well as in the reactions of copper acylpyruvates with hydroxylamine hydrochlorides and *o*-phenylenediamine hydrochlorides, identical products were obtained in comparable yields.

In addition, the use of the copper chelate of pentafluorobenzoylpyruvate **2f** allows one to obtain substituted benzothiazinone **22** by the reaction with *o*-aminobenzenethiol, while pentafluorobenzoylpyruvate **1f** as such undergoes acid scission under the reaction conditions.

VI. Preparation and reactions of 3-substituted polyfluorinated 2,4-dioxo acids

Preparation of fluorine-containing 3-substituted chromones and quinolones by cyclisation of aroylpyruvates requires that an alkoxymethylene group be introduced at the C(3) atom of the initial pyruvates.

Ethyl pentafluorobenzoylpyruvate (**1e**), like other β -DCC,^{11, 12, 23, 24, 67} readily reacts with ethyl orthoformate to form ethyl 3-ethoxymethylidene-2,4-dioxo-4-pentafluorophenylbutyrate (**24**). The reactions of compound **24** with amines followed by cyclisation of the resulting ethyl 3-

alkylaminomethylidene-2,4-dioxo-4-pentafluorophenylbutyrate (**25**) afford 3-ethoxalyl-1-*R*-5,6,7,8-tetrafluoro-4-quinolones (**26**). 2-(1-*R*-5,6,7,8-Tetrafluoro-4-oxo-1,4-dihydroquinolin-3-yl)glyoxylic acids (**27**) were prepared by hydrolysis of the esters **26**.⁶⁸

$R = H, Me, Et, cyclo-C_3H_5, C_6H_{13}, C_2H_4OH, o-MeC_6H_4$.

The active methylene group in compounds containing a β -dicarbonyl fragment is the reaction site for azocoupling with aryldiazonium salts to form the corresponding arylhydrazones.⁶⁹ Until recently, the data on the participation of fluorine-containing β -DCC in azocoupling have been limited to only a few examples of the reactions of fluorinated β -diketones,^{70, 71} trifluoroacetates⁷⁰ and pentafluorobenzoylaceticates.⁷² Recently, the synthesis of fluorinated 2-arylhydrazono-1,3-dicarbonyl compounds was reported and their reactivity with respect to N,O-dinucleophilicities was studied.⁷³ Data on the possibility of the synthesis of arylhydrazones using fluorine-containing acyl(aryl)pyruvates are lacking in the literature although nonfluorinated analogues of acyl(aryl)pyruvate arylhydrazones were reported.⁷⁴

3-Arylhyaones of 5,5,5-trifluoro-2,3,4-trioxopentanoates and 4-pentafluorophenyl-2,3,4-trioxobutyrate **28a–f** were first prepared by the reactions of trifluoroacetyl(pentafluorobenzoyl)pyruvates **1b,e** and their copper chelates **2b,e** with aryldiazonium chlorides in an aqueous medium.⁷⁵

28: $R^1 = CF_3$; $R^2 = H$ (**a**), Me (**b**), OMe (**c**);
 $R^1 = C_6F_5$; $R^2 = H$ (**d**), Me (**e**), OMe (**f**).

Arylhyaones **28a,d** were subjected to heterocyclisation with hydrazines and *o*-phenylenediamine. Compound **28a** reacts with hydrazine hydrate and phenylhydrazine to give 1-*R*³-5-ethoxycarbonyl-4-phenylazo-3-trifluoromethyl- Δ^2 -pyrazolines **29a,b**, unlike pentafluorobenzoyl-substituted arylhydrazone **28d**, which reacts with hydrazine hydrate to form a mixture of products which are difficult to separate. 3-(2-*R*-Ethyl-2-oxo-1-phenylhydrazono)-1,2-dihydroquinoxalin-2-ones **30a,b** were synthesised from arylhydrazones **28a,d** and *o*-phenylenediamine by boiling in diethyl ether (Scheme 4).⁷⁵

Thus, arylhydrazones of fluoroacyl(aryl)pyruvates, like their nonsubstituted analogues, react with hydrazines and *o*-phenylenediamine at the β -dicarbonyl and α -oxo-ester fragments, respectively.

The presence of a pentafluorobenzoyl substituent in arylhydrazones **28d–f** makes it possible to use them for constructing heterocyclic compounds of the cinnolone series. Thus when heated in DMSO in the presence of K_2CO_3 or refluxed in chloroform with a twofold excess of triethylamine, arylhydrazones **28d–f** give 3-ethoxalyl-5,6,7,8-tetrafluoro-1-(4-*R*²-phenyl)-1,4-dihydrocinnolin-4-ones **31a–c**.⁷⁵

Cyclisation of quinoxalinone **30b** upon heating affords 5,6,7,8-tetrafluoro-3-(2-oxo-1,2-dihydroquinoxalin-3-yl)-1-phenyl-1,4-dihydrocinnolin-4-one (**32**). Compound **32** is also formed in the reaction of cinnolinone **31a** with *o*-phenylenediamine.

Nucleophilic replacement of the fluorine atom at position 7 in the reactions with various alkylamines is typical of fluorine-containing cinnolinones, fluorochromones and quinolones.¹² For example, the reaction of cinnolinone **32** with an excess of

29: $R^3 = H$ (**a**), Ph (**b**); **30**: $R^1 = CF_3$ (**a**), C_6F_5 (**b**); **31**: $R^2 = H$ (**a**), Me (**b**), OMe (**c**).

Scheme 4

morpholine in DMSO yields a product of replacement of the fluorine atom, *viz.*, 5,6,8-trifluoro-7-morpholino-3-(2-oxo-1,2-dihydroquinoxalin-3-yl)-1-phenyl-1,4-dihydrocinnolin-4-one (**33**).⁷⁵

From the aforesaid it may be concluded that modification of fluoroacyl(aroyl)pyruvates by introducing alkoxyethylidene and arylhydrazone fragments at position 3 qualitatively changes and substantially extends synthetic possibilities of the compounds under consideration.

VII. Reactions of 2-ethoxycarbonyl(carboxy)-5,6,7,8-tetrafluorochromone

A characteristic feature of pentafluorobenzoylpyruvate **1e** and its chelate **2e** (see Scheme 1) is their conversion into 2-ethoxycarbonylchromone **3a** due to their ability to undergo intramolecular cyclisation to form a six-membered ring.^{23,24} Under analogous conditions, ethyl pentafluorobenzoylacetate (**34**) undergoes self-condensation. The latter reaction is accompanied by the Dieckmann condensation and intramolecular cyclisation of an intermediate product to yield 1-oxo-3-pentafluorophenyl-1*H*-pyrano[4,3-*b*]-6,7,8,9-tetrafluorochromone (**35**).⁷⁶ 2-Pentafluorobenzoylmethyl-5,6,7,8-tetrafluorochromone (**36**) was prepared by acid hydrolysis of compound **35**. It should be mentioned that self-condensation is typical of both fluorinated⁷⁷ and nonfluorinated β -oxo esters.⁷⁸ However, in the case of pentafluorobenzoylpyruvate **1e**, intramolecular cyclisation dominates.

It should also be noted that ethyl 2-ethoxymethylidenepentafluorobenzoylacetate (**37**), like the ester **1e**, undergoes cyclisation to form 3-ethoxycarbonyl-5,6,7,8-tetrafluorochromone (**38**).^{23,24}

Chromones **3a** and **38** are readily hydrolysed to the corresponding acids **3c** and **39**, which undergo decarboxylation upon heating to form 5,6,7,8-tetrafluorochromone (**40**).^{23,24}

The reactivity of fluorochromones was discussed⁷⁹ with recourse to quantum-chemical AM-1³⁷ calculations of the charges and Fukui indices for tetrafluoro-2-methoxycarbonylchromone, 2-carboxytetrafluorochromone and its anion and their nonfluorinated analogues using the MNDO-90 method³⁶ (Table 2).

The calculated data make it possible to reveal the following regularities. The introduction of fluorine atoms into the aromatic ring of chromone has virtually no effect on the charge distribution in the pyrone ring. The maximum positive charges in the pyrone and fluorine-containing aromatic rings are localised on the C(9) and C(5) atoms, respectively.⁷⁹

In the pyrone rings, the maximum values of the Fukui indices for LUMO correspond to the C(2) atom in the fluorine-substituted ester and acid and to the C(4) atom in the anion. In the fluorine-containing aromatic rings of the ester, acid and anion, the maximum values of the Fukui index correspond to the C(7) atom.⁷⁹

Thus, according to the charge control, the kinetically controlled reactions of chromones with nucleophilic reagents should occur predominantly at the C(9) atom of the ester fragment, carboxyl group and the anion of the acid. According to orbital control, the reactions of the ester and acid should occur at the C(2) atom of the pyrone ring, while the reactions of the anion should occur at the C(4) atom. The orbital-controlled nucleophilic replacement of the fluorine atom should occur predominantly at the C(7) atom.⁷⁹

2-Ethoxycarbonyl- **3a** and 2-carboxychromones **3c** possess different reactivity with respect to ammonia and primary amines.⁴³ Thus 2-ethoxycarbonylchromone **3a** does not react with ammonia or aniline. Methylamine reacts with the ester group and the C(7) atom of the fluorinated ring of compound **3a** to form *N*-methyl-5,6,8-trifluoro-7-methylaminochromone-2-carboxamide (**41**) (Scheme 5). This behaviour is untypical of the known nonfluorinated chromones. Under these conditions, the latter add a nucleophile at the C(7) atom with the opening of the heterocycle.⁷⁸ Under the action of cyclohexylamine, only the fluorine atom at the C(7) atom of chromone **3a** is replaced to form chromone **6** (see Scheme 5).⁷⁹ It should be noted that the replacement at the C(7) atom is an orbital-controlled reaction, while the formation of methylamide at the C(9) atom is a charge-controlled process.

Table 2. Charges and Fukui indices for the electrophilic centres in substituted chromones.

^a Anion of 2-carboxychromone.

The reactions of chromone **3a** with secondary amines (morpholine, *N*-methylpiperazine or piperidine) proceed analogously without the opening of the heterocycle (which is typical of the reactions of nonfluorinated chromones with secondary amines) to form the corresponding 2-ethoxycarbonyl-7-*R*-5,6,8-trifluorochromones **42a–c**. Boiling of chromone **42a** with HCl gives 5,6,8-trifluoro-7-morpholinochromone-2-carboxylic acid (**43**) (see Scheme 5).⁴³

Thus, the reactions of 2-ethoxycarbonylchromone **3a** with primary and secondary amines are orbital-controlled and yield products of replacement at the C(7) atom.

In contrast to 2-ethoxycarbonylchromone **3a**, the reactions of 2-carboxychromones **3c** and **43** with ammonia are accompanied by the opening of the pyrone ring, which is typical of the known chromones.⁷⁸ These reactions afford 2-amino-3-(4-*R*-3,5,6-trifluoro-2-hydroxybenzoyl)acrylic acids **7** and **44**, which can undergo recyclisation to form the initial compounds **3c** and **43** upon boiling in an acidic medium.⁴³

The reactions of 2-carboxychromone **3c** with primary amines are governed by both the nature of the amine and the reaction conditions.⁷⁹ Thus boiling of chromone **3c** with an equimolar amount of amine (cyclohexylamine or hexylamine) in dioxane affords cyclohexylammonium (hexylammonium) 5,6,7,8-tetrafluorochromone-2-carboxylate (**45a,b**). Salts **45a,b** are stable on prolonged boiling in toluene. In the presence of an excess of amine, the pyrone ring in compound **45a** is opened to form 2-cyclohexylamino-3-(3,4,5,6-tetrafluoro-2-hydroxybenzoyl)acrylate (**46**). Acidification of the salt **46** affords 2-cyclohexylamino-3-(3,4,5,6-tetrafluoro-2-hydroxybenzoyl)acrylic acid (**47**). Treatment of the hexylammonium salt **45b** with hydrochloric acid affords the initial chromone **3c** (Scheme 6).⁷⁹

Scheme 6

45: R = cyclo-C₆H₁₁ (a), C₆H₁₃ (b).

The reactions of chromone **3c** with hexylamine and aniline in a mixture of chloroform and water at 30–35 °C can proceed both as nucleophilic addition of the amine at the activated C = C bond and as the reaction at the carbonyl group of the chromone. Thus chromone **3c** reacts with aniline to form anilinium 4-anilino-5,6,7,8-tetrafluoro-4-hydroxychromene-2-carboxylate (**48**). The reaction of chromone **3c** with hexylamine affords hexylammonium 2,4-bis(hexylamino)-5,6,7,8-tetrafluoro-4-hydroxychromene-2-carboxylate (**49**), which is converted into 5,6,7,8-tetrafluoro-2-hexylamino-4-oxochromane-2-carboxylic acid (**50**) upon acidification (Scheme 7).⁴³

The reaction of 2-ethoxycarbonylchromone **3a** with hydrazine yields a mixture of products, which are difficult to identify. 2-Carboxychromone **3c**, like nonfluorinated analogues, reacts with hydrazine and phenylhydrazine more selectively to form the corresponding 1-R-5-(tetrafluoro-2-hydroxyphenyl)pyrazole-3-carboxylic acids **51a,b**.⁷⁹

The reaction of 2-ethoxycarbonylchromone **3a** with ethylenediamine yields either piperazin-2-one **16e** as a result of the reaction at the C(2) atom and the ester group or a product of nucleophilic aromatic replacement of the fluorine atom at position 7, *viz.*, *N,N'*-ethylenebis(7-amino-2-ethoxycarbonyl-5,6,8-trifluorophenylchromone) (**52**), depending on the solvent (Scheme 8).⁴³ The formation of these compounds is attributable to an increase in the electron-withdrawing ability of the polyfluoroaryl ring (and consequently, the ability to undergo nucleophilic replacement of the fluorine atom) in going from protic solvents (alcohols) to a bipolar aprotic solvent (DMSO).⁸⁰ However, the reaction of chromone **3a** with ethylenediamine in acetonitrile also affords piperazin-2-one **16e**.⁴³ Apparently, acetonitrile, unlike DMSO, does not hinder the formation of an ionic pair of ethylenediamine with chromone at the electrophilic carbon atom of the ester group or at the C(2) atom.

Scheme 8

2-Ethoxycarbonylchromone **3a** reacts with diethylenetriamine with the involvement of all three nucleophilic centres to form a binuclear triazaheterocyclic derivative, *viz.*, 9-(3,4,5,6-tetrafluoro-2-hydroxybenzoyl)perhydropyrazino[1,2-*a*]pyrazin-1-one (**53**).⁸¹ An analogous bicyclic system is obtained by the reaction of 2-amino-4-iminoperfluoropent-2-ene (an aza analogue of heptafluoroacetylacetone) with diethylenetriamine.^{82, 83}

The reaction of chromone **3a** with *N*-(2-hydroxyethyl)-ethylenediamine under analogous conditions is completed in the stage of formation of a mononuclear heterocyclic compound, *viz.*, 3-(3,4,5,6-tetrafluoro-2-hydroxybenzoylmethylidene)-4-(2-hydroxyethyl)piperazin-2-one (**54**).⁸¹

Attempts to perform further intramolecular heterocyclisation of compound **54** with the use of acid or base catalysis, which favours nucleophilic addition of the hydroxy group at the C = C bond, failed. Under conditions of acid catalysis in the presence of water, compound **54** is readily hydrolysed to form carboxychromone **3c**. When boiled in toluene with *p*-toluenesulfonic acid, the initial piperazinone **54** remains unchanged. Heating of compound **54** in an alkaline medium results in its decomposition to 3,5,6-trifluoro-2,4-dihydroxyacetophenone **55** or, in the case of the shorter reaction time, to tetrafluoro-2-hydroxyacetophenone **56**.⁸¹

Analogous hydrolytic cleavage to form dihydroxy(hydroxy)-polyfluoroacetophenones was also observed in the cases of piperazinone **16e** and aminoacrylic acid **7**.⁸⁴

2-Ethoxycarbonylchromone **3a** and 2-carboxychromone **3c** react with *o*-phenylenediamine to form quinoxaline derivative **17e** (the yields were 70% and 30%, respectively) (Scheme 9).⁷⁹ The reactions of compounds **3a** and **3c** with *o*-aminophenol afford benzooxazinone **21b** containing the tetrafluorohydroxyphenyl fragment.^{53, 66}

R = Et (**3a**), H (**3c**); X = NH (**17e**), O (**21b**).

The reaction of 2-methoxycarbonylchromone **3b** with *o*-aminothiophenol yields only a product of nucleophilic replacement of the fluorine atom, *viz.*, 7-(2-aminophenylthio)-5,6,8-trifluoro-2-methoxycarbonylchromone (**57**).³⁹

R = *o*-H₂NC₆H₄S.

When heated in DMSO in the presence of triethylamine, both quinoxalones containing the hydroxy group in the fluoroaromatic fragment (**17e**) and hydroxy-free quinoxalones (**17d**) undergo heterocyclisation to form 1,2,3-trifluoro-4-R-(5*H*)-5-oxoquinolino[1,2-*a*]-8*H*-quinoxalin-7-ones **58a,b** due apparently to the completely aromatic character of the possible zwitterion.⁷⁹

R = F (**17d**, **58a**), OH (**17e**, **58b**).

In this connection it should be noted that piperazinone **16e** whose nitrogen atoms should be more nucleophilic than those in quinoxalones does not give the corresponding heterocyclic system **59** either under analogous conditions or under more drastic conditions (K₂CO₃ or LiH). Apparently, this is associated with the fact that none of its possible tautomeric forms is completely aromatic.⁷⁹

It is remarkable that the benzooxazinone derivative **21a** also undergoes intramolecular cyclisation upon heating in DMSO. This reaction, unlike the above-mentioned transformation of quinoxalones **17d,e** into quinolinoquinoxalones **58a,b**, affords 4,5,6-trifluoro-3*H*-pyrido[3,2,1-*k*]phenoxazin-3-one (**60**). Apparently, the formation of compound **60** proceeds *via* intermediates shown in the following scheme:⁸⁵

Summarising the data on the reactions of 2-alkoxycarbonyl- (**3a,b**) and 2-carboxy-5,6,7,8-tetrafluorochromones (**3c**) with binucleophiles, it can be suggested that the mechanisms of the first stages of the reactions of chromones **3a,b** and **3c** are different, although the reactions can afford identical products (for example, in the reactions with *o*-phenylenediamine and *o*-aminophenol).

Apparently, the initial stage of the reactions of chromones **3a,b** with N-dinucleophiles involves the charge-controlled attack of one amino group of the reagent on the electrophilic C(9) centre. It counts in favour of this suggestion that the reaction of chromone **3a** with methylamine affords *N*-methylamide **41** (see Scheme 5). However, the reaction with an excess of methylamine involves also the orbital-controlled attack of the nucleophile on the C(7) centre. In this connection it should be noted that the orbital control may become predominant, *e.g.*, in the reactions of chromone **3a** with primary and secondary amines in dioxane yielding 7-substituted products **42** and **6** (see Scheme 5) or in the reaction of chromone **3a** with ethylenediamine in DMSO to form product **52** (see Scheme 8). This regioselectivity is apparently determined by the effect of specific solvation of the initial reagents by the solvent, much as in the reactions of 5-aryl-2,3-dihydrofuran-2,3-diones with aromatic amines in dioxane.⁸⁶

The second amino group of the N-dinucleophile (ethylenediamine, *o*-phenylenediamine or *o*-aminophenol) attacks the nearest C(2) atom of chromone **3a**. In this case, the pyran ring is opened to form new heterocyclic compounds, *viz.*, piperazinones **16e**, quinoxalones **17e** or oxazines **21b**, respectively (see Schemes 8 and 9). Evidently, this process is governed by thermodynamic factors.

Unlike 2-alkoxycarbonylchromones **3a,b**, 2-carboxychromone **3c** reacts with an equimolar amount of primary amines to form stable salts **45** (see Scheme 6). The reactions of these salts with an excess of amine follow different routes. Thus heating in dioxane results in resinification of the reaction mixture. In an aqueous medium, the reversible interaction of the amino group of primary amine with the electrophilic C(4) and C(2) centres occurs. In the latter case [the reaction at the C(2) atom], either products of

addition at the double C(2) = C(3) bond (products **49** and **50**) can be formed (see Scheme 7) or derivatives of aminoacrylic acid, viz., compounds **46** and **47**, can be obtained due to the opening of the heterocycle of the chromone, as in the case of the reaction with cyclohexylamine (see Scheme 6). However, when heated in dioxane, the products of addition of cyclohexylamine undergo identical conversions to form apparently the more stable initial salts.

It is remarkable that under kinetically controlled conditions the reaction at the C(4) atom can occur as a charge-controlled process because the charge on this atom is the second largest, exceeded in value only by the C(9) atom. However, the reaction of amine at the C(2) atom of the carboxylate anion, as in the case of 2-ethoxycarbonylchromone, is not apparently kinetically controlled. Actually, calculations of model compounds demonstrated that the attack of a nucleophile on the C(2) atom of the fluorinated carboxylate anion affords a thermodynamically more stable reaction product than the attacks on the C(4) and C(7) nucleophilic centres. This is evident from the comparison of the enthalpies of formation of the following compounds (ΔH /kJ mol⁻¹):⁷⁹

In our opinion, the formation of the corresponding carboxylate anion followed by the attack of a nucleophile (an excess of amine in the case of hydrazines and the second amino group in the case of *o*-phenylenediamine and *o*-aminophenol) on the C(2) atom is also typical of the reactions of 2-carboxychromone **3c** with hydrazines, *o*-phenylenediamine and *o*-aminophenol. The subsequent reaction path is determined by the thermodynamic stability of the final products, as in the case of nonfluorinated aroylpyruvic acids.

VIII. Conclusion

Analysis of the above-considered published data demonstrated that the reactions of fluorinated acyl(aroyl)pyruvates are analogous to the reactions of nonfluorinated α - and β -DCC. Thus fluoroacyl(aroyl)pyruvates react at the β -dicarbonyl fragment (for example, with hydrazines) and enter into the reactions at the active methylene group as β -DCC (for example, with orthoformate and aryldiazonium salts) and at the α -oxo-ester fragment as α -DCC (for example, with diamines).

However, the introduction of fluorine atoms into aroylpyruvate molecules can radically change their reactivity. Thus the heterocyclisation of fluoroaroylpyruvates, which is untypical of their nonfluorinated analogues, affords 2-ethoxycarbonyl(carboxy)-5,6,7,8-tetrafluorochromones. The latter, in turn, can react with HO-, HN- and HS-nucleophiles to form various fluorinated heterocyclic compounds.

In summary the above-considered data substantially extend the knowledge of synthetic potentialities of fluorinated 2,4-dioxo acids and their derivatives for constructing various classes of heterocyclic systems.

IV. Other reactions of phosphine with organic compounds	224
V. Conclusion	225

Abstract. Published data on the synthesis of organophosphorus compounds based on phosphine are fully surveyed, described systematically and analysed for the first time. The bibliography includes 211 references.

I. Introduction

Phosphine is used in the chemistry of organic compounds of phosphorus for the formation of C–P bonds and for the synthesis of organic and heteroorganic phosphines including functionally substituted ones, which are important auxiliary reagents, building blocks, intermediate products, ligands for metal-complex catalysts, extractants and fire-proofing agents.^{1–11}

Phosphine, possessing versatile reactivity, reacts with various classes of organic compounds (oxidants, organyl halides, alkenes, alkynes, aldehydes, ketones, oxiranes, thiiranes, amines, alcohols, esters, organyl isocyanates, *etc.*) both with transition into the tetracoordinated state and according to the substitution–addition patterns under conditions of base and acid catalysis and radical initiation.

The interest in the chemistry of phosphine does not attenuate; in our opinion, phosphine deserves even more attention. Known methods for the synthesis of organic compounds of phosphorus based on phosphine are being developed and improved; simultaneously, new phosphine-based methods for the synthesis of organophosphorus compounds appear (for example, the method based on the use of superbasic suspensions such as ‘alkali metal hydroxide–high-polarity non-hydroxylic solvent’ systems^{6, 7, 12} or phase transfer catalysis^{6, 7, 12}).

In recent years, considerable attention has been paid to nucleophilic reactions of phosphine with organyl halides^{12, 13} and reactions with electrophilic aryl(hetaryl)alkenes^{14–20} and -alkynes^{21–23} in superbasic systems, which permit selective and efficient syntheses of primary, secondary and tertiary phosphines. Most of these reactions occur under mild conditions at an atmospheric pressure of phosphine. The use of these methods was greatly facilitated by the development of a convenient

procedure for the generation of phosphine from red phosphorus and an alkali metal hydroxide in a water-organic medium.¹⁴

Although the chemistry of organic phosphines has been the subject of numerous reviews^{10, 11, 24, 25} and even monographs,^{1, 9, 25} the reactions of phosphine with organic compounds have not been considered systematically and are represented by few examples. Several reactions of phosphine are described in monographs^{1, 2, 9} and handbooks (see, for example, Ref. 25). The data on the use of phosphine in the synthesis of organophosphorus compounds published before 1961 were discussed most fully (but not exhaustively) in a short (13 pages) review,³ the bibliography of which includes 70 references. In another review,¹¹ which is devoted to α -hydroxyalkylphosphines and -phosphine oxides, reactions of PH_3 and organic phosphines with carbonyl compounds have been considered in detail.

The purpose of the present review, in which data on the phosphine-based methods of the synthesis of organophosphorus compounds are described fully and systematically for the first time, is to provide the reader with not only general information but also data concerning particular reactions of phosphine and its organic derivatives.

II. Phosphine in substitution reactions

1. Alkylation of phosphine

a. Alkylation with organic halides

According to patents,^{26–29} the vapour-phase (210–280 °C) catalytic alkylation of phosphine with alkyl halides yields alkylphosphonium halides, their structures being dependent on the ratio of the reactants. Activated carbon or Pt, Pd and Au supported on Al_2O_3 or SiO_2 are used as catalysts. When excess alkyl halide with respect to phosphine is used, the reaction (210–280 °C, 11 atm, 85 h, activated carbon) gives tetraalkylphosphonium halides (in up to 83% yields).^{26, 27}

R = Alk(C_1 – C_4); X = Cl, Br.

The reactions of phosphine with alkyl chlorides (equimolar ratio, 280 °C, 5 days, activated carbon) afford mixtures of mono-, di- and trialkylphosphonium chlorides, monoalkylphosphonium chloride being the major product, which are converted into the corresponding phosphines on treatment with aqueous NaOH.²⁸

Received 11 June 1998

Uspekhi Khimii 68 (3) 240–250 (1999); translated by Z P Bobkova

R = Alk, cyclo-Alk, PhCH₂.

Having been bound in a complex on heating (70–80 °C) with an equimolar amount of AlCl₃, phosphine reacts with alkyl halides,^{30–31} cycloalkyl halides³⁰ and adamantyl bromide³² to give, after the subsequent treatment of the reaction mixture with ice water and HCl, primary phosphines in 15%–83% yields. When alkyl iodides are used, phosphorylation is complicated by side processes. Aryl halides do not enter into this reaction.³⁰

R = Alk(C₄–C₆) (37%–64%), Alk(C₈–C₁₈) (62%–83%), cyclo-Alk (15%–28%); X = Cl, Br.

It should be noted that even when the complex PH₃·AlCl₃ reacts with excess alkyl halide, the reaction occurs as monoalkylation; the formation of minor amounts of secondary phosphines was detected only for lower alkyl halides.³⁰

The reactions of phosphine with alkyl halides under the Friedel–Crafts conditions occur most likely by a carbocationic mechanism. This is indicated, in particular, by the fact that the reaction of dodecyl bromide with the complex PH₃·AlCl₃ yields a mixture of primary phosphines, presumably,³¹ structural isomers of dodecylphosphine.

The reaction of phosphine with chlorides of aromatic carboxylic acids in dry pyridine gives rise to tris(aryl)phosphines.^{33–35}

Ar = Ph,³³ 3-MeC₆H₄, 4-MeC₆H₄, α-C₁₀H₇, β-C₁₀H₇.^{33–35}

b. Alkylation with alcohols, ethers and amines

The synthesis of alkylphosphines by high-temperature catalytic alkylation of phosphine with alcohols,³⁶ ethers³⁶ and amines^{37,38} has been described in patents.^{36–38}

Thus aliphatic and cycloaliphatic primary and secondary phosphines are formed in good yields when phosphine reacts (200–300 °C, atmospheric pressure) with alcohols and ethers in the presence of dehydrated natural and synthetic metal aluminosilicates or zeolites of various brands, the pores of which are permeable for mono- and diorganylphosphines but impermeable for triorganylphosphines.³⁶

R = Alk, cyclo-Alk; R' = H, Alk.

A method for the preparation of primary, secondary and tertiary alkylphosphines by heating phosphine (150–400 °C, pressure up to 2 atm) with amines in the presence of a catalyst (activated carbon, copper chromite, Group IB and VIIIB metals) has been proposed.³⁷

R = Me, Et, Pr; n = 1–3.

Under the same conditions, phosphine can also be alkylated by mixtures of amines with hydrogen halides and/or alkyl halides, *i.e.* by the corresponding ammonium salts.³⁸

2. Reactions of phosphide ions with organic halides

In the presence of strong bases, phosphine is converted into phosphide ions, which react with organyl halides by nucleophilic substitution to give primary and secondary phosphines. The role of bases in these reactions is played by the systems 'alkali (or alkaline earth) metal–organic solvent (or liquid ammonia),'

organometallic compounds (triphenylmethylsodium, phenyllithium, butyllithium) or strong bases generated from alkali metal hydroxides in polar non-hydroxylic solvents or under conditions of phase transfer catalysis.

a. Reactions of metal phosphides

Phosphorylation of organyl halides by the 'phosphine–alkali (or alkaline earth) metal' systems yields predominantly primary phosphines.^{1,2,39–45} This reaction can be carried out for alkyl halides,^{39–41} aryl halides,^{1,42} aminoalkyl halides,⁴³ sodium halocarboxylates^{44,45} and dihaloalkanes.^{41,46–49} The process is carried out in an organic solvent or in liquid ammonia using stoichiometric amounts of reactants.

Thus alkylphosphines and allylphosphines have been obtained in good yields (55%–78%) by a one-pot procedure which includes the reaction of sodium, dispersed preliminarily in hexamethylphosphotriamide (HMPA), with phosphine and the addition of alkyl halides to the resulting solution of sodium dihydrophosphide.⁴⁰

R = Me, Et, CH₂=CHCH₂; X = Cl, Br.

When calcium metal is used in this process instead of sodium and liquid ammonia is used instead of HMPA, phosphorylation becomes more efficient; for example, the reaction between chloromethane and phosphine gives methylphosphine in 87% yield.⁴¹

It has been reported that aryl halides can be involved in the reaction with alkali metal phosphides.^{1,42} Thus potassium phosphide prepared from phosphine and potassium in liquid ammonia slowly reacts with bromo- and iodobenzene to give phenylphosphine.¹ A mixture of (5-isopropyl-2-methylphenyl)phosphine and 2-isopropyl-5-methylphenyl)phosphine is formed when 2-bromo-4-isopropyl-1-methylbenzene reacts with sodium phosphide or lithium phosphide in boiling ether.⁴²

M = Li, Na.

The 'phosphine–sodium–liquid ammonia' system has been used successfully in phosphorylation of aminoalkyl halides⁴³ and halocarboxylic acids^{44,45} aimed at synthesising the corresponding functionalised primary phosphines. Thus (2-R,R'-aminoethyl)phosphines have been obtained in 54%–70% yields from 2-R,R'-aminoethyl chloride and phosphine.⁴³

R, R' = H, Et.

When sodium halocarboxylates are treated with phosphine in the 'sodium–liquid ammonia' system and then the reaction mixture is treated with dilute sulfuric acid, 1- and 2-carboxyalkylphosphines are formed in 70%–85% yields.^{44,45}

R = CH₂, CHMe, CHEt, CMe₂, CH₂CH₂; X = Cl, Br.

Under the same conditions, sodium 2,5-dibromoadipate was converted into 2,5-diphosphinoadipic acid formed as a mixture of racemic and meso forms in 45 : 55 ratio.⁴⁴

The synthesis of 3-carboxypropylphosphine from 4-chlorobutyric acid demonstrated that not only salts but also acids themselves can efficiently react with phosphine and excess sodium in liquid ammonia.⁴⁴

Thus, metallation of phosphine with an alkali or alkaline earth metal followed by treatment of the phosphide with an organyl halide results in the formation of primary phosphines of various structures in high yields.^{40, 41, 43–45} However, this approach has scarcely been used for the synthesis of diorganylphosphines, apparently, due to the difficulty of formation of disubstituted metal derivatives upon metallation of phosphine.¹ Only preparation of dimethylphosphine in a relatively low yield (33%) by treatment of calcium hydrophosphide with chloromethane in liquid ammonia has been reported.⁴¹

Dihaloalkanes can be phosphorylated by the 'PH₃–alkali metal–liquid ammonia' system to give, depending on the length of the alkylene chain, either cyclic phosphines or their mixtures with primary alkylendiphosphines. The reaction of 1,2-dichloroethane with sodium dihydrophosphide in liquid ammonia yields phosphirane **1** as the main product (yield 74%).^{47–49}

The cyclisation was suggested⁴⁷ to occur as follows:

Methyl- and ethylphosphiranes have been prepared from the corresponding 1,2-dichloroalkanes under the same conditions (yields 30% and 25%, respectively).⁴⁰

R = Me, Et.

α,ω-Dihaloalkanes with a number of methylene units $n \geq 3$ are phosphorylated by phosphine in the 'sodium–liquid ammonia' system yielding simultaneously cyclic secondary phosphines and alkylendiphosphines.^{48, 49}

X = Cl, Br; $n = 3–7$.

The transformation of 1,4-dichlorobutane under these conditions gave a mixture of phospholane and 1,4-diphosphinobutane (each in 47% yield).⁴⁸

Phosphine can be metallated with equal success by some organometallic compounds, for example, triphenylmethylsodium,¹ phenyllithium^{1, 50, 51} and butyllithium.⁵²

For example, when a fast stream of phosphine is passed through diethyl ether to which phenyllithium is being simultaneously added, lithium dihydrophosphide is formed; its subsequent treatment with organyl halide affords primary phosphines in 65%–75% yields.⁵⁰

R = Et, Prⁿ, Bu^t, PhCH₂; X = Cl, Br.

Depending on the reactant ratio, the reaction of butyllithium with phosphine gives rise to lithium phosphide, trilithium phosphide or its mixture with dilithium phosphide. The reactions of these phosphides with chlorotrimethylsilane at 0–10 °C resulted in the formation of trimethylsilylphosphine (yield 30%), a mixture of bis- and tris(trimethylsilyl)phosphines (yields 35% and 24%, respectively) or tris(trimethylsilyl)phosphine (yield 45%).⁵²

b. Reactions of phosphine in the presence of a strong base

Methylation was the first example of alkylation of phosphine with an organyl halide in the presence of a strong base.^{53, 54} When methyl iodide is added to a DMSO suspension of KOH preliminarily saturated with phosphine, methylphosphine or dimethylphosphine is formed, depending on the initial ratio of reactants (yields 75%⁵³ and 65%,⁵⁴ respectively).

Later, other organyl halides have also been involved in this reaction; this gave monoorganylphosphines in 70%–94% yields.¹² The reaction was carried out in a mixture of a 56%–64% aqueous solution of KOH with DMSO (depending on the nature of the halide used, the temperature and pressure varied in the ranges 0–60 °C and 4–7.5 atm).

R = Me, Et, CH₂=CHCH₂, Buⁿ, Bu^t, PhCH₂; X = Br, Cl.

Diallyl- and dibutylphosphines were obtained in this reaction (yields 53% and 23%, respectively) by using a two- or four-fold excess of potassium hydroxide with respect to the corresponding organyl bromide.¹²

R = Bu, CH₂=CHCH₂.

No products of the possible prototropic rearrangement — propen-1-yl- or di(propen-1-yl)phosphines — have been obtained under these conditions, although this rearrangement does occur during phosphorylation of allyl halides with red phosphorus in a highly basic aqueous-organic emulsion.^{5, 55, 56}

Recently dibenzylphosphine has been prepared in 50% yield from phosphine and benzyl chloride.^{13, 57} The reaction occurs under mild conditions (atmospheric pressure, 40 °C). Benzyl chloride is slowly added to a suspension of KOH in DMSO in the presence of a slight amount of water and simultaneously, a phosphine–hydrogen mixture, generated from red phosphorus and an alkali metal hydroxide, is vigorously passed through the suspension.

This reaction gives as well a noticeable amount of dibenzyl ether (up to 20%) resulting from solvolytic transformations of benzyl chloride.¹³

Unlike reactions of metal phosphides with dihalopropane, which afford phosphorus-containing heterocycles^{48, 49} (Section II.2.a), the reactions of phosphine with 1,3-dihalopropane or -butane in the KOH–DMSO(H₂O) system give only acyclic products, 1,3-diphosphinopropane or -butane (yields 59% and 75%, respectively).¹²

R = H, Me.

Phosphorylation of 1,4-dibromopentane under similar conditions gives rise to 2-methylphospholane (yield 80%), only minor amounts of the corresponding acyclic product, 1,4-diphosphinopentane, being formed.¹²

Alkylation of phosphine with organyl halides has also been carried out in the presence of bases generated under conditions of phase transfer catalysis, *i.e.* in the systems ‘aqueous potassium hydroxide–organic solvent (toluene, pentane)–tetraalkylammonium or tetraalkylphosphonium salt.’^{12, 58, 59} Depending on the reactant ratio and the reaction conditions (temperature, pressure), primary or secondary phosphines are formed in the 55%–92% yields.

R = Alk(C₁–C₂₄), CH₂=CHCH₂,^{12, 58} PhCH₂,⁵⁸

-CH₂CH₂,¹² Ph₂PCH₂,⁵⁹ R' = Me,¹² Ph₂PCH₂,⁵⁹ X = Cl, Br.

1,3-Dihaloalkanes react with phosphine under the conditions of phase transfer catalysis to give, as in the KOH–DMSO system,¹² 1,3-diphosphinoalkanes in yields of up to 89%.^{12, 58}

R = H, Alk; X = Cl, Br.

III. Phosphine in addition reactions

1. Addition to C = C bonds

The reaction of phosphine with alkenes is a convenient method for the synthesis of organic phosphines. Phosphine can add to C = C bonds by both ionic and radical mechanisms. The reaction pathway is determined by its conditions and the nature of the alkene used.

a. Nucleophilic addition

Nucleophilic addition of phosphine to the C = C bond was first described by Rauhut *et al.*^{60, 61} for alkenes containing strong electron-withdrawing substituents at the *sp*² carbon atom. In the presence of bases (a 10 M aqueous solution of KOH, heptamethylbiguanide, a concentrated solution of ammonia, solid sodium hydroxide), phosphine reacts with acrylonitrile,^{60, 62} acrylamide, nitroethylene, mesityl oxide and lauryl acrylate⁶¹ to give a mixture of primary, secondary and tertiary phosphines.

R = CN, CONH₂, NO₂, *etc.*

The process selectivity can be increased by varying its conditions (the molar ratio and the rate of mixing of the reactants, temperature, heating duration or pressure).^{60, 61} For example, when a flow of phosphine is passed through the system ‘aqueous KOH–acetonitrile’ heated to 30–35 °C and acrylonitrile is simultaneously added to it, the addition rate being adjusted in such a way as to maintain a slight excess of acrylonitrile relative to phosphine, tris(2-cyanoethyl)phosphine is obtained in 80% yield. A decrease in the concentration and the rate of addition of acrylonitrile under the same conditions results in bis(2-cyanoethyl)phosphine being formed predominantly (yield 63%). The primary phosphine is formed in 52% yield in the phosphorylation of acrylonitrile in an autoclave under an elevated pressure of phosphine (28–32 atm).⁶⁰

In the 1970s, a series of studies was published on the nucleophilic addition of phosphine to dialkyl vinylphosphonates,^{63, 64} vinylalkylphosphine sulfides,^{65, 66} and even to relatively weak electrophiles — vinylphenylphosphine^{67–70} and vinylphosphonous diamides.⁷¹ The reactions occur in boiling THF in the presence of Bu^tOK,^{63–66, 70} or in benzene in the presence of PhLi at 100 °C (autoclave),^{67–69} or in the ‘metallic potassium–liquid ammonia’ system⁷¹ and result in the formation of functionalised tertiary phosphines **2a–e**, their yields ranging from 24% (**2a**) to 95% (**2e**).

R = Ph (**a**), Me₂N (**b**), X is absent; R = Me₂CHO (**c**), X = O;
R = Me (**d**), Me₃CCH₂ (**e**), X = S.

Recently^{14–21} it has been found that phosphine is capable of adding to weakly electrophilic C = C bonds in aryl and hetaryl-ethenes in the KOH–DMSO system, and preparative methods for the synthesis of bis- and tris(2-arylethyl)- and -(2-hetaryl-ethyl)phosphines have been developed. In the absence of KOH, all other factors being the same, phosphorylation does not occur, which confirms the nucleophilic mechanism of the reaction. Phosphine is generated as a mixture with hydrogen by the addition of an aqueous solution of KOH (or NaOH) to a suspension of red phosphorus in dioxane.¹⁴

Bis(2-arylethyl)- and bis(2-hetarylethyl)phosphines have been selectively synthesised in 60%–80% yields by slow addition of an alkene to a suspension of KOH in DMSO heated to 45–60 °C with simultaneous vigorous passing of a phosphine stream through the suspension.^{14–20}

R = H, R' = Ph, 4-FC₆H₄, , , , Me-;
R = Me, R' = Ph.

1-Methyl-2-vinylpyrrole could not be involved in the reaction with phosphine, apparently, because of the low electrophilicity of the double bond in this alkene (due to the electron-donating mesomeric effect of the 1-methyl-2-pyrrolyl group).¹⁴

Exhaustive and selective aryl(hetaryl)ethylation of phosphine by styrene and vinylpyridines occurs at 95–98 °C and 65–67 °C, respectively, in the KOH–DMSO system, giving rise to tris(2-phenylethyl)-, tris[2-(4-pyridyl)ethyl]- and tris[2-(2-methyl-5-pyridyl)ethyl]phosphines (yields 65%–76%).^{18, 19}

R = Ph, , Me-.

When this reaction is conducted at a lower temperature (30–40 °C), the corresponding primary phosphines can also be obtained in 20%–24% yields. However, bis(2-phenylethyl)- and bis(2-pyridylethyl)phosphines are the main reaction products under these conditions.^{19, 20}

It has been noted that a base generated under the conditions of phase transfer catalysis (a 60% aqueous solution of KOH–dioxane–benzyltrimethylammonium chloride) is not sufficiently strong to enable phosphorylation of arylalkenes and vinylpyridines with phosphine.¹⁹

An unsuccessful attempt to carry out the reaction of phosphine with diphenylethene and fumaronitrile in the presence of a base has been reported.⁷²

b. Electrophilic addition

The acid-catalysed addition of phosphine to unsaturated compounds is relatively little studied. It has been reported^{73, 74} that alkenes of various structures (linear and branched alkenes, cycloalkenes, polypropenes, polybutenes, styrene, limonene, *etc.*) react with phosphine under relatively rigorous conditions (60–90 °C, 30–47 atm, acid catalysis) according to the Markovnikov rule to give mostly primary phosphines.

R, R' = H, Alk(C₁–C₆₃), Ph, *etc.*

Best results in this reaction are obtained when 1,1-disubstituted alkenes are used, because they form the most stable intermediate tertiary carbocations and in addition, they are the least susceptible to cationic polymerisation.

Thus the highest yield (90%) of the primary phosphine was observed when phosphine was made to react with C₁₂-polypropene.⁷³ The reaction of phosphine with 2-methylprop-1-ene, 2-ethylhex-1-ene and 1-methylcyclopentene is less efficient (the yield of the corresponding primary phosphines is 41%–75%), which is apparently due to the fact that these alkenes are more prone to undergo polymerisation than C₁₂-polypropene. Phosphorylation of linear alkenes, ethene, propene and dodec-1-ene, results in even lower yields (14%–20%) of primary phosphines.

Among the catalysts tested in the reaction of phosphine with alkenes (mineral and organic acids, sulfonic acids, Lewis acids), methanesulfonic acid is the most active.⁷³ It should be noted that for this reaction to go to completion, almost stoichiometric amounts of acid catalysts are needed, because the monoalkylphosphines, which are formed in the process, are stronger bases than phosphine; therefore, they react reversibly with the acid to give phosphonium ions.

The reactions of phosphine with some alkenes (styrene, limonene) in an acid medium are accompanied by polymerisation giving rise to telomeric phosphines.⁷⁴

Since the electrophilic addition of phosphine to alkenes is a carbocationic process, the reactions of linear alkenes with phosphine under these conditions may be accompanied by isomerisation of the hydrocarbon chain (as has been shown in relation to the interaction of phosphine with alkyl halides in the presence of AlCl₃).³¹ However, in the study cited,⁷³ this aspect is not considered.

c. Radical addition

The addition of phosphine to alkenes under conditions of radical initiation [organic peroxides, azobisisobutyronitrile (AIBN), UV irradiation] has been studied fairly comprehensively. This method is used to prepare organic phosphines of various structures, because this reaction has been performed for a broad range of unsaturated organic compounds including functionally substituted ones: linear unsubstituted alkenes with a terminal^{74–88} or (more rarely) internal^{80, 81, 93, 94} double bond, cycloalkenes,^{75, 76, 78, 80, 81, 85, 90} arylalkenes,^{75, 78, 80, 81, 90} dienes,^{78, 79, 90, 113–118} trienes,¹¹⁹ fluorinated alkenes,^{103–109} vinyl^{75, 80, 81} and divinyl^{111, 112} ethers and thioethers,^{80, 81} alcohols,^{76, 80, 81, 85, 95} amines,^{76, 80, 81} ketones,^{80, 81} acrylic acid derivatives,^{75, 80, 81, 96–98} and allyl^{80, 81} and vinyl^{99, 100} carboxylates and phosphonates.^{80, 81, 85}

Radical addition of phosphine to alkenes normally results in the formation of mixtures of primary, secondary and tertiary phosphines, their ratio being dependent most of all on the ratio of the initial reactants.^{75, 77}

R = Alk, Ph, H₂NCH₂, HOCH₂, MeO, BuO, MeS, MeO₂C, EtO₂C, Me(CH₂)₃CH(Et)CH₂O₂C, *etc.*

Primary phosphines are formed as the major products when a substantial excess of phosphine in relation to alkene is used.^{75, 78, 79} Octylphosphine is formed in 65% yield when a mixture of phosphine with oct-1-ene (molar ratio 3.6 : 1) is heated (78–89 °C, AIBN) at a pressure of ~33 atm. The yields of dioctyl- and trioctylphosphines under these conditions are 18% and 4%, respectively.⁷⁵ An even higher yield (80%) of octylphosphine was attained when the reaction was carried out at a phosphine pressure of 120–180 atm,⁷⁸ because at higher phosphine pressures, its solubility in the liquid phase increases and, hence, the yield of primary phosphine also increases.⁷⁵

A similar influence of high pressures of phosphine on the yield of the reaction product was observed⁷⁵ for 2-methylprop-1-ene.

Tertiary phosphines are prepared in high yields (70%–96%) by using excess alkene with respect to phosphine.^{75, 76, 80–85} For instance, phosphorylation of oct-1-ene by phosphine at a molar ratio of 3 : 1 (80–100 °C, pressure 3.3 atm, AIBN) afforded trioctylphosphine in 83% yield.⁷⁵ The synthesis of tributylphosphine in a nearly quantitative yield (96%) from phosphine and but-1-ene under conditions of radical initiation is described in a patent.⁸³

However, the yield of secondary phosphines in the radical addition of phosphine to alkenes is, as a rule, relatively low (20%–30%).⁷⁵

Naturally, the structure of the alkene used also has an influence on the ratio of primary, secondary and tertiary phosphines formed in the alkylation of phosphine with alkenes. Sterically hindered alkenes (2-methylpropene, but-2-ene,^{80, 81, 93, 94} cyclohexene^{75, 76, 78, 80, 81, 85, 90}) react less vigorously than, for example, oct-1-ene to give mostly primary and secondary phosphines even when an excess of alkene with respect to PH_3 is used.

UV irradiation of an equimolar mixture of phosphine and styrene gives rise to phenethylphosphine.⁸¹ The same product is formed, together with bis(phenethyl)phosphine (yields 36% and 29%, respectively), when styrene is phosphorylated with a 1.5-fold molar excess of phosphine in the presence of AIBN (80 °C, ~28 atm).⁷⁵

Phosphorylation of fluorine-substituted alkenes with phosphine is activated by heating (150–160 °C)^{103–105} or UV radiation.^{106–109} This reaction gives mostly primary phosphines, the yields of which are higher (up to 74%–91%) in the case of UV activation.

The reactions of phosphine with alkyl vinyl ethers,^{75, 80, 81} alkyl vinyl sulfides,^{80, 81} allylamines^{76, 80, 81} and allyl alcohol^{76, 80, 81} (a two-fold molar excess of the corresponding alkene was normally used) occurring on exposure to UV radiation^{76, 80, 81} or in the presence of AIBN (80 °C, 31 atm)⁷⁵ afford mostly primary and secondary phosphines (total yield 50%–75%); the yields of tertiary phosphines do not exceed 10%.

On exposure of an equimolar mixture of phosphine and vinyl methyl ketone to UV radiation, (2-acetyethyl)phosphine was formed as the major product.^{80, 81}

A complex mixture of phosphines is formed when ethyl acrylate is made to react with phosphine (70–100 °C, AIBN, 28 atm).⁷⁵ The reaction products contain not only the expected primary, secondary and tertiary phosphines **3a–c** (yields 21%, 20% and 23%, respectively) but also bis(2-ethoxycarbonyl)ethyl-2,4-diethoxycarbonylbutylphosphine **4** (yield 19%).

The phosphine **4** is formed apparently upon the addition of bisphosphine **3b** to diethyl α -methyleneglutarate resulting from dimerisation of the initial ethyl acrylate.

The radical addition of phosphine (AIBN, 90–120 °C, 15 atm) to acrylonitrile at a molar ratio of the reactants of 2.9–3.2 : 1 occurs selectively to give tris(2-cyanoethyl)phosphine in 93% yield.^{97, 98} Nevertheless, the synthesis of this tertiary phosphine from acrylonitrile and phosphine under the conditions of base catalysis (Section III.1.a) is undoubtedly more convenient and practically feasible, because it readily occurs on moderate heating (25–30 °C) under atmospheric pressure.⁶⁰

A mixture of primary, secondary and tertiary phosphines **5a–c** is produced upon photochemical addition of phosphine to allyl^{80, 81} and vinyl^{99, 100} carboxylates (most often, to vinyl acetate).

R = MeCO_2 , MeCO_2CH_2 .

Photoinitiated addition of phosphine to vinyl-^{80, 85} and allylphosphonates⁸¹ has been described. Thus UV irradiation of an equimolar mixture of phosphine and dibutyl allylphosphonate gave 3-(dibutoxyphosphoryl)propylphosphine.⁸¹

NMR analysis of the reaction mixture obtained upon UV irradiation of phosphine and diketene in the presence of AIBN showed the presence of 2-oxo-4-oxetanylmethyl- (**6**) and bis(2-oxo-4-oxetanylmethyl)phosphines **7**; these products were not isolated because of their low stability.¹⁰¹

The addition of phosphine to terpenes and their derivatives in the presence of AIBN has been patented.¹⁰²

On exposure of a mixture of allene and phosphine to UV radiation, the first representative of primary vinylphosphines, propen-2-ylphosphine, was obtained in 3% yield.¹¹⁰

Under conditions of radical initiation (AIBN, 50–70 °C, 10–20 atm), phosphine reacts with penta-1,4-diene to give phosphorinane.⁷⁹

The radical addition of phosphine to divinyl ether (AIBN or UV irradiation, 75–80 °C, 10 atm) results in the formation of both a cyclic phosphine (4-oxaphosphorinane) and a linear primary diphosphine (the yield of each product is 7%–10%).^{111, 112}

According to patent data,¹¹³ the reaction between phosphine and dicyclopentadiene under conditions of radical initiation (AIBN or organic peroxides, 90 °C, 3–20 atm) gives rise to a mixture of isomeric secondary phosphines with the composition $\text{C}_{20}\text{H}_{27}\text{P}$. It was proposed to use this mixture as a ligand for the preparation of metal-complex catalysts and also as a flotation reagent.¹¹³

Bicyclic secondary phosphines are formed upon homolytic addition of phosphine to 4-vinylcyclohex-1-ene¹¹⁴ and to cyclic dienes.^{78, 90, 115–118} Thus heating (70–180 °C) cycloocta-1,5-diene with phosphine under a pressure of 30–40 atm in the presence of AIBN or organic peroxides affords a mixture of 9-phosphabicyclo[3.3.1]nonane and 9-phosphabicyclo[4.2.1]nonane (in a total yield of up to 96%, ratio 1 : 0.8).¹¹⁵

Prolonged (79 h) γ -irradiation (⁶⁰Co) of a mixture of phosphine and cyclododeca-1,5,9-triene has given rise to isomeric tricyclic phosphines **8** and **9** (overall yield 20%).¹¹⁹

d. Addition in the presence of heterogeneous and metal-complex catalysts

Data on the interaction of phosphine with branched and cyclic alkenes and with dienes in the presence of heterogeneous solid catalysts (zeolites, phosphates and metal oxides) at an elevated pressure (8–190 atm) and at temperatures of 100–200 °C have been reported.¹²⁰ Thus heating of phosphine and 2-methylpropene in an autoclave (200 °C, 190 atm) in the presence of a borosilicate zeolite gave *tert*-butylphosphine in 70% yield.¹²⁰

As noted above (Section III.1.b), this reaction can be carried out under milder conditions (60 °C, 33 atm) in the presence of methanesulfonic acid, *tert*-butylphosphine being formed in a comparable yield (61%).⁷³

The addition of phosphine to acrylonitrile has been accomplished in the presence of metal-complex catalysts [a mixture of $\text{P}(\text{CHR}(\text{OH}))_3$, where $\text{R} = \text{H}$ ^{121,122} or Alk ($\text{C}_1\text{--C}_6$),¹²² with reduced iron¹²¹ or chloroplatinic acid¹²²]. The reaction occurs in the medium of a lower aliphatic alcohol at room temperature to give tris(2-cyanoethyl)phosphine.^{121,122} However, this compound can be easily prepared without expensive metal-complex catalysts by cyanoethylation of phosphine with excess acrylonitrile in the presence of an aqueous solution of KOH⁶⁰ (Section III.1.a).

2. Addition to $\text{C}\equiv\text{C}$ bonds

Known examples of the addition of phosphine to triple carbon–carbon bonds are limited to phosphorylation of aryl- and heteroalkynes.^{21–23} The reaction proceeds under mild conditions (55–60 °C, atmospheric pressure) upon passing a phosphine–hydrogen mixture, generated from red phosphorus and potassium hydroxide in aqueous dioxane, through an alkyne–KOH–HMPA (H_2O) suspension. The reaction occurs stereoselectively to give tris(*Z*-2-organylviny)lphosphines **10** in 60%–80% yields.

The kinetic control of this reaction was confirmed by the thermal transformation (160–165 °C, 7 h) of tris[(*Z*)-styryl]-phosphine into the complete *E*-isomer *via* the intermediate formation of the corresponding mixed *E,Z,Z*- and *E,E,Z*-isomers.¹²³ In the absence of KOH, all other factors being the same, phosphine does not react with alkynes, pointing to a nucleophilic mechanism of this process.

Unlike the reactions of phosphine with aryl- and heteroalkynes (Section III.1.a), the addition of phosphine to alkynes in highly basic suspensions (KOH–HMPA) cannot be terminated at the stage of formation of mono- or diadducts;²² this has been explained⁷ by the fact that vinylphosphines are more acidic than alkylphosphines.

3. Addition to $\text{C}=\text{O}$ bonds

a. Reactions of phosphine with aldehydes

Although the first data concerning the reactions of phosphine with aliphatic aldehydes in the presence of hydrogen halides to give tetrakis(1-hydroxyalkyl)phosphonium halides were reported back

in 1888¹²⁴ and in 1921,¹²⁵ this reaction has not attracted attention of researchers for a long period.

Only 35 years later, did a series of studies appear^{126–134} in which tetrakis(hydroxymethyl)phosphonium salts were prepared in quantitative yields by passing a flow of phosphine through an aqueous or aqueous-organic solution of formaldehyde (–10 to 40 °C, atmospheric pressure) in the presence of acids.

$\text{X} = \text{Cl}^-, \text{F}^-, \text{SO}_4^{2-}, \text{MeCOO}^-, -\text{OOC}-\text{COO}^-; n = 1, 2.$

This reaction, which occurs presumably² *via* the intermediate formation of the $\text{H}_2\text{C}^+\text{OH}$ cation, has also been carried out for non-branched aliphatic aldehydes.^{128,135,136}

In the presence of heavy metals (Fe, Pt, Pd, Hg, Ag) or their salts (PtCl_4 , HgCl_2 , *etc.*), phosphine reacts with an aqueous solution of formaldehyde to give, depending on the ratio of the reactants^{137–139} and the nature¹⁴⁰ and the amount¹³⁰ of the catalyst, either tetrakis(hydroxymethyl)phosphonium hydroxide **11**^{128,130,134,137,138,140} or tris(hydroxymethyl)phosphine **12**.^{130,139–142} In the acid-catalysed reaction the latter product was not detected.^{126–134}

Since the phosphine **12** has also been obtained by treatment of the phosphonium hydroxide **11** with PH_3 in the presence of heavy metals or heavy metal salts,^{11,139} it can be suggested that the compound **12** is formed *via* the compound **11**.

Hydroxyalkylation of phosphine is a general reaction, which has been described for a broad range of aliphatic, unsaturated, aromatic and heteroaromatic aldehydes including acrolein, glyoxal, cinnamaldehyde and furfural. Tris(1-hydroxyalkyl)phosphines can be readily prepared by this reaction in high yields (up to 92%).¹⁴³

$\text{R} = \text{Me}, \text{Et}, \text{CH}=\text{CH}_2, \text{Ph}, 2\text{-FC}_6\text{H}_4, \text{Cl}_3\text{C}, \text{etc.}$

If phosphorylation of aldehydes with phosphine is carried out in the presence of a co-reagent, for example, an organyl halide or an alcohol, and a heavy metal or a heavy metal salt, non-symmetrical phosphonium compounds **13** can be obtained.^{144–146}

$\text{R} = \text{H}, \text{Alk}, \text{Ar}; \text{R}' = \text{Alk}, \text{CH}_2=\text{CHCH}_2, \text{PhCH}_2, \text{HOCH}_2\text{CH}_2,$

$\text{CH}_2\text{I}, \text{O} \diagup \text{CH}_2, \text{O} \diagdown \text{CH}_2; \text{X} = \text{Hal}, \text{OH}.$

Benzaldehyde reacts with phosphine in methanol saturated with HCl^{131,147} to give tris[methoxy(phenyl)methyl]phosphine **14** in 85% yield. Phosphorylation of benzaldehyde with phosphine in the medium of $\text{C}_2\text{--C}_4$ alcohols gives the corresponding secondary phosphines **15** as the main products (yield 80%–90%).¹⁴⁷

$\text{R} = \text{Et}, \text{Pr}^n, \text{Pr}^i, \text{Bu}^n.$

In the absence of alcohol, benzaldehyde reacts with the $\text{PH}_3\text{--HCl}$ system to give, in addition to the tris[hydroxy(phenyl)-

meth]phosphine, 2,4,6-triphenyl-1,3,5-dioxaphosphorinane **16** (in a yield of up to 40%).¹⁴⁷

1,3,5-Dioxaphosphorinanes **17** are the main products of the reaction of phosphine with aliphatic aldehydes substituted at the α -carbon atom carried out in an acid medium.^{135, 148–151}

R = R' = Me (78%); R = Et, R' = Bu (90%).

Apparently, the addition of the secondary phosphines $[\text{R}(\text{R}')\text{CHCH}(\text{OH})_2\text{PH}]$, formed initially in this reaction, to a third aldehyde molecule involves the hydroxy group rather than the PH group and thus gives an acetal fragment.¹⁵¹

Unlike the hydroxyalkylation of phosphine with aldehydes in dilute acids, which gives phosphines,^{3, 131, 147} the reaction of PH_3 with aromatic aldehydes in concentrated aqueous solutions of HCl, HBr and H_2SO_4 affords tertiary phosphine oxides **18** (yield 35%–65%),^{152, 153} apparently as a result of transfer of the aldehyde oxygen atom to phosphorus (the mechanism of this process is described in Section III.3.b).

Dialdehydes (glutaric, succinic,^{135, 151, 154} phthalic,¹⁵⁴ etc.) are usually phosphorylated with phosphine in the presence of concentrated aqueous HCl to give spiroposphonium salts **19** in up to 65% yields.

$n = 2, 3$.

α -Halo-containing aldehydes, for example, chloral,^{135, 155, 156} dichloroacetic,^{135, 156} trifluoroacetic, 2,2-dichlorobutyric and 2,2,3-trichlorobutyric¹⁵⁶ aldehydes react with phosphine in the presence of acids^{135, 155, 156} or without acids in an organic solvent (ether)¹⁵⁵ to give secondary phosphines **20** in high yields (80%–90%).

R = CCl_3 , CHCl_2 , CF_3 , EtCCl_2 , MeCHClCCl_2 .

It has been reported¹⁵⁷ that tris(2,2,2-trichloro-1-hydroxyethyl)phosphine is formed in 75% yield from chloral and PH_3 in the presence of aqueous HCl. However, later it has been shown¹⁵⁸ that passing phosphine through the chloral hydrate–HCl– H_2O system yields initially tris(2,2,2-trichloro-1-hydroxyethyl)phosphine, which then undergoes disproportionation with PH_3 to give a secondary phosphine, bis(2,2,2-trichloro-1-hydroxyethyl)phosphine.

The reaction of phosphine with chloral in the presence of concentrated HCl gave only tris(2,2,2-trichloro-1-hydroxyethyl)phosphine in 92% yield.¹⁵⁸

Phosphorylation of fluorinated aldehydes with phosphine occurs under mild conditions (for example, in the case of trifluoroacetic aldehyde, on cooling to -70°C), requires no catalyst and affords tertiary phosphines **21** in 50%–94% yields.¹⁵⁹

R = F_3C , CF_2CHF_2 , $(\text{CF}_2)_4\text{H}$.

It should be noted that in the absence of a catalyst, phosphine reacts with formaldehyde only at elevated temperatures (80 – 150°C) and pressures (4 – 40 atm)^{160–168} to give, depending on the ratio of the reactants, tris(hydroxymethyl)phosphine^{160–164} or tetrakis(hydroxymethyl)phosphonium hydroxide.^{165, 166}

Phosphorylation of formaldehyde with phosphine in the presence of secondary amines follows the Mannich reaction pattern giving rise to tertiary aminomethylphosphines **22**.^{169–171}

R = Alk, cyclo-Alk, Ar; R' = H, Alk.

b. Reactions with ketones

Being weaker electrophiles than aldehydes, unsubstituted aliphatic ketones do not react with phosphine in the absence of acids or catalysts even under relatively rigorous conditions (100°C , elevated pressure);¹⁷² in the presence of hydrogen halides in anhydrous solvents^{2, 11, 124} or in dilute aqueous solutions of acids^{173–175} the reaction does not occur either. However, in the presence of concentrated mineral acids, phosphine adds to ketones at 60°C and 2–3 atm to give a mixture of primary alkylphosphine oxides **23** and secondary alkyl(1-hydroxyalkyl)-phosphine oxides **24**.^{173–175}

R = R' = Me, Et; R = Me: R' = Pr, Ph; R–R' = $(\text{CH}_2)_4$, $(\text{CH}_2)_5$.

The primary phosphine oxides **23**, which were first synthesised by this method, are formed, in the opinion of the researchers cited,¹⁷³ upon the transfer of the oxygen atom from carbon to phosphorus according to the following scheme:

The second stage of the process, which gives rise to the phosphine oxides **24**, occurs as the normal addition of the P–H bond to the carbonyl group.¹⁷³ The **23**:**24** ratio depends on the structure of the initial ketone and increases in the sequence cyclohexanones < cyclopentanone < acetone < pentan-2-one < heptan-2-one < pentan-3-one < acetophenone < heptan-4-one from 1:9 (for cyclohexanone) to 9:1 (for heptan-4-one).^{173, 174}

Trifluoro-^{176, 177} and hexafluoroacetone^{172, 177} react with phosphine without a catalyst at an elevated temperature (60 – 100°C) and pressure (10 – 30 atm) to give primary phosphines **25** in 85% and 62% yields, respectively.

R = Me, CF₃.

It is believed^{172, 176, 177} that the reaction stops at the stage of formation of the primary phosphines **25** because these products are less nucleophilic than PH₃. However, recently the synthesis of a secondary phosphine, bis[(1-hydroxy-1-trifluoromethyl)-ethyl]-phosphine, from phosphine and trifluoroacetone has been reported.¹⁷⁸

Phosphine and hexafluorocyclobutanone readily react at room temperature to give primary (**26**) and secondary (**27**) phosphines. When excess ketone is used, the yield of the phosphine **27** amounts to 91%.¹⁷⁹

The reaction of 1,5-diketones **28** with phosphine occurs in the presence of HCl as addition–cyclisation with simultaneous transfer of oxygen on the phosphorus atom and results in the formation of 2-hydroxyphosphorinane 1-oxides **29** (yield 30%–80%).^{180–182}

R¹ = R⁵ = Ph, R² = R³ = R⁴ = H; R¹–R² = (CH₂)₄, R³ = R⁴ = H, R⁵ = Ph; R¹–R² = R⁴–R⁵ = (CH₂)₄, R³ = Ph; R¹–R² = (CH₂)₄, R³ = R⁵ = Ph, R⁴ = H; R¹–R² = CH₂CM₂OCH₂, R³ = R⁵ = Ph, R⁴ = H.

Unlike 1,5-diketones, 1,3-diketones **30** react with phosphine in the presence of concentrated HCl to give tricyclic phosphines **31**.^{183–185} The reaction occurs apparently *via* the intermediate secondary phosphine **32**, which forms from two 1,3-diketone molecules; this intermediate undergoes intramolecular cyclisation involving the cross attack on the carbonyl carbon atoms by the hydroxy groups and elimination of water.

R = Me, CF₃.

Tricyclic phosphine **33** with three lactone rings has been obtained from phosphine and pyruvic acid.^{153, 186}

The general character of this reaction was confirmed by involvement of some other oxo acids into the interaction with phosphine.¹⁸⁶

4. Addition to C=N bonds

The addition of phosphine to organyl isocyanates occurs in the presence of triethylamine (room temperature, 2–3 atm, anhydrous benzene), involves the C=N bond and gives rise to tricarbamoylphosphine derivatives **34**, their yields being dependent on the nature of the substituent in the isocyanate and ranging from 13% (phosphorylation of phenyl isocyanate) to 100% (the reaction with nitrophenyl isocyanate).^{187–189}

R = Et, C₈H₁₇, Ph, 4-MeC₆H₄, 4-ClC₆H₄, 4-NO₂C₆H₄.

The fact that mono- or diadducts have not been detected during this reaction (even when the reactants were taken in equimolar amounts) suggests that the intermediate organic carbamoylphosphines are more active nucleophilic addends in this process than PH₃.¹⁸⁷

The addition of equimolar amounts of phosphine to the C=N bond in hexafluoroisopropylideneimine stops when primary phosphine **35** has been produced (yield 96%).¹⁹⁰

5. Reactions of phosphine with oxiranes and thiiranes

Cleavage of an oxirane or thiirane ring by phosphine occurs in the presence of various catalysts.

