III. Studies of mechanisms and kinetics of rearrangements in tricarbonylchromium complexes of polycyclic arenes	691
IV. Conclusion	702

Abstract. The results of studies of inter-ring haptotropic rearrangements in π -complexes of transition metals with polycyclic aromatic ligands are discussed. Syntheses and structures of model compounds are surveyed and the classification of dynamic processes in these compounds is proposed. The major regularities, mechanisms and kinetics of inter-ring haptotropic rearrangements in these systems are analysed. The bibliography includes 143 references.

I. Introduction

Diversified dynamic processes occur in molecules of different heteroorganic compounds (HOC) and, in particular, organometallic compounds (OMC), due to changes in the mutual arrangement of various groups in HOC molecules (rotation, small-amplitude oscillation, formation and cleavage of agostic bonds, inversion, etc.). Generally, these processes are degenerate and occur rather rapidly and hence, they are studied primarily by dynamic NMR spectroscopy.¹

One of the dynamic processes most commonly observed in HOC and OMC involves rapid migration of an element (metal) together with the ligand environment from one position in the organic fragment to another. For this type of tautomerism, Academician A N Nesmeyanov introduced the term 'metallotropic tautomerism' (metallotropy). He was the first² to find metallotropic rearrangements in nitrosophenyl and quinoxime compounds of mercury.

Hoffmann³ extended the term 'sigmatropic rearrangements' to π -complexes of transition metals and introduced the term 'haptotropic' rearrangements for these processes. Metallotropy is among the most important problems of chemistry because the

reactivities and catalytic activities of OMC are to a large extent determined by the tautomer ratio.⁴

Metallotropic tautomerism has been studied for more than 40 years. A rich variety of metallotropic rearrangements have been thoroughly studied and a number of basic concepts have been offered, for example, the concepts of dual reactivity and σ, π -conjugation,⁵ stereochemically nonrigid organometallic compounds⁶ and catalytic and intramolecular activation of CH bonds,⁷ which made a noticeable impact on the development of the general theory of chemical bonds, catalytic activity and reactivity of OMC.

Degenerate σ, σ - and π, π -rearrangements in HOC and OMC were among the first to be discovered.^{8,9} For example, σ, σ -rearrangements in allylic complexes of magnesium,¹⁰ boron¹¹ and silicon¹² ([1,3]-sigmatropic rearrangements according to Woodward–Hoffmann) proceed through an intramolecular mechanism.¹³

$n = 1, M = Mg; n = 2, M = B; n = 3, M = Si.$

Rearrangements of *C*- and *O*-substituted derivatives of carbonyl compounds containing MR_3 groups ($M = Ge$ or Sn)^{14,15} as well as the nitrosophenol–quinoxime rearrangement of mercury compounds described above (the first metallotropic rearrangement observed experimentally)² may also be assigned to this type of rearrangements.

$M = Ge, Sn.$

Migration of the organometallic group in the compounds described above is accompanied by rearrangement of the system of multiple bonds. Cross experiments demonstrated that these processes can occur both according to intramolecular and intermolecular mechanisms, but an intramolecular mechanism prevails. Formally, σ, σ -rearrangements are analogues of prototropic rearrangements in organic compounds, whereas σ, π - and π, π -rearrangements have no analogues because migrations of organometallic groups in the latter cases lead to a change in the character of a delocalised multicentre bond. For example, an interesting diotropic σ, π -rearrangement was observed in a binuclear thiophene complex.¹⁶

Received 4 April 2000

Uspekhi Khimii 69 (8) 744–766 (2000); translated by T N Safonova

The [1,5]-sigmatropic rearrangements in cyclopentadienyl and indenyl compounds of many main-group and transition metals have received the most study.¹⁷

M = Si, Sn, Ge.

These rearrangements were also observed in cycloheptatrienyl¹⁸ and cyclononatetraenyl¹⁹ compounds.

Generally, the activation barriers to these migrations are rather low and the migrations are degenerate in the sense that the molecule either undergoes internal conversion or is converted into a mirror image. Hence, these migrations are studied by dynamic NMR spectroscopy.²⁰ Molecules of this type can be described as 'stereochemically nonrigid' in terms proposed by Muettterties.²¹ Cotton²² introduced the term 'fluxional molecule' for their description. Haptotropic rearrangements in monocyclic π -complexes were considered in numerous reviews and monographs.^{23–25} For π -complexes of open polyenes, rearrangements of η^2 -allene²⁶ and η^4 -triene²⁷ derivatives have been studied most extensively.

$MR_n = Fe(CO)_4, Fe(CO)_2(\eta^5-C_5H_5).$

π, π -Rearrangements are often observed in π -complexes of open or cyclic conjugated polyenes with transition metals. These rearrangements are very diverse.²⁸ The η^4, η^4 -rearrangement of the tricarbonyliron complex of cyclooctatetraene provides a typical example. In the course of isomerisation, the $Fe(CO)_3$ group migrates along the system of the conjugated double bonds of the ligand.²⁹

It should be noted that haptotropic rearrangements occur in π -complexes in which the π -ligand can be coordinated to the metal atom through several coordination sites and not all these sites are used, *i.e.*, some double bonds are not involved in coordination.

In $(\eta^4\text{-cyclooctatetraene})(\eta^6\text{-cyclooctatetraene})$ iron, migration of the metal atom is accompanied by a change in the mode of bonding in each ligand (*i.e.*, the η^4, η^6 -rearrangement).³⁰

In early studies, metallotropy in OMC, including metallotropic rearrangements with the participation of the hydrogen atom and alkyl groups, was investigated primarily in open or monocyclic compounds.^{30–34} Much later, inter-ring rearrangements, rapid within the NMR time scale, were found, for example, in nickel complexes of naphthalene³⁵ and anthracene,³⁶ phenalenyl palladium complex³⁷ and dibenzenepentalenyl manganese complex.³⁸

Formally, π -complexes of transition metals (in particular, carbonyl chromium complexes, which are the most readily available and well-studied compounds) with polycyclic aromatic neutral ligands (naphthalene, acenaphthene, acenaphthylene, biphenylene, biphenyl, fluoranthene, *etc.*) are promising models for searching for and revealing new types of haptotropic rearrangements. In these systems, inter-ring haptotropic rearrangements (IHR) involving migration of the transition metal atom together with the ligand environment between the rings of the polyaromatic ligand can proceed.³⁹

Studies of the general regularities of IHR are of considerable importance because they can allow one to obtain further insight into the nature of the transition metal–ligand bond and to elucidate the mechanisms of catalytic processes occurring in solution under the action of metal-complex catalysts because IHR are involved as particular elementary stages in these processes.

In 1971, Nicholas *et al.*⁴⁰ found for the first time nondegenerate IHR. Thus deprotonation of a solution of tricarbonyl(η^6 -fluorene)chromium (**1**) in DMSO with potassium *tert*-butoxide afforded tricarbonyl(η^5 -fluorenyl)chromium (**2**). The authors suggested that tricarbonyl(η^6 -fluorenyl)chromium (**3**) formed in the initial step of the reaction underwent a η^6, η^5 -rearrangement. The anion **3** was not detected by spectral methods and the kinetics and mechanism of its conversion into the isomeric η^5 -anion **2** were not studied in detail.

Later, inter-ring haptotropic rearrangement in the η^6 -anion **3** was studied in detail by Russian^{41–43} and Italian⁴⁴ researchers using IR and NMR spectroscopy and the kinetic and thermodynamic parameters of this rearrangement were determined. It was found that deprotonation of the complex **1** with a base gave rise to the η^6 -anion **3**, which was isomerised to form the η^5 -anion **2**. This rearrangement is reversible and entropy-controlled. The kinetic and thermodynamic parameters ($E_a = 16.29 \text{ kcal mol}^{-1}$ and $\Delta S^\ddagger = -19.62 \text{ e.u.}$) are to a large extent determined by the equilibrium between different ion pairs of the corresponding fluorenyl salts [contact ion pairs (CIP), separated ion pairs (SIP) and ionic associates]. More recently, analogous η^6, η^5 -rearrangements were found in complexes of a series of carbo- and heterocyclic analogues of fluorene.⁴⁵

Nondegenerate inter-ring migrations in fluorenyl complexes are fairly well studied by stationary kinetic methods. Inter-ring migrations in complexes of naphthalene and related unsubstituted polyaromatic systems are degenerate and cannot be studied by conventional procedures. The researchers hoped to find rapid

migrations of the $\text{Cr}(\text{CO})_3$ group between two equivalent rings in the simplest model complexes, *viz.*, tricarbonyl(η^6 -naphthalene)-chromium (**4**)^{40,46} and related (η^6 -acenaphthylene)tricarbonyl-chromium (**5**),⁴⁷ by NMR spectroscopy. Specimens were heated to rather high temperatures; however, no dynamic processes were observed in the spectra. Until the mid-1980s, procedures for the investigation of these degenerate processes were lacking.

As early as 1966, Deubzer, a coworker of the Nobelist Fischer, found⁴⁸ that isomeric tricarbonylchromium π -complexes of 2,3-dimethylnaphthalene **6** and **7** underwent reversible η^6, η^6 -IHR ($E_a \approx 30 \text{ kcal mol}^{-1}$) at 90–110 °C. Both complexes involved in the rearrangement have been isolated from the reaction mixture in pure form (by fractional recrystallisation) and identified for the first time.

However, these pioneering results were not published and remained unknown over 17 years until they were cited in Ref. 47.

In succeeding years, inter-ring haptotropic rearrangements were studied by several research groups. Teams headed by P M Treichel (USA), E P Kündig (Switzerland), A Ceccon (Italy), Ch Elschenbroich (Germany), T A Albright (USA), M J McGlinchey (Canada), Yu A Ustynyuk and N A Ustynyuk (both from Russia) have made the major contribution to this line of investigation.

II. Classification and major regularities of inter-ring haptotropic rearrangements

The classification of IHR is as yet inadequate. I shall follow the classification of IHR depending on the type of bonding of the metal atom with the ligand proposed by N A Ustynyuk,⁴³ which is, in my opinion, the most reasonable and convenient one. According to this classification, the $3 \rightleftharpoons 2$ and $6 \rightleftharpoons 7$ rearrangements are assigned to η^6, η^5 - and η^6, η^6 -IHR, respectively.

1. η^2, η^2 -Rearrangements in nickel complexes of naphthalene and anthracene

Recently, this type of rapid reversible degenerate rearrangement has been observed in phosphine complexes of nickel(0) with naphthalene³⁵ and anthracene.³⁶ The reactions of $[\text{Pr}_2\text{P}(\text{CH}_2)_n\text{PPr}_2]_2\text{Ni}$ ($n = 2$ or 3) with naphthalene^{49,50} in THF afforded complexes, which have η^2 -structures [according to the solid-state ^{13}C NMR spectra measured with the use of cross-polarisation and the magic-angle-spinning technique (CP MAS NMR)]. Solid-state and solution-phase two-dimensional exchange ^{13}C NMR spectra measured with magnetisation transfer demonstrated that the organonickel group migrates between double bonds both within one six-membered ring (E_a are 6 and

23 kcal mol^{-1} in solution and in the solid state, respectively) and between the rings. The migration between the rings is observed only in solution ($E_a = 15 \text{ kcal mol}^{-1}$).

The reactions of $(\text{Bu}_3\text{P})_3\text{Ni}$ with 5-alkyl- and 5,10-dialkylanthracenes⁴⁹ in benzene gave rise to η^2 -complexes whose structures were established by CP MAS ^{13}C NMR spectroscopy.

$\text{R}^1 = \text{Me, Et}; \text{R}^2 = \text{H, Me, Et}.$

Based on the data of ^1H and ^{13}C NMR spectroscopy, these complexes in solutions in benzene- d_6 underwent rapid η^2, η^2 -rearrangements, the organometallic group 'running around' the perimeter of the polycyclic ligand. The dynamic behaviour of these systems was studied using the spin saturation transfer technique and total line-shape analysis. In anthracene complexes, as in naphthalene complexes, the organonickel group was demonstrated to migrate within one ring and between the terminal rings both through intramolecular ($\Delta H^\ddagger = 8 \text{ kcal mol}^{-1}$) and intermolecular ($\Delta H^\ddagger = 20 \text{ kcal mol}^{-1}$) mechanisms.

2. η^3, η^3 -Rearrangements in phenalenyl complexes of palladium and rhodium

η^3, η^3 -Rearrangements were studied in most detail for η^3 -phenalenyl complexes. Thus the reactions of di- μ -chlorobis(η^3 -phenalenyl)dipalladium complexes dissolved in acetone with N, N, N', N' -tetramethylethylenediamine and KPF_6 afforded cationic palladium complexes of the allylic type **8a–c**.^{37,51} At 160 °C, coalescence of the signals for the aromatic protons was observed in the ^1H NMR spectrum of the complex **8a**, which is indicative of a dynamic process, *viz.*, a haptotropic shift of the organometallic group between the six-membered rings.³⁷

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{H}$ (**a**); $\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{Me}$ (**b**);
 $\text{R}^1 = \text{Me}, \text{R}^2 = \text{R}^3 = \text{H}$ (**c**).

In the ^{13}C NMR spectrum of the compound **8b**, the signals for the allylic carbon atoms also coalesce at 102 °C. In this complex, the rate of the haptotropic rearrangement is higher and coalescence starts at lower temperature due apparently to the electronic effect of the methyl groups. The following activation parameters (at 90 °C) were determined from total line-shape analysis of the signals for the methyl groups in the spectra of the compounds **8b, c**.

Compound 8	$\Delta H^\ddagger$ /kcal mol ⁻¹	$\Delta G^\ddagger$ /kcal mol ⁻¹	$\Delta S^\ddagger$ /e.u.	E_a /kcal mol ⁻¹
b	20.9 ± 0.4	21.4 ± 0.1	-1.3 ± 0.3	21.6 ± 0.4
c	23.1 ± 0.7	21.6 ± 0.1	4.1 ± 1.9	23.8 ± 0.7

The reaction of phenalene with Li_2PdCl_4 gave rise to the η^3 -phenalenyl palladium complex in 90% yield. Subsequent treatment of the latter with a solution of acetylacetone in benzene afforded η^3 -phenalenyl complex **9** in 50% yield.^{52,53} The possibility of η^3, η^3 -IHR occurring in the complex **9** was examined.

Calculations by the extended Hückel method demonstrated that structure **10** is less stable than structure **11** as the possible transition state. The difference between their energies is $1.21 \text{ kcal mol}^{-1}$. The energy of the structure **9** is $15.77 \text{ kcal mol}^{-1}$ lower than that of the structure **11**. Based on the results of calculations, it was concluded that the inter-ring haptotropic shift should occur through the transition state **10**. However, no dynamic processes were observed in the complex **9** by NMR spectroscopy, although η^3, η^3 -IHR would be expected to occur by analogy with the complexes **8**.

η^3 -Phenalenyl platinum complexes **12a, b** were prepared as yellow crystals by the reaction of 1-ethoxyphenalenium tetrafluoroborate with bis(triphenylphosphine)(η^3 -ethylene)platinum (the **12a** : **12b** ratio was 10 : 1).⁵⁴ The structures of the complexes **12a, b** were determined by ^{31}P NMR spectroscopy and X-ray diffraction analysis, but their dynamic behaviour in solution was not studied and the possibility of interconversion of the complexes **12a** and **12b** through inter-ring haptotropic rearrangements was not proved.

Calculations by the extended Hückel method demonstrated that the inter-ring haptotropic rearrangement in the η^3 -phenalenyl platinum complex **13a** should occur according to an intramolecular mechanism with a relatively low activation energy ($20.1 \text{ kcal mol}^{-1}$) through transition state **13b**.⁵⁵ The difference between the energies of the complexes **13a** and **13b** was found to be $3.83 \text{ kcal mol}^{-1}$.

It was postulated that the η^3 -phenalenyl rhodium complex was formed in the reaction of the catalytic conversion of cycloprop[*a*]acenaphthylene into phenalene in the presence of the complex $[\text{Rh}(\text{CO})_2\text{Cl}]_2$.⁵⁶ The deuterium label introduced in the starting compound, for example, at position 7, is statistically distributed over positions 1, 3, 4, 6, 7 and 9 in the final product, *viz.*, in phenalene. This is attributable to the fact that the intermediate η^3 -phenalenyl rhodium complex undergoes η^3, η^3 -IHR involving migration of the metalohydride group between the six-membered rings with the 'ricochet' elimination of hydrogen.

3. η^5, η^5 -Rearrangements in dibenzopentalenyl complexes of manganese

Only one example of η^5, η^5 -IHR is available in the literature. Refluxing of 9-methylindeno[1,2-*a*]indene or indeno[1,2-*a*]indene with $\text{Mn}_2(\text{CO})_{10}$ in dodecane for 1.5 h afforded isomeric dibenzopentalenyl complexes **14**–**16**, which differ in the type of fusion of the indene fragments.⁵⁷

Deprotonation of the complexes **14** and **16** with potassium *tert*-butoxide gave rise to complexes **17** and **18**, respectively. In the compound **18**, no migration of the $\text{Mn}(\text{CO})_3$ group, rapid within the NMR time scale, was observed, whereas the complex **17** and the related benzyl complex **19** underwent rearrangements (in the case of the benzyl derivative, the rearrangement was reversible) to form the corresponding isomeric η^5 -complexes at temperatures above -40°C .

The difference in the behaviour of the complexes **17**–**19** was explained based on analysis of the node properties and energies of the highest occupied π -MO of the dibenzopentalenyl complexes **17** and **18** calculated by the INDO method.⁴³

4. η^6, η^5 -Rearrangements in fluorenyl complexes of chromium

η^6, η^5 -Inter-ring haptotropic rearrangements have been studied comprehensively for indenyl and fluorenyl complexes of transition metals of the chromium and iron subgroups. For example, isomerisation in the anionic complexes of such ligands as indene, fluorene, their analogues containing different substituents in five- and six-membered rings and heterocyclic analogues of fluorene was considered in detail in reviews.^{41–43} In the present review, these data are briefly discussed and supplemented with new results. Thus tricarbonyl(η^6 -fluorene)chromium (**1**) is readily deprotonated with different bases, such as phosphoranes (for example, $\text{Ph}_3\text{P}=\text{CH}_2$), proton sponges, alkali metals in hexamethylphosphoramide (HMPA), BuLi and Bu⁺OM (M = Na, K, Rb or Cs),⁵⁸ in THF, ether, HMPA, dioxane and some other polar solvents. In these cases, the anion **3** is initially formed at rather low temperatures. At temperatures above -20°C , the η^6 -form **3** undergoes rapid rearrangement into the η^5 -form **2**. This accounts for the fact that Nicholas *et al.*⁴⁰ failed to detect the anion **3** at room temperature after deprotonation of the neutral complex **1**.

B is base.

The isomeric η^5 -anion **2** was also generated in the pure form by an independent synthesis involving reduction of symmetric mercury derivative **20** with a potassium–sodium alloy in ethereal solutions.

According to the data of IR spectroscopy, salts of the isomeric anions **2** and **3** exist in solution as equilibrium mixtures of contact ion pairs (CIP) and separated ion pairs (SIP) (Tables 1 and 2).^{59–62} In the IR spectra of these salts, the absorption bands in the region of ν_{CO} stretching vibrations of the $\text{Cr}(\text{CO})_3$ fragment are very characteristic, which allows one to obtain data on the type of ion pairs and to infer the position of the cation. In particular, no splitting of the E band of antisymmetric vibrations was observed in the IR spectrum of the contact ion pair formed by the anion **3**. Therefore, it can be concluded that the cation in this ion pair is located above the plane of the five-membered ring of the anion in the *trans* position with respect to the chromium atom.

In the contact ion pair formed by the anion **3**, the negative charge in the ring is substantially decreased due to the strong Coulomb cation–anion interaction. As a result, the symmetry C_{3v} of the $\text{Cr}(\text{CO})_3$ fragment is retained and the E band is degenerate (see Table 1). On the contrary, splitting of the E band is

pronounced in the IR spectra of the contact ion pair formed by the anion **2**, the degree of splitting depending on the nature of the cation (see Table 2). Such splitting indicates that the counterion is coordinated to the oxygen atom of one of the CO groups.

The anions **2** and **3** and bulky cations characterised by high charge delocalisation, such as Rb^+ , Cs^+ , Bu_4N^+ and $\text{Ph}_3\text{P}^+\text{Me}$, form predominantly contact ion pairs.

The η^6, η^5 -inter-ring haptotropic rearrangement of the anion **3** into the anion **2** and the reverse rearrangement were studied by ^1H NMR^{44, 60, 63} and IR spectroscopy.^{59, 64} For these rearrangements, the equilibrium constants (K_{eq}) and the rate constants of the forward and back reactions (k_1 and k_2 , respectively) were determined (Tables 3 and 4). The K_{eq} values (see Table 3) indicate that the metallotropic η^6, η^5 -equilibrium studied for a wide range

Table 3. Equilibrium constants for η^6, η^5 -IHR of salts of anions **2** and **3**.

Cation	Solvent	Type of 3 $\rightleftharpoons$ 2 equilibrium	$K_{\text{eq}} = 2k_1/k_2$

^a The possibility of the **3** $\rightleftharpoons$ **2** rearrangement occurring in both directions was ignored in the study⁵⁹ and, hence, only the refined K_{eq} values for the doubly degenerate process are given.

of systems is very sensitive to the structure of the ion pairs. The thermodynamic data given below testify that these η^6, η^5 -IHR are entropy-controlled processes. It should be noted that many reactions involving ion pairs are entropy-controlled, which is attributed to the fact that several solvent molecules are coordinated about the cation (solvate coat) in separated ion pairs resulting in a substantial decrease in the entropy of this state.⁶² The activation parameters of the **3** $\rightleftharpoons$ **2** rearrangement in THF in the presence and in the absence of the solvating additive (DCH-18-C-6) are given below:

Solvent	E_a /kcal mol ⁻¹	$\Delta H^\ddagger$ /kcal mol ⁻¹	$\Delta S^\ddagger$ /e.u.
THF	16.3 $\pm$ 2.18	15.7 $\pm$ 2.04	-19.6 $\pm$ 2.55
THF + DCH-18-C-6	21.9 $\pm$ 2.13	21.3 $\pm$ 2.10	0.2 $\pm$ 0.02

Cross experiments demonstrated that at moderate temperatures η^6, η^5 -IHR in the anions **2** and **3** proceed through an intramolecular mechanism. In these processes, the tricarbonylchromium group is not eliminated and does not go into solution to form a complex with the solvent (for example, with THF).⁴¹

5. Rearrangements in anionic tricarbonylchromium η^6 - and η^5 -complexes of carbo- and heterocyclic analogues of fluorene

By going from the unsubstituted tricarbonylchromium complex of fluorene to its carbo- and heterocyclic analogues, one can sub-

stantially extend the range of systems in which η^6, η^5 -IHR occur and study the dependence of these processes on the electronic and steric effects of the substituents and heteroatoms.⁶⁵ The introduction of a heteroatom or a substituent into one of the rings of the π -ligand leads to a substantial change in the electron density in the latter. The isomer in which the organometallic group is bound to the ring possessing a higher electron density is thermodynamically more stable resulting in an increase in the content of this isomer in the equilibrium mixture. In the case of carbocyclic analogues of 9-substituted fluorenes (9-methyl-, 9-*tert*-butyl- and 9-phenyl-fluorenes), the ratio between the η^5 and η^6 -isomers depends on the electronic and steric effects of the substituent. The donor effect of the methyl group leads to an increase in the electron density in the five-membered ring of the fluorenyl anion and, correspondingly, to an increase in the proportion of the η^5 -isomer ($K_{\text{eq}} = [\eta^5]/[\eta^6] = 10$). On the contrary, the electron-withdrawing effect of the phenyl substituent leads to a decrease in the electron density in the five-membered ring and, correspondingly, to a decrease in the portion of the η^5 -isomer in the equilibrium mixture ($K_{\text{eq}} = [\eta^5]/[\eta^6] = 0.35$). Tricarbonyl(η^6 -fluoradenyl)chromium (**21**) formed upon deprotonation of fluoradene complex **22** does not undergo rearrangement to form the η^5 -anion **23**.⁶⁶ This is attributable to the fact that the negative charge is delocalised over two five-membered rings and the six-membered ring fused with these rings.