Heating (50–100 °C) phosphine with oxiranes **36** in the presence of inorganic or organic bases or acids has resulted in the synthesis of tertiary phosphines **37** with oligooxyalkylene oxide radicals.¹⁹¹ Complexes of tris(hydroxymethyl)phosphine with nickel(II) chloride¹⁹² or with chloroplatinic acid¹⁹³ can also be used successfully as the catalysts in this reaction.

R = H, Me, CH₂Cl, Ph; n = 3–10.

In the absence of a catalyst (heating a mixture of phosphine with an oxirane in an autoclave), the total yield of mono-, bis- and tris(2-hydroxyalkyl)phosphines does not exceed 17%.¹⁹⁴

A convenient and efficient method for the synthesis of 2-hydroxyethylphosphine (yield 70%) based on phosphorylation of oxirane by the 'phosphine–sodium metal–liquid ammonia' system has been reported.¹⁹⁴

Later, organylethynloxiranes **38** have also been involved in this reaction to give the corresponding primary hydroxyorganylphosphines **39** in yields of up to 73%.¹⁹⁵

R = Me, Bu, CH₂ = CH.

The attempt to carry out phosphorylation of 1-methyl-1-propyloxirane by the 'phosphine–sodium–liquid ammonia' system failed.¹⁹⁵

Thiirane and its alkyl- and dialkyl-substituted derivatives react with alkali metal dihydrophosphides to give primary 2-sulfanylalkylphosphines.^{196–198}

R = R' = H, Me; R = Me, R' = H.

IV. Other reactions of phosphine with organic compounds

1. Synthesis of esters and amides of phosphorous and phosphoric acids

According to patents,^{199–201} phosphine reacts with sodium alkoxides^{199, 200} or with the alcohol–alkali metal hydroxide systems²⁰¹ in a halogenated hydrocarbon solvent to give triorganyl phosphites. Thus trimethyl phosphite was prepared in a quantitative yield from phosphine and sodium methoxide in CCl₄ at 0–20 °C.¹⁹⁹

Apparently, the reaction starts with the formation of phosphonium salt **40**; the chloride ion in this salt is replaced by the methoxy ion to give the phosphonium salt **41**. This is followed by elimination of chloroform, and the resulting methoxyphosphine **42** reacts again with CCl₄ to give phosphonium salt **43**. The latter is converted into salt **44** upon exchange with sodium methoxide and then into dimethoxyphosphine **45** upon elimination of a CHCl₃ molecule. The last hydrogen atom in the compound **45** is substituted in a similar way.

Heating (80 °C) a mixture of phosphine, sodium phenoxide and CCl₄ in a propylene carbonate medium gives not only triphenyl phosphite but also chloromethylphosphonite **46** and dichloromethylphosphonite **47**, the total yield of the products being 90% (30% of each compound).²⁰⁰

Phosphine reacts with trifluoromethanesulfonyl chloride at –95 °C to give, depending on the ratio of the reactants, *S,S,S*-tris(trifluoromethyl) trithiophosphite or *S,S*-bis(trifluoromethyl) phosphonodithioite in 96% and 72% yields, respectively.^{3, 202}

In recent years, studies have been published dealing with oxidative dehydrocondensation of phosphine with alcohols,^{140, 203, 204} primary²⁰⁵ and secondary¹⁴⁰ amines and pyridine;²⁰⁶ these reactions occur in the presence of copper and platinum compounds and give trialkyl phosphites,¹⁴⁰ trialkyl phosphates,^{140, 203, 204} phosphorous triamides,²⁰⁵ alkylimidophosphoric triamides¹⁴⁰ and tris(2-pyridyl)phosphine,²⁰⁶ respectively. Unfortunately, these publications^{140, 203–206} barely give any experimental details and, what is more important, they present no data confirming the structures of the compounds synthesised.

2. Synthesis of organophosphorus compounds with a mono- or dicoordinated phosphorus atom

Synthesis of organophosphorus compounds with mono- or dicoordinated phosphorus atoms based on phosphine is a topical line of research in modern organic chemistry. However, to the best of our knowledge, the data on these reactions are limited to a few publications.^{207–210}

Thus the reaction of phosphine with *O*-nitrosobis(trifluoromethyl)hydroxylamine at room temperature gave *N*-bis(trifluoromethyl)nitroxyiminophosphine (yield 60%).²⁰⁷

The reaction of phosphine with cyanogen bromide affords aminocarbophosphyl hydrobromide **48**.²⁰⁸ The reaction occurs *via* the initial formation of cyanophosphine hydrobromide, which rearranges into the hydrobromide **48**.

Phosphorus analogues of pyridine, phosphorines **49**, have been prepared by treatment of the pyrylium salts **50** with phosphine in butanol in the presence of mineral acids at 120–130 °C (yields up to 61%).^{209, 210} Apparently, the reaction passes through the intermediate formation of primary phosphines **51** and **52**.

R = Me, Ph; X = BF₄.

V. Conclusion

The data considered in this review demonstrate that phosphine, which is the simplest available phosphorus compound, is a convenient reagent for the formation of a C–P bond in the synthesis of various organic, organoelement and functionally substituted phosphines, which are finding ever increasing use as ligands for the preparation of metal-complex catalysts.

The ease and practical feasibility of the preparation of phosphine by direct hydrolysis of elemental phosphorus, which had been noted long ago by D I Mendeleev and V N Ipat'ev,²¹¹ and its high, although not adequately studied, reactivity are the objective prerequisites for more extensive involvement of phosphine in organophosphorus synthesis.

However, it should be noted that unlike its nitrogen analogue — ammonia — which has become the synthetic base for the whole chemistry of the organic compounds of nitrogen, phosphine has not found equally wide use in organophosphorus chemistry despite the numerous obvious advantages of phosphine over, for example, phosphorus chlorides.

The authors hope that this review would be favourable for further development of the chemistry of phosphine and, first of all, development of new convenient methods for the synthesis of various organophosphorus compounds based on phosphine. The exceptionally simple method for the generation of a phosphine–hydrogen mixture by alkaline hydrolysis of red phosphorus that we developed previously may stimulate further studies along this line.^{6, 7, 14, 22}

The review was written with the financial support of the Russian Foundation for Basic Research (Project No. 98-03-32925a).

Abstract. The methods for the introduction of tritium (by chemical synthesis and isotope exchange in both solution and solid state) into biologically active diazines, *viz.*, nucleic acid components (heterocyclic bases, nucleosides, nucleotides), DNA synthesis terminators and cytokinins are considered. The bibliography includes 178 references.

I. Introduction

Recent progress in molecular biology, biochemistry, molecular genetics and experimental medicine are largely determined by the possibility of wide use of various radioactively labelled compounds. The application of such compounds has allowed direct studies of the mechanisms of chemical and biochemical reactions, as well as metabolic pathways in living organisms (*in vivo*) and in open systems (*in vitro*). Determination of quantitative characteristics of biochemical processes with the aid of labelled compounds is important for understanding of the essential features of processes occurring in living organisms and elucidation of the regulatory mechanisms underlying metabolism.

For over three decades now, researchers have been showing unremitting interest in tritium-labelled compounds. This is due to the valuable physical properties of tritium: its half-life period is sufficiently long for conducting experiments of virtually any duration; the low energy of tritium β -particles ($E_{\max} = 18.6$ keV) determines low radiotoxicity of tritium-labelled compounds, which makes it possible to handle relatively large quantities of this isotope without special protective measures. Substitution of one tritium atom for hydrogen yields a compound with a molar radioactivity (A_{mol}) of 29.12 Ci mmol⁻¹. The use of such preparations and modern scintillation counters allows detection of $< 10^{-14}$ mol of a labelled compound.

Pyrimidine (1) is the most important compound among the diazines, since its derivatives, *viz.*, uracil (2), thymine (3), and cytosine (4), form part of nucleic acids. Barbiturates (5), alloxan (6) and orotic acid (7) are also pyrimidine derivatives and contain no condensed rings. Among the polycyclic derivatives of pyrimidine, like pteridine (8), purine (9) deserves to be mentioned. Its derivatives, adenine (10) and guanine (11), also form part of ribo- and deoxyribo-nucleic acids. Other purine derivatives, such as hypoxanthine (12), xanthine (13), theobromine (14), theophylline (15), caffeine (16), and uric acid (17) are important natural compounds, which show biological activity. 2'-Deoxyribose (18) and ribose are linked to nitrogen bases through the N-glycosidic bond. These compounds have been called deoxyribonucleosides (18a) and ribonucleosides (18b), respectively, and the phosphorus esters of nucleosides have been termed nucleotides (18c–18e). We have thus grouped the natural diazines under the common name of 'components of nucleic acids'. The number of such compounds for the main bases (2–4, 10, 11) of nucleic acids is more than 40.

In recent years, considerable attention is being devoted to the so-called cytokinins, which are derivatives of 6-aminopurine, discovered in the 1950s. The cytokinins are natural substances that promote germination and blossoming of plants and retard their wilting. When used at concentrations 10^{-3} – 10^{-5} mol litre⁻¹, they stimulate cell division. The principal cytokinins are kinetin (**19**), zeatin (**20**), benzylaminopurine (**21**) and a number of other compounds.

Analogues of nucleosides with the modified glycoside ring often appear to be DNA synthesis terminators. Azidothymidine (**22**), acyclovir (**23**), nucleoside phosphinates **24a** and nucleoside methylphosphinates **24b**, 5'-O-hydroxyphosphoryl-2'-deoxynucleosides **25a** and the corresponding nucleotides **25b** may be cited as examples. They are potential inhibitors of retroviruses, including the HIV virus.^{1,2}

This review considers methods used for the preparation of the above-mentioned compounds labelled with tritium. The main attention is centred on the general methods allowing synthesis of the widest set of compounds with maximum molar radioactivity.

II. Dehalogenation in solution

The reaction of catalytic hydrogen-for-halogen replacement (hydrogenolysis) has been known for a long time;³ however, its use for the synthesis of tritiated compounds has come into practice relatively recently.^{4,5} Catalytic dehalogenation is usually carried out in air-tight vessels with vigorous stirring of a suspension of a catalyst in solution of a halogenated compound under gaseous tritium. In this type of reaction, both polar and nonpolar solvents are employed. The tritium halide formed in this reaction must be neutralised since it poisons the catalyst, which leads to deceleration of the reaction.⁶ The mechanism of tritium incorporation into the solvent under conditions of catalytic dehalogenation (catalysts PdO, Pd/BaSO₄, Raney nickel) has been considered.⁷

Catalysts of hydrogenation (mainly, supported Pd) are used for dehalogenation. The conditions for catalytic dehalogenation for the synthesis of tritium-labelled compounds have been published.^{8,9} Examples of precursors and target compounds obtained by dehalogenation are given in Table 1.

Table 1. Results of halogen – tritium replacement in purines and pyrimidines.

Precursor	Target compound	<i>A</i> _{mol} (sec ^a)	Ref.
5-Iodocytidine	[5- ³ H]cytidine	17.4	10

^a Dimension/ Ci mmol⁻¹.

Synthesis of a tritium-labelled compound **10** has revealed¹¹ that dehalogenation in aprotic solvents (dimethylformamide, dimethyl sulfoxide, dioxane) in the presence of catalysts (Pd black, Pd on carbon and on BaSO₄) has no advantages over the reaction in a protic solvent (aqueous – ethanolic solution): in both cases the maximum radioactivity is not attained. In the introduction of a tritium label into adenosine and guanosine, the rate of dehalogenation of the corresponding 8-bromo-compounds in 1 M KOH and 0.1 M HCl was higher than that in water; however, the

yields of labelled compounds and their molar radioactivity were larger in alkaline solution.¹⁶ Table 1 presents data that characterise the synthesis of specific compounds. This reaction was not investigated as a method for the synthesis of tritiated diazines. In particular, the isotope effects of hydrogen, the ratio of reactants, the nature of reagents and the activity of catalysts have not been found to influence the yield and the molar radioactivity of the target compounds. Hydrogenolysis has been investigated as a method for the incorporation of a tritium label into diazines.^{26–31} Hydrogenolysis of various compounds was conducted in the same solvents and with the same parameters such as tritium pressure, solvent, temperature, concentration of halogenated compound and reaction time. The basic characteristics of hydrogenolysis with tritium of bromo-substituted purines²⁶ and pyrimidines²⁷ are presented in Table 2.

Table 2. Basic characteristics of catalytic dehalogenation with tritium of 8-bromosubstituted purines and 5-bromo-substituted pyrimidines on supported Pd as the catalyst.^{26,27}

Labelled compound	Tritium concentration (%)	Yield (%)	A_{mol} / Ci mmol^{-1}

^a Trioctylammonium salt (TOA).

The processes occurring in the hydrogen–palladium–water system with participation of hydrogen isotopes (protium and tritium) and their influence on the molar radioactivity (A_{mol}) of hydrogenolysis products have been investigated.²⁷ It was pointed out that one of the major reasons for the decrease in A_{mol} of the target compounds is the dilution of tritium with protium due to isotope exchange with the solvent protons and high values of protium–tritium partition coefficients ($\alpha_{\text{H-T}}$ reaches 12). The processes with different kinetics are analysed below.

1. The rate of the main reaction (dehalogenation, hydrogenation, isotope exchange) is much higher than that of tritium isotope exchange with the solvent (tritium is virtually undiluted with protium). Here, two extreme cases are possible: (a) if the contribution from the reaction of homomolecular isotope

exchange may be disregarded, the molar radioactivity of the reaction product is equal to the A_{mol} of the initial tritium with consideration of the isotope effects of hydrogen on dissolution and adsorption on palladium (for this process $\alpha_{\text{H-T}} = 2.5$); (b) if an isotope equilibrium is established on palladium, it is necessary to take into account the reaction of monomolecular isotope exchange ($\alpha_{\text{H-T}} = 4.7$ or 3.6 for 50% tritium).

2. The rate of the main reaction is comparable or lower than the rate of isotope exchange of tritium with the solvent, *i.e.*, continuous dilution of tritium with protium takes place. Examination of this process requires consideration of the isotope equilibrium in the hydrogen–palladium–water system ($\alpha_{\text{H-T}} = 12$). Table 3 presents data that illustrate the effect of tritium concentration on the molar radioactivity of labelled products obtained by the reaction in an aqueous solution for different protium–tritium partition coefficients. The extreme values of A_{mol} (2.2 and 28.3 Ci mmol^{-1}) were calculated for the extreme cases. Hence, the increase in the molar radioactivity of purine and pyrimidine compounds is related to minimisation of the effect of hydrogen isotope partition on palladium in the course of catalytic dehalogenation in solution.

Table 3. Effect of isotopy on the molar radioactivity of labelled products of hydrogenolysis in aqueous solution.

[³ H] (%)	A_{mol} (Ci mmol^{-1}) for different $\alpha_{\text{H-T}}$ values			
	2.5	3.6	4.7	12
99	28.3	—	27.8	26.0
95	25.4	—	23.3	17.8
90	22.2	—	19.1	12.5
85	19.5	—	15.9	9.3
80	17.1	—	13.4	7.3
75	15.1	13.2	—	5.8
70	13.3	11.5	—	4.7
60	10.2	8.6	—	3.2
50	7.7	6.3	—	2.2

One of the ways of minimisation is enhancement of the rate of the main dehalogenation reaction, which can be achieved using more active palladium catalysts. The A_{mol} can increase with the greater palladium/bromo-substituted compound ratio. This is characteristic mostly of purine compounds.

Yet another method for the increase in molar radioactivity is the use of catalysts with a low (0.01%–0.05%) percentage of supported palladium.³¹ In such catalysts, virtually no dissolution of the hydrogen isotopes occurs, and the hydride form is absent. If the protium–tritium partition coefficient is assumed to be equal to 2.5, the molar radioactivity of the dehalogenation product with 95% tritium must reach 25.4 Ci mmol^{-1} , which is consistent with the experimental data.³¹ In practice, low-percentage supported palladium catalysts are rarely employed, since satisfactory yields of the target products are obtained at definite precursor/catalyst ratios in the reaction mixture (approximately 1 g of a catalyst per 1 mg of a precursor). This requires a larger volume of the solvent and, consequently, leads to a greater volume of the reaction tube, increased uptake of gaseous tritium, more difficult stirring of the reaction mixture, *etc.*

Gordeeva *et al.*³² have described the synthesis of nucleoside 5'-triphosphates labelled with tritium in position 5 of the pyrimidine ring and in position 8 of the purine ring by catalytic dehalogenation of the corresponding bromo-substituted precursors.³² The A_{mol} values of the compounds obtained are presented in Table 4. As a rule, the tritium-labelled nucleoside 5'-triphosphates have higher molar radioactivities than the nucleoside 5'-monophosphates prepared under similar conditions. These results correlate with the suggested³⁰ interrelation of such parameters as the sorption degree of the initial compounds on the catalyst and

Table 4. Results of catalytic dehalogenation of bromo-substituted nucleoside 5'-triphosphates with gaseous tritium.³²

Initial compound	Catalyst	$A_{\text{mol}} / \text{Ci mmol}^{-1}$
8-Bromo-ATP	5% Pd/BaSO ₄	17

[5- ³ H]1- β -D-Arabinofuranosylcytosine	20.0
1-[(3- ³ H]Tetrahydrofuryl-2)-5-fluorouracil	29.7
[8- ³ H]9- β -D-Arabinofuranosyladenine	20.0
5-Amino-7-(2[2',3',5'- ³ H ₂]phenylethyl)-2-(2-furyl)pyrazolo[4,3- <i>e</i>]-1,2,4-triazolo[1,5- <i>c</i>]pyrimidine	68.6

Tritium-labelled purine and pyrimidine nucleoside phosphates have been prepared by catalytic dehalogenation of respective bromo-substituted precursors with gaseous tritium.⁴¹

Baraldi *et al.*⁴² have synthesised three tritiated inhibitors of reverse transcriptase by hydrogenolysis of bromobenzoazole precursors. The molar radioactivity of the compounds obtained was 3–10 Ci mmol^{−1}.

In the process of dehalogenation, tritium can be incorporated not only into the heterocyclic base but also into the carbohydrate moiety of the molecule. Thus dehalogenation of the corresponding precursor has yielded [2',3'-³H]2',3'-dideoxythymidine 5'-phosphate.⁴³

The experimental procedure for the catalytic dehalogenation in solution is relatively simple and the products have rather high molar radioactivity. In these products, the tritium label is as a rule in a definite position determined by the replacement of the halogen atom by tritium. With a set of halogenated precursors at disposal, this reaction can be used for the synthesis of a series of the required tritium-labelled compounds. A disadvantage of this method is the necessity to synthesise special halogenated precur-

sors. For example, in order to prepare [2-³H]ATP it was necessary to carry out a six-stage synthesis of 2-bromo-ATP from guanosine.³⁵

III. Catalytic dehalogenation without a solvent

The solvent-free method of catalytic dehalogenation has been proposed for the synthesis of ³H-labelled uracil.⁴⁴ For this purpose, 5-iodouracil applied onto a Pd catalyst was treated with gaseous tritium under the conditions of a high-voltage and high-frequency discharge. This resulted in the formation of [5-³H]uracil ($A_{\text{mol}} = 16.1 \text{ Ci mmol}^{-1}$). Tritium-labelled thymine was prepared by the dehalogenation of 5-halogenomethyluracil with gaseous tritium over a Pd catalyst at 100 °C.⁴⁵ This method has been studied in detail in the synthesis of tritium-labelled components of nucleic acids and was called solid-state catalytic reductive dehalogenation (SCRD).⁴⁶ The SCR D reaction can be initiated in two ways, *viz.*, by a high-voltage and high-frequency electric discharge⁴⁷ and heating from 50 to 150 °C.⁴⁸ The kinetics of SCR D has been investigated and its mathematical model has been proposed in which the catalyst was regarded as a consumable component of the reaction. The proposed model explains well the dependence of the yield and A_{mol} of the target compounds on the percentage of palladium on the support. Some kinetic characteristics of SCR D are presented in Table 5. The SCR D method was employed for the preparation of the following ³H-labelled compounds:⁴⁶

Compound	$A_{\text{mol}} / \text{Ci mmol}^{-1}$	Compound	$A_{\text{mol}} / \text{Ci mmol}^{-1}$
[5- ³ H]Uracil	16.1	[8- ³ H]2'-deoxyadenosine	16.4
[Methyl- ³ H]thymine	3.1	[8- ³ H]AMP	4.9
[8- ³ H]Guanine	12.4	[8- ³ H]GMP	5.2
[5- ³ H]Cytidine ^a	16.3	[5- ³ H]UMP	2.8
[8- ³ H]Guanosine	6.7	[5- ³ H]CMP	5.9
[8- ³ H]Adenosine ^a	10.6	[8- ³ H]dAMP	2.1
[5- ³ H]Uridine ^a	11.5	[8- ³ H]dGMP	1.6
[5- ³ H]2'Deoxyuridine ^a	18.5	[8- ³ H]dCMP	1.7
[5- ³ H]Deoxycytidine ^a	33.0		

^a Degradation products of the corresponding nucleotides.

If SCR D is carried out at elevated temperatures, some by-products are produced along with the target compounds due to the cleavage of the phosphoester and N-glycosidic bonds. The molar radioactivity of degradation products is higher than that of the target compound, which seems to be related to molecular excitation upon cleavage of these bonds. The results obtained indicate that the A_{mol} of the compounds does not reach its theoretical value on substitution of one halogen atom by tritium (29.12 Ci mmol^{−1}). This is explained⁴⁶ by dilution of the initial gaseous tritium by the mobile hydrogen present in the substance–catalyst system (hydrogen is capable of rapid isotope

Table 5. Kinetic parameters of SCR D of bromo-substituted components of RNA.⁴⁶

Initial compound	Reaction rate constant (min ^{−1} mmol ^{−2}) at different temperatures (°C)					$E / \text{cal mol}^{-1}$
	100	78	56	35	23	
8-Bromo-AMP	30.45	20.62	14.03	10.42	8.06	3380

5-Bromo-UMP	24.00	17.15	10.80	6.55	4.74	4760
5-Bromo-CMP	33.25	16.15	10.29	4.89	1.76	6470

exchange). In the solid-state process, some labile hydrogen is present in the compound to be labelled and in the catalyst itself.⁴⁶ It was found experimentally that 100 mg of 5% Pd/C catalyst contains 0.21 mmol of hydrogen capable of isotope exchange with tritium.

The SCRD process has not found wide practical usage for the synthesis of tritium-labelled diazines, since the reactions in solution are experimentally simpler and make it possible to obtain comparable, and often higher, A_{mol} values of the products. Nonetheless, the appearance of the SCRD method may be regarded as an important stage in the development of solid-state reactions involving gaseous tritium.

IV. Reactions of isotope exchange

There is a certain distinction between reactions of isotope exchange with tritium-containing solvents (including tritiated water) and catalytic reactions involving gaseous tritium. The reactions of catalytic isotope exchange are most often carried out using heterogeneous palladium catalysts,⁴⁹ homogeneous catalysts, such as trifluoromethanesulfonic acid,⁵⁰ rhodium trichloride and ruthenium acetylacetonate,⁵¹ as well as catalysts composed of polymers^{52,53} and metals (Pt, Ni, Rh) applied to hydrophobic supports (Teflon, polyethylene, polystyrene).⁵⁴ The isotope exchange of activated aromatic protons in the $\text{AcO}^3\text{H}-3\text{HCl}$ solution has been investigated.⁵⁵ The catalytic role of metals and hydrogen ions has been discussed in Ref. 56.

1. Reactions with tritium-containing solvents

Reactions with a tritium-containing solvent, which is most often represented by tritiated water, are usually carried out in a strongly alkaline aqueous solution.⁵⁷ Werstiuk and Ju⁵⁸ have proposed a preparative method for the specific introduction of hydrogen isotopes into fused benzoheterocycles. This method is based on the isotope exchange with deuterated or tritiated water at a temperature above 145 °C. The methods for the preparation of heterocyclic and heteroaromatic compounds containing hydrogen isotopes have been reviewed.^{59,60}

The nucleic acid components exchange most readily the proton bound to the C(8) atom of the purine bases. The hydrogen bound to the C(2) atom is exchanged with a much greater difficulty. For example, by employing ^1H NMR spectroscopy (pD 6–7, 100 °C), Wong and Keck⁶¹ have shown that the rate of isotope exchange of hydrogen at the C(8) atom of adenine is ~ 1000 times as high as that at the C(2) atom.

Eidinhoff and Knoll⁶² observed the exchange of the proton bound to the C(8) atom of adenine in the presence of a reduced platinum catalyst. The hydrogen isotope exchange has also been reported to occur on heating (> 90 °C) of purine and adenosine in D_2O .^{63,64} Such an exchange leads to the disappearance of the peak corresponding to signals for the protons at the C(8) atom in the ^1H NMR spectra of these compounds. IR spectroscopy of the isotope exchange in the purine base residues in the DNA macromolecule has also pointed to the preferential exchange of the C(8) hydrogen.⁶⁵

Shelton and Clark⁶⁶ have used the reaction of isotope exchange for the incorporation of tritium into purine compounds. This reaction was conducted in an alkaline medium with tritiated water on heating to 100 °C. It was established that the guanine compounds were labelled more rapidly than the adenine ones. The exchange rate is increased in both bases as the pH is increased from 2 to 11. The conditions for tritium labelling are rather mild. This allowed one to apply them for the preparation of tritium-labelled nucleosides (adenosine, deoxyadenosine, and nucleotides), adenosine 3',5'-cyclomonophosphate⁶⁷ and ATP.⁶⁸

The kinetics of isotope exchange with water and the dependence of the rate constant of isotope exchange in ATP and GTP on pH have been investigated.⁶⁹ The kinetics of the incorporation of the tritium bound to the C(8) atom of purines of poly(A), poly(A)-poly(U) duplex, RNA, tRNA and DNA was studied by Gamble *et*

*al.*⁷⁰ The reaction of tritium–hydrogen exchange has been used for the introduction of tritium into oligonucleotides,⁷¹ oligodeoxyribonucleotides,⁷² polyribonucleotides,⁷³ DNA,^{74–77} tRNA^{Ileu} and tRNA^{Tyr} from yeast.⁷⁸ Drutsa⁷⁹ has proposed optimal conditions for the introduction of tritium into oligodeoxyribonucleotides: 2–4 h at 60 °C in tritiated water in an 0.3 M NaOH solution. Isotope exchange with tritiated water has been used for the preparation of an inhibitor of 5-lipoxygenation of arachidonic acid, which is an antiprosthetic agent ($A_{\text{mol}} = 19.8 \text{ Ci mmol}^{-1}$).⁸⁰ Mackenzie *et al.*⁸¹ have investigated the isotope exchange of the hydrogen bound to the C(2) atom in ethyl 5-amino-1-(2,3-*O*-isopropylidene- β -D-ribofuranosyl)imidazole-4-carboxylate (pH 1.77–12.0, 65 °C).

The analysis of changes in the isotope exchange rate of protons at the C(8) atom of purine residues provided information about conformational changes in natural biopolymers such as polynucleotides^{82–85} and RNA.^{70,86,87} It has been established that the rate of hydrogen exchange at the C(8) atom in adenine, guanine and hypoxanthine in nucleic acids is comparable with the respective rates in nucleoside monophosphates.⁸⁸ In DNA, the protium–tritium exchange is approximately 2.4–2.8 times as slow as that in deoxynucleoside monophosphates.⁸⁹

The study of the mechanism of isotope exchange with water in the C(8)H groups of purines has shown^{87,90,91} that the exchange proceeds by the so-called ylide mechanism, *viz.*, not in neutral molecules, but in the protonated [at the N(7) atom] forms of purine derivatives and in zwitter-ions with a positive charge on the N(7) atom. Agranovich *et al.*⁹² have studied the kinetics of protium–tritium exchange between water and the C(8)H group of purine bases, mono- and polynucleotides for different specific radioactivities of the medium over a wide temperature range (from 4 to 80 °C) and for different pH. It was shown that at high specific radioactivity of the medium, two non-competitive parallel exchange reactions occur simultaneously in the temperature interval studied: one follows the ylide mechanism and the other proceeds with participation of highly reactive radicals resulting from radiolysis of water under the action of β -radiation from tritium. The relative contribution from the radical exchange to the observed reaction rate decreases with higher temperature and lower specific radioactivity of the medium. In the case of polynucleotides and DNA, the isotope exchange follows basically the ylide mechanism at temperatures above 25 °C and in the case of nucleotide **18c** — above 37 °C (at a specific radioactivity of the medium of 1 Ci ml^{-1}). The increase in the medium acidity to pH 1 accelerates appreciably the radical exchange reaction, while the presence of β -mercaptoethanol decelerates it sharply. Changes in the observed hydrogen exchange rate in the C(8)H group of purine allow the estimation of variation of the pK_a of polynucleotides and nucleic acids caused by changes in the macromolecular conformation.⁹³

The protons bound to the C(5) atom of pyrimidines are readily exchanged for tritium from the tritium-containing water in uracil photohydrates. The isotope exchange between 5,6-dihydro-6-hydroxyuridine 5'-phosphate and tritiated water with heating yields 5-tritium-substituted uridine 5'-phosphate.⁹⁴ Boer and Johns⁹⁵ have reported a method for the preparation of tritium-labelled 5,6-dihydro-6-hydroxyuridine 5'-phosphate on heating with tritiated water. Similar exchange was observed in the photohydrates of cytosine derivatives.⁹⁵ The reaction of hydrogen isotope exchange between uracil and tritiated and deuterated water proceeds only in the presence of Pt and Pd catalysts.^{96,97} In the absence of a catalyst, this reaction takes place only under very drastic conditions.^{98–100} The exchange of C(5) hydrogen is markedly easier than that of the C(6) hydrogen. Wechter¹⁰¹ has proposed conditions for isotope exchange allowing the selective deuteration of C(6) in pyrimidine nucleosides. This method consists in the synthesis of 5,6-dideuterio compounds and the reexchange of deuterium from position 6 under special conditions. An analogous method has been proposed by Rabi and Fox.¹⁰² Isotope exchange of the hydrogen bound to the C(5) in pyrimi-

dines is accelerated in the presence of citrate buffer¹⁰³ and such compounds as 2-mercaptoethylamine, ethylamine, ethanolamine, sodium hydroxide,¹⁰⁴ hydrogensulfite anion,^{105, 106} methyl-, dimethyl- and trimethyl-amine hydrogensulfites, ethyl- and diethyl-amine, and imidazole,¹⁰⁷ cysteine and other sulfur-containing compounds, *e.g.*, 2-mercaptoethanol.^{108, 109} Under specific conditions, the reaction of nucleic acids with hydrogensulfite in the presence of tritiated water results in the transformation of the cytidine fragments into uridine fragments.¹⁰⁶ In all cases, the isotope exchange proceeds under mild conditions. Tritium is incorporated into uracil and cytosine derivatives in alkaline and acidic medium, respectively. These reactions can be used for the synthesis of tritium-labelled pyrimidine derivatives.

Hesk *et al.*⁵¹ have described a method for homogeneous hydrogen isotope exchange under the action of RhCl₃ in dimethylformamide at 110 °C, which allows high regioselective introduction of tritium in the *ortho*-position of various aromatic acids, amides, amines and heterocyclic compounds. This study has also shown that in addition to RhCl₃, ruthenium acetylacetonate is another efficient catalyst of isotope exchange in the *ortho*-position of benzoic acids.

The reaction with tritium-containing solvents is a versatile method for the preparation of tritium-labelled compounds, diazines in particular. This method does not require synthesis of special precursors, and the conditions of tritium labelling are sufficiently mild to allow its use for the incorporation of this label into compounds of rather complex structure, *e.g.*, nucleic acids. When employing this reaction, the main attention should be paid to the choice of efficient homogenous or heterogeneous catalysts and solvents (tritium sources). A disadvantage of this method is a relatively low level of molar radioactivity of the target products. This is mainly determined by the specific radioactivity of the tritiated water used, which usually does not exceed 100–200 Ci ml^{−1} (3%–6% of its theoretical level). Tritiated water with higher specific radioactivity is unstable because of its autoradiolysis. Reactions of isotope exchange may be carried out with the tritiated water with very high specific radioactivity if it is mixed with an inert anhydrous organic solvent.¹¹⁰ The isotope exchange with steroids has demonstrated¹¹⁰ that the maximum A_{mol} is reached when a solution of ³H₂O (2%–3%) in an inert solvent is used. This corresponds to a volume radioactivity of a solution of 65–100 Ci ml^{−1}. Solutions of highly active tritiated water were prepared by the oxidation of gaseous tritium over palladium oxide in an anhydrous organic solvent. Tritium-labelled benzylaminopurine has been obtained using highly active ³H₂O ($A_{\text{mol}} = 24$ Ci mmol^{−1}).¹¹¹ The proposed method is laborious, while disadvantages such as relatively low levels of molar radioactivity (a few tens of Ci mmol^{−1}) and the necessity to use large volumes of tritiated water prevent its wide application for the synthesis of tritium-labelled components of nucleic acids. However, this method proves to be virtually the only one possible for compounds containing groups that can be readily reduced and/or hydrogenated (*e.g.*, steroids and pharmaceutical preparations¹¹²).

2. Catalytic liquid-phase heterogeneous isotope exchange with gaseous tritium

In 1974, two reports^{113, 114} were published simultaneously on the method of tritium labelling of organic compounds based on isotope exchange of gaseous tritium with hydrogen in the compound subject to labelling dissolved in an appropriate solvent in the presence of heterogeneous catalysts. Buchman *et al.*¹¹³ have proposed a method of non-specific labelling with gaseous tritium in the presence of an activated platinum catalyst. The catalyst PtO₂ was more active than PdO in the isotope exchange reaction.¹¹⁵ Evans *et al.*¹¹⁴ conducted the isotope exchange reaction in a phosphate buffer in the presence of a PdO/BaSO₄ catalyst. Tritium was incorporated into carbohydrates, aliphatic and aromatic amino acids and nucleic acid components. Table 6 shows the conditions of isotope exchange reactions for the introduction of tritium into purine and pyrimidine compounds

Table 6. Purine and pyrimidine compounds prepared by catalytic heterogeneous isotope exchange with gaseous tritium.¹¹⁴

Compound	Reaction conditions		$A_{\text{mol}} / \text{Ci mmol}^{-1}$
	pH	<i>t</i> / min	
Arabinosyladenosine	8.2	240	5.6
Adenosine	8.2	120	12.0

	8.0	60	2.5

Notes. Abbreviations: IMP, inosine 5'-monophosphate; NAD, nicotinamide adenine dinucleotide.

with this method. This is of a high practical value for the synthesis of tritium-labelled components of nucleic acids. Presumably, the isotope exchange proceeds by the free-radical mechanism and is facilitated for mobile hydrogen atoms, such as aromatic protons and hydrogen bound to the C(8) atom of purines. One could hardly expect high levels of molar radioactivity for the compounds with aliphatic protons, and it seems for protons combined with C(5) and C(6) of pyrimidines. Hanus *et al.*¹¹⁶ have employed heterogeneous catalysts (PdO, PtO₂ and Pd/BaSO₄) in order to investigate the process of tritium incorporation into such compounds as dioxane, tetrahydrofuran, ethyl acetate, dimethylformamide, dimethylacetamide and acetic anhydride. It was shown that the proportion of tritium incorporated by the direct interaction with the solvent is negligibly small compared with that introduced in the presence of catalysts. The degree of tritium incorporation depends on the solvent purity. In extremely pure solvents, the tritium is present in the form of heavy water.

The method of catalytic heterogeneous exchange with gaseous tritium has allowed synthesis of [³H]acyclovir³⁹ and the following tritium-labelled compounds:^{117–120}

Compound	$A_{\text{mol}} / \text{Ci mmol}^{-1}$
5-Azacytidine	17.4
5-Aza-2'-deoxycytidine	19.5
<i>N</i> ⁴ -(5-Aminopentyl)cytidine	3.0
5-Methylcytidine	1.9
5-Methylcytosine	4.2
Arabinosyl-5-azacytosine	12.5
5-Hydroxy[6- ³ H]uracil	0.35
5-Amino[6- ³ H]uracil	2.4
1-β-D-Arabinofuranosyl[5,6- ³ H]cytosine	12.0
9-[(2-Hydroxyethoxy)methyl][8- ³ H]guanine	8.8
9-β-D-Arabinofuranosyl[8- ³ H]adenine	1.0

Kaminskii *et al.*³⁸ have demonstrated that the use of AMP 1-*N*-oxide as the precursor facilitates significantly the tritium exchange

at the C(2) atom of the adenine ring. Introduction of tritium into adenine dinucleoside phosphates¹²¹ and the P–H group of 2'-deoxyadenosine 5'-H-phosphonate has been described.¹²²

The rate constants for liquid-phase catalytic heterogeneous protium–tritium exchange of [8-³H] nucleotides of the adenine series with hydrogen¹²³ have been measured (the experimental procedure is given in Ref. 124). It has been established¹²⁵ that the exchange rate decreases in the following sequence: cAMP > ATP > ADP > AMP. An equation of the dependence of the rate constant for isotope exchange on pH has been deduced. At low concentrations of nucleotides, the reaction order with regard to nucleotide is 1, whereas at higher nucleotide levels it is close to 0.

Lacey *et al.*¹²⁶ have described a general method for specific introduction of tritium label into benzoimidazole carbamates (BIC), which includes catalytic isotope exchange in dioxane at 60 °C under gaseous tritium. The yield of labelled BIC was found to range from 8% to 70% with the molar radioactivity varying from 0.44 to 13.4 Ci mmol⁻¹. The use of gaseous tritium in the presence of a catalyst based on iridium complexes has made it possible to obtain high levels of molar radioactivity for benzophenones, quinolines, 2-aminopyridines, 2-aminobenzoxazole derivatives, benzoazepinone amides and complex benzamides.¹²⁷

It is noteworthy that the reactions of catalytic dehalogenation and catalytic heterogeneous isotope exchange proceed under similar conditions. This fact should be taken into account in conducting catalytic reactions of hydrogenation, dehalogenation, *etc.* The tritium label can be introduced by both a chemical reaction and isotope exchange. For example, dehalogenation of monobromopapaverine on a palladium catalyst yielded a product with $A_{\text{mol}} = 43 \text{ Ci mmol}^{-1}$ (see Ref. 128). In this case, the percentages of the label due to the tritium substitution for bromine and the exchange of the methylene group proton with tritium were 49% and 46%, respectively, with 5% of the tritium introduced in other positions. A similar process takes place on dehalogenation of 2-halogeno-purines: tritium substitutes hydrogen at the C(2) atom owing to dehalogenation reaction and at the C(8) atom owing to isotope exchange.³⁸

This reaction underlies the most versatile method used for the preparation of tritium-labelled compounds. As regards its general character, the method described is comparable to the isotope exchange with a tritium-containing solvent. The main advantage of this method consists in high levels of molar radioactivity of the compounds obtained. This is due to the fact that the isotope source is a high-percentage (> 95%) gaseous tritium whose molar radioactivity is higher than that of any tritium-containing solvent. A disadvantage of this method is that processes of dehalogenation, hydrogenation and reduction of various functional groups can take place under given reaction conditions.

V. Reduction and hydrogenation

Processes of reduction and hydrogenation are used mostly for the introduction of tritium into the methyl group of thymine and its derivatives, and also into the carbohydrate moiety of nucleosides. Reduction is usually performed by means of catalytic reactions using gaseous tritium and tritium-labelled NaBH₄ and LiAlH₄. Coates *et al.*¹²⁹ have proposed to use lithium triethylborotritide (super-tritide) obtained by the reaction of LiT with Et₃B for the incorporation of tritium into various compounds by the reduction of certain functional groups.

Tritium-labelled thymidine ($A_{\text{mol}} = 27.5 \text{ Ci mmol}^{-1}$) was prepared by the reduction of 5-hydroxymethyl-2'-deoxyuridine in the presence of rhodium on alumina as a catalyst.¹³⁰ Tritium-labelled 5-hydroxymethyl-2'-deoxyuridine was synthesised by the reduction of 5-formyl-2'-deoxyuridine in a phosphate buffer.¹³¹

Hydrogenation of 5-hydroxymethyl- and 5-formyluracil in the presence of a palladium catalyst yielded^{132, 133} thymine with up to 2 tritium atoms in the methyl group. Successful application of Raney nickel for the reduction of 5-formyluracil to 5-hydroxymethyluracil has been reported.¹³⁴ Hydrogenation of 5-formyluracil

in water with gaseous tritium over 1.5% Pd/BaSO₄ produced 5-hydroxymethyl[hydroxymethyl-³H]uracil ($A_{\text{mol}} = 64.8 \text{ Ci mmol}^{-1}$).¹³⁵ Further reduction of the latter with tritium over palladium in dry dioxane yielded [methyl-³H]thymine.¹³⁶ In order to prepare thymine with the complete substitution of hydrogen by tritium in its methyl group, Yakovleva *et al.*¹³⁷ carried out catalytic reduction of 5-cyanouracil to aldimine followed by its hydrolysis to 5-formyluracil with subsequent catalytic reduction with gaseous tritium. Reduction of 5-formyluracil ethylene dithioacetal with tritium in dioxane over Raney nickel also led to the formation¹³⁸ of [methyl-³H]thymine ($A_{\text{mol}} = 11.6 \text{ Ci mmol}^{-1}$). Catalytic reduction of 5-formyluracil with gaseous tritium is described in Ref. 139.

One-stage methods for the preparation of tritium-labelled thymidine 5'-monophosphate (TMP, **27**) have been reviewed.¹⁴⁰ The precursors of TMP were 5-hydroxymethyl-dUMP (**26**) and 5-formyl-dUMP. It was established that under specific conditions (depending on the nature of catalyst employed and the reaction medium) hydrogenation can affect the 5,6-double bond of the pyrimidine ring and lead to the formation of 5-hydroxymethyl-5,6-dihydro-dUMP (**28**), 5,6-dihydroTMP (**29**), 2'-hydroxy-3-(N¹-2'-deoxy-5'-phospho-β-D-ribofuranosyl)ureidoisobutyric acid (**30**), and 3-(N¹-2'-deoxy-5'-phospho-β-D-ribofuranosyl)ureidoisobutyric acid (**31**).

The general method used for the synthesis of nucleosides labelled with tritium at the 5'-atom of the carbohydrate residue is based on the reduction of β-D-ribofuranosyl-1,4-furanosides of respective nucleic bases with gaseous tritium or sodium boro[³H]hydride. This method was used for the preparation of compounds labelled at the 5'-position, such as 9-β-arabino-furanosyladenine,¹⁴¹ thymidine,¹³⁸ 2',3'-O-isopropylideneadenosine.¹⁴² In order to prepare adenosine, guanosine and uridine labelled with tritium at C(5'), Akulov *et al.*¹⁴³ conducted the reduction reaction using gaseous tritium in the presence of a catalyst as well as sodium boro[³H]hydride. Synthesis of [5'-³H]3'-azido-3'-deoxythymidine ($A_{\text{mol}} = 14 \text{ Ci mmol}^{-1}$) was carried out

by the oxidation of its precursor to 5'-aldehyde and subsequent reduction with NaB^3H_4 .¹⁴⁴ Introduction of deuterium and tritium in the positions 5' and 4' of 2'-deoxynucleosides is described in Ref. 145. For this purpose, the corresponding 5'-aldehydes were prepared from deoxyguanosine, deoxycytidine and thymidine by the Moffatt method and then reduced with NaBD_4 to form 5'-deuteronucleosides. Heating of 5'-aldehydes in a D_2O –Py mixture (1:1) with subsequent reduction yielded 4'-deuteronucleosides. It is pointed out that the use of a similar procedure for the tritiation yields labelled compounds with low molar radioactivity. A recent US patent¹⁴⁶ describes a method of tritium introduction into oligodeoxyribonucleotides in which an immobilised oligonucleotide with a free 5'-hydroxy group is oxidised with an appropriate agent to aldehyde and then reduced, e.g., with NaB^3H_4 , to give a tritium-labelled 5'-hydroxymethyl group. Riboflavin (vitamin B_2) selectively labelled with tritium in the position 5' was prepared¹⁴⁷ by the reduction of the 5'-aldehyde group with sodium borotr[^3H]hydride. Synthesis of [ribose-2,3- ^3H]2',3'-dideoxycytidine phosphonate,⁴³ [ribose-2,3- ^3H]2',3'-dideoxyadenosine and [ribose-2,3- ^3H]2',3'-dideoxyinosine³³ was carried out by catalytic hydrogenation of the corresponding unsaturated analogues with gaseous tritium.

The key compound in the synthesis of tritium-labelled nucleotides and nucleosides is D-ribose. The use of tritium-labelled D-ribose and heterocyclic bases in enzymic reactions^{12, 24, 148, 149} allows synthesis of nucleosides and nucleotides containing tritium in the ribose and heterocyclic moieties of the nucleoside and nucleotide molecules. We have proposed the following scheme for the synthesis of tritium-labelled D-ribose: reduction of 1,2:5,6-di-*O*-isopropylidene- α -D-ribohexofuranos-3-ulose (**32**) by tritium to 1,2:5,6-di-*O*-isopropylidene- α -D-allofuranose (**33**), oxidation of 1,2-*O*-isopropylidene- α -D-allofuranose (**34**) to 1,2-*O*-isopropylidene- α -D-ribose-5-phosphonate (**35**) and reduction of the latter to 1,2-*O*-isopropylidene- α -D-ribofuranose (**36**) combined with the hydrogen isotope exchange at the C(1) atom.

(The asterisks indicate the sites of tritium incorporation).

These consecutive reactions make it possible to synthesise the tritium-labelled D-ribose (**37**) with up to 3 tritium atoms.

VI. Solid-state catalytic hydrogenation

The method of solid-state catalytic hydrogenation (SCH) was proposed in 1967. Dehalogenation of 5-iodouracil may be regarded as an example of SCH reaction. Subsequent studies have shown that hydrogenation¹⁵⁰ and isotope exchange¹⁵¹ occur under similar conditions. This method consists in the treatment of a solid mixture of the initial compound and catalyst with gaseous tritium. In order to intensify the process, an external supply of energy was provided. The optimum version of the initiation of this reaction proved to be heating of the reaction system. The solid-state reactions of isotope exchange have been further developed in the studies of Meshi and Takahashi.¹⁵² The use of catalysts increases appreciably the extent of tritium incorporation and its

selectivity. Zolotarev *et al.*,^{150, 151} who investigated SCH in the reactions of hydrogenation, reduction and isotope exchange, have concluded that a new process took place in all cases. It has been demonstrated^{153, 154} that the SCH is based on the spillover of hydrogen activated on the catalyst and its diffusion into the layer of organic compound. A diffusion model of this process has been proposed.¹⁵⁵ The applicability of this model was exemplified with solid-state isotope exchange in thymine accompanied by the hydrogenation of the 5,6-double bond.¹⁵⁶ The extent of isotopic substitution in the SCH reaction depends on the nature of the metal used as the catalyst (Pd, Pt, Rh, Ru) and support (BaSO_4 , CaCO_3 , Al_2O_3 , SiO_2 , C), the catalyst–compound ratio and the reaction temperature.

The application of the SCH method for the synthesis of biologically important diazines labelled with tritium gave good results. Solid-state catalytic hydrogenation of 5-formyluracil afforded thymine with the molar activity corresponding to the incorporation of three tritium atoms into the methyl group.^{132, 133} Investigation of the hydrogenation kinetics of 5-formyluracil has shown¹⁵⁷ that starting from a definite temperature, the incorporation of tritium into thymine exceeds the stoichiometry corresponding to the reduction of the formyl group. This is explained by the fact that under given conditions, the reduction is accompanied by a parallel reaction of isotope exchange of the formyl group hydrogen with tritium. This leads to thymine with a virtually complete substitution of hydrogen by tritium in its methyl group ($A_{\text{mol}} \approx 87 \text{ Ci mmol}^{-1}$). The use of another precursor, *viz.*, 5-hydroxymethyluracil, a specially selected catalyst and more drastic reaction conditions have permitted synthesis of thymine¹⁵⁷ in which all tritium was substituted for hydrogen over all the C–H bonds ($A_{\text{mol}} > 100 \text{ Ci mmol}^{-1}$), and the use of 5-hydroxymethyldeoxyuridine as the precursor has yielded tritium-labelled thymidine ($A_{\text{mol}} = 76 \text{ Ci mmol}^{-1}$).¹⁵⁸

Let us consider the basic regularities of the introduction of tritium label by the SCH method with synthesis of specific compounds as an example. It has been shown¹⁵⁷ that in the SCH reaction of tritium with purine bases the rate of isotope exchange is sharply increased in the temperature range 150–170 °C. This leads to a virtually complete substitution of hydrogen by tritium.

The results of synthesis of 11 alkylxanthines labelled with tritium using the SCH reaction are presented in Ref. 159. Analysis of the labelled compounds by ^3H NMR spectroscopy has revealed that the tritium label was incorporated not only in the C(8) position but also in the alkyl groups. The dependences of the yield of compound **22** prepared by SCH with tritium and of its molar radioactivity on temperature and the catalyst/compound ratio have been investigated.¹⁶⁰ The same dependences for compounds **19** and **21** were studied by Lushkina *et al.*¹⁶¹ It has been found that for virtually all the compounds studied the higher temperature and the greater catalyst/compound ratio the lower the yield of specific products but the higher its molar radioactivity. Thus, the variation of reaction conditions [temperature, catalyst, catalyst/compound mass ratio and reaction time] opens wide possibilities for the synthesis of labelled compounds.

The main side reaction of SCH is degradation (thermolysis) of the initial compound. The products of the synthesis of tritium-labelled 2',5'-oligoadenylate were found to include an isomerisation product, *viz.*, 3',5'-isomer, which was separated by chromatography.¹⁶² In the case of SCH of pyrimidines, hydrogenation of the 5,6-double bond of the heterocyclic ring may occur in parallel leading to the formation of compounds **28–31**.

The SCH method was employed for the introduction of a tritium label into compounds of a more complex structure such as polynucleotides and natural polymers,¹⁶² e.g., 15S RNA. The liquid- and solid-state catalytic isotope exchange with gaseous tritium in thymidine 5'-H-phosphonates, 2'-deoxyadenosine, and 2'-deoxy-5-hydroxymethyluridine has been investigated.¹⁶³ Analysis by ^3H NMR spectroscopy has revealed that tritium is incorporated into the P–H group. The solid-state method for the preparation of tritium-labelled DNA synthesis terminators

(**22**, **23**, azidothymidine phosphonate, acyclovir phosphonate, 3'-deoxythymidine) is described in Ref. 43. The tritium-labelled 5'-*O*-phosphorylmethylthymidine ($A_{\text{mol}} = 71 \text{ Ci mmol}^{-1}$) was obtained by the solid-state reaction of isotope exchange at 150 °C.¹⁶⁴

Table 7 lists the A_{mol} values of tritium-labelled purine and pyrimidine compounds prepared by the SCH method. The values presented are higher than those for these and analogous compounds labelled by other methods. For compounds of relatively simple structure, such as **2**, **3**, **10**–**13**, a virtually complete isotope substitution of hydrogen by tritium has been attained. Variation of the solid phase composition and temperature permits the directed modification of the yield and the molar radioactivity of specific compounds. The SCH method does not require synthesis of special precursors and offers the possibility of a greater degree of hydrogen substitution by tritium than do other methods. Degradation of thermally labile compounds, the occurrence of parallel reactions of hydrogenation, dehalogenation and reduction of various functional groups may be regarded as disadvantages of the SCH method. However, in many cases these disadvantages are not critical since a careful choice of reaction conditions makes it possible to minimise (as far as possible) the influence of side reactions and to synthesise compounds containing the groups (the 5,6-double bond of pyrimidines) susceptible to hydrogenation and even some thermally unstable compounds (oligo- and poly-nucleotides, RNAs).

Thus, the SCH method may be regarded as one of the most promising methods for the synthesis of tritium-labelled natural diazines, in particular, of the components of biologically important substances.

Table 7. Molar radioactivities of diazines obtained by SCH reactions.

Compound	$T/^\circ\text{C}$	$A_{\text{mol}}/\text{Ci mmol}^{-1}$
Adenine	170	54.2

Table 8. Characteristics of different methods used for the synthesis of biologically active diazines labelled with tritium.

Reaction	Reaction condition	$A_{\text{mol}}/\text{Ci mmol}^{-1}$
Tritium incorporation by chemical synthesis		
Dehalogenation	in solution	15–45
	in solid state	5–20
Hydrogenation, reduction	in solution	15–40
	in solid state	40–90
Tritium incorporation by isotope synthesis		
Isotope exchange with:		
³ H-solvent	in solution	5–10
highly radioactive water	"	up to 25
gaseous tritium	"	5–25
	in solid state	20–120, up to 250

Comparative characteristics of different methods used for the synthesis of tritium-labelled biologically important diazines are presented in Table 8.

VII. Other methods of tritium labelling

A number of methods exist that did not find wide application for the synthesis of tritium-labelled natural diazines. Some pyrimidine derivatives labelled with tritium in the position 5 were prepared by heating (to 160 °C) the respective iodo-substituted compounds in DMSO with tritiated water.¹⁶⁵ The molar radioactivity of uracil, uridine, cytosine, cytidine and orotic acid thus obtained made up 30% of the A_{mol} level of [³H]H₂O.¹⁶⁶ Electrolytic reduction of 5-bromouracil in tritiated water (mercury cathode, platinum anode) yielded [5-³H]uracil.¹⁶⁷

Decarboxylation of 5-substituted derivatives of orotic acid labelled with tritium in the carboxyl group produced [6-³H]thymine¹⁶⁸ from 5-methylorotic acid, 5-fluoro[6-³H]uracil¹⁶⁹ and 5-bromouracil¹⁷⁰ from the corresponding 5-halogeno-derivatives of orotic acid. The molar radioactivity of these products did not exceed 1 Ci mmol^{−1}. Heating of orotic acid supported on a Cu/BaSO₄ catalyst, which was partially oxidised in air, in the tritium atmosphere yielded [6-³H]uracil (23 Ci mmol^{−1}).¹⁷¹ β-D-Arabinofuranosyladenosine ($A_{\text{mol}} = 0.43 \text{ Ci mmol}^{-1}$) was prepared by isotope exchange with UV-activated gaseous tritium.¹⁷² Alkylation of [2,8-³H₂]adenosine with 4-bromo-2-methylbut-2-ene in dimethylformamide gave *N*⁶-(2-isopentyl)[2,8-³H]adenosine, which was transformed into *trans*-[2,8-³H]zeatin riboside ($A_{\text{mol}} = 22 \text{ Ci mmol}^{-1}$) by allylic oxidation.¹⁷³ Heating (60 °C, 2 h) of *N*⁶-(3-iodobenzyl)-*N*⁹-[methyl(2,3-di-*O*-acetyl-β-D-ribofuranosyl)uronate]-2-chloroadenosine with tritium-labelled methylamine in methanol provided *N*⁶-(3-iodobenzyl)-*N*⁹-[*N*-methyl-(β-D-ribofuranosyl)uronamide] ($A_{\text{mol}} = 29 \text{ Ci mmol}^{-1}$).¹⁷⁴ Azidothymidine was synthesised using tritium-labelled thymidine.¹⁷⁵ Deamination of [5-³H]1-β-D-arabinofuranosylcytosine led to the formation of [5-³H]1-β-D-arabinofuranosyluracil ($A_{\text{mol}} = 20 \text{ Ci mmol}^{-1}$).³⁹ [8-³H]9-β-D-Arabinofuranosyladenine ($A_{\text{mol}} = 10 \text{ Ci mmol}^{-1}$),³⁹ [2-³H]adenine and [2-³H]adenosine³⁸ are the products of catalytic reductive desulfurisation of the corresponding SH-derivatives with gaseous tritium. The processes of tritium incorporation from the gas phase into thymidine and deoxyuridine in an aqueous solution have been considered.¹⁷⁶ Incorporation of tritium into these compounds resulted mainly from the attack by the ³HeT⁺ species rather than the radiolysis induced by β-particles.

VIII. Conclusion

Nowadays, synthesis of tritium-labelled physiologically significant compounds may be regarded as an independent field of applied radiochemistry that makes use of the approaches and methods of bioorganic chemistry, biochemistry and enzymology. This is characterised by both the development of efficient techniques for tritium incorporation and organisation of the production of labelled substances. The above considerations suggest a number of inferences on the state-of-the-art of the synthesis of tritium-labelled diazines.

In the 1970s, rapid progress of molecular biology and molecular genetics increased dramatically the demand for tritium-labelled components of nucleic acids. This has stimulated the development of new methods and the improvement of existing techniques of their synthesis. Tritium-labelled compounds have played an important role in the studies of the structure and functions of nucleic acids. Catalytic dehalogenation in solution may be regarded as the general method for the synthesis of the tritium-labelled components of nucleic acids. The development of this method has allowed synthesis of compounds with a definite position of the tritium label and relatively high molar radioactivities ($20\text{--}30\text{ Ci mmol}^{-1}$). The need for the components of nucleic acids possessing high and superhigh molar radioactivity has stimulated the development of techniques for the preparation of purine and pyrimidine bases multiply labelled with tritium. These include reactions of catalytic dehalogenation (e.g., of 2,8-dichloroadenine, 5-bromouracil and 6-chlorouracil) and solid-state catalytic hydrogenation (e.g., synthesis of [2,8- ^3H]adenine and [methyl-6- ^3H]thymine from the respective unlabelled precursors). The use of the enzymes of purine and pyrimidine metabolism has opened a simple and reliable pathway for the preparation of a virtually complete set of nucleic acid components multiply labelled with tritium.

The recent years witness an ever-increasing interest in the tritium-labelled pharmaceutical preparations of rather complex structures. As regards diazines, these are mainly various DNA synthesis terminators, medicinal drugs in the stage of pharmaceutical assays and coenzymes. These and similar tritium-labelled compounds are most often synthesised by catalytic reactions of isotope exchange, in particular the isotope exchange with gaseous tritium in solution and in solid state. Such reactions may be considered as express-methods that do not require synthesis of special precursors. For example, tritium-labelled nicotinamide adenine dinucleotide (111 Ci mmol^{-1}) and coenzyme A (3.9 Ci mmol^{-1}) were prepared by the solid-state reactions of isotope exchange with gaseous tritium.¹⁷⁷ The application of the reactions of isotope exchange involving gaseous tritium is limited by the requirement that the initial compounds contain groups capable of easy reduction or hydrogenation and are thus susceptible to modification or substitution by tritium. In this case, the reaction of isotope exchange with highly active tritiated water is a promising method. The possibilities of the application of this method for the synthesis of tritium-labelled biologically active substances, including diazines, have been discussed.¹⁷⁸

Dialdehyde-containing nucleic acids and their components: synthesis, properties and affinity modification of proteins

O M Gritsenko, E S Gromova

Contents

I. Introduction	241
II. Introduction of aldehyde groups into the sugar residue of nucleic acids	241
III. Affinity modification of proteins and polypeptides with periodate-oxidised derivatives of nucleic acids	246
IV. Conclusion	250

Abstract. Synthesis, structure and chemical properties of nucleoside dialdehyde derivatives are described. The introduction of aldehyde groups into oligonucleotides is discussed. The methods of affinity modification of proteins with periodate-oxidised nucleic acid derivatives are considered. The bibliography includes 48 references.

I. Introduction

The study of the nature of specific interactions of proteins with nucleic acids (NA) is an important problem of modern molecular biology. Relatively few methods allowing the identification of functional groups of proteins involved in protein–NA recognition are known. Covalent binding of proteins to NA is an efficient approach.¹ It consists in specific covalent attachment of a protein to NA by modification of one of the components of the protein – NA complex or by addition of a cross-linking reagent. The covalently bound protein is subjected to hydrolysis with proteases and then the amino acid composition of the peptide attached to NA, which is the region of the active site or a recognition domain of the protein, is determined. The method of covalent ‘cross-linking’ also makes it possible to study the topography of the protein–NA complexes and to establish their stoichiometry.

Elaboration of optimal conditions for protein–NA recognition is an essential feature required for this method. In this case, the modification must not induce significant distortions in the structure of the components of the complex and not interfere with the recognition of NA analogues by specific proteins. Affinity modification of non-modified proteins with NA upon UV irradiation is a way to perform covalent addition of proteins to NA.¹ Another approach consists in the introduction of chemically or photo-activated groups into a protein or NA followed by their activation. Reactive groups are introduced into heterocyclic bases of NA, into phosphate groups or into sugar residues. The first two types of NA activation and the formation of covalently bound products based on these derivatives have been described in several reviews.^{1–3} In the present work, we shall consider NA derivatives

containing two aldehyde groups in the sugar residue with regard to their synthesis, properties and affinity modification of proteins.

Earlier, dialdehyde derivatives of NA were extensively used for establishing the structure of monomeric components of nucleic acids and for the analysis and separation of oligonucleotide mixtures.⁴ The nucleotide sequences adjacent to the 3′-end of RNA were determined using oxidation of the 3′-terminal nucleotide unit of RNA with subsequent cleavage of the adjacent phosphodiester bond and identification of a heterocyclic base.⁴ At present, dialdehyde derivatives of NA are most often used for introduction of various functional groups into NA and affinity modification of proteins.

II. Introduction of aldehyde groups into the sugar residue of nucleic acids

The methods used for the introduction of two aldehyde groups into nucleosides and mononucleotides as well as into 3′- and 5′-terminal residues of oligonucleotides are well known. A procedure for introduction of aldehyde groups into any position of the oligonucleotide chain has been developed recently.

1. Synthesis and structure of dialdehyde derivatives of nucleosides and nucleotides

The synthesis of dialdehyde derivatives of nucleosides is based on periodate oxidation of ribonucleosides and their derivatives:⁴

Hereinafter B is a heterocyclic base.

The reaction of adenosine 5′-triphosphate (I) with sodium periodate is of the second order (the rate constant k_2 is equal to $1.06 \times 10^3 \text{ litre min}^{-1} \text{ mol}^{-1}$).⁵ The oxidation was carried out with an equimolar amount or a small excess of sodium periodate for 1 h at 4 °C.⁵ In another study,⁶ mono- and dinucleotides were oxidised with a 20-fold excess of sodium periodate for 1 h at 0 °C. The excess of sodium periodate was removed with ethylene glycol,⁶ a small excess of rhamnose⁶ or a 4-fold molar excess of NaAsO₂.⁷ The resulting solutions of oxidised nucleoside derivatives were used as such; the products could be purified by gel chromatography.

The aldehyde groups in various periodate-oxidised ribonucleotides are hydrated;^{8–10} thus the oxidation product of adeno-

sine 5'-triphosphate (oATP) exists as an equilibrium mixture of dialdehyde hydrates (structures **3** and **4**, Scheme 1).^{5,9}

Scheme 1

The ¹H and ¹³C NMR spectra of oATP do not contain resonance signals typical of free aldehyde groups; the polymeric form of oATP was not detected in solution. The cyclic hemiacetal **3** may exist as a mixture of four diastereomers **3a–d**.

These conformers are preferred, since the adenine moieties and CH₂Oppp groups are equatorial.⁹ The coupling constants correspond to the structures **3b–d** (Table 1). Because of steric constraints due to the axial position of two hydroxy groups, the structure **3a** is probably not realised. The structures **3c** and **3d** are more preferable, since the hemiacetal hydroxy groups in 1,4-dioxanes and sugars tend to occupy the axial position (the so-called anomeric effect).¹¹ The ¹H and ¹³C NMR spectra also contained signals corresponding to the dialdehyde dihydrate **4**. Thus, oATP exists in solution as a mixture of four compounds, *viz.*, three diastereomers of the cyclic hemiacetal **3b–d** and the dihydrate **4**, which are in equilibrium with one another, and a small amount of the free dialdehyde **2**.

In aqueous solution at pH 7.0, the UV spectrum of oATP is similar to that of ATP.⁵

The circular dichroism (CD) spectra of dialdehyde derivatives of adenosine, uridine and cytidine revealed strongly reduced

Cotton effects in comparison with those observed for the corresponding nucleosides.¹² This points to enhanced free rotation of the heterocyclic base around the glycosidic bond. On the contrary, in the case of the dialdehyde derivative of guanosine the amplitude of the CD maximum increased, which was ascribed¹² to the self-assembly resulting in the formation of oligomers.

In the solid state, the dialdehyde derivatives of adenosine, guanosine, cytidine and uridine are totally polymerised.¹²

2. Some chemical properties of periodate-oxidised nucleoside derivatives

The chemical properties of periodate-oxidised nucleoside derivatives (*e.g.*, interaction with hydrazines and amines, degradation in alkaline media and reduction of aldehyde groups) are well known.^{4,13} Here, we consider only some model reactions which present interest from the standpoint of affinity modification of proteins.

Dialdehyde derivatives of nucleosides and nucleotides readily react with hydrazides, the structure of the reaction products being dependent on the nature of the starting reagents and reaction conditions. The reaction of a nucleoside dialdehyde derivative with isonicotinohydrazide results in the addition of one hydrazide molecule to the nucleoside to give a morpholine derivative.⁴

An analogous product was obtained in the reaction of the above nucleoside derivatives with thiosemicarbazide.⁴

Dialdehyde derivatives of nucleosides and nucleotides **5** react with phenylhydrazine^{13,14} to give bisphenylhydrazones. Addition of an excess of phenylhydrazine results in the degradation of dialdehyde derivatives of ribonucleosides or ribonucleotides (Scheme 2).¹⁴

Scheme 2

X is the phosphate or H.

In the same way derivatives **5** react with semicarbazide.⁴

The products of periodate oxidation of ribonucleosides and ribonucleotides react readily with amines. The reaction of oxidised adenosine 5'-phosphate with methylamine yields a morpholine derivative of adenosine 5'-phosphate.⁴

Table 1. Conformational analysis of hydrated forms of oATP (predicted and experimental values of coupling constants).⁹

Com- pound	Position of the OH-groups ^a		Predicted coupling constants (J/ Hz)		Experimental coupl- ing constants (J/ Hz)	
	2'-OH	3'-OH	J _{1',2'}	J _{3',4'}	J _{1',2'}	J _{3',4'}
3a	<i>a</i>	<i>a</i>	< 4	< 4	not detected	
3b	<i>e</i>	<i>e</i>	> 6	> 6	7.5	8.0
3c	<i>e</i>	<i>a</i>	> 6	< 4	8.0	1.7
3d	<i>a</i>	<i>e</i>	< 4	> 6	1.8	8.1
4	—	—	3–6	3–6	4.1	5.0

^a *a* — Axial, *e* — equatorial.

Combined treatment of ribonucleotide dialdehyde derivative with primary amines and an excess of sodium periodate results in its degradation with elimination of the free base (Scheme 3).¹⁵

The products of the reaction of periodate-oxidised adenosine with glycine in the presence and absence of sodium cyanoborohydride (NaBH_3CN) were identified by spectral methods.¹⁶ Putative condensation products are shown in Scheme 4. It was found that 2-adeninyl-4-carboxymethyl-6-hydroxymethylmorpholine (**9**) is the main reaction product.

The hydrolytic stability of the condensation products of oxidised adenosine or oATP with diaminoethane following reduction with NaBH_3CN has been studied.¹⁶ It was found that stable reaction products are formed only after reduction with NaBH_3CN .

An ^{125}I -containing reagent, viz., 3-(3-iodo-4-hydroxyphenyl)-propionylcarbohydrazide, has been devised for identification and quantitative determination of periodate-oxidised ribonucleosides and RNA.⁷ Reaction of ribonucleoside-derived dialdehydes with this reagent gives the morpholine derivative **10**, which is stable in neutral and weakly acidic media, but is subjected to rapid degradation in alkaline media and in the presence of ammonia or primary amines.

Dialdehydes from nucleoside 5'-phosphates and their derivatives are readily cleaved in alkaline media ($\text{pH} > 7$) with simultaneous scission of the glycosidic bond and β -elimination of the RPO_4^{2-} residue (Scheme 5).^{4,13} Primary amines also efficiently catalyse this reaction.