On the contrary, delocalisation of the negative charge in the five-membered ring in (η^6 -indenyl)tricarbonylchromium (**24**) is smaller than that in the fluorenyl analogue and hence, the anion of **24** is completely rearranged into the η^5 -isomer **25** in THF even at temperatures above -40 °C. The rate of the η^6, η^5 -inter-ring haptotropic **24** $\rightarrow$ **25** rearrangement is noticeably higher than that of the **3** $\rightarrow$ **2** rearrangement.

The phenyl substituent in the five-membered ring of the complex **24** (like that in the 9-phenylfluorenyl complex) decreases the electron density in the ring and hence, the equilibrium is shifted toward the η^6 -anion.⁴³

The Öfele reaction of tetraphenylcyclopentadiene with $\text{Py}_3\text{Cr}(\text{CO})_3$ afforded tricarbonyl[(η^6 -1-phenyl)-2,3,4-triphenylcyclopentadiene]chromium (**26**),⁶⁷ which is the nonannulated open analogue of (η^6 -indenyl)tricarbonylchromium. Deprotonation of the latter giving rise to the η^6 -anion **27** and the ability of the tricarbonylchromium group to migrate from the six-membered ring to the five-membered ring to form the η^5 -anion **28** were examined.

Ceccon *et al.* studied irreversible η^6, η^5 -IHR in the phenylcyclopentadienyl (**29**), 1-phenylindenyl (**30**) and 9-phenylfluorenyl (**31**) complexes of chromium⁶⁸ and the rearrangement in the very interesting open phenylpentadienyl system **32**.⁶⁹

The activation parameters and the rate constants (k) of η^6, η^5 -IHR in the anions **29**–**31** are given below.

29: $\Delta S^\ddagger = -7.1 \pm 1.1$ e.u., $\Delta H^\ddagger = 22.7 \pm 0.4$ kcal mol⁻¹,

McGlinchey and coworkers studied⁷⁰ the rearrangements of the zwitterionic tricarbonylmanganese complexes and the anionic tricarbonylchromium complexes containing a very interesting ligand, *viz.*, 4H-cyclopenta(phenanthrene), or the corresponding hydrogenated ligand. The possible paths of these rearrangements and the transition states were investigated experimentally as well as theoretically by the extended Hückel method. The η^6, η^5 -inter-ring haptotropic rearrangements both in the manganese and chromium complexes **33** with the completely fused ligand proceed much more readily than those in the anions **34** prepared from the corresponding hydrogenated complexes. The η^6 -anions **33** are kinetically stable at temperatures below -40 °C. At higher temperatures, these anions undergo rearrangements into the η^5 -anions **35**, whereas the rearrangements of the hydrogenated anions **34** into anions **36** occur at high temperatures. The authors attributed this fact to the retention of the stable naphthalene system of the aromatic anion in the course of IHR.

Relatively rapid η^6, η^5 -inter-ring rearrangements in the fluorenyl complexes of manganese,⁷¹ iron,⁷² molybdenum and tungsten⁷³ were studied. The E_a values of these processes were demonstrated to depend substantially on the nature of transition metal. The $\Delta H^\ddagger$ values are in the range of 24–25 kcal mol⁻¹ and the $\Delta S^\ddagger$ values vary from 2 to -1.6 e.u. The rearrangements in the manganese complexes are irreversible.⁷¹

$R = H, Bu^t; L = CO, PBu_3^t.$

Investigations of azafluorenyl systems by the INDO method demonstrated^{43, 74} that the introduction of the electronegative nitrogen atom into the six-membered ring leads to a decrease in electron density in the five-membered ring compared to that in the fluorenyl system, *i.e.*, the inter-ring haptotropic rearrangement results in a decrease in the portion of the η^5 -isomer.

The η^6, η^5 -inter-ring haptotropic rearrangements do not proceed in tricarbonylchromium complexes of carbazoyl and indolyl, which is difficult to explain within the framework of the above-described simplified approach because the electron density in the five-membered rings of these compounds is very high. Apparently, these rearrangements do not occur due to the fact that the electron pair at the nitrogen atom in the pyrrolyl, indolyl and carbazoyl anions occupies an MO orthogonal to the π -MO of the cyclic system, whereas the electron pair at the carbon atom in the cyclopentadienyl, indenyl and fluorenyl anions is involved in a π -MO participating in bonding with the metal atom.

Experimental investigations of the structures and properties of isomeric η^6 - and η^5 -fluorenyl complexes and their analogues and examination of the mechanism of η^6, η^5 -IHR have been summarised.^{74–79} Analysis of the above-considered data demonstrates that the structure of the π -ligand, the nature of the metal atom and its ligand environment affect substantially the metal-ligand equilibrium, the site of location of the organometallic group depending to a large extent on the electron density in the five-membered ring. Apparently, the determination of enthalpies of isomeric complexes and transition states using high-level quantum-chemical calculations can improve the reliability of the prediction of the results of IHP.⁸⁰

6. η^6, η^6 -Rearrangements in tricarbonylchromium complexes of naphthalene and its analogues

Deubzer⁴⁸ demonstrated that isomerisation of tricarbonylchromium complexes of 2,3-dimethylnaphthalene, which is the first example of η^6, η^6 -IHR available in the literature, proceeds slowly and is characterised by a high activation barrier. These results were indirectly confirmed in studies performed by Nicholas,⁴⁰ Kündig⁴⁶ and Albright⁴⁷ with their coworkers. The authors failed to detect the haptotropic rearrangement in tricarbonylchromium complexes of η^6 -naphthalene and η^6 -acenaphthylene by dynamic NMR spectroscopy upon heating of specimens in the probe of an NMR spectrometer. Analogously, inter-ring rearrangements, rapid within the NMR time scale, were not detected at relatively high temperatures in some other naphthalene complexes, for example, in $[(\eta^6\text{-C}_{10}\text{H}_8)\text{Ir}(\eta^5\text{-C}_5\text{Me}_5)]^{2+}$ (70 °C, $\text{CF}_3\text{CO}_2\text{H}$)⁷⁷ and $(\eta^6\text{-C}_{10}\text{H}_8)_2\text{Cr}$ (130 °C, C_6D_6).⁴⁶

Hence, the only possible strategy for studying η^6, η^6 -rearrangements in π -complexes of naphthalene involves the removal of degeneration in these systems, *i.e.*, the use of unsymmetrically substituted compounds, and their study by stationary kinetics methods. This approach was developed in detail only in the mid-1980s.^{81–84} Initially, procedures have been proposed for the regioselective synthesis of tricarbonylchromium complexes of substituted naphthalenes containing a label at a particular position of the coordinated or uncoordinated ring of the naphthalene ligand.

Substituted naphthalenes can form tricarbonylchromium complexes upon heating with $\text{Cr}(\text{CO})_6$,⁸⁵ including reactions in the presence of polar additives⁸⁶ as catalysts. For example, boiling of $\text{Cr}(\text{CO})_6$ with naphthalene in decalin in the presence of ethyl formate afforded $(\eta^6\text{-C}_{10}\text{H}_8)\text{Cr}(\text{CO})_3$ in 88% yield.⁸⁷ Tricarbonylchromium complexes of substituted naphthalenes were also formed in the reactions of the ligand with $(\text{NH}_3)_3\text{Cr}(\text{CO})_3$ (the Rausch reaction⁸⁸) and with the $\text{Py}_3\text{Cr}(\text{CO})_3\text{-BF}_3\cdot\text{OEt}_2$ system (the Öfele reaction^{89,90}). Thus the reaction of fluoranthene with $\text{Cr}(\text{CO})_6$ performed under conditions of thermodynamic control gave rise to η^6 -complex **37** in which the $\text{Cr}(\text{CO})_3$ is located at the benzene ring.⁹¹ The synthesis with the use of the $\text{Py}_3\text{Cr}(\text{CO})_3\text{-BF}_3\cdot\text{OEt}_2$ system yielded complex **38** in which the $\text{Cr}(\text{CO})_3$ is located at the naphthalene fragment. The latter reaction also afforded a small admixture (< 5%) of the compound **37**, which was readily separated from the complex **38** by recrystallisation.

A convenient alternative procedure was developed for the synthesis of substituted naphthalenes. This procedure involves the migration of the tricarbonylchromium group from readily accessible $(\eta^6\text{-C}_{10}\text{H}_8)\text{Cr}(\text{CO})_3$ to another polyaromatic ligand.⁴⁶ The result of this complexation reaction depends on the conditions of control (either kinetic or thermodynamic), which can be used for preparative purposes. However, these methods for the synthesis of complexes of monosubstituted naphthalenes generally give rise to mixtures of both possible isomers **39** and **40** containing the tricarbonylchromium group either in the substituted or unsubstituted rings.

For alkyl-substituted complexes, the **39**:**40** ratio is close to unity and the isomers can be separated by chromatography (TLC or HPLC⁹²). It was demonstrated⁹³ that the very high regioselectivity of the Öfele reaction can be achieved if the substituent possesses pronounced electron-withdrawing or electron-donating properties. This behaviour agrees well with the results of calculations of the relative energies of isomeric tricarbonylchromium complexes of monosubstituted naphthalenes within the framework of density functional theory (DFT).⁸⁰

Thus under the conditions of the Öfele reaction, complexes of the type **39** are predominantly formed if $\text{R} = \text{Br}$, whereas complexes of the type **40** are obtained as the major products if $\text{R} = \text{SiMe}_3$ and, particularly, if $\text{R} = \text{SnMe}_3$. A thorough search for the reaction conditions enables one to achieve satisfactory yields (50% and higher).

The most general and versatile procedure for the regioselective synthesis of substituted complexes **39** and **40** involves the following reaction sequence. Initially, 1- and 2-bromo- or 1- and 2-trimethylstannyl naphthalenes are converted into the corresponding tricarbonylchromium complexes **39a,b** or **40a,b**, respectively, by the Öfele reaction.

39: $\text{R} = 1\text{-Br}$ (**a**), 2-Br (**b**), 1-D (**c**), 2-D (**d**), 1-Me (**e**), 2-Me (**f**), 1-SiMe_3 (**g**), 2-SiMe_3 (**h**), 1-SnMe_3 (**i**), 2-SnMe_3 (**j**), 1-Cl (**k**), 2-Cl (**l**);

40: $\text{R} = 1\text{-SnMe}_3$ (**a**), 2-SnMe_3 (**b**), 1-D (**c**), 2-D (**d**), 1-Me (**e**), 2-Me (**f**), 1-SiMe_3 (**g**), 2-SiMe_3 (**h**), 1-Cl (**i**), 2-Cl (**j**);

(a) $\text{Py}_3\text{Cr}(\text{CO})_3\text{-Et}_2\text{O}\cdot\text{BF}_3$; (b) BuLi ; (c) RX ; (d) Me_3SnCl .

In the reactions of these complexes with BuLi in ether at -70 °C, the Br or SnMe_3 substituents are readily replaced by lithium. Under these conditions, the resulting organolithium compounds neither decompose nor undergo isomerisation. Subsequently, the latter compounds react with various electrophilic reagents to give the complexes **39c–l** or **40c–j** in yields varying from 50% ($\text{R} = \text{Cl}$) to 90% ($\text{R} = \text{D}$). It appeared that the reaction must be performed in ether because this reaction in THF is essentially complicated by intramolecular and intermolecular Li-H exchange (see below).⁹⁴

One of procedures for the selective introduction of a substituent into the coordinated ring involves direct metallation of tricarbonyl(η^6 -naphthalene)chromium (**4**) followed by treatment of the resulting organolithium compound with an electrophilic reagent.⁹³ It is known that coordination with the tricarbonylchromium group leads to a substantial increase in the acidity of the arene protons (the $\text{p}K_a$ values decrease by 6–7⁹⁵). The reaction with the use of BuLi as the metallating agent in THF at -78 °C proceeded nonselectively both at positions 1 and 2 of the coordinated ring to form mixtures of complexes following reactions with electrophiles.

RX = D₂O, MeI, Me₃SiCl, Me₃SnCl.

If lithium salts are generated at a temperature below $-78\text{ }^{\circ}\text{C}$, the ratio between the isomers **A** and **B** in the mixture depends on the nature of the substituent.

RX	Total yield (%)	The ratio A : B
D ₂ O	87	0.80
MeI	66	0.56
Me ₃ SnCl	74	0.44
Me ₃ SiCl	45	0.31

The replacement proceeded regioselectively at position 2 (the yield was 20%) only in the reactions of lithium salts with I₂.

Kündig *et al.* demonstrated⁸³ that the use of sterically hindered 2,2,6,6-tetramethylpiperidyllithium instead of BuLi made it possible to perform regioselective metallation of tricarbonyl(η^6 -naphthalene)chromium. In this case, the replacement occurred exclusively at position 2, which may be due to steric hindrances to electrophilic attack at position 1.

III. Studies of mechanisms and kinetics of rearrangements in tricarbonylchromium complexes of polycyclic arenes

Elucidation of the mechanism is the vital problem in studies of chemical processes. For inter-ring haptotropic rearrangements in tricarbonylchromium complexes of polycyclic arenes, it is important to determine whether the reaction proceeds through an intramolecular or intermolecular dissociation mechanism. In the first case, the migration of the Cr(CO)₃ group along the ligand plane occurs without the cleavage of bonds with the ligand. In the second case, the Cr(CO)₃ group is eliminated from one ring of the ligand and passes into solution. Then this group is coordinated by solvent molecules containing a heteroatom followed by addition to another ring of the same ligand or to another ligand. Bimolecular reactions of the complexes can proceed as well (either with each other⁹⁶ or with free ligands formed upon thermal destruction of the complexes). The latter are accompanied by the migration of the tricarbonylchromium group in the ligand, *i.e.*, IHR can occur through an intermolecular exchange mechanism.

Previously, the intramolecular mechanism of η^6, η^5 -IHR in isomeric fluorenyl complexes **2** and **3** was confirmed by cross experiments.^{42,43} An analogous approach was used in studies of the mechanism of η^6, η^5 -IHR in tricarbonylchromium complexes of naphthalene derivatives. For this purpose, the redistribution of the tricarbonylchromium group between naphthalene and perdeuterionaphthalene was examined.⁹³ It was found that even prolonged heating ($90\text{ }^{\circ}\text{C}$, $>40\text{ h}$) of the complex **39e** with perdeuterionaphthalene in anhydrous decane did not lead to migration of the tricarbonylchromium group to perdeuterionaphthalene. Although the **39e** $\rightleftharpoons$ **40e** inter-ring haptotropic migration

occurred under these conditions, the (η^6 -C₁₀D₈)Cr(CO)₃ complex was not formed. According to the data of mass spectrometry with the use of chemical ionisation, heating of (η^6 -C₁₀H₈)Cr(CO)₃ in the presence of perdeuterionaphthalene at $130\text{ }^{\circ}\text{C}$ (*i.e.*, at a temperature which is substantially higher than that required for IHR to proceed at a noticeable rate) for 6 h afforded only a small amount ($<5\%$) of (η^6 -C₁₀D₈)Cr(CO)₃.⁹³ However, in the reactions with the use of benzene derivatives (which coordinate the tricarbonylchromium group much more readily than polycyclic aromatic compounds) as the solvent, the migration of the Cr(CO)₃ group to monocyclic arene was observed even at $90\text{--}130\text{ }^{\circ}\text{C}$ and monocyclic complexes were obtained in yields of up to 20%. The complete replacement of naphthalene by monocyclic arene was achieved only upon heating of (η^6 -C₁₀H₈)Cr(CO)₃ in unsubstituted benzene ($140\text{ }^{\circ}\text{C}$, 6 h).

Therefore, even before IHR were found to occur in naphthalene complexes, investigations of these compounds have demonstrated that isomerisation can proceed according to both intramolecular and intermolecular mechanisms depending on the nature of the solvent. Later, the most convincing evidence that IHR in tricarbonylchromium complexes of monosubstituted naphthalenes proceeds through an intramolecular mechanism was obtained with the use of enantiomerically pure compounds.

Since chiral organometallic compounds are used in asymmetric synthesis and catalysis, they attract growing interest of researchers in organometallic chemistry.⁹⁷ Although the use of chiral compounds for studying the mechanisms of purely organic reactions has long been a classical method, this approach to investigation of the mechanism of IHR has been used only recently.⁹⁸ With the aim of elucidating the mechanism of η^6, η^6 -IHR in tricarbonylchromium complexes of naphthalene derivatives possessing planar chirality, the ability of their individual enantiomers to retain or lose optical activity in the course of the rearrangements was examined. If η^6, η^6 -IHR proceeds according to an intramolecular mechanism, the optical activity should be retained and isomeric complexes, for example, **39h** and **40h** (for which this process was studied in most detail), should be present in the equilibrium mixture only as either *R* or *S* forms.

If the rearrangement proceeds through either a dissociation or exchange intermolecular mechanism, the individual enantiomer should undergo racemisation due to the equally probable attacks of the tricarbonylchromium group [free ('hot'), σ -bonded to the solvent molecule containing a heteroatom or π -bonded to the solvent molecule, which does not contain a heteroatom (benzene or toluene)] on the arene from opposite sides. In this case, both

isomeric complexes containing the $\text{Cr}(\text{CO})_3$ group in either substituted or unsubstituted ring should be present in the equilibrium mixture both as the *R* and *S* forms.

Some planar-chiral tricarbonylchromium complexes of substituted naphthalenes can be separated by HPLC on an optical Chiracel OD column (Diacel, Japan).⁹⁹ Previously,¹⁰⁰ it had been demonstrated that this column, with modified cellulose as the support, is very efficient for separation of enantiomers of transition metal complexes, including tricarbonylchromium complexes of arenes.¹⁰¹ For a number of complexes of monosubstituted naphthalenes, very high selectivity factors of separation (α)

$$\alpha = \frac{t_2 - t_0}{t_1 - t_0},$$

were achieved, where t_0 is the retention time of the compound not retained (3.35 min) and t_1 and t_2 are the retention times of the enantiomers, which are eluted successively. For example, the selectivity for the complex **40b** was 5.23! The results of HPLC are given in Table 5.

Table 5. Data on separation of enantiomers of tricarbonylchromium complexes of naphthalene derivatives by HPLC on a Chiracel OD column.

Complex 39	t_1 /min	t_2 /min	α	Complex 40	t_1 /min	t_2 /min	α
l	13.32	14.00	1.07	j	9.65	10.35	1.11
f	11.30	11.30	1.00	f	11.53	12.32	1.09
h	7.33	8.66	1.33	h	6.00	14.66	4.27
j	8.65	10.64	1.37	b	6.53	20.00	5.23
k	12.00	17.37	1.62	i	10.00	14.30	1.65
e	12.2	14.69	1.28	e	11.66	18.00	1.76
i	7.34	8.00	1.16	a	8.53	15.20	2.29
g	6.26	8.06	1.62	g	6.66	9.35	1.81

Note. The rate of the mobile phase [9 : 1 (v/v) n-hexane – propan-2-ol] was 10 ml min⁻¹.

To elucidate the mechanism of IHR in the tricarbonylchromium complexes of monosubstituted naphthalenes, **39h** and **40h**, the possibility of their enantiomers retaining optical activity in the course of the rearrangements (85 °C, C_6F_6 or toluene or C_6F_6 with 5% of THF) was examined. The chromatogram (Fig. 1*a*) of one

of the enantiomers of the complex **39h** in C_6F_6 was obtained. [It should be noted that the absolute configuration was determined (for example, by X-ray diffraction analysis) for none of the complexes.] As the inter-ring haptotropic rearrangement proceeds (C_6F_6 , 85 °C, 40 h), two intense peaks appear on the chromatogram. One of them corresponds to an enantiomer of **39h** (peak 1) and the second peak corresponds to an enantiomer of **40h** (peak 2), *i.e.*, the $\mathbf{39h} \rightleftharpoons \mathbf{40h}$ equilibrium occurs ($K_{\text{eq}} = [\mathbf{40h}]/[\mathbf{39h}] = 17.26$). The portions of enantiomers of **39h** (peak 3) and **40h** (peak 4) with another configurations were $\leq 1\%$ (Fig. 1*b*). Analogous results were obtained in the case of the $\mathbf{39h} \rightleftharpoons \mathbf{40h}$ rearrangement in decane.

The absence of racemisation proves that IHR in inert non-solvating solvents through an intramolecular mechanism without participation of dissociation and exchange processes. In this case, the $\text{Cr}(\text{CO})_3$ group ‘slips’ along the plane of the π -ligand, bonding with the ligand being retained. However, the degree of racemisation in pure toluene under the same conditions is $\sim 20\%$ (Fig. 1*c*), *i.e.*, IHP in aromatic solvents proceeds to some extent through an intermolecular exchange mechanism.

In the reaction performed under the same conditions but in C_6F_6 with the addition of 5% of THF, the complexes **39h** and **40h** underwent virtually complete racemisation ($\geq 75\%$) (Fig. 1*d*). For some other complexes, analogous results were achieved upon addition of 10% of dibutyl ether to C_6F_6 . Therefore, thermally induced η^6, η^6 -IHR in tricarbonylchromium complexes of naphthalene derivatives in the presence of solvating solvents proceeds primarily by the dissociation intermolecular mechanism.

The use of chiral complexes shows considerable promise for elucidation of fine details of the mechanism of organometallic reactions, in particular, IHR. For example, studies of racemisation of some complexes in the course of their rearrangements made it possible to determine the kinetic and thermodynamic parameters of IHP in the cases where these parameters cannot be obtained by other methods.

Based on the results of calculations by the extended Hückel method, Albright *et al.*⁴⁷ suggested that the presence of an exocyclic double bond should substantially promote η^6, η^6 -IHR in tricarbonylchromium complex of acenaphthylene **5**. The authors attempted to detect degenerate η^6, η^6 -IHR by dynamic NMR spectroscopy upon heating of the complex **5** in deuteriocalin to 160 °C. However, no broadening of lines caused by migration of the tricarbonylchromium group between the equivalent six-membered rings was observed. Apparently, the activation barrier is such that this rearrangement cannot be studied by two-dimensional NMR spectroscopy. However, the rearrangement can be examined without introduction of a label into the coordinated ring. The enantiomers of the complex **5** can be separated and each isomer should undergo racemisation in the course of IHR, which, in principle, allows one to determine the rate constant of the rearrangement as the rate constant of racemisation.

Figure 1. Chromatograms (HPLC on a Chiracel OD column) of the enantiomers of **39h** in C_6F_6 without heating (*a*) and with heating at 85 °C for 40 h in C_6F_6 (*b*), toluene (*c*) and the C_6F_6 –THF system (95 : 5) (*d*). Peaks (1) and (4) correspond to enantiomers of **39h** and peaks (2) and (3) correspond to enantiomers of **40h**. The integrated intensities of peaks (1) and (4) and of peaks (2) and (3) on the chromatogram (*d*) are equal.

1. η^6, η^6 -Rearrangements in tricarbonylchromium complexes of naphthalene derivatives

The kinetics of IHR in a number of tricarbonylchromium complexes of monosubstituted naphthalenes was studied by NMR spectroscopy. The rearrangements were performed in C_6F_6 at 85 °C.⁹⁴ The $^2H\{^1H\}$ NMR spectra of the deuterium-containing complexes **39c,d** and **40c,d** were measured. For the remaining complexes **39** and **40**, the ^1H NMR spectra were recorded. The signals in the NMR spectra were repeatedly integrated and averaged.

Kinetic studies demonstrated that the parameters obtained are well reproduced for pairs of the complexes, which differ in the position of the $Cr(CO)_3$ group, and are independent of a particular isomer chosen as the starting one. The typical kinetic curves for a pair of the complexes **39g** and **40g** are shown in Fig. 2.

Figure 2. Kinetic curves of isomerisation of the tricarbonylchromium complexes of 1-trimethylsilylnaphthalene **39g** (**1**) and **40g** (**2**) (starting from **39g**).

The 2-iodonaphthalene complex **40k**, unlike the remaining tricarbonylchromium complexes of substituted naphthalenes, was demonstrated to be irreversibly rearranged to the isomeric complex **39m**. However, attempts to measure the kinetic parameters of the rearrangement failed due to instability of both complexes in all solvents under study.

It should be noted that no noticeable destruction of the remaining compounds accompanied by the appearance of free ligands in the reaction mixtures was observed. In all cases, the rearrangements

39k	0.15 ± 0.01	4.36 ± 0.06	0.034	30.6 ± 0.4
39l	0.40 ± 0.01	3.46 ± 0.06	0.12	30.2 ± 0.8

^a Calculations were performed based on the data reported in Ref. 83; cyclohexane- d_{12} was used as the solvent.

are described with a high degree of accuracy by a model of a reversible first-order reaction. The kinetic and thermodynamic parameters of the rearrangements of the complexes **39** in solutions in C_6F_6 are given in Table 6.

2. η^6, η^6 -Rearrangements in tricarbonylchromium complexes of naphthalene-related ligands

The kinetics of rearrangements in isomeric (η^6 -dimethylsilaacenaphthene)tricarbonylchromium complexes **41** and **42**, related to naphthalene complexes, was studied. The complexes **41** and **42** were prepared starting from dimethylsilaacenaphthene by the Öfele reaction in 76% yield.¹⁰²

The **41** : **42** ratio was equal to 1 : 6. *i.e.*, as discussed above, the tricarbonylchromium group tends to occupy the position in the ring containing an electron-donating substituent. Under conditions of TLC, the complexes **41** and **42** are characterised by virtually identical mobilities due to which they were separated by HPLC.

At 75–130 °C, the kinetically less stable complex **41** in C_6F_6 underwent rearrangement to the thermodynamically more stable complex **42**.

The content of the complex **42** in the equilibrium mixture was higher than 70%, which made it possible to measure a large number of points for the time dependence of the concentration, thus improving the accuracy and reliability of the experimental data. The kinetic data measured for the forward and back processes agree well with each other.¹⁰³

The relative concentrations of the complexes **41** and **42** were determined by repeated integration followed by averaging of the well-resolved signals for the protons of the methyl groups in the ^1H NMR spectra. The measurements were carried out in the temperature range of 105–118 °C because the rate of IHR at temperatures below 100 °C is very low, whereas at temperatures above 118 °C the complexes decompose (in the NMR spectrum, a signal for the protons of the methyl groups of the ligand appears at δ 0.52). The dependence of the concentration of the isomer **42** on the time (t) was calculated according to the equation for a reversible first-order reaction:¹⁰⁴

$$\ln \left(\frac{A_0 - A_e}{A_t - A_e} \right) = (k_1 + k_2) \Delta t,$$

where A_e , A_0 and A_t are the equilibrium, initial and actual concentrations of the complex **42**, respectively. The linear kinetic dependences were processed by the least-squares method. The kinetic dependences in the above-mentioned temperature range are shown in Fig. 3. The rate constants for the back and forward reactions **41** $\rightleftharpoons$ **42** are given in Table 7. The activation parameters of this rearrangement are given below.

Reaction	E_a /kcal mol ⁻¹	$\Delta H^\ddagger$ /kcal mol ⁻¹	$\Delta S^\ddagger$ /e.u.	$\Delta G^\ddagger$ /kcal mol ⁻¹
41 $\rightarrow$ 42	26.9 ± 0.8	26.1 ± 0.8	-8.1 ± 0.2	30.0 ± 1.0
42 $\rightarrow$ 41	26.7 ± 0.8	25.9 ± 0.8	-10.4 ± 0.2	30.5 ± 1.0

These results agree well with those reported in the literature for the related systems, in particular, for tricarbonylchromium complexes of methyl-⁸³ and methoxynaphthalenes.⁸⁴ The results of studies are unambiguously indicative of the absence of the

Figure 3. Kinetic first-order dependences obtained for IHR in the tricarbonylchromium complexes of η^6 -dimethylsilaacenaphthene **41** and **42** (starting from **41**) at 105 (**1**), 110 (**2**) and 118 °C (**3**).

Rate constant $/s^{-1}$	Temperature /°C			
	85	105	110	118
$10^5 k_1$	1.15 ± 0.10^a	11.8 ± 0.4	14.0 ± 1.2	37.3 ± 1.1
$10^5 k_2$	0.64 ± 0.06^a	5.1 ± 0.2	5.80 ± 0.5	7.68 ± 0.8

^a The rate constants were calculated taking into account the thermodynamic parameters.

contribution of the intermolecular dissociation mechanism to the IHR under examination. This is also confirmed by the relatively small negative entropies of activation both of the back and forward reactions because dissociation processes are generally characterised by higher negative $\Delta S^\ddagger$ values.⁶¹

The η^6, η^6 -inter-ring haptotropic rearrangements in a number of naphthalene-related tricarbonylchromium complexes in degassed anhydrous decane (an inert nonsolvating solvent) were examined.^{105, 106} For example, four possible isomeric tricarbonylchromium η^6 -complexes **43**–**46** (two isomers with the *exo* configuration of the methyl group and two isomers with the *endo* configuration) were obtained starting from 1-methylacenaphthene under the conditions of the Öfele reaction¹⁰⁵ in 37% total yield; the **43** : **44** : **45** : **46** ratio was 1 : 1 : 0.8 : 0.7. The complexes **43** and **44** were isolated in the individual state by HPLC. Attempts to separate the complexes **45** and **46** failed, but their mixture enriched with the isomer **45** was obtained (**45** : **46** = 3 : 1).

The individual complex **43** was prepared by deprotonation of (η^6 -acenaphthene)tricarbonylchromium (**47**) followed by the reaction of the resulting anion **48** with MeI.

The electron-withdrawing tricarbonylchromium group substantially increases the acidity of the protons bound to the sp^3 -hybridised carbon atoms as a result of which deprotonation proceeds regioselectively only at the CH_2 group that is located more closely to the substituted ring. The reaction of the anion **48** with MeI is stereoselective. The methyl group attacks the negatively charged carbon atom from the side opposite to the bulky tricarbonylchromium group. The low yield (23%) of the target product **43** indicates that the anion **48** is unstable and decomposes to form, apparently, the corresponding carbanion. This agrees with the fact that 1-methylacenaphthene was isolated from the reaction mixture in a substantial amount. Previously, the stereo- and regioselectivity of such reactions was established for derivatives of fluorene⁷⁸ and indene⁷⁹ by ^1H NMR spectroscopy (the ASIS effect) and X-ray diffraction analysis. In the case of the complex **43**, irradiation of the methyl multiplet in the nuclear Overhauser effect (NOE) experiment led to an increase in the intensity of the corresponding doublet for the protons of the coordinated ring, which proves that the methyl group is located in the vicinity of this ring. In addition, the signal for the protons of the methyl group in the complex **43** is observed at higher field than those in the complexes **44**–**46**. Based on the ASIS effect,^{70, 79} this fact is indicative of the *exo* structure of **43**.

The η^6, η^6 -inter-ring haptotropic rearrangement

proceeded in solution in decane at 90 °C with a noticeable rate [$k_1 = 1.00 \times 10^{-5} s^{-1}$, $K_{eq} = 1.13$, $\Delta G^\ddagger(363) = 29.7 kcal mol^{-1}$] with retention of the *exo* configuration of the methyl group. Under the same conditions, the rearrangements of the complexes **45** and **46** proceeded with retention of the *endo* configuration of the methyl group. Isomerisation was monitored by HPLC. The addition of 10% of THF to decane resulted in the formation of a mixture of all four possible stereoisomers without regard to the particular isomer used as the starting compound. This is unambiguous evidence that the rearrangements in a nonsolvating medium proceed through an intramolecular mechanism, whereas the rearrangements in the presence of solvating solvents occur according to an intermolecular mechanism.¹⁰⁵ These results agree with the data of more recent studies confirming the retention of optical activity of enantiomerically pure tricarbonylchromium complexes of naphthalene derivatives in the course of η^6, η^6 -IHR.⁹⁸

The η^6, η^6 -inter-ring haptotropic rearrangements in isomeric tricarbonylchromium complexes of methylacenaphthylene (**49** and **50**) were examined.¹⁰⁶ A mixture of these complexes was obtained by the Öfele reaction in 78% yield (the **49** : **50** ratio was 45 : 55). The compounds **49** and **50** were isolated in pure form by HPLC.

The necessity of studying IHR in methylated derivatives of tricarbonylchromium complexes of acenaphthylene stems from the fact that attempts to introduce a label directly into the six-membered ring of (η^6 -acenaphthylene)tricarbonylchromium (**5**)¹⁰⁷ [as in the case of tricarbonyl(η^6 -naphthalene)chromium] failed. The course of isomerisation

in solution in decane at 90 °C was monitored by NMR spectroscopy and HPLC. The rearrangement proceeded somewhat more rapidly [$k_1 = 2.29 \times 10^{-5} \text{ s}^{-1}$, $K_{\text{eq}} = 1.18$, $\Delta G^\ddagger(363) = 29.1 \text{ kcal mol}^{-1}$] than those in the case of analogous acenaphthene or naphthalene complexes. This fact agrees with the results of theoretical analysis.⁴⁷ In the cited study, potential energy surfaces were calculated by the extended Hückel method and it was demonstrated that the presence of an exocyclic double bond in the polyaromatic ligand should lead to a decrease in the activation barrier to IHR.

1,1-Dimethyl-1-silaphenalene (**51**) also contains an exocyclic double bond and two different aromatic fragments suitable for coordination to the transition metal atom. Hence, one would expect that η^6, η^6 -IHR will also readily proceed in the corresponding isomeric tricarbonylchromium complexes.

The compositions of the products of the reaction of 1,1-dimethyl-1-silaphenalene (**51**) with chromium carbonyls performed under different conditions were examined.¹⁰⁸ It was found that the reaction of the compound **51** with $(\text{NH}_3)_3\text{Cr}(\text{CO})_3$ in boiling dioxane or with $(\text{MeCN})_3\text{Cr}(\text{CO})_3$ in boiling THF afforded complex **52** as the only product. According to the data of ^1H and ^{13}C NMR spectroscopy, the tricarbonylchromium group in the complex **52** is coordinated at the silicon-substituted ring.

- (a) $(\text{NH}_3)_3\text{Cr}(\text{CO})_3$, dioxane, 100 °C (42%);
(b) $(\text{MeCN})_3\text{Cr}(\text{CO})_3$, THF, 64 °C (6%).

Both possible isomers **52** and **53** were formed only when the reaction temperature was decreased. The reaction of the compound **51** with $(\text{MeCN})_3\text{Cr}(\text{CO})_3$ at 34 °C gave rise to a mixture of the complexes **52** and **53** in a total yield of $\leq 1\%$. The reaction of the compound **51** with $\text{Py}_3\text{Cr}(\text{CO})_3$ at 0 °C afforded a mixture of the isomers in 54% yield with the complex **53** predominating.

- (a) $(\text{MeCN})_3\text{Cr}(\text{CO})_3$, 34 °C (1%) (**52**:**53** = 3:2);
(b) $(\text{Py})_3\text{Cr}(\text{CO})_3$, 0 °C, 1 h (54%) (**52**:**53** = 2:3).

This is yet another example of the effect of thermodynamic and kinetic factors on the formation of tricarbonylchromium complexes with polycyclic aromatic ligands.

The complexes **52** and **53** were identified by ^1H and ^{13}C NMR spectroscopy and mass spectrometry. Since the complex **53**, unlike the complex **52**, is unstable under conditions of TLC, it was not isolated in pure form. The complex **52** decomposes upon storage of a mixture of the complexes even in the solid state.

Heating of a mixture of the complexes **52** and **53** in the C_6F_6 – C_6D_{12} system or in heptane to 90 °C for 5 h resulted in the complete rearrangement of the complex **53** to form the thermodynamically more stable complex **52**. The absence of traces of the free ligand in the reaction mixture and the fact that the rearrangement proceeds in nonpolar media are indicative of an intramolecular mechanism of IHR. The reverse **52** $\rightarrow$ **53** rearrangement was observed in none of the experiments.

The rearrangements of silaphenalene complexes proceed under milder conditions than the rearrangements of silaacenaph-

thene complexes. This is indicative of a decrease in the activation energy of the process, although the rate constant of this process was not estimated. It should be noted that the isomer in which the tricarbonylchromium group is coordinated at the silicon-substituted ring is thermodynamically more stable in the case of the silaphenalene complexes **52** and **53** and the silaacenaphthene complexes **41** and **42**. The complex **52** acts as a catalyst of hydrosilylation of butadiene. The catalytic action is achieved upon addition of 0.2% of the compound **52** to an equimolar mixture of diene and silane.¹⁰⁹ The characteristic feature of the reaction is its regio- and stereospecificity. Hydrosilylation afforded (*Z*)-1-triethoxysilylbut-2-ene as the only product in a yield of $\geq 90\%$. Its structure was established by ^1H and ^{13}C NMR spectroscopy.¹⁰⁹

The catalytic activity of tricarbonylchromium complexes of polycyclic arenes (naphthalene, phenanthrene and anthracene) in hydrogenation of conjugated dienes and acetylenes, isomerisation of dienes, Kharasch addition of CCl_4 to alkynes, *etc.* was attributed to the ability of the tricarbonylchromium group, which is η^6 -bonded to the arene ring, to change the mode of bonding to form an η^4 -intermediate.¹¹⁰

3. η^6, η^6 -Rearrangements in tricarbonylchromium complexes of biphenylene

Tricarbonylchromium complexes of biphenylene are of considerable interest from the viewpoint of studies of η^6, η^6 -IHR. The η^6 -mononuclear (**54**) and η^6 -binuclear (**55**) tricarbonylchromium complexes of biphenylene were synthesised by the Öfele reaction in 66% total yield (**54**:**55** = 15.5:1).¹⁰⁶ The individual complexes were isolated from the reaction mixture by TLC.

Previously, the complexes **54** and **55** were obtained in the reaction of biphenylene with $(\text{NH}_3)_3\text{Cr}(\text{CO})_3$ in boiling dioxane in a similar ratio.^{111,112} It was assumed that the binuclear complex **55**, like the structurally similar binuclear complex of fluorene,⁷⁸ contains the $\text{Cr}(\text{CO})_3$ group in the *trans* position because such a structure was established for the biphenylene binuclear complex of molybdenum $\eta^6, \eta^6\text{-C}_{12}\text{H}_8[\text{Mo}(\text{CO})_3]_2$ by X-ray diffraction analysis.¹¹³

The directed introduction of substituents into the coordinated ring was performed by a procedure analogous to that used in the case of tricarbonyl(η^6 -naphthalene)chromium. Metallation of the complex **54** with butyllithium in THF proceeded regio- and stereoselectively to form complexes **56a,b** in which the label is located exclusively at position 1 of the coordinated ring.

R = D (**a**), Me (**b**).

The η^6, η^6 -inter-ring haptotropic rearrangements in tricarbonylchromium complexes of 1-substituted biphenylenes **56a,b** containing the planar ligand (according to the data of X-ray diffraction analysis) proceed more slowly than the corresponding

rearrangements in monosubstituted naphthalene complexes. Thus, the isomers **57a,b** were detected in the reaction mixture obtained upon heating of the complexes **56a,b** only at temperatures above 100 °C, IHR proceeding with a noticeable rate at 120 °C. In the course of the rearrangement, the tricarbonylchromium group migrates between the nonequivalent six-membered rings.

R = D (**a**), Me (**b**).

According to the data of ^2H NMR spectroscopy, the equilibrium for the deuterium-containing complexes **56a** and **57a** in decane was established at 120 °C in 6 h [$k_1 = 4.79 \times 10^{-5} \text{ s}^{-1}$, $K_{\text{eq}} = 1.00$, $\Delta G^\ddagger(393) = 31.00 \text{ kcal mol}^{-1}$]. The η^6, η^6 -rearrangements in the methyl-substituted complexes **56b** and **57b** proceeded somewhat more slowly [$k_1 = 3.41 \times 10^{-5} \text{ s}^{-1}$, $K_{\text{eq}} = 1.10$, $\Delta G^\ddagger(393) = 31.25 \text{ kcal mol}^{-1}$].

4. Synthesis of tricarbonylchromium complexes of substituted biphenyls and studies of the mechanism and kinetics of rearrangements in these complexes

Until the mid-1980s, the data on IHR in complexes with bi- or polycyclic open ligands were virtually lacking in the literature. Biphenyl complexes represent the simplest model systems.^{114–116} More complex analogues, *viz.*, tricarbonylchromium complexes of 1,3,5-triphenylbenzene,¹¹⁷ triphenylene,¹¹⁸ 9-phenylanthracene,¹¹⁹ 9,10-dihydrophenanthrene,¹²⁰ siloxaphenanthrene,¹²¹ 9,9-dimethyl-9-silafluorene,¹²² fluorene,⁷⁴ carbazole⁷⁴ and fluoranthene,^{91,123} were also prepared. Procedures for the introduction of a label into tricarbonylchromium complexes of biphenyl derivatives are scarce. [The only procedure for the introduction of a label into (η^6 -biphenyl)tricarbonylchromium involving the reaction of its stannylated derivative with butyllithium has been reported.¹²⁴] Only two examples of rearrangements in complexes of biphenyl and its derivatives with transition metals were described before 1985. The inter-ring haptotropic rearrangement in the ethylbiphenyl complex of iridium was described in the study¹²⁵ with reference to the Ph. D. Thesis of Mellea.¹²⁶

The reaction proceeded under mild conditions (40 °C) and the equilibrium ratio of the isomers was 1 : 1.

Isomerisation of tricarbonylchromium complexes of 9-phenylanthracene¹¹⁹ proceeded under more drastic conditions (dibutyl ether, 130 °C). The tricarbonylchromium group successively migrates first over the biphenyl system and then over the fused system to the peripheral rings.¹¹⁹ The mechanism of this rearrangement is not entirely known. Although the authors assumed that the rearrangement proceeds through an intermolecular mechanism, this statement is questionable and calls for special studies.

Recently, the first example of η^6, η^6 -IHR in sandwich chromium complexes was reported.¹²⁷ The vapour-phase (350 °C)

reaction of fluoranthene with metal vapour was demonstrated to afford complex **58** as the major product along with isomeric complex **59**. In the former complex, the chromium atom is located at the benzene rings, whereas one ligand in the complex **59** is coordinated at the 'naphthalene' fragment.

Prolonged heating (for several days) of the isomer **59** in deuteriobenzene at 100 °C resulted in the reversible rearrangement to form complex **60** in which both ligands are coordinated at the 'naphthalene' fragment, *i.e.*, η^6, η^6 -IHR of the biphenyl type occurred.

Migrations of the $\text{Cr}(\text{CO})_3$ group in biphenyl-related open systems, *viz.*, in tricarbonylchromium complexes of diphenylalkanes [$(\eta^6\text{-Ph})\text{Cr}(\text{CO})_3(\text{CH}_2)_n\text{Ph}$ ($n = 1-4$), unsymmetrically substituted *cis*- and *trans*-stilbenes and 1,1-diarylethylenes, were observed.^{128,129} At 140 °C, the $\text{Cr}(\text{CO})_3$ group in complexes of substituted stilbenes (**61** and **62**) and diarylethylenes migrates between the rings containing the methyl and CD_3 groups.

The rate of the intramolecular rearrangement is noticeably higher than that of the rearrangement proceeding through the dissociation mechanism, which is evidenced by an insignificant amount of products of replacement of the ligand in these complexes by the 'trapping' ligand.

The rate constants of IHR were determined for the *cis*- and *trans*-isomers of stilbene complexes at 140 °C. For the rearrangement **61** $\rightarrow$ **62** proceeding by an intramolecular mechanism, the rate constants are $4.20 \times 10^{-5} \text{ s}^{-1}$ and $6.95 \times 10^{-5} \text{ s}^{-1}$ for the *trans*- and *cis*-isomers, respectively. The rate constants of exchange through a dissociation mechanism are substantially smaller ($0.18 \times 10^{-5} \text{ s}^{-1}$ and $0.066 \times 10^{-5} \text{ s}^{-1}$, respectively).

a. Synthesis of tricarbonylchromium complexes of substituted biphenyls

It was not until 1985 that progress was achieved in the synthesis of tricarbonylchromium complexes of biphenyl derivatives labelled at one of the rings. For this purpose, insignificantly modified

procedures, which had been developed primarily for the synthesis of tricarbonylchromium complexes of monocyclic arenes, were used. The reactions of the ligands (biphenyl and 2-bromo-, 4-bromo- and 4-trimethylstannylbiphenyls) with chromium carbonyls $L_3Cr(CO)_3$ ($L = CO$,¹³⁰ NH_3 ,⁸⁷ or Py ;⁸⁸ $L_3 = C_{10}H_8$,⁴⁶) afforded complexes **63–68** in moderate yields (30%–40%).¹³¹

(a) $L = CO$, $R = H$, $Bu_2O:THF = 1:6$, $140^\circ C$, 4 h; (b) $L = CO$, $R = 2-Br$, $Bu_2O:THF = 1:5$, $140^\circ C$, 5 h; (c) $L = CO$, $R = 4-Br$, $Bu_2O:THF = 1:7$, $140^\circ C$, 7 h; (d) $L = NH_3$, $R = 4-SnMe_3$, dioxane, $100^\circ C$, 2 h.

Either both possible isomers or only one isomer are formed depending on the nature of the substituent in the ligand, its position and the type of chromium carbonyl used in the reaction. Thus the reaction of 4-trimethylstannylbiphenyl with $(NH_3)_3Cr(CO)_3$ gave rise exclusively to the complex **68**. Due to the strong electron-donating properties of the trimethylstannyl group, the electron density at the substituted ring increases resulting in coordination of the $Cr(CO)_3$ group at this ring. Analogously, the Rausch reactions of 2- and 4-bromobiphenyls with $(NH_3)_3Cr(CO)_3$ (dioxane, $100^\circ C$, 2 h) afforded only the complexes **65** or **67** containing the $Cr(CO)_3$ group in the unsubstituted ring due to the electron-withdrawing properties of bromine (kinetic control). Prolonged heating of the bromo derivatives **65** or **67** with $Cr(CO)_3$ in a mixture of dibutyl ether and THF at $140^\circ C$ (thermodynamic control) yielded a mixture of the isomers **64** and **65** or **66** and **67**, respectively, with the complex containing the bromine atom in the uncoordinated ring predominating. Although the isomers can be readily isolated by TLC, the above-considered procedure cannot be used for the preparative synthesis of complexes containing halogen in the coordinated ring.

Based on analysis of the above-considered results, it can be stated with assurance that individual complexes containing a substituent either in the uncoordinated or coordinated rings can be selectively prepared starting from bromo- or trimethylstannyl derivatives of biphenyl by the Rausch reaction. Subsequently, the bromine atom or the $SnMe_3$ group can be first replaced by lithium under the action of $BuLi$ and then by the R substituent by the reactions of the lithium derivatives with electrophilic reagents RX .