The aldehyde groups of nucleoside and nucleotide dialdehyde derivatives can be completely or partially reduced depending on

Scheme 5

R = H or an oligoribonucleotide.

pH.¹⁴ This results in the formation of the corresponding triols or dihydroxy aldehydes.

Periodate oxidation of pseudouridine gives the corresponding dialdehyde and two unidentified products.⁴ Treatment of the dialdehyde with sodium borohydride and alkali results in 5-(α,β -dihydroxyethyl)uracil (Scheme 6).

Scheme 6

3. Introduction of the dialdehyde fragment into oligonucleotides

a. Introduction of the aldehyde groups into terminal nucleotide residues

The introduction of the dialdehyde fragment into 3'-terminus of RNA or oligoribonucleotides is effected by periodate oxidation. To introduce such a fragment into 3'-terminus of oligodeoxyribonucleotides or 5'-terminus of oligoribo- or oligodeoxyribo-nucleotides, one should first elongate them by attaching a ribonucleotide residue and then subject it to periodate oxidation. The conditions for oxidation of RNA do not practically differ from those for ribonucleosides and their derivatives.¹⁷

Thus the introduction of a dialdehyde fragment into the 3'-terminus of an oligodeoxyribonucleotide was preceded by attachment of a ribonucleotide.¹⁸ To this end, the oligodeoxyribonucleotide was incubated with ribonucleoside 5'-triphosphate in the presence of terminal deoxyribonucleotidyl transferase. In another study,¹⁹ cytidine 3',5'-diphosphate (pCp) was attached to

an oligodeoxyribonucleotide using T4 RNA-ligase. Then the 3'-terminal phosphate group of the resulting 5'-(oligodeoxyribonucleotide)-pCp3' was eliminated with alkaline phosphatase after which the 2',3'-*cis*-diol group was oxidised with periodate. The reaction was carried out with oligodeoxyribonucleotides having cytidine^{18–20} or uridine¹⁸ residues at the 3'-end.

X is 5'-(oligodeoxyribonucleotide)-3'.

An equimolar amount or a small excess of sodium periodate was used for the oxidation. The reaction was completed within 30 min at room temperature¹⁸ or within 2 h at 0–4 °C.¹⁹ The excess of sodium periodate was destroyed with ethylene glycol.¹⁸

The dialdehyde fragment was also introduced into the 5'-end of an oligodeoxyribonucleotide.²¹ The uridine residue was attached to the oligodeoxyribonucleotide by automated solid-phase, phosphoramidite synthesis using a derivative with protected 2'-OH and 3'-OH groups.

Px is 9-phenylxanthen-9-yl (pixyl).

In this case, the 5'-end of the ribonucleoside was attached to the 5'-end of the oligodeoxyribonucleotide. After deprotection, the ribose residue was oxidised with periodate to give a dialdehyde derivative.

Oligodeoxy- and oligoribo-nucleotides containing oxidised ribose residues have found practical applications. Modified oligodeoxyribonucleotides with a 3'-terminal dialdehyde fragment were used for the introduction of the phosphate group into the 3'-end of the oligodeoxyribonucleotide. To this aim, the oligodeoxyribonucleotide with an oxidised 3'-terminal ribonucleoside residue was treated with a primary amine to give oligonucleotide 3'-phosphate, a dialdehyde derivative of ribose and a heterocyclic base.^{18,20} Radioactive labelling of the 3'-terminal nucleoside residue of RNA was based on the reaction of the aldehyde groups with [³⁵S]-thiosemicarbazide, [¹⁴C]-semicarbazide, [³H]-isonicotinohydrazide or [³H]-sodium borohydride.⁴

Dialdehyde derivatives of oligodeoxyribo- or oligoribo-nucleotides can be used for the introduction of a non-radioactive label by treating oligonucleotides with a compound containing an amino group and a non-radioactive label (*e.g.*, with biotin hydrazide, LNH₂) (Scheme 7a)²¹ or by preliminary introduction

of a primary amino group into the oligonucleotide with subsequent addition of a non-radioactive label (Scheme 7b).²²

Ribonucleic acids (and oligoribonucleotides) can be cleaved at the internucleotide bond from the 3'-end of the polyribonucleotide chain by combined treatment with periodate and primary amines or by treatment with sodium periodate in an alkaline medium (see Scheme 5).^{4,13} Such a treatment yields an oligo- or a polynucleotide 'shortened' by one nucleotide unit from the 3'-end. The whole cycle of conversions can be repeated. A base identified by conventional analytical methods is split off from the product of conversion of the original terminal nucleotide unit by treatment with an acid (pH < 3) or an alkali (pH > 11). This property of dialdehyde derivatives of RNA is the basis for a method for determination of nucleotide sequences in short oligoribonucleotides. Stepwise degradation from the 3'-end was used for the analysis of terminal sequences in various tRNA and tobacco mosaic virus RNA.⁴

The effects of several basic amino acids and primary amines, pH and temperature on the rate of hydrolysis of the phosphodiester bond in the dialdehyde derivatives of some oligoribonucleotides have been studied.⁴ It was found that the cleavage of the required phosphodiester bond in the presence of lysine, cyclohexylamine or methylamine occurs most efficiently at elevated temperature (45 °C), while that in the presence of aniline is the most efficient at 24 °C (at pH 6–9).⁴ No side reactions were observed at room temperature. A rise in temperature may favour side reactions, such as cleavage of ψ U units and heterocyclic nuclei of other nucleosides.⁴

b. Introduction of the aldehyde groups into any position of the oligonucleotide strand

It is not until very recently that the methods for the introduction of aldehyde groups into any position of the oligodeoxyribonucleotide have been developed. Two types of oligonucleotides were used: (1) oligonucleotides containing a hexopyranosyl residue in the oligonucleotide strand^{23–25} instead of a deoxyribose residue and (2) oligonucleotides with an additional ribose residue in the 2'-position of ribose.²⁶ The simplest approach is based on the introduction of galactose residues into the oligonucleotide

strand.²³ Prior to the oligonucleotide synthesis, the hydroxy groups designed for subsequent oxidation are protected with appropriate protective groups. It was suggested²⁴ to introduce both the *cis*-glycol group as a D-galactose residue and the *trans*-glycol group (as a D-glucose residue) into the oligonucleotide.

Preparative syntheses of 1-(3,4-*O*-isopropylidene- β -D-galactopyranosyl)thymine²³ and 1-(2,3-di-*O*-acetyl- β -D-glucopyranosyl)thymine²⁴ from D-galactose and D-glucose, respectively, have been carried out. Then, 14–21-membered oligodeoxyribonucleotides containing a 1-(β -D-glucopyranosyl)thymine (**11**)^{23,25} or a 1-(β -D-galactopyranosyl)thymine (**12**)²⁴ residue at a definite position of the oligonucleotide strand were obtained using standard phosphoramidite procedures.

The 1-(β -D-galactopyranosyl)thymine residue was introduced into the oligonucleotide strand through the 2'- and 6'-OH groups, while the 1-(β -D-glucopyranosyl)thymine residue, through the 4'- and 6'-OH groups. The model dinucleoside phosphates, *viz.*, 1-(β -D-glucopyranosyl)thymine-4'-*O*-phosphoryl-(4'-5')-2'-deoxyadenosine (**13**)²⁴ and 1-(β -D-galactopyranosyl)thymine-2'-*O*-phosphoryl-(2'-5')-2'-deoxyadenosine (**14**)²³ were synthesised for detailed studies of periodate oxidation.

The oxidation of the *trans*-diol group in compound **13** with a 10-fold excess of sodium periodate at 20 °C proceeded very slowly; the half-reaction time was 9–10 h.²⁴ The oxidation of compound **14** containing a *cis*-diol group was completed within 1.5 h under these conditions.²³ This circumstance determined the use of oligonucleotides containing a galactopyranose residue for the synthesis of reagents carrying dialdehyde fragments and designed for affinity modification of proteins.

The oxidation of 14-membered galactose-containing oligonucleotides was carried out in 20–200 mM NaIO₄ (1.5–2.5 h, 25–37 °C).²⁵ The yields of the oxidation products (65%–75%) were determined by cleavage of the phosphodiester bond from the 5'-end at the oxidised galactose residue, which was carried out in 10% piperidine (25 min, 95 °C). Under these conditions, oligonucleotides containing a non-oxidised galactose residue remained intact. The structure of oligonucleotides containing an oxidised galactose residue was confirmed by selective cleavage of the phosphodiester bond of the oxidised galactose residue (Fig. 1). This was carried out under conditions of β -elimination analogous to those used for chemical sequencing of RNA.²⁷ The reaction was conducted in 1 M aniline–acetate buffer (pH 4.5) for 15 min at 95 °C.²⁵ In contrast with the oligonucleotides **15**–**17** containing a galactose residue, the 14-membered oligonucleotides containing an oxidised galactose residue (**15***–**17***) in different positions of the oligonucleotide chain were cleaved. Their cleavage gave a ³²P-labelled tetranucleotide (from **15***), a heptanucleotide (from **16***) and an undecanucleotide (from **17***) containing a 3'-phosphate group (see Fig. 1). In control experiments, insignificant degradation of periodate-oxidised oligonucleotides during gel electrophoresis took place.²⁵

Another approach to regiospecific introduction of additional *cis*-diol groups into oligonucleotides is based on the use of nucleoside disaccharide derivatives **18**.^{26, 28, 29}

In these compounds, the *cis*-diol groups are converted into aldehyde groups upon oxidation. Disaccharide nucleosides have been identified in tRNAs as minor components; some antibiotics also involve disaccharide fragments. Synthesis of 2'-*O*-ribofuranosyl nucleosides **18** was carried out in three steps by condensation of 3',5'-*O*-blocked *N*-acylribonucleoside (**19**) and a small excess of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl- β -D-ribofuranose (**20**) in the presence of tin tetrachloride^{28, 29} followed by a two-step deprotection. The glycosylation reaction was stereospecific and resulted in the formation of a β -D-glycosidic bond (Scheme 8).

Scheme 8

The periodate oxidation has been studied using a model dinucleoside phosphate **21** containing the disaccharide residue.²⁹

Figure 1. Gel-electrophoretic analysis of stability of the oligonucleotides 5'-GCCAXCCTGGCTCT3' (**15**, **15***), 5'-GCCAACCCXGGCTCT3' (**16**, **16***) and 5'-GCCAACCTGGCXCT3' (**17**, **17***) containing a nonoxidised (**15**–**17**) or oxidised (**15***–**17***) 1-(β -D-galactopyranosyl)thymine residue (X).

(a) Incubation of the oligonucleotides containing a galactose residue: (1, 3, 5) — in aniline–acetate buffer, pH 4.5, 95 °C, 15 min; (2, 4, 6) — in 40 mM Tris–HCl buffer, pH 7.9, 5 mM dithiothreitol, 50 mM NaCl, 15 mM MgCl_2 , 95 °C, 25 min; (1, 2) oligonucleotide **15**; (3, 4) oligonucleotide **16**; (5, 6) oligonucleotide **17**.

(b) Incubation of the oligonucleotides containing an oxidised galactose residue in aniline–acetate buffer, pH 4.5, 95 °C, 15 min; (1) oligonucleotide **15***; (2) oligonucleotide **16***; (3) oligonucleotide **17***.

The model dinucleoside phosphate was oxidised with sodium periodate within 10 min at 20 °C. 14–22-Membered oligonucleotides containing 2'-*O*-ribofuranosylcytidine residues were synthesised using the phosphoramidite method with modified phosphoroamidite (compound **22**).²⁶

DNA duplexes used for affinity modification of some DNA-binding proteins have been formed on the basis of oligonucleotides containing dialdehyde fragments at definite positions of the nucleotide strand.

III. Affinity modification of proteins and polypeptides with periodate-oxidised derivatives of nucleic acids

Periodate-oxidised derivatives of nucleotides containing dialdehyde fragments were used for affinity modification of enzymes that use nucleoside triphosphates as cofactors or substrates and transcription factors. In addition, conjugates of 13- and 15-membered oligodeoxyribonucleotides containing 3'-terminal aldehyde groups with poly(L-Lys) have been synthesised to study the regulation of gene expression.¹⁹ 14- and 22-Membered DNA duplexes with internal dialdehyde fragments were used for covalent cross-linking with restriction endonucleases and methylases (*Eco*RII and *Mva*I²⁵) and RNA polymerase of bacteriophage T7.³⁰

1. Covalent binding of proteins with nucleotide dialdehyde derivatives

The fundamental process that satisfies the bioenergetic requirements of living organisms is versatile for practically all the objects of the living nature. It consists in the hydrolysis of one of pyrophosphate bonds in adenosine 5'-triphosphate (ATP) or, less often, guanosine 5'-triphosphate (GTP). Numerous biochemical processes occur by virtue of energy released upon hydrolysis of nucleoside triphosphates.

2',3'-Dialdehyde derivatives of ATP, ADP, GTP and GDP (oATP, oADP, oGTP and oGDP, respectively) were used for affinity modification of some enzymes, mainly for the study of their cofactor-binding or active sites.

The ATP dialdehyde derivative was cross-linked to mitochondrial ATPase and histone kinase in order to study the active sites of these enzymes.^{31, 32} Pyruvate carboxylase, acetyl-CoA carbox-

ylase and NAD-dependent isocitrate dehydrogenase require ATP for their cofactor function (the catalytic reaction utilises the energy of ATP hydrolysis). These enzymes have several substrates and cofactors. oATP and oADP were used for covalent binding of these enzymes with the allosteric site as well as for the analysis of interaction of this allosteric site with other sites.^{8,33,34} The phosphate group of ATP is added to the 5-ribulose phosphate fragment by phosphoribulokinase to give ribulose-1,5-diphosphate. oATP was used for affinity modification of the binding site in one of phosphoribulokinase substrates.³⁵

Binding of aminoacyl-tRNA with ribosomes requires the elongation factor EF-Tu. This reaction is accompanied by hydrolysis of GTP. GTP 2',3'-dialdehyde derivative was covalently linked to the elongation factor EF-Tu in order to identify the binding site for the cofactor.³⁶ Functioning of a human protein c-H-ras p21 also is accompanied by GTP hydrolysis. This protein, which is localised in the cytoplasmic membrane, accepts external signals stimulating cell growth and transmits them to target proteins localised inside the cell, thus promoting its growth and division. In order to investigate the interaction of GTP and GDP with this protein in more detail the latter was subjected to affinity modification with periodate-oxidised GTP and GDP derivatives.³⁷ A periodate-oxidised derivative of 1,N⁶-ethenoadenosine-5'-monophosphate (oEAMP) was used for covalent addition to alkaline phosphatase from human placenta.³⁸

Depending on the object of investigation, proteins and periodate-oxidised components of NA are used for cross-linking in various ratios (Table 2). The time of incubation of proteins with the monomeric analogues of NA containing aldehyde groups varied, on the average, from 5 min to 2 h. In kinetic studies of the oADP interaction with isocitrate dehydrogenase, the incubation time varied from 1 to 8 h.³⁴ The kinetic curve of inactivation of the tetrameric enzyme was biphasic: the fast phase is coupled with covalent binding of oADP with one enzyme subunit, and subsequent slow phase consists in covalent binding of oADP with the remaining three subunits of the enzyme and results in its complete inactivation.

Traditionally, NA components that contain a radioactive label (¹⁴C, ³H or ³²P) were used for covalent binding with proteins. The degree of affinity modification was estimated from the radioactivity after electrophoresis in 8%–10% polyacrylamide gel

containing 0.1% SDS,³¹ gel filtration^{19,32} or washing of filters containing reaction mixtures.³⁶ The degree of affinity modification of pyruvate carboxylase with various concentrations of oATP was determined from the residual activity of the enzyme.⁸ The conditions for the preparation of the covalent complexes and subsequent specific cleavage of the covalently bound proteins are listed in Table 2.

Let us consider the mechanism of reaction of the NH₂ groups of proteins with dialdehyde derivatives of monomeric components of NA proposed by Gregory and Kaiser³⁹ (Scheme 9). As can be seen from Scheme 9, the reaction of the NH₂ group of a protein with a periodate-oxidised nucleotide derivative yields either a dihydroxymorpholine derivative **23** or a Schiff's base **24**.

Enz is enzyme.

It was pointed out^{31,33–35} that stable morpholine derivatives of enzymes with oATP or oADP are formed without reduction. Following addition of an oxidised derivative of a nucleotide to the enzyme, splitting of the tri- or di-phosphate anion upon β-elimination occurs faster than in the absence of the enzyme due to the involvement of the electron pair of the nitrogen atom of the

Table 2. Conditions for the preparation of covalent complexes of proteins with periodate-oxidised derivatives of mononucleotides and for specific cleavage of cross-linked proteins.

Protein or polypeptide (concentration)	Modified analogue of NA (concentration)	Reducing agent	Amount of the reducing agent	Duration of reduction / min	Enzymes or chemical reagents for specific cleavage of the protein fragment	Ref.
Mitochondrial adenosine triphosphatase (100 µg ml ⁻¹)	Mg-oATP (9.4 or 2.5 µmol)	—	—	—	—	31
NAD-dependent isocitrate dehydrogenase (0.4–0.5 mg ml ⁻¹)	oADP in the presence of MnSO ₄ (0.2 mmol litre ⁻¹)	—	—	—	pronase, carboxypeptidase A, carboxypeptidase B, aminopeptidase	34
Pyruvate carboxylase (10–20 un ml ⁻¹ or 13.3 un mg ⁻¹)	Mg-oATP (2 mmol litre ⁻¹)	NaBH ₄	10-fold excess with respect to oATP	35	trypsin, chymotrypsin, pronase, α-aminopeptidase	8
Histone kinase	20-fold excess of oATP relative to the enzyme	NaBH ₄	20-fold excess with respect to oATP	60	trypsin	32
Elongation factor from <i>T. thermophilus</i> (20 mmol litre ⁻¹)	ATP ^a (10 mmol litre ⁻¹)	NaBH ₃ CN	20 mmol litre ⁻¹	1	BrCN	36

^a The oxidation with sodium periodate was carried out after incubation of the elongation factor EF-Tu and ATP (incubation time 10 min, oxidation time 1 min).

morpholine derivative in the splitting of the tri(di)phosphate anion (see Scheme 9).

According to other reports,^{8,32,36} the reduction of intermediate products (a dihydroxymorpholine derivative or a Schiff's base) with borohydrides (NaBH_4 or NaBH_3CN) is necessary for stable covalent binding of the enzyme with the nucleotide.

So what is the information that one may derive from cross-linking of proteins with periodate-oxidised mononucleotides? In the first place, specific cleavage of a protein covalently bound with a nucleotide by enzymes or by chemical reagents provides information about the location of amino acids or a protein fragment that form the active or cofactor-binding site of the enzyme. Enzymic hydrolysis is conventionally carried out with trypsin or other specific proteases, while chemical cleavage of proteins at the methionine residues is performed with BrCN (see Table 2).

Enzymic hydrolysis of a modified and reduced conjugate yields a small peptide covalently bound with the nucleotide and then the amino acid sequence of the peptide is determined. To this end, the peptide cross-linked to a radiolabelled oATP is subjected to acid hydrolysis, dansylation and separation by two-dimensional gel electrophoresis followed by identification of dansyl amino acids.³² The mobility of the radiolabelled dansylated derivative coincided with that of the synthetic dansylated derivative of the covalent adduct of lysine with oATP. The amino acid sequence of the peptide cross-linked with oGDP or oGTP was determined using the Edman degradation.³⁷

The lysine residues involved in the covalent binding with periodate-oxidised nucleotide derivatives were identified after proteolysis of products of cross-linking of oATP to histone kinase³² and pyruvate carboxylase⁸ as well as of oGDP and oGTP to the protein c-H-ras p21.³⁷ It was suggested that the lysine residues present in the active or cofactor-binding sites of enzymes are responsible for the binding of the phosphate groups of ATP due to the basic properties of the ϵ -amino group of lysine.

As it has been noted above, treatment of the protein–nucleotide conjugate with BrCN results in the cleavage of the covalently bound protein at the methionine residues (Met). Since these residues are rare in occurrence, large protein fragments are usually formed. This method allowed one to demonstrate that the GTP-binding domain of the elongation factor Tu is localised in the N-terminal part of the protein.³⁶

Affinity modification of active or cofactor-binding sites of pyruvate carboxylase,⁸ mitochondrial ATPase,³¹ isocitrate dehydrogenase,³⁴ phosphoribulokinase³⁵ and alkaline phosphatase from human placenta³⁸ with ATP, ADP or ϵAMP 2',3'-dialdehyde derivatives led to the inhibition of these enzymes. There are several nucleotide analogues that contain a reactive group and can be used for covalent linking to nucleotide-binding sites of proteins. However, only some of them are inhibitors that can specifically bind with the active site. Site-directed modification should meet two criteria. Let us consider these criteria with oATP as an example. First, ATP must protect the protein from inactivation with oATP. Second, oATP must serve as a substrate for this enzyme. Wherever these two criteria were met, it was demonstrated that oATP is a site-directed inhibitor of mitochondrial ATPase³¹ and phosphoribulokinase,³⁴ whereas o ϵAMP is a site-directed inhibitor of alkaline phosphatase from human placenta.³⁸ The dependence of inactivation of multisubunit proteins, e.g., pyruvate carboxylase⁸ and NAD-dependent isocitrate dehydrogenase,³⁵ on the concentration of oATP or oADP and the effects of other cofactors and substrates of enzymes (multisubunit proteins have several substrates and cofactors) on the affinity modification of these proteins with oATP or oADP have been studied in a number of papers. The affinity modification of these proteins with dialdehyde derivatives of nucleotides allowed one to suggest the relative arrangement of the active and cofactor-binding sites of the enzymes.^{8,35}

Thus, in some cases affinity modification of proteins with periodate-oxidised derivatives of nucleotides has made it possible to establish the active and cofactor-binding sites of enzymes that

are covalently bound with periodate-oxidised derivatives of mononucleotides and to suggest the location of the oATP-(cofactor-) binding sites in multisubunit proteins.

2. Affinity modification of proteins and polypeptides with oligonucleotides containing dialdehyde fragments

Methods for cross-linking of histones to DNA containing randomly introduced aldehyde groups were developed in the 1980's by Mirzabekov *et al.* in structural studies of chromatin.^{40–45} The aldehyde groups could be introduced into DNA in several ways. One of them is based on acid treatment of DNA, which results in its depurination and concomitant liberation of the aldehyde group in the sugar moiety. However, this approach can hardly be applied to covalent cross-linking of DNA to proteins, because low pH values prevent the formation of DNA–protein complexes. Yet another method for the random introduction of the aldehyde groups into DNA strands is based on methylation of DNA purines with dimethyl sulfate and subsequent depurination.⁴⁰ In order to identify contacts of DNA with histones, cell nuclei were treated with dimethyl sulfate, then depurination was carried out in a neutral medium followed by reduction with sodium borohydride.^{41–43} Such a treatment resulted in the covalent binding of the aldehyde groups of DNA with the histone amino acid residues interacting with DNA. The same approach was used to establish DNA–protein contacts in complexes of RNA polymerase with the promoter *lacUV5*,⁴⁶ of *lac* repressor with DNA⁴⁷ and in the cowpox virus.⁴⁸

The interaction of DNA duplexes and oligonucleotides containing dialdehyde fragments with proteins and polypeptides has been studied recently.^{19,25,30} The aldehyde groups were introduced regiospecifically both into terminal and nonterminal positions of the oligonucleotide strand. The possibility to introduce aldehyde groups into any position of the oligonucleotide strand has made it possible to investigate template-driven enzymes (RNA polymerases) and enzymes recognising specific sequences in DNA (DNA restriction–modification enzymes). The obvious advantage of dialdehyde reagents is their specificity with respect to adjacent lysine ϵ -amino groups. Special mention should be also made of the ability of these reagents to form stable covalent complexes with the protein after their reduction. The proximity of definite sugar residues of DNA to the lysine residues of the active or DNA-binding sites of proteins can be established by means of introduction of the aldehyde groups into a definite sugar residue of the DNA duplex and subsequent cross-linking of the modified duplex to the proteins.

The specificity of the dialdehyde fragment with respect to the lysine amino group was used for efficient covalent binding of poly(L-Lys) with two aldehyde groups I in the 3'-terminus of an oligonucleotide.¹⁹

Probing of the functional sites of the DNA restriction-modification enzymes *EcoRII* and *MvaI* which recognise the sequence

in DNA, was carried out.²⁵ The restriction endonuclease *EcoRII* (*R.EcoRII*) cleaves the phosphodiester bonds at the positions indicated by the arrows. The DNA-methyltransferases *EcoRII* (*M.EcoRII*) and *MvaI* (*M.MvaI*) methylate the inner cytosine residues at C(5) (*M.EcoRII*) or at N(4) (*M.MvaI*). The cross-linking of these enzymes to DNA duplexes (substrate analogues) that contain an oxidised 1-(β -D-galactopyranosyl)thymine residue was carried out.²⁵ The modified sugar residue was introduced either into the recognition site (duplex **25***) or into the flanking nucleotide sequences (duplexes **26*** and **27***).

Table 3. Conditions for the preparation of covalent complexes of DNA-binding proteins with oligonucleotides containing dialdehyde fragments.

Protein or polypeptide (concentration)	Modified analogue of NA (concentration)	Reducing agent	Amount of the reducing agent	Duration of reduction / min	Yield of cross-linked products (%)	Ref.
Poly(L-Lys) (80 nmol)	oligodeoxyribonucleotides: 5'CATTGTTGATTACTGTC*3', 5'AACGAGGCACATTC*3' (40 nmol), where C* is the oxidised cytidine residue	NaBH ₃ CN	10 µmol	120	25–30	19
<i>Eco</i> RII or <i>Mva</i> I methylases (<i>M.Eco</i> RII — 3.16 µmol litre ⁻¹ ; <i>M.Mva</i> I — 3.3 µmol litre ⁻¹)	14-membered DNA duplex containing an oxidised galactose residue (0.23 µmol litre ⁻¹) (duplexes 25* and 27*)	NaBH ₄	3.75 mmol litre ⁻¹	40	9–20	25
Restriction endonuclease <i>Eco</i> RII (3.16 µmol litre ⁻¹)	14-membered DNA duplex containing an oxidised galactose residue (0.23 µmol litre ⁻¹) (duplex 27*)	NaBH ₄	3.75 mmol litre ⁻¹	40	4	25
RNA polymerase of bacteriophage T7 (0.1–0.5 µmol litre ⁻¹)	22-membered DNA duplex containing an oxidised 2'- <i>O</i> -ribofuranosylcytidine residue (0.1–0.5 µmol litre ⁻¹)	NaBH ₄	0.05 µmol litre ⁻¹	60	—	30

cross-linked product did not depend on the presence of the cofactor (Mg²⁺ ions). This led the authors²⁵ to assume that cross-linking of DNA duplexes containing aldehyde groups to *R.Eco*RII occurs not at the active site.

None of the DNA duplexes containing an oxidised 2'-*O*-ribofuranosylcytidine unit was able to cause affinity modification of T7 RNA polymerase.³⁰ However, covalent cross-linking of the DNA duplex containing an oxidised 2'-*O*-ribofuranosylcytidine residue at position +2 of the consensus promoter to the mutant form of T7 RNA polymerase (Tyr639 → Lys) did take place. In wild type enzyme, Tyr639 is apparently involved in the NTP binding and should be located in close proximity to the initiation site, which suggests that Lys639 is the residue that was subjected to modification.³⁰

The first results of affinity modification of DNA-binding proteins are important for determining specific DNA–protein contacts and for studying the structure of active centres of enzymes as well as for elucidating the mechanisms of catalysis by restriction-modification enzymes and RNA polymerases.

IV. Conclusion

Introduction of reactive aldehyde groups into NA makes it possible to use them for attachment of fluorescent or any other label. In addition, oligonucleotides containing dialdehyde fragments are convenient for the synthesis of antisense oligonucleotides. Affinity modification of proteins with DNA duplexes containing regiospecifically introduced aldehyde groups proceeds with sufficiently high yields and results in stable covalent bonds. The results of cross-linking of this type of reagents to proteins allow one to recommend them as an efficient and flexible tool in the study of a broad range of DNA–protein interactions.

Dioxiranes: from oxidative transformations to chemiluminescence

V P Kazakov, A I Voloshin, D V Kazakov

Contents

I. Introduction	253
II. Synthesis and spectral characteristics of dioxiranes	254
III. Thermal decomposition of dioxiranes	257
IV. Dioxiranes as oxidants	262
V. Chemiluminescence and photochemistry of dioxiranes	274
VI. Conclusion	280

Abstract. Experimental data on the chemistry of a new class of highly effective oxidation reagents, dioxiranes, are summarised. The main methods used to generate dioxiranes and reactions in which dioxiranes have been proposed as intermediates are considered. The full notion about an important property of dioxiranes, *i.e.* the ability to oxidise rapidly, selectively and under mild conditions various classes of organic compounds (alkanes, alkenes, compounds containing heteroatoms, organometallic substrates, *etc.*) is given. Various aspects and mechanisms of these reactions are discussed. The attention is focused on the analysis of mechanisms of dioxirane decomposition in the absence of oxidisable substrates. One of the most attractive aspects of the dioxirane chemistry, chemiluminescence, is considered (the mechanisms of the generation of excited products during both thermal and catalytic decomposition and upon photochemical activation are discussed). The bibliography includes 401 references.

I. Introduction

The chemistry of three-membered cyclic peroxides, dioxiranes **1**, has swiftly developed during the last twelve years.

In 1985, when successful synthesis of a number of 'isolated alkyl dioxiranes'† had been reported,¹ these compounds became available for wide employment. Since then, they have been in the

† From here on, the term 'isolated dioxirane' implies a solution of dioxirane in the corresponding ketone or in a solvent isolated from the reaction mixture. This term, which is generally accepted in the literature and reflects features of the peroxide method for the synthesis of dioxiranes (see Section II), is used in order to distinguish the cases where isolated dioxiranes are used from those when dioxiranes are generated *in situ* and are not isolated from the reaction mixture.

Uspekhi Khimii 68 (4) 283–317 (1999); translated by Z P Bobkova

centre of chemists' attention and the number of publications devoted to them has constantly increased. What is the reason for this interest? The main cause is the exceptionally high reactivity of these compounds, which is remarkably combined with high selectivity of oxidation. The most typical reactions of dioxiranes include oxidative functionalisation of alkanes, alkenes and their functionally substituted derivatives containing heteroatoms X

It is this fact that attracts the attention of chemists engaged in organic synthesis to oxiranes. The most often used derivatives are dimethyldioxirane **1a** and methyl(trifluoromethyl)dioxirane **1b**; the oxidative properties of these compounds have been the subject of numerous publications including several excellent reviews,^{2–9} devoted mainly to synthetic aspects.

However, this does not exhaust the properties of dioxiranes. Chemiluminescence (CL) is another, equally important feature of these compounds. A fairly attractive feature of dioxiranes, found recently, is that they are capable of forming products in electronically excited states upon both thermal decomposition and photochemical activation.^{6, 10–17}

The research along this line started only recently, most of the studies being performed by the authors of this review. Even these few studies allow one to appreciate the great opportunities and prospects opened for researchers in the wonderful world of chemiluminescence of dioxiranes. Although it is difficult to predict the extent to which dioxiranes would be able to compete with their chemical relatives, 1,2-dioxetanes **2**^{18–22}

it can be claimed with confidence that these three-membered cyclic peroxides have already occupied a special place in the world of shining reactions.

The great interest in dioxiranes is also due to the fact that they represent an isomeric form of carbonyl oxides $R^1R^2C^+ - O - O^-$ (**3**), which are oxidants and important reactive intermediates in many oxidative processes.^{23–32} Despite the fact that the behaviours of dioxiranes and carbonyl oxides are substantially different, both should be taken into account in consideration of the mechanisms of some oxidation processes. Moreover, photocyclisation of carbonyl oxides **3** is the main method used to synthesise dioxiranes **1** in a matrix.³³

The mechanism of decomposition of dioxiranes in the absence of easily oxidisable partners also presents interest. The mechanism of their reactions with alkanes, which has unexpectedly become the object of sharp debates, is equally interesting (see, for example, Refs 34–39).

There are grounds for believing that dioxiranes can be formed in the upper atmosphere,^{1, 3, 40} upon interaction of alkenes with ozone.^{41–44} Study of gas-phase reactions of dioxiranes with polyaromatic hydrocarbons (PAH)^{3, 45–47} including those yielding carcinogens (which can affect the environment) could provide deeper insight into the processes occurring in the atmosphere.

This review covers these and many other aspects. We hope that it would present interest not only for organic chemists but also for specialists in physical chemistry.

II. Synthesis and spectral characteristics of dioxiranes

The history of the dioxirane chemistry covers almost a century. In 1899, Baeyer and Villiger,⁴⁸ who studied the reaction of menthone with monoperoxydisulfuric acid, postulated that the formation of the corresponding lactone is preceded by the formation of a cyclic oxygen-containing intermediate, dioxirane.

Now this reaction is named after the authors. They were the first to introduce the term 'dioxirane' into scientific literature. The next mention of dioxiranes dates back to 1910, when Harries⁴⁹ suggested that decomposition of 1,2,3-trioxolanes, resulting from ozonisation of alkenes, affords carbonyl oxide and a peroxide and ascribed a dioxirane structure to the latter product.

Only many years after these two publications had appeared, was the first dioxirane really prepared and characterised. This was done by Talbot and Thompson⁵⁰ in 1972. The authors reported on the synthesis of perfluorodimethyldioxirane **1c** and chlorodifluoromethyl(trifluoromethyl)dioxirane **1d** by oxidation of the corresponding dialkoxides with fluorine. However, this method has not been further developed.

X = F (**c**), Cl (**d**).

The dioxiranes **1c** and **1d** were isolated using low-temperature gas chromatography; they were coloured pale yellow both in the liquid and solid states (the absorption maximum of the dioxirane **1c** lies at $\lambda = 306$ nm).⁵⁰ The compound **1c** was described as unstable and explosive.⁵⁰

At present, two main lines in the dioxirane synthesis can be distinguished: (1) the peroxide method, which is used most often and successfully to prepare dioxiranes and (2) non-peroxide

methods (e.g., ozonolysis of hydrocarbons, photooxidation of diazo compounds in a matrix and some other methods.)

1. Non-peroxide methods for the synthesis of dioxiranes

When considering the known non-peroxide methods for the generation of dioxiranes, we dwelt not only on the studies the authors of which succeeded in isolating dioxiranes and obtaining their spectral characteristics but also on those in which dioxiranes were only suggested as possible intermediates (the latter type is represented by a few examples).

a. Ozonolysis of saturated and unsaturated compounds

In 1977 two groups of researchers working independently^{41–44} presented convincing experimental evidence (obtained by microwave spectroscopy and mass spectrometry) for the formation of the simplest dioxirane **1e** in the gas-phase ozonisation (-130 to -75 °C) of ethylene. Dioxirane **1e** was also detected among the products of ozonolysis of propene, vinyl fluoride and but-1-ene.

The microwave spectroscopy data showed that dioxirane **1e** has a shorter C–C bond (1.3878 Å) and a longer O–O bond (1.5155 Å) than ethylene ozonide, in which the corresponding bond lengths are 1.416 and 1.461 Å.

A large variety of reactions of ozonisation of unsaturated substrates involving dioxiranes have been reported.^{51–59} Thus Keay and Hamilton^{51, 52} carried out ozonisation of but-2-yne in CH_2Cl_2 (-70 °C). By varying the temperature and adding portions of methanol to the solvent, the researchers isolated three different products, capable of epoxidising alkenes; the first compound was identified as the peroxy acid $MeC(O)OOH$, the second one was identified as trioxolene **4**, and the structure of dioxirane **1f** was attributed to the third compound.

Pryor *et al.*⁵³ carried out a similar reaction in the presence of nitron as a spin trap; they detected the adduct of the nitron with the acetyl radical formed from the dioxirane **1f**. Bufalini *et al.*⁵⁴ interpreted the formation of acetic acid in the ozonisation of but-2-ene as being due to the following sequence of reactions:

Eastman *et al.*^{55, 56} explained in a similar way the formation of methyl acetate and an ester of formic acid in the gas-phase ozonisation of tetramethylethylene and cyclohexene.

O'Neal and Blumstein⁵⁷ proposed a general mechanism of gas-phase ozonolysis based on participation of the biradical form of carbonyl oxide and the subsequent transformation of the biradical into dioxirane. Conversely, Vaccani *et al.*⁵⁸ suggested direct formation of dioxirane from 1,2,3-trioxolane during the gas-phase reaction of ozone with vinyl chloride.

The liquid-phase ozonisation of 1,2-dimethoxy-1,2-diphenylethene gave (methoxy)phenyldioxirane **1h**, which was studied by ¹³C NMR spectroscopy.⁵⁹

In several studies, dioxiranes have been considered as intermediates in ozonisation of saturated compounds. Thus ozonolysis of ketones **5** occurs presumably⁶⁰ via an attack by ozone on the

carbonyl group of **5** to give compounds **7** or **8**, which eliminate an oxygen molecule being thus converted into either carbonyl oxide or dioxirane (Scheme 1).

Scheme 1

It has been suggested⁶¹ that the formation of anhydrides in the ozonisation of some α -diketones occurs by a similar scheme.

b. Cyclisation of carbonyl oxide to dioxirane in a matrix

Yet another aspect of the dioxirane chemistry is related to low-temperature photochemistry. In a series of studies,^{28, 33, 62–72} a new pathway to dioxiranes has been found, which is based on low-temperature irradiation of carbonyl oxides in an argon matrix.

This method was used to prepare diphenyldioxirane, chloro(phenyl)dioxirane, phenyl(trifluoromethyl)dioxirane, a series of substituted dioxiranes based on quinone *O*-oxides, silicon-containing dioxiranes, *etc.*^{28, 33, 62, 65–77}

Evidence has been obtained for the formation of unsubstituted dioxirane **1e** in the oxidation of carbene $:CH_2$ in an oxygen-containing matrix.⁷⁸ Photocyclisation of propynal *O*-oxide **3a** to give propargyldioxirane **1i** has been reported.⁷⁹

Despite the fact that photooxidation of diazo compounds made it possible to detect several dioxiranes, this method for their synthesis has not found wide application because it requires thorough control of the photolysis conditions, temperature and the solvent (in order to avoid side reactions of carbenes) and because carbene and carbonyl oxide are unstable. The lifetimes of these species have to be sufficiently long and, in addition, photodecomposition of the diazo compound and photocyclisation of carbonyl oxide have to occur at those wavelengths where the dioxirane is stable in order to avoid its rearrangement into an ester. Until recently, dioxiranes obtained in this way could be studied only at low temperatures.

However, in 1994, Sander *et al.*⁸⁰ succeeded in preparing the relatively stable dimesityldioxirane **1j** at quite plausible temperatures (about -80°C). This compound was synthesised from dimesityldiazomethane **9** via the corresponding carbonyl oxide **3b**, the lifetime of which is several orders of magnitude longer than that of diphenylcarbonyl oxide.

An advantage of this system is that the dioxirane **1j** does not absorb in the spectral range needed to synthesise it. Later, Sander *et al.*⁸¹ proposed several convenient procedures for the synthesis of dimesityldioxirane **1j**, resulting in the formation of this compound both in solution and in the crystalline state (melting point $62–64^\circ\text{C}$).

c. Formation of dioxiranes in other peroxide systems

Among various non-peroxide methods for the synthesis of dioxiranes, studies by Russo and DesMarteau^{82, 83} deserve attention. They prepared difluorodioxirane **1k**, which is stable in the gas phase at room temperature over a period of several days, and characterised it by IR spectroscopy (the boiling point of the dioxirane **1k** is -80 to -90°C , and the melting point is $< -160^\circ\text{C}$).

In some studies dioxiranes are considered to be possible intermediates in various chemical reactions. Thus in a study of the oxidation of acyl-substituted diazo compounds by singlet oxygen, Ando *et al.*^{84, 85} concluded that this reaction can give both carbonyl oxide and dioxirane; it is these compounds that are responsible for the oxidation of sulfides.

Apparently, the photosensitised oxidation of phenyl(tri-methylsilyl)diazomethane with singlet oxygen also occurs via a dioxirane.⁸⁶

Dioxiranes have been suggested as intermediates in the decomposition of α -azo hydroperoxides by pyridine,^{87–90} oxidation of some azines⁹¹ and ylides^{92, 93} by singlet oxygen, in the reaction of the $T(F_2C:)$ carbene with O_2 in the presence of alkenes⁹⁴ and in the decomposition of some endoperoxides.^{95, 96}

Steinfatt,^{97–100} who observed chemiluminescence during the reaction of geminal dichloro-derivatives of hydrocarbons with Na_2O_2 , suggested that luminescence is due to a dioxirane formed as the key intermediate in this reaction. A dioxirane intermediate has been postulated to interpret the mechanism of bioluminescence of bacteria.¹⁰¹ Recently, we suggested that chemiluminescence in the $Ph_2CCl_2-NaOH-H_2O_2$ system, which is similar to the Steinfatt systems, is also associated with a dioxirane¹² (studies

dealing with the chemiluminescence of dioxiranes are described in greater detail in Section V).

2. Peroxide method for the synthesis of dioxiranes

Despite the existing successful examples where dioxiranes have been synthesised using the procedures described above, the peroxide method for the synthesis of dioxiranes is still the most convenient and the most widely used in synthetic practice. The discovery of this method was preceded by the publication of Montgomery,¹⁰² who found that some ketones catalyse decomposition of monoperoxysulfuric acid (Caro's acid) and accelerate various oxidative transformations involving this acid. Montgomery suggested that dioxirane is formed as an intermediate in the catalytic decomposition of H_2SO_5 . Somewhat later,^{103–108} the presence of dioxirane in the H_2SO_5 – R_2CO system has been proved by the isotopic dilution method using the ^{18}O isotope (Scheme 2).

Scheme 2

Su: is substrate, O is 50% ^{16}O and 50% ^{18}O .

It was in the above series of studies^{103–107} that the researchers showed for the first time that dioxirane itself is also a strong oxidant, which is able, for example, to accomplish highly efficient epoxidation of alkenes (Scheme 2, pathway *b*). The reactions were carried out *in situ* in the system ' KHSO_5 [or $\text{K}_2\text{SO}_4 \cdot \text{KHSO}_4 \cdot 2\text{KHSO}_5$ (oxone)]–ketone–substrate (Su):' at $\text{pH} \approx 7.5$. The necessity of maintaining a constant pH value is due to the fact that $\text{pH} > 7.5$ leads to an increase in the concentration of the $-\text{O}-\text{OSO}_3^-$ dianion, which reacts with dioxirane (Scheme 2, pathway *a*) to destroy the latter, whereas at $\text{pH} < 7.5$, deprotonation of intermediate **A** is virtually terminated and the formation of intermediate **B** and then of dioxirane becomes unlikely.

However, the main difficulty lay in the fact that dioxirane itself could exist *in situ* only together with the corresponding ketone, oxone, H_2O and other reagents needed to maintain pH; of course, this created certain problems hampering the use and investigation of dioxirane. Therefore, the main challenge was to isolate dioxirane from the reaction mixture. This was attained in 1985 by Murray and Jeyaraman,¹ who developed a procedure for the preparation of the individual dioxirane **1a** and some other alkyl dioxiranes (ethylmethyldioxirane, diethyldioxirane, methyl-*n*-propyldioxirane, *n*-butylmethyldioxirane, *etc.*). This study was the first to make dioxiranes accessible for investigations and to open up the way for their extensive use.

A key point in the Murray method¹ was the fact that the reaction of oxone with the initial ketone was carried out in a stream of an inert gas and under a slightly reduced pressure; this made it possible to separate dioxirane as a vapour, which was then collected in cooled traps. Later, this procedure was somewhat modified;^{109–111} however, the basic principle remained the same. This method was also used to prepare the dioxirane **1b**,¹¹¹ which proved even more reactive than **1a**.

It is noteworthy that the Murray procedure for the preparation of dioxiranes is fairly simple and can be performed almost in any laboratory (see, for example, Ref. 110). It should only be borne in mind that the reactants need to be thoroughly purified

from possible impurities in order to avoid decomposition of dioxirane (see Section III) and that drying agents, if required, should be chosen with caution because it has been noted (see, for example, Refs 2, 112 and 113) that some drying agents affect the stability of the dioxirane **1a** and shorten its lifetime. Therefore, when the purpose of the study does not imply thorough drying, it is better to avoid this procedure and to remove water by decanting the solution from H_2O crystals at a low temperature (-75°C).

The drawbacks of the peroxide Murray method are that it yields dioxiranes only in small amounts and that the initial ketone is distilled from the reaction mixture together with the dioxirane. Thus the concentrations of the dioxiranes **1a** and **1b** in the initial ketone are only 0.06–0.12 and 0.65–0.82 mol litre⁻¹, respectively. The concentrations of other alkyl dioxiranes prepared by this procedure are even lower.¹ The attempts to increase the concentration of the dioxirane **1a** by varying the synthesis conditions and the experiments on its distillation failed.³ Thus, acetone is an immutable 'companion' of the dioxirane **1a** in all its chemical transformations.

However, in the case of the dioxirane **1b**, the initial ketone, 1,1,1-trifluoropropanone (TFP), has been completely separated. For this purpose, the dioxirane obtained was dissolved in the corresponding solvent ($\text{CCl}_2\text{FCClF}_2$, CCl_4 , CH_2Cl_2 , *etc.*) and the solution was washed with doubly distilled water. The initial ketone, which reacts with water forming a hydrate, is extracted into the aqueous phase, whereas the dioxirane **1b** remains in the organic phase.¹¹⁴ To obtain more concentrated solutions, frozen solutions of the dioxirane **1b** (77 K) were slowly evaporated ($< 10^{-2}$ Torr) and then recovered in cooled traps.¹¹⁴

A similar concentration procedure has been developed by Messegueur *et al.*^{115,116} for the dioxirane **1a**. The method is based on the fact that **1a** is more lipophilic than acetone. Although complete removal of acetone was not attained in this case, extraction of an acetone solution of the compound **1a** with an organic solvent (CCl_4 , CH_2Cl_2 , CHCl_3) followed by washing of the organic extract with a phosphate buffer (pH 7) made it possible to obtain more concentrated solutions of the dioxirane **1a** (0.23–0.35 mol litre⁻¹).

In conclusion, another study by Murray *et al.*¹¹⁷ should be mentioned; the researchers reported a procedure for preparation of a number of dioxiranes (0.2–0.8 mol litre⁻¹) from ketones poorly soluble in water.

Unfortunately, the peroxide method described above cannot be used for the synthesis of 'heavier' dioxiranes with bulky substituents, in particular, phenyl-substituted dioxiranes.

3. Identification and analysis of dioxiranes

NMR, UV and IR spectroscopy are the most informative methods, used most often to identify dioxiranes. As can be seen from Table 1, common features of dioxiranes include a characteristic signal (δ 100 ppm) for the carbon atom bound to the peroxide group in the ^{13}C NMR spectrum and a relatively weak absorption band in the near UV region ($\lambda = 300$ – 380 nm), ending in the visible region, which is due to the 'forbidden' $n-\pi^*$ transition and is responsible for the pale yellow colour of dioxirane solutions (Fig. 1).

Configurations of dioxiranes are determined using their reactions with methyl phenyl sulfide and triphenylphosphine, iodometric titration and spectrophotometry (the latter method is applicable provided that the extinction coefficient of dioxirane is known).

Table 1. Main spectroscopic characteristics of some dioxiranes (the data were taken from Refs 1, 3, 81, 109, 111 and 117).

Dioxirane	<i>T</i> /°C	δ /ppm				$\lambda_{\max}$ /nm	ϵ /litre mol ⁻¹ s ⁻¹

^a ¹³C NMR spectra were recorded relative to Me₄Si. ^b Acetone labelled by the ¹⁷O-isotope was used as the initial ketone. ^c The measurements were performed in 1,1,1-trifluoropropanone. ^d ¹⁹F NMR spectra were recorded relative to CFCl₃. ^e The measurements were performed in methyl ethyl ketone.

**Figure 1.** Absorption spectrum of the dioxirane **1a**.

4. Thermochemistry of dioxiranes

The data obtained by microwave spectroscopy^{41–44} for unsubstituted dioxirane **1e** indicate that this compound contains the longest peroxide bond (1.52 Å) among such bonds known so far. This strained character of the peroxide ring should favour the homolytic cleavage of the O–O bond to give the biradical intermediate

According to theoretical calculations, the activation energy of this process is ~15 kcal mol⁻¹, whereas the activation barrier to the back reaction (cyclisation) is negligibly small,⁴ < 1 kcal mol⁻¹ (note that in a study¹¹⁸ which is considered in more detail below, the activation energy of cyclisation of the biradical has been suggested to be ~10 kcal mol⁻¹). The results of studies of various energy states of dioxirane **1e**, the corresponding biradical and the carbonyl oxide indicate that dioxirane **1e** cannot pass into carbonyl oxide without substantial energy expenditure, because the energy of the carbonyl oxide is much higher.⁴ Indeed, no examples of this transformation are known. The back reaction, which also requires additional activation energy, equal to

~22 kcal mol⁻¹, occurs on irradiation of dioxiranes.^{28, 29, 33, 62, 65–77, 80, 81}

III. Thermal decomposition of dioxiranes

Despite the substantial progress attained in the studies of oxidative processes of dimethyl- (**1a**) and methyl(trifluoro-methyl)dioxiranes **1b**, the behaviour of these compounds in solutions in the absence of easily oxidisable substrates is still enigmatic and contradictory and remains the least studied aspect in the chemistry of dioxiranes. At present, facts are being accumulated along this line; however, they are often fairly contradictory. In fact, there is still no general agreement concerning either the products of decomposition of the dioxirane **1a** or its stability (the values for the time needed for decomposition of the dioxirane **1a** at room temperature reported in the literature^{109, 112, 119} range from 7 h¹⁰⁹ to 26 days¹¹²).

This situation is due to the properties of dioxiranes; apparently, their decomposition is a complex process depending on numerous factors and conditions.

1. The products and mechanism of decomposition of methyl(trifluoromethyl)dioxirane

Decomposition of methyl(trifluoromethyl)dioxirane **1b** in the initial ketone gives methyl trifluoroacetate (MTFA) and trifluoroacetic acid, formed upon its hydrolysis, as the major products.¹¹¹

The half-life of the dioxirane **1b** in the initial ketone is ~20 h at 15 °C (at -20 °C, the decrease in the concentration is ~6% over a period of 48 h).¹¹¹ In addition, it was noted¹¹¹ that decomposition of the dioxirane **1b** at 0 °C follows complex kinetics corresponding to a mixed first and second order.

Later, when solutions of the dioxirane **1b** in inert solvents were obtained, the full picture of its decomposition occurring at elevated temperatures or on exposure to UV radiation was identified.¹¹⁴ Whereas at low temperatures the dioxirane **1b** is

rather stable in inert solvents (at $-20\text{ }^{\circ}\text{C}$, the decrease in its concentration in CCl_4 or CH_2Cl_2 is 5%–6% over a period of 168 h), at elevated temperatures ($60\text{ }^{\circ}\text{C}$, CCl_4), it decomposes by almost 50% within 30 min.¹¹⁴ Thorough investigation of the products of thermolysis ($60\text{ }^{\circ}\text{C}$) and photolysis of solutions of the dioxirane **1b** free from the corresponding ketone showed that under these conditions, decomposition occurs by a radical chain mechanism¹¹⁴ and affords MTFA, trifluoromethyl acetate (TFMA) and methyl acetate (MA). Apart from the esters listed above, the reaction mixture contains acetic and trifluoroacetic acids, which, in the opinion of the authors cited,¹¹⁴ have resulted from hydrolysis of TFMA and trifluoromethyl trifluoroacetate (TFMTFA), respectively. In addition, evolution of CO_2 was noted in all cases. These facts and the fact that in the presence of O_2 , the photolytic process is substantially retarded and the formation of esters is markedly depressed provide strong evidence for the chain radical mechanism of decomposition of the dioxirane **1b** (Scheme 3).

In conformity with the Scheme 3, decomposition of methyl-(trifluoromethyl)dioxirane gives rise to the radical pair $[\dot{\text{C}}\text{H}_3 \dot{\text{C}}\text{F}_3]$, which then either recombines according to pathway *a* or generates free radicals $\dot{\text{C}}\text{H}_3$ and $\dot{\text{C}}\text{F}_3$ (pathway *b*); these radicals, in turn, attack dioxirane yielding alkoxy radicals **A•** and **B•**. Pathway *a* is realised when methyl(trifluoro-methyl)dioxirane is photolysed in a matrix. In this case (unlike experiments in solution), 1,1,1-trifluoroethane is a major product of decomposition of dioxirane.

Radicals **A•** and **B•** undergo β -cleavage to give esters with the regeneration of alkyl radicals, which carry the chain (Scheme 4).¹¹⁴

It is of interest that no radical chain processes are involved in the vacuum flash pyrolysis ($500\text{ }^{\circ}\text{C}$) of the dioxirane **1b**,¹¹⁴ which gives only MTFA. Apparently, in this case, dioxirane simply isomerises to ester according to reaction (4).

The radicals formed upon decomposition of the dioxirane **1b** were detected at low temperatures using 1,1,3,3-tetramethyl-1,3-dihydroisindolin-2-yloxyl **10** as a spin trap.¹²⁰ However, the adduct of the nitroxide **10** and the $\dot{\text{C}}\text{H}_3$ radical is formed apparently *via* the dioxirane radical anion, resulting from the transfer of an electron from the nitroxide **10** to the dioxirane **1b**

(Scheme 5, pathway *a*).¹²⁰ Yet another channel of consumption of the radical anion is pathway *b*.

Scheme 5

The decomposition of the dioxirane **1b** can also be induced by various impurities. Thus it has been noted¹²¹ that the presence of even traces of metals can cause rapid decomposition of dioxiranes. Messeguer *et al.*¹²² have found that catalytic amounts of dialkyl ethers (*e.g.*, diethyl or dihexyl ether) induce rapid decomposition of the dioxirane **1b** in a radical chain process. This finding appears very important because the same researchers reported¹²² that these ethers are contained in the initial TFP even after distillation. However, they can be removed. Thus when TFP is washed with water and an inert solvent, the ethers are accumulated in the organic phase, whereas TFP passes into the aqueous phase as hydrate.

2. The products, kinetics and mechanism of decomposition of dimethyldioxirane

Several routes for decomposition of dioxiranes **1a** can be found in the literature (Scheme 6).

Scheme 6

Evidently, the realisation of one or another channel of transformation of the dioxirane **1a** depends on a whole series of conditions such as temperature, the content of O_2 , the presence of impurities, *etc.* Some of these factors can be controlled; the influence of some other factors can be reduced (for example, by thorough purification of the initial compounds). Table 2 contains data on the products of decomposition of the dioxirane **1a** and on the reaction mechanisms that have been invoked by the researchers in order to interpret the results obtained and that are considered in detail below.

Table 2. Products of decomposition of dimethyldioxirane (**1a**) under various conditions.

Reaction conditions	Proposed mechanism (Scheme 6)	Decomposition products	Ref.
Room temperature, no special purging with oxygen or an inert gas	<i>a</i>	diperoxide 11	1
	<i>b</i>	hydroxyacetone (12) + MA ^a	119
	the mechanism is not discussed	MA ^a	112
Vacuum flash pyrolysis, 150–180 °C	<i>e</i>	MA	112
In boiling acetone	<i>d</i>	MA + 1-(acetyl-oxy)propan-2-one	112
Decomposition in the presence of BF ₃	pathways <i>b</i> and <i>e</i> occur in parallel	MA + 12	112
Room temperature	<i>e</i>	MA	15
Decomposition in the presence of CCl ₃ Br, 20 °C	<i>d, e</i> and <i>f</i>	MA ^b , 1-(acetyl-oxy)propan-2-one, CH ₃ CO ₂ H, CH ₃ Br, CHCl ₃ , CH ₃ OH, ClCH ₂ C(O)CH ₃	37
Decomposition in the presence of the Ru(II) tris-(bipyridine) complex, 40 °C	<i>e</i> (see ^c)	MA	15

^a Some quantity of MA was already present in the initial solutions of **1a**.
^b Methyl acetate was the major product. ^c In this case, we are dealing with catalysed isomerisation of dioxirane to MA according to the electron transfer mechanism (see Section V).

a. Dimerisation of dimethyldioxirane

The first data on the products of decomposition of dimethyldioxirane **1a** were published in 1985. Murray *et al.*¹ reported on the conversion of the dioxirane **1a** into cyclic diperoxide **11**:

Later, however, they were unable to reproduce their own results¹¹² and suggested that compound **11**, which they had observed previously, must have been formed as a side product during the synthesis of dioxirane.

b. Decomposition with participation of the enol form of acetone

Decomposition of the dimethyldioxirane **1a** at room temperature has been reported¹¹⁹ to give hydroxyacetone **12** together with a minor amount of methyl acetate. It was noted¹¹⁹ that solutions of dioxirane always contain some MA, which appears apparently during the synthesis of dimethyldioxirane. Based on this finding, a decomposition mechanism has been proposed, the key stage of which includes the reaction of the dioxirane **1a** with the enol form of acetone **13** followed by rearrangement of the resulting epoxide intermediate to hydroxyacetone **12**.

However, the possible formation of the hydroxy ketone **12** upon direct insertion of an oxygen atom into the C–H bond of acetone or in a free-radical process also cannot be ruled out.¹¹⁹

The contribution of reaction (5) to decomposition of the dioxirane **1a** increases in the presence of BF₃. In the opinion of Murray and Singh,¹¹² boron trifluoride exerts a dual effect: on the one hand, it increases the rate of conversion of **1a** into MA and, on the other hand, it favours an increase in the concentration of the enol **13**, which then reacts with **1a** [reaction (5)] to give hydroxyacetone (see Table 2).

It was also found that solutions of the dioxirane **1a** are sensitive to the presence of bases; the addition of KOH to a solution of dioxirane results in its rapid decomposition, which follows first-order kinetics.¹¹⁹ A similar situation has been observed in the case of a solution of deuterated dioxirane **1a**, which proved to be more stable than the non-deuterated compound ($k_{\text{H}}/k_{\text{D}} \sim 4$).¹¹⁹

c. Catalysis by decomposition products

Many researchers (see, for example, Refs 109, 112, 118, 119, 123) have noted that at high concentrations (≥ 0.06 mol litre⁻¹), decomposition of the dimethyldioxirane **1a** does not follow first-order kinetics; instead, it has a fairly long induction period, which is followed by rapid decomposition (Fig. 2). It was found that the higher the temperature and the dioxirane concentration, the shorter the induction period.^{118, 123} It was suggested that reaction products have a catalytic effect on the decomposition of the dioxirane **1a**. Indeed, comparison of curves 2 and 3 in Fig. 2 shows that **1a** decomposes much faster in the presence of decomposition products. Unfortunately, the products of decomposition of **1a** were not specified in the study cited.¹¹⁸

Figure 2. Kinetic curves for the consumption of dimethyldioxirane **1a** in acetone at 50 °C (solutions of **1a** in acetone were used without preliminary dehydration).¹¹⁸

The initial concentration of the dioxirane **1a** (mol litre⁻¹): (1) 0.12, (2) 0.02, (3) 0.02 (in the presence of the products formed upon decomposition of 0.12 mol litre⁻¹ of a solution of the dioxirane **1a**).

When the concentration of the dioxirane **1a** is low (0.02 mol litre⁻¹), its decomposition follows first-order kinetics (Fig. 2, curve 2).^{112, 118, 123} This fact was used¹¹⁸ to determine the activation parameters of the decomposition of **1a** in the temperature range 25–75 °C: $\log k = 12.4 - 24.9/(2.3RT)$. Thus, at 25 °C, $k = 1.53 \times 10^{-6}$ s⁻¹, and the activation energy of decomposition of the dioxirane **1a** is about 9–10 kcal mol⁻¹ higher than the value calculated theoretically (~ 15 kcal mol⁻¹) for unsubstituted dioxirane **1e**.⁴ The latter result was interpreted¹¹⁸ as being due to

the consumption of **1a** in a radical chain process, which is manifested as a sharp acceleration of the reaction. This is quite consistent with the decrease in the induction period following an increase in the temperature¹¹⁸ and also with the substantial effect of argon. Even when the concentration of the dioxirane **1a** is relatively low (0.03 mol litre⁻¹) and the temperature is moderate (20 °C), the induction period in the reaction performed under argon decreases to ~150 min.¹²⁴ It comes as no surprise that the dioxirane decomposition under an atmosphere of O₂, which inhibits the radical chain process, strictly follows first-order kinetics irrespective of the initial dioxirane concentration or temperature (30–49.5 °C).¹³²

e. Isomerisation of dimethyldioxirane to methyl acetate

Although arguments in favour of the radical mechanism of decomposition of the dioxirane **1a** are quite forcible, the existence of a parallel channel of the decomposition of **1a**, namely, its isomerisation to MA *via* a biradical intermediate, can also be considered to be proven.

It was found¹⁴ that reaction (6) occurs under conditions of photolysis of the dioxirane **1a** in a matrix (77 K) (isomerisation is also a major pathway of the low-temperature phototransformation of some other dioxiranes³³). In addition, at higher temperatures, ($T = 150\text{--}180$ °C, vacuum flash pyrolysis), reaction (6) is regarded as the major pathway for decomposition of dimethyldioxirane (remarkably, under these conditions some **1a** remains intact!).¹¹² Apparently, rearrangement to give MA is the main route of decomposition of the dioxirane adsorbed on the Silipor surface from the gas phase.^{11, 16}

However, it is reasonable to suggest that decomposition of the dimethyldioxirane **1a** in solution also involves reaction (6). Its contribution depends most likely on the temperature and other experimental conditions. Due to the influence of impurities and at elevated temperatures, which promote the occurrence of parallel routes of the radical chain decay of the dioxirane **1a**, the fraction of isomerisation should decrease. However, it has been shown experimentally that even under conditions most favourable for a radical chain process (46 °C, absence of O₂), reaction (6) still does occur, because it is this reaction that is responsible for the chemiluminescence observed under these conditions¹³ (this aspect is considered in greater detail in Section V). In our opinion, the contribution of reaction (6) markedly increases at lower temperatures; apparently, at room temperature and below room temperature, it becomes the major route for the dioxirane consumption.

Note that reaction (6) can also be induced by a catalytic influence of various compounds. Thus ruthenium tris(bipyridine) complex Ru(bipy)₃²⁺ and some polyaromatic hydrocarbons, which act as activators of the CL arising by the chemically

initiated electron-exchange luminescence (CIEEL) mechanism, catalyse isomerisation of dioxirane.^{6, 10, 12, 15, 16, 123} Apparently, the Silipor surface also functions as a catalyst.^{11, 16}

e. Catalysed (induced) decomposition of dimethyldioxirane by impurities

Some impurities have an exceptionally significant influence on the stability and the decomposition mechanism of the dioxirane **1a**. These impurities include some metals, traces of dehydrating agents (*e.g.*, molecular sieves,¹¹² MgSO₄, *etc.*) and reactive compounds present in the initial acetone or introduced into a solution of the dioxirane **1a** from the reaction vessel at the stage of its synthesis. Murray² noted that the lifetime of dioxirane depends on the pre-history of the sample and can be sensitive to admixtures of the dehydrating agent used (*e.g.*, Na₂SO₄).

An example of dioxirane decomposition induced by impurities has been reported.³⁷ It was shown that the stability of dimethyldioxirane **1a** is substantially affected by the addition of CCl₃Br. Whereas decomposition of the dioxirane **1a** under ordinary conditions follows first-order kinetics ($k = 6.2 \times 10^{-6}$ s⁻¹), the addition of CCl₃Br, especially with simultaneous removal of O₂ from the system, sharply accelerates the process (Fig. 4), the product composition leaving no doubt as to the participation of free radicals in the dioxirane decomposition in the presence of CCl₃Br³⁷ (Scheme 9).

Presumably,³⁷ CCl₃Br can also participate in the formation of a biradical-ion pair with the dioxirane, resulting from transfer of an electron from the bromide to **1a**. The subsequent reverse electron transfer from the radical anion to the radical cation increases the concentration of biradical **A** and, hence, the probability of formation of the $\dot{\text{C}}\text{H}_3$ radical from it.

Figure 4. Kinetics of decomposition of dimethyldioxirane (**1a**) in the absence (*1*) and in the presence (*2*, *3*) of an equimolar amount of CCl₃Br; (*2*) under atmospheric conditions, (*3*) under inert atmosphere (N₂).

The occurrence of another parallel channel for the transformation of the biradical-ion pair, resulting in the formation of $\cdot\text{CCl}_3$ and $\text{BrO}^{\cdot}$ radicals, capable of participating in the radical chain decay of dioxirane, also cannot be ruled out.³⁷ It was noted^{37,121} that traces of metals can cause rapid decomposition of the dioxirane **1b**. Recently we have confirmed experimentally that this warning is also true for the dioxirane **1a**. It was found¹⁵ that even catalytic amounts of ruthenium(II) $[(4-24) \times 10^{-5} \text{ mol litre}^{-1}]$ induce rapid decomposition of the dioxirane **1a**. It can be anticipated that other metals would also influence the stability of dioxiranes.

The stability of dioxiranes can be affected not only by traces of metals and dehydrating agents but also by organic impurities. The radical chain decay of methyl(trifluoromethyl)dioxirane **1b** in the presence of dialkyl ethers (for example, diethyl and dihexyl ethers)¹²² has been already mentioned. The addition of ethers to dimethyldioxirane **1a** has a similar influence, although it is less pronounced.¹²² Unfortunately, since the boiling points of dialkyl ethers and acetone are close, purification of acetone by distillation does not always lead to the desired result. The situation is aggravated by the fact that some impurities can form directly in the reaction vessel and, therefore, they can appear in a solution of dioxirane at the stage of its synthesis. For example, this concerns MA, small amounts of which get into solutions of **1a** in exactly this way.^{112,119} Impurities that have got into a dioxirane solution *via* this route can be involved in the radical decomposition of dioxirane; hence, the different lifetimes of the dioxirane **1a** synthesised by various researchers and the non-reproducibility of the kinetic data^{15,109,112,118,119,123,132} can be due to different natures and amounts of non-controllable impurities able to accelerate decomposition of the dioxirane **1a** and promote the formation of different decomposition products (see Table 2). This resembles the situation observed in the study of the kinetic and activation parameters of decomposition of tetramethyldioxetane (TMD). In these studies, the so-called 'false solvent effect' had been discovered, manifested as a sharp acceleration of the reaction on passing from aprotic solvents (benzene, CCl_4) to alcohols (MeOH and EtOH) and poor reproducibility of the kinetic data in alcoholic solutions.^{21,133} The reason was that admixtures of transition metal ions were present even in distilled solvents.^{21,134,135} Treatment of alcoholic solutions of TMD with complexonates improved the reproducibility, and the kinetic and activation parameters acquired values typical of aprotic solvents.

However, in the case of the dioxirane **1a**, the situation must be more complicated. Thermal decomposition of dimethyldioxirane **1a** is a complex process, its mechanism depending on numerous factors. To elucidate the extent of influence of each factor, further studies are needed.

3. Decomposition of other dioxiranes

The formation of H_2 and CO is the main pathway of decomposition of gaseous unsubstituted dioxirane **1e** (-115°C).^{42,43}

It has been noted that decomposition of dioxirane **1e** follows different channels, resulting in the formation of atomic hydrogen.⁴³

Gaseous difluorodioxirane **1k** is more stable than **1e**. No decrease in its concentration has been noted over a period of

12 h at 22°C and 15 Torr. The unusual stability of the dioxirane has become the subject of a special theoretical study.¹³⁶

When a small amount of ClF is added to difluorodioxirane **1k**, the dioxirane is destroyed fairly rapidly to give COF_2 and O_2 .⁸²

The spirocyclic dioxirane **11** is relatively unstable:¹¹⁷ at room temperature, the yellow colour, typical of dioxiranes, completely disappears in 5–10 min and the solution becomes colourless. Simultaneously, the solution substantially warms up, indicating the exothermic character of the decomposition of **11**. Interestingly, instead of the expected lactone **18**, decomposition of the dioxirane **11** at room temperature gives its linear oligomer **17** as the major product (90%).