On the whole, the selective synthesis of tricarbonylchromium complexes of substituted biphenyls by the exchange reaction of bromine for lithium is analogous to the procedure used for the preparation of naphthalene complexes. The reaction of the complex **67** containing the tricarbonylchromium group in the unsubstituted ring with $BuLi$ in anhydrous ether at $-78^\circ C$ led to the replacement of Br by Li . The lithium derivative is stable at low temperatures and reacts rather smoothly with electrophiles (D_2O ,

Me_3SnCl , MeI , etc.) at $0^\circ C$ to form selectively labelled complexes **69–71** containing the label at position 4 of the uncoordinated ring.¹³¹

$RX = D_2O$, Me_3SnCl , MeI ; $R = D$ (**69**), Me (**70**), Me_3Sn (**71**).

Attempts to prepare the corresponding complexes containing a label at position 2 of the uncoordinated ring starting from the compound **65** have not met with success even when the reactions were performed at room temperature, which is, apparently, due to steric hindrance to the replacement of Br by Li .

It should be noted that it is necessary to perform these reactions, like the synthesis of naphthalene complexes, in ether because direct metallation of the coordinated ring in THF proceeds more rapidly than the replacement of Br by Li . Thus the reaction of the derivative **65** with $BuLi$ in THF followed by treatment of the reaction mixture with methyl iodide gave rise to the complexes **72a–c** (**72a**:**72b**:**72c** = 13:57:30). The low content of the complex **72a** in the mixture is attributable to steric hindrances, which appear either in the stage of metallation or, what is less probable, in the stage of the reaction of the lithium derivatives with MeI .

$R = 2-Me$ (a), $3-Me$ (b), $4-Me$ (c).

The replacement of the Me_3Sn group by lithium in the biphenyl complexes **68** was not performed. However, by analogy with the corresponding naphthalene complexes, complexes selectively substituted at the coordinated ring can be apparently prepared according to this procedure.

$RX = D_2O$, MeI , Me_3SiCl , etc.

The synthesis of tricarbonylchromium complexes of substituted biphenyls by direct metallation of $(\eta^6$ -biphenyl)tricarbonylchromium was described. Thus the reaction of the complex **63** with $BuLi$ in THF was accompanied by metallation of the coordinated ring. Then the reaction of the resulting lithium derivatives with the electrophile RX at $-78^\circ C$ afforded a mixture of all three possible isomers.¹³¹

R = D (**a**), Me (**b**).

For example, the reactions of lithium derivatives with D₂O or MeI at $-78\text{ }^{\circ}\text{C}$ gave rise (according to the data of ²H NMR spectroscopy) to a mixture of deuterated complexes **73a**–**75a** in 84% total yield (**73a**:**74a**:**75a** = 10:65:25) or a mixture of methyl derivatives **73b**–**75b** in 17.5% total yield (**73b**:**74b**:**75b** = 12:58:30), respectively. The ratios of the isomers of deuterio- and methyl-containing derivatives are rather similar, which does not allow one to consider the effects of kinetic and thermodynamic control on their formation. Storage of the reaction mixture at $0\text{ }^{\circ}\text{C}$ for 1 h followed by treatment with MeI afforded only the isomer **73b**. Apparently, the 2-lithium-substituted derivative is the thermodynamically most stable compound and is predominantly formed through the replacement of H by Li. On the whole, the procedure for the synthesis involving metalation of the coordinated ring in the complex **63** is inferior to the above-described procedures (see Section III.1.b) in the preparative respect. However, the use of all available synthetic approaches enables one to prepare various tricarboxylchromium complexes of substituted biphenyls. It should be noted that in the general case these procedures are applicable to all polyaromatic arenes.

b. Studies of rearrangements in tricarboxylchromium complexes of substituted biphenyls

For all available tricarboxylchromium complexes of substituted biphenyls, the possibility of IHR was studied upon their heating in anhydrous oxygen-free decane in the temperature range of $140\text{--}174\text{ }^{\circ}\text{C}$ for 4–20 h.¹³¹

R = 4-SnMe₃ (**68**, **71**), 2-Br (**64**, **65**), 4-Br (**66**, **67**), 4-D (**69**, **75a**), 4-Me (**70**, **75b**).

The course of the rearrangement was monitored by withdrawing samples every 30 min and recording the ¹H NMR spectra (²H NMR spectra were measured for deuterated derivatives) to determine the isomer ratio. Heating was terminated if the isomer ratio ceased to change (according to the NMR data). In some cases, this approach made it possible to estimate the rate constants and equilibrium constants for IHR. The structures of the complexes were established by ¹H and ¹³C NMR spectroscopy.

The inter-ring haptotropic rearrangements in the biphenyl complexes **64**, **66** and **68** are irreversible. Heating of the stannylated derivative **71** in boiling decane ($174\text{ }^{\circ}\text{C}$, 5.5 h) resulted in the complete migration of the Cr(CO)₃ fragment from the unsubstituted ring to the substituted fragment to form the complex **68** [$k_2 = 6.42 \times 10^{-5}\text{ s}^{-1}$, $\Delta G^\ddagger(447) = 35.10\text{ kcal mol}^{-1}$], whereas the corresponding isomeric complex **68** did not undergo rearrangement under these conditions, *i.e.*, the reaction is actually irreversible. At $174\text{ }^{\circ}\text{C}$, the tricarboxylchromium group in the 2- and 4-bromophenyl derivatives (**64** and **66**) migrates irreversibly from the substituted ring to the unsubstituted one in 13 and 6 h, respectively [$k_1 = 2.23$ and $5.13 \times 10^{-5}\text{ s}^{-1}$, $\Delta G^\ddagger(447) = 36.04$ and $35.3\text{ kcal mol}^{-1}$ for the complexes **64** and **66**, respectively]. Reverse migration of the tricarboxylchromium group was not observed, which is evidence in favour of the irreversibility of IHR. Analysis of the kinetic data demonstrated that the rearrangement in the 2-bromo derivative **64** proceeds much more slowly than that

in the 4-bromo derivative **66**. Apparently, this is due to steric interactions in the complex **64** existing between the bulky bromine atom, on the one hand, and the *ortho*-proton of the adjacent ring and the organometallic group, on the other hand, resulting in the appearance of a twisting angle (a nonzero dihedral angle) and distortion of conjugation of the phenyl rings (see, for example, Refs 132 and 133). Ceccon *et al.*¹³⁴ also revealed the presence of the twisting angle and a noticeable degree of noncoplanarity of the five- and six-membered rings in the tricarbonylchromium complexes **29** and **30**. For the thermodynamically more stable (and, correspondingly, more populated) conformation of the *ortho*-derivatives of (η^6 -biphenyl)tricarbonylchromium, the degree of noncoplanarity of the six-membered rings is higher than that in the corresponding *para*-derivatives. This effect is manifested in a substantial decrease in NOE between the protons of the coordinated and uncoordinated rings due to an increase in the average distance between their *ortho*-protons. The appearance of the nonzero dihedral angle between the benzene rings agrees with the data obtained by the DFT method for tricarbonyl(η^6 -2-chlorobiphenyl)chromium containing the Cr(CO)₃ group in the unsubstituted ring, which was chosen instead of the 2-bromo derivative to simplify calculations. In this compound, the dihedral angle is 58.14° and the halogen and chromium atoms are oppositely directed.¹³⁵

The results of quantum-chemical calculations with the use of the HyperChem program (the PM3 method) for uncoordinated biphenyl and 2-bromobiphenyl also confirm the above-considered experimental and theoretical data. According to these calculations, the biphenyl molecule is virtually planar (the dihedral angle is 0.2°), whereas the phenyl rings in 2-bromobiphenyl are essentially noncoplanar (the dihedral angle is 52.9°).

It should also be noted that the corresponding dihedral angle in the tricarboxylchromium complex of unsubstituted biphenyl (calculations by the DFT method) is 21.38° , *i.e.*, coordination to the transition metal atom leads to an increase in steric hindrance.¹³⁵

The inter-ring haptotropic rearrangements in 4-deuterated and 4-methyl derivatives of tricarboxylchromium complexes of biphenyl, unlike those in the corresponding trimethylstannyl and bromo derivatives, are reversible. Heating of the complexes **75a,b** in decane at $174\text{ }^{\circ}\text{C}$ for 5 and 8 h, respectively, resulted in reversible rearrangements to form the isomeric complexes **69** and **70**, respectively ($K_{\text{eq}} = [\text{75a}]/[\text{69}] = 1.0$ and $K_{\text{eq}} = [\text{75b}]/[\text{70}] = 1.4$). The binuclear complex **76** was isolated from a mixture of the 4-methylbiphenyl complexes **70** and **75b** (which was formed as a result of IHR) by TLC in 5% yield.

The structure of the compound **76** was established by mass spectrometry and ¹H NMR spectroscopy. The formation of **76** indicates that insignificant dissociation of the complexes with elimination of the tricarboxylchromium group that passes into solution did occur under drastic thermal conditions even in inert nonsolvating decane. An alternative explanation assumes that a bimolecular reaction proceeded giving rise to a molecule of the binuclear complex **76** and the ligand from two molecules of the complex **75b**.

Therefore, inter-ring haptotropic rearrangements in tricarboxylchromium complexes of biphenyl derivatives proceed through an intramolecular mechanism. However, due to the high temper-

atures of the reactions, an intermolecular mechanism is realised to a small extent. This conclusion is consistent with kinetic evidence that metallotropic rearrangements in tricarbonylchromium complexes of diphenylalkanes proceed predominantly by an intramolecular mechanism.^{128, 129}

Analogous results were obtained upon heating of a mixture of the biphenyl complexes **73a**–**75a** containing deuterium in the coordinated ring in decane at 174 °C for 6 h. Under these conditions, the reversible rearrangement proceeded accompanied by migration of the tricarbonylchromium group from the deuterium-labelled ring to the deuterium-free ring. The ratio between the isomers containing deuterium in the coordinated and uncoordinated rings is close to unity in all three pairs of 2-, 3- and 4-deuterium-substituted complexes (according to the ^2H NMR data; acetone as the solvent).

When a mixture of complexes containing 2-, 3- and 4-methyl-substituted coordinated rings (**73b**–**75b**) was heated under the same conditions, only isomers **74b** and **75b** underwent rearrangements to form complexes containing substituents in the uncoordinated ring (K_{eq} is 1.6 and 1.4 for the isomers **74b** and **75b**, respectively).

The fact that IHR did not occur in the 2-methyl-substituted complex **73b**, as in the case of the corresponding bromo derivative, is attributable to the fact that the phenyl rings are essentially noncoplanar in the most populated rotamer. This is consistent with a decrease in NOE between the *ortho*-protons of the coordinated and uncoordinated rings in the complex **73b** (3%–4%) compared to the corresponding values obtained for the complexes **74b** and **75b** (7%–9%).

The dihedral angle in the 2-methylbiphenyl complex containing the $\text{Cr}(\text{CO})_3$ group in the unsubstituted ring calculated by the DFT method is 62.01°.¹³⁵

Interestingly, a mixture of 2-methyl-substituted complexes containing the $\text{Cr}(\text{CO})_3$ group either in the coordinated or uncoordinated rings did form from 2-methylbiphenyl and $\text{Cr}(\text{CO})_3$ upon refluxing in the dibutyl ether–THF system. The isomeric 2-methyl-substituted tricarbonylchromium complexes were separated by TLC. The isomer ratio (1.3 : 1) appeared to be similar to that obtained as a result of inter-ring haptotropic rearrangements in tricarbonylchromium complexes of 3- and 4-methyl-substituted biphenyls.

The absence of IHR in 2-methyl-substituted tricarbonylchromium complexes of biphenyl and the fact that their mixture can be readily obtained by the reaction of the ligand with chromium hexacarbonyl is additional evidence in favour of the intramolecular character of IHR. Therefore, a necessary condition of IHR to occur in complexes of substituted biphenyls and related ligands is a small degree of noncoplanarity of the rings (the dihedral angle should be smaller than 22°, as in the case of the biphenyl complex), which is impossible in 2-substituted complexes due to steric effects.

5. η^6, η^6 -Rearrangements in tricarbonylchromium complexes of biphenyl-related ligands

Biphenyl-related 10,10-dimethyl-10-sila-9-oxa-9,10-dihydrophenanthrene, which contains substituents possessing different electronic properties in both rings, is of interest. Tricarbonylchromium and -tungsten complexes of this compound were prepared by reactions with different chromium and tungsten carbonyls.^{121, 136} In the case of $\text{M} = \text{Cr}$, the bis(tricarbonyl)chromium complex $\mu\text{-}\eta^6\text{:}\eta^6\text{-C}_{12}\text{H}_8\text{OSiMe}_2[\text{Cr}(\text{CO})_3]_2$ (**79**) was formed in a small amount.

The six-membered rings in the tricarbonylchromium complexes **77a** and **78a** are noncoplanar and the dihedral angles between these rings are (according to the X-ray diffraction data) 20.4° and 15.5°, respectively.¹³⁷

Heating of the complex **77a** in anhydrous degassed decane at 130 °C led to IHR yielding the isomer **78a**. The equilibrium was established in 6 h. According to the data of ^1H and ^{13}C NMR spectroscopy, the **77a** : **78a** ratio was 12 : 1 (the same isomer ratio was obtained upon heating of the complex **78a**). In both cases, the ^1H NMR spectra of the equilibrium mixtures have low-intensity signals belonging to the ligand and the binuclear complex **79**. However, their total amount was no higher than 5% even after heating of the reaction mixture at 174 °C for 20 h. The binuclear complex and the ligand were formed due to either thermal destruction or bimolecular reactions proceeding in the complexes **77a** and **78a**. Analogously (but under substantially milder conditions), the inter-ring haptotropic rearrangement proceeded in the tricarbonyltungsten complex **77b**. After heating of **77b** in decane at 100 °C for 6 h, the ^1H NMR spectrum had additional signals, which were assigned to the isomer **78b** (**77b** : **78b** = 15 : 1). Attempts to isolate the complex **78b** from the reaction mixture by TLC failed and the ^1H NMR spectrum of the pure complex was not measured.¹³⁶

Fluoranthene is of considerable interest because η^6, η^6 -IHR both of the 'biphenyl' and 'naphthalene' types can proceed in this compound.

In this case, the complex **38** exists as two enantiomers, which are interconverted in the course of the 'naphthalene' rearrangement. Apparently, the kinetic parameters of such degenerate rearrangements may be determined from the rates of racemisation of the corresponding enantiomers in the future.

Heating of the η^6, η^6 -fluoranthene complex **38** in which the $\text{Cr}(\text{CO})_3$ group is located at the naphthalene fragment even at rather low temperature (in decane or benzene at 100 °C for 10 h) led to IHR to form the complex **37** in which the $\text{Cr}(\text{CO})_3$ group is located at the benzene ring.^{91, 123} On the contrary, prolonged heating (> 100 h) of the complex **38** under the same conditions did not give rise to the isomer **37**. The inter-ring haptotropic

rearrangement was not accompanied by substantial decomposition of the complexes or migration of the $\text{Cr}(\text{CO})_3$ group to the benzene ring, which is consistent with the results of other studies.^{46,90} It was demonstrated that when tricarbonyl(η^6 -naphthalene)chromium was heated in benzene, the migration of the tricarbonylchromium group to the benzene ring proceeded with a noticeable rate ($k_{\text{sub}} = 1.73 \times 10^{-4} \text{ s}^{-1}$)⁴⁶ only at 140 °C and was completed in 6 h.

The rate constant of the irreversible η^6, η^6 -inter-ring haptotropic rearrangement $38 \rightarrow 37$ was determined from the data of ^1H NMR spectroscopy (C_6F_6 as the solvent). The corresponding kinetic curves are shown in Figs 4 and 5. The rate constant of the rearrangement is equal to $(5.5 \pm 0.2) \times 10^{-6} \text{ s}^{-1}$; $E_a = 30.13 \text{ kcal mol}^{-1}$. The complexes **37** and **38** were separated by TLC and their structures were established by ^1H and ^{13}C NMR spectroscopy and X-ray diffraction analysis.

Therefore, IHR in planar fluoranthene complexes proceed under substantially milder conditions (80–90 °C) than those in open biphenyl complexes (even in the cases of 4-bromo- or 4-methyl-substituted complexes, IHP started at temperatures above 130 °C). At 100 °C, the replacement of the fluoranthene ligand by C_6D_6 in the course of η^6, η^6 -IHR was not observed. This replacement was achieved only at 130 °C. After 10 h, the ligand: $\text{C}_6\text{D}_6\text{Cr}(\text{CO})_3$ ratio reached 1:1 and the replacement of fluoranthene by C_6D_6 was completed in 30 h (data from ^1H and ^2H NMR spectroscopy and TLC).

In isomeric fluoranthene complexes, η^6, η^6 -IHR were observed in melts for the first times, *i.e.*, the rearrangements proceed in the absence of solvating interactions with solvent molecules, which can lead to elimination of the tricarbonylchromium group from the ligand. Thus when melted in a tube at 154 °C, the complex **38** was completely converted into the isomer **37**, which was established by TLC and NMR spectroscopy. This fact is yet further evidence of the intramolecular character of η^6, η^6 -IHR in tricarbonylchromium complexes of polycyclic aromatic compounds.

Figure 4. Kinetic curves for changes in the concentration (c) of the complexes **37** (**1**) and **38** (**2**) in the course of IHR.

Figure 5. Kinetic first-order dependence for irreversible IHR $38 \rightleftharpoons 37$ at 90 °C; c_0 and c (%) are the initial concentration of the complex **38** and the concentration at time t , respectively.

The rearrangements in fluoranthene complexes proceed substantially more readily than those in biphenyl derivatives for two reasons. First, the ligands in the complexes **37** and **38** are planar (according to the X-ray diffraction data). Second, the difference in thermodynamic stability of the complexes **37** and **38** is substantially larger than that in the case of analogous biphenyl pairs.

The Öfele reaction of the complex **37** with an excess of $\text{Py}_3\text{Cr}(\text{CO})_3$ afforded a binuclear fluoranthene complex (**80**) in 70% yield. The complex **80** has, apparently, a *trans*-structure. It should be noted that the complex **38** did not react with $\text{Py}_3\text{Cr}(\text{CO})_3$ under the same conditions.

Recently, η^6, η^6 -IHR in tricarbonylchromium complexes of 2-acetylfluorene, which is a planar analogue of biphenyl, have been studied by ^1H NMR spectroscopy (deuteriotoluene, 120 °C).¹³⁸

Under these conditions, the intramolecular inter-ring haptotropic rearrangement was accompanied by the replacement of the fluorenyl ligands by deuteriotoluene ($k_{\text{sub}} = 0.19 \times 10^{-5} \text{ s}^{-1}$). According to the kinetic and thermodynamic data [$k_1 = 0.18 \times 10^{-5} \text{ s}^{-1}$, $k_2 = 0.024 \times 10^{-5} \text{ s}^{-1}$, $\Delta G^\ddagger = 33.5 \text{ kcal mol}^{-1}$], the η^6, η^6 -rearrangements in these complexes proceed much more rapidly than those in biphenyl complexes because the ligand in the former complexes (as in the complexes **37** and **38**) is planar.

Therefore, IHR in tricarbonylchromium complexes with different polycyclic aromatic ligands have been studied in sufficient detail. The kinetic and thermodynamic parameters of these rearrangements, which depend on the structure of the ligand and the nature of the substituents, are summarised in Table 8. The

Table 8. Kinetic and thermodynamic data for η^6, η^6 -IHP in tricarbonylchromium complexes with polycyclic ligands.

Ligand	T/K	K_{eq}	$10^5 k_1^a$ / s^{-1}	$\Delta G^\ddagger$ / kcal mol^{-1}	E_a^b / kcal mol^{-1}
2-Methyl-naphthalene	358	2.09	3.02	28.5	26.9
Methylace-naphthene ^c	363	1.13	1.00	29.7	27.5–26.8
Fluoranthene	363	(see ^d)	0.73	30.0	27.8–28.1
Methylace-naphthylene	363	1.18	2.29	29.1	26.9–25.5
1-Deuteriobiphenylene	393	1.00	4.79	31.0	28.6–27.8
4-Deuteriobiphenyl	447	1.00	6.42	35.1	32.4–31.5
4-Bromobiphenyl	447	(see ^d)	5.13	35.3	32.6–31.72
2-Bromobiphenyl	447	(see ^d)	2.23	36.04	32.5–33.4

^a The rate constant k_1 defines the rate of migration of the tricarbonylchromium group between the substituted and unsubstituted rings. ^b The value was calculated taking into account average $\Delta S^\ddagger$. ^c Data for the *exo*-complexes. ^d Irreversible IHR.

data on IHR in complexes of other transition metals with polyaromatic ligands are scarce. Nevertheless, these data indicate that the rates of rearrangements depend substantially on the nature of transition metal and the ligand environment.

In conclusion, note that the first example of η^6, η^6 -IHR in fused nonplanar polycycles, *viz.*, in tricarbonylchromium complexes of substituted heptalene, which occur under rather drastic conditions, has been reported recently.¹³⁹

6. Theoretical approach to studies of inter-ring haptotropic rearrangements in transition metal complexes with polycyclic aromatic ligands

During the progress of experimental investigations of IHR it became evident that further advances in studies of these processes could not be achieved without application of quantum-chemical methods. At present, *ab initio* high-level quantum-chemical calculations for heteroorganic and organometallic compounds are complicated. The restricted Hartree–Fock–Roothaan method with the use of small basis sets is well suited to studies of organic molecules. However, this method is inefficient in investigations of organometallic compounds. In the latter cases, it is necessary to perform calculations using larger basis sets with polarisation functions taking into account electronic correlations and relativistic corrections. As a result, theoretical studies were generally performed using semiempirical methods for calculating the structures and properties of organometallic compounds and only qualitative results were obtained. Recently, the application of the DFT method has opened prospects for obtaining reliable quantitative data.

Theoretical studies of the mechanisms and the major regularities of IHR in different systems were surveyed in a review.¹⁴⁰ The pioneering investigations in this field were carried out by Albright *et al.*⁴⁷

7. Studies of the mechanism of η^6, η^6 -haptotropic rearrangements in naphthalenechromium tricarbonyls by the density functional method

Recently, it has been demonstrated that time-saving calculations by the DFT method can give high-quality data competitive with the results of *ab initio* high-level quantum-chemical calculations.¹⁴¹ The fact that the kinetic parameters of IHP in naphthalene complexes are weakly sensitive to the effect of the substituents in the ligand is somewhat unexpected (see Table 6) because the effects of the substituents are pronounced in the majority of other metallotropic rearrangements. Detailed investigations of the mechanism of the rearrangements by the DFT method provided reasonable explanations for this fact. Calculations were carried out with the use of the most-time-saving program with extended basis sets.¹⁴¹ The results reproduced adequately the geometric parameters of tricarbonyl(η^6 -naphthalene)chromium (**4**) determined by X-ray diffraction analysis,⁸⁵ including such details as the differences between the Cr–C(1) and Cr–C(2) bond lengths and between the Cr–C(4a) and Cr–C(8a) bond lengths (see the note in Table 9).

The results of calculations are given in Tables 9 and 10. These results agree qualitatively with the results obtained in another study.⁴⁷ In particular, migration of the Cr(CO)₃ group from one ring to another along the shortest path through the midpoint of the C(4a)–C(8a) bond is forbidden in the case of the basis states **A** and **B**.

Table 9. Comparison of the calculated geometric parameters of the model molecules with the experimental data.

Bond	Calculated values /Å	Experimental values /Å	Deviation ^a
Cr(CO) ₆ (see ^b)			
Cr–C	1.908	1.924	–0.016
C–O	1.153	1.165	–0.012
(η^6 -C ₆ H ₆)Cr(CO) ₃ (see ^c)			
Cr–C _{CO}	1.846	1.863	–0.017
Cr–C _{PhH}	2.222	2.208	0.014
C–C	1.410, 1.426	1.417	0.001
(η^6 -C ₁₀ H ₈)Cr(CO) ₃ (see ^d)			
Cr–C _{CO}	1.847	1.815–1.830	0.025
Cr–C(1)	2.218	2.186, 2.214	0.018
Cr–C(2)	2.214	2.213, 2.214	0.001
Cr–C(4a)	2.336	2.306, 2.337	0.015

C(3)–C(4)	1.405	1.389, 1.383	0.019
C(4)–C(4a)	1.439	1.447, 1.404	0.014
C(4a)–C(8a)	1.442	1.439	0.003

Note. The atomic numbering scheme used for (η^6 -C₁₀H₈)Cr(CO)₃ is shown in Scheme 1.

^a The difference between the experimental and calculated values. ^b The experimental values were determined by electron diffraction study.¹⁴²

^c The experimental values were determined by electron diffraction study.¹⁴³ ^d The experimental values were determined by X-ray diffraction analysis.⁸⁵

Table 10. Relative energies of the isomeric complexes **A** and **B** and the transition states **C** and **D** (kcal mol^{–1}).

R	A	B	C	D
H	0	0	30.44	30.44
1-Cl	0	2.78	33.93	30.82
2-Cl	0	2.22	30.23	30.91
1-SiMe ₃	–1.64	0	29.59	30.63
2-SiMe ₃	–4.47	0	26.41	26.62
1-Me	0.52	0	32.18	30.38
2-Me	–0.19	0	28.86	29.92

The transition state for (η^6 -C₁₀H₈)Cr(CO)₃ (**3**) has the structure of the trimethylenemethane complex with the symmetry C_{2v} in which the Cr(CO)₃ group is coordinated through the C(4), C(4a), C(5) and C(8a) atoms and is slightly shifted to the periphery of the ligand. The potential energy surface does not have a stationary point (a local minimum) corresponding to an inter-

mediate of the η^3 -allylic type, which had been postulated in another study.⁴⁷

For tricarbonylchromium complexes of substituted naphthalenes, the tricarbonylchromium group can migrate between the substituted and unsubstituted rings *via* two paths through the transition states **C** and **D**. The results of calculations reproduce adequately the relative stabilities of the isomers **A** and **B**, which differ by the position of the $\text{Cr}(\text{CO})_3$ group in the unsymmetrically substituted naphthalene ligand. The presence of the substituent changes the energy of the transition state **C** in which this substituent is located in the immediate vicinity of the migrating group, whereas the energy of the transition state **D** changes only slightly ($\pm 0.5 \text{ kcal mol}^{-1}$). Therefore, the existence of two reaction pathways one of which is virtually undisturbed is, on the whole, responsible for the low sensitivity of the kinetic parameters of the rearrangement to the effects of the substituent in the ligand. Taking into account the assumptions made (the isolated-molecule approximation was used and the difference in the zero-point energy was ignored), the calculated activation barriers agree well with the experimental $\Delta G^\ddagger$ values.

IV. Conclusion

Essentially all known data on IHR in π -complexes of transition metals with fused polycyclic ligands are surveyed in the present review. Metallotropic rearrangements revealed in new complexes and elucidation of the general regularities of these rearrangements are of considerable importance because they gave impetus to the development of new synthetic procedures.

Presently, the general concepts of IHR are rather clearly stated. Further studies should be aimed at the more detailed theoretical description of these processes, in particular, it is necessary to have an idea of the structures of transition states in the course of IHR to perform the directed construction of new tautomeric systems. In this respect, calculations of the potential energy surfaces for the rearrangements with the use of more rigorous quantum-mechanical methods will be of paramount importance.

Abstract. The compositions, properties and concepts of the structure of fluoroindate glasses are considered. These glasses are characterised by low phonon energies and hence very low theoretical optical losses in the IR region. According to the vibrational spectroscopic data, the degree of polymerisation of octahedra in fluoroindate glasses is lower than in fluorogallate and fluoroaluminate glasses. The compositions of fluoroindate glasses containing up to nine components cannot be regarded as being completely optimised. Comparative analysis of the chemical and thermal stability of fluoroindate and fluorozirconate glasses was performed. It is shown that the high susceptibility of indium fluoride to hydrolysis accounts for the instability of glasses and optical losses. The prospects for the use of fluoroindate glasses in lasers, fibre optics and scintillation instruments are discussed. The bibliography includes 157 references.

I. Introduction

Intensive studies of fluoride glasses began in the mid-1970s. At that time, fluoroberyllate and fluoroaluminate glasses were well known. An unexpected discovery of fluorozirconate glasses with high values of coordination numbers (c.n.) of glass-forming atoms (c.n. 6–8) stimulated the development of studies of glass formation in multicomponent fluoride systems and revealed other fluorides as 'progenitors of glass'. Fluoride glasses are promising optical materials, including their prospective use in telecommunication systems, because they are characterised by a much wider

transmission region in the IR range compared to silicate glasses. Various experimental and computational methods are employed in the studies of the structure of fluoride glasses. Experimental results are described using different models of glassy state (crystal, disordered network, stressed mixed clusters, chemical twinning, ionic glass, polymeric, colloidal, *etc.*). A number of criteria of glass formation have been proposed.^{1–11}

At present, the best studied glasses are based on zirconium fluoride of the type ZBLAN (53 ZrF₄ · 20 BaF₂ · 4 LaF₃ · 3 AlF₃ · 20 NaF).[†] In order to prevent reduction of Zr⁴⁺ to Zr³⁺, the fluorozirconate glasses of ZBLAN type are doped with small amounts of indium fluoride (0.015 mol.% – 0.25 mol.%).^{12, 13} In this case, no reduction occurs because the couple In³⁺/In⁺ (like, *e.g.*, Sn⁴⁺/Sn²⁺ but not Ga³⁺/Ga⁺) has a larger electrochemical potential than the couple Zr⁴⁺/Zr³⁺ (see Refs 14 and 15). The following redox reaction takes place

An analogous role seems to be played by the additive InF₃ to fluorohafnate glasses: they prevent reduction of Hf⁴⁺ to Hf³⁺.^{16–18} The presence of univalent indium in the glass leads to the appearance of a double absorption peak in the UV region.¹⁴

Upon addition of up to 4 mol.% of InF₃ to ZBLAN, the resistance of this glass to crystallisation is slightly increased. The refractive index is also increased but less essentially than upon addition of PbF₂.¹⁹ Upon addition of up to 3 mol.% of InF₃ to the fluorozirconate glass of ZBLALi type with a high (~ 8 mol.%) content of PbF₂, no stabilisation effect was achieved.²⁰ The increase in the InF₃ concentration in the fluorohafnate glass containing 5 mol.% of CeF₃ induced a decrease in the integral yield of Ce³⁺ luminescence.¹⁸ Attempts to stabilise the glass with composition 24 CdF₂ · 29 CdCl₂ · 11 BaF₂ · 36 NaF by adding up to 8 mol.% of InF₃ were unsuccessful.²¹

In recent years, investigators have shown an appreciable interest in glasses with high content of indium fluoride, the so-called fluoroindate glasses. These glasses are characterised by lower mean values of the energy of phonons (~ 510 cm⁻¹) than conventional fluorozirconate glasses (~ 580 cm⁻¹).²² Thus, fluoroindate glasses absorb in a farther IR region. The range of transparency extends from the UV region to ~ 7–8 μm in the IR region (for fluorozirconate and fluoroaluminate glasses, this extends from the UV region to ~ 5.5 μm).[‡] Consequently, the

[†] Hereinafter, the compositions of glasses are given in mol.%.

[‡] The edges of transparency are determined approximately, since they depend not only on the sample composition, but also on its thickness.

calculated values of minimum optical losses determined by the sum of the Rayleigh scattering and the multiphonon absorption are substantially smaller in fluoroindate glasses than in fluorozirconate glasses. For example, for the glass BIZYbT (30 BaF₂ · 30 InF₃ · 20 ZnF₂ · 10 YbF₃ · 10 ThF₄) such losses reach ~ 0.002 dB km⁻¹ at a wavelength of 3 μm,²³ while for ZBLAN they are ~ 0.044 dB km⁻¹ at a wavelength of 2.55 μm.²⁴ Therefore, fluoroindate glasses may be regarded as promising materials for the IR instrumentation, in particular in systems of optical fibre communication for the transmission of information in the IR region. However, because of technological difficulties the real optical losses are far from the calculated values: they are larger than in the ZBLAN-based fibres and still larger than in the silicate optical fibres (see below). We are still far from the time when it will be possible to use the calculated characteristics of fluoroindate glasses for the development of many-kilometre fibre optical systems for the transmission of information in the range of 2.5–3.7 μm. Characteristically, the impurities of 3d elements which affect the transmittance in fluoride glasses in the 0.7–1.5 μm range, even if present in negligible amounts, have virtually no effect on the transmission in the 2.5–3.2-μm range. In the latter range, an essential contribution to the absorption is made by the OH groups (the band at 2.9 μm),^{24–26} which creates technological difficulties because of easy hydrolysis of indium fluoride. Other anionic impurities, in particular SO₄²⁻, also influence essentially optical characteristics of fluoroindate glasses in this range.²⁷

The prospects for the use of fluoroindate glasses in the communication optical fibre systems is related to specific features of real silicate fibre-based systems with losses below 1 dB km⁻¹. In the first-generation systems known since 1976, use is made of multi-mode fibres (the operating wavelength is 0.8 μm). Systems of the next generation developed in 1983 are based on the use of both single- and multi-mode fibres (the operating wavelength is 1.3 μm, the second telecommunication window). Modern third-generation systems operate at the wavelength 1.5 μm (the third communication window), which corresponds to the minimum optical losses of the silicate fibre.²⁸ The systems of all the three generations require installation of laser amplifiers of the signal at intervals of a few tens of kilometres.

The fluoride glasses and especially the fluoroindate glasses are characterised by low energies of phonons; therefore, they can be used as a base for the design of efficient lasers with high quantum yield (up to 6%–7%).²⁹ For different operating wavelengths, glasses are doped with ions of rare-earth elements, *viz.*, with Tm³⁺, 0.8 μm; Pr³⁺ or Nd³⁺, 1.3 μm; Er³⁺, 1.5 μm (Ref. 30). Doping of fluoroindate glasses with ions of rare-earth elements is easier than that of fluorozirconate glasses.³¹ In recent years, the subject of most active development is the fluoride fibre doped with Pr³⁺ ions, which is required for the design of optical amplifiers used in telecommunication systems.^{17, 32, 33}

The active element of fibre communication is the optical fibre composed of the core and the cladding. A number of requirements are set for the respective materials. The refractive index of the core (*n*₁) should be larger than that of the cladding (*n*₂), while the coefficients of thermal expansion and the temperatures of glass transition and crystallisation of the core and the cladding should be close. In order to achieve the maximum operation efficiency of laser amplifiers, it is necessary to use single-mode optical fibres (*i.e.*, fibres with a small diameter of the core ranging from 3 to 5 μm) with a large (0.35–0.4) aperture.^{20, 34}

$$N_A = (n_1^2 - n_2^2)^{1/2}$$

or the quantity

$$\Delta n = \frac{n_1 - n_2}{n_1}.$$

It is possible that fluoroindate glasses will also find application as optical waveguides (in particular in medicine) for the transmission of laser radiation in the IR region from Er:YAG solid

(2.94 μm) and CO gas (4.8–5.5 μm) lasers. The limiting factor is the threshold of glass damage.²⁹

Chalcogenide (of the As₂S₃ type) and chalcogen halide glasses [*e.g.*, formed in the Ge–As–Te–I and Hg–Pb–SI systems,³⁵ as well as halide (*e.g.*, bromide³⁶ and mixed chloride-fluoride²¹)] glasses are characterised by lower mean energies of phonons than fluoroindate glasses. Chalcogenide glasses are transparent much farther into the IR region; however, their transmission in the visible spectral region is limited. Mixed halide glasses are unstable in the ordinary atmosphere and undergo easy hydrolysis.

Compared to the fluorozirconate glasses, the fluoroindate glasses possess enhanced thermal stability judging from the difference in glass transition temperatures (*T*_g) and the onset of exothermic of crystallisation (*T*_x) on the heating curves

$$\Delta T = T_x - T_g$$

or from the Hruby criterion³⁷

$$H = \frac{T_x - T_g}{T_m - T_x},$$

where *T*_m is the melting temperature.[§]

In the opinion of some investigators (see, *e.g.*, Ref. 39), the fluoroindate glasses are more stable than the fluorozirconate ones. The preparation of bulk castings of fluoroindate glasses requires lower cooling rates of glass-forming melts.⁴⁰ Apparently, this characteristic depends strongly on the technology of preparation of glasses (oxygen-containing impurities induce their crystallisation).⁴¹

The critical cooling rates (*R*_c) of glass-forming melts can be determined experimentally (*e.g.*, by the method proposed by Barandiaran and Colmenero⁴²), *viz.*, from the dependences of the observed supercooling Δ*T*₁ (the difference between the temperatures of liquidus and the beginning of crystallisation) on the cooling rate *R* (linear extrapolation to the infinite supercooling using ln*R*–1/Δ*T*₁² coordinates). Yet another method consists in calculations using the data derived from the TTT (temperature–time–transformation) curves.^{43, 44} Both methods require laborious experiments. The values of *R*_c reported from different studies show strong discrepancies. Thus the *R*_c values measured by the former method for the five-component glass (30 BaF₂ · 30 InF₃ · 20 ZnF₂ · 10 YbF₃ · 10 ThF₄) differ by nearly two orders of magnitude: 1.7 K min⁻¹ (Ref. 45) and 120 K min⁻¹ (Ref. 44) (for ZBLAN, these values were 0.7 and 3 K min⁻¹, respectively). Measurements by the last-mentioned method gave *R*_c = 102 K min⁻¹ (for ZBLAN, this value was 8 K min⁻¹).²³ Such a difference is possibly explained by different conditions of preparation of the samples.

II. Physicochemical properties of indium fluoride

At normal pressure, indium fluoride has the high-temperature cubic polymorph of the ReO₃ type.⁴⁶ As the temperature decreases, it passes into the trigonal polymorph of the VF₃ type, space group *R* $\bar{3}c$ (Fig. 1). The melting temperature of InF₃ is 1320 °C.^{48, 49} Indium fluoride is characterised by high vapour pressure,⁵⁰ it vaporises strongly upon heating above 900 °C, undergoes easy hydrolysis upon slight heating and absorbs moisture when stored in air. Its hydrate InF₃ · 3H₂O can hardly be dehydrated because its hydrolysis with water of crystallisation occurs even at room temperature⁵¹

The ionic radius of In³⁺ is substantially smaller than those of lanthanide cations, it is close to the radius of scandium ion and is

§ In the original paper,³⁷ the temperature of the beginning of melting (solidus) is used in this formula; in a number of other papers (see, *e.g.*, Ref. 38) the temperature of liquidus is used. The difference between them may be substantial.

Figure 1. Structural types ReO_3 (a), $\beta\text{-YF}_3$ (b)⁴⁷ and VF_3 (c).

Figure 2. Phase diagrams of the systems $\text{LiF}-\text{InF}_3$ (a), $\text{BaF}_2-\text{InF}_3$ (b), $\text{PbF}_2-\text{InF}_3$ (c) and $\text{YbF}_3-\text{InF}_3$ (d).^{48,53} (1) DTA data; (2) single-phase samples; (3) two-phase samples from X-ray powder diffraction data; L, melt; F, solid solution with the fluorite structure; S, solid solution with the ReO_3 structure; α , solid solution with the $\alpha\text{-YF}_3$ structure.

substantially larger than the radii of gallium and aluminium ions.⁵²

Ion	La^{3+}	Y^{3+}	Lu^{3+}	In^{3+}	Sc^{3+}
$r/\text{\AA}$ (c.n. 8)	1.30	1.159	1.117	1.06	1.01

A morphotropic transition occurs on going from InF_3 to trifluorides of heavy rare-earth elements (Lu–Er, Y). Indium fluoride is partially dissolved in high- and low-temperature RF_3 polymorphs corresponding to the structural types $\alpha\text{-YF}_3$ and $\beta\text{-YF}_3$, respectively.⁵³

Being a strong Lewis acid, indium fluoride forms numerous compounds with fluorides of uni- and divalent metals (Fig. 2).^{46,54}

III. Optimisation of glass compositions

Undoped indium fluoride is not vitrified. However, like other Lewis acids, such as AlF_3 , ZrF_4 , GaF_3 , ZnF_2 (Fig. 3), it is the ‘progenitor’ of glass. According to the proposed classification,¹¹ indium fluoride is classed as a glass former of second degree, since at ordinary quenching rates ($\sim 10^3 \text{ K s}^{-1}$) glasses are formed in some binary systems, namely, $\text{InF}_3-\text{BaF}_2$,^{55,56} $\text{InF}_3-\text{PbF}_2$ ⁵⁷ and $\text{InF}_3-\text{SrF}_2$.⁵⁸ The regions of glass formation in the first two systems are in the vicinity of eutectic points; the phase diagram of the third system has not been studied.

First reports on the synthesis of fluorindate glasses appeared in the early 1980s.^{55,59} A double glass-forming system $\text{BaF}_2-\text{InF}_3$ was found;⁵⁵ however, the glass formed in this system was not sufficiently stable. Numerous stabilising components, viz., YF_3 , UF_4 ,⁵⁵ FeF_3 ,⁶⁰ ZnF_2 , ThF_4 ,⁶¹ YbF_3 ,^{23,55,62} ScF_3 , GaF_3 , CdF_2 ,⁶³ SrF_2 ,⁵⁸ MgF_2 ,^{57,64} BiF_3 ⁶⁵ and $\text{In}(\text{PO}_3)_3$,⁶⁶ were proposed. A second glass-forming system $\text{PbF}_2-\text{InF}_3$ was found almost simultaneously which was doped with CdF_2 , ZnF_2 , MnF_2 and SnF_2 as stabilising ingredients.

The regions of glass formation in some ternary systems are shown in Fig. 4. Note that the boundaries of the regions of glass formation are tentative. These depend on the experimental conditions and are in particular very strongly dependent on the cooling rate. The data from different studies on the regions of glass formation correlate but do not coincide. For example, glass formation was observed in the binary system $\text{BaF}_2-\text{InF}_3$,^{55,61} whereas according to the results of another study,⁶³ only three-component systems $\text{BaF}_2-\text{InF}_3-\text{MF}_n$ did undergo vitrification. The results of studies on the system $\text{BaF}_2-\text{InF}_3-\text{YF}_3$ (cf. Refs 57 and 61) are at variance [two regions of glass formation were revealed (cf. Ref. 57, Fig. 4b)]. It was stated that the system $\text{BaF}_2-\text{InF}_3-\text{GaF}_3$ has an isolated region of glass formation,⁶³ while Boutarfaia *et al.*⁵⁷ revealed a ‘belt’ region between the systems $\text{BaF}_2-\text{InF}_3$ and $\text{BaF}_2-\text{GaF}_3$ (see Fig. 4d). Some discrepancies are found even within the framework of a single study. In particular, in a study,⁶⁰ of all the studied systems $\text{PbF}_2-\text{InF}_3-\text{MF}_n$ the glass formation in a binary system $\text{PbF}_2-\text{InF}_3$ was revealed only in a single case (see Fig. 4g), while in other cases the glass formation was observed only in three-component systems (Fig. 4h,i).

In three-component systems, the rate of devitrification is great. Only in the system $\text{PbF}_2-\text{BaF}_2-\text{InF}_3$ was a glass which has prospects for practical application found. Videau *et al.*⁵⁵ have described the four-component glass $40 \text{ InF}_3 \cdot 32 \text{ BaF}_2 \cdot 17 \text{ YF}_3 \cdot 11 \text{ PbF}_2$. A 2 mm-thick sample of this glass had the optical transmission edge of $13 \mu\text{m}$. Auriault *et al.*⁶⁰ obtained a bulk casting for the glass $30 \text{ PbF}_2 \cdot 20 \text{ BaF}_2 \cdot 50 \text{ InF}_3$, the transmission edge in the IR region being $\sim 8.2 \mu\text{m}$ for a 3 mm-thick sample. Attempts were undertaken to vary the composition of this glass by doping it with ZnF_2 , SrF_2 , AlF_3 , YF_3 , CdF_2 and PbF_2 to enhance stabilisation. Optical characteristics of some 5–8-component glasses (the refractive indices being in the range from 1.549 to 1.566, the edges of IR transmission varying from 7.7 to 8.9 μm) were determined. The possibility of replacement of InF_3 by GaF_3 as well as doping of glasses with rare-earth fluorides were also

Figure 4. Regions of glass formation in systems involving InF_3 : (a) $\text{BaF}_2\text{--InF}_3\text{--MF}_n$ ($M = \text{Y, Th, Zn}$);⁶¹ (b) $\text{BaF}_2\text{--InF}_3\text{--YF}_3$;⁵⁷ (c) $\text{BaF}_2\text{--InF}_3\text{--ZnF}_2$;⁵⁸ (d) $\text{BaF}_2\text{--InF}_3\text{--GaF}_3$;⁵⁷ (e) $\text{BaF}_2\text{--InF}_3\text{--MgF}_2$;⁵⁷ (f) $\text{BaF}_2\text{--InF}_3\text{--SrF}_2$;⁵⁸ (g) $\text{PbF}_2\text{--InF}_3\text{--MnF}_2$;^{59, 60} (h) $\text{PbF}_2\text{--InF}_3\text{--BaF}_2$;⁶⁰ (i) $\text{PbF}_2\text{--InF}_3\text{--ZnF}_2$;⁶⁰ (j) $\text{SrF}_2\text{--InF}_3\text{--ZnF}_2$;⁵⁸ (k) $\text{PbF}_2\text{--InF}_3\text{--YF}_3$;⁵⁷ (l) $(0.5 \text{ BaF}_2 + 0.5 \text{ SrF}_2)\text{--InF}_3\text{--ZnF}_2$;⁵⁸ (1) quenched glasses; (2) cast glasses; (3) glass-ceramic.

metals) below 10 mol.%. The modified glass IZBS with composition $12.5 \text{ BaF}_2 \cdot 30 \text{ InF}_3 \cdot 30 \text{ ZnF}_2 \cdot 12.5 \text{ SrF}_2 \cdot 8 \text{ NaF} \cdot 5 \text{ CdF}_2 \cdot 2 \text{ LaF}_3$ ⁵⁸ was taken as the base. It turned out that upon substitution of zinc for indium the stability of the glass is decreased. The problem of stability was solved in part by replacement of certain portion of InF_3 by GaF_3 and optimisation of the content of modifiers.

Qui *et al.*⁷⁶ studied the possibility of incorporation of SnF_2 into a glass of the IZBS type with composition $15 \text{ BaF}_2 \cdot 40 \text{ InF}_3 \cdot 20 \text{ ZnF}_2 \cdot 20 \text{ SrF}_2 \cdot 2 \text{ NaF} \cdot 3 \text{ GdF}_3$. It was found that it is possible to replace BaF_2 , ZnF_2 or SrF_2 by SnF_2 (up to 15 mol.-%–20 mol.-%); however, in all the cases T_g and the difference $T_x - T_g$ decreased. With the SnF_2 content above 20 mol.%, crystal phases appear, including that of InF_3 . Upon variation of the BaF_2 to SrF_2 ratio, a glass with intermediate composition was selected which exhibited maximum stability (judging from the ΔT value).