However, at lower temperatures the reaction gives the lactone **18**.¹¹⁷ This example clearly illustrates the statement that the reaction temperature can dictate the predominance of one or another channel of dioxirane decomposition.

Dimesityldioxirane **1j** can exist both in solution and in the crystalline state.^{80,81} In both cases, the dioxirane **1j** isomerises to the corresponding ester, mesityl mesitoate **19**:

The dioxirane **1j** is relatively stable at room temperature (its concentration decreases by 14% over two weeks) and virtually stable at -20°C . However, on exposure to radiation, it completely isomerises into the ester **19** in several minutes.^{80,81} The stability of the dioxirane **1j** under ordinary conditions is due to the facts that its molecule is sterically hindered and the O—O bond is relatively strong and, in addition, it is the shortest (1.503 Å) among the O—O bonds in dioxiranes.⁸¹

IV. Dioxiranes as oxidants

Highly selective oxidation of organic compounds of various classes is a well-studied aspect of the chemistry of dioxiranes, which is becoming more and more significant in organic synthesis. This feature, discovered even in the first studies on *in situ* generation of dioxiranes,^{103–107} has fully come to light in the subsequent studies carried out using pure solutions, most often of the dioxiranes **1a** and **1b**. The main types of oxidative transformations involving **1a** and **1b** include oxidation of alkanes, alkenes, their functionally substituted derivatives containing heteroatoms (O, S, N, P), and organometallic compounds.

1. Oxidation of saturated compounds

Highly selective oxidation of saturated compounds to the corresponding hydroxy- and oxo-derivatives is one of the most important and most difficult problems in organic chemistry.¹³⁷ At present, peroxy acids, hydroperoxides, ozone, catalytic systems including transition metals and some other compounds are used most often for this purpose.^{138–144} Dioxiranes, capable of oxidising selectively and under mild conditions non-activated C—H bonds in alkanes, occupy a unique place in the series of organic oxidants.

The reactions of dioxiranes with alkanes give rise to the corresponding alcohols. The oxidation of *cis*- and *trans*-1,2-

dimethylcyclohexanes by the dioxirane **1a**, reported by Murray *et al.*,¹⁴⁵ was among the first examples of this reaction.

A similar reaction with participation of the dioxirane **1b**, which is more reactive than **1a**, occurs much faster.¹¹¹

Oxidation of optically active (*R*)-(-)-2-phenylbutane **20** to (*S*)-(-)-2-phenylbutan-2-ol **21** by the dioxiranes **1a** and **1b** occurs with retention of the absolute configuration.^{39, 146}

In this reaction, too, methyl(trifluoromethyl)dioxirane **1b** demonstrates obvious advantages over dimethyloxirane **1a**. Thus when the dioxirane **1a** is used, a 50% degree of conversion of the alkane **20** into the alcohol **21** requires a 10-fold excess of **1a**, 2 days, and a temperature of 25 °C, whereas in the case of **1b**, 100% conversion is attained with only a 2-fold increase of the oxidant and takes 1 h at a temperature of 24 °C.

Dioxiranes have also been used successfully for the synthesis of hydroxy-derivatives of 2,3-dimethylbutane **22**, cumene **23** (X = H)^{121, 147, 148} and its derivatives and a series of other alkanes.

X = H, I, Me, OH, OMe, OPh, COMe.

In all cases (except for norbornane), a tertiary C–H bond in the substrate is oxidised more efficiently than secondary C–H bonds.¹²¹ Non-activated primary and secondary C–H bonds in alkanes can also undergo selective oxidation, for example, in the presence of trifluoroacetic anhydride.¹⁴⁹

Oxidation of cage compounds yields the corresponding alcohols.^{37, 117, 121, 147, 150–152} Thus oxidation of binor **S** by dimethyldioxirane **1a** gave rise to mono- and dihydroxy-derivatives.

Oxidation of adamantane **24** by the dioxirane **1b** gives predominantly, depending on the ratio of the reactants, either adamantane-1-ol (**1b**:**24** = 1:1) or adamantane-1,3-diol (**1b**:**24** = 2:1).¹²¹ When **1b** was taken in a larger excess, adamantane-1,3,5-triol and adamantane-1,3,5,7-tetraol were obtained.

The dioxirane **1a** has also been used to oxidise adamantane^{37, 151} and its derivatives¹⁴⁷ and also 2,4-didehydroadamantane **25**¹⁵² to the corresponding alcohols; however, it is much less reactive than **1b**.

It is of interest that the dioxirane **1b** is 4 times more reactive towards the oxidation of adamantane than **1a**.¹¹⁷

The dioxiranes **1a** and **1b** have been used to synthesise¹⁵³ hydroxy- and polyhydroxy-derivatives of several centropolyindans [triptindan, 1,1'-(*o*-phenylene)-2,2'-spirobiindan, 10-methyltribenzoquinacene, fenestrindan, *etc.*]. Thus oxidation of fenestrindan **26** by the dioxirane **1b** in the CH₂Cl₂–CF₃C(O)Me–Bu^tOH system affords, depending on the reaction conditions, either alcohol **27** or tetraol **28**.¹⁵³

(a) 1.5 equiv. **1b**, CH₂Cl₂:CF₃C(O)Me:Bu^tOH = 9:1:1, –10 °C, 25 min, conversion 56%;

(b) 10 equiv. **1b**, CH₂Cl₂:CF₃C(O)Me:Bu^tOH = 5:4:1, –10 °C, 25 min, conversion 97%.

The alcohol **27** reacts with the dioxirane **1b** (1.7 equiv. of **1b**; CH₂Cl₂:CF₃C(O)Me = 9:1, 0 °C, 15 min, conversion 60%) to give a diol, 4b,8b-dihydroxyfenestrindan (yield >88%).³⁸

Hydroxylation of several natural products,^{154–158} for example, estrone acetate,¹⁵⁶ by the dioxiranes **1a** and **1b** has been reported.

The reactions of a ~0.16 M solution of the dioxirane **1a** in a CHCl₃–Me₂CO mixture with a number of 5β-H-cholic acids (lithocholic **29a**, ursodeoxycholic **29b**, chenodeoxycholic acid **29c**, *etc.*) have been studied.¹⁵⁷ In all cases, oxidation of the C–H bond in the 5β position occurred. However, whereas lithocholic acid **29a** reacts relatively rapidly, the corresponding 5β-hydroxy-derivative being the only reaction product,¹⁵⁷ the acids **29b** and **29c**, containing an electron-withdrawing acetoxy group at the C(7) atom, react slowly because the 5β position is

deactivated and, apart from the 5 β -hydroxy-derivative, the reaction gives, the 14 α - and 17 α -hydroxylation products.¹⁵⁷

R = H (**a**), β -OCOMe (**b**), α -OCOMe (**c**).

Cholestane derivatives, for example, 5 α -cholestan-3-one **30**, 3 β -acetoxy-5 α -cholestan-3-one **31** and 3 β -acetoxy-5 α ,6 β -cholestan-3-one **32** are also oxidised by dioxiranes at the C(25) position to give the corresponding alcohols.¹⁵⁸

30: Y = O, X = H;
31: Y = β -OAc, H, X = H;
32: Y = β -OAc, H, X = Br.

The rate of oxidation of C–H bonds by dioxiranes can depend on ‘external’ factors. Whereas oxidation of 1,3-dicarbonyl compounds by even a substantial excess of the dioxirane **1a** requires about three days,¹⁵⁹ the same reaction carried out in the presence of Ni(II) salts as the catalyst occurs markedly faster, the reaction time being reduced to several hours.¹⁶⁰

This reaction is one of the few examples of ‘external’ interference in the course of oxidative reactions involving isolated dioxiranes. Previously, acid catalysis has been used¹⁶¹ to accomplish selective oxidation of methoxybenzenes by the dioxirane **1a** to the corresponding *p*-benzoquinones.

In some cases, the alcohols formed from alkanes are oxidised by excess dioxirane to give the corresponding ketones.¹²¹ Several secondary alcohols have been oxidised¹⁶² to the corresponding ketones (yields 92%–99%) by the dioxirane **1b** (oxidation of secondary alcohols proceeds more smoothly and requires less time than the oxidation of primary alcohols). A remarkable selectivity was found in the reaction of the dioxirane **1b** with 2-norborneol:

the *endo*-isomer was found to be 40 times more reactive than the *exo*-isomer.¹⁶² Oxidation of chiral α -epoxy alcohols **33** by dioxiranes does not affect the oxirane groups and occurs with retention of the configuration of the asymmetric centre adjacent to the hydroxy group.¹⁶²

On treatment with dimethyldioxirane **1a**, several *para*-substituted α -methylbenzyl alcohols have been converted into the corresponding acetophenones in good yields.¹⁶³

X = H, F, Cl, Br, Me, OMe, CN.

Oxidation of simple phenols by dioxiranes affords complex mixtures of products;¹⁶⁴ the best results were obtained in the reactions of dioxiranes with substituted phenols and catechol.^{164, 165}

Aliphatic diols (including optically active ones) react with the dioxiranes **1a** and **1b** to give α -hydroxy ketones.^{166, 167} It is noteworthy that oxidation of (+)-pinane-2,3-diol to (–)-2-hydroxypinan-3-one occurs with virtually complete retention of the configuration (the optical yield of the ketone is >97%).¹⁶⁶

Oxidation of non-symmetrical 1,2-diols results in their complete conversion to the corresponding mono- and dioxo derivatives (regioselectivity of the process depends considerably on the nature of the substituents).¹⁶⁸

R = H, *p*-OMe, *o*-OH, *o*-NO₂, *p*-NO₂.

Optically active *O*-isopropylidene derivatives of 1,2-diols are converted into 2-hydroxy ketones, formed in high optical yields and with retention of the optical purity.¹⁶⁹

Depending on the reaction conditions and the nature of the substrate, oxidation of allylic alcohols by dioxirane **1a** occurs as either epoxidation of the double bond^{106,107} or competing oxidation of the hydroxy group to an oxo group.¹⁷⁰ In the oxidation of unsaturated nitro alcohols **34**, the double bond remains intact because it is deactivated by the NO₂ group.¹⁷¹

The deactivation effect is also manifested in the oxidation of nitro diols: the hydroxy group remote from NO₂ is oxidised, whereas the OH group occurring in the α - or β -position to the NO₂ group remains intact.¹⁷¹

When dioxiranes are made to react with allyl hydroperoxides, the corresponding epoxy hydroperoxides are formed.¹⁷²

Oxidation of aliphatic esters with the dioxirane **1b** affords oxo and hydroxy derivatives.¹⁷³ Acetals and cyclic and acyclic ethers are also oxidised by dioxiranes to give the corresponding carbonyl compounds,¹⁷⁴ whereas aldehydes are converted into the corresponding carboxylic acids;¹ oxidation of substituted benzaldehydes by the dioxirane **1a** follows a radical mechanism.¹¹⁹ Ethylene ketals undergo oxidative cleavage.¹⁷⁴

The reaction of diphenylmethane with dimethyldioxirane affords Ph₂CO (92%). In this case, the methylene carbon atom, which is absolutely inert under other circumstances, can be oxidised because the CH₂ unit is activated by the two phenyl groups.¹⁷⁵ Phenylcyclopropanes and halophenyl-substituted cyclopropanes do not react with the dioxirane **1a**,¹⁷⁶ whereas bicyclo[4.1.0]heptane and *exo*-9-bromobicyclo[6.1.0]nonane are converted into the corresponding ketones.¹⁷⁶

Dioxiranes have also been used to oxidise vegetable oil components,¹⁷⁷ caffeine and purine nucleosides.¹⁷⁸

At present, two possible mechanisms for the reaction of dioxiranes with alkanes are being discussed in the literature, namely, insertion of an oxygen atom into the C–H bond of the substrate (by analogy with the oxenoid mechanism, proposed previously for the oxidation by ozone¹⁷⁹) [reaction (8)] and a free-radical mechanism [reaction (9)].

In the former case, oxidation of the substrate by a dioxirane passes through the formation of transition state **A** [reaction (8)], while in the latter case, dioxirane first undergoes homolytic cleavage at the O–O bond, the dioxirane biradical abstracts an H atom from the substrate and then the radicals either undergo intracage recombination [reaction (9), pathway (a)] to give the oxidation products or leave the cage and initiate a radical chain process [reaction (9), pathway (b)], or both pathways occur in parallel.

The main argument favouring the former mechanism is the high selectivity of a large number of reactions of oxidation of saturated hydrocarbons by dioxiranes, which could hardly be expected in the case of a radical chain mechanism. The selectivity of the reactions of the dioxiranes **1a** and **1b** with *cis*- and *trans*-1,2-dimethylcyclohexanes,^{111,145} 2-norborneols¹⁶² and with the *para*-substituted isopropylbenzenes **23**^{121,145,147,148} have already been noted above. The oxidation of 3-methyltetrahydropyran is equally selective:¹⁷⁴ an oxygen molecule is inserted exclusively at the two α -positions, whereas in the case of a radical mechanism, the β -positions of the substrate would also undergo oxidation. Oxidation of *R*-(–)-2-phenylbutane **20** occurs with retention of the configuration [reaction (7)], whereas in the case of a radical chain process, at least partial racemisation would be observed. The relatively large negative values of activation entropy¹⁴⁶ (Table 3) provide more evidence for the formation of an ordered transition state of type **A** [reaction (8)].

Table 3. Rate constants (k_2 /litre mol^{–1} s^{–1}) and activation parameters for the oxidation (E_a /kcal mol^{–1}; $\Delta S^\ddagger$ /cal mol^{–1} K^{–1}; $\Delta G^\ddagger$ /kcal mol^{–1}) of 2-phenylbutane with the dioxirane **1b**.¹⁴⁶

Solvent	$T/^\circ\text{C}$	$k_2 \times 10^2$	E_a^a	$\log A$	$\Delta S^\ddagger^a$	$\Delta G^\ddagger$

	9.7	5.82				

^a Found from the plot for $\log k_2$ vs $1/T$ (in K).

The formation of transition state **A** is supported by the data¹⁸⁰ on the reaction of dimethyldioxirane **1a** with *cis*-1,2-dimethylcyclohexane in various solvents (Table 4). The reaction is facilitated by proton-donating solvents, which stabilise the spiro transition state.

Table 4. Second-order rate constants for the reaction of dimethyldioxirane (**1a**) with *cis*-1,2-dimethylcyclohexane.¹⁸⁰

Solvent	$k_2 \times 10^3$ /litre mol ^{–1} s ^{–1}	Relative reactivity
MeC(O)Me	1.37±0.03	1.00
MeC(O)Et	1.29±0.01	0.94
MeC(O)OEt	1.02±0.02	0.74
CH ₂ Cl ₂	3.08±0.06	2.25
CHCl ₃	4.44±0.13	3.24
CDCl ₃	4.05±0.04	2.96

Note. The reaction was carried out in a solvent–acetone mixture (1 : 1) at 0 °C.

Kinetic data provide additional evidence supporting the 'insertion' mechanism; reactions described in numerous studies^{8, 37–39, 121, 145–147, 151, 162, 180} obey second-order kinetics (first-order kinetics with respect to each reactant). The fairly moderate primary kinetic isotope effect observed in the oxidation of cyclohexane-*d*₁₂ ($k_{\text{H}}/k_{\text{D}} \approx 2$)¹²¹ also points to a molecular mechanism of the reaction. In those cases where the reaction rate is limited by radical abstraction of a hydrogen atom from an *sp*³-hybridised carbon atom, the primary isotope effect increases substantially and can be greater than 10.^{181, 182}

Comparison of the relative reactivity of the dioxiranes **1a** and **1b** with respect to cumene and ethylbenzene^{121, 145} with the reactivity of the BuO[•] radical showed that dioxiranes are more selective; this also provides evidence for reaction (8). Finally, the mechanism of insertion is in good agreement with the results of theoretical calculations.¹⁸³

Despite all the above facts, which attest to the insertion mechanism, the radical reaction mechanism [reaction (9)] has been still considered in a number of recent publications.^{34–36, 184–190} An early publication that considered the radical character of the interaction of the dioxirane **1a** with alkanes and appeared in 1989¹¹⁹ dealt with the influence of O₂ on the products formed upon oxidation by dimethyldioxirane **1a** of a series of substituted benzaldehydes. The radical mechanism has been considered as a possible mechanism of oxidation of *para*-substituted α -methylbenzyl alcohols.¹⁶³

Later, the Minisci's research group³⁴ has obtained data on the strong influence of oxygen and inhibitors on the rate and the products of oxidation of a number of alkanes by the dioxirane **1a**. Thus it was found that the degree of conversion of alkanes in oxygen-free systems is much lower than that attained under ambient conditions, the corresponding alkyl acetates being formed as the major reaction products. Meanwhile, in the presence of O₂, the formation of acetates is largely suppressed. Trapping by TEMPO made it possible to detect the corresponding adducts with alkyl radicals. However, it was noted that TEMPO could induce decomposition of the dioxirane. This assumption has later been confirmed in another study.¹²⁴

When the reaction of the dioxirane **1a** with cyclohexane and adamantane was carried out in the presence of chinaldine, adducts of the trap with alkyl radicals were isolated.¹⁸⁴ The reactions of alkanes and adamantane with the dioxirane **1a** in the presence of CBrCl₃ resulted in a set of halo-containing products, their ratio being dependent on the **1a**:CBrCl₃ ratio.³⁵ These and other experimental facts led Minisci *et al.*^{34, 35, 184–186} to the conclusion that in the presence of alkanes, the compound **1a** undergoes radical chain decomposition induced by the alkyl radicals that have left the cage according to pathway *b* [reaction (9)]. The radical chain model has later been extended to reactions of dimethyldioxirane **1a** with esters and aldehydes.¹⁸⁴

The high selectivity of the oxidation of alkanes by dioxiranes was attributed to the unusual selectivity of the dioxirane biradical, compared with other alkoxy radicals; this biradical can selectively abstract an H atom from the substrate, which leads subsequently to the formation of the reaction products [reaction (9), pathway *a*]. Meanwhile, oxygen present in the system reacts with the radicals having left the cage [reaction (9), pathway *b*] and thus prevents the development of a radical chain process.³⁴

Analysis of the kinetic features of the oxidation of cumene by dimethyldioxirane **1a** and the products and the thermochemistry of the process also attest in favour of the radical character of the reaction.³⁶ An indirect proof of the formation of radicals is the slight chemiluminescence (obviously, caused by recombination of peroxy radicals¹⁹¹) in the visible region of the spectrum, which accompanies the reaction in question when it is carried out in the presence of oxygen.¹⁸⁷ According to the radical mechanism being discussed, chain decomposition of the dioxirane **1a** (in the absence of O₂) is responsible for its 'idle' consumption; therefore, the yields of the products of oxidation of cumene based on the converted dioxirane are relatively low.³⁶ A radical mechanism has also been

proposed for reactions of the dioxirane **1a** with isopentane¹⁸⁹ and adamantane.¹⁹⁰

However, it can be easily seen that a radical chain mechanism for the reactions of dioxiranes with saturated hydrocarbons is at variance with the kinetic curves and with the high selectivity of oxidation reactions, which can be perfectly explained in terms of the insertion mechanism [reaction (8)]. These contradictions were partially eliminated in the study by Curci *et al.*,³⁷ which dealt with the oxidation of adamantane **24** by the dioxirane **1a** under various conditions. When the **1a**:**24** molar ratio was $\sim 1:1.2$, the oxidation gave an alcohol, 1-AdOH (91.5%), and a diol, 1,3-Ad(OH)₂ (4.5%). However, the reaction in the presence of CCl₃Br (*i.e.*, under the conditions used in the above-mentioned study by Minisci *et al.*³⁵) was appreciably less selective and yielded a series of side products: 1-AdBr (42.3%), 1-AdCl (9.2%), 2-AdBr (10.5%), 2-AdCl (2.5%), 2-AdOH (2.0%), adamantanone (<0.5%), *etc.*³⁷ The reaction kinetics, which corresponded to the simple second order without CCl₃Br (both in air and under an atmosphere of N₂), became more complex in the presence of this additive. It was also found that the addition of CCl₃Br induces rapid radical decomposition of the dioxirane **1a**.³⁷

Curci, Adam, *et al.*^{37–39} suggested that, when there are no factors able to induce decomposition of dioxirane (various admixtures, for example, metal ions, irradiation with light, *etc.*) and when there is no O₂, the radical chain mechanism is not involved in the oxidation of alkanes. The influence of drying agents (*e.g.*, MgSO₄) and impurities introduced together with drying agents can also be regarded as destabilising factors of this type. Other factors that should also be taken into account include temperature (it is reasonable to expect that at higher temperatures, the proportion of radical processes would increase and thus the process selectivity would decrease) and the nature of the substrate being oxidised (structural features, C–H bond strength, *etc.*).

An interesting view on the mechanism of reactions of dioxiranes with saturated hydrocarbons has been expressed by Asensio *et al.*¹⁹² A thorough study of the primary kinetic isotope effect and the products of the reaction of the dioxirane **1a** with cyclohexane and methylcyclohexane at various reaction conditions, both in solution (0 °C, Ar atmosphere) and in the gas phase (25 °C) showed that the radical chain process actually does contribute to the oxidation of cyclohexane and methylcyclohexane under experimental conditions but the major reaction products — cyclohexanone (in the case of cyclohexane) and the corresponding alcohol (in the case of methylcyclohexane) — are formed by the insertion mechanism.¹⁹² The researchers suggested that the formation of free radicals can be due to a change in the electronic configuration of dioxirane [namely, transition into the triplet (π, π^*)³ state with the properties of a biradical] induced by interaction with an alkane. Depending on the energy and the route of this interaction, the process follows either a radical chain mechanism (β -cleavage of the biradical to give methyl radicals) or an insertion mechanism [reaction (8)].¹⁹²

2. Oxidation of unsaturated compounds

Epoxidation of compounds containing double bonds is the best studied oxidative reaction of dioxiranes, which is often used for synthetic purposes.

These reactions usually proceed at high rates, give products in good yields and are stereospecific. Yet another advantage of these reactions is that the possibility of conducting them under mild conditions (low temperatures, neutral medium) is combined with the possibility of isolating unstable epoxides; this can be seen taking the synthesis of pH-sensitive oxaspiropentanes from the corresponding methylenecyclopropanes as an example.¹⁹³ Dioxiranes efficiently epoxidise alkenes containing electron-donating

substituents,^{104, 107, 194–196} which obviously makes them better epoxidising agents compared to other peroxides because dioxiranes are more reactive; this allows the synthesis of relatively labile epoxides. The fact that dioxiranes are able to oxidise electron-unsaturated alkenes is equally significant.^{103, 104, 197–199} Although these reactions are usually rather slow, the use of excess dioxirane makes it possible to attain high yields of epoxides.

Epoxidation can be carried out both using isolated dioxiranes and *in situ*.^{103, 104, 106, 107, 200–205} In the latter case, the pH of the medium should be strictly controlled (7.3–7.5). The procedures using isolated dioxiranes are not faced with this problem. In some cases, phase transfer catalysts are used (for example, for water-insoluble substrates). In this respect, the *in situ* procedure with the use of Caro's acid derivatives (peroxomonosulfates) seems quite promising.²⁰⁶ In this procedure, dioxiranes are generated in a homogeneous organic medium, which substantially facilitates the oxidation. An advantage of the *in situ* method is that ketone is virtually not consumed in the reaction (only the oxone is consumed) and can be quantitatively recovered after its completion.

The *in situ* reactions in which the corresponding optically active ketones are used as the precursors of dioxiranes present considerable interest.^{107, 203–205} Thus the use of (+)-3-(trifluoroacetyl)camphor or *R*-(+)- and *S*-(-)-4,4,4-trifluoro-3-methoxy-3-phenylbutan-2-one as the initial ketones allowed asymmetric epoxidation of prochiral alkenes (*trans*- β -methylstyrene, *trans*-oct-2-ene, *cis*-2-methyloctadec-7-ene) with optical yields of 12%–20%.²⁰³ Enantioselective epoxidation of *trans*-stilbene and its 4,4'-dialkyl-substituted homologues catalysed by chiral ketones in the presence of oxone (2KHSO₅·KHSO₄·K₂SO₄) at ~20 °C affords the corresponding epoxides (yields 90%–95%) with 75%–93% enantiomeric purity.²⁰⁴

Regarding the *in situ* oxidation, it is noteworthy that, based on the experiments with ¹⁸O isotope labelling, it has been suggested that the dioxirane intermediate is not responsible for the *in situ* epoxidation of alkenes.²⁰⁷ Thus in the epoxidation of cyclohexene, it is not dioxirane that acts as the main oxidation agent but rather the product of addition of the HOOSO₃⁻ anion to the carbonyl group of the transferring ketone — compound **35** (corresponding to intermediate **A** in Scheme 2).²⁰⁷

The reactions of dioxiranes (both *in situ* and in a pure state) with *cis*- and *trans*-alkenes are stereoselective: *cis*- and *trans*-alkenes are converted into *cis*- and *trans*-epoxides, respectively (the *cis*-compounds are more reactive).^{103, 104, 107, 195, 196, 208}

Treatment of strained polycyclic alkenes with the dioxirane **1a** resulted in the synthesis of the corresponding epoxides.²⁰⁹

Oxidation of hexamethylbenzene by the dioxirane **1a** gives hexamethylbenzene polyoxides *via* the intermediate formation of 2,3,4,5,6,7-hexamethyloxepine.²¹⁰

exo,exo,exo-3,6,9-Tris(4-methylphenylsulfonyloxymethyl)-*cis,cis*-cyclonona-1,4,7-triene reacts with this dioxirane in a similar way.²¹¹

The dioxirane **1a** oxidises allenes and their derivatives (allene alcohols and acids) to give the corresponding dioxides.^{212–216}

On treatment with the dioxirane **1a**, (*E*)- and (*Z*)-arylideneindolones give the corresponding spiro epoxides in 70%–90% yields (the process is fully diastereoselective).²¹⁷

The reactions of 6,6-disubstituted pentafulvenes, containing conjugated double bonds with different reactivities, with an excess of the dioxirane **1a** afford endocyclic diepoxides in good yields. When the reactants are taken in stoichiometric amounts, a mixture of mono- and diepoxides is formed²¹⁸ (the exocyclic double bond remains intact, pointing to an electrophilic nature of **1a** in the oxidation).

Dioxiranes are able to oxidise allyl alcohols,¹⁰⁶ alkenyl hydroperoxides,¹⁷² vinylsilanes²¹⁹ and unsaturated ketones, acids and esters^{220, 221} to give the corresponding epoxy derivatives in good yields.

Oxidation of 4-dioxenylcyclohexanone gives rise to epoxide **36**.²²²

Oxidation of silyl ethers of enols by peroxides, resulting in the formation of α -hydroxy ketones, has been suggested to occur *via* intermediate epoxide.²²³ This type of epoxide also proved to be produced from silyl ether, phosphates and esters of enols as well as from γ,δ -unsaturated 5- and 6-membered lactones on treatment with the dioxirane **1a**. These compounds can be isolated in a pure state.²²⁴

High yields (92%–97%) of spiro oxiranes have also been detected in the oxidation of enol ethers, for example alkoxy(aryl)methylidenadamantanes and methoxy(2-naphthyl)methylidene-2-bornane by the dioxirane **1b**.²²⁵ Note for comparison that synthesis of epoxy esters and strained oxaspiroalkanes involving peroxy acids often does not lead to acceptable results, because the oxiranes formed in the reaction rearrange in the presence of acids to give α -alkoxy or α -hydroxy ketones.

The ability of the dioxiranes **1a** and **1b** to epoxidise electron-unsaturated alkenes can be illustrated by the oxidation of 4-substituted (*E*)-ethyl cinnamates by the dioxirane **1a**.¹⁹⁸ Enol ethers of

β -diketone, which are relatively inert, can also be quantitatively epoxidised by the dioxirane **1a**.¹⁹⁹

$R^1 = H, Me$; $R^2 = Et, Bu, Ph$.

The corresponding epoxides are also formed in the oxidation of enol phosphates,²²⁶ γ -methylene- γ -butyrolactones²²⁷ and acyl- and allylferrocenes.²²⁸

Epoxidation of primary and secondary alkenylammonium salts by the dioxiranes **1a** and **1b** gives rise to epoxy derivatives; on treatment with sodium carbonate, they are readily converted into epoxyalkylamines, formed in good yields.²²⁹ The epoxidation rate is lower than that in the case of epoxidation of simple alkenes because the double bonds are deactivated due to the ammonium groups.

Adam *et al.*²³⁰ were able to detect the low-temperature NMR signals of epoxides of *cis*- and *trans*-(2-methyloxiranyl)benzamide, which result from oxidation of (*E*)- and (*Z*)-*N*-propenylbenzamides by the dioxirane **1a**.

Examples of catalytic epoxidation of alkenes by dioxiranes have been reported in several studies.^{231–233} Thus epoxidation of 2,2-dimethyl-2*H*-chromenes by the dioxirane **1a** in the presence of chiral Mn(III)(salen) complexes (Jacobsen catalysts) occurs enantioselectively. Selective synthesis of epoxides of uracil derivatives (important intermediates in oxidative transformations of DNA) catalysed by metal porphyrins has been described.²³³ (The attempt to prepare uracil epoxides without a catalyst using the dioxirane **1a** as the oxidant was less successful; the yields of the corresponding epoxides were low and side products formed²³⁴). The reaction was carried out in CH_2Cl_2 –MeCN (1 : 1) at 20 °C in the presence of imidazole.

Other dioxiranes also possess high oxidative potentials.^{1, 81, 82, 117, 235} Thus ethylmethyldioxirane **1m** has been used to epoxidise natural triglycerides in the butan-2-one–water two-phase system in the presence of the 18-crown-6 ether,²³⁵ while difluorodioxirane **1k** has been employed to epoxidise fluorinated alkenes $CF_3CF=CF_2$ and $F_2C=CFCl$ (the yields of epoxides are >95%).⁸²

Special mention should be made of those studies that are valuable not only for synthetic purposes but also from the medical or biological viewpoint. For example, this is true for several works^{236–245} dealing with epoxidation of furans by dioxiranes. Benzofurans are known to be toxic for animals and humans. Their toxicity may be due to the presence of labile epoxides, resulting from oxidation of the furan ring.^{236, 246, 247} However, benzofuran epoxides had not been detected even at low temperatures. This became possible only using the dioxirane **1a**.^{236–243} This reagent was employed to prepare epoxides of substituted benzofurans, occurring in equilibrium with the corresponding quinonemethides.

$R^1 = H, Me, OMe, Cl, MeCO$; $R^2 = H, Me, CH_2OH, CH(OMe)Ph, CO_2Et$; $R^3 = H, Me, Bu^t, C_6H_3R^4R^5-3,4$ ($R^4 = H, NO_2$; $R^5 = H, MeO$).

Using the dioxirane **1a**, regio- and stereoselective oxidation of the C(3) = C(4) enol bonds in the molecules of biologically active triterpenes containing a norquinonemethide fragment (*e.g.*, pristimerin, tingenone) was attained.²⁴⁸

Oxidation of steroids, flavones and chalcones by dioxiranes is equally important.^{249–257} Chalcone epoxides are significant building blocks in organic synthesis; they play an important role in the biosynthesis of many flavonoid systems. Oxidation of hydroxychalcones by the dioxirane **1a** resulted in the formation of epoxide products, unstable in acidic or alkaline media, in high yields.²⁴⁹

R^1	R^2	R^3	R^4	R^5
H	Cl	H	H	H
H	H	H	H	Cl
H	H	MeO	H	H
H	H	H	MeO	H
Me	H	H	H	H
H	Me	H	H	MeO
H	Cl	H	H	MeO

Epoxidation reaction has been successfully used to prepare the 8,9-epoxide of the aflatoxin B₁, noted for its carcinogenic properties.²⁵⁸

The reactions of the dioxiranes **1a** and **1b** with vitamin D₃ and its 3-*O*-acylated derivatives were reported to be highly selective.²⁵⁹ The reaction of 3 β -acetyl- (**37**) and 3 β -(*p*-bromobenzoyl)-derivatives (**38**) of vitamin D₃ with methyl(trifluoromethyl)dioxirane **1b** gives rise to the corresponding (*R,R,R*)-triepoxides.

On treatment with the same dioxirane, vitamin D₂ and its 3 β -*O*-acetyl-derivative are converted into the corresponding (*R,R,R,R*)-tetraepoxides.²⁶⁰

R = Ac (37), *p*-BrC₆H₄CO (38).

Mention should be made of interesting studies^{261, 262} in which dioxiranes have been used to synthesise epoxy-derivatives of insect juvenile hormones, which play an important role in the growth and development of insects. An example of epoxidation of a compound containing a CF₃ group at a double-bond carbon atom has been reported.²⁶²

Epoxidation of aminoalkenes is used to prepare indole alkaloids. However, epoxidation of this type of substrates by traditional reagents is hampered by the predominant oxidation of the nitrogen atom. Only recently,²⁶³ were epoxides of several tertiary amines containing alkenyl groups synthesised chemoselectively using dioxiranes in the presence of BF₃·Et₂O.

The reactions of dioxiranes with alkenes (Table 5) is described by a second-order equation^{39, 116, 195, 196, 198, 264, 265} (*cis*-isomers react approximately 10 times faster than *trans*-isomers). Based on experimental data, a reaction mechanism has been proposed,¹⁹⁶ which includes a stage of formation of a spiro-type concerted transition state (Y).

This mechanism is in good agreement with the results obtained by Murray and Gu²⁶⁴ concerning the influence of solvents on the rates of epoxidation of *trans*-ethyl cinnamate and cyclohexene; analysis of the kinetic data in terms of the Kamlet–Taft equation, which takes account of the ability of a solvent to act as a hydrogen bond donor (HBD) or acceptor (HBA), showed that HBD solvents increase the rate of epoxidation, whereas HBA solvents retard this process.²⁶⁴ Transition state Y', which is similar to Y but takes into account the solvent effect on the reaction rate, explains well the characteristic features observed.

Table 5. Second-order rate constants for epoxidation of di- and mono-substituted alkenes by the dioxirane **1a** in dry acetone (according to Ref. 195).

Alkene	$k_2 \times 10^2 / \text{litre mol}^{-1} \text{s}^{-1}$	Relative reactivity
<i>cis</i> -Hex-3-ene	47±3	8.3
<i>trans</i> -Hex-3-ene	5.7±0.4	1.0
<i>cis</i> -4,4-Dimethylpent-2-ene	33±2	5.8
<i>trans</i> -4,4-Dimethylpent-2-ene	2.3±0.1	0.4
<i>cis</i> -2,5-Dimethylhex-3-ene	39±2	6.8
<i>trans</i> -2,5-Dimethylhex-3-ene	2±1	0.4
<i>trans</i> -2,2,5,5-Tetramethylhex-3-ene	0.024±0.004	0.004
Cyclohexene	48±2	8.4
<i>cis</i> -1-Phenylpropene	18±2	3.2
<i>trans</i> -1-Phenylpropene	29±2	5.1
<i>cis</i> -Stilbene	4.0±0.1	0.70
<i>trans</i> -Stilbene	4.3±0.2	0.75
Indene	22±1	3.9
4-Methoxystyrene	57±3	10.0
4-Methylstyrene	25±1	4.4
Styrene	13±1	2.3
4-Bromostyrene	8.9±0.3	1.6
3-Nitrostyrene	3.0±0.3	0.53
3,3-Dimethylbut-1-ene	3.3±0.1	0.58
3-Methylbut-1-en-3-ol	1.6±0.2	0.28

In fact, HBD solvents (MeOH, CDCl₃, AcOH) stabilise the negative charge on the oxygen atom involved in H-bonding with a solvent molecule and thus facilitate epoxidation. Conversely, HBA solvents destabilise the transition state, which decelerates the reaction. This assumption accounts for the fact that addition of water (which can be regarded as an HBD solvent) increases the epoxidation rate.¹⁹⁵ The relatively large negative values of the entropy factor $\Delta S^\ddagger$ also support the assumed formation of an ordered spiro transition state.²⁶⁴

The data obtained by Messeguer *et al.*,¹¹⁶ who studied the influence of solvents on the epoxidation of *cis*-stilbene by more concentrated solutions of the dioxirane **1a** (see Section II), are in good agreement with the results of Murray and Gu²⁶⁴ with the only difference that in the former case,¹¹⁶ the effect was more pronounced due to the use of acetone-free solutions of **1a**.

The solvent effect, like the influence of substituents, is manifested not only as a change in the reaction rate but also as a change in the diastereoselectivity and regioselectivity of epoxidation.^{266–268} It was shown^{266, 267} that diastereoselectivity of epoxidation of substituted cyclohexenes by the dioxirane **1a** is determined by the substrate structure and the solvent, which includes steric effects, dipole–dipole interactions, effects of hydrogen bonding and other factors. A similar solvent effect is involved in the epoxidation of acyclic allyl alcohols,²⁶⁸ in particular, geraniol **39**.

In a polar medium, MeOH–Me₂CO (9 : 1), the ratio of the 6,7- and 3,2-monoepoxides is 88 : 12, whereas in a less polar system, CCl₄–Me₂CO (9 : 1), it is equal to 51 : 49.²⁶⁸ In fact, the Δ^6 double bond in the alcohol **39** is more nucleophilic than the Δ^2 bond, deactivated by the OH group; hence, it is the Δ^6 bond that will be attacked predominantly by dioxirane. Methanol stabilises the transition state due to the formation of a hydrogen bond, so that the contribution of the geraniol OH group to the stabilisation of the transition state is minimised.²⁶⁸ Conversely, in non-polar CCl₄, the external stabilisation is much less pronounced and the transition state is largely stabilised by the OH group belonging to the alcohol **39** molecule, resulting in a higher yield of the 2,3-epoxides.²⁶⁸

An interesting situation is observed when 4,4-dimethyl-2,3-dihydro- γ -pyran **40** is oxidised by the dioxirane **1a**.²⁶⁹

Measurements of the secondary kinetic isotope effect showed that in the transition state *en route* to the epoxide, the degree of rehybridisation of the β -carbon atom is higher than that of C $_{\alpha}$. Hence, this reaction does not proceed *via* a symmetrical transition state but occurs as a non-synchronous concerted process.²⁶⁹ This result cannot be extended to simple alkenes in which the electron densities at the C $_{\alpha}$ and C $_{\beta}$ atoms are identical. In fact, the experimental values for the α - and β -isotope effects found for the reactions of **1a** with 3-methyl-1-phenylbut-2-ene and 2,2,7,7-tetramethyl-*cis*-oct-4-ene and their deuterated analogues support the formation of a concerted transition state of the spiro type.²⁷⁰

Study of the epoxidation kinetics also confirms the electrophilic mechanism of the reaction: Hammett correlations for a series of substituted styrenes¹⁹⁵ and 4-substituted (*E*)-ethyl cinnamates¹⁹⁸ give the values $\rho^+ = -0.9$ and -1.153 , respectively. Study of the kinetics of epoxidation of chalcones (anhydrous acetone, 30 °C) showed that electron-donating substituents at 4 and 4'-positions accelerate the reaction (for 4- and 4'-substituted chalcones, $\rho^+ = -1.03$ and -0.182 , respectively).²⁶⁵

As noted above, experimental results point to a molecular mechanism of the epoxidation of alkenes by dioxiranes [reaction (10)]. However, arguments for a free radical mechanism of epoxidation have also been reported.¹⁸⁵ Thus the oxidation of α -methylstyrene by the dioxirane **1a**, in addition to the epoxide (35%) and α -phenylpropionaldehyde (51%), resulting from its rearrangement, gave the allyl alcohol PhC(CH₂OH) = CH₂ (6%) and the corresponding aldehyde PhC(CHO) = CH₂ (5%). It was suggested¹⁸⁵ that alkenes can induce homolysis of dimethyldioxirane **1a** and the formation of epoxides can be explained in terms of a radical mechanism.

These data, which contradict the molecular mechanism of the reaction, have been specially considered in the study by Adam, Curci, *et al.*³⁹ The results obtained by these researchers³⁹ indicated that the reactions of alkenes with dioxiranes involve no radical processes. In particular, the reaction of the dioxirane **1a** with α -methylstyrene obeys second-order kinetics both under ordinary conditions and under an inert atmosphere (N₂), the corresponding epoxide being the only reaction product (neither allyl alcohol nor the aldehyde were detected even under conditions most favourable for radical chain processes, *viz.*, in the presence of

CBBrCl₃ at 56 °C). Investigation of epoxidation of *trans*-cyclooctene and 2-vinylcyclopropane also supported the hypothesis that no radical chain processes are involved.³⁹

These examples indicate once again that, in all probability, in the absence of factors that could induce a radical chain process, oxidation of alkanes and alkenes by dioxiranes does not include radical pathways of transformation.^{37–39}

3. Oxidation of polyaromatic hydrocarbons

Study of the chemical transformations of PAH on treatment with dioxiranes is an exceptionally important problem, if for no other reason than that many PAH are hazardous carcinogens. The mutagenic and carcinogenic action of PAH is preceded by a metabolic activation process,²⁷¹ comprising a complex sequence of oxidative transformations, unstable arene oxides being the most significant intermediates in these processes. These important intermediates are prepared in most cases using multistage syntheses. The use of direct oxidation by classical reagents (peroxy acids, hypochlorites, *etc.*) is often restricted because many arene oxides are sensitive to acids, water or nucleophiles.

Dioxiranes are convenient reagents for oxidative functionalisation of PAH.^{1, 3, 40, 47–47, 272, 273} Thus the reactions of the dioxiranes **1a** and **1b** with phenanthrene in solution afford the corresponding oxide in 83% and 96% yields, respectively.^{1, 272}

Another typical example is the reaction of the dioxirane **1b** with naphthalene, which gives *anti*-1,2:3,4-dioxide.²⁷²

However, the reaction with pyrene **41** occurs less effectively.²⁷²

Among the products of reaction (11), CF₃COOMe (a product of decomposition of the dioxirane **1b**, see Section III) was also detected, and the EPR spectrum of the system (–30 °C) contained a signal for the pyrene radical cation.²⁷² It was suggested²⁷² that the low yield of the oxidation products is due to the competing electron transfer reaction, giving rise to CF₃COOMe.

An essentially similar mechanism has been proposed to interpret the chemiluminescence of dioxiranes in the presence of some activating agents, which is discussed in detail in Section V.

In view of the formation of dioxiranes in gas-phase ozonisation of unsaturated hydrocarbons,^{41–44} the relatively high concentrations of O₃, alkenes and PAH in the atmosphere and the carcinogenic properties of PAH, Murray *et al.*^{1,3,40,46} suggested that reactions of dioxiranes with PAH might be responsible for the formation of carcinogenic compounds in the atmosphere. To verify this hypothesis, gas-phase oxidation of PAH under conditions close to the atmospheric conditions was carried out.^{3,46,47} A gas stream of the dioxirane **1a** in acetone or a Me₂CO–CH₂Cl₂ mixture was directed at PAH supported on silica gel. Although in most cases, the yield of the resulting oxides was lower than that in the case of liquid-phase oxidation, this experiment demonstrated that dioxiranes can be involved in possible atmospheric reactions with PAH. Moreover, when PAH deposited on silica gel were oxidised by the O₃–Me₂C=CMe₂ gas mixture,⁴⁷ the reaction gave products similar to those obtained when the dioxirane **1a** is used as the oxidant (ordinary ozonolysis does not yield this type of products under these conditions).

4. Oxidation of compounds containing heteroatoms

a. Nitrogen-containing compounds

Oxidation of primary amines by dimethyldioxirane **1a** occurs rapidly (taking from several minutes to several hours) and affords the corresponding nitro compounds.^{274,275}

Polyamines are also converted into nitro compounds. Thus 1,4-diaminocubane reacts with **1a** to give 1,4-dinitrocubane.²⁷⁵

The latter compound can also be obtained by the reaction of the dioxirane **1a** with 1,4-diisocyanatocubane (however, in this case, the presence of H₂O is required).²⁷⁶ Yet another typical example of oxidation of polyamines is the transformation of 1,3,5,7-tetraaminoadamantane,²⁷⁵ which is extremely explosive although thermally stable.

Chiral amines are converted into the corresponding nitro compounds with retention of the configuration.²⁷⁷

Presumably,²⁷⁴ oxidation of primary amines includes several stages, hydroxylamines and nitroso compounds being formed as intermediate products; the process can be partially controlled at the stage of formation of hydroxylamine.²⁷⁸

This sequence of reactions can include either insertion of oxygen into the N–H bond (similar to the insertion into C–H bonds of saturated hydrocarbons) or formation of an intermediate such as *N*-oxide followed by its rearrangement into hydroxylamine.²⁷⁷

Nitro compounds are not always the only reaction products. Thus oxidation of some aliphatic primary amines by the dioxirane **1a** (either isolated or *in situ*) gives, depending on the reaction conditions, oximes, nitrosoalkanes, nitroalkanes and oxaziridines.²⁷⁹ In some cases, the corresponding nitrones, arising upon oxidation of intermediate imines, can also be found among the reaction products.²⁷⁹ Oxidation of ketoximes by the dioxirane **1a** gives the corresponding ketones in high yields.²⁸⁰

Secondary amines react with the dioxirane **1a** (1:1) to give hydroxylamines.²⁸¹ When excess dioxirane is used, the process affords either nitron **42** (in the presence of hydrogen at the α-position in relation to the amino group) or stable nitroxide **43** (in the absence of hydrogen).²⁸²

A series of nitrones have been prepared by the reaction of the dioxirane **1a** with aryl-substituted secondary amines.^{283,284}

while oxidation of *N*-methylaniline gives rise to dinitrone.²⁸⁴

Nitroxides are formed in good yields when secondary amines are oxidised by dioxiranes generated *in situ* in the system Me₂CO–(2KHSO₅·KHSO₄·K₂SO₄)–CH₂Cl₂–H₂O–Bu₄NHSO₄ (phase transfer catalyst).²⁸⁵

Tertiary amines including pyridines are oxidised by the dioxiranes **1a** and **1b** to give *N*-oxides.^{3,105,263,286,287}

It is noteworthy that some *N*-oxides cause decomposition of dioxiranes,^{3,263,286} which gives singlet oxygen²⁸⁶ (see Section V).

Dioxiranes proved to be convenient reagents for the recovery of the initial ketones from derivatives of hydrazones,²⁸⁸ which are often used in organic chemistry to isolate carbonyl compounds from reaction mixtures and to purify them.

Recently²⁸⁹ new versions of the oxidation of amines with participation of the dioxirane **1a** have been found. They include (1) oxidative fragmentation of 2-amino alcohols **44a,b** or 1,2-diamines **45a,b** to give the corresponding mono- and dioximes of bicyclic diketones and (2) intramolecular oxidative transforma-

tion of the latter into tricyclic 2-nitro alcohols **46b** and 1,2-dinitro compounds **47a,b**.

X = CH₂ (**a**), C₆H₄-*o* (**b**).

b. Sulfur- and phosphorus-containing compounds

Dioxiranes selectively oxidise sulfides to the corresponding sulfoxides (equimolar ratio of the reactants) and sulfones (excess dioxirane).

Thus thioesters are quantitatively oxidised by dimethyldioxirane **1a** to give labile α -oxo sulfones.²⁹⁰

Oxidation of (*Z*)-thioaurones, (*E*)-3-arylidene-1-thiochroman-4-ones and (*E*)-3-arylidene-1-thioflavan-4-ones by the dioxirane **1a** gives rise to the corresponding sulfoxides and/or sulfoxides.²⁹¹ The reaction of the dioxirane **1a**, taken in an excess, with ketene *S,S*-acetals, thioacetals and thioketals affords the corresponding bis(sulfoxides) in excellent yields.²⁹² When bis(sulfides) are treated with one, two or three equivalents of dimethyldioxirane, this gives monosulfoxides, bis(sulfoxides) and sulfoxide sulfones, respectively, the ratio of the products depending appreciably on the reaction temperature and the order in which the reactants are mixed.²⁹²

The corresponding sulfides and sulfones are formed in high yields in the chemoselective oxidation of the pentacarbonyl[amino(arylthioalkyl)carbene]chromium(0) complex by the dioxirane **1a**.²⁹³

Low-temperature (−20 °C) oxidation²⁹⁴ of bis(*p*-methoxyphenyl)trisulfane **48** results in the formation of monooxide **49** and a small amount of 1,1-dioxide **50** and trisulfane-1,1,3-trioxide **51**.

Ar = 4-MeOC₆H₄.

High enantiomeric yields have been attained in the oxidation of prochiral sulfides to chiral sulfoxides by dioxiranes generated *in situ*.²⁹⁵

In reactions with sulfides, dioxiranes act as electrophilic reagents; the Hammett correlations found for the oxidation of a series of methyl 4-*R*-phenyl sulfides to sulfoxides and oxidation of sulfoxides to sulfones gave the values $\rho^+ = -0.77$ and -0.76 , respectively, the reactions of dioxiranes with sulfides being faster than those with sulfoxides.²⁹⁶ Using the reaction with thianthrene 5-oxide as an electrophilicity test,²⁹⁷ Adam and Golsch²⁹⁸ also confirmed the electrophilic nature of the dioxirane **1a** as an oxidant.

This is indicated by the fact that the rate of oxidation of sulfolimines containing electron-donating substituents in the aromatic nucleus by the dioxirane **1a** is markedly higher than the rate of oxidation of sulfolimines with electron-withdrawing substituents.²⁹⁹ It is noteworthy that the above-described method proved to be convenient for the synthesis of chiral sulfoxylimines (optical purity 80%).

When considering the mechanism of oxidation of sulfur-containing compounds, mention should be made of a study³⁰⁰ dealing with the oxidation of methyl phenyl sulfide by the dioxirane **1a** and postulating the formation of a hypervalent sulfurane intermediate **52**.

Among the few examples of oxidation of phosphorus-containing compounds by dioxiranes, the reaction of methyl(trifluoromethyl)dioxirane **1b** with triphenylphosphine, resulting in the phosphine oxide, deserves attention; this reaction is used to determine dioxirane concentrations.

c. Oxidation of organometallic compounds

The above oxidative transformations involving dioxiranes also take place during oxidation of metal-containing compounds.³⁰¹ In the majority of cases, these reactions are highly chemoselective, because they are not accompanied by oxidative decomposition of metal complexes.

Oxidation of tricarbonyl iron complexes **53a**, containing a furylcyclohexadiene ligand is accompanied by opening of the furan ring and gives rise to the corresponding carbonyl compound.³⁰²

Oxidation of iron complex **53b** having a similar structure yields a 1:1 mixture of diastereoisomeric epoxides. The most plausible results were attained at elevated temperatures (at low temperatures, oxidative decomposition of the complex upon direct oxidation of iron occurs as a side reaction).³⁰³

The reaction of the tungsten alkene complex with the dioxirane **1a** results in the quantitative formation of the corresponding epoxide.³⁰⁴

Ferrohydrosilanes react with **1a** to give the corresponding ferrosilanol.^{305, 306}

The reaction of the ylide (η^6 -arene)chromiumtricarbonyl complex **55** with the dioxirane **1a** gives the corresponding lactone complex, which is converted in the metal-free lactone on further addition of the oxidant.³⁰⁷

$\text{R}^1 = \text{H, Me, Ph; R}^2 = \text{R}^3 = \text{Me, R}^2 - \text{R}^3 = (\text{CH}_2)_5, \text{R}^2 = \text{Me, R}^3 = \text{cyclo-C}_3\text{H}_5.$

The oxidative capacity of dioxiranes is clearly illustrated taken as an example the transformation of tolane manganese-containing complexes into α -oxocarbene complexes (apparently, this reaction proceeds *via* intermediate epoxidation of the alkyne).³⁰⁸

Oxidation of iron and tungsten phosphine complexes gives rise to the corresponding metal phosphine oxides.³⁰⁹ Sulfur-containing metal complexes are also oxidised by dioxiranes.^{310–312} Thus a new approach to the synthesis of chiral sulfoxides *via* diastereoselective oxidation by the dioxirane **1a** of a prochiral thioether incorporated in a metal complex was reported.^{311, 312} A chiral sulfoxide complex of ruthenium is formed as an intermediate in this reaction. The subsequent decomposition of this complex results in the liberation of chiral sulfoxide.

Enantiomerically pure vinyl-substituted complex **56** has been synthesised by the oxidation of chiral amino-containing (η^6 -arene)chromiumtricarbonyl complex by the dioxirane **1a**.³¹³

Apart from oxidation of the ligands, dioxiranes can be used for oxidative decomposition of metal complexes. Thus the organic ligands incorporated in the (η^6 -arene)chromiumtricarbonyl complexes are quantitatively liberated on treatment with the dioxirane **1a**.³¹⁴

The reaction of dioxiranes with Fischer carbene complexes follows a similar pathway.^{301, 315–317}

However, in the case of the Fischer complexes **57**, containing conjugated enamine fragments, the reaction loses the above-noted selectivity and yields, instead of the expected enamino ester, amide **59** *via* intermediate **58**.³¹⁷

During decomplexation of (η^4 -diene)irontricarbonyl and μ -(η^2 -alkyne)dicobalthexacarbonyl complexes, the process of liberation of organic ligands induced by dioxirane **1a** competes with the oxidation of the unsaturated fragments present in the compounds being liberated.³¹⁸

Lithium, sodium and titanium enolates are converted in most cases into the corresponding α -hydroxy carbonyl products.^{159, 319, 320} It is of interest that the best results are achieved when the reaction is carried out at reduced temperatures.

The stereoselectivity of oxidation of chiral enolates hardly depends on the temperature and the solvent but depends on the nature of the ligands attached to the central metal atom.³²⁰ The highest enantiomeric excess for 2-hydroxy-1-oxo-1-phenylpropane (63% *R*) is attained in the oxidation of the enolate **60** containing a chiral ligand with bulky 1-naphthyl groups, where the steric differences between the two conformers are the most pronounced.³²⁰

Ar is 1-naphthyl, Cp is cyclopentadienyl.

d. Other reactions of dioxiranes

Single-electron transfer reactions involving dioxiranes have been considered to a degree in Sections IV.3 and III.2 in relation to the mechanisms of oxidation of pyrene²⁷² and reactions of dioxiranes with nitroxides.^{120, 124} A typical single-electron transfer reaction is the rapid decomposition of the dioxirane **1b** to give $\text{CF}_3\text{C}(\text{O})\text{Me}$ and O_2 in the presence of catalytic amounts of lithium or tetrabutylammonium iodide.³²¹ Based on experimental data, a chain electron mechanism was proposed for the dioxirane **1a** consumption, according to which the dioxirane accepts an electron from the I^- anion being thus converted into a radical anion, which interacts with a second dioxirane molecule to give a dimeric radical anion; the latter decomposes to ketone and $\text{O}_2^{\cdot -}$. Then the $\text{O}_2^{\cdot -}$ radical anion passes an electron to a new dioxirane molecule and thus closes the catalytic cycle. Thus, the superoxide ion carries the chain, whereas the iodide anion acts as the initiator (Scheme 10).³²¹

Scheme 10

A possible mechanism of the reaction between quadricyclane and the dioxirane **1a** also implies an electron transfer.^{322, 323} It is known that the dioxirane **1a**, even present in small amounts (7.4×10^{-4} mmol), is able to catalyse isomerisation of quadricyclane into norbornadiene.

In addition, it is the electron transfer that is responsible for chemiluminescence observed in the reactions of dioxiranes with PAH and $\text{Ru}(\text{II})$.^{6, 10, 12, 15–17} Note that the capability of dioxiranes to accept an electron is in good agreement with their theoretically calculated electron affinity (2 eV).³²⁴

The reaction of the dioxirane **1a** with fullerene³²⁵ is a unique example of a reaction with an organic substrate in which dioxirane

displays its biradical nature; the 1,3-dioxolane derivative **63** was detected among the products of fullerene oxidation, in addition to epoxide **61** and oxo derivative **62**.³²⁵

The use of the dioxirane **1a** to prepare silanol-containing polymers has been reported.³²⁶ These polymers were synthesised by selective oxidation of SiH groups in appropriate polymer precursors.³²⁶

Owing to their oxidising capacity, dioxiranes have found wide use as bleaching or disinfecting reagents.^{327–333}

It is worth noting in conclusion that rhenium peroxides (**64** and **65**) formed in the $\text{MeReO}_3 - \text{H}_2\text{O}_2$ system resemble dioxiranes in their structure and behave remarkably similarly to dioxiranes in the oxidation of alkenes, nitro compounds and alkanes.^{334–340}

V. Chemluminescence and photochemistry of dioxiranes

Study of the dioxirane chemiluminescence started with the pioneering work by Adam and Curci,³⁴¹ who were the first to propose the possibility of CL during isomerisation (at that time, hypothetical) of dimethyldioxirane **1a** to MA [see reaction (6)]. In fact, the sum of the activation energy and enthalpy of this reaction is quite sufficient for an ester to be formed in, at least, the triplet state (Fig. 5); hence, CL is possible.^{4, 5, 341} It was found that reaction (6) should also comply with other criteria necessary for the generation of electronically excited states.³⁴¹ Thus, even before alkyldioxiranes were isolated,¹ Adam and Curci³⁴¹ had discovered a new interesting chapter in their chemistry.

Figure 5. Diagram of the energy levels of the dioxirane **1a** in relation to the product of its decomposition, methyl acetate.

1. Non-activated chemiluminescence

Decomposition of the dioxirane **1a** in solutions under ordinary conditions is not accompanied by CL (despite the theoretical prerequisites). This can be due both to a low efficiency of emission by the electronically excited MA^* in the triplet state and to efficient side 'dark' pathways of decomposition of **1a** (see Sectio-

n III). The third reason for the absence of luminescence is associated with efficient emission quenching, in particular, with the presence of traces of O₂ (which is a triplet biradical in its ground state). Dioxxygen does not suppress fluorescence (FL) of electronically excited singlet states but functions as an efficient quencher for triplet states. The removal of dioxxygen from the solution may result in a substantially greater contribution of phosphorescence (PH); this was demonstrated, in particular, in the study of the CL that accompanies decomposition of tetramethyldioxetane (TMD).³⁴² We used a similar expedient and found that thermal (46 °C) decomposition of both non-deuterated and deuterated **1a** in acetone purified from traces of oxygen was actually accompanied by CL in the visible region;¹³ the CL maximum occurs within a band with $\lambda_{\text{max}} = 390$ nm, typical of the phosphorescence of the resulting electronically excited triplet state of methyl acetate (MA*).¹⁴

The decay of CL follows first-order kinetics (for non-deuterated **1a**, $k_{\text{eff}} = 8.5 \times 10^{-3} \text{ s}^{-1}$).¹³ The quantum yield of CL ($\phi_{\text{CL}} = 2.2 \times 10^{-11}$ and 6×10^{-11} Einstein mol⁻¹ for non-deuterated and deuterated dioxirane, respectively) and the yield of excited MA [$\phi^*(\text{MA}) = 10^{-4}\%$] are relatively low[‡] compared, for example, with the ϕ^* values for ketones formed upon decomposition of 1,2-dioxetanes^{21,22} (the yield of excitation of triplet acetone in the decomposition of TMD is 37%). This low ϕ^* value for MA* is evidently due to 'dark' decomposition of **1a** occurring in parallel (in the absence of O₂ at high temperatures) by a radical chain mechanism (see Section III). However, according to energy estimates, the reaction sequence presented in Scheme 7 cannot lead to excitation of MA.¹³ Therefore, reaction (13) is the most probable CL channel. Apparently, this reaction proceeds in parallel with those shown in Scheme 7, but in the absence of O₂, its contribution must be low, which accounts for the low intensity of luminescence. Under 'normal' conditions, isomerisation also occurs, however CL is suppressed almost completely by the O₂ present in the system.

It should be noted that reaction (13), according to which the excited state is formed upon a direct isomerisation event without fragmentation of the molecule, is a very uncommon process.

Decomposition of dimethyldioxirane **1a** upon sorption from the gas phase on the Silipor surface is accompanied by much brighter CL than its decomposition in solution (MA* is the emitter).¹¹

———— Silipor.

In fact, the minimum possible CL characteristics under these conditions were estimated^{16,343} to be two orders of magnitude

‡ Since no data on the yield of emission of MA (ϕ_{emis}) can be found in the literature, this value is assumed to be at least not greater (actually, it must be smaller) than the ϕ_{emis} values for related compounds, ketones, for which $\phi_{\text{emis}} = 10^{-5}$. Thus, from here on, we should imply the minimum possible CL characteristics.

larger ($\phi_{\text{CL}} \geq 4 \times 10^{-9}$ Einstein mol⁻¹; $\phi^*(\text{MA}) > 0.01\%$)[§] than the corresponding values for decomposition of **1a** in oxygen-free acetone solutions.¹³ Among other reasons, this may be due to lower efficiency of quenching processes on the Silipor surface. However, in our opinion, the main reason for the increase in the CL yield on the Silipor surface lies in the mechanism of dioxirane decomposition; whereas in the solution in the absence of O₂ at elevated temperatures, the 'dark' radical chain decomposition (see Scheme 7) is the predominant process, on the Silipor surface, where radical reactions are much less efficient, chemiluminescent isomerisation [reaction (14)] becomes the major channel for the consumption of **1a**.

The kinetics of the decay of CL during decomposition of dimethyldioxirane **1a** adsorbed on a Silipor surface is described by a first-order equation; however, the effective rate constant ($k_{\text{eff}} = 0.01 \text{ s}^{-1}$), found from the kinetic curves for CL decay plotted on the semilogarithmic coordinates, scarcely depends on the temperature (in the range 65–90 °C).^{16,343} Evidently, the observed rate constant, which is an effective value, depends not only on the isomerisation constant of the dioxirane **1a** but also on the adsorption equilibrium ($k_{\text{des}}/k_{\text{ads}}$), so that the increase in the rate constant for the desorption of the dioxirane **1a** from the Silipor surface following an increase in the temperature makes up for the increase in the isomerisation rate constant, the k_{eff} value remaining almost invariable.

It is noteworthy that low-intensity chemiluminescence is also observed in a cell containing no Silipor.¹¹ This may be due to both isomerisation of the dioxirane **1a** in the gas phase and its decomposition on the internal surface of the cell. The addition of Silipor to a solution of the dioxirane **1a** in acetone causes a short burst of luminescence, characterised by a relatively low intensity.³⁴³

2. Activated chemiluminescence

Luminescence activation by polyaromatic hydrocarbons is widely used to study the CL arising during oxidation of hydrocarbons^{344–348} or decomposition of 1,2-dioxetanes.^{21,22,349–352} Taking the reaction of the dioxirane **1b** with rubrene (RB) as an example, Adam, Curci, *et al.*⁶ demonstrated the applicability of the luminescence activation method to detection of CL during decomposition of dioxiranes.

Scheme 11

It was suggested that rubrene activates the CIEEL mechanism (Scheme 11, pathway *a*). In addition to CIEEL, there is also another channel of dioxirane consumption, namely, oxidation of rubrene (Scheme 11, pathway *b*), which decreases the CL intensity.⁶ Detection of the EPR signal of the radical cation **41**^{•+}, formed in the reaction of pyrene with the dioxirane **1b** by reaction (12), is an additional argument pointing to the CIEEL mechanism in the chemiluminescence reactions of dioxiranes.²⁷²

The reaction of the dioxirane **1a** with PAH is also accompanied by CL. Thus CL has been discovered in the thermolysis of the dioxirane **1a** (35 °C, Ar) in the presence of 9,10-diphenylanthracene (DPA), 9,10-dibromoanthracene (DBA) and anthracene (A).¹⁰ In all cases, the activators acted as the emitters of the observed luminescence (the maximum CL intensity increases in

§ The CL characteristics were estimated under the assumption that all the dioxirane present in the cell with Silipor is accumulated on the sorbent surface; in reality, this proportion can be only several percent and, hence, the real CL yield and $\phi^*(\text{MA})$ are an order of magnitude greater.

the sequence $I_A < I_{DPA} < I_{DBA}$). The mechanism of activation of CL depends on the nature of the activator. Based on experimental results, it has been suggested^{10,343} that anthracene and 9,10-diphenylanthracene, which are oxidised during the reaction, activate the CIEEL mechanism, and 9,10-dibromoanthracene activates luminescence by the mechanism of energy transfer from MA^* to the activator (Scheme 12).

Scheme 12

In the presence of DBA, the CL decay follows first-order kinetics; however, the observed rate constant depends on the activator concentration, which implies that 9,10-dibromoanthracene catalyses the dioxirane decomposition.^{123,343} However, anthracene and DPA influence the process kinetics in a more complicated way than DBA: the curve for the luminescence decay has two sections, 'fast' and 'slow' (Fig. 6).^{123,343} It can be suggested that decomposition of the dioxirane **1a** accounts for only the 'fast' section of the curve (section 1), whereas an intermediate labile compound (perhaps, of the peroxide type), resulting from oxidation of the activators by the dioxirane, is responsible for the luminescence in the slow section (section 2). Indeed, after the CL kinetics had reached section 2 (Fig. 6) and acetone had been completely evaporated from the reaction cell, the addition of a new portion of acetone restored the luminescence intensity nearly up to the previous level.^{123,343} Similar kinetics observed in the presence of anthracene may be due to analogous reasons.

Figure 6. Kinetic curve for the decay of luminescence in the presence of DPA. $[DPA]_0 = 6.7 \times 10^{-4}$ mol litre⁻¹, $[1a]_0 = 2 \times 10^{-2}$ mol litre⁻¹, acetone, 35 °C.

Besides PAH, luminescent metal compounds can also be used to activate the CL of dioxiranes. Thus the reaction of $Ru(bipy)_3Cl_2$ with dimethyldioxirane **1a** in solution is accompanied by bright CL,¹⁵ emitted by $Ru(II)^*$ (Fig. 7).

The CL decay obeys a first-order equation, the observed first-order rate constant for the CL decay (k_{CL}) being proportional to the $Ru(II)$ concentration: $k_{CL} = k_1 + k_2[Ru(II)]$. The activation parameters found from the temperature dependence of the bimolecular rate constant for the reaction k_2 are the following: $E_a = 9.6 \pm 1.6$ kcal mol⁻¹, $\log A = 9.1 \pm 1.0$. It can be seen that the reaction of $Ru(II)$ with the dioxirane **1a** has a markedly lower (by ~ 13 – 14 kcal mol⁻¹) activation energy than non-catalysed

Figure 7. Absorption (*I*, 2) and photoluminescence (*I'*, 2') spectra of $Ru(II)$ ($[Ru(II)] = 5 \times 10^{-6}$ mol litre⁻¹, CH_3CN , 25 °C): (*I*, *I'*) before the reaction with the dioxirane **1a**; (2, 2') after the reaction with **1a** ($[1a] = 2 \times 10^{-2}$ mol litre⁻¹); (3) chemiluminescence spectrum ($[Ru(II)] = 1.25 \times 10^{-4}$ mol litre⁻¹, $[1a] = 6 \times 10^{-3}$ mol litre⁻¹).

decomposition,^{8,118} because the ruthenium complex substantially catalyses the dioxirane decomposition. For $[Ru(II)] = 1.25 \times 10^{-4}$ mol litre⁻¹, the rate of catalysed decomposition of the dioxirane **1a** at 40 °C is greater than the rate of non-catalysed decomposition by a factor of 170 (!).¹⁵

Apparently, the activation of $Ru(II)^*$ luminescence and at least one pathway of the dioxirane decomposition catalysed by the ruthenium complex (Scheme 13) occur by the CIEEL mechanism, as has been shown for the reaction of $Ru(II)$ with 1,2-dioxetanes.^{353–357}

Scheme 13

Comparison of the photoluminescence and absorption spectra of $Ru(II)$ before and after completion of the reaction (see Fig. 7) indicates that the reaction of the $Ru(II)$ complex with dioxirane leads to oxidation of the complex; this, however, has no influence on the CL kinetics and does not distort the results because noticeable changes in the spectra can be observed only when a

4×10^3 -fold excess of the dioxirane **1a** is present, whereas most of the kinetic measurements were carried out at lower ratios of **1a** to Ru(II).¹⁵

The CL quantum yield found from the plot for the light sum *versus* concentration (Fig. 8) using the equation $S = \varphi^*(\text{Ru}) \varphi_{\text{FL}} k_2 [\text{Ru(II)}]_0 [\text{1a}]_0 / (k_1 + k_2 [\text{Ru(II)}]_0)$ is equal to $\varphi_{\text{CL}} = (9.5 \pm 3) \times 10^{-5}$ Einstein mol⁻¹, and the yield of excitation of Ru(II) (with allowance for the fact that the yield of ruthenium emission $\varphi_{\text{FL}} = 0.0095$) equals $\varphi^*(\text{Ru}) = 0.01 \pm 0.005$.¹⁵ The CL characteristics obtained indicate that the dioxirane **1a**–ruthenium complex system is a fairly bright chemiluminescence system. However, the $\varphi^*(\text{Ru})$ value for the reaction of Ru(II) with 1,2-dioxetanes is much greater (0.2).³⁵⁷ Among other factors, the low ruthenium excitation yield in the CIEEL reaction of Ru(II) with the dioxirane **1a** may be due to the existence of a parallel channel for the dioxirane consumption, which yields no excited Ru(II). Below we demonstrate that this channel actually exists.

Figure 8. Chemiluminescence light sum in the reaction of the dioxirane **1a** with Ru(II) *vs* the concentration of Ru(II) (straight line 1) ($[\text{1a}] = 6 \times 10^{-3}$ mol litre⁻¹) and the concentration of **1a** (straight line 2) ($[\text{Ru(II)}] = 1.25 \times 10^{-4}$ mol litre⁻¹).

The catalytic activity of Ru(II) increases appreciably on excitation of the complex,¹⁵ which is in good agreement with the theory of electron transfer. In fact, the k_2 value is known to depend on the oxidation potential of the activator (E_{Ox}) and the reduction potential of the peroxide (E_{Red}) according to the following equation:

$$k_2 = A \exp \left[-\frac{E_{\text{Ox}} - E_{\text{Red}} - e^2/\epsilon R_0}{RT} \right], \quad (15)$$

where e is the electron charge, ϵ is the dielectric constant of the solvent and R_0 is the distance between ions in the transition state. Since the oxidation potential of Ru(II)* decreases by the energy of excitation,³⁵⁸ i.e., $E_{\text{Ru(II)}^*/\text{Ru(III)}} = E_{\text{Ru(II)/Ru(III)}} - E^* = 1.29 - 2.12 = -0.83$ V, then, in conformity with Eqn (15), an increase in k_2 by several orders of magnitude should be expected. In fact, the Stern quenching constant (K), found from the linear section of the kinetics of quenching of Ru(II)* by dioxirane using the Stern–Volmer equation

$$\frac{\varphi_0}{\varphi} = \frac{\tau_0}{\tau} = 1 + K[\text{Q}], \quad (16)$$

(φ_0 and τ_0 are the quantum yield and the decay time of the luminescence without quencher Q, and $[\text{Q}]$ is the quencher con-

Figure 9. Kinetics of quenching of Ru(II) photoluminescence by the dioxirane **1a** in the coordinates of the Stern–Volmer equation. $\lambda_{\text{excit}} = 450$ nm, $[\text{Ru(II)}] = 2.5 \times 10^{-5}$ mol litre⁻¹, 16 °C.

centration), is the following: $K = k_Q \tau_0 = 1800 \pm 200$ litre mol⁻¹ [k_Q is the rate constant for the interaction of Ru(II)* with **1a**]. From this it follows that the catalytic activity of Ru(II) increases on excitation by a factor of more than 8×10^7 .¹⁵ It can be seen from Fig. 9 that at $[\text{1a}] > 2.5 \times 10^{-4}$ mol litre⁻¹, a negative deviation from the linear Stern–Volmer dependence is observed, obviously, due to the apparent decrease in the quenching efficiency caused by the recovery of the excited Ru(II) complex.

α is the excitation regeneration coefficient.

The calculation of the excitation regeneration coefficient gives the value $\alpha = 0.30 \pm 0.01$, which is much greater than $\varphi^*[\text{Ru(II)}]$ for the reaction of **1a** with non-excited ruthenium. This leads to the conclusion that the contribution of the catalysed isomerisation of **1a** occurring by the reversible electron transfer mechanism (see Scheme 13, pathway *a*) increases markedly.¹⁵

As noted above, the relatively low $\varphi^*[\text{Ru(II)}]$ value for the reaction of Ru(II) with the dioxirane **1a** (compared to this value for the reaction with 1,2-dioxetanes) may be due to the occurrence of a parallel channel of consumption of **1a**, which does not give excited Ru(II). This route actually does exist but this is not a dark reaction! On the contrary, it is accompanied by very bright CL, which occurs in the infrared region (1270 nm), indicating the formation of singlet oxygen in the system.^{17,343} The yield of ¹O₂ based on the decomposed dioxirane **1a** in the Me₂CO–CD₃CN (1 : 2) system is 0.03%. It is notable that the kinetics of the IR CL decay, unlike that for the Ru(II)* luminescence in the visible region of the spectrum, follows a fairly complex pattern (Fig. 10).^{17,343} Thus, the Ru(II)–**1a** system contains two luminescence emitters,^{15,17,343} Ru(II)* in the visible region and ¹O₂ in the infrared region. A possible pathway to ¹O₂ is the reaction of Ru(II) with the dioxirane **1a** by the electron chain mechanism (Scheme 13, pathways *b* and *c*). Pathway *b* is similar to that found in the I⁻–**1b** system (the Adam–Curci system³²¹) (see Scheme 10) with the only difference that in this case, Ru(II) serves as the electron donor. However, unlike the I⁻–**1b** system,³²¹ in the Ru(II)–**1a** system, the oxidised trivalent ruthenium can be reduced to recover the initial divalent species (Scheme 13, pathway *c*), which apparently gives rise to the singlet oxygen [the interaction of Ru(III) with the superoxide ion is known to lead to the generation of ¹O₂].³⁵⁹

Thus, in the reaction of Ru(III) with **1a**, the dioxirane is consumed, in all probability, *via* two competing pathways,

Figure 10. Typical kinetic curve for the decay of the $^1\text{O}_2$ chemiluminescence (IR region) in the reaction between Ru(II) and the dioxirane **1a** (25 °C, Ar, $[\mathbf{1a}]_0 = 5.25 \times 10^{-2} \text{ mol litre}^{-1}$, $[\text{Ru(II)}]_0 = 1 \times 10^{-4} \text{ mol litre}^{-1}$, solvent $\text{Me}_2\text{CO} - \text{CD}_3\text{CN}$ (1 : 2)).

namely, the CIEEL mechanism to give excited Ru(II) (Scheme 13, pathway *a*) and the electron chain decomposition to give singlet oxygen (Scheme 13, pathways *b* and *c*). The reactions of other transition metals with dioxiranes might also give rise to singlet oxygen.[†]

The above-described thermal decomposition of **1a** upon adsorption of the Silipor surface from the gas phase can be substantially enhanced by applying CL activators [DBA, DPA, Ru(II)] on the Silipor surface.^{16, 343} For example, in the presence of Ru(II) or DPA (concentration of the additive $1 \times 10^{-6} \text{ mol g}^{-1}$), the maximum luminescence intensity increases 100- and 10-fold, respectively. The activators function as the luminescence emitters, which are apparently activated in the same way as in solutions.^{16, 343} The CL yield ($0.03 \times 10^{-5} \text{ Einstein mol}^{-1}$)^{165, 343} for the decomposition of **1a** in the presence of Ru(II) applied to the Silipor surface proved to be about three orders of magnitude lower than the CL yield observed in the reaction of **1a** with Ru(II) in solution.¹⁵ Since the electron transfer is controlled by diffusion, this difference can be explained by the decrease in the rate of the diffusion of the reactants on passing from the homogeneous system (solution) to heterogeneous conditions (Silipor–gas phase).

It is of interest that in the **1a**–Ru(II)–Silipor system, no CL from singlet oxygen is observed.¹⁶ Apparently, the diffusion restrictions prevent development of the processes shown by pathway *b* (or *c*) (see Scheme 13).

3. Other chemiluminescence reactions involving dioxiranes and dioxirane intermediates

Although the examples of formation of singlet oxygen in decomposition of dioxiranes are still few in number, they deserve attention, because the reactions described below are apparently far from being the last examples in which an extremely efficient oxidant (dioxirane) gives rise to another one, namely, $^1\text{O}_2$, which plays a very significant role in both chemistry and biology.^{360–362}

Even the synthesis of dioxiranes itself is accompanied by the formation of $^1\text{O}_2$.³⁶³ Non-catalysed decomposition of Caro's acid is known to give $^1\text{O}_2$.³⁶⁴ Decomposition of Caro's acid catalysed by ketones is also accompanied by the evolution of oxygen (see Scheme 2). Previously,⁴ this has been suggested to be singlet oxygen; later, this suggestion was confirmed experimentally by Lange and Brauer,³⁶³ who observed CL of singlet oxygen at $\lambda = 1270 \text{ nm}$ during decomposition of Caro's acid induced by

various ketones (acetone, butan-2-one, fluoroacetone, cyclohexanone, *etc.*). In addition to the detailed study of the reaction kinetics, they measured the yield of $^1\text{O}_2$ (in the case of acetone) per HSO_5^- molecule, which proved to be 0.5; this means that all the oxygen evolved is in the singlet state.³⁶³

Adam *et al.*²⁸⁶ were the first to detect the evolution of $^1\text{O}_2$ in the reactions of isolated dioxirane. Previously, Murray³ had noted that some *N*-oxides induce decomposition of **1a** with evolution of oxygen, which may be in the singlet state. Somewhat later, the Messeguer's group²⁶³ found a catalytic effect of *N*-oxides on the decomposition of dioxiranes. Adam *et al.*²⁸⁶ observed the same phenomenon in the oxidation of 4-dimethylaminopyridine by the dioxirane **1a**: 4-dimethylaminopyridine *N*-oxide formed in the reaction induced rapid decomposition of **1a** (Scheme 14). The reaction was accompanied by evolution of $^1\text{O}_2$ (at 37 °C, the fraction of $^1\text{O}_2$ in the total number of O_2 molecules was 5%), which was proved by CL registered in the infrared and visible regions of the spectrum. Luminescence in the visible region might be due to the dimol emission of $^1\text{O}_2$ (634 and 703 nm).²⁸⁶

Scheme 14

Finally, the third example of evolution of $^1\text{O}_2$ in the reactions of dioxiranes, namely, in the decomposition of **1a** catalysed by the complex $\text{Ru}(\text{bipy})_3\text{Cl}_2$ ¹⁷ was considered in detail above.

When drawing indirect analogy with 1,2-dioxetanes, it is noteworthy that only one example of the formation of $^1\text{O}_2$ during decomposition of 1,2-dioxetane (namely, 3-hydroxymethyl-3,4,4-trimethyl-1,2-dioxetane) has been reported.³⁶⁵ The excitation of O_2 occurs *via* a trivial mechanism consisting in the transfer of energy from the triplet-excited carbonyl fragment (the product of dioxetane decomposition) to oxygen.

By now we have considered CL of isolated dioxiranes. However, several studies in which dioxiranes are considered as possible intermediates in various chemical and biochemical chemiluminescence systems have also been reported.^{12, 97–101} In the 1980s, Steinfatt^{97–100} published a series of studies, dealing with the reactions of a number of organic *gem*-dichlorides with sodium peroxide and hydroperoxide in the presence of aromatic sensitizers. These reactions were accompanied by fairly bright chemiluminescence. The yield of activated CL in the reaction of Na_2O_2 with 3,3-dichlorophthalide⁹⁷ was $10^{-3} \text{ Einstein mol}^{-1}$ (!). Steinfatt also studied activated CL reactions of 1,8- $\text{C}_{10}\text{H}_6(\text{COCl})_2$ with Na_2O_2 ¹⁰⁰ and Cl_2CO with NaOOH .⁹⁸ The following scheme was proposed to interpret the CL observed:

[†]This should depend appreciably on the energy characteristics of the reaction. Thus we were unable to detect CL of singlet oxygen in the reaction of the dioxirane **1a** with Ce(III).^{17, 343} apparently, due to the too high redox potential of the Ce(III)/Ce(IV) pair (1.4 V),³⁵⁸ which precludes the transfer of an electron from Ce(III) to the dioxirane.

Dioxirane was also proposed as an intermediate to explain the CL of peroxyoxalate.⁹⁹

Later¹² we have observed non-sensitised CL in the Ph_2CCl_2 – H_2O_2 – NaOH system, similar to the Steinfatt systems. The maximum of the luminescence intensity was concentrated in the range 400–450 nm, pointing to the possible formation of triplet phenyl benzoate, the product of isomerisation of diphenyldioxirane.¹²

It is significant that CL of diphenyldioxirane (provided that it is actually formed in this system) can be observed even in the absence of luminescence activators. On addition of Ru(II) , the luminescence intensity increases by several orders of magnitude, the maximum intensity being directly proportional to the concentration of the complex. Apparently, in this case, as in the case of isomerisation of dimethyldioxirane **1a**, the CIEEL mechanism is involved.¹²

The formation of a dioxirane intermediate has also been assumed to interpret the mechanism of bioluminescence of bacteria.¹⁰¹ The mechanism of excitation in these reactions cannot yet be considered to be conclusively established. The overall process is known to be catalysed by an enzyme — luciferase (E) — and consists in the oxidation of the reduced form of flavine mononucleotide (FMNH_2) by oxygen with participation of a long-chain aldehyde. A mechanism for the generation of luminescence was proposed¹⁰¹ (Scheme 15); according to this mechanism, the

reaction of O_2 with the complex $\text{E} \cdot \text{FMNH}_2$ yields $\text{C}(4a)$ -peroxydihydroflavine **66**, which subsequently reacts with the aldehyde to give a tetrahedral intermediate **67**. These stages are in good agreement with known mechanisms. Presumably,¹⁰¹ the next step includes the formation of a dioxirane intermediate and $\text{C}(4a)$ -hydroxyflavine **68**. After that, there are two pathways for the generation of CL¹⁰¹

— decomposition of dioxirane to give an excited carboxylic acid and subsequent energy transfer on the hydroxyflavine **68**, which acts as the CL emitter; in this case, luminescence is activated by the energy transfer mechanism (Scheme 15, pathway *a*);

— the CIEEL mechanism in which the hydroxyflavine **68** acts as the fluorophore and the electron donor (Scheme 15, pathway *b*).

4. Photochemistry of dioxiranes

As many other peroxides, dioxiranes are sensitive to light; this was partially illustrated in Section III in relation to the dioxirane **1b** (see Schemes 3 and 4).¹¹⁴ A similar type of behaviour is displayed by the dioxirane **1a**. Thus the quantum yield of photodecomposition of the dioxirane **1a** at 23 °C proved to be much greater than unity ($\phi = 13.9 \pm 0.6$, 12.9 ± 1.7 and 13.1 ± 0.7 Einstein mol^{-1} at 340, 350 and 360 nm, respectively),¹⁴ indicating that decomposition occurs by a radical chain mechanism. More evidence in favour of this mechanism is provided by the detection of adducts formed from alkyl radicals during the photolysis ($\lambda = 300$ nm) of the dioxiranes **1a** and **1b** in the presence of the trap **10** (**1b** completely decomposes under these conditions over a period of 30 min).¹²⁰

$\text{R}^1 = \text{Me}$ (**1a**), CF_3 (**1b**).

However, at 77 K in a matrix, radical chain processes are less significant, and decomposition of **1b** ($\lambda > 300$ nm) yields 1,1,1-trifluoroethane (41%) and MTFA (51%) as the major reaction products together with small amounts of trifluoromethyl acetate (TFMA, 8%). Thus, the photolysis of the dioxirane **1b** in a matrix occurs as either isomerisation (Scheme 16, pathway *a*) or β -cleavage followed by cage recombination of the resulting radical pair (Scheme 16, pathway *b*) or follows simultaneously both channels.¹¹⁴

Scheme 15

Scheme 16

It should be noted that isomerisation to give the corresponding ester is the main route in the low-temperature photolysis of a whole series of other dioxiranes obtained in a matrix.^{33, 62, 65, 67, 69, 71, 72, 75, 80, 81} It has been suggested⁷ that the $[\sigma, \pi]$ -configuration of the dioxirane biradical should be responsible for the generation of an excited product.

Indeed, when the dioxirane **1a** in a matrix (77 K) is irradiated at a wavelength corresponding to its absorption band, phosphorescence of MA is observed (Fig. 11),¹⁴ which is evidently due to the following process:

Figure 11. Phosphorescence spectra (77 K) of methyl acetate (**1**), dioxirane **1** (**2**, **2'**, **2''**) and acetone (**3**, **4**).

(**1**) $\lambda_{\text{excit}} = 260$ nm, $[\text{MA}]_0 = 0.09$ mol litre⁻¹, MeCN;
(**2**, **2'**, **2''**) $\lambda_{\text{excit}} = 350$ nm, $[\mathbf{1a}]_0 = 0.09$ mol litre⁻¹, acetone (spectra **2'** and **2''** were recorded at 25 min intervals under permanent irradiation);
(**3**) $\lambda_{\text{excit}} = 320$ nm; (**4**) $\lambda_{\text{excit}} = 350$ nm.

In addition to the triplet-excited MA*, photodecomposition of the dioxirane **1a** in a matrix affords triplet-excited acetone, probably, due to the transfer of energy from MA* to acetone.

The formation of MA* and the fact of energy migration suggest the existence of one more channel of dioxirane consumption by a quantum chain (QC) mechanism. In the 1960s, Shilov and Vedenev³⁶⁶ discovered experimentally a new class of chain gas-phase reactions involving vibrationally excited states. Some-

what later, in the 1970s, taking decomposition of 1,2-dioxetanes in solution as an example, the occurrence of chain processes with participation of species existing already in electronically excited states was demonstrated.^{349, 367–369} In this case, a product of dioxetane decomposition — a triplet excited ketone — or an activator molecule is included in the chain propagation reactions.

Since decomposition of dioxiranes also gives a triplet-excited product (for example, decomposition of **1a** affords MA*), it can be expected that in the case of dioxiranes, QC processes are, in principle, quite probable (Scheme 17).

Scheme 17

Certainly, a solution of the dioxirane **1a** in acetone is far from being a perfect system for QC processes, first of all, due to the low efficiency of MA excitation and emission. In addition, the QC decomposition should be strongly hampered by the competing radical chain mechanism. However, other dioxiranes, in particular, those with chromophore-containing substituents, which give esters characterised by markedly larger emission yields, may prove to be prone to undergo photo and, perhaps, also thermal decomposition by the QC mechanism. Dimesityldioxirane **1j** seems quite promising in this respect.

VI. Conclusion

Dioxiranes remarkably combine two significant properties — the ability to act as strong oxidants and the ability to form products in the electronically excited states. It is these specific features that distinguish dioxiranes from other related compounds, in particular, 1,2-dioxetanes, the principal property of which is CL, or from a number of peroxy compounds, which have found application as oxidants in organic synthesis.

The high oxidative capacity of dioxiranes combined with the selectivity and mild conditions of reactions permitted researchers to perform a great number of oxidative transformations, which would have been impossible with other reagents. In addition, due to the availability of initial compounds and the ease of preparation of dioxiranes, these reagents can be used almost in any chemical laboratory.

Study of the CL of dioxiranes resulted in the discovery of a unique pathway to excited states. In fact, the rearrangement of dioxiranes into the corresponding esters initiated either thermally or photochemically is an exceptionally uncommon example of generation of an excited state directly upon an isomerisation event without fragmentation of the molecule (decomposition of 1,2-dioxetanes occurs *via* fragmentation of the molecule to give several products, one being in the excited state). A similar reaction route has been observed previously only for isomerisation of Dewar's benzene to excited Kekule's benzene.³⁷⁰

It can be conjectured that in the future, the chemistry of dioxiranes will develop along these lines. Without doubt, studies on the oxidative properties of dioxiranes and physicochemical

regularities of these reactions will be continued. Until now, the mechanism of decomposition of dioxiranes in the absence of oxidisable compounds has not been ultimately determined. The role of isomerisation in the set of other channels of dioxirane decomposition, which depend substantially not only on the external conditions but also on the structure of dioxiranes themselves, is still to be elucidated.

Despite the obvious difficulties, the search for the routes and conditions for the synthesis of new dioxiranes of various structures still remains a topical task. It is beyond doubt that success along this line (the first successful steps are being taken^{59, 80–83, 117}) would substantially extend the possibilities of studying the properties of this new class of peroxides. This refers both to oxidative transformations (in particular, with the outlook for the preparation of chiral dioxiranes suitable for attaining prochiral oxidation) and chemiluminescence. Thus decomposition of a dioxirane with chromophore-containing substituents, for example dimesityldioxirane **1j** already synthesised,^{80, 81} can be accompanied by CL comparable with the CL of dioxetanes. The presence of these dioxiranes including some bisdioxiranes would be useful for the study of energy migration paths in a matrix, in solution or on a sorbent surface and also for the study of quantum chain and energy coupled reactions.^{21, 371} However, we are sure that the study of CL of the dioxiranes **1a** and **1b** would provide not less impressive results. Apart from the CL of dioxiranes themselves, one should also expect luminescence during their oxidative reactions with various organic and organometallic substrates, oxidation of which by other oxidants (XeF₂, XeO₃, O₂, etc.) results in bright CL.^{372–374} This is equally true for inorganic compounds. It is known that in the recent decades, a large number of bright CL reactions accompanying oxidation of low-valence uranium species (e.g., by xenon compounds, XeF₂ or XeO₃) were discovered.^{375–386} If dioxiranes are included in the set of oxidants, high excitation yields can be expected in these systems.

A lot of interesting discoveries would result from combination of the chemistry of dioxiranes and 1,2-dioxetanes with the chemistry of complexes of *f*- and *d*-elements.^{387–401} A dioxirane–lanthanide complex system may prove to be the second system, after a similar dioxetane-containing system, in which a new class of chain processes — quantum-chain reactions with energy branching — can be observed.^{399–401}

The authors are grateful to the Russian Foundation for Basic Research (Project No. 99-03-32140a) for financial support. We also wish to thank Professor R Curci (Bari University, Italy) and Professor W Adam (Würzburg University, Germany) for help in overcoming the difficulties that we have faced in recent years due to the non-availability of foreign publications and also for the fruitful discussion of some aspects of the peroxide chemistry.

Alkoxy(alkyl)silylalkyl derivatives of nitrogen-containing heterocycles

O M Trofimova, N F Chernov, M G Voronkov

Contents

I. Introduction	287
II. Synthesis	287
III. Chemical properties	292
IV. Biological activities and practical applications	294

Abstract. The published data on the synthesis, properties and transformations of alkoxy(alkyl)silylalkyl derivatives of nitrogen-containing heterocycles of the general formula $\text{Het}(\text{CH}_2)_n\text{SiX}_3$ are surveyed and systematised. Data on the biological activities and applications of these compounds are presented. The bibliography includes 255 references.

I. Introduction

Considerable interest in organosilicon compounds containing a heterocyclic fragment in a hydrocarbon chain linked to the silicon atom is due to their valuable properties. These compounds served as the basis for the preparation of a large series of adsorbents, immobilised catalysts, synthetic intermediates, medicinal drugs, pesticides and other substances endowed with specific biological activities.

To date, a great number of publications are devoted to organosilicon derivatives in which the silicon atom is directly linked to a heterocyclic substituent (*e.g.*, see, Refs 1–7). However, the publications which describe carbofunctional organosilicon compounds with a silicon atom attached to the heterocyclic fragment through a hydrocarbon bridge are still few in number. Among those, special mention should be made of the review⁸ which describes the compounds containing a heterocyclic substituent with one nitrogen atom (the studies surveyed therein had been published before 1970) and two more recent reviews^{9,10} concerned with the synthesis of organosilicon derivatives of pyridine and quinoline.

The present review gives a systematic and critical analysis of the data published after 1970 concerning heterylalkylsilanes containing at least one nitrogen atom in their heterocycles.

II. Synthesis

1. Organometallic synthesis

One of the methods for preparing alkoxy(alkyl)silylalkyl derivatives of nitrogen-containing heterocycles in which the silicon atom is linked to the nitrogen or the carbon atom through a hydrocarbon bridge, $-(\text{CH}_2)_n-$, where $n = 1, 3$, is based on the reaction of organolithium, -sodium, -potassium or -magnesium derivatives of the corresponding heterocycles with silicon-substituted (chloroalkyl)silanes:^{11–70}

$\text{R}^1 = N\text{- or } C\text{-heteryl}; \text{R}^2, \text{R}^3 = \text{Me, Et}; \text{M} = \text{Li, Na, K, MgBr, ZnCl}; n = 1, 3; m = 0-3.$

Thus silicon-substituted *N*-heterylalkylsilanes were obtained from the corresponding alkoxy(alkyl)chloroalkylsilanes and *N*-potassium derivatives of phthalimide,¹¹ imidazole, 1,2,4-triazole,^{12,13} benzothiazinone,¹⁴ piperidine, perhydroazepine, morpholine¹⁵ and purine¹⁶ in boiling benzene or toluene. The use of Bu_4NBr as a phase transfer catalyst permits one to reduce the reaction time.¹²

The reaction of *C*- or *N*-sodium derivatives of quinoline,^{17,18} 2-pyrrolidinone,¹⁹ substituted 1,2,4-triazole,^{20–31} imidazole,^{22,23,26,30–35} uracil, thymine and adenine,³⁶ pyridone,³⁷ pyrazine³⁸ and benzotriazole³⁹ with $\text{Cl}(\text{CH}_2)_n\text{SiR}_m^2(\text{OR}^3)_{3-m}$ (where $n = 1, 3$ and $m = 0-3$) in DMF gave the corresponding *C*- or *N*-substituted heterylalkylsilanes.

The silicon-substituted (heterylthiomethyl)silanes $\text{HetSCH}_2\cdot\text{SiMe}_n(\text{OMe})_{3-n}$, where $n = 0$ or 1, were synthesised in 65%–86% yields by the reaction of *S*-sodium derivatives of 8-mercaptoquinoline, 2-mercaptobenzoxazole, 2-mercaptobenzothiazole and 2-mercaptobenzimidazole with trimethoxy-(chloromethyl)- and dimethoxymethyl(chloromethyl)silanes (**1**) in a polar aprotic solvent (DMF, DMSO) for 2–3 h at 80–90 °C.^{40–42}

Received 28 May 1998

Uspekhi Khimii 68 (4) 318–330 (1999); translated by R L Birnova

$n = 0, 1$; $Y = \text{NH}, \text{O}, \text{S}$.

The synthesis of trimethylsilylalkyl-substituted pyrrole,^{43, 44} piperidine,⁴⁵ pyridine,^{46–49} 2-pyridone,⁵⁰ pyrrolidine,^{51, 52} pyrazole, imidazole, benzoimidazole,⁵³ quinoline,^{54–56} 3,4-dimethylisoxazole,^{57, 58} 2-mercaptobenzothiazole,^{59, 60} benzothiazole,⁶¹ indole,⁶² tetrazole,⁶³ pyrimidine⁶⁴ and carbazole⁶⁵ makes wide use of *C*-, *N*- or *S*-lithium derivatives of these heterocycles. The latter are obtained by the reaction of the corresponding heterocyclic compounds with RLi ($\text{R} = \text{Me}, \text{Bu}^n, \text{Bu}^t, \text{Ph}, \text{NPr}_2$) in THF or hexane. Thus the 2-ethylpyridine carbanion prepared by the reaction of ethylpyridine with butyllithium (THF, -70°C) readily reacts with *tert*-butyldimethylchlorosilane. In this case, the silyl group enters into the α -position of the alkyl substituent.⁴⁷

The reactions of 2-, 3- and 4-methylquinoline⁵⁴ with lithium diisopropylamide and then with trimethylchlorosilane give rise to 2-, 3- and 4-trimethylsilylmethyl derivatives (in this case, 3-substituted derivatives are formed with the lowest yield). Metallation of 2-methyl-6-(2,5-dimethylpyrrolo)pyridine (THF–hexane, -25°C) with lithium diisopropylamide and subsequent reaction with trimethylchlorosilane gave 2-trimethylsilylmethyl-6-(2,5-dimethylpyrrolo)pyridine in 77% yield.⁴⁴ Lithium derivative of 2-methylbenzothiazole reacts with trimethylchlorosilane analogously.^{59, 60}

The reaction of halogen-substituted pyridines and quinolines with trimethylsilylmethylmagnesium chloride or -zinc chloride in ether in the presence of a catalytic amount of $\text{Cl}_2\text{Ni}[\text{Ph}_2\text{P}(\text{CH}_2)_3\text{PPh}_2]$ afforded 2- and 3-trimethylsilylmethylpyridines (72% and 35% yields, respectively), 2,6-bis(trimethylsilylmethyl)pyridine (yield 69%) and trimethylsilylmethylquinoline (yield 44%).⁶⁶

The reaction of 2-bromopyridine with (1-trimethylsilylvinyl)zinc chloride or -magnesium bromide in the presence of a palladium–phosphine complex results in 2-(1-trimethylsilylvinyl)pyridine.^{67, 68}

$\text{MX} = \text{MgBr}, \text{ZnCl}$.

2-(3-Trimethylsilylbut-3-enyl)pyridine was obtained unexpectedly when a fourfold excess of 2-bromopyridine was used.

(2-Trimethylsilylvinyl)magnesium bromide or -zinc chloride was used in the synthesis of the corresponding organosilicon derivatives of pyrrole and indole.⁶⁷ Thus trimethyl(α -bromovinyl)silane reacts with 1-methyl-2-pyrrolyl- and 1-methyl-2-indolylmagnesium bromide or -zinc chloride in the presence of a catalytic amount of $\text{Cl}_2\text{Pd}[\text{Ph}_2\text{P}(\text{CH}_2)_4\text{PPh}_2]$ to give the corresponding 1-methyl-2-trimethylsilylvinyl derivatives of these heterocycles in 74%–87% yields.⁶⁷ For example:

$\text{MX} = \text{MgBr}, \text{ZnCl}$.

The reaction of 6-methylpyridine with methyl chloroformate and trimethylsilyl ethynylmagnesium bromide gives exclusively 2-trimethylsilyl ethynyl-6-methyl-*N*-methoxycarbonyl-1,2-dihydropyridine (yield 79%).⁶⁹

The reaction of 7-chloro-4-(4-iodopyrazolo)quinoline with CuI and $\text{Me}_3\text{SiC}\equiv\text{CH}$ in the presence of $\text{Cl}_2\text{Pd}(\text{PPh}_3)_2$ gives 7-chloro-4-(4-trimethylsilyl ethynylpyrazolo)quinoline.⁷⁰

2. Amination reactions

The following methods are also used in the synthesis of alkoxy(alkyl)silylalkyl derivatives of nitrogen-containing heterocycles:

1. Reaction of the corresponding derivatives of (halogenoalkyl)silanes $\text{X}(\text{CH}_2)_m\text{SiR}_m^1(\text{OR}^2)_{3-m}$ with compounds containing an endocyclic (>NH) group.

2. Reaction of halogen-substituted nitrogenous heterocycles with organosilicon derivatives containing a $(\text{CH}_2)_n\text{NH}_2$ group at the Si atom.

3. Attachment of substituted nitrogenous heterocycles containing endocyclic (>NH) groups with an active hydrogen atom to unsaturated organosilicon compounds.

Organosilicon derivatives of morpholine,⁷¹ perhydroazepine,^{71–73} piperazine,^{71, 73, 74} piperidine,^{71, 72, 74, 75} pyrrolidine^{71–73, 76} and imidazole^{77, 78} were obtained by heating trialkyl(chloroalkyl)- or trialkoxy(chloroalkyl)-silanes with an excess of the corresponding N-heterocycle which acts simultaneously as an acceptor of hydrogen chloride:

$\text{R}^1\text{R}^2\text{Si} = \text{Me}_3\text{Si}, \text{Et}_3\text{Si}, \text{Me}(\text{EtO})_2\text{Si}, (\text{EtO})_3\text{Si}, \text{Me}(\text{Me}_3\text{SiO})_2\text{Si}, (\text{Me}_3\text{SiO})_3\text{Si}; n = 1, 3;$

Hereinafter HN is a nitrogen-containing heterocyclic base.

This reaction is carried out in a boiling non-polar solvent (benzene, hexane, toluene). Trialkoxy(chloromethyl)silanes react faster than the corresponding trialkyl derivatives.

The synthesis of silicon-substituted *N*-silylmethylacetams,^{79–81} 1-trialkylsilylmethyl(propyl)piperazine⁸² and 1-trimethylsilylmethyl-1,2,4-triazole^{83–85} was carried out in the presence of anhydrous potassium carbonate or sodium carbonate.

Siliconalkylation of pyrrole, carbazole, pyrazole, imidazole, benzoimidazole, 1,2,4-triazole, 1,2,3-benzotriazole and tetrazole with trialkyl(3-halogenopropyl)silanes gave the corresponding *N*-(3-trialkylsilylpropyl)azoles in 80%–90% yields.^{86, 87} The reaction was carried out in a biphasic system (benzene–60% aqueous KOH) with boiling for 4–6 h in the presence of 5 mol. % of tetrabutylammonium hydrogen sulfate as a phase transfer catalyst. Attempts to obtain these compounds by hydrosilylation of *N*-allyl derivatives of the corresponding azoles failed.⁸⁶ The reaction of 4-amino-1,2,4-triazole with trimethyl(halogenomethyl)silanes in DMSO (8 h, 80°C) afforded 4-amino-1-trimethylsilylmethyl-1,2,4-triazolium halides. 4-Amino-3-trimethylsilylmethyl-1,2,4-triazole is formed when boiling nitromethane is used as a solvent.⁸⁸

Triethylamine was used as a hydrogen chloride acceptor in the synthesis of *N*-(trialkylsilylalkyl)- and *N*-(trialkoxysilylalkyl) derivatives of piperazine,⁸⁹ 3,5-dimethylpyrazole,⁹⁰ 1,2,3,4-tetrahydro(iso)quinoline,^{91–93} pyrrolidone⁹⁴ and other lactams.⁹⁵ This reaction is carried out in boiling toluene or xylene. *N,N'*-Bis(triethoxysilylalkyl)piperazines were obtained by heating triethoxy(chloroalkyl)silane with piperazine in a 2 : 1 molar ratio.⁸⁹

Heating of quinoline-2- and -4-carbonyl chlorides,⁹² 9-chloroacridine⁹⁶ and chloroquinolines^{91, 97–99} with (3-aminopropyl)-trialkylsilanes gives the corresponding 3-(trialkylsilyl)propyl-amino derivatives of these heterocycles.

$\text{R}^1\text{R}^2\text{Si} = \text{Et}_3\text{Si}, \text{MeBu}_2\text{Si}, \text{Bu}^t\text{Me}_2\text{Si}.$

Their isolation is usually simplified when diglyme is used as a solvent and triethylamine is used as a hydrogen chloride acceptor.

A two-step procedure for the synthesis of *N*-[3-(trialkoxysilyl)propyl]phthalimide has been developed. The first step consisted in condensation of phthalic anhydride with 2-aminopyridine to give the corresponding imide; its interaction with (3-aminopropyl)trialkoxysilane (toluene, 10–15 h) resulted in 3-(trialkoxysilyl)propylphthalimide with good yield.¹⁰⁰

R = Me, Et.

Heterocycles containing an endocyclic NH group are smoothly and regioselectively added to unsaturated organosilicon compounds containing a SiCH=CH₂ or SiCH₂CH=CH₂ fragment in the presence of alkali metals (Li, Na, K or their amides). In both cases, the adducts formed contain a nitrogen atom in the β-position relative to the silicon atom. The addition of pyrrolidine,⁷¹ perhydroazepine,⁷¹ piperazine,⁸² 3,5-dimethylpyrazole, imidazole, benzoimidazole,^{90, 101} 3(5)-methylpyrazole,¹⁰² aziridine,¹⁰³ piperidine^{71, 104, 105} and azetidine¹⁰⁶ to vinyltrialkyl- and vinyltrialkoxysilanes proceeds rather easily even at 20–75 °C. The adducts are formed in 70%–85% yields.

R = Alk, Alko.

The rate of addition of nitrogenous heterocycles to silicon-substituted vinylsilanes depends substantially on the nature of the solvent. Thus the yields of the addition products of aziridine and piperidine to triethylvinylsilane in 2 h under identical conditions were 39% and 72% in the absence of a solvent, 20% and 15% in *n*-heptane and 55% and 92% in THF.¹⁰³

The nature of the substituents at the silicon atom has also a profound effect on the reactivity of the original silicon-substituted vinylsilanes. Thus the yield of 2-(aziridinoethyl)triethylsilane formed in the reaction of triethylvinylsilane with aziridine is 90% (7 h, 100 °C). 2-(Aziridinoethyl)triethoxysilane, the addition product of aziridine to triethoxyvinylsilane, was obtained in 69% yield in 10 h at 100 °C. The rate of catalysed addition of *N*-heterocycles to silicon-substituted vinylsilanes R¹R²SiCH=CH₂ increases in the following order depending on the substituents R¹ and R² at the silicon atom: (OEt)Me₂ < Et₃ < Me₃ < Me₂Ph < -MePh₂. This was ascribed to an increase in the *p*_π–*d*_π interaction of the vinyl group with the silicon atom which resulted in electron density displacement toward the α-carbon.¹⁰³ At present, this effect is interpreted as σ–π conjugation, *i.e.*, the interaction of the C=C bond π-orbital with the Si–C bond σ-orbitals. The decrease in the rate of addition of *N*-heterocycles to triethoxyvinylsilane was attributed to the consumption of the catalyst upon cleavage of the Si–OR bond.¹⁰³

As the double bond in compounds of the R¹R²Si(CH₂)_{*n*}CH=CH₂ series, where *n* = 0, 1 and 2 becomes more distant from the silicon atom, the rate of addition of

N-heterocycles decreases. In the case of *n* = 1, β-elimination often accompanies the addition reaction.

The yield of the addition product of aziridine to allyltriethylsilane is 35%. However, aziridine is not added to allyldimethylphenylsilane, the β-degradation product, *viz.*, aziridinyl-dimethylphenylsilane (10% yield), and propene are formed instead.¹⁰⁵

3. Hydrosilylation reactions

Hydrosilylation of heteroalkenes usually gives a mixture of two isomers the yields and ratio of which depend on the structure of each of the reagents and the catalyst as well as on reaction conditions (solvent, temperature).

R¹, R² = Alk, Alko, Cl.

Trichlorosilane is added to 2-vinyl-, 4-vinyl- and 2,6-dimethyl-4-vinylpyridines in the absence of a catalyst to give the corresponding pyridylethyltrichlorosilanes.⁸ It is assumed that the role of a catalyst is played by the heterocyclic base itself. Labile yellow complexes Cl₃SiH·*n*B (*n* = 3 for 4-vinylpyridine; *n* = 4 for 2-vinylpyridine) are intermediate products of this reaction.

Triorganyl- and diorganyl-chlorosilanes are added to the same vinylpyridines only in the presence of catalysts. Thus the corresponding β-adducts are formed in the presence of an Me₂NCH₂CH₂NMe₂–Cu₂Cl₂ complex, while a mixture of α- and β-adducts with the predominance of the former is formed in H₂PtCl₆-catalysed hydrosilylation of 2-vinylpyridine.¹⁰⁷ In the absence of a catalyst, triethylsilane does not react with 2- and 4-vinylpyridines, whereas in the presence of H₂PtCl₆ it is added to 4-vinylpyridine and 2-methyl-5-vinylpyridine to give solely β-adducts (in 46% and 36% yields, respectively).

Hydrosilylation of 2-vinylquinoline catalysed by H₂PtCl₆ also results in a mixture of α- and β-adducts. Thus ethyldichlorosilane is added to 2-vinylquinoline to give predominantly the β-adduct (75% yield); trialkylsilanes give a mixture of regioisomers with the predominance of the α-adduct (10 h, 120–160 °C, overall yield 65%), while triethoxysilane gives a mixture of α- and β-adducts in a 1:1 ratio. The use of non-polar aprotic solvents (xylene, dioxane, diglyme) has no effect on the ratio of isomeric adducts but permits one to increase the total yield from 55% to 70%.¹⁰⁸ As for polar solvents (pyridine, quinoline), these favour the formation of the β-isomer; the total yield of the adducts decreases to 40% under these conditions. No hydrosilylation takes place in DMF.

2-(1-Triethoxysilylethyl)pyrrolidone^{109–111} and 2-(1-triethoxysilylethoxy)perhydroazepine^{112, 113} were obtained by the reaction of *N*-vinylpyrrolidone and *N*-vinylcaprolactam with triethoxysilane. This reaction was catalysed by rhodium or palladium complexes, rhodium dicarbonyl acetylacetonate being the most efficient catalyst.^{111, 112} With this catalyst, the reaction was selective and gave only the α-adduct in 73% yield.

Hydrosilylation of 2- and 2,3-substituted 1-vinylpyrroles and 1-vinyl-4,5,6,7-tetrahydroindole with triethylsilane catalysed by H₂PtCl₆ and ClRh(PPh₃)₃ (4–10 h, 80–100 °C) was highly regioselective and resulted exclusively in the β-adducts in 55%–80% yields.^{114–118} The use of polar aprotic solvents (THF, acetone) and increase in the reaction time allow one to increase the yield of the adduct up to 90%. No hydrosilylation of

these 1-vinylpyrroles with alkyldichloro-, trichloro- and trialkoxy-silanes occurred.

Hydrosilylation of *N*-allyl pyrrolidine, -piperidine,^{71, 119} -*N*'-methylpiperazine,¹²⁰ -morpholine^{120, 121} and -benzotriazole¹²² with triorganylsilanes catalysed by 0.1 M H₂PtCl₆ resulted in *N*-(3-triorganylsilylpropyl)derivatives of the corresponding heterocycles.

R¹ = Me, R² = Et, Pr, Bu, C₅H₁₁, Ph, Cl;

R¹ = Et, R² = Et, Pr, Bu;

R¹ = R² = Pr, Bu, EtO.

No individual reaction products could be obtained upon hydrosilylation of *N*-allylcarbazole with ethyldichlorosilane.¹²³

Hydrosilylation of *N*-propargyl-substituted pyrrolidine, piperidine, perhydroazepine and morpholine with triethylsilane in the presence of H₂PtCl₆ gives the γ -adducts with a *trans*-structure.^{71, 124, 125}

The yields of the hydrosilylation products formed upon 10-h boiling of the reaction mixture vary from 25% to 53%. Substitution of silanes with more electronegative substituents for triethylsilane favours the formation of the α -adduct.

4. Cyclisation reactions

The reaction of carbohydrazides with ethyl β -trimethylsilylpropionimide (**2**) yields 3-alkyl-5-(2-trimethylsilylethyl)-1,2,4-triazoles.¹²⁶ Trimethylsilylethylamidrazones are the primary products of this reaction; their intramolecular cyclisation results in the corresponding organosilicon derivatives of 1,2,4-triazole upon heating *in vacuo*.

R = H, Me.

Dicarboxylic acid dihydrazides are converted into 3,3'-Di[5-(2-trimethylsilyl)ethyl]-1,2,4-triazoles less easily (only upon heating to 200 °C).

R = CH₂, (CH₂)₄, C₆H₄.

The addition of ethyl *N,N*-dichlorocarbamate to allyltrimethylsilane (**3**) with subsequent reduction with sodium hydrogen-sulfite and dehydrochlorination affords ethyl-*N*-chloro-*N*-(2-chloro-3-trimethylsilylpropyl)carbamate and ethyl-*N*-chloro-*N*-(1-chloromethyl-2-trimethylsilylethyl)carbamate. Intramolecular alkylation of the latter results in ethyl 2-(trimethylsilylmethyl)aziridine-2-carboxylate in 20% yield.¹²⁷

The reaction of allyltrimethylsilane with PhMeNCH₂O.*C*(O)Me in dichloromethane results ultimately in the corresponding 4-trimethylsilylmethyl derivative of 1,2,3,4-tetrahydroquinoline.¹²⁸

The addition of nitrile oxides to vinyl- and allyltrialkylsilanes **4** gave the corresponding organosilicon derivatives of 4,5-dihydroisoxazole **5** in 50%–70% yields.^{129, 130}

R¹ = R² = R³ = Me (**a**), Et (**b**); *n* = 0, 1; R⁴ = Br, Ph, 4-C₆H₄NO₂.

The rate of this reaction decreased upon substitution of phenyl or methoxy groups, having a negative inductive effect for methyl or ethyl groups at the silicon atom.

Vinyl- and allyltrialkylsilanes **4** react with nitroethane or 1-nitropropane in the presence of phenyl isocyanate and catalytic amounts of Et₃N in benzene to give the corresponding 3-alkyl-5-trialkylsilylisoxazolines **5** in 64%–88% yields.¹³¹

The reaction of vinyl- and allyltrialkyl(aryl)silanes [R¹ = R² = R³ = Me (**4a**), Ph (**4c**)] with hydroxyamoyl halides proceeds regioselectively and yields only one isomer.

R¹ = R² = R³ = Me (**a**), Ph (**c**); *n* = 0, 1; R⁴ = Ph, COOEt, Br; X = Cl, Br.

The reaction of trinitromethane *O*-methyl ester with vinyl- and allyltrimethylsilanes (**4a**) results in *N*-methoxy-3,3-dinitro-5-(trimethylsilyl)- and -5-(trimethylsilylmethyl)isoxazolidine.¹³⁰

n = 0, 1.

The reaction of these silanes with diethyl nitromalonate *O*-methyl ester proceeds in a similar way.¹³²

The reaction of dinitromethane *O*-methyl ester with allyl(trimethyl)silane is also accompanied by the formation of a cyclic adduct. However, 3-nitro-5-(trimethylsilylmethyl)isox-azoline is formed in high yield instead of the expected product, *N*-methoxy-3-nitro-5-(trimethylsilylmethyl)isoxazolidine.

It can be inferred from these data that the cyclisation is regiospecific, *viz.*, the oxygen atom always attacks the least hydrogenated carbon atom.

At 50–75 °C, triorganylsilylalkylamines react with divinyl sulfoxide to give 4-(triorganylsilylalkyl)tetrahydro-1,4-thiazine oxides (in 62%–80% yields).¹³³ At lower temperatures (30–50 °C), a linear monoadduct is predominantly formed.

$\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Me, Et, Bu}$; $\text{R}^1 = \text{R}^2 = \text{Et, EtO}$; $n = 1, 3$.

Cyclisation of methyl(2-cyanoethyl)diethoxysilane with ethylenediamine in the presence of sulfur as a catalyst gives 2-(2-methyldiethoxysilylethyl)-4,5-dihydroimidazole.¹³⁴

5. Transsilylation reactions

The reactions of halogeno- and alkoxydimethyl(chloro-methyl)silanes $\text{ClCH}_2\text{SiMe}_2\text{X}$ with *N*-trimethylsilyl derivatives of 2-piperidone,^{135–144} pyrrolidone,^{81, 136, 138–148} caprolactam,^{81, 138, 139, 141–144, 148} butyrolactam¹³⁹ and morpholinone¹⁴⁹ occur in three steps: (a) transsilylation (substitution of $\text{CH}_2\text{SiMe}_2\text{Cl}$ for SiMe_3); (b) intramolecular silylmethylation of the oxygen with migration of the chlorine atom from the carbon atom to silicon and (c) *O,N*-migration of the silylmethyl group. For instance:

$\text{X} = \text{F, Cl, Br, I, OR}$.

Data from X-ray analysis¹⁴⁸ confirmed the conclusion that the silicon atom in *O*- (compound **B**) and *N*-alkylation (compound **C**) products is five-coordinate. It should be noted that *N*-trimethylsilyl derivatives of piperidone and caprolactam react with $\text{ClCH}_2\text{SiMe}_2\text{X}$ at room temperature, whereas the *N*-trimethylsilyl derivative of butyrolactam reacts with these silanes at 110–130 °C.¹³⁹ This reaction is catalysed by AlCl_3 , $\text{Me}_3\text{SiOSO}_2\text{CF}_3$ or PhNEt_2 . In this case, the reaction time decreases

from 3 to 0.5 h but the yield of the final product does not change (32%–71%).¹⁴²

In the reaction of $\text{ClCH}_2\text{SiR}_n^1(\text{OR}^2)_{3-n}$ with *N*-trimethylsilyl-substituted 3,5-dimethylpyrazole, imidazole, benzimidazole^{90, 150, 151} and 2,2'-dipyridylamine,¹⁵² the main *N*-silylmethylation reaction (reaction *a*) is accompanied by transsilylation (reaction *b*):

$\text{R}^1, \text{R}^2 = \text{Me, Et}$; $n = 0–3$; $m = 0, 2$.

Thus in the case of 3(5)-methylpyrazole, the ratio of silylmethylation and transsilylation products is 85 : 15.¹⁰²

The reaction of 8-trimethylsiloxyquinoline (**6**) with dimethyl(chloromethyl)chlorosilane proceeds according to the following scheme:^{153, 154}

Methyl(chloromethyl)dihalogenosilanes react with 8-trimethylsiloxyquinoline to give a spirocyclic ionic derivative of five-coordinate silicon.

This review provides only a superficial description of transsilylation reactions resulting in heterocyclic derivatives of hypervalent silicon, because they have been surveyed in other reviews.^{141, 142, 146, 148}

6. Miscellaneous reactions

2-(3'-Trimethylsilylpropyl)benzothiazole was obtained by the reaction of 2-aminobenzenethiol with 3-trimethylsilylbutyryl chloride (**7**) in a polar solvent and in the presence of triethylamine (50–150 °C).¹⁵⁵

1,2,3,4-Tetrahydroquinoline, 1,2,3,4-tetrahydroisoquinoline and *N*-methylpiperazine are more reactive than 8-hydroxyquinoline with respect to the acid chloride **7** in inert solvents (ether, hexane) at 0–10 °C.¹⁵⁶

Depending on the position of the substituent (CH_2SiMe_3) in the heterocycle, the reactivity decreases in the following order (the relative reaction rates are given in parentheses): 2-Q CH_2SiMe_3 (41) > 4-Q CH_2SiMe_3 (37) > 4-Py CH_2SiMe_3 (8.9) > 2-Py CH_2SiMe_3 (1.0) > 3-Q CH_2SiMe_3 (0.161) > 3-Py CH_2SiMe_3 (0.03).⁵⁴ These data suggest that quinoline derivatives are desilylated faster than the corresponding pyridine derivatives.

In the presence of tetrabutylammonium fluoride in DMF or CsF in HMPA, *N*-trimethylsilylmethyl-substituted phthalimide,¹¹ 2-piperidone,³⁷ 2-mercaptobenzothiazole,⁶⁰ 2-benzothiazole,⁶¹ 1,2,4-triazole^{83,85,169} and 4-methylpyridine¹⁷⁰ are smoothly desilylated with aldehydes in THF (20–25 °C) to give the corresponding heterocyclic alcohols. Similar reactions of acid chlorides give the corresponding heterocyclic ketones.³⁷ For example:

$\text{R}^1 = \text{Pr}^n, \text{Pr}^i, \text{Ph}$; $\text{R}^2 = \text{Pr}^n, 4\text{-MeC}_6\text{H}_4, \text{PhO}$.

Oxidative desilylation of trimethylsilylmethyl derivatives of pyridine and quinoline with $\text{PhI}(\text{OCOCF}_3)_2$ yields the corresponding alcohols in good yields.¹⁷¹

CsF-Induced desilylation of trimethyl[3-(2-trimethylsilylmethylpyridyl)methyl]ammonium bromide in acetonitrile (55 °C) affords a pyridinium analogue of *o*-quinodimethane.^{172,173}

The reaction of 2-(trimethylsilylmethyl)pyridine with perfluoro(2-methylprop-1-enyl)methyl ether and perfluoro(2-methylpent-2-ene) gave 2-[2-methoxy-3-(trifluoromethyl)but-1-enyl]pyridine (yield 50%) and 2-pentafluoroethyl-3-trifluoromethyl-4*H*-quinolizin-4-one, respectively.¹⁷⁴

3. Reactions with functional substituents at the silicon atom

KOH-Catalysed transesterification of (heterylmethyl)trialkoxysilanes with triethanolamine results in the corresponding heterylmethylsilatrane.^{40–42,72,89,91,117,118,133,142,175–178} For example:

The molecular and crystal structures of 1-(2-benzothiazolylthiomethyl)silatrane was established by high-resolution X-ray analysis.¹⁷⁸

The reactions of trimethoxysilylmethyl- and methyltrimethoxysilylmethyl derivatives of pyridine, 8-mercaptoquinoline, 8-hydroxyquinoline, 2-mercaptobenzoxazole, 2-mercaptobenzothiazole, pyrrolidine and pyridine with HF , $\text{BF}_3 \cdot \text{Et}_2\text{O}$ or SbF_3 give the corresponding heterylalkyltrifluoro- and methyl(heterylalkyl)difluorosilanes in 61%–72% yields.^{117,118,179–183} For example:

According to X-ray analysis data, the molecules of (2-benzoxazolylthiomethyl)- and (2-benzothiazolylthiomethyl)-trifluorosilanes contain an intramolecular $\text{N} \rightarrow \text{Si}$ coordination bond, which closes the five-membered ring.^{117,181}

$\text{Y} = \text{O}, \text{S}$.

Etherification of the corresponding chlorides in the presence of triethylamine as the HCl acceptor is the most versatile method for the synthesis of *N*-(dimethylalkoxysilylmethyl)lactams.^{184,185}

$\text{R} = \text{Me}, \text{Pr}^i, \text{C}_{10}\text{H}_{21}, \text{CH}_2\text{Ph}$.

The $\text{O} \rightarrow \text{Si}$ coordination bond is destroyed in the synthesis of alkoxy derivatives. With substitution of an $\text{RONa} - \text{PhMe}$ for an $\text{ROH} - \text{Et}_3\text{N}$ system, the yields of *N*-(dimethylalkoxysilylmethyl)lactams ($\text{R} = \text{Me}$ and Pr^i) are only 46% and 38%, respectively. This is due to the cleavage of the $\text{Si}-\text{CH}_2$ bond, which occurs simultaneously with the formation of *N*-methyl-lactams.

Trialkylalkoxystannanes can also be used instead of sodium alkoxides. This method was used to prepare *N*-(dimethylalkoxysilylmethyl)-substituted pyrrolidones and 2-azepinones in 79%–96% yields.¹⁸⁶

N-Chlorodimethylsilyllactams react with the Grignard reagents (MeMgI , PhCH_2MgCl) at the $\text{Si}-\text{Cl}$ bond with high chemoselectivity to give the corresponding *N*-(trimethylsilylmethyl)- and *N*-(benzyltrimethylsilylmethyl)-lactam derivatives.¹⁸⁷

$\text{R} = \text{Me}, \text{CH}_2\text{Ph}$; $\text{X} = \text{Cl}, \text{I}$; $n = 1-3$.

4. Hydrolytic reactions

The hydrolysis of *N*-(methoxydiphenylsilylmethyl)-1,2,4-triazole,²⁸ *N*-(methoxydimethylsilylmethyl)-3,5-dimethylpyrazole,⁹⁰ *N*-(chlorodimethylsilylmethyl)-¹⁸⁸ and *N*-(alkoxydimethylsilylmethyl)lactams¹⁸⁹ gives the corresponding linear 1,3-bis(*N*-heterylmethyl)tetraorganylsiloxanes in 60%–82% yields. For example:

The hydrolytic polycondensation of *N*-[3-(diethoxy)methylsilylpropyl] derivatives of uracil, thymine and adenine gives rise to the corresponding polyorganylsiloxanes.³⁶

The hydrolysis of 4-(trialkoxysilylalkyl)tetrahydro-1,4-thiazine oxide,¹³³ 2-(2-trimethoxysilylmethylthio)benzimidazole, -benzoxazole and -benzothiazole,^{40–42, 190} as well as of (*N*-trialkoxysilylpropyl)morpholine¹⁹¹ proceeds with the formation of the corresponding polyheterylalkylsiloxanes in 10%–63% yields. For example:

5. Complex formation

2-[3-(Triethylsilylpropyl)methyl]quinoline,⁹¹ *N*-trimethylsilylmethyl-1,2,3,4-tetrahydroisoquinoline,^{75, 93, 192} *N*-[3-(diphenylmethylsilyl)propyl]morpholine and piperazine¹¹⁰ and *N*-[3-(trialkylsilyl)propargyl]pyrrolidine and -piperidine¹²⁴ react with a saturated solution of hydrogen chloride in ether to yield the corresponding hydrochlorides. The reaction of (8-quinolythiomethyl)trimethylsilanes, -trimethoxysilanes and -silatrane with CuCl₂, ZnCl₂, PtCl₂ and SnCl₄^{193–195} gave various types of coordination compounds the structure of which depended on the nature of the metal and substituents at the silicon atom. Thus the reaction of (8-quinolythiomethyl)trimethylsilane with potassium tetrachloroplatinate results in a planar-tetragonal chelate complex with PtCl₂.

R = Me, OMe; R₃ = (OCH₂CH₂)₃N; MCl_n = CuCl₂, ZnCl₂, PtCl₂, SnCl₄, HCl.

IV. Biological activities and practical applications

Many of the compounds considered in this review possess highly specific biological activities which are determined by both the presence of a heterocyclic system and the silicon atom flanked with the corresponding substituents. Therefore, such compounds

have attracted considerable attention in the past decade. *N*-(Triorganylsilylalkyl)imidazoles,^{12, 13, 20, 22, 23, 26, 30, 31, 196, 197} and -1,2,4-triazoles,^{12, 13, 20–24, 26–31, 84, 85, 196–206} 8-(trimethoxysilylpropylamino)quinoline and -5,7-dibromoquinoline,²⁰⁷ as well as 2-(trimethylsilyl)methylpyridines²⁰⁸ possess a broad spectrum of bactericidal and fungicidal activities. Used as fungicides (20–100 g hectare^{−1}), these compounds inhibit the growth of *Puccinia recondita*, *Sphaerotheca fuliginea*, *Erysiphe graminis* and *Podosphaera leucotricha*. Thus 1-[2-(4-bromophenyl)ethyldimethylsilylmethyl]imidazole (50–200 mg litre^{−1}) exhibits a fungicidal activity against *Erysiphe cichoracearum*, *Erysiphe graminis*, *Puccinia recondita*, *Puccinia coronata* and *Phalosophaeria nodorum*.²⁶

Substituted (trimethylsilyl)-3,5-bisaminomethyl-1,2,4-triazole and 2-(trimethylsilylmethoxy)pyrrolidone manifest high insecticidal activity.⁹⁴ *N*-[3-(4-Chlorophenyl)dimethylsilylpropyl]piperidine (2 and 5 g kg^{−1}) inhibits the growth of tobacco sucking discs.¹⁵

(4-Halogenophenyl)methyl-bis(1,2,4-triazol-1-ylmethyl)silane (Hal = F, Cl),²⁴ 3-[bis-(4-fluorophenyl)methylsilyl]imidazole³⁴ and 7-chloro-4-(4-trimethylsilylethynylpyrazolo)quinoline⁷⁰ used at a concentration of 500 mg litre^{−1} exert catalytic systemic effects against various diseases of wheat, rice, barley, oats, maize, cotton, soybean, coffee, sugar cane, apple trees, etc. *N*-Trialkylsilylmethyl-2-pyrrolidones and -caprolactams inhibit the growth of certain bacteria inducing diseases in vine and cucurbitaceous plants.⁸⁰ *N*-Trimethylsilylmethylbenzoxazine is an active and non-phytotoxic (for culture plants) component of herbicidal preparations which are commonly used in doses of 0.06–1.00 kg hectare^{−1} (see Ref. 209). 3,5-Diamino-6-(trimethylsilylethyl)-1,2,4-triazine is used for elimination of organisms attacking cabbage, beetroot and tobacco seedlings.²¹⁰ Poly-[2-methyl-5-vinylpyridinium 1-pentamethylsilyloxymethylide] possesses high pesticidal and growth-regulating activities.^{211, 212}

4-[3-(Trimethylsilyl)propylamino]quinolines manifest not only herbicidal but also selective antimicrobial activities,^{97, 99} viz., they efficiently suppress pathogenic fungi and exhibit moderate inhibiting action on the growth of gram-positive bacteria without any effect on gram-negative bacteria. 4-[3-(Trialkylsilyl)propylamino]-7-chloroquinolines exhibit high fungistatic activity. Incorporation of a methoxy group at position 6 of these compounds markedly increases their bacteriostatic activity.^{98, 99}

Flusilazole, 1-[bis(4-fluorophenyl)methylsilylmethyl]-1,2,4-triazole, is an efficient organosilicon ergosterol-like fungicide able to suppress various biosynthetic reactions.^{25, 213–231}

At present, flusilazole is one of the most widely used broad-spectrum agricultural fungicides. It is used against a complex of diseases in cereals, vine, seed fruits, sugar beet and peanut induced by asco-, basidio- and deuteromycetes (also in combination with other fungicides) in the doses of 80–240 g hectare^{−1}.

(*N*-Methylpiperazinylmethyl)phenylcyclohexylsilanol sulfomethylate exerts a potent and highly selective antimuscarinic effect and is used in experimental pharmacology for classification of various subtypes of muscarine receptors.⁷⁴

N-(Triethylsilylpropargyl)piperidine and -pyrrolidine hydrochlorides have a neurotropic effect on animals.¹²⁴ 6-[4-(Trimethylsilyl)butylamino]quinoline hydrochloride manifests an antiviral activity against influenza A virus.⁹² 1-(2-Chlorophenyldiphenyl)methyl-3-(dimethylphenylsilyl)methylimidazolium chloride,⁷⁷ *N*-[3-(trialkylsilyl)propyl]imidazole,^{86, 87} *N*-[3-(triorganylsilyl)propyl]piperazine and -morpholine,¹¹⁰ *N*-[1-(trimethylsilylmethyl)]-1,2,4-triazole,²⁰⁹ as well as 4-trialkylsilylpropylaminoquinoline^{91, 93, 156} and -pyridine²³² possess high antimicrobial activities. These compounds display high fungistatic and cytotoxic activities.

4-(Triorganylsilylalkyl)tetrahydro-1,4-thiazine 1-oxides produce a potent effect on the central and peripheral nervous systems and possess a bacteriostatic activity.¹³³

Weakly toxic [1-(2-oxopyrrolidino)ethyl]triethoxysilane exerts antishock and tranquillising effects.¹¹⁶ Methyl-2-butyl-(3-piperidinopropyl)silane and 2-(3-trimethylsilylpropargyloxy)-pyrazine-6-thiocarboxamide hydrochlorides and *N*-(triethylpropargylsilylmethyl)piperidine manifest a tuberculostatic activity *in vitro* against *M. tuberculosis* and a bacteriostatic activity against *Staphylococcus aureus haemolyticus* 209.^{38, 233}

4-[3-(Trialkylsilyl)propylamino]quinolines, 1-(trialkylsilylpropyl)fluorouracil,²³⁴ *N*-trimethylsilylmethyl-1,2,3,4-tetrahydroisoquinoline hydrochloride,⁹³ 4-quinolylaminoalkyl-, 1-(1-tetrahydroquinolylmethyl)- and 1-[1-(4-quinolylamino)propyl]-silatrane²³⁵ manifest an antitumour activity, Ehrlich ascites tumour and leukemia L_D 5178 cells being especially sensitive to the cancerostatic effects of these compounds. (Heterylalkyl)trialkylsilanes are less active than the corresponding silatrane derivatives.

1-(3-Trialkylsilylpropyl)piperidine is used as an active component of a disinfectant used for the treatment of textiles.²³⁶ 4-(2-Trimethoxysilyl)ethyl-*N*-alkylpyridinium bromide, which has the property to increase the volume and softness of textile fibres, also manifests an antimicrobial activity.²³⁷

(Triorganylsilyl)benzotriazole derivatives are used as additives to sun protection lotions.¹¹²

N-(Trimethoxysilylpropyl)maleimide²³⁸ and 3-(triorganylsilylalkyl)-2-pyrrolidone²³⁹ are added to polymer-based pharmaceuticals in order to improve their mechanical properties.

5-[(Trimethylsilyl)methylthio]- and 5-[(diethylmethylsilyl)methylthio]-8-mercaptoquinolines are used as organic analytical reagents.^{18, 240, 241}

2-(2'-Trimethoxysilyl)pyridine is used for the preparation of rhodium carbonyl complexes. The latter are immobilised on silica gel and used as catalysts.²⁴²

1-(Trialkoxysilylalkyl)-3,5-diaminotriazine,²⁴³ -piperidine²⁴⁴ and -2-(4-triazolyl)benzoimidazole²⁴⁵ derivatives are used for treatment of fibre glass fabrics in order to improve their coupling with the polymeric binders. *N*-Substituted organosilicon derivatives of imidazole,²⁴⁶ benzoimidazole²⁴⁷ and triazine²⁴⁸ are used to protect metal surfaces owing to their ability to form highly thermostable films that withstand 100 heating cycles.

2-(Trialkylsilylalkyl)benzothiazole has been patented as a binder in the production of siliceous fillers for rubber tyres.^{78, 249–253}

Polysilanes containing *N*-alkylpyrrole groups²⁵⁴ and *N*-trimethoxysilylpropyl imidazole derivatives²⁵⁵ are used in the production of conducting materials.

Abstract. New results of studies on the electron density of silicates are considered in accordance with the traditional structural classification. Precision X-ray diffraction data and results of structure refinement based on high-angle and multipole models are discussed. Bonded radii, charges on atoms and bond ionicities in Si, Al, B and Be tetrahedra are estimated from the deformation electron density maps in relation to the electronic structures of the atoms and their electronegativities. New possibilities for the solution of problems of isomorphism, for investigations on hydrogen bonds and for the classification are demonstrated. It is noted that the electron density distributions allow one to consider fundamentals of traditional structural chemistry of silicates on the electronic level. For selected compounds, the results of experimental studies of the electron density and of quantum-chemical calculations are compared. The bibliography includes 97 references.

I. Introduction

Silicates are substances whose structures contain different combinations of silicon-oxygen tetrahedra as the major anionic components. Their negative charges are compensated for by charges of cations bulkier than silicon (for example, by magnesium, iron, calcium, sodium or potassium cations). Silicates belong to rock-forming minerals, which account for 90% of the Earth's crust. Virtually all elements of the Periodic table ranging from hydrogen to uranium and transuranium elements are the components of these minerals. Many silicates are mined and used as sources of raw materials.

The discovery of X-ray diffraction and the development of a fundamentally new method for studying compounds, *viz.*, X-ray diffraction analysis, have had a crucial effect on the studies of silicate structures. Before this method had been developed, numerous 'salts of polysilicic acids,' which are virtually insoluble in strong acids, had presented a puzzle for chemists. In the first

studies performed in the mid-1920s, the structures of garnet (the first silicate), quartz, olivine, sphene, zircon, diopside, topaz, phenakite, willemite, beryl, vesuvianite, benitoite, hypersthene, staurolite, hemimorphite and thortveitite were solved.^{1,2} Abundant data on silicate structures have now been accumulated. Russian scientists, namely, Academician N V Belov and his followers, have contributed significantly to the development of the notion of silicate structures.³

The advent of automated diffractometers and programme packages for special data processing marked the beginning of precision X-ray diffraction studies. The review by Tsirelson⁴ was the first Russian publication in which the current state of precision X-ray diffraction investigations and the modern notion of the electron density distribution in crystals have been covered most comprehensively. Examples of structural studies of organic and inorganic compounds, including silicates, were also reported in the cited review. Presently, studies on the electron density are among intensively developing lines of investigation in the structural chemistry. The principles and methods of investigations of the electron density are considered in detail in the monographs.^{4–7}

Classical (traditional) investigations in the field of structural chemistry of silicates were most completely surveyed in the monograph by Liebau.⁸ In this monograph, precision X-ray diffraction studies of silicates were briefly considered and the deformation electron density maps for orthoenstatite and coesite were presented. However, the currently available factual data are substantially more abundant.