Zhang and Poulain³¹ studied the effect of additions of rare-earth fluorides on the properties of the glass with composition $30 \text{ PbF}_2 \cdot 20 \text{ GaF}_3 \cdot 15 \text{ InF}_3 \cdot 20 \text{ GdF}_2 \cdot 15 \text{ ZnF}_2$; up to 10 mol.% of RF_3 ($R = \text{La, Ce, Pr, Nd, Gd, Er, Yb}$ and Lu) was introduced. It was established that the stability of the glass first increased and then diminished passing through a maximum with 1 mol.-%–2 mol.-% of RF_3 . On the whole, rare-earth fluorides act as modifiers. Up to 20 mol.% of GdF_3 may be incorporated into the glass-forming system $\text{BaF}_2 \cdot \text{InF}_3 \cdot \text{ZnF}_2$;⁷⁷ however, the compositions including 10 mol.% of GdF_3 and 10 mol.% of SrF_2 are the most stable.

Akella *et al.*⁷⁸ studied the possibility of variation of the composition of the nine-component glass $28 \text{ InF}_3 \cdot 20 \text{ ZnF}_2 \cdot 16.5 \text{ BaF}_2 \cdot 12 \text{ GaF}_3 \cdot 9 \text{ PbF}_2 \cdot 6 \text{ NaCl} \cdot 5 \text{ SrF}_2 \cdot 3 \text{ CaF}_2 \cdot 0.5 \text{ PrF}_3$, which has the optical transmission edge at 10 μm . Sodium

chloride was introduced to increase the cross-section of absorption at $f\text{--}f$ transitions of rare-earth elements. It was found that 10 mol.% of GaF_3 can be replaced by InF_3 , 4 mol.% of GaF_3 can be replaced by YF_3 , whereas PbF_2 can be totally replaced by CaF_2 or partially replaced by SrF_2 or BaF_2 without crystallisation.

Delben *et al.*⁷⁹ studied a glass of the type IZBS doped with 5 mol.% of NaCl or LiCl . Complex temperature dependence of viscosity was established and bifurcation of temperature T_g was noted. Taking this into account, a two-phase model of glass was proposed.

Compositions and properties of some fluoroindate glasses are listed in Table 1, while the evolution of their compositions is reflected by Scheme 1.

The stabilities of glasses could be enhanced upon increase in the number of components of the system. This method is known as 'the confusion principle'.⁷⁰ The efficacy of this approach is explained by the fact that it is difficult to attain an ordered structure (the obstruction effect)^{76, 86} with great diversity of types of local ordering, *i.e.*, polymorphism of clusters. It is of note that the glasses BIGaZYbTZr and BIGaZYbTMn ⁶⁹ contain each six (!) glass formers per one modifier. In many cases, the increase in the number of components and isomorphous replacements of one glass component by another result in the appearance of a stabilising 'polycationic effect', which consists in the enhancement of glass stability reaching a maximum for some intermediate composition.⁸⁷ For fluoroindate glasses of different compositions, this effect is observed upon partial isovalent substitution of GaF_3 for InF_3 ^{43, 57, 75, 88} and heterovalent substitution of ZnF_2 for InF_3 ⁷⁵ (isomorphism of glass formers) as well as strontium for barium⁷⁵ (isomorphism of modifiers). Destabilisation observed upon substitution of ZnF_2 for InF_3 is apparently explained by the fact that the initial glass has already been stabilised (the optimum

ratio InF₃:ZnF₂ has been reached). Upon partial substitution of AlF₃ for InF₃,^{38,43} the stabilities of glasses did not change. Substitutions of SrF₂ for PbF₂ and of PbF₂ for BaF₂ have not been studied systematically. Substitution of PbF₂ for BaF₂ in the BIZYbT glass leads to its destabilisation.⁴³

Considering the isomorphism concept, the substitutions observed are well expected and correspond to the so-called 'geochemical star' of indium.⁸⁹ In particular, a wide heterovalent isomorphism of indium and zinc is known among compounds with different ionicities. From the physicochemical viewpoint and

in conformity with the Rawson principle, the essence of the 'confusion principle' is reduced to the decrease in the temperatures of eutectics as the number of components in the system is increased.¹⁰ It is of note that Bouaggad *et al.*²³ suggested that the five-component composition of BIZYbT with a melting temperature of 650 $^{\circ}\text{C}$ is close to the eutectic composition; however, the thermogram derived from the same study contradicts this suggestion. The thermogram of the IZSB glass does not correspond to the eutectic either.⁹⁰ This discrepancy may be indicative of the potential reserves of the stability enhancement. However, the

Scheme 1

^a k is the number of components; only cationic composition of glasses is indicated.

studies performed so far show that the stabilities of fluoroindate glasses virtually reach 'saturation' with the number of components equal to 6 or 7. The attainment of saturation corresponds to the Bereznoi rule⁹¹ for the temperatures of multicomponent eutectics.

IV. The structures of fluoroindate glasses

In order to elucidate the structures of fluoroindate glasses, it is necessary to know the structures of crystalline compounds which are similar in their compositions to those of the glasses under study and to reveal the types of polymers favouring the glass formation (Stewart's criterion¹). Relevant measurements showed that the temperature dependences of the viscosities of melts of a number of fluoroindate glasses (like those of fluorozirconate glasses) are substantially non-linear in the coordinates $\log \eta \sim 1/T$. This is the indication of 'fragile' glasses and suggests that the polymerisation processes occur during the cooling of melts. This also points to higher ionicities of fluoride glasses compared, *e.g.*, with 'strong' silicate glasses.^{92, 93}

The crystal structures of indium fluoride compounds are very diverse and are similar to the structures of ScF_3 compounds. The indium cation can have c.n. 6 or 7 (it is not ruled out that its c.n. is 8 in solid solutions).

The most characteristic polyhedra are octahedra, often distorted. The structure of InF_3 is a three-dimensional framework of octahedra connected through their vertices (the octahedra are slightly deformed in the low-temperature polymorph). Successive addition of fluorides of uni- and divalent metals to indium fluoride leads to a typical structural depolymerisation of octahedral structures (Fig. 5) with the following sequence: a framework – a layer ($[\text{InF}_4]^-$, compounds MInF_4) or a corrugated layer (LiInF_4) – a framework ($[\text{In}_3\text{F}_{14}]^{5-}$, compounds $\text{M}_3\text{In}_3\text{F}_{14}$ of the chiolite type) – a chain ($[\text{InF}_5]^{2-}$, BaInF_5) – isolated octahedra ($[\text{InF}_6]^{3-}$, compounds M_3InF_6). In all the cases, the octahedra are linked by vertices through the bridging fluorine atoms.^{54, 94, 95}

The structure of high-temperature $\beta\text{-Ba}_3\text{In}_2\text{F}_{12}$ (the structural type $\text{Sr}_3\text{Fe}_2\text{F}_{12}$) comprises chains of octahedra, in addition to isolated octahedra. Ternary compounds with octahedral formations are known (*e.g.*, of the type of weberite $\text{Na}_2\text{M}^{\text{II}}\text{InF}_7$). Compounds with octahedra $[\text{InF}_6]^{3-}$ are isostructural to the corresponding fluoroaluminates and fluorogallates.⁹⁴

Yet another important structural motif, which can give polymeric structures, are seven-vertex pentagonal bipyramids $[\text{InF}_7]^{4-}$. In compounds of the KIn_2F_7 type, such bipyramids bind to each other through equatorial edges, form layers which are in turn linked to form a three-dimensional framework through the vertices of bipyramids. In compounds $\text{M}_2\text{In}_3\text{F}_{11}$ and $\text{MIn}_3\text{F}_{10}$

($\text{M} = \text{K}, \text{Rb}, \text{Cs}$), junctions of bipyramids with octahedra occur. Crystallochemical analysis showed that the structures containing $[\text{InF}_7]^{4-}$ are related to the $\alpha\text{-U}_3\text{O}_8$ structure, which in turn is a derivative of the $\alpha\text{-UO}_3$ structure.⁹⁶ Thus, the corresponding fluoroindates may be regarded as the products of depolymerisation of the virtual InF_3 polymorph of the $\alpha\text{-YF}_3$ ($\alpha\text{-UO}_3$) type. According to the data of X-ray powder diffraction, the structural type inherent in high-temperature polymorphs of fluorides of heavy rare-earth elements is identical to $\alpha\text{-UO}_3$. It may also be described as anti- Li_3N . The structure of hypothetical RF_3 proposed by Aleonard *et al.*⁹⁶ may also be one of the $\alpha\text{-YF}_3$ models. On the basis of the corresponding RF_3 polymorphs, solid solutions with indium fluoride are formed (see Fig. 2). The structures of BaR_2F_8 compounds of the type of ortho-rhombic BaTm_2F_8 ($\text{R} = \text{Dy} - \text{Yb}$) and monoclinic BaLu_2F_8 , in which isomorphous substitutions of indium for rare-earth elements are possible, are related to the structural type $\alpha\text{-YF}_3$.⁹⁷

Yet another type of seven-vertex polyhedron which is found in fluoroindates may be described as trigonal prisms with one capped lateral face. Slightly distorted polyhedra of this type are present in the structures Sr_2InF_7 ⁹⁸ and Pb_2InF_7 , which is isostructural to the former, whereas paired seven-vertex polyhedra linked along the edge are found in the low-temperature polymorph of $\alpha\text{-Ba}_3\text{In}_2\text{F}_{12}$.⁹⁹ Judging from the interpretation of KYF_4 ,¹⁰⁰ which is isostructural to NaInF_4 , the structure of the latter contains chains of the above-mentioned seven-vertex polyhedra. They may be regarded as the products of polymerisation through collectivisation of the 'caps' of dimeric groups identified in $\alpha\text{-Ba}_3\text{In}_2\text{F}_{12}$. The structure of ortho-rhombic polymorphs of $\beta\text{-YF}_3$ (see Fig. 1) in which InF_3 can also be dissolved (see Fig. 2) may also be represented as the result of polymerisation of such polyhedra to form a three-dimensional framework due to which they are transformed into eight-vertex polyhedra by acquiring one more 'cap' (trigonal prisms with two centred faces).

Thus, in fluoroindate (like in fluorozirconate) glasses different structural units can be responsible for glass formation. In conformity with the known diagrams,^{57, 61} the regions of glass formation in the systems $\text{BaF}_2 - \text{InF}_3 - \text{MF}_n$ adjoin the region of primary crystallisation of compound BaInF_5 (see Figs 2, 4), which testifies in favour of the octahedral structures of these glasses.

However, the facts that the system $\text{BaF}_2 - \text{InF}_3 - \text{YF}_n$ contains, in addition to the region of glass formation adjoining the side $\text{BaF}_2 - \text{InF}_3$, yet another region similar in composition to that of BaY_2F_8 ⁵⁷ and that two types of glasses exist with considerably different T_g allow one to suggest the presence of two structural motifs in fluoroindate glasses (octahedra and pentagonal bipyramids). However, this may simply be related to the existence of two eutectics (without structural differentiation). Grande *et al.*¹⁰¹

Figure 5. Packings of $[\text{InF}_6]^{3-}$ and $[\text{InF}_7]^{4-}$ polyhedra in structures of fluoroindates: (a) $[\text{InF}_6]^{3-}$ in the M_3InF_6 structure; (b) $[\text{InF}_5]^{2-}$ in the BaInF_5 structure; (c) $[\text{In}_3\text{F}_{14}]^{5-}$ in the $\text{M}_5\text{In}_3\text{F}_{14}$ structure; (d) $[\text{InF}_4]^-$ in the MInF_4 structure; (e) $[\text{InF}_4]^-$ in the LiInF_4 structure; (f) InF_3 ; (g) $[\text{In}_3\text{F}_{10}]^{3-}$ in the $\text{MIn}_3\text{F}_{10}$ structure; (h) $[\text{In}_3\text{F}_{11}]^{2-}$ in the $\text{M}_2\text{In}_3\text{F}_{11}$ structure; (i) $[\text{In}_2\text{F}_7]^-$ in the MIn_2F_7 structure; (j) $[\text{InF}_7]^{4-}$ in the Sr_2InF_7 structure; (k) $[\text{In}_2\text{F}_{12}]^{6-}$ in the structure of low-temperature phase $\text{Ba}_3\text{In}_2\text{F}_{12}$; (l) $[\text{In}_2\text{F}_{11}]^-$ in NaInF_4 .

noted the glass formation on the basis of lithium nitride, which is structurally related to BaY_2F_8 .

Wide isomorphism with Ga in fluoride glasses (*cf.*, *e.g.*, Refs 57, 75, 82) suggests the octahedral surrounding of indium. Isomorphism with aluminium is usually restricted;³⁸ however, complete isomorphism of Al^{3+} and In^{3+} (though, with the conjugated replacement of barium and lead) in both the crystalline and glassy states occurs in the system $\text{PbF}_2\text{--BaF}_2\text{--AlF}_3\text{--InF}_3$.^{41, 102}

Analysis of binary glasses containing 50 mol.%–67 mol.% of InF_3 in combination with BaF_2 or SrF_2 by the EXAFS method showed that the nearest surrounding of indium is octahedral, the distance In--F (2.06–2.07 Å) being virtually the same as in InF_3 (2.05 Å).¹⁰³ According to the data from EXAFS, X-ray radial distribution function and molecular dynamics for the glass $45\text{InF}_3\cdot 40\text{BaF}_2\cdot 15\text{ErF}_3$, the mean c.n. values are 7.15, 8.86 and 7.83 for In, Ba and Er, respectively. According to the X-ray photoelectron spectroscopy, the energies of the F_{1s} bond are virtually equal to the arithmetic mean of the energies of the bonds of glass components.¹⁰⁴ Todotoki *et al.*⁶⁸ studied the up-

conversion luminescence[¶] of Er^{3+} in the glass $48\text{InF}_3\cdot 24\text{PbF}_2\cdot 24\text{BaF}_2\cdot 3\text{LaF}_3\cdot 1\text{ErF}_3$ and found that the local frequency of vibrations in the vicinity of Er^{3+} ions ($260\pm 10\text{ cm}^{-1}$) is considerably lower than the mean frequency of the phonon spectrum of the matrix ($470\pm 5\text{ cm}^{-1}$) as determined by Raman scattering. The EPR data on transition metal ions (Cr^{3+} , Ti^{3+} , Fe^{3+} , Mn^{2+} , Co^{2+} , Cu^{2+}) in the glass $25.2\text{PbF}_2\cdot 22.5\text{BaF}_2\cdot 44\text{InF}_3\cdot 3.7\text{SrF}_2\cdot 3.8\text{YF}_3\cdot 0.8\text{AlF}_3$ provide evidence of their octahedral surrounding.¹⁰⁵

Important information on the structures of glasses is provided by spectroscopic methods. In the IR and Raman spectra of fluoroindate glasses, there are bands corresponding to the vibrational modes of isolated octahedra $[\text{InF}_6]^{3-}$.^{106, 107} According to the interpretation of the data from vibrational spectroscopy for the IZBS glass,¹⁰⁶ its structure contains isolated octahedra $[\text{InF}_6]^{3-}$. Later, the octahedral coordination of In^{3+} was con-

¶ The up-conversion is the ionic fluorescence at a shorter wavelength than that of the acting laser radiation.

firmed for the series of glasses $60\text{InF}_3 \cdot 40\text{BaF}_2$, $40\text{InF}_3 \cdot 20\text{ZnF}_2 \cdot 20\text{SrF}_2 \cdot 15\text{BaF}_2 \cdot 5\text{CdF}_2$ and $20\text{InF}_3 \cdot 40\text{ZnF}_2 \cdot 20\text{SrF}_2 \cdot 15\text{BaF}_2 \cdot 5\text{CdF}_2$. A suggestion was put forward about the high content of vertex-bound octahedra in the binary glasses and the transition to almost unbound structures in the multi-component glasses.^{108, 109} The vibrational modes of the octahedra $[\text{ZnF}_6]^{4-}$ and $[\text{InF}_6]^{3-}$ lie close to each other. Ignat'eva *et al.*¹⁰⁷ studied glasses in the system $\text{RF}_3\text{--PbF}_2\text{--MF}_2$ ($\text{R} = \text{Ga}, \text{In}$; $\text{M} = \text{Zn}, \text{Mn}, \text{Ba}$). Analysis by IR and Raman spectroscopy showed that the glasses contain octahedral groups $[\text{InF}_6]^{3-}$ and $[\text{GaF}_6]^{3-}$, the degree of their polymerisation being higher in the fluorogallate glasses. Based on the analysis of the IR spectra in the system $\text{PbF}_2\text{--BaF}_2\text{--AlF}_3\text{--InF}_3\text{--LiF}$, Ignat'eva *et al.*¹¹⁰ suggested that their structures consist of frameworks formed by the octahedra. Upon successive substitution of AlF_3 for InF_3 , starting approximately from the ratio 1 : 1 (~ 15 mol.% of AlF_3), aluminium fluoride forms an independent framework in the glass close to the structural motif in the crystalline $\text{Pb}_3\text{Al}_2\text{F}_{12}$. Incorporation of lithium fluoride disturbs the degree of connectivity of polyhedra in the glass. The fluoroindate glass $15\text{BaF}_2 \cdot 40\text{InF}_3 \cdot 20\text{ZnF}_2 \cdot 20\text{SrF}_2 \cdot 2\text{NaF} \cdot 3\text{GdF}_3$ underwent destruction as the degree of polymerisation of octahedra was increased judging from the IR spectra (devitrification upon polymerisation).⁷⁶

Bureau *et al.*¹¹¹ used precision ^{19}F NMR spectroscopy to investigate glasses in the system $\text{BaF}_2\text{--PbF}_2\text{--InF}_3$ (PBI) and $48\text{PbF}_2 \cdot 25\text{ZnF}_2 \cdot 27\text{InF}_3$ (PZI). They found that three types of fluoride ions contribute to the chemical shift: the ions unbound to the glass former, the ions present in isolated octahedra around the glass-forming atom and the bridging fluoride atoms binding the octahedra to each other. The relative contents of these ions are 5%–11%, 62%–68% and 21%–32% for the PBI glasses and 11%, 37% and 52% for the PZI glasses. The dimensionality of octahedral formations for PZI is 2D, whereas for PBI it is in the interval between 1D and 2D.

Thus, according to the classification based on c.n. of the glass-forming cation,¹¹ the fluoroindate glasses, like the aluminate ones, may be referred to the octahedral glasses. Upon replacement $\text{Al} \rightarrow \text{Ga} \rightarrow \text{In}$, the degree of the glass polymerisation decreased on the whole (it depends strongly on the particular glass composition).

A number of complex fluoroindate glasses include different glass formers. Presumably, these glasses have complex micro-heterogeneous structures. Azkargorta *et al.*¹¹² studied properties of the glass $30\text{BaF}_2 \cdot 18\text{InF}_3 \cdot 12\text{GaF}_3 \cdot 20\text{ZnF}_2 \cdot 9\text{LuF}_3 \cdot 6\text{ThF}_4 \cdot 4\text{MnF}_2 \cdot 1\text{NdF}_3$. Emission of the stimulated radiation at two wavelengths, *viz.*, 1050.2 and 1054.9 nm, was obtained for the laser transition $^4F_{3/2} \rightarrow ^4I_{11/2}$, which suggests the existence of two spatially separated subsystems with different coordination surroundings of the neodymium ions.

V. Properties and prospects for the application of fluoroindate glasses

Refractive indices of fluoroindate glasses ($n \simeq 1.5$) are somewhat higher than those of the ZBLAN glasses (see Table 1); the values of Abbe numbers ($v \simeq 80$), which characterise the dispersion of refractive indices, correspond to the values of this parameter for the fluorozirconate glasses. In the generalised v – n diagram, the fluoroindate glasses occupy approximately the same area as the fluorozirconate glasses.¹¹³ The dispersion of refractive indices of glasses of the types BIZYTh and IZBS was measured.^{72, 114} The refractive indices and dispersions, as well as the theoretical minima of optical losses,¹¹⁵ can be calculated from the molecular increments.¹¹³ Upon addition of Pb^{2+} and Bi^{3+} , the refractive indices of these glasses increased, while upon substitution of Ga^{3+} for In^{3+} they decreased on the contrary⁷² (like upon substitution of Hf^{4+} for Zr^{4+} in the fluorozirconate glasses).

The values of heat and thermal conductivities in fluoroindate glasses are $\sim 20\%$ higher than those in ZBLAN, but are approximately the same magnitude lower than those in majority of

silicate and phosphate glasses.¹¹⁶ Studies of the stress relaxations for the glass $40\text{InF}_3 \cdot 20\text{SrF}_2 \cdot 16\text{BaF}_2 \cdot 20\text{ZnF}_2 \cdot 2\text{GdF}_3 \cdot 2\text{NaF}$ at temperatures below T_g showed that this process is strongly influenced by the atmospheric moisture.¹¹⁷ Characteristics of some fluoroindate glasses are presented in Table 2.

Table 2. Densities (d), heat capacities (C) and thermal conductivities (λ) of some fluoroindate glasses.¹¹⁶

Composition (mol.%)	d /g cm ^{−3}	C /J g ^{−1} K ^{−1}	$10^3 \lambda$ /W K ^{−1} cm ^{−1}
$30\text{PbF}_2 \cdot 15\text{InF}_3 \cdot 15\text{ZnF}_2 \cdot 20\text{GaF}_3 \cdot 20\text{CaF}_2$	5.359	0.67	10.4 ± 0.9
$34\text{InF}_3 \cdot 20\text{ZnF}_2 \cdot 20\text{SrF}_2 \cdot 16\text{BaF}_2 \cdot 6\text{GaF}_3 \cdot 4\text{NaF}$	4.761	0.67	9.9 ± 0.8
$40\text{InF}_3 \cdot 20\text{ZnF}_2 \cdot 20\text{SrF}_2 \cdot 16\text{BaF}_2 \cdot 2\text{GdF}_3 \cdot 2\text{NaF}$	4.753	0.67	10.2 ± 0.8

As it was mentioned above, smooth pyrohydrolysis of indium fluoride complicates the preparation of high-quality glasses, the appearance of oxofluoride phases inducing devitrification. Jha *et al.*⁸³ studied the influence of the fluorinating atmosphere on the quality and stability of the glass $15\text{InF}_3 \cdot 20\text{GaF}_3 \cdot 30\text{PbF}_2 \cdot 20\text{CdF}_2 \cdot 15\text{ZnF}_2$ in the course of its casting. The best samples were obtained when SF_6 was added to nitrogen as the carrier gas, whereas the flow of hydrogen fluoride had a somewhat weaker effect. The poorest effect was produced by ammonium hydrogen fluoride.

In studies of the possibility of the use of fluoroindate glasses as the laser matrices, spectroscopic data on the following dopant ions were analysed: UO_2^{2+} (Ref. 118), Er^{3+} (Refs 84, 119–121), Nd^{3+} (Refs 85, 122–125), Pr^{3+} (Refs 126–128), Tm^{3+} (Refs 129–131), Cr^{3+} (Ref. 132), Yb^{3+} (Ref. 133) and Eu^{3+} (Refs 125, 134). The non-linear effects appearing upon the laser radiation in fluoroindate glasses doped with erbium and neodymium were studied.^{121, 135}

The up-conversion was studied in the glasses activated by Nd^{3+} (Ref. 136), Tm^{3+} (Refs 131, 137), Yb^{3+} (Ref. 138), $\text{Yb}^{3+} + \text{Er}^{3+}$, $\text{Yb}^{3+} + \text{Tm}^{3+}$ or $\text{Yb}^{3+} + \text{Pr}^{3+}$ (Refs 139–141).