The publications by Tsirelson *et al.*,^{9,10} can be considered as the first reviews devoted to the studies on the electron density of silicates. In the latter review, the major concepts, including principles of interpretation of electron density maps, were reported. A total of about 20 structures were discussed in these publications.

The present review surveys the results of studies on the electron density distribution in silicates published in recent years. Taking into account new data, crystal-chemical notions, such as the bond ionicity, the effective radius and the charge on the atom, as well as principles of the classification of silicate structures, which are compared with the classical views, are considered.⁸ For selected structures, the results of experimental studies on the electron density are compared with the results of quantum-chemical calculations.

Uspekhi Khimii 68 (4) 331–348 (1999); translated by T N Safonova

In the analysis of the results of investigations of silicate structures by the precision X-ray diffraction method, particular attention is given to the chemical bonds (especially, to those in silicon–oxygen tetrahedra). The data on these bonds can be obtained from electron density maps. The experimental electron density maps constructed with the use of the known procedures^{4–7} revealed regions of concentration of the electron density which were identified with overlapping orbitals. The silicon atom in the [SiO₄] tetrahedron possesses four equivalent *sp*³-hybrid orbitals corresponding to single covalent σ -bonds.^{11,12} In silicates, the experimental average SiO distance is shorter than that calculated with the use of Shomaker–Stevenson's equation taking into account the covalent radii of the silicon and oxygen atoms for the single bond. Cruickshank suggested¹¹ that the remaining *p*-orbitals of the oxygen atoms overlap with the *d*-orbitals of the silicon atoms to form additional π -bonds, which impart a somewhat double character to Si–O interactions. This fact was noted by Liebau⁸ and Tsirelson *et al.*¹⁰

Most studies on the chemical bonds in silicates involved calculations of deformation electron density distribution maps on the basis of an independent spherical-atom model (IAM), which is refined based on high-angle reflections (high-angle refinement), and the determination of the deformation component of the density ($\delta\rho$) responsible for the chemical bond with the use of difference Fourier series^{4–7}

$$\delta\rho(\mathbf{r}) = \frac{1}{V} \sum [F_{\text{exp}}(\mathbf{s}) - F_{\text{IAM}}(\mathbf{s})] \exp(-2\pi i \mathbf{s} \cdot \mathbf{r}),$$

where *V* is the unit cell volume, *F*_{exp} is the experimental structure amplitude, *F*_{IAM} is the calculated structure amplitude of the independent spherical model, *s* is the scattering vector of the reciprocal lattice, which describes the reflection of the *hkl* node, and *r* is the radius vector.

Therefore, the deformation electron density $\delta\rho$ characterises the electron density redistribution upon the involvement of atoms in chemical bonding.

The method of the multipole analysis of the electron density differs fundamentally from that of the high-angle refinement.^{4–7,10,13,14} The atomic scattering factor can be calculated from the following formula:

$$f(q) = P_c f_c(q) + P_v f_v\left(\frac{q}{\alpha}\right),$$

where *P*_c and *P*_v are population coefficients of the core and valence shells, respectively, and *f*_c(*q*) and *f*_v(*q*/α) are their scattering factors. The parameter α accounts for contraction or expansion of the valence shell of the atom. Chemical bonding leads to deviation from the spherical symmetry of the valence shell. However, this deviation is relatively small and can be described by the low-order expansion of the electron density in terms of nucleus-centred angular harmonics. For this purpose, different models are used, those suggested by Hansen and Coppens¹³ and by Stewart and Spackman¹⁴ are most generally employed. As an example let us consider the equation for the electron density suggested by Hansen and Coppens

$$\rho_a(\mathbf{r}) = P_c \rho_c(r) + P_v \alpha'^3 \rho_v(\alpha' r) + \sum_{l=0}^4 \alpha''^3 R_l(\alpha'' r) \sum_{lm} P_{lm} y_{lm}\left(\frac{\mathbf{r}}{r}\right),$$
 where *r* is the radius vector, *P*_c, *P*_v and *P*_{lm} are the population coefficients of the core, valence and deformation components, respectively, α' and α'' are the expansion–contraction parameters of the valence and multipole shells, respectively, *R*_{*l*} are the radial functions and *y*_{*lm*} are spherical harmonics (up to the fourth order); *r* = |*r*|.

The atom is represented as the sum of the core, valence and deformation (multipole) electron densities. The population coefficients of the valence and multipole terms, the parameters of the radial functions *P*_{*lm*} and the α' and α'' parameters are refined by the least-squares method. The refinement is performed until the

closest agreement between the calculated and experimental structure factors is achieved.

Precision calculations of silicate structures are carried out with the use of different programme packages, which allow one to process experimental data, to perform the refinement within the framework of a particular model and to construct sections of the electron density distribution passing through the interacting atoms. The following programmes can serve as examples: LINUS and its modified version EARTH,¹⁵ RADIEL,¹⁶ CRYLSQ,¹⁷ FOURR,¹⁸ SADIAN90,¹⁹ MINEXTL,²⁰ *etc.* The improved programme packages MOLLY¹³ and VALRAY¹⁴ are most generally used for the multipole refinement. Presently, the XD programme package,²¹ which involves modern investigation techniques, including topological analysis of the electron density, provides the greatest scope.

In the present review, most attention is concentrated on the results of high-angle refinement because only five examples of multipole refinement are known for silicates. The structures are considered in accordance with the degree of condensation of tetrahedra in the [Si_{*n*}O_{*m*}]^{*q*–} anionic silicon–oxygen motif. In crystal chemistry, this motif is also referred to as a radical. This consideration corresponds to the classical mineralogical classification.^{22–25}

II. Orthosilicates

Orthosilicates involve structures consisting of isolated (island) silicon-oxygen *ortho* groups. Natural and synthetic orthosilicates, *viz.*, Mg-, Fe-, Ni-, Co- and Mn-olivines,^{26–30} Fe-, Co- and Nispinel,^{31,32} phenakite,^{33,34} euclase,³⁵ eulytine,³⁶ topaz³⁷ and sphene,³⁸ were studied by precision methods.

1. Topaz

A specimen of natural topaz from the Volyn' deposit (Ukraine) was studied.³⁷ Intensities of reflection were measured within four octants of the reciprocal space related by a $\bar{4}$ axis. The principal crystallographic characteristics and conditions of the X-ray diffraction study are given in Table 1. Calculations were carried out using the MINEXTL programme. The extraordinarily high extinction was taken properly into account using the Zachariasen algorithm. An independent atomic model was obtained in the high-angle refinement, the *c* coefficient in the weighting scheme being varied:

$$w_s = [\sigma^2 + (cF^2)]^{-1},$$

where σ is the standard deviation and *F* is the structure factor. The correctness of the choice of the weighting scheme and of the determination of the scale factor was checked using Abrahams –

Figure 1. Structure of topaz.

Note. Notation adopted: *A* is the number of measured reflections; *B* is the number of independent reflections; *C* is the number of reflections used in the high-angle or multipole refinement.

Keve's test.³⁹ The refined real structural formula of the specimen is $\text{Al}_2[\text{SiO}_4](\text{F}_{0.95}\text{OH}_{0.05})$; its structure is shown in Fig. 1.

The deformation density distribution in the sections of the $[\text{SiO}_4]$ tetrahedron is in agreement with the concept of the presence of sp^3 -hybridisation and σ -bonds. The map calculated for the $\text{O}(1) - \text{Si} - \text{O}(3)$ section in topaz based on the experimental results and the map calculated for $\text{O} - \text{Si} - \text{O}$ in the H_4SiO_4 molecule by the quantum-chemical method⁴⁰ are similar. Thus the $\delta\rho$ maxima have close values (0.40 and 0.35 $\text{e} \text{ \AA}^{-3}$ for topaz and $\text{O} - \text{Si} - \text{O}$, respectively) and these maxima in both maps are shifted toward the more negative oxygen atom (Fig. 2*a, b*).[†] In other orthosilicates (olivine, spinel, euclase and phenakite), the values of the corresponding maxima are in the range of 0.2–0.4 $\text{e} \text{ \AA}^{-3}$. Calculations of the error maps demonstrated that these errors in the chemical bond region were 0.05 $\text{e} \text{ \AA}^{-3}$. A comparison of the electron density distributions at the faces of the tetrahedra in topaz and olivine also demonstrates that they are basically similar. However, a slight spread in values of the maxima in the σ -bonds is

observed. Note that topaz is characterised by a four-layer close packing, while olivine is described by a two-layer close packing.

The average $\text{Si} - \text{O}$ distances in the tetrahedra are diminished as the degree of their condensation increases.^{8, 25, 41} This is associated with the electrostatic interactions of the atoms. In the cases that electropositive cations (potassium, sodium, magnesium or calcium) in the structure dominate over electronegative silicon ions, simple anionic motifs, in which oxygen atoms adopt high coordination numbers and the $\text{Si} - \text{O}$ bonds are elongated, are realised.²⁵ The potassium, sodium, magnesium and calcium cations rather readily donate electrons to the oxygen atoms, thus increasing their effective charges upon chemical bonding so that the ability of oxygen atoms to ionise silicon atoms decreases.⁴² Hence, the second coordination sphere of the silicon atom has a determining effect on the electron density distribution in the silicon–oxygen tetrahedra in orthosilicates. In topaz and olivine, this sphere is formed by the Al atoms or by the Fe and Mg atoms, respectively. These atoms occupy octahedral cavities of the close packings in different fashions. The influence of the cations of the second coordination sphere is most clearly manifested in the electron density map as the splitting of the peak at the oxygen atom due to interactions between the oxygen atom and two aluminium atoms located to its right and left above the closely

[†] In the figures, which present the electron density distributions, the maps are contoured as follows: the solid lines indicate positive values of $\delta\rho$; the dash-and-dot lines indicate the zero level; the dashed lines indicate negative values of $\delta\rho$.

Figure 2. The electron density distribution in the H_2SiO_4 molecule (*a*) and in topaz (*b, c*); (*a*) the deformation density calculated for the SiO_2 group in the H_4SiO_4 molecule, the map is contoured at intervals of 0.07 $\text{e} \text{ \AA}^{-3}$ (see Ref. 40); (*b*) the experimental deformation density in the $\text{O}(1) - \text{Si} - \text{O}(3)$ section; (*c*) the static deformation density in the $\text{O}(1) - \text{Si} - \text{O}(3)$ section, the maps are contoured at intervals of 0.1 $\text{e} \text{ \AA}^{-3}$.

packed layer. The sections through the layers of the close packing indicate that the electron density of the oxygen atoms is shifted along the bond toward the occupied octahedral (Al) and tetrahedral (Si) holes.

The multipole refinement of the $\rho(\mathbf{r})$ function⁴³ based on the same experimental results as those used in another study,³⁷ confirmed the principal characteristic features of the electron density distribution and the crystal-chemical conclusions made previously. Calculations were carried out with the use of the MOLDOS96 and SALDOS97 programmes.⁴⁴ The characteristics of the refinement ($R = 0.91\%$, $R_w = 1.1\%$, $S = 1.13$) were improved compared to the data given in Table 1.

The calculated and experimental deformation density maps for the silicon–oxygen tetrahedron are virtually identical (see Fig. 2*a,c*). Analysis of the static deformation density maps calculated based on the results of multipole refinement most clearly revealed the shift of the electron density of the oxygen atoms in the close packed layer toward the occupied holes (Fig. 3). The splitting of the maximum at the O(2) atom toward two aluminium atoms was also reproduced.

Figure 3. The static deformation density distribution in the section of topaz passing through close packed layers of O(1) (in the centre) and O(3) atoms (at the vertices of the internal hexagon); the map is contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$. The positions of the atoms: (1) Al in octahedral holes above the close packed layer; (2) unoccupied octahedral holes below the close packed layer; (3) Si in tetrahedral holes.

The charges on the atoms in topaz were estimated on the basis of the results of determination of population coefficients of valence shells.⁴³ In this work, considerable attention has been given to the topological analysis of the electron density, which is an intensively developing modern method^{6,7} (this method is not considered in the present review). Note however that according to

Bader's theory^{4,6} chemical interactions in the silicon–oxygen tetrahedron are interpreted to a greater degree as ionic (*i.e.*, as interactions of atoms with closed electron shells) rather than as covalent interactions. This is inconsistent with the experimental and theoretical data obtained to date.

2. Sphene

A synthetic crystal of sphene $\text{CaTiO}[\text{SiO}_4]$ grown by Czochralski's method (Fig. 4) was investigated.³⁸ This mineral possesses antiferroelectric properties. The investigators attempted to relate these properties to the electronic structure. The conditions of the X-ray diffraction study are given in Table 1. Calculations were carried out with the use of the MINEXTL programme package.

Figure 4. Structure of sphene.³⁸

The distances in the silicon–oxygen tetrahedra in sphene and topaz (Table 2) are close to each other and are larger than those in other silicates containing condensed anionic groups. The deformation electron density distribution corresponds to four σ -bonds (sp^3-p) with maxima of $0.2-0.4 \text{ e } \text{\AA}^{-3}$. The effect of the second coordination sphere on the electron density in the isolated $[\text{SiO}_4]$ tetrahedron can be judged from the difference in the values of peaks in the bonds between the silicon atom and the oxygen atoms belonging to the edge shared by Ti octahedra in a column and to the edge shared by Ti octahedra of two different columns (Fig. 5*a*). An electron-density 'bridge' ($0.2 \text{ e } \text{\AA}^{-3}$) is clearly seen on the edge. This bridge can be interpreted as the manifestation of a somewhat double character of the bridging Si–O bonds in this structure. The error of $\delta\rho$ in the chemical-bond region was $0.2 \text{ e } \text{\AA}^{-3}$.

The asymmetrical deformation density distribution was observed in the Ti octahedron, the density being concentrated at the shortened titanyl Ti–O(1) bond [$1.7594(7) \text{ \AA}$; Fig. 5*b*], which

Figure 5. The experimental deformation density distribution in the section of the Si tetrahedron (*a*) and Ti octahedron (*b*) in sphene;³⁸ (*a*) the O(2)–Si–O(4) section, the map is contoured at intervals of $0.05 \text{ e } \text{\AA}^{-3}$; (*b*) the O(2)–Ti–O(4)–O'(1) section, the map is contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$.

is apparently responsible for the appearance of the electric moment in the structure. The difference in the bond lengths and, correspondingly, in the charges on these bonds is typical of many compounds containing titanium atoms. For example, the titanyl bond in KTiOPO_4 , which exhibits nonlinear-optical properties, is often considered as a double bond. This conclusion was made on the basis of calculations of the valence forces of the bond. The antiferromagnetic properties of sphene may result from the antiparallel distribution of the anisotropy of Ti—O interactions.

The radii of the best separation or the bonding radii were estimated from the full electron density maps.⁴⁵ It was noted that these radii were distributed over two pairs of the bonds of the silicon atom (0.85 and 0.49 Å; the average value is 0.67 Å). The estimation of the radius of the oxygen atom from the corresponding bonds in sphene gave the values 0.78 and 1.17 Å (the average value is 0.98 Å). The latter value differs only slightly from the corresponding values reported for coesite and stishovite⁴¹ (0.95 and 1.05 Å, respectively).

III. Ring silicates

Ring silicates are minerals the structures of which consist of silicon—oxygen tetrahedra arranged in rings. This group of silicates considered previously^{9, 10} was supplemented with a large number of new subjects.

1. Beryl

A specimen of natural beryl which was virtually free of impurities with the real structural formula $\text{Na}_{0.04}\text{Be}_{2.98}\text{Al}_2[\text{Si}_6\text{O}_{18}] \cdot 0.3\text{H}_2\text{O}$ (Fig. 6) was studied.^{9, 10} Investigation of the electron density

Figure 6. Structure of beryl.⁴⁶

distribution made it possible to characterise chemical bonds in the six-membered $[\text{Si}_6\text{O}_{18}]$ ring, the Be tetrahedron, the Al octahedron and in the structure as a whole.^{46,47} Actually, a group of beryls (exhibiting microisomorphism) containing various impurities of 3d elements (Fe, Co, Cu and Cr) which impart a typical colour to the crystals (*viz.*, aquamarine is pale-blue, emerald is green, *etc.*) was studied. The results of studies of microisomorphism were considered in detail.⁴⁸ Chromophore impurity ions occupy the positions of Al in octahedra (Fe, Co or Cr) or Be in tetrahedra (Cu) rather than interstitial sites as suggested previously. In addition to 3d elements, beryl structures contain small impurities of sodium atoms and water molecules. Their positions were determined as $2(b)$ (0 0 0) for the Na atom and $2(a)$ (0 0 1/4) for the oxygen atom of the water molecule. On the basis of the arrangement of the $\delta\rho$ maxima ($0.4 \text{ e } \text{\AA}^{-3}$) in the electron density maps, the planes of the water molecules were found to be oriented horizontally (parallel to the ab plane), their own twofold axes being perpendicular to the principal sixfold axis (Fig. 7a). This distribution was characterised on the assumption that molecules are statistically disordered about the sixfold axis. The electron density distributions in all horizontal and vertical (parallel to the c axis) sections for isomorphous modifications of beryls steadily reproduced the hydrogen bond pattern. The errors of the maps were $0.02\text{--}0.05 \text{ e } \text{\AA}^{-3}$.

Figure 7. The experimental deformation density distribution in the section of beryl passing through the oxygen atom of the water molecule, $z = 0.25$ (a) and the difference Fourier map (neutron diffraction data, 30 K), $z = 0.317$ (b).⁴⁹

The horizontal orientation of the water molecules corresponds to one of two models of beryl structures proposed for interpreting their IR spectra. The model that assumes the vertical orientation of the planes of the water molecules was not confirmed by our investigations. Neutron diffraction studies^{49,50} of the structure of beryl confirmed the horizontal orientation of the water molecules established previously^{46,47} (Fig. 7b). The statistical disorder was assumed. However, the peaks around the position $2(a)$ (0 0 1/4) were misinterpreted as those possessing the mirror symmetry: in the space group of beryl (see Table 1) this position has the point symmetry 622, while the point symmetry $6/m$ is typical of position $2(b)$ (0 0 0) (Na atoms). The maxima on the sixfold axis in the

vicinity of the site (0 0 1/4) are apparently due to lone electron pairs of the water molecules. Other orientations of the water molecules in beryls are also not ruled out.^{49,50} Unfortunately, the vertical sections in which the positions of the hydrogen atom under consideration could be clearly seen were not presented.

2. Cordierite

The mineral cordierite $\text{Mg}_2\text{Al}_3\text{AlSi}_5\text{O}_{18}$ is structurally similar to beryl although its symmetry is lower (see Table 1).⁵¹ The high-temperature modification of cordierite with the beryl structure has long been known.⁵² Both minerals consist of six-membered rings of tetrahedra occupied by silicon atoms in beryl and by silicon and aluminium atoms in cordierite. Additional Be tetrahedra in beryl and Si and Al tetrahedra in cordierite are linked with the tetrahedra of rings *via* shared vertices to form open-work tetrahedral frameworks with bulky cavities filled by Na atoms and H_2O and CO_2 molecules (Fig. 8). Currently, cordierite in the form of ceramics is considered as an adsorbent of harmful Zn-containing exhausts of motor transport.⁵³ In this connection, the problem of incorporation of impurities into this zeolite-type framework is under investigation. In addition to studies on microisomorphism of 3d elements in beryls,⁴⁸ incorporation of Cu^+ and Cu^{2+} ions into cordierites was examined by the Rietveld method.⁵⁴ The electron density maximum at the site (0 0 0), which is analogous to that observed in beryl, was attributed to the incorporation of copper atoms.

Figure 8. Structure of cordierite.⁵¹ M is the (Mg, Fe, Mn) octahedron.

Precision investigation of a single crystal of cordierite (a natural specimen from the Tuva deposit) demonstrated that the crystal-chemical formula of the mineral taking into account microisomorphism was $\text{Na}_{0.04}(\text{Mg}_{1.13}\text{Fe}_{0.78}\text{Mn}_{0.05})\text{Al}_2\text{Si} \cdot [\text{Al}_2\text{Si}_4\text{O}_{18}] \cdot 0.02\text{H}_2\text{O} \cdot 0.06\text{CO}_2$. X-ray diffraction data were collected within a hemisphere of the reciprocal space. Calculations were carried out with the use of the MINEXTL programme. An iron impurity in Mg octahedra was detected. The site (0 0 0) of the Na atoms is identical with that in beryl. It is worthy of note that this position is too 'bulky' for copper atoms, which should cause the impurity atom to displace from the centre of the cavity. It seems more likely that copper and zinc impurity atoms in the structure of cordierite occupy positions of 'non-ring' tetrahedra or Mn octahedra. Water molecules together with CO_2 occupy the position (0 0 1/4) in a channel identical with that in the above-considered structure of beryl.

It is of most interest to compare the electron density distributions and to reveal the difference in the chemical bonds when different atoms fill the same structural units. The deformation density distributions in the $[\text{Si}_6\text{O}_{18}]$ and $[\text{Al}_2\text{Si}_4\text{O}_{18}]$ rings in beryl and cordierite, respectively, are shown in Fig. 9a,b. In the low-temperature modification of cordierite, Al and Si atoms are distributed over tetrahedral positions in an orderly fashion (see

Figure 9. The experimental deformation density distributions in the sections passing through the central T atoms of the tetrahedra and bridging oxygen atoms of the $[T_6O_{18}]$ rings; (a) beryl, the symmetry of the ring is $6/m$; (b) cordierite, the symmetry of the ring is $2/m$; (c) diopside, the symmetry of the ring is $\bar{3}$, the maps are contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$; (d) tourmaline, the symmetry of the ring is $3m$, the map is contoured at intervals of $0.05 \text{ e } \text{\AA}^{-3}$.

Table 2). At high temperature, these atoms are disordered, which leads to a phase transition. The interatomic Si—O distances in the tetrahedra of these minerals consisting of linked tetrahedra are shorter than those in orthosilicates. According to the rules of electrostatics, the distance between two silicon atoms interacting *via* the bridging oxygen atom is increased due to their repulsion. However, both in beryl and cordierite, all oxygen atoms act as bridges, minerals have the framework structures, the tetrahedral positions are occupied by Be, Si and Al atoms and the above-described effect is not manifested.

For both structures, the deformation electron density maps (see Fig. 9 *a, b*) reveal accumulation of the density at the bridging oxygen atoms. The maxima in the Si—O and Al—O bonds are $0.30\text{--}0.40 \text{ e } \text{\AA}^{-3}$ and $0.20\text{--}0.25 \text{ e } \text{\AA}^{-3}$, respectively, which correspond to different electronic structures of the atoms. However, this difference in the Si, Al ring in cordierite is smoothed. Calculations of the error maps demonstrated that these errors were $0.02\text{--}0.05 \text{ e } \text{\AA}^{-3}$ in the chemical-bond region and 0.05 and $0.04 \text{ e } \text{\AA}^{-3}$ at the silicon and aluminium atoms, respectively. As in the case of beryl, no difference between the bridging and terminal

Figure 10. The experimental deformation density distributions in the sections passing through the common fragments of the structures of beryl and cordierite; (a) beryl, Si tetrahedron, Be tetrahedron, Al octahedron, the map is contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$; (b) cordierite, Al(1) tetrahedron, Si(1) tetrahedron, (Mg, Fe) octahedron; (c) cordierite, Si(3) tetrahedron, Al(2) tetrahedron, (Mg, Fe) octahedron, the maps are contoured at intervals of $0.05 \text{ e } \text{\AA}^{-3}$.

oxygen atoms was observed as regards the values of the maxima in the σ -bonds.

In the framework structure, virtually all oxygen atoms are shared by two tetrahedra. Therefore, the assignment of beryl and cordierite to framework beryllsilicates⁵⁵ and framework aluminosilicates, respectively, is valid from the viewpoint of the electronic structure and chemical bonds in these compounds.

The structural fragment common to beryl and cordierite consists of the octahedron (Al or Mg, Fe) and the tetrahedra (Be, Al and Si tetrahedra) linked to the octahedron *via* shared edges or vertices. The differences in the electron density redistribution which occur if the centres of the corresponding polyhedra are occupied by atoms with different electronic structures and electronegativities (Be, Al or Si)^{8,56} are in complete agreement with those expected (Fig. 10): 0.2, 0.2–0.25 and 0.3–0.4 e Å⁻³ for the Be–O, Al–O and Si–O distances, respectively. An increase in the shift of the $\delta\rho$ maxima toward the more electronegative oxygen atom with increasing difference in the electronegativities of the Si–O, Al–O and Be–O pairs of elements allows one to estimate the bond ionicity. In agreement with the traditional crystal-chemical criteria, an increase in the bond ionicity is also observed for the M–O bond in the octahedron where Al is replaced by (Mg, Fe) (see Fig. 10). Note that even a small impurity of iron atoms in the case of hexagonal distortion of the octahedron is manifested in the map as an additional maximum directed toward the threefold axis of the coordination polyhedron, which corresponds to 3d-electrons of the iron atom located on the d_{z^2} -orbital (a_g level).

3. Diopase

The mineral diopase has the formula Cu₆[Si₆O₁₈]·6H₂O. A specimen of natural diopase from Kazakstan was studied by the same methods as described above for the specimens of beryl and cordierite.⁵⁷ The reflections within a hemisphere of the reciprocal space were reindexed from the hexagonal to the trigonal setting. The rings in silicates under consideration have different symmetry, *viz.*, 6/*m*, 2/*m*, $\bar{3}$ and 3*m* in beryl, cordierite, diopase and tourmaline (discussed below), respectively.

By virtue of the absence of the horizontal mirror plane and corrugation of the [Si₆O₁₈] ring in the case of the symmetry $\bar{3}$, the electron density map for this ring was constructed from fragments (see Fig. 9 *c*). The difference in the Si–O bond lengths in diopase is consistent with the classical concepts.⁸ As in the case of cordierite, the deformation density is accumulated at the bridging oxygen atoms. Of particular interest is the difference in the maxima in the bonds with the participation of the bridging and terminal oxygen atoms (see Fig. 9 *c,d*): 0.6–0.8 and 0.2–0.3 e Å⁻³, respectively (the error in the chemical-bond region is 0.1 e Å⁻³). These data are indicative of the nonequivalence of the bonds in the silicon–oxygen tetrahedron in diopase (unlike beryl and cordierite) and underline the role of the bridging oxygen atoms that fasten the corrugated ring as the structural unit in the overall three-dimensional construction. Hence, the characteristic features of the chemical bonds in this mineral confirm the assignment of diopase to ring silicates.

The structure of diopase (Fig. 11) is characterised by the presence of corrugated six-membered rings of silicon–oxygen tetrahedra that alternate with analogous six-membered rings of water molecules, which can be considered as the fragments of the ice structure. The positions of the protons in diopase were determined by neutron diffraction analysis.⁵⁸ The electron density distribution in the section passing through the water molecules (Fig. 12 *a*) is similar to the calculated distribution (Fig. 12 *b*)⁵⁹ and other experimental distributions. The observed decrease in the electron density on the lone electron pairs is associated with interactions of water molecules with other atoms (in particular, with copper atoms).⁶⁰ The calculated geometrical characteristics (bonds and angles) of the hydrogen bonds correspond to the standard values. The hydrogen bonds are directed toward the water molecules within the ring as well as upward and downward

Figure 11. Structure of diopase.⁵⁷

Figure 12. The deformation electron density distributions in the sections passing through water molecules; (a) the H(1)–O_w–H(2) section (experiment) in diopase; (b) the H–O–H section (calculation) for the isolated water molecule.⁵⁹

(toward the silicon–oxygen rings) thus holding the ring of water molecules in the structure. The experimental and calculated electron densities for the hydrogen bond between two water molecules in the ring are in satisfactory agreement.⁶¹ In the structure of diopase, unlike the structure of ice (Pauling's model), all lone electron pairs are oriented outward the ring.

In the structure of diopase, all divalent copper atoms occupy Jahn–Teller-distorted octahedra. The effect of the ligand crystal field on the distribution of the 3d-electrons of the copper atom ([d⁹] configuration) can be described assuming the symmetry D_{4h} (the true symmetry C_1) of a distorted octahedron. The 3d-level splits into 4 sublevels, *viz.*, $e_g(d_{xz}, d_{yz})$, $b_{2g}(d_{xy})$, $b_{1g}(d_{x^2-y^2})$ and $a_{1g}(d_{z^2})$.⁶² When the axes of coordinates are directed along the Cu–ligand bonds with the z axis directed toward the apical water molecules, depletion of the $b_{1g}(d_{x^2-y^2})$ orbitals in electron density is observed, all other orbitals being occupied. Hence, in accordance with the Jahn–Teller removal of degeneration, the $a_{1g}(d_{z^2})$ level is stabilised, while the $b_{1g}(d_{x^2-y^2})$ level is destabilised. In

chalcantite,⁶³ in which the Cu octahedron possesses a symmetry centre, this pattern is more pronounced.

4. Tourmaline (elbaite)

A specimen of natural tourmaline from Afghanistan was studied by Belokoneva and Tsirelson⁶⁴ (see Table 1). Intensities of reflections were measured within a hemisphere of the reciprocal space in the hexagonal setting and, as in the case of diopase, the reflections were reindexed to the trigonal setting.

The tourmaline family is characterised by a broad spectrum of isomorphism. Five major modifications are distinguished according to the composition and colour of the minerals, *viz.*, dravite, elbaite, buergerite, schorl and ulvite.²³ Based on the results of investigations on isomorphism in this specimen and on the results of X-ray microspectral analysis, the formula of tourmaline (elbaite) was established to be $(\text{Na}_{0.85}\text{Ca}_{0.05}) \cdot (\text{Al}_{1.10}\text{Li}_{1.15}\text{Fe}_{0.41}\text{Mn}_{0.22}\text{Mg}_{0.12}) \cdot \text{Al}_6\text{B}_3\text{Si}_6\text{O}_{27}(\text{OH})_{3.92}$. The structure of the mineral is shown in Fig. 13.

Figure 13. Structure of tourmaline.⁶⁴ Dotted hatching indicates (Al, Li, -Fe, Mn, Mg) octahedra.

Unlike all the above-considered ring anionic groups which possess a symmetry centre, the ring of silicon–oxygen tetrahedra in tourmaline is polar and corresponds to the symmetry $3m$. Tourmaline is a pyroelectric mineral.[‡] The structural prerequisites for this phenomenon still remain unclear. Hence, analysis of the electron density distribution in the crystal of tourmaline is a topical problem.

The triangular O(4)–O(5)–O(7) faces in the ring of the silicon–oxygen tetrahedra of tourmaline are nearly parallel to the *a* and *b* axes of the unit cell and the polar vertices of the O(6) tetrahedra are located directly above the silicon atoms exactly along the *c* axis. In the silicon–oxygen ring (unlike the analogous rings in the three above-considered minerals), weak $\delta\rho$ maxima are observed in the vicinity of the bridging oxygen atoms (see Fig. 9*d*), *viz.*, outside the ring close to the O(4) atom and within the ring close to the O(5) atom. These maxima correspond to O(H)···O hydrogen bonds. The most remarkable characteristic feature of the deformation density maps is the displacement of the electrons toward the base of the silicon–oxygen tetrahedron with the maximum located directly below the silicon atom (Fig. 14*a*). In this case, the apical oxygen atom is depleted in electrons in the bond and the $\delta\rho$ maximum is displaced from the bond line

Figure 14. The experimental deformation density distributions in the sections of tourmaline; (a) the O(6)–Si–O(4) section with the maximum under the Si atom; (b) the O(6)–Si–O(7) section, the maps are contoured at intervals of $0.05 \text{ e } \text{\AA}^{-3}$; (c) O(3)–H(2)···O(4) and O(1)–H(1)···O(5) hydrogen bonds, the map is contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$; (1) hydrogen donor, (2) hydrogen acceptor; (3) the position of the (Al, Li, Fe, Mn, Mg) octahedron.

(Fig. 14*a,b*). The interatomic distance to the apical oxygen atom is shortened, while the distances to the bridging oxygen atoms are elongated (see Table 2). The experimental errors of the determination of the $\delta\rho$ maps in the bond region were $0.06 \text{ e } \text{\AA}^{-3}$. An asymmetrical charge distribution within the tetrahedron and within the ring as a whole may be responsible for the appearance of an electric dipole moment in the structure and the pyroelectric properties.

The maximum of the deformation electron density was experimentally detected in the $[\text{VOCl}_3]$ tetrahedron on the opposite side of the metal–ligand bond,⁶⁵ as is the case in the silicon–oxygen tetrahedron in tourmaline. The phenomenon of deformation of the inner electronic shell of the vanadium atom under the action of the polarisation ligand field to produce the local concentration of the charge exterior to the bond was predicted by Bader and co-workers^{66,67} on the basis of the results of quantum-chemical calculations. Apparently, the polarisation field of the oxygen ligands in the ring of tourmaline is responsible

‡ It was in crystals of tourmaline that the phenomenon of pyroelectricity was discovered.

for the unusual deformation electron density distribution and pyroelectric properties.

Tourmaline is a borosilicate the boron atoms of which have a triangular coordination. The electron density distribution in the section passing through the $[\text{BO}_3]$ triangle is indicative of the bonds described by the sp^2 -hybrid state of the orbitals of the boron atom, which overlap (to form σ -bonds) with the p -orbitals of the oxygen atoms.

In the structure of tourmaline, the hydrogen bonds directed from one of the so-called antigorite fragment to another were studied.³ Figure 14c shows maxima ($\sim 1 \text{ e } \text{\AA}^{-3}$) corresponding to the electron density of the hydrogen atoms involved in the O–H bonds. The hydrogen bonds are directed from the O(3) and O(1) donor atoms to the O(4) and O(5) acceptor atoms of the silicon–oxygen ring.

Note that studies of the above-described ring silicates were preceded by only one publication devoted to the investigation of the synthetic analogue of wadeite, $\text{K}_2\text{Si}[\text{Si}_3\text{O}_9]$, which contains three-membered rings of Si tetrahedra and silicon atoms in octahedra.⁶⁸

IV. Chain and band silicates

The group of chain and band silicates includes three orthopyroxenes containing a two-membered $[\text{Si}_2\text{O}_6]$ chain (enstatite, ferrosilite and its cobalt analogue),⁶⁹ three clinopyroxenes (diopside, $\text{Mg}_2\text{Si}_2\text{O}_6$ and α -spodumene $\text{LiAlSi}_2\text{O}_6$)²⁹ and pectolite containing a three-membered chain.⁷⁰

Andalusite, which has been considered by Tsirelson *et al.*¹⁰ in the section devoted to orthosilicates, should be assigned to band aluminosilicates.⁷¹

The electron density distributions in structures of chain and band silicates have been investigated.^{9, 10} Since these publications, this group of silicates has not been supplemented with new members.

V. Sheet silicates

In sheet silicates, bonds between the layers (sheets) are weakened owing to which virtually all these minerals exhibit perfect cleavage. Sheet silicates very rarely occur as faceted crystals. If these crystals do occur, they are strongly flattened along the $[0001]$ direction. When ground to spheres, these crystals either collapse into plates or the spheres obtained give a large diffuse scattering component. For these samples, it is difficult to take proper account of absorption as well as to apply other corrections, which does not allow one to achieve a required precision of experimental data.

A specimen of natural datolite from the Tetuyche deposit (Far East) was studied.⁷² The mineral has the layered structure. The configuration of the layer is analogous to that in apophyllite $\text{KCa}_4[(\text{Si}_4\text{O}_{10})_2] \cdot 8\text{H}_2\text{O}$. Attempts to prepare a spherical sample of the latter mineral, which could give sharp reflections, have failed. In contrast, high-quality spherical samples of datolite crystals were prepared and precision investigation was performed. Intensities of reflections were measured within a hemisphere of the reciprocal space and within an additional hemisphere with $2\theta_{\text{max}} = 50^\circ$. The preliminary data processing was carried out with the use of the profile analysis procedure on the basis of Lehmann–Larsen's algorithm. This procedure allows one to obtain more reliable estimations of integrated intensities, particularly, those of weak reflections. Calculations were carried out using the CSD programme.

Microisomorphous relations were studied in the specimen and microimpurities of sodium and iron were detected. The content of the latter correlated with the hydrogen content. The formula of datolite was established to be $(\text{Ca}_{0.986}\text{Na}_{0.014})\text{Fe}_{0.012} \cdot \text{H}_{0.988}[\text{BSiO}_5]$; its structure is shown in Fig. 15. The incorporation of the iron atoms into the datolite structure indicates that it is related to minerals such as gadolinite and homilite.²³

Figure 15. Structure of datolite.⁷²

The structure of datolite is built up of silicon–boron–oxygen $[\text{BSiO}_5]_\infty$ layers, which consist of tetrahedra linked *via* shared vertices. A characteristic feature of these layers is that the apical vertices of the B tetrahedra occupied by the OH groups are oriented upward and downward with respect to the layer, while the silicon–oxygen tetrahedra are oriented so that their edges are parallel to the layer surface.

Hydrogen bonds were examined on the basis of the electron density maps (Fig. 16) and characterised as bifurcated bonds exhibiting the typical geometrical characteristics. Their crystal-chemical function is to link free vertices of the B tetrahedra and the oxygen atoms in the layer, thus strengthening the boron–oxygen layer.

Figure 16. The experimental deformation density distributions in the sections of datolite passing through bifurcated O(5)–H···O(4) (a) and O(5)–H···O(2) (b) hydrogen bonds, the maps are contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$.

The deformation electron density distribution in the silicon–oxygen tetrahedron corresponds to the above-described quantum-chemical concepts. The values of the maxima in the bonds vary from 0.25 to $0.40 \text{ e } \text{\AA}^{-3}$ (the average value is $0.35 \text{ e } \text{\AA}^{-3}$). The $\delta\rho$ distribution is characterised by the presence of electron-density bridges ($0.2 \text{ e } \text{\AA}^{-3}$) between the maxima corresponding to the Si–O bonds [the bridges are parallel to the edges of the tetrahedra and to the layer (Fig. 17a)] and by the absence of such bridges at

Figure 17. The experimental high-angle (*a–c*) and multipole (*d–f*) deformation density distributions in the O(1)–Si–O(4) (*a, d*), O(2)–B–O(5) (*b, e*) and B–O(2)–Si (*c, f*) sections of datolite, the maps are contoured at intervals of $0.1 \text{ e } \text{\AA}^{-3}$. The central points of the peaks are marked with asterisks.

the inclined edges. The electron density distribution in the B tetrahedron (Fig. 17*b*) is similar to that in the silicon–oxygen tetrahedron. The peak heights corresponding to the B–O bonds (on the average, $0.29 \text{ e } \text{\AA}^{-3}$) are smaller than those corresponding to the Si–O bonds. The difference in the electronegativities of the B–O and Si–O pairs is readily followed from the shifts of the $\delta\rho$ maxima, which are located approximately at the midpoints of the $R(\text{B–O})$ distances and displaced by $\sim 0.38 R(\text{Si–O})$ toward the oxygen atoms (Fig. 17*c*).

The multipole refinement of the datolite structure was performed based on the experimental data reported previously⁷² with the use of the MOLDOS96 and SALDOS97 programmes.⁴⁴ The refinement characteristics remained virtually unchanged. The calcium atoms were described by monopoles with the wave functions for the Ca^{2+} ion. The calculated static deformation electron density maps agree well with those based on the high-angle model and confirm the principal characteristic features of the electron density distribution in the mineral as well as the crystal-chemical conclusions drawn previously. Thus the static electron density maps for the silicon–oxygen and B tetrahedra have maxima ($0.5 \text{ e } \text{\AA}^{-3}$) corresponding to σ -bonds (Fig. 17*d,e*). For the silicon–oxygen tetrahedron, the electron-density bridge ($0.1 \text{ e } \text{\AA}^{-3}$) is clearly seen. The distances from the oxygen atoms to the peaks in the bonds between the bridging oxygen atoms and the silicon and boron atoms are different, *viz.*, $0.38 R(\text{Si–O})$ and $0.50 R(\text{B–O})$ (Fig. 17*f*), respectively. The bond ionicity can be estimated from the displacement of the peak from the midpoint toward the oxygen atom

$$1 - i = 100 \frac{r_i/R}{1/2},$$

where i is the ionicity, r_i is the distance from the maximum to the oxygen atom and R is the interatomic distance. For the Si tetrahedron in datolite, the ionicity and covalence calculated by this formula are 24% and 76%, respectively. Note that the static

electron density maps match better the theoretical maps than those calculated based on the high-angle model.

The charge on the silicon atom $q = +0.75 \text{ e}$, estimated in the determination of the population coefficients of valence shells, was lower than that estimated with the use of alternative modern multipole refinement procedures for the structures of silicates.⁴³ This fact is attributable to the involvement of the d -orbitals of the silicon atom in bonding and the presence of the π -component as was suggested by Cruickshank.¹¹ As a result, the electrons of the d -orbital decrease the charge on the silicon atom thus increasing its radius.

As demonstrated above (see Fig. 9*c*), the ‘force’ (tightening) function of the bridging oxygen atom is manifested in the corrugated silicon–oxygen ring in diopside. Similarly, chemical bonds in the layer in datolite are also strengthened to retain the layer as a structural unit. In the structure of datolite, layers are linked to each other only *via* bulky polyhedra (Thomson’s cubes) about calcium atoms.

For layered silicates, such as kaolinite⁷⁴ and lizardite,^{75–77} a series of quantum-chemical calculations was performed with the use of the CRYSTAL programme.⁷⁸ For kaolinite, the deformation electron density maps were calculated and the characteristics of the oxygen atoms that differ in their crystal-chemical function in the layer were obtained. It was concluded that contributions of the $2s$ - and $2p$ -orbitals of the oxygen atoms to the valence state density dominate over those of the $3s$ - and $3p$ -orbitals of the silicon atoms. The results of calculations of the electron density in the tetrahedral layer of lizardite⁷⁵ allowed conclusions to be drawn that both the $3d$ -orbitals of the silicon atoms and the d -orbitals of the oxygen atoms play a significant role in bonding. The population coefficient of the d -orbital of the silicon atom with the charge of 0.6 e was determined. The charges on the silicon and oxygen atoms calculated with account of the d -orbitals agree more closely with the most probable values than those calculated without considering these orbitals.

VI. Framework silicates

1. Coesite

The minerals α - and β -quartz^{79,80} and a high-pressure modification of SiO_2 , viz., coesite,^{81,82} belonging to framework silicates were studied by precision methods. The structure of coesite is shown in Fig. 18. In the classical crystal chemistry of silicates, considerable attention is given to the analysis of the Si—O bonds and the Si—O—Si bond angles. Histograms of angles for different structural types were reported, the typical value of the Si—O—Si bond angle was determined (140° ; the experimental values are in the range of 120 – 180°) and the correlations between the bond angles and thermal parameters of the bridging oxygen atoms were treated in the monograph.⁸ Coesite is an advantageous subject for

Figure 18. Structure of coesite.⁸¹

precision investigations because it contains crystal-chemically nonequivalent Si—O—Si groups with different geometry (viz., the geometry varies from linear with the angle of 180° to bent with angles of up to 137°).⁸¹ The chemical bonds in these groups were studied with the use of the multipole refinement based on Stewart's model. The following deformation electron density distributions were obtained: static (thermal vibrations of atoms were ignored) and dynamic (thermal vibrations were taken into account). For the Si—O—Si groups characterised by the smallest angles (142° and 137°), the electron density bridges between the maxima in the bonds were observed; these bridges were located within the bent Si—O—Si fragment (Fig. 19a,b).

A diversity of crystal-chemically different Si—O—Si groups in the structure of coesite made it possible to reveal the regularities relating the bond lengths to the bond angles in these groups. The results of precision investigations demonstrated that the linear group is characterised by the shortest Si—O distances, the electron

density symmetrically 'enveloping' the bridging oxygen atoms. The Si—O bond length increases and a bond bridge appears within the angle as this angle decreases. The transfer of the electron density and formation of a bond bridge within the Si—O—Si angle are manifested in the electron density distribution map of diopside (see Fig. 9c). In diopside, the Si—O—Si angle in the ring (132.77°) is smaller and the average bridging Si—O distance ($1.609 \text{ \AA}$) is larger than the corresponding values in beryl (167.99° and $1.633 \text{ \AA}$, respectively; see Table 2). In beryl, the electron density almost uniformly envelopes the bridging oxygen atom (see Fig. 9a).

In the dependence of $R(\text{Si—O})$ on $1/[1 - \sec(\text{Si—O—Si})]$, all points determined in calculations^{8,11} for different angles lie along a straight line which runs parallel and below the experimental straight lines constructed on the basis of the results of multipole refinement. This fact is indicative of the possible participation of the $3d$ -orbitals of the silicon atom in bonding. A comparison of the dynamic and static experimental and calculated $\delta\rho$ maps demonstrated that they are basically alike.

The structure of coesite was reinvestigated by Downs in more detail.⁸² This investigation was also performed with the use of Stewart's model (VALRAY programme) but another monopole was specified and a different number of parameters were finally refined. Maps of the experimental full electron density and of the total and deformation electrostatic potentials were calculated in addition to static maps $\delta\rho$. The radii of best separation (bonded radii) were estimated from the full electron density distributions analogously to that described in Refs 38,45. The silicon and oxygen radii were found to be 0.68 and $0.94 \text{ \AA}$, respectively. These values are close to those determined previously and differ from Shannon–Prewitt's radii⁸³ estimated for an ionic model. Analysis of the $\delta\rho$ distributions in the static maps for different Si—O—Si angles revealed (as in Ref. 81) that the density accumulated as bridges at the Si—O(2) and Si—O(5) bonds (the smaller Si—O—Si angles) and its transfer inward the angle. For the O(5) atom, which is characterised by the minimum bond angle, the maximum is also observed in the nonbonding region (Fig. 19c). The perpendicular section was not reported by Downs.⁸² However, it was suggested that the O(5) atom is sp^2 -hybridised, which invokes an additional reasoning.

The electrostatic potential maps in the vicinity of different bridging oxygen atoms are not the same. This confirms the general conclusion that long-range interactions should be taken into account in calculations of catalytic properties. These interactions affect substantially the local density and, consequently, the probability of localisation of an impurity. Using coesite as an example, let us note that dynamic models which include the monopole term of the multipole function as a subtrahend⁸¹ are close to models used in high-angle refinement. From the viewpoint

Figure 19. The experimental deformation density distributions in the Si(1)–O(5)–Si(2) section of coesite; (a) dynamic density; (b) static density,⁸¹ (c) static density (multipole refinement);⁸² the maps are contoured at intervals of $0.1 \text{ e \AA}^{-3}$.

of characteristic features of chemical bonds, dynamic models are as informative as static multipole models.

2. Danburite

A natural specimen of danburite from Japan was studied.⁸⁴ The structure of danburite $\text{CaB}_2\text{Si}_2\text{O}_8$ is shown in Fig. 20. The investigation of the tetrahedral borosilicate framework was of prime interest. The calcium atoms were described by a monopole with the wave functions for the Ca^{2+} ion. The complete and difference electron density distributions as well as their topological characteristics and the electrostatic potential were calculated and examined. Unfortunately, the complete three-dimensional and, particularly, difference maps contained numerous small split peaks and hence, their quality was poorer compared to those reported, for example, by Geisinger *et al.*⁸¹ Downs and Swope⁸⁴ noted this fact and gave preference to the multipole model because it can serve as a 'filter' for experimental results of poor quality. The main aim of the cited work was to determine the topological characteristics. For borosilicate, these characteristics were determined for the first time. However, the conclusion, which was drawn on the basis of these data according to Bader's theory, that the ionic component prevails in the bonds (closed shell interactions) in danburite (as in topaz) is inconsistent on the whole with the commonly accepted view of the predominantly covalent character of these bonds. Possibly, new investigations as well as a deeper insight into the essence and interpretation of the topology of chemical bonds in complex structures of silicates will help in explaining this disagreement.

Figure 20. Structure of danburite.⁸⁴

3. Natrolite

Natrolite $\text{Na}_2\text{Al}_2\text{Si}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$ is a framework silicate belonging to zeolites. Specimens from the Czech Republic were studied.^{85–87} The mineral was originally investigated with the use of the high-angle refinement^{85, 86} (see §) and then studied with the use of the multipole analysis procedure.⁸⁷ Zeolites are characterised by a high degree of disorder, which precludes precision investigations of these minerals. However, natrolite is characterised by the ordered distribution of the silicon and aluminium atoms in the framework as well as of the sodium atoms and water molecules within the channels. The deformation electron density distributions were calculated with the use of the CRYLSQ, FOURR and

SADIAN90 programme packages. Stuckenschmidt and co-workers⁸⁶ tested different modes of refinement and gave preference to atomic scattering curves for half-ionised atoms. All necessary corrections were applied and errors of the electron density maps were evaluated. Natrolite was described⁸⁶ as an aluminosilicate studied for the first time without considering the results of investigations reported previously.^{47, 51} However, the characteristic features of the chemical bonds under consideration as well as the conclusions made agree well with the results of other studies.^{47, 51} On the basis of the shift of the $\delta\rho$ maximum, it was established that the Al–O bond is more ionic than the Si–O bond in accordance with the electronic structures of the Al and Si atoms, and the height of this maximum is smaller (Fig. 21 *a, b*). The distances to the maxima in the bonds (M) in the tetrahedra are identified with the radii of the overlapping orbitals in the silicon–oxygen tetrahedra ($\langle\text{Si}M\rangle = 0.90 \text{ \AA}$ and $\langle\text{O}M\rangle = 0.73 \text{ \AA}$) and Al tetrahedra ($\langle\text{Al}M\rangle = 1.09 \text{ \AA}$ and $\langle\text{O}M\rangle = 0.70 \text{ \AA}$). The radii of

Figure 21. The experimental deformation density distributions in the O(1)–Si–O(1) (*a*) and Al–O(1)–Si(1) (*b*) sections (the maps are contoured at intervals of $0.1 \text{ e \AA}^{-3}$)⁸⁶ and the static deformation density distribution in the Si(1)–O(1)–Al section (*c*) (the map is contoured at intervals of $0.05 \text{ e \AA}^{-3}$)⁸⁷ in natrolite.

§ The experiment was detailed in the former study and the deformation density was examined in the latter study.

the silicon and aluminium atoms thus determined agree with the calculated maximum radii of the outer orbitals (0.904 and 1.044 Å for the 3s-orbitals of Si and Al, respectively). However, the radii for the 3p-orbitals have larger values (1.068 and 1.312 Å for Si and Al, respectively). It can be suggested that the values of the radii of overlapping hybrid orbitals are intermediate between the above values. It was concluded⁸⁶ that the maxima in the bonds are located at positions predicted for a covalent bond in tetrahedra.

The interest in studies of the electron density and electrostatic characteristics of zeolites stems from the fact that this group of silicates possesses ion-exchange properties. With the aim of relating the characteristics of natrolite to the ion-exchange properties, the multipole refinement of the structure of natrolite was carried out, the charges on the atoms were estimated and the electrostatic potential was examined.⁸⁷ General approaches and refinement procedures were detailed. All necessary corrections were applied to the experimental data (see Table 1). The multipole refinement was carried out using Hansen–Coppens's model and the MOLLY programme. The choice of the system of coordinates on atoms and the number of refinable multipole parameters were described in detail and the coefficients of radial functions were reported. The isotropic extinction, the scale factor, the positional and anisotropic thermal parameters of the atoms, the population coefficients of valence (P_v) and multipole (P_{lm}) orbitals and their contraction-expansion parameters (α and α' , respectively) were refined.

In the calculated static multipole maps (STATDENS programme), the deformation density is concentrated at more electronegative oxygen atoms (Fig. 21 c). The maxima in the Si–O and Al–O bonds are 0.25 and 0.45 e Å⁻³, respectively, although an inverse ratio, which is in better agreement with the electronic structures of the silicon and aluminium atoms, had been obtained previously. The shifts of the maxima toward the oxygen atoms correspond to the difference in the electronegativities of the oxygen and silicon atoms and of the oxygen and aluminium atoms and are consistent with a more covalent character of Si–O bond. The electrons of the silicon atoms occupy the sp^3 -bonding orbitals. Regions of localisation of the electron density of the hydrogen atoms and the lone electron pairs of the water molecules are clearly seen in the maps (see Fig. 21 c). Ghermany and co-workers⁸⁷ calculated the charges on the atoms, reported

the maps of the total potential and determined the electrostatic energy of the sodium atoms in the structure of natrolite. A comparison of the latter characteristic with an analogous value for dehydrogenated zeolite A demonstrated that the Na⁺ ion is more tightly held in the crystal structure of natrolite.

4. Phenakite

The results of studies of the electron density of phenakite Be₂SiO₄ were considered earlier¹⁰ in the section devoted to island silicates. However, investigations of the character of chemical bonds demonstrated^{33,34,88} that phenakite belongs to framework beryllosilicates (Fig. 22). In the studies^{33,34} published almost simul-

Figure 22. A fragment of the phenakite structure.

taneously, the deformation electron density distributions (Fig. 23 a,b) were calculated with the use of high-angle and multipole models. The dynamic and static maps were reported.³⁴ It was demonstrated that the Si–O and Be–O chemical bonds possess different ionicities (in accordance with the classical concepts of the electronegativities of pairs of interacting atoms). The difference in the maxima in the bonds (0.2 and 0.4 for Be–O and Si–O, respectively) and their substantial shifts toward the oxygen atom along the Be–O bond compared to the Si–O bond are clearly seen in the electron density distribution maps for the structure of phenakite (like beryl). The static density maps more closely resemble the calculated maps compared to the dynamic density maps.

The multipole refinement with the use of the α -technique allowed the determination of charges on atoms in silicates for the first time.³⁴ The deformation³³ and total electrostatic³⁴ potentials

Figure 23. The experimental deformation density distributions in the sections of phenakite passing through ...Si–O(4)–Be(1)–O(1)–Be(2)–O(3)–Si... chains; (a) according to Ref. 33; (b) according to Ref. 34; (c) the static multipole refinement based on the experimental results.³³

were determined, which made it possible to reveal the electrostatic properties of beryllium and silicon.

Recalculations for phenakite were performed with the experimental results^{33, 34} using Hansen–Coppens's model with the use of the MOLDOS96 and SALDOS97 programme packages. The potential and topological characteristics of this mineral were also calculated. The static deformation maps (Fig. 23 c) as well as the charges on the atoms agree on the whole with the bonding pattern reported previously.^{33, 34}

VII. Quantum-chemical calculations of selected framework structures

The structure of neither danburite nor natrolite was calculated by the quantum-chemical methods, while the completely dealuminated form of zeolite $\text{Si}_{48}\text{O}_{96}$, viz., mordenite $(\text{Ca}, \text{Na}_2, \text{K}_2)[\text{Al-Si}_5\text{O}_{12}]_2 \cdot 6\text{H}_2\text{O}$, was investigated by these methods.⁸⁹ The results obtained in independent studies were used as the initial data in *ab initio* calculations (CRYSTAL programme). It was found that the bond strain increases as the bond angle decreases, which agrees with the results of studies of chemical bonding in coesite and diopside (the appearance of the above-described bridges). According to the results of calculations of the valence state density, the deformation and full density maps were constructed (Fig. 24). The results of determination of the sizes of cavities (chains) along the *c* axis with the use of isosurfaces of the complete density are intriguing. The diameter of the cavities (~ 7 Å) agrees well with the experimental values. Analysis of the characteristics of the potentials with the aim of predicting the behaviour of extraframework species (guests) demonstrated that the cations are preferentially located in the vicinity of the edges of large channels rather than in their centres.

Figure 24. The deformation density distribution in the section of mordenite (calculation).⁸⁹

Quantum-chemical calculations of various frameworks were carried out for the $\text{H}_6\text{Si}_2\text{O}_7$ molecule.⁹⁰ Starting from four SiO_2 units, 23 tetrahedral framework structures characterised by different symmetry and different unit-cell dimensions were found from local energy minima. Initially, triclinic symmetry was assumed for these structures. However, only seven structures under study have this symmetry. The symmetry groups of other structures varied from monoclinic (*Pc*) to cubic (*I43d*).

Gibbs and co-workers⁹¹ carried out quantum-chemical (Hartree–Fock self-consistent field) calculations of electron densities and the topology of the electron density of the molecules of ‘polysilicic acids,’ viz., $\text{Si}^{\text{I}}\text{O}$, $\text{Si}^{\text{II}}\text{O}_2$, $\text{H}_4\text{Si}^{\text{IV}}\text{O}_4$, $\text{H}_6\text{Si}_2^{\text{IV}}\text{O}_7$, $\text{H}_8\text{Si}_3^{\text{IV}}\text{O}_{10}$, $\text{H}_{10}\text{Si}_5^{\text{IV}}\text{O}_{18}$ and $\text{H}_{12}\text{Si}_6^{\text{IV}}\text{O}_{24}$ (the coordination number of the silicon atom is designated by a Roman numeral). The effect of the bond length on the values of the maxima in the bonds as well

as the bond ionicity and atomic charges were examined. It was found that the bond ionicity increases as the coordination number of the silicon atom increases. On the contrary, the covalent character of the bond and the values of the bond maxima increase as its length decreases and the Si–O–Si angle increases. Thus the $\rho(r)$ value at the critical point in the bond as determined in topological analysis increases from $0.50 \text{ e } \text{\AA}^{-3}$ for the Si–O distance of $1.96 \text{ \AA}$ in the octahedron to 0.92 , 0.95 and $1.36 \text{ e } \text{\AA}^{-3}$ for the Si–O distances of 1.621 , 1.595 and $1.48 \text{ \AA}$, respectively, in the tetrahedron. The ionic (crystal) radius of the oxygen anion is not a constant and increases from $0.86 \text{ \AA}$ at $R(\text{Si–O}) = 1.48 \text{ \AA}$ to $1.20 \text{ \AA}$ at $R(\text{Si–O}) = 1.96 \text{ \AA}$. The atomic charge increases in accordance with an increase in the size of the ion because the atomic ‘reservoir’ and the bond ionicity increase. It was demonstrated that the bond ionicity could be estimated by determining the bonding radius of the anion from electron density maps using the Gibbs empirical formula

$$f_i(\text{XO}) = 1.0 - \exp \left\{ -\frac{1}{4} [-0.85 + 2.64r_b(\text{O})]^2 \right\},$$

where $r_b(\text{O})$ is the bonding radius. It was also concluded that weak π -bonds ($p-d$) are formed due to the involvement of the atomic $3d$ -orbital of the silicon atom the contribution of which increases as the angle decreases and the bond strain increases, as described for coesite, diopside and datolite.

Worthy of mention are also calculations of the structures of ilmenite MgSiO_3 ^{92, 93} and a high-pressure modification of stishovite.^{94, 95} The silicon atoms in these minerals occupy octahedra. Different computational methods were used, which supplemented investigations^{96, 97} on the electron density of this unusual modification of SiO_2 (stishovite) analogous to rutile.

VIII. Determination of charges on atoms in silicates

In structural chemistry, the notion of the charge on the atom is closely associated with the notion of the ionic radius and with the development of the concept of the bond ionicity. Liebau⁸ recalled that according to Pauling the ionicity of the Si–O bond was evaluated at 50%. In the work of Stewart and co-workers⁷⁹ cited in the monograph,⁸ the ionicity *i* was defined as the ratio of the residual (effective) charge to the formal charge expressed in percent. Thus if the residual charge on the silicon atom is equal to $+1$, then $i = 25\%$. Consequently, four very similar bonds are each 75% covalent.⁷⁹ The charges on the silicon and oxygen atoms can be independently determined from the data of direct precision X-ray diffraction studies or from the results of quantum-chemical calculations. The CRYSTAL programme package opens up possibilities of calculations for not only clusters but also periodical systems. Model charges on atoms can be also determined according to correlation formulas from the positions of lines in X-ray emission spectra.

For the purpose of evaluating charges in some silicates from precision X-ray diffraction data, Fujino and co-workers²⁷ proposed a procedure according to which the number of electrons was initially determined for cations within a sphere corresponding to the effective radius based on radial distributions of difference maps. Then, it was proposed to apply a procedure according to which the charge of the cation determined by the above procedure was fixed, the neutrality of the crystal was prescribed and atomic scattering factors of oxygen atoms were refined. In such a manner charges in a series of island and chain silicates were determined. For oxygen atoms, the values vary from -1.1 to -1.5 e and the charge for the silicon atom is $+1.4 \text{ e}$. For wadeite, these values were found to be higher (-1.43 and $+3.29 \text{ e}$ for oxygen and silicon, respectively).⁶⁸ The similar values (-1.8 and $+3.5 \text{ e}$, respectively) were obtained for diopside. The electron density was integrated within a sphere about the atom with the radius of the best separation found from valence density maps (with the use of

the MINEXTL programme package); however, the charges varied too sharply as the radii were changed.

The best procedure for the determination of the charges involves the multipole refinement of the population coefficient P_v simultaneously with the parameter α' , which characterises 'contraction' ($\alpha' > 1$) or 'expansion' ($\alpha' < 1$) of the atom. The values of the charges with the use of the α -technique and the VALRAY programme were calculated for the first time for phenakite.³⁴ For oxygen and silicon, these charges are, on the average, -1.01 and $+1.49$ e, respectively. Calculations for the layer in lizardite using the CRYSTAL programme gave the following charges on the silicon atom: $+2.39$ e when the d -orbitals of the silicon atom were ignored and $+1.66$ and $+1.58$ e when these orbitals were taken into account. For the structure of datolite, the values obtained from the experimental results were lower than those for other silicates:

Atom	Si	B	O(1)	O(2)	O(3)	O(4)	O(5)
Charge /e	+0.75	+0.84	-0.71	-0.66	-0.76	-0.72	-0.66

In this case, the charge on the calcium atom was taken to be equal to $+2$ (by analogy with danburite). In natrolite, the charge on the sodium atom was taken as equal to $+1$ and the charges on two independent silicon atoms were found to be $+1.84$ and $+1.65$ e, the charge on the aluminium atom was $+1.51$ e and the charges on the O(1), O(2) and O(3) atoms were -0.73 , -1.08 and -0.99 e, respectively, for the values of the α' parameter corresponding to a slight contraction of the shell of the silicon atom and expansion of the shell of the oxygen atom. Note that after the multipole refinement, the refinement of only P_v and α' was repeated, *i.e.*, the total multipole component that corresponds to the density in the bond was excluded. This procedure was not performed for danburite. As a consequence, the P_v values reported involve the multipole component and are unsuitable for the estimation of charges. For natrolite, the determined charges were compared with those calculated for α -quartz. In α -quartz, the charges on the silicon and oxygen atoms vary from $+2.4$ to $+1.6$ e and from -1.13 to -0.83 e, respectively. Calculations for topaz performed with the use of a procedure analogous to that used for natrolite gave the following effective charges:

Atom	Al	Si	O(1)	O(2)	O(3)	F
Charge /e	+1.53	+1.75	-0.76	-1.11	-1.03	-0.44

For phenakite, the charges were calculated using two experimental data sets (I and II):⁸⁸

Atom	Si	Be(1)	Be(2)	O(1)	O(2)	O(3)	O(4)
Charge (I) /e	+1.12	+1.19	+1.19	-0.87	-0.88	-0.87	-0.89
Charge (II) /e	+0.87	+1.53	+1.26	-0.90	-0.95	-0.91	-0.89

The charges obtained in the multipole refinement agree most closely with the real charges on atoms. A comparison of these values with each other as well with the results of quantum-chemical calculations demonstrated that the most typical values for the silicon and oxygen atoms are in the ranges of $+1.1$ to $+1.8$ e and of -0.7 to -1.1 e, respectively. Thus, in spite of the indefiniteness of the notion of the charge on the atom, it is applicable for semiquantitative estimations in structural chemistry. According to the new data on the charges, the Si—O bond ionicity determined with the use of equations given in Ref. 79 was $\sim 33\%$ with a correspondingly higher degree of covalence ($\sim 67\%$). Undoubtedly, this line of investigation is of interest.

IX. Conclusion

The data of precision X-ray diffraction studies allow one to take a new view of problems associated with investigations of structures and bonds in silicates and their classification. From the structural standpoint, positional and thermal parameters can be determined

with a better accuracy, isomorphous relations in silicates can be examined with the use of electron density distribution maps by determining structural positions of small amounts (less than 1 mass %) of impurities, in particular, of chromophore ions responsible for the colour of crystals, and hydrogen bonds can be reliably localised to the extent that positions of electrons of hydrogen atoms and lone electron pairs of oxygen atoms in water molecules can be revealed.

The experimental and calculated electron density distribution maps demonstrate that in the case of formation of a chemical bond in the silicon—oxygen tetrahedron as well as in the B, Al and Be tetrahedra, the electrons of these atoms occupy the sp^3 -bonding orbitals to form σ -bonds with the oxygen atoms, which corresponds to the classical concepts. In special cases, which require strengthening (strain) of the bond, in particular, in a silicon—oxygen layer, in a corrugated isolated ring of diopside or in strained bonds with a small Si—O—Si angle in the coesite framework, it was assumed that the $3d$ -orbitals of the silicon atom are involved in bonding with a contribution of the π -component to the bond. The presence of the π -component may account for the existence of electron-density 'bridges' in the silicon—oxygen tetrahedra in diopside, datolite and coesite (for the last-mentioned mineral, this fact is also confirmed by calculations).

The values of the $\delta\rho$ maxima correlate with the electronic structures of the elements. In most instances, the values of the maxima for the silicon atom vary within a rather narrow range (0.3 – 0.4 e $\text{\AA}^{-3}$) for various structures examined in different studies, which is indicative of the reliability of the results. The differences in the values may occur due to the characteristic features of the structures of compounds under study and chemical interactions in them.

The deformation density distribution maps for tetrahedra visualise the effect of the difference in the electronegativities of the elements involved in chemical bonding. In the B—O, Si—O, Al—O and Be—O series, an increase in the ionicity for these primarily covalent bonds can be quantitatively estimated. The effective radii of atoms, their effective charges (for the silicon and oxygen atoms, the most probable values are in the ranges from $+1.1$ to $+1.8$ e and from -0.7 to -1.1 e, respectively) and the Si—O bond ionicity can be quantitatively estimated from the $\rho(\mathbf{r})$ maps.

The traditional classification of silicates in accordance with the degree of condensation of anionic groups and the regularities of changes in the bond lengths and bond angles⁸ correlate with their electronic structures. Thus cations of the second coordination sphere play the major role in orthosilicates. These cations cause a change in the values of the $\delta\rho$ maxima and their shifts up to splitting. On condensation of tetrahedra, the electron density is accumulated at the bridging oxygen atoms. When all oxygen vertices are shared, the maxima in all four bonds are equal. This equality is disturbed in the case of formation of isolated tetrahedral groups, for example, rings.

Investigations of electron density distributions make it possible to consider the fundamentals of the traditional structural chemistry of silicates on the electronic level. Specifically, a particular classification of structures can be chosen taking into account the character of the electron density distribution.

Due to intensive development of computational quantum-chemical procedures in recent years, these procedures approach the accuracy of experimental methods and make it possible to perform a semiquantitative comparison of the results of two methods with the use of density maps and populations of orbitals. These combined investigations can provide most reliable data on structures of complex silicate systems on the electronic level.

Abstract. The data on compatibility and on the properties of polymer blends are generalised. The emphasis is placed on the formation of strong intermolecular interactions (dipole–dipole interaction and hydrogen bonding) between the components of blends, as well as on the chemical reactions between them. A criterion for the prediction of compatibility of polymers is described in detail. Different cases of compatibility are considered and the dependences of the glass transition temperatures on the composition of blends are analysed. The published data on the effect of strong intermolecular interactions between the blend components on the glass transition temperature are considered. The preparation of interpolymers is described whose macromolecules are composed of incompatible polymers, which leads to the so-called ‘forced compatibility.’ The bibliography includes 80 references.

I. Introduction

In the studies of polymer blends much attention is currently given to the effect of strong intermolecular and chemical interactions between the polymer blend components on their compatibility.

Investigation of compatibility of polymers is of importance from both scientific and practical points of view.^{1–3} In one of the concepts, it is proposed to analyse compatibility of polymers using the solubility parameter (the density of cohesive energy). The equation used to assess the parameter of the polymer–polymer interaction (χ) includes the solubility parameters of each polymer

$$\chi = \frac{V}{RT}(\delta_1 - \delta_2)^2, \quad (1)$$

where V is the molar volume of the rubber-like phase per repeating unit of the polymer; δ_1 and δ_2 are the solubility parameters of the polymers 1 and 2, respectively; R is the universal gas constant and T is the absolute temperature.

According to this concept, polymers are compatible if the interaction parameter is positive and its value is close to zero. Limitations of this approach have been analysed.⁴ One of the limitations is associated with the necessity to calculate and measure the solubility parameter to a high accuracy. This is impossible for polymers since this parameter is assessed indirectly using determination of intrinsic viscosity of polymer solutions in various solvents followed by construction of the dependence of the intrinsic viscosity on the solubility parameter of the solvent in which the measurements have been carried out; construction of the dependence of the degree of swelling on the solubility parameter of the solvent in which swelling occurs, *etc.* The critical value of the parameter χ , *viz.*, the upper limit of solubility, is determined from the following relationship⁵

$$\chi_c = \frac{1}{2(N_1^{-1/2} + N_2^{-1/2})^2},$$

where N_1 and N_2 are the degrees of polymerisation of the components 1 and 2, respectively. Calculations or experimental measurements of the solubility parameters should be carried out with an accuracy of $0.1 \text{ (J cm}^{-3}\text{)}^{1/2}$.

A concept of compatibility of polymers using the solubility parameter has been developed in detail.⁴ In this study, individual contributions of the components into the solubility parameter were considered and the compatibility parameter (introduced previously⁶), which is the difference between the cohesive energy densities of the components, was used.

Let us consider other approaches to the prediction of the compatibility of polymers and the properties of blends obtained.

According to the reported data,^{7–11} the solubility of polymers occurs if the following inequality holds

$$\mu < 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a}). \quad (2)$$

Here $\mu = \delta_p^2/\delta_s^2$, where δ_p is the solubility parameter of the polymer, δ_s is the solubility parameter of the solvent; the Φ value is found from the relationship

$$\Phi = \frac{4(V_s V_p)^{1/3}}{(V_s^{1/3} + V_p^{1/3})^2}, \quad (3)$$

A A Askadskii A N Nesmeyanov Institute of Organoelement Compounds of the Russian Academy of Sciences, ul. Vavilova 28, 117813 Moscow, Russian Federation. Fax (7-095) 135 50 85. Tel. (7-095) 135 93 98. E-mail: andrey@ineos.ac.ru

where V_p and V_s are the molar volumes of the polymer and the solvent, respectively, and the a value is calculated using the formula

$$a = \frac{\gamma_{sp}}{\gamma_s}, \quad (4)$$

where γ_{sp} is the interface tension and γ_s is the surface tension of the solvent. The right part of the criterion (2) is represented in the

form $2\rho\beta$, where $\rho = 1.374/2$ and $\beta = \Phi(\Phi - \sqrt{\Phi^2 - 1 + a})$.

The interface tension is defined as follows:

$$\gamma_{sp} = \gamma_s + \gamma_p - 2\Phi(\gamma_s\gamma_p)^{1/2}, \quad (5)$$

where γ_p is the surface energy of the polymer.

An attempt to analyse the compatibility of polymers using the criterion for the polymer solubility in organic solvents, *viz.*, relationship (2), has been undertaken.¹¹ Let us consider this criterion in detail.

II. Criteria for the compatibility of polymers

If a small amount of a polymer 1 is introduced into a polymer 2, the polymer 1 and the polymer 2 are considered as the 'polymer' and the 'solvent', respectively. The following cases are possible when using criterion (2).

1. Polymers 1 and 2 are incompatible. A small amount of a polymer 1 is introduced into a polymer 2 and, *v.v.*, a small amount of a polymer 2 is introduced into a polymer 1. Then the compatibility criterion has the form

$$\mu_1 = \frac{\delta_{p1}^2}{\delta_{p2}^2} > 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a_1}) = 2\rho\beta_1, \quad (6)$$

$$\mu_2 = \frac{\delta_{p2}^2}{\delta_{p1}^2} > 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a_2}) = 2\rho\beta_2, \quad (7)$$

where δ_{p1} and δ_{p2} are the solubility parameters of the polymers 1 and 2, respectively;

$$\Phi = \frac{4(V_{p1}V_{p2})^{1/3}}{(V_{p1}^{1/3} + V_{p2}^{1/3})^2}, \quad (8)$$

where V_{p1} and V_{p2} are the molar volumes of repeating units of the polymers 1 and 2, respectively;

$$a_1 = \frac{\gamma_{p1,p2}}{\gamma_{p2}}, \quad (9)$$

$$a_2 = \frac{\gamma_{p1,p2}}{\gamma_{p1}}, \quad (10)$$

$$\gamma_{p1,p2} = \gamma_{p1} + \gamma_{p2} - 2\Phi(\gamma_{p1}\gamma_{p2})^{1/2}, \quad (11)$$

where $\gamma_{p1,p2}$ is the tension at the polymer 1–polymer 2 interface and γ_{p1} and γ_{p2} are the surface energies of the polymers 1 and 2, respectively.

Since the values of the left sides of the criteria (6) and (7) are larger than those of their right sides, polymers 1 and 2 are completely incompatible.

2. If a small amounts of a polymer 1 is introduced into a polymer 2, criterion (2) indicates that the 'solubility' of the first polymer in the second polymer occurs, *i.e.*,

$$\mu_1 = \frac{\delta_{p1}^2}{\delta_{p2}^2} < 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a_1}) = 2\rho\beta_1. \quad (12)$$

However, as indicated by calculations using the criterion (2), no 'solubility' of the second polymer in the first polymer should occur

on introduction of the polymer 2 into the polymer 1, *i.e.*, inequality (7) holds.

Usually, compatibility of two polymers is judged by the glass transition temperature of a blend. A blend of completely compatible polymers is characterised by one glass transition temperature, which is intermediate between those of the initial components. Blends of completely incompatible polymers are characterised by two glass transition temperatures corresponding to those of the initial components. In the case of partial compatibility, where both components are present in each microphase in different amounts, two glass transition temperatures are also observed; however, they are shifted 'towards each other' as compared to the glass transition temperatures of the initial components.

The dependence of the glass transition temperature on composition for the case where a polymer 1 is soluble in a polymer 2, whereas the polymer 2 is insoluble in the polymer 1, is shown in Fig. 1. As can be seen, initially the introduction of the polymer 2 into the polymer 1 affects slightly the glass transition temperature of the blend (curve 1). Such a shape of the curve will be rationalised below taking a particular system as an example. It should be noted that in this case one glass transition temperature is observed for each blend, which suggests that the components are compatible. This behaviour of the blend can be associated with the microphase separation, which is characteristic of even homogeneous systems.¹²

Figure 1. Dependences of the glass transition temperature on the composition for a system that meets criteria (7) and (12) (1) and for a blend of two completely compatible polymers (2).

3. Complete compatibility of the polymers occurs, *i.e.*, the polymer 1 is soluble in the polymer 2, which is soluble in the polymer 1. In this case, the blend prepared is completely homogeneous, no microphase separation occurs and the 'property–composition' dependences are analogous to those of random copolymers. The criteria for compatibility take the form:

$$\mu_1 = \frac{\delta_{p1}^2}{\delta_{p2}^2} < 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a_1}) = 2\rho\beta_1, \quad (13)$$

$$\mu_2 = \frac{\delta_{p2}^2}{\delta_{p1}^2} < 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a_2}) = 2\rho\beta_2. \quad (14)$$

Such a blend is characterised by one glass transition temperature. A typical dependence of T_g on the blend composition is shown in Fig. 1 (curve 2).

This dependence is described by the following relationship¹⁰

$$T_g^0 = \left[\alpha_1 \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \left[\alpha_1 \frac{\left(\sum_i \Delta V_i \right)_1}{T_{g1}} + \alpha_2 \frac{\left(\sum_i \Delta V_i \right)_2}{T_{g2}} + 2\alpha_1(1 - \alpha_1) \times 0.03 \right]^{-1}, \quad (15)$$

where α_1 and α_2 are the mole fractions of the polymers 1 and 2, respectively; $\left(\sum_i \Delta V_i \right)_1$ and $\left(\sum_i \Delta V_i \right)_2$ are the van der Waals

volumes of repeating units of the polymers 1 and 2, respectively; and T_{g1} and T_{g2} are their glass transition temperatures (calculated or experimental), respectively.

Let us consider the behaviour of polymer blends taking a number of well studied polymer blends as examples. The first of them is a blend of polystyrene (PS) (polymer 1) with poly(vinyl methyl ether) (PVME) (polymer 2).

The characteristics of this blend of various compositions have been studied in detail.^{13–19} It is clearly seen in the plot of the dependence of the glass transition temperature on composition (Fig. 2, curve 2) that the T_g value changes only slightly and is virtually independent of the blend composition as the PS content increases from 0 to 0.4. This dependence is not described by Eqn (15), which can be applied to random copolymers and homogeneous polymer blends.

Figure 2. Dependence of the glass transition temperature of the PS–PVME blend on the PS content; (1) calculations using Eqn (15); (2) calculations using Eqns (22) and (23).

Let us analyse in detail the compatibility of PS and PVME using criterion (2). First, we assume that PS is the solvent for PVME. The initial characteristics [solubility parameters (δ), surface energies (γ), molar volumes (V_m), cohesive energies ($\sum_i \Delta E_i^*$), the van der Waals volumes ($\sum_i \Delta V_i$), and glass transition temperatures (T_g)] required to calculate the values of the left and right sides of the criterion (2), are listed in Table 1. By substituting the corresponding values into criterion (14) we obtain in this case

$$\mu_2 = 0.684 < 1.218 = 2\rho\beta_2.$$

The value of the left side of the criterion is smaller than that of the right side; hence PVME is readily soluble in PS.

Let us assume now that PVME is the solvent for PS. Using the compatibility criterion (6) and the data listed in Table 1, we get

$$\mu_1 = 1.462 > 1.175 = 2\rho\beta_1.$$

The value of the left side of the criterion is larger than that of its right side; hence PS is insoluble in PVME. Hence introduction of PS into PVME can lead to microphase separation and the blend

is expected to have one glass transition temperature. This is due to the fact that a portion of PVME will be compatible with PS. As a result, two microphases can be formed, one of which will contain only PVME, while the other will be a PVME–PS blend. The compatibility of the latter microphase with PVME will be improved as the PVME concentration in the second microphase is increased and at a certain PVME concentration, the second microphase will be completely compatible with PVME. Let us assess this critical PVME concentration. The relationship for calculating the solubility parameter of this polymer blend, which follows from the general relationship (see a monograph¹⁰), has the form

$$\delta^2 = \frac{\alpha \left(\sum_i \Delta E_i^* \right)_2 + 1(1-\alpha) \left(\sum_i \Delta E_i^* \right)_1}{N_A \left[\alpha \left(\sum_i \Delta V_i \right)_2 + (1-\alpha) \left(\sum_i \Delta V_i \right)_1 \right]}, \quad (16)$$

where α is the mole fraction of PVME in the blend; $\left(\sum_i \Delta E_i^* \right)_1$ and $\left(\sum_i \Delta E_i^* \right)_2$ are the molar cohesive energies of PS and PVME, respectively; N_A is the Avogadro constant; and $\left(\sum_i \Delta V_i \right)_1$ and $\left(\sum_i \Delta V_i \right)_2$ are the van der Waals volumes of repeating units of PS and PVME, respectively.

Substituting the characteristics of the polymers (see Table 1) into relationship (16), we get

$$\delta^2 = \frac{22988 - 14292\alpha}{66.13 - 29.57\alpha} 4.18 \text{ J cm}^{-3}. \quad (17)$$

It was proposed¹⁰ that the surface energy of a blend be assessed using the equation

$$\gamma = [\alpha C_1 + (1-\alpha)C_2] \left[\alpha \left(\sum_i \Delta E_i^* \right)_2 + (1-\alpha) \left(\sum_i \Delta E_i^* \right)_1 \right] \left\{ \left[\alpha \left(\sum_i \Delta V_i \right)_2 + (1-\alpha) \left(\sum_i \Delta V_i \right)_1 \right]^{2/3} [am_2 + (1-\alpha)m_1]^{1/3} \right\}^{-1}, \quad (18)$$

where C_1 and C_2 are the coefficients for PVME (nonpolar polymer) and PS, respectively, and m_1 and m_2 are the numbers of atoms in repeating units of PS and PVME, respectively.

After substituting the values of the parameters (see Table 1) into relationship (18) we obtain

$$\gamma = (0.0231\alpha + 0.1046) \frac{22988 - 14292\alpha}{(109.8 - 49.1\alpha)^{2/3} (16 - 6\alpha)^{1/3}}. \quad (19)$$

To perform further analysis, it is necessary to estimate the molar volume of the blend

$$V = \alpha \cdot 53.68 + (1-\alpha) \cdot 97.08. \quad (20)$$

To calculate the values of the left and right sides of the criterion (2), let us use expressions (17), (19) and (20). In this case, we will consider a two-component blend in which one of the components is PVME, while the second component is a PVME–PS blend (microphase) with various mole fractions of PVME (α). The results of calculations are shown in Fig. 3 in the form of two dependences of both parts of the criterion (2) on α . The intersection point of the dependences corresponds to the PVME content in the microphase at which PVME becomes compatible with this microphase. The threshold concentration (α_{cr}) is equal to 0.62. At this PVME concentration, the van der Waals volume of the blend is

$$\left(\sum_i \Delta V_i \right)_{cr} = 60.7 \times 0.62 + 109.8 \times 0.38 = 79.36 \text{ \AA}^3.$$

Table 1. Values of δ (J cm^{-3})^{1/2}, γ (mJ m^{-2}), V_m ($\text{cm}^3 \text{ mol}^{-1}$),

$\sum_i \Delta E_i^*$ (J mol^{-1}), $\sum_i \Delta V_i$ ($\text{\AA}^3$) and T_g (K) for PS, PVME and poly(2,6-dimethyl-1,4-phenylene oxide) (PPO).

Polymer	δ	γ	V_m	$\sum_i \Delta E_i^*$	$\sum_i \Delta V_i$	T_g
PS	18.6	41.6	97.1	22988	109.8	373
PVME	15.4	33.4	60.7	8696	60.7	245
PPO	18.2	44.4	103.8	23587	117.4	—

Figure 3. Dependence of μ and β on the PVME content in the micro-phase.

Now we can calculate the glass transition temperature of the blend with $\alpha_{cr} = 0.62$. To this end, let us use the following equation¹⁰

$$T_g = \left\{ \alpha_{cr} \left[\left(\sum_i \Delta V_i \right)_2 - \left(\sum_i \Delta V_i \right)_1 \right] + \left(\sum_i \Delta V_i \right)_1 \right\} \times \left\{ \alpha_{cr} \left[\left(\sum_i \Delta V_i \right)_2 / T_{g2} - \left(\sum_i \Delta V_i \right)_1 / T_{g1} \right] + \left(\sum_i \Delta V_i \right)_1 / T_{g1} + 2\alpha_{cr}(1 - \alpha_{cr}) \times 0.03 \right\}^{-1} \quad (21)$$

Substitution of the parameters for the components of the system (see Table 1) into relationship (21) gives $T_{gcr} = 284$ K. To find the dependence of T_g on composition of the blend formed by PVME and the critical blend, *i.e.*, by a blend composed of PS and PVME with $\alpha_{cr} = 0.62$, let us use Eqn (21). Finally, we get

$$T_g = \left\{ \alpha \left[\left(\sum_i \Delta V_i \right)_2 - \left(\sum_i \Delta V_i \right)_{cr} \right] + \left(\sum_i \Delta V_i \right)_{cr} \right\} \times \left\{ \alpha_{cr} \left[\left(\sum_i \Delta V_i \right)_2 / T_{g2} - \left(\sum_i \Delta V_i \right)_{cr} / T_{gcr} \right] + \left(\sum_i \Delta V_i \right)_{cr} / T_{gcr} + 2\alpha_{cr}(1 - \alpha_{cr}) \times 0.03 \right\}^{-1}, \quad (22)$$

where α is the mole fraction of PVME.

Relationship (22) is suitable only in the range $0.62 < \alpha < 1$. The dependence plotted using Eqn (22) is shown in Fig. 2 (curve 2). It can be seen that this dependence fits well the experimental points.

To describe the dependence of T_g on the composition of the PVME–PS blend on the interval $0 < \alpha < 0.62$, first of all it is necessary to calculate the van der Waals volume of the blend with $T_g = 284$ K. The corresponding formula has the form

$$\sum_i \Delta V_i = 0.62 \left(\sum_i V_i \right)_2 + 0.38 \left[0.62 \left(\sum_i \Delta V_i \right)_2 + 0.38 \left(\sum_i \Delta V_i \right)_1 \right].$$

Substituting the required values (see Table 1) into this equation, we get

$$\sum_i \Delta V_i = 67.8 \text{ \AA}^3.$$

The dependence of T_g on the composition of the blend, one of the components of which is PS and the second component is a microphase with $T_g = 248$ K, is as follows:

$$T_g = \left[\alpha' (109.8 - 67.8) + 67.8 \right] \times \left[\alpha' \left(\frac{109.8}{373} - \frac{67.8}{284} \right) + \frac{67.8}{284} + 2\alpha'(1 - \alpha') \times 0.03 \right]^{-1}, \quad (23)$$

where α' is the effective mole fraction of PS (from 1 to 0.38). Actual mole fraction of PS in the blend is found from the following equation

$$(1 - \alpha) = 0.38 + \alpha' 0.62,$$

where α is the mole fraction of PVME and $(1 - \alpha)$ is the mole fraction of PS in the combined blend.

Substituting the right part of the equality

$$\alpha' = \frac{(1 - \alpha) - 0.38}{0.62}$$

into relationship (25), one can find the dependences of T_g on the blend composition at high PS content, *i.e.*, on the interval $0 < \alpha < 0.62$ (see Fig. 2).

Thus, the solubility criterion (2) can be used to describe the dependence of the glass transition temperature of a polymer blend in which one of the components is a good solvent for the second component, but the second component is a poor solvent for the first component.

Let us consider a simpler case where two polymers are completely compatible with each other taking a well studied PS–PPO blend as an example. Let us assume that PS is the solvent for PPO. Using the solubility criterion (2) and the values of the physical characteristics of the blend components (see Table 1), we obtain: $\mu_2 = \delta_2^2 / \delta_1^2 = 0.959$; $\Phi = 1.0$; $\gamma_{1,2} = 0.0456$; $a = 0.001096$ and $2\rho\beta_2 = 1.328$ (δ_1 and δ_2 are the solubility parameters of PS and PPO, respectively). Since $\mu_2 < 2\rho\beta_2$, then, according to criterion (2), PS is a good solvent for PPO.

Let us assume now that PS is the solvent for PPO, then $\mu_1 = \delta_1^2 / \delta_2^2 = 1.043$, $\Phi = 1.0$, $\gamma_{1,2} = 0.0456$, $a = 0.00103$ and $2\rho\beta_1 = 1.33$. In this case, the value of the left side of the criterion (2) is smaller than its right side, *i.e.*, compatibility can also occur. Experiments confirm that this pair of polymers is completely compatible, therefore the dependence of the glass transition temperature on composition of the PS–PPO blend is the same as that for random copolymers [*i.e.*, it is described by relationship (21)]. The plot of this dependence is shown in Fig. 4. As can be seen, the calculated curve fits well the experimental points.

Figure 4. Dependence of the glass transition temperature of the PS–PPO blend on the content of the second component.

It should be noted that this approach used to predict compatibility of polymers has the advantage that no introduction of fitting parameters is required. In other words, to analyse compatibility of polymers using the approach considered, one needs to know only the chemical structure of the components, which makes it possible to calculate the necessary physical characteristics of the polymers.

III. The effect of strong intermolecular interaction on the compatibility of polymers

Mixing of two and more polymers can be accompanied by additional strong intermolecular interaction between their chains, e.g., by hydrogen bonding or strong dipole-dipole interactions, which does not occur between the macromolecules of individual polymers.

In studies concerned with the analysis of the compatibility of polymers and properties of the blends prepared, primary emphasis is placed on these specific interactions. The scheme below illustrates an example of such an interaction:

This interesting phenomenon is observed, e.g., in blends of poly[styrene-*co-p*-(hexafluoro-2-hydroxy-2-propyl)styrene] (STHFPS) with such polymers as a polycarbonate based on bisphenol A, poly(butyl methacrylate) and PPO.²⁵ Due to the presence of hydroxyl groups in this copolymer, hydrogen bonds between the copolymer and polycarbonate are formed, which determines substantial improvement of their compatibility. Two glass transition temperatures (which suggests incompatibility) are clearly seen in the thermograms obtained by the DSC method for PS–polycarbonate blends. The situation becomes quite different when the above copolymer is introduced into the blend instead of PS; in this case, one glass transition temperature (which suggests compatibility) is observed in the thermograms and the T_g value increases as the polycarbonate concentration increases.

This effect is also observed in a blend of STHFPS and crystalline poly(ethylene oxide) (PEO).²⁶ The degree of crystallinity of PEO in the blend changes in such a manner that the melting temperature of the blend decreases. The formation of hydrogen bonds between PEO and the copolymer was studied as a function of temperature. Hydrogen bonds dissociate as temperature increases; however, they reform on cooling. Even in the case of crystalline polymer such as PEO, hydrogen bonding between chains of polymers mixed leads to the improvement of their compatibility, the suppression of crystallisation and to the formation of a homogeneous system.

The behaviour of blends of STHFPS with such polymers as poly(vinyl acetate), poly(methyl methacrylate) (PMMA), poly(ethyl methacrylate), poly(*n*-butyl methacrylate) (PBMA), PVME, PPO, polycarbonate based on bisphenol A, poly(styrene-*co*-acrylonitrile), as well as with amorphous and crystalline esters and polyamides has been studied.²⁷ The effect of intermolecular interaction between macromolecules of the blend components on their compatibility was confirmed by measurements of the glass transition temperatures and by FT-IR spectroscopy.

Compatibility of STHFPS with a number of aliphatic polyamides such as nylon-6,12 and *N,N'*-dimethyl-nylon-6,12 was studied in detail.²⁸ Observation of one glass transition temperature for a blend was considered as the compatibility criterion. Polymers with glass transition temperatures that differ appreciably from T_g of PS and the copolymer were used. For instance, nylon-6,12 has a T_g of 46 °C, whereas its melting temperature lies in the interval 206–215 °C. To estimate the effect of crystallinity on the compatibility, nylon-6,12, *N,N'*-dimethyl-nylon-6,12 and copolymers with variable content of the latter were used. It has been shown that (i) hydrogen bonds are formed between the blend components; (ii) they dissociate on heating and restore on cooling and (iii) the introduction of a small amount of hydroxyl groups into PS improves compatibility of such incompatible polymers as

PS and polyamide. Hence, the copolymer considered can serve as a compatibiliser.

Compatibility of substituted phenol condensation resins with PMMA was studied²⁹ and it was shown that the formation of hydrogen bonds between the blend components plays an important role for the improvement of compatibility. Thermodynamic parameters (enthalpy and entropy) of hydrogen bond dissociation were determined. The strongest effect on the compatibility have such substituents as NO₂ and Cl. All blends of these phenol resins with PMMA had one glass transition temperature, which indicated that the components were compatible. Dependences of the glass transition temperature on composition of the blends considered corresponded to three different cases.

1. The glass transition temperatures of blends are higher than the averaged glass transition temperature.

2. The glass transition temperatures of blends are lower than the averaged glass transition temperature.

3. The dependence of the glass transition temperature on the composition is S-shaped.

It was suggested that the behaviour of the blend corresponding to the first and the second case be describes using the following relationship:²⁹

$$T_g = W_1 T_{g1} + W_2 T_{g2} + q W_1 W_2, \quad (24)$$

where T_{g1} and T_{g2} are the glass transition temperatures of the polymers 1 and 2, respectively; W_1 and W_2 are the weight fractions of the polymers 1 and 2, respectively; the parameter q characterises the strength of hydrogen bonding and can be interpreted as the contribution of hydrogen bonds, which can be considered as pseudocross-links.

It was found experimentally that the q values are negative and approximately equal in absolute values for NO₂ and Bu^t groups as substituents and positive for the Cl substituent. If F and Cl atoms are used as substituents, the q values are positive. (All the aforesaid is true in the case of *para*-substitution of the aromatic nucleus.) Hence, the dependences of the glass transition temperature on the composition of blends of phenol resins containing 4-*tert*-butyl or 4-nitro groups in the aromatic nucleus with PMMA correspond to the second case. For unsubstituted resins, these dependences correspond to the third case. Finally, for chlorine-substituted resins, the dependences correspond to the first case.

The S-like shape of the curve of the T_g dependence on the composition can be described by the following expression, which is more general than relationship (24)

$$T_g = \frac{W_1 T_{g1} + k W_2 T_{g2}}{W_1 + k W_2} + q W_1 W_2, \quad (25)$$

where k is a coefficient.

Relationship (25) was used to describe the dependence of the glass transition temperature on the concentration of components in blends of substituted phenol resins (see above) with poly(ethyl methacrylate) and PMMA (F and Bu^t were used as substituents in the resin) and in blends based on the unsubstituted phenol resin.³⁰ All three above-mentioned cases of changes in the glass transition temperature of the blends were established and all the parameters of Eqn (25) were found.

Hydrogen bonding of macromolecules in these polymer blends was studied by FT-IR spectroscopy,^{31,32} using the Patterson and Robard theory³³ and by construction of lower critical solution temperature (LCST) diagrams. Solubility and compatibility of poly(2-ethyl-2-oxazoline) was studied.

To assess the compatibility of poly(ethyloxazoline) with other polymers, two series of experiments were carried out. In the first series, films were studied based on blends of pairs of polymers, one of which was poly(ethyloxazoline), while in the second series the complexes were studied based on the same pairs of polymers. These complexes were prepared by mixing polymer solutions, separating the precipitate and drying it *in vacuo* to constant weight. It was established that the composition of the complex

differs from that of the initial blend, the former being determined by the ratio of polar groups responsible for the strong intermolecular interaction. The glass transition temperatures of blends of poly(ethyloxazoline) with polyacrylic acid are lower, whereas those of the complexes are higher than the additive values. The authors believe that this is due to the formation of a network of physical bonds in the complexes.

When studying the compatibility of PVME and styrene–methyl methacrylate copolymers, a critical composition of the copolymer was found³⁴ at which compatibility was observed. The PS content in such a copolymer must be ~ 60 mol. %. Phase diagrams were constructed on which the so-called ‘compatibility windows’ of these blends were determined.

In addition to the glass transition temperature, thermal stability of blends was also studied taking blends of poly(*p*-hydroxystyrene) with poly(vinylpyrrolidone) and poly(ethyloxazoline) as examples.³⁵ It was established that a small weight loss of poly(*p*-hydroxystyrene) (6%) on heating in the temperature interval 200–250 °C is due to the cross-linking reaction with the formation of ether bonds. It was mentioned that hydrogen bonds between the polymer chains affect the compatibility of the polymers.

Intermolecular complexes can be formed directly in the course of polymerisation.³⁶ For instance, they are formed upon photopolymerisation of acrylic acid in which PEO is dissolved. The glass transition temperatures of intermolecular complexes are higher not only than those of blends, but also than those of the initial components. These complexes are soluble in such solvents as dimethylformamide and dimethyl sulfoxide and swell to a certain degree in water and methanol; however, they do not swell in dioxane. A decrease in the number of groups capable of forming hydrogen bonds, *e.g.*, by copolymerising acrylic acid with methyl methacrylate, reduces the ability for complexation.

The stability to thermal oxidation also depends on the formation of hydrogen bonds between the polymer chains (*e.g.*, for blends of PVME with modified PS).³⁷ The modified PS was a copolymer of styrene and *p*-(hexafluoro-2-hydroxy-2-propyl)styrene (2.5 mol. %), *i.e.*, it contained functional groups prone to form hydrogen bonds. However, due to the presence of hydroxyl groups in the copolymer, the stability of the system to thermal oxidation was enhanced (*i.e.*, these groups ‘operated’ as antioxidants). This resulted in lengthening of the induction period of the thermal oxidation of PVME and in a decrease in the rate of the process.

The above-mentioned formation of intermolecular complexes was also observed for poly(*N,N'*-dimethylacrylamide) and a phenol–formaldehyde (PF) resin.³⁸ The complexes were precipitated from solutions in acetone, ethyl acetate and dioxane. As before, the compositions of the complexes corresponded to the molar ratios of the components. The glass transition temperatures of the complexes were higher than those of the initial components. Complexes of poly-*N,N'*-dimethylacrylamide with *p*-methoxyphenol–formaldehyde resin were also formed; their glass transition temperatures were much higher than that of each component.^{39,40}

Synthesis of interpenetrating polymer networks (IPN) based on compatible polymers, *viz.*, poly(1-hydroxy-2,6-methylphenylene) and PMMA, was reported.⁴¹ Hexamethylenetetramine and 1,3-dioxolane were used as the cross-linking agents at different temperatures. The strength of hydrogen bonding in blends and IPN was shown to be determined by the change in the cross-linking temperature and by the decrease in the concentration of the groups capable of forming hydrogen bonds. The concentrations of these groups were varied by using methyl methacrylate–styrene copolymers. It was shown by FT-IR spectroscopy that the compatibility in these blends is retained unless the intermolecular interaction due to hydrogen bonds is lower than a certain critical value.

Hydrogen bonding affects the phase behaviour of polymer blends.⁴² This study was performed with blends of poly(methyl

methacrylate-*co*-styrene) with a PF resin in which hydroxyl groups were partially methylated. Compatibility diagrams were constructed and the so-called ‘compatibility windows’ were found, *i.e.*, regions of the diagram corresponding to complete compatibility or to the microphase separation.

The compatibility of homopolymer–copolymer blends was studied.⁴³ The first pair was a blend of poly(4-hydroxystyrene) with poly(*n*-butyl acrylate-*co*-*tert*-butyl acrylate). These blends are compatible when the butyl methacrylate content in the copolymer is $\geq 64\%$. The second pair was poly(*tert*-butyl acrylate) and poly(styrene-*co*-4-hydroxystyrene). The ‘compatibility window’ for this pair was observed at a concentration of 4-hydroxystyrene in the copolymer between 28 mol. % and 66 mol. %. The glass transition temperatures of compatible blends of poly(*tert*-butyl acrylate) and poly(styrene-*co*-4-hydroxystyrene) are much lower than the additive values and, which is the most interesting, they depend only slightly on the blend composition and are approximately equal to the glass transition temperatures of the copolymers. This can be explained only by the formation of hydrogen bonds between the blend components, which was experimentally confirmed by IR spectroscopy.

The concepts of the effect of strong intermolecular interactions on the compatibility of polymers were developed by Kim, Kwei and Pearce⁴⁴ who studied hydrogen bonding in IPN prepared from a compatible polymer blend of poly(1-hydroxy-2,6-methylphenylene) and PMMA. To decrease the number of carbonyl groups, poly(methyl methacrylate-*co*-styrene) at different monomer ratios was also used. Different cross-linking agents, *e.g.*, hexamethylenetetramine and 1,3-dioxolane, were used to prepare IPN. The strength of hydrogen bonding in IPN was varied by varying the conditions of the cross-linking reaction (in particular, temperature). Hydrogen bonding in the compatible blend of two above-mentioned polymers demonstrated reversible temperature dependence. In the case of semi-IPN and IPN prepared at temperatures higher than the T_g of the blend, the number of hydrogen bonds after cooling to room temperature differed from that in the initial blend. If poly(PMMA-*co*-styrene) was used instead of PMMA (*i.e.*, the number of carbonyl groups was appreciably decreased), semi-IPN did not form a single phase. However, semi-IPN and IPN synthesised at relatively low temperatures (below T_g of the blend) were homogeneous and contained a larger number of hydrogen bonds as compared with semi-IPN and IPN synthesised at high temperatures.⁴⁵

Makhija *et al.*⁴⁶ studied poly[2,2'-(5,5'-bibenzimidazole)diyl-*m*-phenylene] (PBI). Its blends with poly(4-vinylpyridine) of various monomer ratios were characterised by one glass transition temperature, which indicated that the components were compatible, and the T_g values were higher than the additive values. As in the previous studies, the authors explained this fact by the formation of the N–H–N hydrogen bonds. This was confirmed experimentally by FT-IR spectroscopy.

Based on the aforesaid, the following practically significant conclusion can be drawn, *viz.*, the compatibility of polymers in a blend can be improved by introducing a small number of functional groups (*e.g.*, hydroxyl groups) into one of the blend components; this will lead to the formation of hydrogen bonds between the blend components. In this case, domains of different size can be formed. To reduce the size of domains, it is sufficient to introduce a certain number of hydroxyl groups. For instance, compatibility of PS with poly(*n*-butyl acrylate) is achieved by introducing 4.4 mol. % of hydroxyl groups. Relaxation times and domain size were assessed by NMR spectroscopy.^{47–52}

Complexes based on poly(4-hydroxystyrene) and poly-*N,N'*-dimethylacrylamide were studied by ¹³C CPMAS NMR spectroscopy. The size of inhomogeneous domains determined by this method was ~ 2.5 nm.⁵¹ Analogous study of inhomogeneous domains in IPN has shown that the domain size in this case is smaller (~ 2.2 nm).⁵⁰

The effect of microtacticity of PMMA on its compatibility with poly(styrene-*co*-4-hydroxystyrene) was studied by NMR

spectroscopy.⁴⁸ It turned out that syndiotactic PMMA possesses better compatibility with the above copolymer and that the blend based on both methyl methacrylates is homogeneous over a wide range of compositions. The size of inhomogeneous domains for most blends established by NMR spectroscopy was ~ 2 nm. Analogous studies of poly[(4-vinylphenyl)dimethylsilanol] (PVPDMS) and its copolymers with styrene^{49,50} also showed a strong effect of hydrogen bonding between the phenol and phosphate groups, which was confirmed by IR and ^{13}C and ^{31}P NMR spectroscopy.⁵³

Blends were studied⁵⁴ of PEO and poly(butyl methacrylate) with modified poly(butyl methacrylate) that contained groups capable of forming hydrogen bonds.^{55–60} Introduction of 4-hydroxy-4,4-bis(trifluoromethyl)butyl group even in the siloxane polymer

possessing low surface energy, makes it possible to prepare compatible blends with PEO and PBMA.

The parameter of the polymer–polymer interaction was assessed on the basis of studies of steam diffusion and solubility in blends.⁶¹ In all cases its value was negative and became more negative on introduction of hydroxyl groups into the polymer, thus indicating better compatibility. Correlations between the diffusion coefficient and the specific free volume of the polymer were found.

Functionalisation of polystyrene due to introduction of hydroxyfluoroalkyl (or hydroxyl) groups enhances its thermal stability, oxidation stability, retards combustion and improves compatibility with other polymers.⁶²

The compatibility of a number of polyamides in blends was studied.^{63–65} Huang *et al.*⁶⁴ studied the sulfonated poly(*p*-phenyleneterephthalamide)

Based on its blends with poly(vinylpyrrolidone), poly(4-vinylpyridine) and poly(vinyl alcohol) (PVA), the so-called molecular composites were prepared in which the rigid-chain sulfonated polyamide was used as reinforcing element. It was established that hydrogen bonding between the elements of the molecular composite has a strong effect on its properties. The glass transition temperatures of blends with poly(vinylpyridine) and PVA were lower than the additive values, which, according to the authors' opinion, indicates a small number of contacts between the macromolecules.

Modifications of nylon-6, *viz.*, its blends with small amount of PF resins, were studied.⁶⁵ The addition of 1.2% of PF resins results in an increase in the modulus of elasticity and in lowering of moisture absorption. In this case, spherulites of larger size are formed. Further increase in the content of PF resins in the blend does not improve its properties. It was thus concluded that the compatibility of nylon-6 with PF resins is limited (to 3% of PF resins).

The mechanism was studied⁶³ of polymer-analogous reactions of poly(trichlorobutadiene) (PTCB) with aliphatic amines, *viz.*, *tert*-butylamine, diethylamine and triethylamine, which simulate chemical processes occurring in individual fragments of polymer chains in the reaction of PTCB with branched poly(ethyleneimine).

Using FT-IR and electronic spectroscopy, it was shown that hydrogen-bonded ionic charge-transfer complexes are formed in the reaction of poly(1,1,2-trichlorobutadiene) with amines in

parallel to the substitution reactions of the chlorine atom of the allyl group by the amino group and dehydrogenation reactions. The contribution of each of these processes to the overall conversion of functional groups of the polymer depends on the nature of the amine (the degree of N-substitution) and on the type of the solvent. Primary and secondary amines are more prone to form stable hydrogen-bonded complexes with the polymer, whereas the tertiary amine causes mostly dehydrochlorination of the polymer and the formation of polyene fragments of various length. If dioxane is used as solvent, then dehydrochlorination predominates, whereas substitution and complexation predominate in chloroform.

A model in the framework of the Flory theory was developed⁶⁶ that makes it possible to describe self-association and inter-association of the molecules of the components in the case of hydrogen bonding between them. This model was experimentally tested in studies of poly(4-hydroxystyrene)–PMMA blends. These studies have been extended.⁶⁷ This model uses the equilibrium constants that are determined from the IR spectral data, so there is no need to use fitting parameters for the description of the phase properties.

In studies of compatibility of poly(vinylpyridine) and a polyethylene–PVA copolymer, this model was used to analyse the equilibrium association of hydroxyl groups present in the copolymer with the pyridine fragment.⁶⁸

Thus, to predict compatibility of polymers and to establish the reasons for the compatibility, one should pay attention not only to the properties of individual components, but also to the specific intermolecular interaction between them.

IV. The effect of hydrogen bonding and strong dipole–dipole interactions on the glass transition temperature of compatible polymer blends

If no specific intermolecular interaction occurs between cross-linked polymers, the glass transition temperature of a homogeneous blend of compatible polymers is calculated using Eqn (15) in which the glass transition temperatures of homopolymers based on the components 1 and 2 (T_{g1} and T_{g2} , respectively) appear. The T_g value of the blend can be assessed using either calculated or experimental values of T_{g1} and T_{g2} . Equation (15) can be written in another form

$$T_g^0 = \left[\alpha_1 \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \left[\alpha_1 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 + \alpha_2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2 + 2\alpha_1\alpha_2 \times 0.03 \right]^{-1}, \quad (26)$$

where a_i and b_j are constants related to the energy of the weak dispersion forces and strong intermolecular interaction (dipole–dipole interaction, hydrogen bonding), respectively.

Let us assume that the addition of polymer 2 to polymer 1 gives rise to hydrogen bonding.

Then, the term $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1$ should contain an addend (a constant) characterising the contribution of hydrogen bonds, *viz.*,

$$b_h = -140 \times 10^{-3} \text{ \AA}^3 \text{ K}^{-1},$$

since a portion of repeating units of the polymer 1 becomes bonded to the component 2 by hydrogen bonds. In this case we have

$$T_g = \left[\alpha_1 \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \left[\alpha_1 \left(\sum_i a_i \Delta V_i + \sum_j b_j + 2\alpha_2 b_h \right)_1 + \alpha_2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2 + 2\alpha_1 \alpha_2 \times 0.03 \right]^{-1} \quad (27)$$

This equation was derived assuming that two repeating units (one unit of the polymer 1 and one unit of the polymer 2) are bonded by hydrogen bonds. Taking into account Eqn (15) and the relationship $\alpha_1 = 1 - \alpha_2$, we obtain

$$T_g = \left[(1 - \alpha_2) \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \left[(1 - \alpha_2) \frac{\left(\sum_i \Delta V_i \right)_1}{T_{g1}} + 2(1 - \alpha_2)\alpha_2 b_h + \alpha_2 \frac{\left(\sum_i \Delta V_i \right)_2}{T_{g2}} + 2(1 - \alpha_2)\alpha_2 \times 0.03 \right]^{-1} \quad (28)$$

Let us analyse the dependence of the glass transition temperature on the blend composition, which is described by Eqns (27) and (28). Let us consider three cases.

1. The van der Waals volumes of repeating units of the polymers 1 and 2 are approximately equal

$$\left(\sum_i \Delta V_i \right)_1 \approx \left(\sum_i \Delta V_i \right)_2 \quad (29)$$

2. The van der Waals volume of the repeating unit of polymer 1 is much smaller than that of the repeating unit of the polymer 2

$$\left(\sum_i \Delta V_i \right)_1 < \left(\sum_i \Delta V_i \right)_2 \quad (30)$$

3. The van der Waals volume of the repeating unit of the polymer 1 is much larger than that of the repeating unit of the polymer 2

$$\left(\sum_i \Delta V_i \right)_1 > \left(\sum_i \Delta V_i \right)_2 \quad (31)$$

The initial values of $\left(\sum_i \Delta V_i \right)_1$, $\left(\sum_i \Delta V_i \right)_2$, T_{g1} , T_{g2} , $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1$ and $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2$ for blends corresponding to all three cases are listed in Table 2.

Table 2. Initial parameters for calculation of the glass transition temperature of a compatible blend of two homopolymers ($T_{g1} = 376$ K, $T_{g2} = 426$ K).

Curve number	$\left(\sum_i \Delta V_i \right)_1 / \text{\AA}^3$	$\left(\sum_i \Delta V_i \right)_2 / \text{\AA}^3$	I	II

2	340	115	904	260
3	440	115	1170	260
4	540	115	1436	260

Note. Here and in Table 3 the parameters $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 \times 10^3$ and $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2 \times 10^3$ are denoted as I and II, respectively; both parameters have dimensions of $\text{\AA}^3 \text{ K}^{-1}$.

The dependences of the glass transition temperature of blends on the content of the component 2 shown in Fig. 5a correspond to the first case. The blends were chosen so that $T_{g1} \approx T_{g2}$, whereas the van der Waals volumes vary over a wide range. If the van der Waals volume of a repeating unit is small, the sum $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2$ is also small. In this case the value of the b_h constant is rather large. From Eqns (27) and (28) it can be seen that the smaller the van der Waals volume, the higher the glass transition temperature of the blend and the larger the difference between T_g of the blend and that of a blend in which no additional specific interaction between components occurs [see Eqns (15) and (26), i.e., $T_g > T_{g1}^0$]. This affects the shape of the dependences of T_g on α_2 (see Fig. 5a). If the van der Waals volumes of repeating units of both components increase, the effect of additional interaction

Figure 5. Dependences of the glass transition temperatures on the content of the second component for blends of compatible polymers in which the components are bonded by hydrogen bonds. Relationship (29) (a), (30) (b) and (31) (c) holds. The values of initial parameters for constructing curves (1–4) are listed in Table 2. Curves (1'–4') correspond to the case where no additional hydrogen bonding between the components occurs.

Figure 6. Dependences of the glass transition temperature on the content of the second component for blends of compatible polymers in which dipole–dipole interaction between the components occurs. Relationship (29) (a), (30) (b) and (31) (c) holds.

decreases and the glass transition temperatures of blends are only slightly higher than the T_g values calculated using Eqns (15) and (26).

The dependences shown in Fig. 5b illustrate the second case. Here $T_g > T_g^0$. Even if no additional hydrogen bonding occurs, the T_g values are higher than those of blends calculated on the basis of the mole fractions of the components.

In the third case [see relationship (31) and Fig. 5c], the effect of additional hydrogen bonding decreases, since the total energy of dispersion interaction is appreciably higher than that of the hydrogen bonding.

A similar situation is observed when mixing of blend components gives rise to additional dipole–dipole intermolecular interaction due to the presence of polar groups in repeating units. This interaction is characterised by the b_d constant. In this case, to calculate the T_g values of the blend, one should use the b_d constant instead of b_h in Eqns (27) and (28).

If relationship (29) is valid, the effect of additional intermolecular interaction on the dependence of T_g on composition is much weaker than in the case of hydrogen bonding between the components (Fig. 6a), since $b_d < b_h$.

If inequality (30) holds, the deviation of T_g of blends from the average values is positive (Fig. 6b); however, it is not as large as in the case of hydrogen bonding. If condition (31) is met, the effect of additional intermolecular interaction is not so strong (Fig. 6c) and the T_g of blends are rather close to T_g^0 .

The curves of dependences of the glass transition temperature on the blend composition may have maxima, minima and be S-shaped (Fig. 7). This is due to the fact that one of the blend components is a copolymer containing a limited number of polar groups capable of forming hydrogen bonds. Let us assume that the copolymer 2 whose formula is as follows

Figure 7. Dependences of the glass transition temperature on the composition of blends of compatible polymers: convex (1), S-shaped (2) and concave (3) curves.

contains a limited number of the $-[B(OH)]-$ repeating units capable of forming hydrogen bonds.

Let us denote the mole fraction of repeating units of the type $-[B(OH)]-$ by β . Let us assume that the second polymer (polymer 1) is capable of forming hydrogen bonds with the repeating units of the type $-[B(OH)]-$, contained in the copolymer 2. Taking into account the notation introduced, Eqns (27) and (28) can be written in the form

$$T_g = \left[(1 - \alpha_2) \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \quad (32)$$

$$\times \left[(1 - \alpha_2) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 + 2(1 - \alpha_2) \alpha_2 \beta b_h + \alpha_2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_2 + 2(1 - \alpha_2) \alpha_2 \times 0.03 \right]^{-1},$$

$$T_g = \left[(1 - \alpha_2) \left(\sum_i \Delta V_i \right)_1 + \alpha_2 \left(\sum_i \Delta V_i \right)_2 \right] \times \quad (33)$$

$$\times \left[(1 - \alpha_2) \frac{\left(\sum_i \Delta V_i \right)_1}{T_{g1}} + 4(1 - \alpha_2) \alpha_2 \beta b_h + \alpha_2 \frac{\left(\sum_i \Delta V_i \right)_2}{T_{g2}} + 2(1 - \alpha_2) \alpha_2 \times 0.03 \right]^{-1}.$$

Let us consider the cases where conditions (29)–(31) are met.

If the van der Waals volumes of repeating units are approximately equal, the initial parameters for calculating the glass transition temperature of the blend are $T_g = 376$ and 426 K,

$$\sum_i \Delta V_i = 110 \quad \text{and} \quad 115 \text{ \AA}^3, \quad \sum_i a_i \Delta V_i + \sum_j b_j = 293 \quad \text{and}$$

$260 \text{ \AA}^3 \times \text{K}^{-1}$ for the polymer 1 and the copolymer 2, respectively. The content of the $-[B(OH)]-$ component in the copolymer 2 was varied in calculations. The results of calculations are shown in Fig. 8a. The S-like shape of the dependences of the glass transition temperature of blends on composition is observed as β varies from 0.1 to 0.4.^{23, 26, 27, 38, 46, 54, 56}

If strong dipole–dipole interactions occur between the copolymer 2 and the polymer 1 [the condition (30) is met], the glass transition temperature is calculated using Eqns (32) and (33); however, the b_d constant is used in this case instead of b_h . The initial parameters required to calculate the dependence of T_g on the composition are the same as in the former case. The results of calculations are shown in Fig. 8b. It should be noted that the

Figure 8. Dependence of the glass transition temperature on the content of the second component for a blend of compatible homopolymer and copolymer in the case of hydrogen bonding (*a*) and strong dipole–dipole interaction (*b*) between the blend components; β : (1) 0.1; (2) 0.2; (3) 0.3; and (4) 0.4.

S-like shape of the curves is observed only if the content of the $-\text{B}(\text{OH})-$ component in the copolymer 2 is high. In all cases, these dependences differ from those obtained without consideration of an additional dipole–dipole interaction between the blend components. Calculations of changes in glass transition temperatures due to the additional intermolecular interaction between the components show that these interactions play a significant role. The T_g values differ from the T_g^0 values. It should be emphasised that the equations used for analysing the dependences of the glass transition temperature on the blend composition contain no fitting parameter and all calculations are performed using only the data on the chemical structure of the blend components.

Let us consider particular blends of compatible polymers taking PBMA–poly(styrene-*co*-VPDMS) blends⁵⁶ as the first example.

It is required to calculate the glass transition temperature of poly(styrene–VPDMS) at different content of the second component. The results of calculations performed using Eqn (15) and experimental T_g values are listed in Table 3. To calculate the glass transition temperatures of blends of PBMA with this copolymer,

one should know the $\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{PBMA}}$ and $\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{styrene-VPDMS}}$ values, which can be determined using the following equation¹⁰

$$T_g = \frac{\sum_i \Delta V_i}{\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)}, \quad (34)$$

where $\sum_i \Delta V_i$ is the van der Waals volume of the repeating unit.

These values for copolymers of different compositions are also listed in Table 3. They were used to calculate the glass transition temperatures of a number of PBMA–poly(styrene-*co*-VPDMS)

Table 3. Composition and characteristics of PS–PVPDMS copolymers.

blends. The results of calculations for two blends are shown in Fig. 9 in the form of dependences of the glass transition temperature on the composition. These dependences for compatible blends containing poly(styrene-*co*-VPDMS-34) and poly(styrene-*co*-VPDMS-9) were obtained using Eqn (32). For each blend, the calculated values are in fairly good agreement with experimental data (see Figs 9*a,b*). In addition, let us analyse the dependence of T_g on the composition for the PBMA–poly(styrene-*co*-VPDMS-9) blend using Eqn (33) and experimental T_g values. As a result, good agreement is observed between the calculated and experimental data (Fig. 9*b*).

If the content of modified polystyrene [*i.e.*, poly(styrene-*co*-VPDMS)] in the blend is low, the glass transition temperatures of blends are lower than the additive values. As the content of this component in the blend increases, the glass transition temperatures appear to be higher than the average values. This is explained by the formation of a large number of hydrogen bonds between the components on their mixing.

Blends of PBI and poly(4-vinylpyridine) have been studied.⁴⁶ It was shown that hydrogen bonds are formed between the 4-vinylpyridine residues and the NH groups in PBI. Therefore homogeneous blends based on these polymers are formed. The dependences of experimental and calculated glass transition temperatures on blend compositions are shown in Fig. 10. Glass transition temperatures of the blends are higher than the T_g values of the initial components. The calculated curve fits well the experimental points if the mole fraction of PBI in the blends does not exceed 0.3. Deviation of the experimental points from the calculated curve at high PBI content is associated with the fact that destruction of poly(4-vinylpyridine) begins above 375 °C. It should be noted once again that calculations were carried out using the equations containing no fitting parameters.

Thus, the aforesaid makes it possible to draw the following conclusions. In the case of compatible blends of two homopolymers, the shape of the dependence of the glass transition temperature on the blend composition can be different. If the van der Waals volumes of repeating units of the homopolymers are approximately equal and no additional strong intermolecular interaction between the components occurs, the glass transition temperature is lower than the average values. If the van der Waals volume of the unit of a homopolymer 1 is substantially smaller than that of the unit of a homopolymer 2, the glass transition temperature is slightly higher than the average values (even in the absence of additional intermolecular interactions). If these interactions occur, the T_g value of the blend is always higher than the average values.

For blends of a homopolymer with a copolymer containing a limited number of polar groups that can participate in strong intermolecular interaction with the other component (dipole–dipole interaction, hydrogen bonding), the dependences of T_g on

Figure 9. Dependences of the glass transition temperature on the content of the second component for compatible poly(styrene-co-VPDMS-34)–PBMA (*a, c*) and poly(styrene-co-VPDMS-9)–PBMA (*b, d*) blends; calculations using Eqns (32) (*a, b*) and (33) (*c, d*); (1) calculations; (2) average values; and (3) experiment.

composition are *S*-shaped. The above peculiarities of changes in the characteristics of compatible blends can be described by the equations given above which contain the parameters obtained using the data on the chemical structure of the components. It is needless to say that this approach is not versatile and further investigations are needed to understand how should, *e.g.*, the effects of various specific interactions and peculiarities of the structure of blend components on their thermomechanical behaviour be taken into account.

V. Formation of chemical bonds between components of polymer blends

Processing of polymers often results in the formation of chemical bonds between the components, which improves their compatibility.⁶⁹ Let us consider a case of the so-called ‘forced mixing’ of two incompatible polymers by synthesising interpolymers.[†] The reaction is conducted in solution and repeating units of the polymers contain functional groups capable of chemical reaction

with one another. Such an approach makes it possible to prepare macromolecules composed of finished polymers whose repeating units cannot be united in the course of synthesis.

In Fig. 11, the structures of various polymers are represented schematically. The difference between interpolymers and random copolymers is obvious and needs no special explanation. The difference between interpolymers and block copolymers lies in the fact that the chemical reaction between two unlike macromolecules (blocks), resulting in the addition of one block to another one, involves functional groups within the repeating units of macromolecular chains rather than the end functional groups.

Figure 11. Different types of structures of polymers and copolymers: (a) random copolymer; (b) graft copolymer; (c) block copolymer; (d) a fragment of interpolymer; (e) a polymer network; and (f) a macromolecular interpolymer coil.

Graft copolymers and interpolymers differ not only in the structure, but also in the procedure for preparation. Grafting of chains in solution is due to the interactions of the end functional groups in repeating units of the polymers. Grafting from the gas phase on the surface of a polymeric product is carried out by polymerisation of a monomer on this surface and the product obtained has nothing to do with an interpolymer.

Additional explanation is required as to cross-linking reactions, even in the case where one polymer is cross-linked by the other polymer (*e.g.*, curing of epoxide resin with polyanhydride belongs to this type of reaction). In this case, branched products are formed in the first stage of curing due to the interaction of one

[†] Interpolymers are polymacromolecular compounds formed in a chemical reaction occurring in a solution of two polymers.^{70–78}

or several polymer (or oligomer) macromolecules with those of the curing agent, whereas in the second stage the reaction proceeds in such a way that an increase in the degree of conversion leads to an increase in the degree of cross-linking up to complete insolubility of the product.

In the synthesis of interpolymers, chemical reactions between functional groups in repeating units of unlike macromolecules occur in a different manner. The conditions of reaction in solution are chosen so that the increase in the degree of conversion is due to consumption of functional groups in the chemically bonded macromolecules rather than to the formation of cross-links. In this case, conversion of functional groups is not accompanied by an increase in the molecular weight of the system and the reaction occurs in the region of mutual penetration of unlike coils (see Fig. 11d). Such a reaction results in the formation of soluble products, *viz.*, interpolymers. It should be noted that the degree of conversion of functional groups does not exceed 10%.

Without dwelling on peculiarities of chemical reactions between two unlike polymers in dilute solutions, we should note that the degree of conversion of the same functional groups in the case of two polymers is always much lower than in the case of one polymer and a low-molecular weight substance. Chemical reaction between polymers can occur only in the region of their mutual penetration and the role of excluded volume is of particular importance in those cases where functional groups are arranged in the repeating units along the chain.

Preparation of interpolymers can be exemplified taking the reaction of PTCB with PS. It should be noted that if AlCl_3 is used as catalyst, PTCB readily reacts with the aromatic nuclei of low-molecular weight compounds, *e.g.*, with benzene and its derivatives, and the degree of conversion can be very high. In the reaction of PTCB with PS using the same catalyst, interaction with the aromatic nucleus of PS also occurs

The reaction between PTCB and PS is carried out in nitrobenzene at a low blend concentration (from 0.5 to 5 g dl^{-1}). Fractionation of the interpolymer obtained gives several fractions (A–D) that can be isolated and characterised. Fractions A and B are soluble in the same solvents as the initial polymers; however, unlike fraction A, fraction B is insoluble in carbon tetrachloride. Fraction C is soluble only in tetrachloroethane and nitrobenzene on heating. Finally, fraction D is insoluble.

It should be noted that the increase in the degree of conversion is virtually not accompanied by the increase in the molecular weight of the product, which indicates that the chemical process occurs in the region of mutual penetration of two bonded macromolecules formed in the first reaction stage. In other words, interpolymers are the products of reactions between two or several unlike macromolecules; the molecular weight of the interpolymer is approximately equal to the sum of those of the macromolecules that had reacted.

The aforesaid can be contrasted with the following. First, the molecular weight mentioned above is the apparent molecular weight rather than the true molecular weight, since the experiments have been carried out in one solvent.^{73, 74} However, the true molecular weight can only be lower than the apparent molecular weight; therefore, one cannot say that the process occurs as conventional chaotic branching resulting in a considerable increase in the molecular weight.

Second, it can be assumed that in the case of polydisperse specimens, substantial enlargement of individual macromolecules can be accompanied by a slight increase in the weight-average molecular weight. This issue requires a special consideration. Let us perform such an analysis in the general form.

The weight-average molecular weight is determined from the relationship

$$M_w^0 = \left(\sum_i n_i M_i^2 \right) \left(\sum_i n_i M_i \right)^{-1}, \quad (35)$$

where n_i is the number of macromolecules with the molecular weight M_i .

Let us assume that both reacting polymers have equal molecular weights, which can be calculated using formula (35), and the same molecular weight distributions (MWD). Different variants of chemical reactions can be considered. Let small macromolecules of different types react respectively in pairs with one another and let the same be true for medium-size and large macromolecules. Then the formula for calculating the M_w of the reaction product will have the form

$$M_w = \left[\sum_i n_i (2M_i)^2 \right] \left[\sum_i n_i (2M_i) \right]^{-1} = 2M_w^0, \quad (36)$$

i.e., the M_w value becomes doubled as compared to the initial M_w^0 value. If n macromolecules of each type react in the same way, then

$$M_w = \left[\sum_i \frac{2n_i}{n} (n_i M_i)^2 \right] \left[\sum_i \frac{2n_i}{n} (n_i M_i) \right]^{-1} = n_i M_w^0, \quad (37)$$

i.e., the weight-average molecular weight of the reaction product is equal to the number of macromolecules that had reacted multiplied by the initial molecular weight. In other words, in this case the weight-average molecular weight of the reaction product is equal to the sum of those of the initial macromolecules.

If the smallest and the largest macromolecules react in pairs (cross reaction), the formula for calculating the M_w of the product has the form

$$M_w = \frac{n_1(M_1 + M_x)^2 + n_2(M_2 + M_{x-1})^2 + \dots}{n_1(M_1 + M_x) + n_2(M_2 + M_{x-1}) + \dots}, \quad (38)$$

where M_x is the molecular weight of the final fraction x .

The dependence of the molecular weight of a fraction on its number can be linear: $M_i = M_1 i$, where M_1 is the molecular weight of the first fraction and i is the fraction number. In this case, from Eqn (38) it follows that

$$M_w = M_1 + M_x,$$

i.e., a monodisperse specimen is obtained.

Thus, in all cases considered above, the weight-average molecular weight of the reaction product is equal to the sum of the molecular weights of the macromolecules that had reacted. Clearly, if initial specimens and reaction products are monodisperse, the M_w of the reaction product will be equal to nM_w^0 , where n is the number of the macromolecules that had reacted.

Experiments shows that the reaction product has a very broad MWD.^{73, 74}

Let us consider a case of exaggeratedly broad MWD where all fractions are present in equal proportions, *i.e.*, each fraction also contains an equal number of macromolecules ($n_1 = n_2 = \dots = n_x = n$). In this case, the weight-average molecular weight M_w^0 of the initial products is

$$M_w^0 = \left(\sum_i^x n M_i^2 \right) \left(\sum_i^x n M_i \right)^{-1} = \left(\sum_i^x M_i^2 \right) \left(\sum_i^x M_i \right)^{-1}, \quad (39)$$

where x is the number of fractions.

The number-average molecular weight M_n^0 of the initial product is

$$M_n^0 = \left(\sum_1^x n M_i \right) (nx)^{-1} = \left(\sum_1^x M_i \right) x^{-1}. \quad (40)$$

The polydispersity index of such a system is

$$\frac{M_w^0}{M_n^0} = x \left(\sum_1^x M_i^2 \right) \left(\sum_1^x M_i \right)^{-2}. \quad (41)$$

Let us assess the polydispersity of the initial system, which is characterised by a linear dependence of the molecular weight of a fraction on the fraction number, $M_i = M_1 i$. The formulae for calculating the M_w^0 and M_n^0 values will take the form

$$M_w^0 = \sum_1^x (i M_1)^2 \left(\sum_1^x i M_1 \right)^{-1} = \quad (42)$$

$$= M_1 \sum_1^x i^2 \left(\sum_1^x i \right)^{-1} = M_1 \frac{2x+3}{3},$$

$$M_n^0 = M_1 \sum_1^x \frac{i}{x} = M_1 \frac{x+1}{2}. \quad (43)$$

The polydispersity index is

$$\frac{M_w^0}{M_n^0} = \frac{x \sum_1^x i^2}{\left(\sum_1^x i \right)^2} = \frac{x \times x(x+1)(2x+1)4}{6(1+x)^2 x^2} = 1.33 \quad (x \rightarrow \infty). \quad (44)$$

Therefore, if the condition $M_i = M_1 i$ is met, the polydispersity index cannot be high and for $x \rightarrow \infty$ its value approaches 1.33. This also holds for the reaction products. The polydispersity index can be high (as is observed in the experiment) if the dependence of the molecular weights fractions on their numbers is nonlinear.

Let us consider the modes of reactions between unlike polymers to form highly polydisperse specimens, assuming that the initial specimens are monodisperse.

If the products of reaction between such polymers also are monodisperse, their weight-average molecular weights will be equal to the sum of the molecular weights of the chains that had reacted with one another. This statement requires no special proofs.

To prepare specimens with high polydispersity index, it is necessary that the molecular weights of the final fractions be markedly different. Let us consider the exaggeratedly broad MWD once again. Let us assume that the number of chemically bonded macromolecules in each fraction is $n_1 \times 10^i$, where n_1 is a constant for each fraction and i is the fraction number. Then the molecular weight of the macromolecules in the first fraction will be $M_1 n_1 \times 10$, that of the macromolecules in the second fraction will be $M_1 n_1 \times 10^2$, etc., where M_1 is the weight-average molecular weight of the initial monodisperse specimens. Then the weight-average molecular weight of specimens obtained will be

$$M_w = \left[\sum_1^x (M_1 n_1 \times 10^i)^2 \right] \left(\sum_1^x M_1 n_1 \times 10^i \right)^{-1} = \quad (45)$$

$$= \left(M_1 n_1 \sum_1^x 10^{2i} \right) \left(\sum_1^x 10^i \right)^{-1}.$$

After simplification of this formula we get (to some approximation) $M_w \approx M_1 n_1 \times 10^x$.

If $M_w^0 = M_1$, then $M_w/M_w^0 \approx n_1 \times 10^x$, i.e., this ratio is equal to the number of chemically bonded macromolecules in each fraction. Therefore, the weight-average molecular weight of the reaction products must be equal to the sum of the molecular weights of the macromolecules constituting the interpolymer.

Let the dependence of the molecular weight of a fraction on its number be of power type, which means that the number of bonded

macromolecules in each fraction is n_1^i . Then, the molecular weight of a fraction is

$$M_i = M_1 n_1^i,$$

and the weight-average molecular weight is

$$M_w = \left[\sum_1^x (n_1^i M_1)^2 \right] \left(\sum_1^x n_1^i M_1 \right)^{-1} = \left(M_1 \sum_1^x n_1^{2i} \right) \left(\sum_1^x n_1^i \right)^{-1}. \quad (46)$$

After simplification of this equation we get (to a certain approximation)

$$M_w = M_1 n^x,$$

i.e., in this case the weight-average molecular weight of the reaction product is also equal to that of the initial specimen M_1 multiplied by the number of macromolecules in each fraction.

Let us assume now that the initial specimens of two polymers are polydisperse. The weight-average molecular weight of a blend of such macromolecules is calculated using relationship (35). A polydisperse reaction product can be prepared using different procedures. One of them was considered above, viz., small macromolecules should react in pairs with one another and large macromolecules should react in pairs with large macromolecules. In this case the weight-average molecular weight of the reaction products formed is higher than that of the initial specimens. The ratio of these weights is equal to the number of macromolecules which react with one another and bind to form the interpolymer.

Let us consider an exaggerated case where all large macromolecules in the fraction x , as well as all other macromolecules in other fractions, react with one another. As a result, only two giant macromolecules are formed. Analogous situation is also observed upon completion of the network formation. The weight-average molecular weight of such a reaction product will be

$$M_w = \left[\left(\sum_1^{x-1} n_i M_i \right)^2 + (n_x M_x)^2 \right] \left(\sum_1^{x-1} n_i M_i + n_x M_x \right)^{-1}. \quad (47)$$

The ratio of this weight to that of the initial specimens, M_w^0 , is

$$\frac{M_w}{M_w^0} = \left[\left(\sum_1^{x-1} n_i M_i \right)^2 + (n_x M_x)^2 \right] \left(\sum_1^x n_i M_i^2 \right)^{-1}. \quad (48)$$

For an exaggeratedly broad MWD, $n_1 = n_2 = \dots = n_x = n$. After several transformations, we get

$$\frac{M_w}{M_w^0} = n \left[\left(\sum_1^{x-1} M_i \right)^2 + M_x^2 \right] \left(\sum_1^x M_i^2 \right)^{-1}. \quad (49)$$

Let us assume that $M_i = M_1 \times 10^i$, where i is the fraction number. Then

$$\frac{M_w}{M_w^0} = n \left[\left(\sum_1^{x-1} 10^i \right)^2 + 10^{2x} \right] \left(\sum_1^x 10^{2i} \right)^{-1} \approx n, \quad (50)$$

i.e., in this case the ratio of the weight-average molecular weight to that of the initial specimens is also equal to the number of macromolecules that are chemically bound to one another.

Thus, in both cases of (i) initially monodisperse and exaggeratedly polydisperse specimens and (ii) monodisperse and exaggeratedly polydisperse reaction products, the ratio of the weight-average molecular weights of the reaction products to those of the initial specimens is equal to the number of macromolecules in the interpolymer.

In studies of fractions A and B of interpolymers by dynamic mechanical analysis⁷⁵ it was shown that the formation of chemical bonds between the macromolecules decreases the mobility of each macromolecule. In the plot of temperature dependence of the loss factor $\tan \delta$ the peaks or their 'shoulders', characteristic of PTCB and PS, are shifted toward higher temperatures as compared to those of the mechanical mixture. The interpolymer is characterised by a large storage modulus E' and a higher glass transition

temperature as compared to that of each of the polymers and of their mechanical mixture.

Studies of thermomechanical properties of interpolymers⁷⁶ have shown that their glass transition temperatures increase from 58 to 100 °C as the polymer blend is converted into the polymer A and then into the polymer B. This effect is analogous to that observed at the formation of a ladder polymer the glass transition temperature of which is higher than that of the strands that form the ladder. The T_g value decreases to 30 °C in the later reaction stages, *i.e.*, as the polymer B is converted into the polymer C and then into the polymer D. In the case of formation of conventional polymer networks, the T_g value monotonically increases as the number of cross-links increases.