In order to increase the pumping efficiency of praseodymium lasers used for the fibre amplifiers at 1.3 μm , it was proposed to coactivate (sensitise) the fluoroindate glasses containing ytterbium with a third rare-earth element, *viz.*, neodymium or erbium.^{16, 17}

When selecting the cladding for the glass $30\text{BaF}_2 \cdot 18\text{InF}_3 \cdot 12\text{GaF}_3 \cdot 20\text{ZnF}_2 \cdot 10\text{YbF}_3 \cdot 6\text{ThF}_4 \cdot 4\text{ZrF}_4$, Rigout *et al.*³⁸ found that the addition of 10 mol.% of KF , 3 mol.% of NaF (instead of a part of BaF_2) and 6 mol.% of AlF_3 (instead of $\text{InF}_3/\text{GaF}_3$) led to $\Delta n = 1.53\%$ with virtually the same coefficients of thermal expansion and T_g . The critical cooling rate is somewhat increased (20 instead of 6 K min^{−1}). Soufiane *et al.*⁷² selected the compositions of the core and claddings of glasses of the IZIBS type by varying n by way of incorporation of GaF_3 and PbF_2 : $\Delta n = 0.24\%$ was achieved.

Jiang *et al.*³² described the selection of the cladding for the fluoroindate fibres. Good results were obtained for fluorophosphate glasses in combination with the GIPCZ glass. The components of the glass fibre, $29\text{PbF}_2 \cdot 3\text{PbCl}_3 \cdot 15\text{InF}_3 \cdot 20\text{GaF}_3 \cdot 13\text{ZnF}_2$ (the core) and $20\text{NaPO}_3 \cdot 10(\text{NH}_4)_2\text{HPO}_4 \cdot 40\text{ZnF}_2 \cdot 15\text{PbF}_2 \cdot 15\text{BaF}_2$ (the cladding), have close values of T_g and the coefficients of thermal expansion. Both glasses mix in unlimited proportions.

The technology of manufacture of the optical fibres based on the fluoroindate glasses is making good progress. The first fibres based on the BIZYbT glass had the optical losses of $\sim 10\,000$ dB km^{−1}.¹⁴² For the fibres based on the BIGaZYbTMn glass this value was already 500 dB km^{−1}.²⁶ Soufiane *et al.*⁷² reported the fabrication of an optical fibre with

losses of 400 dB km⁻¹ at 1.2 µm. Kanamori *et al.*¹⁴³ described the technology of preparation of single-mode fibres with a length up to 500 m from fluoride glasses of the system InF₃–GaF₃–PbF₂–BaF₂–SrF₂–LaF₃–YF₃–LiF–NaF. Based on the fluoroindate glass doped with Pr³⁺ with $\Delta n = 3.6\%$, the minimum level of optical losses was achieved (114 dB km⁻¹ at a wavelength of 1.23 µm). The coefficient of signal amplification at the wavelength 1.3 µm is 0.18 dB mW⁻¹. This is sufficient for these fibres to be used as laser amplifiers, although the level of optical losses is very far from the theoretical level and is fivefold higher than the level achieved for the optical fibre based on ZBLAN. The reason for such a difference seems to be latent crystallisation. In order to decrease the optical losses, it is necessary to enhance the resistance of glasses to crystallisation and to increase the degree of purification from oxygen-containing admixtures.

Itoch *et al.*¹⁴⁴ used a single-mode fibre with the core from the glass 18 InF₃·20 GaF₃·32 PbF₂·10.5 ZnF₂·10.5 CdF₂·4 LaF₃·5 HfF₄ doped with Pr³⁺ and the cladding from the ZBLAN glass. The main characteristics of this fibre are: $N_A \approx 0.55$ at 0.6 µm, the optical losses are 150–250 dB km⁻¹, the coefficient of signal amplification is 0.29 dB mW⁻¹ at 1.3 µm. Optical amplifiers based on fluoroindate glasses doped with Nd³⁺ (Ref. 145) and Pr³⁺ (Ref. 146) have been described.

There are prospects for the use of planar and channel waveguides based on the fluoride glasses, including the fluoroindate glasses, as elements of solid lasers. The idea is to create surface structures with high refractive indices. P de Melo *et al.*¹⁴⁷ obtained such a structure by diffusion of silver ions from the AgF film deposited on the surface of fluoroindate glass. Ionic exchange was observed¹⁴⁸ (Na⁺ for Li⁺ and K⁺) in the glass 15 BaF₂·18 InF₃·12 GaF₃·20 ZnF₂·10 YbF₃·10 ThF₄·15 NaF dipped in the melts of salts. An increase in the refractive index was found in both cases, although judging from the bulk samples,⁷³ the incorporation of potassium instead of sodium should rather decrease the value of n . The effect observed was explained by the mechanical stresses. Josse *et al.*¹⁴⁹ used the surface pyrohydrolysis (treatment with the water vapour): the refractive index increased owing to the ionic substitution of OH⁻ for F⁻. The surface structure was applied by the photolithography method. The fluoride films for planar waveguides can be obtained by physical vapour-phase deposition.⁸⁰

Fluoroindate glasses, particularly those enriched in lead fluoride, are characterised by rather high fluorine ion conductivities,¹⁵⁰ which are however smaller than the conductivities of the crystalline phases of analogous compositions. High mobility of fluorine ions was detected in fluoroindate glasses by the ¹⁹F NMR spectroscopy.^{107, 151, 152} For the glasses of the type IZBS and 40 RF₃·40 BaF₂·20 YbF₃, the ionic conductivity was observed to decrease^{82, 153} upon replacement of indium by gallium and then aluminium. Costa *et al.*¹⁵⁴ studied the mechanical properties of fluoroindate glasses.

VI. Conclusion

In contrast to the fluorozirconate glasses, the compositions of fluoroindate glasses cannot be regarded as optimised. Apparently, in the multicomponent systems involving InF₃ there are several concentration-dependent regions of the stabilities of glasses. It was found that the replacement of InF₃ by GaF₃, BaF₂ or SrF₂ induced a stabilising polycationic effect; however, the possibility of isomorphous substitutions of PbF₂ for BaF₂ has not been studied systematically. It should be noted that the following techniques have a potential in a search for the optimum composition of glasses, *viz.*, the multifactorial design of experiment, the addition of a new component until a new crystalline phase appears as described by Mukhin and Gutkina^{10, 155} and physicochemical analysis including prognostication of the coordinates of multicomponent eutectics.¹⁵⁶

The statements about the higher chemical and thermal stabilities of fluoroindate glasses compared to the fluorozirconate

glasses are questionable. Great discrepancies (by two orders of magnitude) in the determination of the critical cooling rates of multicomponent fluoroindate glasses suggest non-reproducibility of the technology of their preparation. The proneness of InF₃ to hydrolysis determines the instability of these glasses and optical losses in the range of 2.0–3.2 µm.

According to the data from vibrational spectroscopy, fluoroindate glasses are characterised by lower degrees of polymerisation of octahedra than fluorogallate and fluoroaluminat glasses. The reasons for this phenomenon are unclear.

The fields of possible applications of fluoroindate glasses have been little studied. Optical transparency over a wide spectral range, comparatively high density and the possibility of doping with different activators increase the prospects of the practical applications of fluoroindate glasses. It is expedient to investigate the possibility of the production of scintillation materials (including those doped with cerium) with the short decay time.¹⁵⁷ Owing to high concentration of indium fluoride, fluoroindate glasses may be applied for the creation of scintillation media for the neutrino detection.⁹⁶ In order to manufacture highly efficient readjustable lasers, it seems attractive to co-activate fluoroindate glasses with neodymium and chromium ions.

Abstract. The known methods for the assessment of the molecular mass distribution of bulk polymers are considered. These are based on the analysis of the melt flow curves, the frequency dependence of the relaxation modulus, the shape of the free induction decay curve (pulse nuclear magnetic resonance spectroscopy) and the temperature dependence of compliance in the region of the rubbery elasticity plateau (thermomechanical analysis). The bibliography includes 121 references.

I. Introduction

The molecular mass (MM) and molecular mass distribution (MMD) are important structural characteristics which determine many physical properties of polymers.

Various methods are used for the determination of MM; however, only a few of them can be applied to assess MMD. Gel permeation chromatography (GPC)¹ is the most popular, since it is simple, fast in operation, reliable and relatively cheap. Other methods, in particular, those based on fractionation of a polymer, are time-consuming. All methods are based on analysis of the properties of dilute solutions. Therefore, MMD of many insoluble polymers cannot be assessed at all. This holds for, *e.g.*, polymer networks, where it is desired to know the size distribution of linear chain segments between cross-link points. On the other hand, a method based on destruction of polymers has been developed.² However, this method has found no practical use since it is laborious and requires preliminary establishment of the destruction mechanism, which itself is a rather complicated problem.

Attempts at using the relaxation properties of bulk polymers for the determination of MMD are also known. To this end, studies aimed at finding the relation between MMD and the relaxation time spectrum of a polymer were carried out. In this review, the results of such studies carried out over the last three decades are analysed.

Several short reviews devoted to the studies on the assessment of MMD based on the analysis of the relaxation properties of polymers have been published.^{3–10} However, the authors dwelled, as a rule, on one particular approach without comparing different methods of attacking the problem.

II. The direct problem

To find the MMD function from relaxation data, one should know the dependence of the relaxation properties of polymers on their MMD. This problem has rather long been posed;^{11–17} however, no unambiguous solution has been found so far. Because of this, mixing rules of the contributions of polymer fractions to the relaxation properties are widely used. Theoretical prerequisites to the use of this approach can be found mainly in the reptation theory.^{14, 17, 18} For instance, it is suggested that the time dependence of the relaxation modulus, $G(t)$, be described by the following expression¹⁸

$$G(t) = G_0 \varphi(t) \mu(t),$$

where G_0 is the modulus of elasticity in the region of the rubbery elasticity plateau; $\varphi(t)$ is the function which takes into account the tube renewal, $\mu(t)$ is the probability that motion of an arbitrarily chosen segment of a polymer chain is confined to a deformed tube. For a monodisperse system,

$$\mu(t) = \frac{8}{\pi^2} \sum_{p=1,3,\dots} p^{-2} \exp\left(-\frac{p^2 t}{\lambda}\right) \equiv \mu_1\left(\frac{t}{\lambda}\right),$$

where p is the summation index (an odd number), t is the current time, λ is the maximum relaxation time for the Doi–Edwards model.¹⁷ For a binary polymer blend, a linear mixing rule of the weight fractions w_i of each component is valid

$$\mu(t) = w_1 \mu_1\left(\frac{t}{\lambda_1}\right) + w_2 \mu_2\left(\frac{t}{\lambda_2}\right).$$

An analogous linear mixing rule has been used in other studies.^{19–21}

A more complex $G(t)$ dependence based on the double reptation model has been proposed^{22–25}

$$G(t) = \left[\sum_i w_i G_i^{1/2}(t) \right]^2.$$

V I Irzhak Institute of Problems of Chemical Physics, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region, Russian Federation. Fax (7-096) 515 35 88. Tel. (7-096) 517 16 90. E-mail: irzhak@icp.ac.ru

Maier *et al.*²⁶ suggested a generalised empirical formula for calculating the time dependence of the relaxation modulus

$$G(t) = G_0 \left[\int_{\ln M_e}^{\infty} F^{1/\beta}(t, M) w(M) d \ln M \right]^\beta. \quad (1)$$

Here, $F(t, M)$ is the function which describes the relaxation behaviour of a polymer fraction with $MM = M$, t is the current time, β is the parameter characterising the mixing rule and M_e is the MM of a chain segment between entanglements.

The results obtained using different theoretical models were compared with the experimental data on the relaxation behaviour of binary polystyrene blends.²⁶ It was shown that dependence (1) fits the experimental data best with $\beta = 3.84$ virtually irrespective of the form of the function $F(t, M)$. In addition to the above-mentioned theoretical models,^{18, 22–25} the step²⁷ and exponential²⁸ functions and an empirical function containing a finite number (up to 25) of exponential terms with an empirical relaxation time spectrum (the so-called BSW spectrum)²⁹ were also considered. The last-mentioned function was found from the relaxation data for monodisperse specimens. It was found that none of the models considered described adequately the relaxation curves of both polymer blends and even monodisperse polymeric systems. This is consistent with the conclusions reported in a recent study³⁰ in which the results of calculations using the Doi–Edwards model were compared with the experimental results obtained for monodisperse polystyrene specimens.

Empirical mixing rules found mainly in the studies on the analysis of relaxation properties of binary blends of monodisperse polymers are applied to the relaxation time spectrum $H(\lambda)$ (λ is the relaxation time), which is defined as follows:

$$G(t) = \int_{\lambda_{\min}}^{\lambda_{\max}} H(\lambda) \exp\left(-\frac{t}{\lambda}\right) d\lambda.$$

The simplest relation proposed by Ninomiya³¹ has the form

$$H(\lambda) = \sum_{i=1}^N w_i H_i \left(\frac{\lambda}{A_i} \right),$$

where $H_i(\lambda)$ is the relaxation time spectrum of a monodisperse polymer; A_i is the time shift factor due to intermolecular interaction between polymers (such an interaction facilitates the relaxation of the components with higher MM and hampers the relaxation of the components with lower MM). Attempts at taking into account these interactions by deriving generalised formulae lead to sophisticated expressions^{32–34}

$$H(\lambda) = \sum_{i=1}^N \sum_{j=1}^N w_i w_j H_{ij} \left(\frac{\lambda}{A_{ij}} \right),$$

$$H(\lambda) = \sum_{i=1}^N \sum_{j=1}^N \sum_{k=1}^N w_i w_j w_k H_{ijk} \left(\frac{\lambda}{A_{ijk}} \right),$$

which seem to be hardly applicable in practice.

No simpler is yet another relationship^{35, 36}

$$H(\lambda) = \sum_{i=1}^N B_i H_i \left(\frac{\lambda_i}{A_i} \right), \quad (2)$$

where $B_i = w_i^2 + w_i \sum_{j=i+1}^N a_{ij} w_j$ is the form factor,^{37, 38}

which is a function of MM, and $H_i \left(\frac{\lambda_i}{A_i} \right)$ is the BSW spectrum, namely,²⁹

$$H(\lambda_i) = n \left(\frac{\lambda_i}{\lambda_{\max}} \right)^n h \left(1 - \frac{\lambda_i}{\lambda_{\max}} \right),$$

n is a constant ($n < 1$) and h is the Heaviside step function.

Table 1. Characteristics of components and parameters A_i and B_i of Eqn (2) for a binary polystyrene blend.³⁹

124000	2810000	0.01	0.00040	1.20	0.04000

^a $w_1 + w_2 = 1$.

As an example, Table 1 lists the values of the parameters of Eqn (2) taken from Ref. 39. As can be seen, the parameters A_i and B_i depend on the composition and MM of the polymer blend and on the ratio of MM of the blend components. It was also found that all these characteristics affect the values of the maximum relaxation time of each component. This can be exemplified in the data of a study on the relaxation of polymer chains by infrared dichroism⁴⁰ (Table 2).

Table 2. Maximum chain relaxation time (s) in a binary blend of deuterated and hydrogenated polyisoprene.⁴⁰

Content of a high-molecular-mass component (vol. %)	λ_L (for H + L blend)	λ_M (for L + M blend)	λ_H (for M + H blend)
10	20	2.8	50
20	60	3.5	70
30	120	4.5	130
50	150	6.4	160
75	180	6.7	186
100	210	7.0	210

Note. H, M and L denote the blend components with high (370×10^3), medium (125×10^3) and low (53×10^3) molecular mass, respectively.

No general rule exists which would allow passage from the relaxation properties of monodisperse polymers to those of polydisperse polymers. This is largely due to the lack of a theory which can give an adequate description of the dynamic behaviour of polymeric systems.⁴¹ Currently, there is no unique solution of the direct problem of obtaining a relaxation time spectrum based on a particular model or the relaxation properties of a known blend of monodisperse fractions. Obviously, this severely hampers the solution of the inverse problem, consisting of finding the MMD of a polydisperse polymer from its relaxation characteristics.

III. Relations between rheological properties and molecular mass distribution of polymers

Much attention has been paid to the studies on the relations between MMD and viscosity (η) of polymer melts and concentrated solutions.^{12, 42} Most often, this problem was solved by relating the viscosity to the number-average ($\bar{M}_n$), or weight-average ($\bar{M}_w$), or a high-level-average MM ($\bar{M}_z$), or even to their combination (e.g., $\bar{M}_n \bar{M}_z / \bar{M}_w$).

These approaches have not been supported by any theoretical concepts. Attempts to represent the relation between viscosity and MMD in the form

$$\eta \propto \left(\sum_i M_i^\alpha \right)^{1/\alpha},$$

where α characterises the dependence of viscosity on the MM of a monodisperse polymer,

$$\eta \propto M^\alpha$$

are equally unjustified.

An attempt to find a physically substantiated method relating the rheological properties and MMD of a polymeric system has been undertaken.⁴³ This approach was based on the following assumptions: (i) the relaxation time spectrum is limited by the maximum relaxation time $\lambda_{\max}(\dot{\gamma})$, where $\dot{\gamma}$ is the shear rate; (ii) the maximum relaxation time is inversely proportional to the shear rate; (iii) the maximum relaxation time of a given polymer is affected by the presence in the blend of another polymer with a lower MM and (iv) the relaxation time spectrum of a given polymer is independent of the type of polydispersity of the polymer.[†]

Based on these assumptions, the following formula relating the MMD function to the viscosities of the polymer fractions was derived⁴³

$$\sum_{i=m+1} w_i = \left[\left(\frac{\eta_{m+1}}{K} \right)^{1/3.4} - \left(\frac{\eta_m}{K} \right)^{1/3.4} \right] (M_{m+1} - M_m)^{-1}, \quad (3)$$

where w_i is the weight fraction of a polymer fraction with MM = M_i , η_m is the viscosity of a polymer with MM = M_m , K is the coefficient in the equation relating the viscosity of a monodisperse polymer to its MM

$$\eta = KM^{3.4}.$$

Hence it follows that

$$w_m = \left(\frac{1}{K} \right)^{1/3.4} \left(\frac{\eta_m^{1/3.4} - \eta_{m-1}^{1/3.4}}{M_m - M_{m-1}} - \frac{\eta_{m+1}^{1/3.4} - \eta_m^{1/3.4}}{M_{m+1} - M_m} \right). \quad (3a)$$

Expression (3a) was used for analysing a number of binary blends and commercial polystyrene specimens.⁴⁴ It was shown that the polydispersity indices,

$$\gamma = \frac{\bar{M}_w}{\bar{M}_n},$$

determined by rheological methods are close to those found by GPC.

A physical substantiation of the rheological approach has been given by Malkin and Teishev^{45–47} who used the phenomenon of flow separation in monodisperse polymers, discovered by Vinogradov,⁴⁸ as the basis for their consideration. Mathematically, this phenomenon can be described by the relation

$$\eta(\dot{\gamma}) = \begin{cases} \eta_0 & \text{for } \tau \leq \tau_s \\ \tau_s / \dot{\gamma} & \text{for } \tau > \tau_s. \end{cases}$$

Here η_0 is the highest Newtonian viscosity and τ_s is the stress at which flow separation occurs in the polymer.

Based on the known relationship,

$$\eta_0 = KM^a,$$

Malkin and Teishev derived the formula^{45, 46}

$$\eta(\dot{\gamma}) = \left[\int_0^{M(\dot{\gamma})} (KM^a)^{1/a} f(M) dM + \left(\frac{\tau_s}{\dot{\gamma}} \right)^{1/a} \int_{M(\dot{\gamma})}^0 f(M) dM \right]^a, \quad (4)$$

where the integration limit is

$$M(\dot{\gamma}) = \left(\frac{\tau_s}{K\dot{\gamma}} \right)^{1/4},$$

and $f(M)$ is the MM function.

Formula (4) can be used for unimodal MMD functions which include a small number of parameters (Malkin and Teishev⁴⁶ analysed the Bisley, lognormal and other two-parameter distribution functions). In this case, the melt flow curve is sufficiently sensitive to the parameters of the distribution function.

Gordon and Shaw⁴ calculated the MMD function using another analytical expression for the flow curve, namely,

$$\eta(\dot{\gamma}) = \begin{cases} \eta_0 & \text{at } \tau \leq \tau_s \\ \dot{\gamma}^{-v} & \text{at } \tau > \tau_s, \end{cases}$$

where τ_s (and, correspondingly, $\dot{\gamma}_s$) defines the point of transition from Newtonian to a non-Newtonian flow and v is the exponent in the power law of the melt flow

$$\eta \propto \dot{\gamma}^{-v}.$$

The position of this point depends on the MM of the polymer.

The procedure for the calculation of the MMD function depends on which mixing rule for viscosities is used. Gordon and Shaw considered the following mixing rule:

$$\log \eta = w_1 \log \eta_1 + w_2 \log \eta_2.$$

Using this mixing rule, the relation between the integral MMD function $F(M)$ and parameters of the melt flow curve has the form

$$F(M) = 1 + \frac{1}{v} \frac{d \ln \eta}{d \ln \dot{\gamma}} \Big|_{\dot{\gamma}=g(M)},$$

where the function $g(M)$ relates the shear rate to the MM of the polymer and the parameter v .

A more general mixing rule,

$$\eta^{1/a} = w_1 \eta_1^{1/a} + w_2 \eta_2^{1/a}$$

leads to the following formula,

$$F(M) = 1 + \frac{1}{v} \left(\frac{\eta}{\eta_0} \right)^{1/a} \left(\frac{\dot{\gamma}}{\dot{\gamma}_s} \right)^{v/a} \frac{d \ln \eta}{d \ln \dot{\gamma}} \Big|_{\dot{\gamma}=\dot{\gamma}_s M^{-a/v}},$$

where

$$m = \frac{M}{\bar{M}_w}.$$

An algorithm and software for calculations of the MMD function using the last two formulae have been published in a monograph.⁴ It should be noted that the exponent a is not known with certainty. Recently,⁴⁹ it was shown that the parameter a depends on the shear rate (and frequency) in such a manner that its magnitude decreases from values in the range between 3 and 5, which is typical of low shear rates (the highest Newtonian viscosity), down to 0 for high shear rates (the lowest Newtonian viscosity). Moreover, it was empirically found that the parameter a depends also on MMD of the polymer as follows

$$a = \beta_0 + \beta_1 \left(\frac{M_h}{M_l} \right), \quad (5)$$

where $\beta_0 = 3.39 \pm 0.37$, $\beta_1 = 0.03 \pm 0.04$, and M_h and M_l are the MM of the high-molecular and low-molecular mass components of a binary polymer blend, respectively. The values of the

[†]This assumption seems to be not universally true for systems with entanglements.

coefficients of equation (5) also vary to a certain degree depending on the type of the polymer.

With some grounds, it is believed^{44, 46} that the rheological approach can hardly be used for characterisation of an arbitrary MMD function; however, the authors of a monograph (Ref. 4) have a more optimistic view on these things.

IV. Methods based on dynamic measurements

Attempts at using the frequency dependences of the real and imaginary parts of the relaxation modulus of elasticity for the determination of the MMD of polymers have long been undertaken. Ninomiya and Fujita seem to be the first who reported studies in this line of investigation as long ago as 1957.^{50–52} This approach is based on theoretical or empirical relationships between the relaxation time spectrum and MM of polymers^{12, 13, 53} (see also Section II).

In the simplest form, the theory of polymer dynamics was reported by Rouse who developed the well-known single-chain model which is basic to the studies by Ninomiya.^{31, 50–52, 54, 55} More recent investigations⁵⁶ were based on the Doi–Edwards model in which interchain interaction is considered as interweaving of polymer chains, or entanglements, which confine mainly lateral displacements of the polymer chains.