Blends of PTCB with PS form transparent solutions up to a concentration of 10%; however, in studies of these blends by electron microscopy it was found⁷⁵ that phase separation of blend components occurs even in dilute solution. The interpolymer solution is also transparent; however, unlike the polymer blend, no indications of phase separation are observed in this case. Uniformly distributed large spherical particles are clearly seen when analysing the interpolymer using electron microscopy.

Interpolymer films are transparent and display no indications of phase separation, whereas films of PTCB–PS blends are turbid, with distinct phase separation. However, indications of microphase separation were found in the studies of interpolymer films by physical methods.⁷⁵ Two separated peaks characteristic of PTCB and PS and shifted toward higher temperatures are observed in the plot of the temperature dependence of the loss factor $\tan \delta$ of the interpolymer. Two maxima characteristic of PS are also seen in the X-ray diffraction patterns of interpolymers isolated in the initial reaction stages; however, their intensities decrease as the extent of reaction increases. In the latest stage (polymer D), the maximum completely disappears.⁷⁶ Most likely, microaggregation of PS and PTCB fragments occurs on solution casting; however, the size of domains built of unlike fragments is small and therefore the films retain transparency.

It was also shown⁷⁹ that poly(vinyl chloride) (PVC) also can enter into the Friedel–Crafts reaction with PS; however, it is less reactive than PTCB. From the data in Tables 4 and 5 it can be seen that the mechanical properties of films and moulded blocks of interpolymers based on PVC (and PTCB) with PS depend largely on their composition. The characteristics of mechanical properties of interpolymers are intermediate between those of the initial polymers and in some instances even surpass them. Particularly large is the increase in the impact strength of PVC–PS interpolymers in the range of compositions close to the equimolar composition. The strength of interpolymers is much higher than that of mechanical mixtures of the initial polymers of the same composition (Table 6).

Table 4. Tensile strength (σ_t) and percentage elongation at rupture (ε) of films of interpolymers based on PTCB and PS.

Parameter	PTCB:PS (mol. %)					
	100:0	75:25	50:50	34:66	10:90	0:100

Table 6. Mechanical properties of interpolymers of equimolar composition.

Initial polymers	Characteristic	Polymer blend	Interpolymer
PTCB + PS	σ_t /MPa	10.8	32.0
PVC + PS	γ /kJ m ⁻²	1.2	3.0
	σ_b /MPa	6.7	30

Chemical reaction between two unlike macromolecules in solution was theoretically analysed using the Monte Carlo dynamic simulation.⁷⁴ The major conclusion drawn on the basis of results of the computer experiment is that the reaction between unlike macromolecules occurs by a mechanism of disordered formation of chemical bonds between the macromolecules of the ‘coil-in-coil’ type. The reacting macromolecules are ‘drawn into’ each other (the distance between their centres of gravity is shortened), and the reaction proceeds inside the region of interpenetration.

In actual experiments, changes in the number of chemical bonds between macromolecules were monitored using a specially developed precise refractometric method.⁸⁰ In the first stage, a very small number of chemical bonds between the macromolecules is formed; however, most of the macromolecules become bonded in pairs. In the second stage, the reaction proceeds in the macromolecular coils formed in the first stage and consists in an increase in the number of chemical bonds between macromolecules already bonded, *i.e.*, it is an intramolecular reaction of the first kind. Acceleration of this reaction compared to the interchain reaction is due to the appreciably lower activation energy, which is equal to 96.6 and 37.4 kJ mol⁻¹ in the first and in the second stage, respectively.

Thus, preparation of interpolymers is an efficient method for the preparation of compatible polymers from initially incompatible ones. Such a compatibility can be called ‘forced compatibility’. Interpolymers should be considered as individual class of polymers which possess the same and even improved properties compared with those of the initial polymers.

VI. Conclusion

The results of numerous studies show that there are several methods for the improvement of compatibility of polymers.

First, it is selection of polymer pairs or modification of polymers. These are performed to give rise to strong intermolecular interaction (*e.g.*, hydrogen bonding) between unlike polymer chains. This issue was analysed in detail above.

Second, it is conducting of chemical reactions between blend components that result in the formation of interpolymers.

Third, it is introduction of compatibilisers into the system. Compatibilisers are low-molecular weight and high-molecular weight compounds whose molecules contain functional groups capable of strengthening specific intermolecular interactions between the chains. Copolymers can be used as compatibilisers.

Analysis of compatibility of polymers showed that the dependences of the glass transition temperature of blends on the composition vary in shape and can be described by relationships that require no fitting parameters; only the chemical structure of the components needs to be known to perform such an analysis. It is needless to say that this approach does not cover all possible cases of compatibility of polymers. Further investigations, including those in the framework of the approach considered, are required in order to take into account all peculiarities of the chemical structure of polymers that strongly affect their compatibility and properties.

VI. Conclusion	340

Abstract. Chemical approaches to the study of the chromatin structure and certain aspects of its functioning are reviewed. The main attention is given primarily to those based on the method of 'zero-length cross-linking' aimed at the investigation of the structure of histone complexes within nucleosomes and of the interactions of histones and other proteins with chromosomal DNA. The changes in the nucleosome structure during chromatin transcription are discussed. Recent data on the chemical modification of DNA and several chromatin proteins with reactive oligonucleotide derivatives are considered and analysed. The bibliography includes 89 references.

I. Introduction

Chromatin is one of the most complex supramolecular structures of eukaryotic cells which is responsible for the storage, multiplication, repair and expression of genetic information.¹ Chromatin comprises a great number of constituents and its structure manifests high dynamism associated with dramatic changes both during the cell cycle and as cell responses to incoming (mitogenic, *etc.*) signals. The eukaryotic nucleus is made up of several molecules of double-stranded DNA distributed between individual chromosomes. The human haploid genome consists of 3×10^9 base pairs (b.p.). Assuming that this DNA exists entirely in the *B* form where one loop (10 b.p.) has the length of 3.4 nm, the total length of DNA is ~ 1 m, *i.e.*, the whole set of 23 chromosome pairs measures ~ 2 m in length. This DNA is packed into a nucleus with a diameter ~ 20 μ m. Thus, the degree of compactisation must be of about five orders. In the course of its functioning (replication, transcription, repair, recombination and formation of mitotic chromosomes), DNA is subject to substantial topological rearrangements, so that the array of proteins interacting with it changes drastically.

At the molecular level, the structure and function of chromatin cannot be adequately investigated by physical methods alone. Not only the whole chromatin, even its domains are too large to allow their crystallisation for X-ray analysis, NMR studies or

calculation of the DNA structure by the molecular dynamics method. Therefore, chemical methods appear to be highly suitable for the study of chromatin structure. Affinity modification of chromatin seems to hold especially great promise in gaining information about the structural rearrangements occurring in the nucleus during its functioning. In the first place, this refers to photomodification, which allows specific modifications of definite sites of chromatin over a very short time. The latter circumstance opens up new possibilities for the investigation of events that take place during the functioning of chromatin components.

Chromatin represents a nucleoprotein complex of DNA with nuclear proteins, *viz.*, with basic proteins (histones) and nonhistone proteins including the most well-studied HMG proteins which are considered in this review. It should be noted that during its functioning the nucleoprotein complex interacts with a large set of proteins involved in matrix synthesis, with nuclear matrix proteins (the structure of the nucleus which remains intact after its dissociation from the central nucleoprotein), *etc.* These compounds may be regarded as chromatin-associated proteins.¹

The first level of chromatin organisation is the nucleosomal fibril with a diameter of ~ 10 nm. It represents a DNA chain wound with definite periodicity around a complex made up of four histone pairs (an octamer) designated as H2A, H2B, H3 and H4. These discrete repeat units are obtained by mild treatment of nuclei or isolated chromatin with micrococcal nuclease. A complete nucleosome contains DNA of up to 200 b.p. in length. The core particle contains DNA of 145–146 b.p. in length, which forms 1.75 turns of the left superhelix around the histone octamer. The rest of the nucleosome is regarded as a linker. The structure of the core nucleosome has been solved by X-ray analysis with a 7 Å resolution.² The linker region of DNA of a variable length is complexed with histone H1. This histone seems to play an important role in the formation of the next level of the structural organisation of chromatin, *viz.*, the packing of the nucleosomal chain into a solenoid (a fibril which contains six nucleosomes per turn and has a diameter of 30 nm). In addition to histone H1, chromatin of avian, reptilian, amphibian and fish erythrocytes also contains linker histone H5. After removal of all nuclear histones with a concentrated sodium chloride solution containing detergents, DNA remains bound with the nuclear matrix and forms supercoiled loops.³ It was concluded from these data that DNA is attached to the protein backbone of the nucleus (the nuclear matrix) at definite sites. Electron microscopic studies revealed that after treatment of metaphase chromosomes with 2 M NaCl or an ionic detergent DNA forms loop-shaped domains fixed on the proteins of the chromosome backbone ('scaffold').⁴

Thus, a fibril with a diameter of 30 nm forms domains appearing as 18 radial loops (each of them has an average length of 60 000 b.p.) that are fixed on the nuclear matrix. These densely stacked rosettes form the next organisational level, *viz.*, the chromatid (Fig. 1).⁵

Figure 1. Various levels of chromatin organisation.⁵

The chemical approaches to the study of nucleosome structure were used to solve three main problems, *viz.*, to establish the structure of histone complexes, to identify the sites of DNA interaction with histones and to study the rearrangements in chromatin resulting from the transition of genes into an active or inactive state.

II. Study of interhistone interactions in chromatin

The relative arrangement of histones in the octamer was studied using cross-linking with bifunctional reagents. Such bifunctional reagent as dimethyl suberimidate, which has a large 'radius of action' (10–20 Å), cross-links practically all histone pairs within

the nucleosome. This finding corroborates the theory according to which the histone octamer is the basic structural element of the nucleosome.^{6–8} The use of dimethyl suberimidate has made it possible to establish the following interactions: Lys74(H2A)–Lys24 and Lys27(H2B), Lys85(H2B)–Lys115(H3) and Lys77(H4), Lys85(H2B)–Lys91(H4).^{9–11} However, the radius of action of this lysine-specific reagent was too large to allow one to obtain information about the relative arrangement of histones in the core. Experiments with chemical (tetranitromethane and formaldehyde) and UV-induced cross-linking of nucleosomes gave more extensive information.^{9,12–14} The strongest contacts were established between histone pairs H2A–H2B, H2B–H4 and H3–H3. UV irradiation of nucleosomes has made it possible to detect the interaction of histone H2A (Pro26) with histone H2B (Tyr37, Tyr40, Tyr42).¹⁵ Histones H4 and H2B are cross-linked with tetranitromethane and formaldehyde as well as upon UV irradiation. The strongest contacts are localised in the C-terminal fragment of histone H2B and the N-terminal fragment of histone H4. It was thus concluded that histone H2B has two domains which interact with other histones. One of these domains localised in the C-terminal fragment interacts with histone H4, while the other one localised in the central domain interacts with histone H2A.⁹ Analysis of a large body of experimental evidence on cross-linking of histones with bifunctional reagents of various lengths did not reveal a single case of histones H4–H4 interaction even where 'lengthy' cross-linking reagents were used. This prompts a conclusion that a crucial role in the formation of the (H3–H4)₂ tetramer is played by H3–H3 contacts. The use of carbodiimides as the cross-linking reagents has made it possible to establish the presence of H1–H2A contacts.^{16–18} Cross-linking of nucleosomal chain histones with carbodiimide has shown that the 74–106 segment of histone H1 interacted with the 58–129 segment of histone H2A. Moreover, cross-links of histone H1 to all core histones, especially to histone H3, could be obtained through the use of bifunctional reagents.^{19–22} It may thus be concluded that histones H3 and H2A are localised in the sites where DNA enters and leaves the nucleosomal core, which is consistent with the model of a nucleosome proposed by Mirzabekov *et al.*²³

III. Study of DNA interactions with histones. 'Zero-length cross-linking'

The works by Mirzabekov *et al.*^{23–31} have made a weighty contribution to the study of the fine organisation of nucleosomes by chemical methods. The approach suggested is based on methylation of DNA resulting in 7-methylguanine and 3-methyladenine derivatives. Comparison of kinetics of formation of 7-methylguanine and 3-methyladenine derivatives upon methylation of free DNA and DNA within chromatin revealed that histones have no effect on the alkylation of adenine residues from the side of the minor groove. However, the rate of methylation of guanine residues from the side of the major groove of chromatin DNA is by 15% lower in comparison with that of free DNA.^{27–29} Determination of the length of DNA fragments in chromatin obtained by cleavage of the modified molecule at the sites of methylation revealed that histones do not protect from methylation rather extended regions of DNA in the nucleosomal chains. It was therefore concluded that histones shield the major groove of chromatin DNA uniformly, over its whole length by 15% but do not shield the minor groove. Similar results were obtained in experiments with the binding of antibiotics distamycin A and netropsin with the minor groove of DNA.³¹

The method used to determine DNA–protein interactions in chromatin is based on chemical cross-linking of definite monomeric units in the DNA molecule with amino acid residues of histones that directly interact with them. Such cross-linking (Scheme 1) involves: (a) labilisation of glycosidic bonds of deoxyribose residues with purine bases resulting from methylation of the latter at position 7 of guanine or at position 3 of adenine; (b)

Scheme 1

R is the fragment of DNA; R' is the fragment of a protein molecule; (a) Me_2SO_4 ; (b) pH 6.8, 45 °C; (c) formation of the Schiff base; (d) NaBH_4 or NaBH_3CN .

cleavage of the glycosidic bond at the modified residues to yield deoxyribose fragments carrying the aldehyde groups; (c) formation of covalent linkages of partially depurinated DNA with the protein (in particular, the Schiff bases with the ϵ -amino groups of lysine provided these are nearby) followed by cleavage of the polynucleotide chain at the site of formation of these derivatives through the reaction of β -elimination and (d) reduction of the histone–DNA covalent bond that formed. As the covalent bond is formed directly between the deoxyribose residue of the nucleotide and the amino acid residue of the histone without any spacer, this method was named 'zero-length cross-linking'.^{25, 30}

Methylation [step (a)] is carried out with dimethyl sulfate. Generation of a positive charge in the 7-methylguanine or 3-methyladenine fragment makes possible hydrolysis of the glycosidic bonds of DNA at the sites of modification by gentle heating at neutral pH. The deoxyribose residue that formed exists in an equilibrium between the open aldehyde and cyclic hemiacetal forms. The reaction of the aldehyde group with the neighbouring amines results in covalent addition of the DNA fragment to the histone to yield the Schiff base. The length of the cross-linked fragment is equal to the distance from its 5'-end to the cross-linking site. At low degree of DNA modification, when DNA is mostly cross-linked at only one site, the length of the cross-linked fragment indicates the position of the contact site relative to the end of nucleosomal DNA. Since the Schiff bases are rather labile, they should be stabilised by reduction with sodium borohydride or sodium cyanoborohydride to the corresponding alkylamines for further manipulations. If the reduction of the primary cross-links is carried out with NaBH_4 , the number of cross-links formed will be close to the number of histidine residues in the protein molecule interacting with DNA. Thus, this approach is sometimes referred to as histidine cross-linking. If reduction is performed with NaBH_3CN simultaneously with cross-linking, this favours the cross-linking of DNA *via* lysines. This procedure has been termed the 'lysine' protocol.³²

The next step is sizing of the DNA fragments that formed and identification of the nature of the histones cross-linked to each of these fragments. This was carried out by two-dimensional diagonal electrophoresis, which is the second principal element of the approach proposed by Mirzabekov *et al.*^{23–31} Polyacrylamide gel electrophoresis of the whole cross-linked material in the first direction was carried out under denaturing conditions in the presence of urea and sodium dodecyl sulfate (SDS). The DNA fragments cross-linked to histones are separated according to the sizes of both the DNA fragment and the protein cross-linked to them. In other words, nucleoproteins containing polynucleotide

fragments of identical lengths migrate at different rates, this being the slower the larger is the size of the cross-linked histone. After treatment of the gel with pronase, which hydrolyses completely the proteins, the DNA fragments are fractionated according to their lengths in the second (perpendicular) direction. This procedure allows one to determine the lengths of these fragments using the corresponding markers. Identical fragments that had been attached to different histones appear to be displaced relative one another depending on the retardation upon separation in the first direction. On the other hand, each set of DNA fragments of different lengths which corresponds to cross-linking with the same protein is partitioned into diagonal stripes. Such DNA fragments contain no protein and can be regarded as 'protein images'. The position of the diagonal points to the relatedness of each DNA fragment of particular size to a definite histone. In most experiments, an isotope label has been introduced into the 5'-end of DNA by a conventional procedure. It consists in enzymic phosphorylation of DNA with polynucleotide kinase, which transfers [^{32}P]phosphate from [γ - ^{32}P]ATP. The separated fragments are identified by autoradiography (for detailed description, see Ref. 33). It was found that the sites of DNA contacts with histones on each DNA strand are separated by a distance multiple of 10 nucleotides, which corresponds to the size of one turn of the double helix. This means that the histone octamer with the DNA wound around it interacts with one side of the double helix. Then, the opposite site is exposed to the action of DNase I.

The arrangement of histones on both strands of the nucleosomal core DNA established by the above-described method is shown in Fig. 2.³⁴ Each histone forms several contacts with DNA;

Figure 2. A symmetrical model of arrangement of histones on both strands of DNA within the core nucleosome particle. The numbers from 0 to 146 designate the distance (the number of nucleotide residues) from the 5'-end of DNA. Each of the two histone copies in a core particle is marked with a superscript 1 or 2. The histones are arranged along one strand of DNA in the following order: $\text{H2B}_{25,35} - \text{H4}_{55,65} - \text{H3}_{75,85} / \text{H4}_{88} - \text{H2B}_{105,115} - \text{H2A}_{118} - \text{H3}_{135,145} / \text{H2A}_{145}$.^{23, 26}

histones H3 and H4 are associated with the centre of the core particle, while histones H2A and H2B are shifted to the periphery of the nucleosomal core. The contacts between the 3'-terminal fragment of the core DNA and histones H3 have also been established. The positions of the histone dimers H2A–H2B and the histone octamer (H3–H4)₂ on the double-helical molecule of the core DNA are rather autonomous (Fig. 2). This is consistent with the leading role of such specific complexes in the nucleosome assembly.³⁵ [Presumably, nucleosomes are assembled during chromatin replication by cross-linking of the (H3–H4)₂ octamer to DNA to form a primary unstable nucleoprotein particle, to which the H2A–H2B dimer is then attached to stabilise the nucleosome].

Thus, the full pattern of interactions of each of the four histones with the DNA molecule within the nucleosomal core emerges. The main structural nucleosome components revealed by this approach are largely identical both in the isolated nucleosomes and within intact chromatin. The similarity of the primary organisation of nucleosomes isolated from different sources provides support for their conservative structure.^{24, 25, 36}

The crucial role of histone H1 in chromatin condensation and maintenance of the 30 nm fibril, which is the next hierarchic level of chromatin organisation, was demonstrated in early studies of Georgiev *et al.*³⁷ The zero-length cross-linking method allowed one to establish that DNA of chromatin from *Drosophila* embryos is bound simultaneously with histone H1 and core histones.^{38, 39} It is known that the linker histone H1/H5 has three structurally and functionally different domains, *viz.*, a central globular domain which is evolutionarily the most conservative, a relatively short N-terminal domain and a highly basic lengthy C-terminal domain (terminal domains are the most variable parts of the histone).^{40, 41} Cross-linking revealed that histone H1 interacts with the termini of the core DNA. It was found that the conservative, globular part of the H1 molecule interacts with the termini of the nucleosomal DNA and the nonstructured N- and C-terminal fragments of histone H1 interact with the external regions of the nucleosomal DNA. It was supposed that the H1 molecule serves as a bridge which binds together two neighbouring nucleosomes by folding the nucleosomal chain into a 30-nm fibril.²⁶

Many polycyclic molecules having a rigid planar structure are able to intercalate, *i.e.*, to be incorporated between two adjacent, stacked base pairs in the double helix of DNA. Intercalators, such as acridine, are bound predominantly to the linker site of DNA.⁴² A photoaffinity reagent based on acridine, *viz.*, AcrNH(CH₂)₃N(COC₆H₄N₃-p)-(CH₂)₃NHAc, where Acr is the acridine residue, was proposed for elucidation of the contacts of the linker DNA.⁴³ Irradiation of a complex of this reagent with a complete nucleosome results in photoaffinity modification, predominantly of proteins H1, H2A and H3. These data are in agreement with the results of binding of histone H1 with the linker DNA and corroborate the position of the other two histones on the periphery of the nucleosomal core DNA (see Fig. 2).

In its original version, the zero-length cross-linking method provided information only about the nature of the nucleotide residue involved in the interaction with one or another histone. However, a methodology of identification of amino acid residues involved in the cross-linking has been exemplified with the interaction of chromosomal DNA with histones H5⁴⁴ and H4.^{45, 46} To this end, the cross-linked product was treated with nucleases or with 66% HCOOH/2% diphenylamine, after which the short oligo- or di-nucleotide fragment which remained bound to the protein was labelled with ³²P using polynucleotide kinase. Identification of labelled fragments was carried out by traditional methods of peptide chemistry. It was shown that modifications in histone H5 predominantly affected the histidine residues (His25 and His62) in the globular fragment of the histone molecule and the N-terminal amino group of the threonine residue (Thr1). In histone H4, the cross-linking occurred predominantly at the His18 residue localised in the central globular domain.⁴⁶

IV. Study of functionally active chromatin

Elucidation of the mechanism of rearrangements of chromatin, which take place during its passage into a functionally active state, primarily as a result of its involvement in transcription, is of considerable importance. Identification of nucleosomes associated with regulatory and transcribed sites is carried out by the method of diagonal electrophoresis with nonlabelled DNA. Then the 'protein images' formed are hybridised with the corresponding ³²P-labelled probes. Heat shock genes of *Drosophila* cultured cells the heating of which to 37 °C triggers transcription of heat shock proteins (*hsp*), are studied in most details. This approach allows one to conduct parallel experiments with transcriptionally active and transcriptionally silent chromatin.^{32, 47–49}

The first investigations of this kind were carried out using zero-length cross-linking approach and employed both the 'histidine' cross-linking method and the 'lysine' protocol. The results of these studies were not identical, though. In the 'histidine' method, where cross-linking of DNA to histones mostly occurs in the promoter, structural and 3'-flanking sites of heat shock activated *Drosophila* genes with the central globular protein domain, transcription evokes initial reduction of the number of core histones followed by complete removal of the linker histone H1 and, ultimately, of all histones.⁴⁷ In the case of the 'lysine' protocol, cross-linking of histones affects their terminal domains, there was no significant difference in cross-linking of active and silent chromatin. It was concluded from these data that activation of transcription did not result in complete removal of histones from the transcriptionally active site of chromatin with the exception of the promoter site where histone–DNA interactions are practically absent (at least the sites in the promoter region with the length of up to 200 b.p. are free from histones). With further progress of transcription, the interactions of central globular domains of histones with DNA are weakened but the contacts of histone N- and C-terminal fragments with DNA are preserved.³² Thus, the passage from transcriptionally silent to transcriptionally active chromatin is accompanied by loosening or unfolding of the nucleosome structure, *i.e.*, significant structural rearrangements take place.

More recent studies made use of UV irradiation of whole cells for cross-linking of DNA to proteins. Hybridisation with 'protein images' was carried out with DNA probes which represent a promoter fragment of *hsp70* gene DNA, a fragment with the length of 900 b.p. within the transcribed subunit of the *hsp70* gene and a nontranscribed fragment of ribosomal DNA. It was found that interactions of histone H1 with DNA occur even under conditions of active transcription. The exception is the promoter region where DNA–histone H1 contacts are absent. At the same time, in the case of active chromatin the promoter site interacted with two additional proteins with molecular weights of 50 and 100 kDa. Probably, these proteins are the factors responsible for the regulation of transcription. The 100 kDa protein binds predominantly to the encoding strand, whereas the 50 kDa protein binds to the complementary noncoding strand.⁴⁹ It should be noted that cross-linking of the promoter to these two proteins takes place only upon activation of the heat shock gene and is absent in the inactive gene. It was shown⁵⁰ that the set of histones modified with azidoarylhisacridinylspermidine and cross-linkable to the active fraction of chromatin which is preferentially split with nucleases is different from that of the total preparation of chromatin. In the active fraction of chromatin, only histone H1 is subject to photoactive labelling, whereas histones H2A and H3 are not. This finding seems to corroborate the conclusion that DNA in the active fraction of chromatin is less tightly bound to the histone core and the active chromatin has a more loose structure.

Among nonhistone proteins of chromatin, HMG proteins with high electrophoretic mobility are studied in most details. HMG14 and HMG17 (10 000 and 9247 kDa, respectively) have been defined as proteins of transcriptionally active chromatin.⁵¹

These proteins are known to bind to nucleosomes, this binding being especially tight in the case of active chromatin. Core nucleosomes and nucleosomes containing histone H1 were isolated from chicken erythrocyte chromatin, reconstituted with HMG14/17 proteins and then the proteins were cross-linked to DNA.⁵² Analysis of the cross-linked material by two-dimensional gel electrophoresis revealed that cross-linking of HMG14/17 to nucleosomes does not influence the distribution of histones along the DNA strand either in the core particle or in the complete nucleosome. The main contact sites of these proteins with DNA are at a distance of 25 and 115 nucleotides from the 5'-end of the core particle. The contacts of the core histones H2A, H2B and H3 are grouped in the same terminal fragment of core DNA (see Fig. 2). These data are consistent with the results of cross-linking of proteins HMG14/17 and core histones to the lysine-specific bifunctional reagent, 2-iminothiolane.⁵³ The photoactivated reagent, *N*-hydroxysuccinimide 3-[(4-azidophenyl)dithio]propionate (SADP), cross-linked HMG proteins to the central fragment of histone H3.⁵⁴ The proteins isolated from cell suspensions of chicken blood were used.⁵⁴ The radioactive label was introduced into the proteins by reductive alkylation with [¹⁴C]H₂CO after which the proteins were derivatised with SADP. Acylation at lysine residues converted the individual proteins HMG14 and HMG17 into their photoactive analogues carrying the N₃C₆H₄SS(CH₂)₂C(O) fragment at amino groups of several lysine residues. UV irradiation of a complex with nucleosomes generated nitrene from the azide residue, which was cross-linked to one of the neighbouring proteins. After separation of the cross-linked proteins, the disulfide bridge can be cleaved by disulfide exchange with mercaptoethanol, which facilitates identification of histones cross-linked to HMG proteins. A more lengthy reagent, *viz.*, *N*-hydroxysuccinimide 3-[(1-(2-nitro-4-azidophenyl)-2-aminoethyl)-dithio]propionate (SNAP), preferentially cross-links HMG14/17 to histone H2A.⁵⁵ Probably, owing to differences in the geometry and size of SNAP and SADP molecules, they interact through their hydrophobic and photoreactive termini with different groups on the histone core surface where histones H2A and H3 are in close proximity to each other. These results suggest that the HMG fragment cross-linked to histone H3 is close to the Cys110 residue of histone H3 localised on the nucleosome surface. The Cys110 residue is in the open state; its conformation is characteristic of transcriptionally active chromatin.⁵⁶ This finding prompts a conclusion that cross-linking of HMG14/17 proteins to the nucleosome may strengthen this conformation.

Experiments with Ehrlich ascites cell nuclei fixed with formaldehyde and subjected to DNA–protein cross-linking were undertaken to study the distribution of histones in the *de novo* synthesised DNA strand. The latter was synthesised in the presence of 5-bromodeoxyuridine 5'-triphosphate. Thus, it contained 5-bromodeoxyuridine residues and could therefore be identified and investigated using polyclonal antibodies against 5-bromodeoxyuridine. It was shown that histones of *de novo* synthesised chromatin had the same stoichiometry as the original one. Histone H1 binds to the daughter DNA strand simultaneously with, or immediately after, the cross-linking of core histones, although the cross-linking to the *de novo* synthesised DNA is weaker in comparison with the original chromatin.⁵⁷

An important role in the cross-linking of transcription factors to nucleosomes is played by specific proteins, *viz.*, nucleoplasmin, or its yeast analogue, NAP-1 (nucleosome assembly protein). These proteins induce the formation of a ternary complex of the transcription factor (nucleoplasmin or NAP-1). The use of a chemical approach based on cross-linking of histone octamer proteins with dimethyl suberimidate confirmed the fact that the mechanism of action of these proteins consists in elimination of the H2A–H2B dimer followed by elimination of the remaining histone tetramer (H3–H4)₂. This study made use of the yeast activating factor GAL4-AH, which binds to a definite DNA sequence preceding the lacZ gene. This factor was investigated with the help of a specially designed system which included a DNA

fragment (153 b.p.) and a binding site for GAL4 separated by a distance of 35 b.p. from one of the ends of the nucleosomal core. It was found that the stimulating effect of nucleoplasmin or NAP-1 (which under normal conditions stimulate the binding of GAL4-AH to native nucleosomes) was not manifested when nucleosomes with histone octamers cross-linked with dimethylsuberimidate were used. However, after reconstitution of nucleosomes from the cross-linked H2A–H2B complex with subsequent introduction of all the other core histones, the functions of nucleoplasmin and NAP-1 were not disturbed. Thus, separate removal of the first pair of histones H2A–H2B from the remaining part is problematic.⁵⁸ According to previous reports, such removal may not be complete but rather result from significant bond loosening.

Mapping of DNA–protein contacts along definite sequences of DNA was carried out using a model of ribosomal genes. This model is very convenient for establishing the relationship between the regulation of gene activity and structural rearrangements in chromatin.^{59,60} Ribosomal RNA genes are present in *Drosophila* cells as 250 copies where they are grouped into tandem repeats in which transcription elements are separated by spacers containing repeating sequences (239 b.p.) flanked by recognition sites for AluI restrictase. Restriction enzymes (restrictases) catalyse the cleavage of DNA at tetra- or hexa-nucleotide sequences which are strictly specific for each restrictase. These repeating sequences are homologous to the promoter sites of ribosomal genes and play a prominent role in their transcription. UV-induced cross-linking and hybridisation with 'protein images' allowed one to identify two proteins (mol. masses 50 and 70 kDa) associated with the Alu-repeat.

V. Study of chromatin using reactive oligonucleotide derivatives

Studies of affinity modification of chromatin with various oligonucleotide derivatives are of interest as an approach to the investigation of the structure of this most important type of DNA–protein complexes as well as due to the necessity of elaboration of methods for targeted attack on definite genes and mRNA with complementary oligonucleotides aimed at modulating their expression and induction of directed mutagenesis. This approach was first proposed by Grineva *et al.*⁶¹ and exemplified with reactive oligonucleotide derivatives in order to direct (address) a bound reactive group to a definite site in the target nucleic acid with the help of a complementary oligonucleotide. Hence, the original name of this method is 'complementarily addressed modification'. At present, the methods based on the reactions of definite sense sites of a target nucleic acid with specific oligonucleotides, their derivatives or analogues are referred to as the antisense approach. This approach is gaining popularity as a helpful tool in molecular-biological studies and the reagents are considered as potential therapeutically valuable compounds, in the first place, antiviral and antitumour preparations which interact with genetic structures.^{62,63}

In the majority of cases, antisense oligonucleotides are used for cross-linking to single-stranded (matrix or viral) RNA. The possibility to act upon DNA by suppressing the effects of oncogens or integrated viral genomes would significantly extend the range of their therapeutic applications. Therefore, DNA presents an attractive object for application of such oligonucleotide derivatives.

In this connection, a great deal of effort is given to the design of oligonucleotides able to suppress the DNA function due to the formation of ternary complexes.⁶³ However, an alternative approach consisting in the treatment of unwound regions of DNA that exist in chromatin with oligonucleotide derivatives is also possible.

Chromatin DNA of eukaryotic cells is not a strictly double-helical structure over its whole length. In the course of cell functioning (*e.g.*, during replication or transcription), definite

sites of DNA can be temporarily unwound. The DNA of complex nuclear structures may contain single-stranded regions which can interact with oligonucleotide derivatives. Such single-stranded sites of the DNA molecule can be formed as a result of DNA interaction with specific proteins able to unwind the double helix or due to the presence of superhelical domains in DNA. The possibility of specific chemical modification of DNA within chromatin and in the intact nuclei with complementarily addressed reagents was experimentally studied at the Novosibirsk Institute of Bioorganic Chemistry of the Siberian Branch of the Russian Academy of Sciences (see below).^{64–68}

Repeating sequences, which are abundant in the eukaryote genome and represent a fundamental distinction of the genome organisation in higher eukaryotes, were selected as targets to study the interaction of oligonucleotides with chromatin DNA.⁶⁹ The human genome contains short (about 300 b.p.) repeats which alternate with unique sites and contain a site recognisable by restrictase AluI.⁷⁰ These repeats are referred to as Alu-repeats and constitute about 3% of the human genome (3×10^5 copies per genome). The left and the right halves of the Alu-repeat are characterised by a high degree of homology and are flanked with oligoadenylic regions (up to 20 b.p. in length). The dinucleotide repeat (dG-dT)_n with its complementary oligonucleotide p(dA-dC)₆ comprises about 0.5% of the eukaryotic genome. The occurrence of relatively short (up to 50 b.p.) sites of this repeat occur in the eukaryotic genome in 1 per 30 000–100 000 base pairs, on the average.^{71,72} According to numerous reports, the (dG-dT)_n repeat was detected in the sites of transition of DNA from the B- to the Z-conformation.^{73–75} Such a transition may provoke local unwinding of DNA in these sites of chromatin and thus make them accessible to complementary interaction with the corresponding oligonucleotide derivatives, *e.g.*, p(dT)₁₆, p(dA)₁₆, p(dA-dC)₆ and pd(TTCTCCTGCCTCAGCCTCTT) (which is complementary to the most conservative site of the Alu-repeat family).

In the first series of these investigations, oligonucleotide derivatives, *e.g.*, p(dT)₁₆, were used containing a reactive alkylating group, *viz.*, 4-[(N-2-chloroethyl-N-methyl)amino]benzylamine attached through a phosphamide bond to the 5'-terminal phosphate group. The experiments were carried out on chromatin isolated from rodent and human cells as well as on metaphase chromosomes and intact nuclei.

The study of a possibility of specific cross-linking of an oligothymidylate derivative, complementary to the polyA-repeats of DNA widely distributed in the eukaryotic genome, to DNA from the soluble fraction of human placenta chromatin demonstrated that the alkylating derivative modifies chromatin at room temperature.⁶⁴ Nonmodified p(dT)₁₆ strongly inhibits the modification. At the same time, the oligonucleotides which are not complementary to the polyA-repeats do not influence the modification, which points to the specificity of interaction. Preliminary treatment of chromatin with RNase A under conditions ensuring hydrolysis of polyriboadenylate sequences present in the majority of chromatin matrix RNAs does not virtually exert any influence on the degree of modification with the same reagent. Hence, it is DNA that is subjected to modification.

It was shown that reactive oligonucleotide derivatives can specifically modify DNA both within chromatin and in the most densely packaged deoxyribonucleoproteins, *viz.*, metaphase chromosomes. However, nuclear DNA was not subjected to modification under identical conditions.^{65,76}

In the case of modification of the Alu-repeat, the specificity of modification was additionally confirmed by data from restriction analysis. An oligonucleotide selected for modification was complementary to one of the most conservative sites of the Alu-repeat localised inside the 170 b.p. fragment cut out with Sau3A restrictase. After modification of human HeLa cell chromatin, DNA was isolated and cleaved with restrictase Sau3A. The resulting fragments were separated by electrophoresis in polyacrylamide

gel. Autoradiography of the gel revealed that the radioactivity imparted by the covalently attached oligonucleotide derivative was detected in the 170-b.p. fragment, whereas in control experiments where the oligonucleotide derivative had a different sequence, the radioactivity was not found.⁷⁷

It was shown that preliminary treatment of chromatin preparations with S1-nuclease, which cleaves under mild conditions single-stranded regions of DNA with preservation of the general morphology of these specimens, results in practically complete inhibition of chromatin modification with oligonucleotide derivatives.^{76,77} This indicates that the interaction of oligonucleotide derivatives with DNA occurs *via* the formation of their complementary complexes with unwound regions of chromatin DNA.

A study of the interaction of the alkylating oligothymidylate derivative with chromatin isolated from various types of cells (*e.g.*, replicating cells of regenerating rat liver and chicken erythrocyte cells in which chromatin was completely repressed both in transcription and replication) made it possible to gain insight into the nature of structural peculiarities of DNA in chromatin that are responsible for the formation of local unwound regions allowing for specific interaction with oligonucleotide derivatives.^{67,68}

Regenerating rat liver is a classical object for investigation of various processes occurring in the cell during intensive replication. The maximum replication in liver cells is observed 22–24 hours after partial hepatectomy. The nuclei isolated from intact and regenerating rat liver cells were treated with the p(dT)₁₆ alkylating derivative. The relative degrees of modification of DNA appeared to be identical in both cases. This suggests that the formation of replication forks does not cause any significant increase in the number of polydeoxyadenylate sites accessible to the complementarily addressed reagent. Similar results were obtained in the studies designed to compare the degree of modification of DNA at polydeoxyadenylate sequences in the nuclei of both non-synchronised cells and cells synchronised in the S-phase of the cell cycle where DNA synthesis occurs with the greatest intensity.

Differentiation of erythroblasts into erythrocytes is accompanied by inhibition of replication and transcription. Fully repressed (both in transcription and replication) chicken erythrocyte chromatin is modified at poly(dA) sequences with the same efficiency as does chromatin isolated from regenerating rat liver. This suggests that activation of replication and transcription does not increase the accessibility of poly(dA) sites of DNA to complementarily addressed modification.⁶⁸

It has been shown that the presence of a nuclear membrane is not an obstacle to the penetration of the oligonucleotide inside the cell. The degree of modification of DNA in both intact nuclei and the 'suspension' chromatin obtained by mechanical disintegration of the nuclear membrane are nearly identical. Therefore, it would be logical to suppose that the existence of unwound sites of DNA containing the targets is most likely determined by the level of superhelicalisation of DNA and the structural and functional characteristics of chromatin.

It is known that in contrast with suspension chromatin and intact nuclei, the soluble fraction of chromatin in a buffer containing no bivalent metal ions is largely represented by unwound nucleosome strands. The degree of modification of DNA of the 'soluble' fraction was one order of magnitude lower than that of the 'suspension' chromatin and intact nuclei.⁷⁶ This result may be due to the presence in the latter of loop-shaped structures formed by DNA fibrils fixed on the nuclear matrix (which enhances superhelicalisation of DNA) and nonhistone proteins.

Evidence for the role of superhelicalisation of DNA in addressed alkylation of chromatin can be also derived from the dependence of the relative degree of DNA modification in intact nuclei on ionic strength. An increase in NaCl concentration up to 0.15–0.2 M is accompanied by a decrease in the degree of modification of DNA.⁶⁷ In this concentration range, the activity

of endogenous topoisomerase I, which favours relaxation of the superhelical conformation of DNA, is at maximum.

The effect of changes in chromatin structure caused by removal of definite protein groups on the degree of accessibility of DNA for affinity modification was studied in experiments with deoxyribonucleoproteins DNP-0.35, DNP-0.6 and DNP-2.0 obtained from chromatin by treatment with 0.35, 0.6 and 2.0 M NaCl, respectively.

It is known that treatment of chromatin with 0.35 M NaCl yields a fraction of nonhistone proteins containing HMG-proteins. Removal of these proteins from HeLa cell chromatin decreases the relative degree of modification of poly(dA) and (dG-dT)_n sites of DNA by addressed reagents.

Treatment of chromatin with 0.6 M NaCl results in the removal of histone H1 and some nonhistone proteins. The degree of modification may increase under these conditions because the removal of histone H1, which binds to the linker sites of chromatin DNA, results in their liberation. It is these sites that are potentially more accessible to complementarily addressed modification with the chloroalkyl derivative. Treatment of chromatin with 2 M NaCl results in the removal of the majority of nonhistone proteins and of all histones. The relative degree of modification of poly(dA) and (dG-dT)_n sites of DNA decreases, but still markedly exceeds that of isolated DNA. Electron microscopy of DNP-2.0 obtained by such treatment revealed DNA fibrils as loops fixed on the nuclear matrix. Our experimental results may testify to the contribution of specific chromatin proteins preserved in the structure of chromatin after its treatment with 0.6 M NaCl but completely removed by treatment with 2 M NaCl to the appearance of sites in DNA that are accessible for modification and enriched with poly(dA)- and (dG-dT)_n-repeats.

Among alkylating oligonucleotide derivatives, that with a cholesterol residue at its 3'-end manifested the greatest efficiency for modification of DNA from intact nuclei which exceeded that of the oligonucleotide derivative devoid of cholesterol residue by an order of magnitude.⁷⁸

Later it was shown that the alkylating oligonucleotide derivatives modify not only DNA when they form specific complexes with chromatin DNA, but also definite proteins, presumably localised at the site of their interaction with the DNA 'target'.^{76, 77, 79}

Despite intensive investigations into the structure of metaphase chromosomes and interphase chromatin, the topography of chromosomal proteins is still poorly examined. Most often, specific binding of proteins to definite sequences of DNA is carried out by gel filtration or affinity chromatography on columns with immobilised DNA. However, the conditions for complex formation provided by these methods do not strictly simulate the conditions inside the cell. Moreover, they do not reflect the dependence on the DNA conformation stabilised by superhelicalisation or DNA-protein interactions. Therefore, the use of these methods for the study of dynamic changes in the protein environment of DNA sequences in chromatin and regulatory processes is limited. In this context, addressed modification may become promising in the study of protein environment of DNA sequences in the unwound regions of chromatin.

The chromatin proteins subjected to specific modification with oligonucleotide derivatives that are complementary to poly(dA)-, (dG-dT)_n- and Alu-repeats were analysed by gradient SDS electrophoresis. Protein specimens were treated with micrococcal nuclease to destroy the oligonucleotide fragment covalently attached to the protein. This fragment might change the mobility of the modified protein in electrophoresis.

It has been shown that modification with the p(dT)₁₆ alkylating derivative affects at least two major proteins in intact rat liver nuclei with average molecular weights of 19–20 and 27–28 kDa.⁷⁹ Addition of a 10-fold excess (with respect to the reagent) of nonlabelled p(dT)₁₆ results in inhibition of alkylation of these proteins. However, an excess of the oligonucleotide pd(CATGCAAACCTTCCC) having the same length but a

random nucleotide sequence does not interfere with the protein alkylation, which points to the specificity of the interaction of the reagent with the proteins. Such interaction may occur in both the complementary complexes of the oligonucleotide with the target DNA and with proteins showing affinity for oligothymidylate. Analysis of the chromatin protein components alkylated with p(dA)₁₆ and p(dT)₁₆ derivatives revealed them to be the same in both cases. These data suggest that this reaction occurs through the formation of a complementary complex between the oligonucleotide address of the reagent and the corresponding sites of the unwound chromatin DNA.

Interestingly, the protein with the molecular weight of 19–20 kDa is modified with the reagent within both intact chromatin and the DNP complex prepared by treatment of chromatin with 2 M NaCl (DNP-2.0). Hence, this protein can be related to the group of nuclear matrix proteins.⁷⁹

Alkylation of nuclei with the (dA-dC)₆ derivative yields a radically different set of modified proteins. Six proteins (or groups of proteins) are specifically modified with the p(dA-dC)₆ derivative. An oligonucleotide having the same length but a different sequence has no effect on their modification.

Treatment of HeLa cell nuclei with the p(dA-dC)₆ derivative gave a more complex set of modified proteins.⁷⁶ In addition to proteins presumably analogous to modified proteins from rat liver (19.5, 21, 25.5, 31, 33 and > 66 kDa), modification affects a number of other proteins the alkylation of which is not inhibited by an excess of the oligonucleotide. Since inhibition of modification with an excess of the oligonucleotide of the same sequence does not rule out the possibility of alkylation of proteins that are not associated with local unwinding sites but show affinity for the address oligonucleotide, cell nuclei were treated with S1-nuclease (under conditions of cleavage of single-stranded regions of chromatin DNA) to demonstrate the specificity of modification of the proteins in the complementary complex. This study showed that seven proteins presumably localised in local unwinding sites were subjected to specific modification.⁷⁶

Several researchers have demonstrated^{80–83} that natural polyamines (spermine and spermidine) induce the transition of DNA from the *B*- to the *Z*-conformation and stabilise the left-helical *Z*-conformation under physiological ionic conditions. The affinity modification of chromatin and intact eukaryotic (human and rat liver) cell nuclei with the p(dA-dC)₆ alkylating derivative at the (dG-dT)_n-repeats of DNA has been studied under physiological conditions and at high concentrations of spermine and spermidine.⁸⁴ Analysis of chromatin proteins subjected to specific modification with this oligonucleotide derivative revealed that the efficiency of modification of both DNA and the proteins increases in the presence of high concentrations of spermine and spermidine and sharply decreases after preliminary treatment of chromatin with S1-nuclease under conditions of mild hydrolysis of single-stranded regions of DNA. These data testify to the fact that the *B* → *Z* transition is a reason for the presence of unwound sites accessible for the interaction with a complementary oligonucleotide in the DNA containing the (dG-dT)_n repeating units.

Modification of HeLa cell nuclei with the p(dT)₁₆ derivative affects four proteins (19, 47, 61 and > 66 kDa). Their modification is inhibited by an excess of the nonmodified oligonucleotide and by preliminary treatment with S1-nuclease.

Treatment of cell nuclei with the alkylating derivative of pd(TTCTCCTGCCTCAGCCTCTT), which is complementary to the most conservative site of the Alu-repeat, allowed one to identify a number of proteins that are modified apparently during the formation of a complementary complex between the oligonucleotide address and the unwound regions of chromatin DNA. Data from modification with an excess of the free oligonucleotide and its inhibition upon prior treatment with S1-nuclease testify to specific modification of proteins or groups of proteins with molecular weights of 18, 22, 26, 28, 43, 68 and 93 kDa and of two proteins with molecular weights > 94 kDa.

The transition of chromatin from the interphase state to metaphase chromosomes is accompanied by significant structural rearrangements resulting in structures with the maximum level of DNA compactisation. The use of reactive oligonucleotide derivatives for modification of interphase nuclei and metaphase chromosomes clearly demonstrates that the sets of specifically modified proteins for these two chromatin states differ essentially. Thus, the 28 kDa protein is not subjected to modification within chromosomes, while proteins with molecular weights of 27, 31 and 40 kDa, which are not modified within the interphase nuclei, do undergo modification.

Comparison of the sets of the alkylated proteins isolated from the nuclei of intact and regenerating rat liver cells has demonstrated the presence in the latter of two additional modified proteins with molecular weights of 22–23 and 29–30 kDa along with 19–20 and 28–29 kDa proteins.⁷⁹

The differences in the sets of modified proteins can be explained either by changes in their accessibility for alkylation due to the structural rearrangements resulting from activation of chromatin during replication or by changes in the protein environment in the poly(dA) sites of DNA.

In order to make sure that the given set of proteins is not directly related to the chemical nature of the reagents used for their modification, analogous experiments were carried out with p(dT)₁₆ derivatives. In this study, photoactivated fragments carrying an azido group, instead of the alkylating group, *viz.*, XC(O)NH(CH₂)₂NH, where X = 2-NO₂-5-N₃C₆H₃, 4-N₃C₆H₄ and 4-N₃C₆F₄, have been attached to the 5'-ends. The set of modified proteins was practically identical in both cases. The degree of DNA modification with photoactivated reagents was lower, whereas the degree of protein modification was much higher than with the alkylating reagent. In all cases studied, the modification was specific, *viz.*, oligothymidylate, which contained no reactive group, strongly inhibited this process.⁸⁵

Recently it has been established that reagents with a *p*-azidoaniline residue as a photoreactive group stand out among other commonly used photoactivated reagents in terms of specificity. Such reagents have practically no effect on the nucleotide components.⁸⁶ Therefore, the spectrum of proteins modified by the oligothymidylate derivatives carrying a photoreactive arylazido group, 2-NO₂-5-N₃C₆H₃C(O)NH(CH₂)₂NH(pdT)₁₆ (**1**) and 4-N₃C₆H₄NH(CH₂)₄NH(pdT)₁₆ (**2**), have been compared.⁸⁷ Photomodification of intact nuclei isolated from HeLa cells has shown that the degree of modification with the reagent carrying a *p*-azidoaniline residue (**2**) is much higher, while the set of modified proteins is practically identical.

In the same study,⁸⁷ the authors compared the sets of proteins photomodified with reagent **1** within the nuclei isolated from HeLa cells and synchronised at the G₁/S interface and in the S-phase. In this case, the spectra of modified proteins were different, *viz.*, the 160 kDa protein was present only in the nuclei isolated from cells synchronised at the G₁/S interface. This result points to the possibility of usage of photoreactive oligonucleotide derivatives for the analysis of changes in the protein environment in regions containing unwound DNA sequences and for the study of their accessibility in different stages of the cell cycle.

A p(dT)₁₆ derivative which contains simultaneously an alkylating group (CIX) at the 5'-end and a biotin residue (Bio) at the 3'-end of the oligonucleotide [CIX-p(dT)₁₆-Bio] has been synthesised in order to visualise the sites of cross-linking of oligodeoxyribosylthymidylate to chromatin.⁸⁸ Biotin manifests extremely high affinity for streptavidin and its conjugates. It was demonstrated that the introduction of the biotin residue into the 3'-end of the alkylating derivative of the oligonucleotide does not influence its reactivity. The efficiency of DNA modification with both CIX-p(dT)₁₆ and CIX-p(dT)₁₆-Bio is nearly identical. This fact was used to visualise the modification sites by luminescence microscopy. The study was carried out on HeLa cells and on cells of hybrid clones containing human and Chinese hamster chromo-

somes.⁸⁹ Modified cells were treated with the streptavidin–fluorescein isothiocyanate conjugate.

The specific luminescence of nuclei after treatment of hybrid cells was of two types. The luminescence was the most intense in the nucleoli. However, in some cells point luminescence was observed in the sites that are not directly linked with the nucleoli but are discretely distributed over the nucleus volume. This suggests that the regions of active transcription of chromatin (nucleoli) are subjected to the most intense modification, whereas the densely packaged DNA of heterochromatin is inaccessible.

Modification of HeLa cell chromatin has demonstrated that in these cells the common signal elicited by the nucleus is much higher in comparison with hybrid human–hamster cells, apparently as a result of intensive proliferation of HeLa cells. In addition, the genome of a hybrid cell is partly inactivated. Apart from nucleolar and point signals, HeLa cell nuclei display a third type of specific luminescence, namely the luminescence of the near-membrane region of the nucleus where polyA sites are especially abundant.

We have developed⁸⁹ a procedure for visualisation of modification sites in chromatin which is based on *in situ* hybridisation but differs essentially from it. In the case of standard technologies, the preparations used for hybridisation are first fixed to preserve the morphology, after which DNA is denatured for further hybridisation with the probe. This method involves specific modification of a target sequence of DNA within the native chromatin or intact nuclei, which affects only those sequences of DNA that are localised in the sites of its local unwinding.

VI. Conclusion

In-depth studies of chromatin by chemical methods based on molecular resolution and registration of the dynamic events are still in the initial stage. However, one can see from the above data that chemical approaches make it possible to establish the fine structure of nucleoprotein complexes within chromatin, to identify even the interacting amino acid residues in the case of protein–protein contacts and the interacting amino acid and nucleotide residues in the nucleoproteins. A methodology has been developed for establishing these contacts for one of the most essential functional processes, *viz.*, the transition of chromatin into a transcriptionally active state. There is no doubt that these approaches will gradually progress to hold a central position in the study of other vital processes, such as replication, repair and recombination.

Another important feature of chemical methods is the possibility to detect new components of nucleoprotein complexes as can be evidenced from the discovery of two novel proteins interacting with the promoter sites of the hsp gene. At present, separation of hundreds of proteins by two-dimensional electrophoresis does not present any problem. However, establishing of physical and functional contacts between individual proteins and between proteins and nucleic acids (especially those localised directly in the intact nucleus) is a task which can be successfully solved through the use of chemical approaches.

Finally, the changes in the spectrum of protein contacts observed during activation of transcription in chromatin and interactions of oligonucleotides with proteins in different phases of the cell cycle provide evidence that chemical approaches offer new possibilities for recording the changes that take place during transitions from one state of chromatin to another.

To the 275th anniversary of the Russian Academy of Sciences

The Russian Academy of Sciences was founded as an ‘assembly of educated people’ by a decree of Peter the Great dated January 28, 1724. The three main goals clearly defined in the decree were (1) production of the scientific knowledge itself, (2) training of scientists and (3) education of young people in the fundamentals of sciences.

It is remarkable that none of these goals has lost its urgency nowadays and the modern Charter of the RAS could easily begin with the decree of Peter the Great. Moreover, Peter the Great thought the activity of the Academy of Sciences in the education sphere to be one of the most important. That is why in 1726, a secular University (a higher-education establishment), later called Academic, which was the first in Russia, was founded by the Academy. Unfortunately, it stopped existing in 1766, despite the efforts of M V Lomonosov, who was the vice-chancellor of the University from 1758 to 1765. Thus, the efforts undertaken now for integration of the fundamental science and higher education are directed to the realisation of the idea put forward by the founder of the Academy of Sciences, of course, in the present-day conditions.

The beginning of the establishment of the chemical science in Russia is associated with the name of M V Lomonosov. Chemical laboratories with analytical, technological and pharmaceutical profiles had also existed in Russia before Lomonosov, but he created the first research chemical laboratory. And what is more, his laboratory had been the prototype of the research institutes of the Academy, which appeared later. This laboratory existed till 1793 in its original form. Then hard times began, when academicians in chemistry had to carry out their research work either in their home laboratories or in the chemists’ shops or higher-education establishments. It was not until the beginning of the XIX century that a room in the main building of the Academy on the Neva quay was allocated for a chemical laboratory. K S Kirchhoff, G I Gess and Yu F Fritzsche carried out their experiments there. After a conflagration in 1859, a new laboratory was built by the initiative of Yu F Fritzsche and N N Zinin in the Eighth Line of the Vasil’evskii island; this building still exists. A M Butlerov, N N Beketov, F F Beilstein, P I Walden, N S Kurnakov and V N Ipatieff also worked in this well-known laboratory.

An Academy printing office and type-foundry were founded during the Peter the Second’s reign. The Academy started spreading its scientific production in publications. In the course of time, the Russian Academy of Sciences started publishing periodicals and monographic editions in various fields of science.

In the early stages, virtually no reviews were published in scientific journals because there was no need for them. However, the increase in the amount of scientific information and the appearance of new fields of science, mostly in border areas, caused the necessity of summarising and analysis of the scientific information.

In 1932, the ‘Uspekhi Khimii’ journal was founded by a decree of the USSR People’s Commissariat on Education in order to ‘publish the major reviews in theoretical and experimental chemistry and chemical technology, which are of high generalising and summarising importance and are the result of creative and critical

thought uniting the latest scientific achievements into a harmonious single whole.’

The early stage of activity of the ‘Uspekhi Khimii’ journal is associated with the names of its founders — N P Gorbunov, A N Bakh, A M Berkengeim, B M Berkengeim, S I Vol’fkovich, N D Zelinsky, N S Kurnakov and A N Frumkin.[†]

The main aim of the journal in those years was to acquaint people with the achievements of the fundamental chemical science and the practical use of them in the national economy. ‘Uspekhi Khimii’ efficiently responded to the needs of the chemical industry in the solution of fuel and energy problems, development of the effective chemical and technological processes, chemisation of agriculture and forestry and development of the mineral-stock base. In particular, an article by A E Fersman entitled ‘New problems in the investigation of mineral raw materials’ was published in the first issue of the journal.

In the initial stage, ‘Uspekhi Khimii’ paid considerable attention to the reviewing of monographs and information material. Reports on scientific sessions and general meetings in the USSR Academy of Sciences, on international conferences and congresses and Mendeleev Congresses on General and Applied Chemistry were published.

From the methodological point of view, the most significant achievement of ‘Uspekhi Khimii’ in its starting period was elaboration of an independent and consistent strategy of reporting on the present-day chemical achievements. This strategy, in particular, was to orient the journal towards the quantitative aspects of various fields of chemistry and elucidation of the physical processes underlying chemical transformations.

Yet another important feature of ‘Uspekhi Khimii’ was the fact that since its foundation, the journal has published not only reviews in chemistry but also those in related branches of science. Papers on X-ray diffraction analysis (W Bragg), Raman spectroscopy (L I Mandel’shtam and G S Landsberg), geochemistry (A P Vinogradov), internal rotation in molecules and rotational isomerism (M V Vol’kenshtein) and the problems of chemical topology (V Prelog) were published in the journal in different years. Being aware of the fact that the progress of chemical science is largely determined by the advances in modern theoretical and experimental physics, the journal published in these years many purely physical reviews of Russian and foreign researchers such as P Debye, E V Shpolsky, F Joliot-Curie, I Joliot-Curie, O Hahn, N Bohr, E Rutherford, E Schrödinger and others. The development of quantum mechanics in these years served as a powerful stimulus for the progress in the classical fields of physical chemistry and for the creation of a new one referred to as chemical physics.

The pre-war decades have been marked by great achievements in the development of chemical physics. The journal showed a great efficiency at publishing the fundamental works on this

[†] A comprehensive analysis of the activity of the ‘Uspekhi Khimii’ journal from 1932 to 1982 can be found in the paper by V A Nikanorov published in issue 11, 1982.

subject, which were performed not only in Russia but also abroad. N N Semenov, D A Frank-Kamenetsky, S Hinshelwood and V N Kondratiev were among its authors.

For a long period, along with the reviews specially written for it, the journal also published translations of articles from foreign review journals. Later, this was no longer necessary and the journal became written mainly by Russian scientists, although some outstanding works of foreign authors still appeared.

The scope of publications in 'Uspekhi Khimii' at that period was extremely broad. It included organic chemistry (the reviews by N Ya Dem'yanov and M Tiffeneau on the molecular rearrangements of cyclic hydrocarbon systems discovered by them), coordination chemistry (works by I I Chernyaev and A A Grinberg), the chemistry of organometallic compounds (A N Nesmeyanov and K A Kocheshkov), geochemistry (A P Vinogradov), and the polymer chemistry (H Staudinger and W Carothers).

It is typical that in different years, the journal has published reviews by almost all the winners of the Nobel Prize in chemistry.

The 1930s were characterised by intense development of the chemistry of natural compounds. Suffice it to say that during fifteen pre-war years, about ten Nobel Prizes were awarded in this field. The majority of the laureates appeared in the pages of 'Uspekhi Khimii' with their reviews: A Windaus (sterols), P Karrer (carotenoids and flavins, vitamins A and B₂), R Kuhn (carotenoids and vitamins of group B), A Butenandt (hormones) L Ružička (polymethylenes and higher terpenoids), and H Wieland (cholic acids and oxidative dehydrogenation in the series of natural products).

During the post-war years, the journal published reviews by R Robinson (study of plant anthocyanines), R B Woodward (vitamin B₁₂ and the development of the chemistry of natural substances), A Todd (nucleotides and coenzymes), D Crowfoot-Hodgkin (X-ray diffraction analysis of protein crystals) and I N Nazarov (the chemistry of vinylethynylcarbinols).

In the pre-war and post-war years, the journal published a series of important reviews by N D Zelinsky, A A Balandin, B A Kazansky, N I Kobozev and A V Frost devoted to various aspects of catalysis and catalytic transformations.

During the war and the first post-war years, the size of scientific publications in 'Uspekhi Khimii' diminished but the information and bibliographic material was exceptionally diversified.

In the 1950s and the 1960s, vigorous development of chemical science and industry started. The size of the journal in that period increased and the activity of the Editorial Board, which directed the journal to new lines of research in chemistry and promising related branches of science, was enhanced.

One new branch of science was the chemistry of organoelement compounds. Beginning with the paper by A N Nesmeyanov entitled 'The organoelement compounds and the Periodic system,' which appeared just after the war, the journal has regularly published reviews on various aspects of the chemistry of organoelement compounds.

The chemistry of polymers was yet another priority of the journal in the 1960s; various aspects of this branch of chemistry have been considered in reviews by V A Kargin, V V Korshak and other scientists.

The 1960s were marked by one more event important for the journal. Since 1960, it started to be translated into English under the title 'Russian Chemical Reviews'; this significantly broadened the area in which the journal was distributed and gave the possibility for the foreign readers to get acquainted more extensively with the achievements of Russian scientists.

When observing the present-day period of activity of 'Uspekhi Khimii,' it is necessary to mention the truly avalanche-like growth of the size of primary information accompanied by an increase in its difficulty and weight. In this connection, review journals become even more important. In addition, a modern review

journal is not only to inform the reader on the new scientific achievements but also to orient him correctly and neatly.

An important quality characteristic of review scientific literature is the so-called 'data compression index,' which is the ratio of the size of primary information to the size of the review. As early as 1936, this coefficient for the 'Uspekhi Khimii' journal was equal to 20 and by 1976, it reached 50, which is considered by specialists to be the optimum value. On further increase in this index, the information may become distorted.

Yet another quantitative parameter for estimating the quality and topicality of scientific publications is the 'citation index'. It is not by chance that the highest citation index among all the chemical periodicals belongs to 'Chemical Reviews'. Regarding this index, the 'Uspekhi Khimii' journal occupies a honourable place among other journals with similar subject matter all over the world and has the highest citation index among all the chemical periodicals in Russia.

The citation index sharply increased after the English version of the journal started being published by the Russian Academy of Sciences together with the Royal Chemical Society of the UK in 1993. The English version of the journal is an exact translation of the Russian one and appears almost simultaneously with it.

The whole size of the journal is approximately 1200 pages per year, which makes up 12 issues. Each issue contains 4 to 6 reviews. From 1996 the reviewing of the papers has become stricter (two Russian referees and one British referee), which contributes to the quality of publications.

Since 1997, in addition to the hard copy of the journal, an electronic version has also been produced. Annual archive CD-ROM's are also produced. Undoubtedly, all this is favourable for the popularity and availability of the journal.

At present, the journal publishes reviews on the following fields of chemistry: molecular structure and quantum chemistry, chemistry of coordination compounds, analytical chemistry, chemical physics, physical chemistry (including catalysis), organic and organometallic chemistry, chemistry of macromolecules, biochemistry and bioorganic chemistry and materials science.

The majority of papers published in the last years have been submitted by scientists working in the RAS or in the Academies of Sciences of the CIS countries. The geographic area in which the authors of the journal work is quite large. Moscow together with some nearby scientific centres (Chernogolovka, Pushchino) comes first in the number of articles published, St. Petersburg occupies the second place.

The 'Uspekhi Khimii' journal makes a significant contribution to the development of the chemical science in Russia and to popularisation of the achievements of the Russian science abroad. It properly represents the Russian Academy of Sciences, which celebrates its 275th anniversary.

Molecular ferromagnets

Abstract. The state-of-the-art, achievements, problems and prospects of an actively developing area of supramolecular chemistry, viz., the design of molecular ferromagnets, are considered. The bibliography includes 343 references.

I. Introduction

This review deals with a rapidly developing area of modern chemistry, viz., the design of molecular ferromagnets. Like any other area of natural sciences which is still in its infancy, it is not yet liable to generalisations, as many works are pioneering. Various approaches are used to solve the diverse problems arising in these studies, which require a high level of integration of the efforts of specialists in different fields of knowledge. Nevertheless, certain approaches to the design of molecular ferromagnets have now taken shape.^{1–18}

It is obviously impossible for a single review to consider every aspect of the design of molecular ferromagnets in detail. Therefore, in this paper we dwell on the basic classes of the chemical compounds which are characterised by established synthetic strategies and the principal ways for the construction of highly dimensional multispin systems.

When the development of methods for the synthesis of highly dimensional systems is concerned, one has, to some extent, to part with the classical chemical thinking, which generally deals with the design, modification or transformation of an individual molecule. No doubt, a molecule taken as a subunit is also important. However, the arrangement of the molecules is no less important in the design of molecular ferromagnets. Even more important is their selective arrangement in a highly dimensional assembly. Arrangement of individual molecules in a highly effective assembly bound by exchange interactions is a key problem in the design of molecular ferromagnets. Before we start a detailed discussion of this problem it is necessary to define the notion of a 'molecular ferromagnet'.

The term 'molecular ferromagnet' may seem to a certain degree paradoxical. The classical ferromagnet is a macroobject, for example, a piece of iron, nickel, or cobalt or an alloy of these metals, but in no way a separate molecule. By its very nature, a magnetic phase transition into the ferromagnetic state is a cooperative phenomenon inherent in a macroobject as a phase. Nevertheless, in recent years the term 'molecular ferromagnet' has been widely used in scientific publications dealing with the design of multispin systems.[†] Let us define the essence of this term more precisely.

The studies in the field of molecular ferromagnets deal with the synthesis of organic, organometallic and, currently, mostly coordination compounds the solid phases of which are formed from separate molecules or ions that existed initially in a solution and contained paramagnetic centres. In these solid phases, as in classical ferro- and ferrimagnets or weak ferromagnets, magnetic phase transition into the ferro-, ferrimagnetic or weak ferromagnetic state is detected below a critical temperature.

These days, researchers can plan beforehand, with a certain degree of success, the synthesis of compounds with a desired solid state structure that will be formed from molecular precursors in solution. These molecules should form layered or framework polymers when crystallised from solution. As a matter of fact, this field of studies which implies the design of highly dimensional structures is the subject of supramolecular chemistry.

The formation of layered or framework structures in the solid phase of molecular ferromagnets is a prerequisite for the magnetic phase transition into the ferromagnetic state. This condition is necessary but insufficient in the chemical design of molecular ferromagnets. For this transition to occur, the paramagnetic centres in polymers should be linked with such an atomic chain serving as an exchange channel¹³ that the polymer has the ability to undergo magnetisation in a magnetic field. The following consideration is important in this case: the higher the efficiency of the exchange channels in exchange interactions between the unpaired electrons of the paramagnetic centres the higher critical temperature (T_c) that can be achieved. It is within the limits set by these requirements that regular studies of the effect of conditions of directed chemical synthesis on the magnetic parameters (the

Received 2 February 1999

Uspekhi Khimii 68 (5) 381–400 (1999); translated by S S Veselyi

[†] Reviews and monographs on 'molecular ferromagnets' have been published, the titles of which, like the present paper, sometimes contain this word combination (or the equivalent expressions: 'molecular magnetics', 'molecular magnets', 'molecule-based ferromagnets') as the key words.^{1–14}

Curie temperature or the Neel temperature, spontaneous magnetisation, *etc.*) of the final magnetically active product are being performed, *i.e.*, the effects of the composition, structure of the starting molecules, conditions of the synthesis and crystallisation on the magnetic properties of the resulting solid phases are being studied. Magnetic-structural relationships understood as relationships between the observed magnetic properties of a compound and its chemical and structural characteristics are used in the search for subjects with the required properties. These relationships are either calculated or determined experimentally.

Thus, the word 'ferromagnet' in the term 'molecular ferromagnet' is used in the ordinary sense, while the definition 'molecular' reflects the methodology of the approach: the starting individual molecules and/or molecular ions should have a structure which would enable them to form a spatial structure favourable for a magnetic phase transition during formation of a solid phase. The problem can be solved by various chemical methods combined by the term 'chemical design of molecular ferromagnets'.

The development of principles for the synthesis of molecular ferromagnets and the determination of their inherent magnetic-structural relationships are fundamental problems. There are few natural magnetic materials. Most of them are transition metals and their oxides; the number of magnetic materials was mainly increased by virtue of metal alloys and binary oxides. However, studies on the design of molecular ferromagnets make it possible to expand considerably the range of magnetically active compounds and magnetic materials. In addition, the design of molecular magnets and conventional, mild synthetic approaches provide a possibility to create new magnetic materials using technologies alternative to the traditional power-consuming metallurgical technologies for the production of magnetically active oxides materials.