The results of studies carried out on monodisperse specimens of different polymers and their blends (for the most part, binary blends)^{26, 39, 40, 57–61} can be outlined as follows.

For polymers with narrow MMD, the log-log plots of the frequency dependence of the real part of the relaxation elasticity modulus, $G'(\omega)$, nearly coincide in the high-frequency region (the region of the rubbery elasticity plateau). Marked distinctions are observed in the region of low-frequency ‘tails’ where $G'(\omega)$ depends on ω as

$$G'(\omega) \propto \omega^2.$$

The ‘tails’ can be matched by using a shift factor proportional to MM raised to a certain power; it is commonly accepted^{12, 13, 62, 63} that the exponent value lies between 3.4 and 3.7.

The frequency dependences of the imaginary part of the relaxation modulus of elasticity, $G''(\omega)$, pass through a maximum. The position of the maximum depends on MM of a polymer in the same way as the low-frequency ‘tails’ of the $G'(\omega)$ and $G''(\omega)$ curves.

In binary polymer blends, the polymer fractions possess similar relaxation properties; however, no complete coincidence with the behaviour of monodisperse systems is achieved. That is, the low-frequency ‘tails’ are shifted towards higher frequencies for the component with the higher MM and towards lower frequencies for the component with the lower MM.

This phenomenon is associated with the interchain interaction (coupling effect, nematic interaction),^{39, 40, 64–68} which also manifests itself as the orientation of low-molecular-mass chains (even oligomers) in the bulk of the oriented high-molecular-mass matrix.

It should be noted that this frequency shift should occur even in the absence of intermolecular interaction. Indeed, let the relaxation properties be determined by the only relaxation time, which is of course dependent on the MM of the high-molecular-mass fraction. Then, for $\omega \rightarrow 0$, the real part of the relaxation modulus of elasticity of a binary polymer blend takes the form

$$G'(\omega) = w_1 \frac{\omega^2 \lambda_1^2}{1 + \omega^2 \lambda_1^2} + w_2 \frac{\omega^2 \lambda_2^2}{1 + \omega^2 \lambda_2^2} \rightarrow \omega^2 (w_1 \lambda_1^2 + w_2 \lambda_2^2).$$

Obviously, it is this effect that should be observed if $\lambda_1 > \lambda_2$, namely, a shift of the relaxation moduli of elasticity of the high-molecular-mass and low-molecular-mass fractions towards high and low frequencies, respectively. An analogous relationship is also valid for $G''(\omega)$, for $\omega \rightarrow 0$

$$G''(\omega) = w_1 \frac{\omega \lambda_1}{1 + \omega^2 \lambda_1^2} + w_2 \frac{\omega \lambda_2}{1 + \omega^2 \lambda_2^2} \rightarrow \omega (w_1 \lambda_1 + w_2 \lambda_2).$$

The aforesaid can be illustrated by the corresponding plots shown in Fig. 1. On the other hand, a direct mutual effect of the polymer fractions (see Table 2) cannot also be ruled out.

Figure 1. Frequency dependences of the real (a) and imaginary (b) parts of the relaxation modulus of elasticity for specimens with one relaxation time of 100 (1) and 1 arbitrary unit (2) and for their blend containing 25% of the first component (3).

A salient feature of the $G'(\omega)$ and $G''(\omega)$ curves of binary blends is that the height of the rubbery elasticity plateau (in the first case) and that of the peak (in the second case) depend on the relative concentration of components. Similarly to the $G(t)$ curve, a ‘step’ appears on the $G'(\omega)$ curves. The $G''(\omega)$ curves are characterised by two peaks and the peak height ratio depends on the ratio of the blend components.

However, data on the relation between the peak heights and the concentration of the blend components are contradictory. Different authors use different formulae. For instance, a linear dependence was suggested⁶⁹

$$G(t) = w_1 G_1 \left(\frac{t}{d_1} \right) + w_2 G_2 \left(\frac{t}{d_2} \right);$$

the parameter d is associated with the coupling effect.

Other (mainly quadratic) types of mixing rules have also been suggested.^{13, 70–72} For instance, based on the concept that each polymer fraction can be characterised by a frequency corresponding to the MM of the fraction and that at lower frequencies the contribution of this fraction to the relaxation modulus can be neglected, a procedure was developed²⁶ for the determination of the MMD function taking into account a quadratic dependence of the real part of the relaxation modulus of elasticity on the concentration of the high-molecular-mass component. Each fraction makes a contribution

$$w_i = \left[\frac{G'(\omega_i)}{G_0} \right]^{1/2}.$$

Comparison of the results obtained using this procedure with those obtained by GPC showed²⁷ that for binary polymer blends the dynamic approach is less accurate than the rheological method based on the analysis of the melt flow curve.

The complex viscosity, $\eta^*(\omega)$, was also proposed^{44,49} to be used for assessing the MMD function.

$$\eta^*(\omega) = \frac{\sqrt{[G'(\omega)]^2 + [G''(\omega)]^2}}{\omega}.$$

In the high-frequency region (for $\omega \rightarrow \infty$), the complex viscosity decreases nearly proportionally to ω^{-2} , whereas in the low-frequency region (for $\omega \rightarrow 0$) it takes the limiting value corresponding to the highest Newtonian viscosity. It is in the low-frequency region that the strongest dependence of $\eta^*(\omega)$ on MMD of a polymer melt is observed and the parameter a [see Eqns (4) and (5)] has the maximum value. Thus, the frequency dependence of viscosity is similar to the dependence of viscosity on the shear rate, which corresponds to the Cox–Merz rule.¹²

Comparison of different approaches to the solution of the problem of determining the MMD function allowed Tuminello and Cudre-Mauroux⁴⁴ to conclude that the best results can be obtained by analysing the frequency dependence of the complex viscosity; it was also found that analysis of the real part of the relaxation modulus of elasticity gives overestimated, whereas analysis of the imaginary part gives underestimated values.

Investigations on the relaxation of dielectric properties are widely used for studying the relaxation properties of polymers. The relation between dielectric properties and MMD has been analysed^{73–77} taking *cis*-polyisoprene as an example. It was shown that in this case the dielectric loss function can be predicted with ease if the autocorrelation function of a single chain, the mixing rule and the MMD function are known. Difficulties arise when considering the inverse problem. An attempt has been undertaken⁷⁷ to find the MMD function from the dielectric relaxation data using the Tikhonov regularisation, which was previously used for calculating the relaxation time spectra.^{78,79} This study was carried out assuming a linear mixing rule and that the MMD function is described by the Flory–Schulz equation

$$f(M) \propto M^v \exp\left(-\frac{M}{M_n}\right).$$

Information on the width of MMD can be obtained from the analysis of the effective relaxation time⁸⁰ in the low-frequency region or, in other words, of the low-frequency ‘tails’ of the $G'(\omega)$ and $G''(\omega)$ curves. Indeed, assuming that the relaxation time of a monodisperse polymer depends on its MM,

$$\lambda = KM^a,$$

for $\omega \rightarrow 0$ we get

$$G'(\omega) \approx G_0 \omega^2 \sum_i w_i \lambda_i^2 = G_0 \omega^2 K^2 \sum_i w_i M_i^{2a},$$

$$G''(\omega) \approx G_0 \omega K \sum_i w_i M_i^a.$$

Hence

$$\langle \lambda \rangle_2 \equiv \frac{G'(\omega)}{G''(\omega)} = \omega K \frac{\sum_i w_i M_i^{2a}}{\sum_i w_i M_i^a} = \omega K \langle M^a \rangle_2,$$

$$\langle \lambda \rangle_1 \equiv \frac{G''(\omega)}{G_0} = \omega K \sum_i w_i M_i^a = \omega K \langle M^a \rangle_1.$$

The subscripts 2 and 1 on the mean values of λ and MM correspond to a greater degree of averaging in the former case and to a lesser one in the latter. The ratio of the mean values can serve as a measure of the width of MMD. This algorithm is analogous to that which is commonly accepted for assessing the width of MMD and uses the mass-average and number-average MM and their ratio as the polydispersity index; the difference is that in the latter case $a = 1$ (in the relaxation method, $a \approx 3-4$).

Of course, it should be kept in mind that even monodisperse polymers possess a relaxation time spectrum; as a rule, the higher the MM the broader the relaxation time spectrum.²⁹

V. Spin-spin relaxation technique (pulse NMR spectroscopy)

Both rheological and relaxation approaches have been used for the analysis of the MMD of linear polymers. For polymer networks, a steady flow is impossible. However, analysis of stress relaxation data (especially, of the frequency dependences of the relaxation modulus) can be used for extracting information on the MMD of chains of a polymer network. This was done using the spin-spin relaxation technique (pulse NMR spectroscopy).^{81–89}

At sufficiently high temperatures ($T > T_g + 100$), the dependence of the free induction decay on time is given by the following expression

$$G(t) = \int_1^N \int_0^{\pi/2} \{ [g(N, \theta, t) P(N) \sin \theta] d\theta \} dN, \quad (6)$$

where N is the number of segments (the chain length) and θ is the angle between the vector connecting the chain ends and the direction of external magnetic field.

$$g(N, \theta, t) \approx \exp \left[-\omega_1^2 (3 \cos^2 \theta - 1)^2 t^2 \frac{\ln N}{N^2} \right],$$

where ω_1 is the second moment of the free induction decay curve, expressed in frequency units.

In the time domain, the free induction decay has a long slowly descending component. The initial portion of this component contains information on MMD, while the length of its ‘tail’ is proportional to the average length of the chain segment between entanglements and inversely proportional to the current time t . Hence it follows that one can assess the MMD for those chains which are shorter than the length of the chain segment between entanglements (N_0). As was shown experimentally,⁸⁵ $N_0 \approx 10^5$ segments. It should be noted that no independent determination of the chain segment length was performed, which introduces an error into the results obtained. However, even assuming that the segment is a unit of the polymer chain, this method can be applied to those linear polymers for which MM is much higher than 10^6 .

An essential result obtained in a series of studies^{85–89} is that formula (6) can be used for assessing MMD of chain segments between entanglements in polymer networks. At $T > T_g + 100$, intermolecular interaction has almost no effect on the relaxation of sufficiently long chains with the number of segments $N > 10$. Hence the curve of the free induction decay characterises the MMD of chain segments between entanglements. In this case, the integral of the function $G(t)$ can be represented in a linearised form

$$F(t) = \int_0^t G(t_1) dt_1 \approx -0.03 \langle N^2 \rangle + \langle N \rangle t \frac{\pi}{2\sqrt{3}}.$$

The coefficients of this equation define the polydispersity index of the chains of the polymer network, γ_n :

$$\gamma_n = \frac{\overline{M}_{nw}}{\overline{M}_{nn}} = \frac{\langle N^2 \rangle}{\langle N \rangle^2}$$

(the index n indicates that the chains of the polymer network are considered).

Thus, the analysis of the curve of the free induction decay makes it possible to assess MMD of both linear polymers and chain segments between entanglements of the polymer network.

The theoretical conclusions have been confirmed experimentally taking poly(tetrahydrofuran) with isocyanate end groups as an example.⁹⁰ In this case, the polymer network resulted from a trimerisation reaction,⁹¹ which would ensure identical MMD for both the initial prepolymer and chain segments between entanglements. Comparison of the GPC data on MMD of poly(tetrahydrofuran) macromolecules with the results of NMR studies on MMD of the chains of the polymer network made it possible to

draw a conclusion that NMR spectroscopy can be effectively used in this case.

Pulse NMR spectroscopy was used for studying the MMD of the chains in different polymer networks depending on the conditions of the synthesis,⁸⁸ as well as the evolution of MMD during ageing⁹² and at thermal^{92,93} and mechanical⁹⁴ destruction.

Limitation on the use of NMR spectroscopy for assessing the MMD of the chains of polymer networks with low concentration of nodes is due to the fact that entanglements behave as chemical cross-link points, which leads to the anisotropy of the molecular motion of chain segments. This limitation is similar to that which appeared in the determination of the equilibrium modulus of elasticity of polymer networks: for networks with low node concentration, the number of nodes is equal to the sum of chemical (covalent) cross-link points and topological entanglements.^{95–102}

In highly cross-linked polymer networks, the effective dipole-dipole interaction is determined not only by the interaction of protons in the same chain, as is theorised; an appreciable contribution comes also from the interaction between protons of different chains. This imposes some limitations on the use of NMR spectroscopy. Finally, one should keep in mind that the model network considered here has a simple topology (chains linked by tri- or tetrafunctional cross-link points), whereas the real network contains 'tales', small rings, a sol fraction and other defects responsible for considerable uncertainty of the relaxation time spectra of a polymer.^{95, 103, 104}

VI. Thermomechanical analysis

Usually, thermomechanical curves of polymers are analysed based on the concepts of the relaxation time spectrum and the temperature dependence of relaxation times.¹² It is this approach that has been used for the rationalisation of (i) the relation between the temperature dependence of the extent of the rubbery elasticity plateau and the MM of linear polymers discovered by Kargin and Slonimskii¹⁰⁵ and (ii) such an important relation as the Williams–Landel–Ferry formula.¹³ It is the relaxation nature of deformation phenomena that is responsible for the fact that the shape of a thermomechanical curve is 'sensitive' to the polydispersity of a polymer.¹⁰⁶

Recently,¹⁰⁷ a procedure for solving the direct problem, which implies theoretical determination of the flow point (temperature) of a linear polymer, T_f , under conditions of thermomechanical analysis (TMA) from the structure and MM of the polymer, has been proposed. However, the authors were rather sceptical of the possibility of using TMA for the determination of MMD of polymers.

On the other hand, such a possibility has been demonstrated.^{108, 109} Physical substantiation^{110–113} of the approach used was based on the model of a network of physical links.^{41, 114}

In its most explicit form, the relaxation modulus (compliance or deformation at a given stress) can be related to the MMD of a polymer using the classical theory of rubbery elasticity of polymer networks and the temperature dependence of the concentration of physical nodes.¹¹⁰ However, an analysis¹¹² showed that the concentration of nodes formed by weak intermolecular bonds cannot vary substantially in a rather narrow temperature range between the glass transition temperature and the flow point (for linear polymers) or the temperature at which the equilibrium modulus is attained for covalent polymer networks (the extent of the rubbery elasticity plateau). Much stronger is the temperature dependence of the lifetime of the nodes as well as the dependence of the relaxation of the polymer chain conformations on the temperature–time superposition. Irrespective of the details of the physical pattern of the phenomenon, the kinetic law can be to sufficient accuracy expressed by a step function.¹¹⁰ Relaxation

occurs in a narrow time range near the characteristic relaxation time, which depends on the MM of a polymer or a chain segment between entanglements of the polymer network.

If mechanical properties of a system are considered according to the Kelvin–Voigt model, the following formulae relating the function $\varphi(T)$ containing information on MMD to compliance (deformation) are valid:

for a linear polymer

$$\varphi(T) = \frac{J_T - J_0}{J_T}, \quad (7)$$

for a polymer network

$$\varphi(T) = \frac{J_T - J_0}{J_T} \frac{J_{eq}}{J_{eq} - J_0},$$

where J_T , J_{eq} and J_0 is the compliance at a given temperature, the equilibrium compliance (for a polymer network) and the compliance of a hypothetical polymer with infinite MM, respectively.

The function $\varphi(T)$ is in essence the integral MMD function expressed in terms of the flow point of a chain with a given MM rather than the MM of a polymer fraction:

$$\varphi(T) = \sum_{i=1}^{\infty} w_i \delta_i(t, T),$$

$$\delta_i(t, T) = \delta[t - \lambda_i(T)] = \begin{cases} 0 & \text{for } t < \lambda_i(T) \\ 1 & \text{for } t \geq \lambda_i(T), \end{cases}$$

$\lambda_i(T)$ is relaxation time of the chain conformation. The J_0 value characterises that part of the temperature dependence of the modulus of elasticity (compliance) which is unaffected by the MM and MMD of the polymer and serves as a basis for the calculations of the function $\varphi(T)$ [see Eqn (7)].

Schematically, the procedure for the determination of $\varphi(T)$ using the temperature dependence of deformation (compliance) of a linear polymer is shown in Fig. 2. From the rod displacement with respect to the dilatometric curve *1* one can determine the J_0 value (in rod displacement units, this is the value h_0 calculated as the difference between the corresponding points on curves 2 and *1*) and compliance J , which is proportional to h calculated as the difference between the corresponding points on curves 3 and *1*.

The main problem of TMA studies is to determine the relation between the temperature and MM, *i.e.*, to pass from the function $\varphi(T)$ to the integral MMD function $\varphi(M)$. Such a relation can be found after choosing a particular mixing rule. As in many cases considered above, it seems reasonable to assume that the relaxation time of a chain conformation with a given MM is independent

Figure 2. Rod displacement (h) curves obtained in TMA studies. Experimental curves (*a*) and difference between the rod displacement and dilatometric curves (*b*). Dilatometric curve (*1*), hypothetical curve for a polymer with infinite MM (*2*) and the real rod displacement curve (*3*).

of whether it is a monodisperse or a polydisperse polymer. As can be seen, this problem is common to all methods for the determination of the MMD function.

At first glance, if this condition is met, the problem seems to be simple. That is, one needs to find a relation between the extent of the rubbery elasticity plateau,

$$\Delta T = T_f - T_g$$

and MM. However, constructing this dependence faces some difficulties. The first problem is to determine the basic function, $J_0(T)$. This requires studying the temperature dependence of the deformation of model polymer specimens with narrow MMD and high MM in the region of the rubbery elasticity plateau. Here, it is encouraging that such a dependence is rather weak,^{110, 113} so to a sufficient accuracy the function $J_0(T)$ can be considered constant.

Yet another problem is associated with the fact that the temperature range corresponding to passage from the rubbery elasticity plateau to the flow of a polymer is rather wide and depends on both the MM and MMD of the polymer. That is why several formulae for calculating the function $\Delta T(M)$ were derived, e.g., the Kargin–Slonimskii formula¹⁰⁵ and a number of similar formulae,¹⁰⁹ e.g.:

for polar polymers

$$\log M = 1.6 + \frac{20\Delta T}{200 + \Delta T},$$

for non-polar polymers,

$$\log M = 2.0 + \frac{10\Delta T}{100 + \Delta T}.$$

In a recent study¹¹³ of monodisperse specimens of poly(oxyethylene glycol) with low-molecular masses (1500–12000), a rather sharp transition from the rubbery elasticity plateau to the flow of a polymer was observed and a calibration curve was constructed in the form

Figure 3. Integral MMD functions (a, b) and calibration curve (c) for amorphous polypropylene.¹¹⁵ Obtained from GPC (a) and TMA (b) studies. Rod load, g: 0.5 (1), 2.0 (2). 10^{-3} MM: 180 (a, b); c: 52 (1), 189 (2) and 330 (3).

$$\ln M = A + B \left(1 - \frac{T_g}{T} \right). \quad (8)$$

It was found that for a wide array of polymers $A \approx 3$ and $B \approx 17$.

A calibration procedure was proposed,¹¹⁵ which refers to a polymer with an arbitrary MMD characterised by, e.g., GPC. To this end, the integral curve $\varphi(M)$ is compared with the integral curve $\varphi(T)$ which can be constructed in the $\varphi(T) - T_g/T$ coordinates. By comparing the MM and T values corresponding to the same value of the integral fraction it is possible to find the relation between MM and temperature, i.e., to construct a calibration curve for a wide range of MM using the data for one polymeric specimen.

The integral MMD curve of amorphous polypropylene is shown in Fig. 3a and the dependence $\varphi(T)$ in the coordinates of Eqn (8) is shown in Fig. 3b. The calibration curve (Fig. 3c) was constructed by comparing the MM and T values. As can be seen, the results obtained for three samples of polymers with different MM give a versatile dependence of the type (8).

Thermomechanical analysis can be applied to different types of loading of polymeric specimens, among which penetration and tension are the most popular.^{106, 113}

VII. Conclusion

Consideration of 'solution-free' approaches to the determination of MMD of polymers proposed by different authors shows that, in essence, there are no well-developed methods so far. First of all, this is due to the fact that the inverse problem, viz., determination of the relaxation time spectrum and, hence, the MMD of a polymer from the relaxation data, belongs to the so-called ill-posed mathematical problems.^{26, 47, 77–79, 116–118} Attempts at solving the problem require some *a priori* statements or experimental establishment of the relaxation time spectrum (or other property, e.g., viscosity or the flow point) with the MM of a polymer. In essence, it is this point to which all the approaches discussed above come. Regularisation methods for solving ill-posed problems,¹¹⁹ as applied to the problem of determining the relaxation time spectrum or, more particularly, the MMD of a polymer^{77–79, 117, 118} are also based on certain assumptions (see, e.g., Ref. 77).

Baumgarten *et al.*²⁹ derived the relaxation time spectrum (the so-called BSW spectrum) of monodisperse polystyrene specimens without any preliminary postulates by analysing the relaxation data using IRIS software (see Ref. 120). More recently, the BSW spectrum was used for the description of the relaxation properties of polybutadiene.^{38, 39} Empirical constants characterising the BSW spectrum, as well as the relaxation time spectrum itself, have no theoretical substantiation and it is unclear to what extent the expansion of the function $G(t)$ in exponents is unique.

It is likely, the lack of a well-founded theory which takes into account mutual effects of polymers with different MM is the most serious obstacle to the development of a relevant relaxation method for the determination of MMD of polymers. Similarly to the Rouse and Doi–Edwards theories, such a theory would help to obtain an exact relation between the MM and the corresponding relaxation time. An empirical relation,

$$\lambda(M) \propto M^\alpha,$$

where $\alpha \approx 3.4$ casts some doubt since there are strong reasons (see, e.g., Refs 30, 41, 80, 121) to believe that $\alpha = 4$.

Thermomechanical analysis seems to be the most promising method. Probably, mutual effects of polymers are more pronounced in isothermal (rheological and frequency) experiments than in the studies on the temperature dependence of deformation parameters. The relaxation time spectrum uniquely characterises both the frequency and temperature dependences of the relaxation properties of a polymer. However, as was shown experimentally, the relation between the flow point and the MM of a polymer is

much more pronounced than the relation between the frequency (time) of this transition and MM.

Further development of 'solution-free' methods will open prospects for the determination of MMD of polymer blends and composite matrices. This may give an impetus to scientific research in this area.

This review has been written with the financial support by the Russian Foundation for Basic Research (Project No. 96-03-33358).

VIII. Conclusion	742

Abstract. Data on the structures of tetrahydroborate complexes from X-ray diffraction analysis, neutron and electron diffraction, and IR and NMR spectroscopy are considered. It is shown that, in addition to the diversity of stabilising ligands, complexes of Group III and IV transition metals are characterised by diverse types of coordination of terminal (η^1 , η^2 and η^3) or bridging (between neutral molecular units) tetrahydroborate groups. Compounds with BH₄ groups with different denticities can be found among these complexes. Most tetrahydroborates of these metals in the oxidation states +3, +4 comply with the principle of maximum occupancy of the coordination sphere. Tetrahydroborates of Group III and IV metals exhibit clear-cut stereochemical non-rigidity (fluxionality): the protons of the BH₄ ligand are equivalent on the NMR time scale. Group I and V–VIII transition metals mainly form η^2 -complexes, which are stereochemically much more rigid than complexes of Group III and IV metals. It is suggested that electronic configuration of the central atom is the crucial factor determining different structures and stereochemical behaviours of the tetrahydroborate complexes. Data on the structures and properties of post-transition and s-element tetrahydroborates are also consistent with this assumption. The bibliography includes 248 references.

I. Introduction

Coordination compounds containing the simplest hydroborate anion BH₄[−] as a ligand possess many practically valuable properties. Tetrahydroborate complexes are used as selective reducing agents, starting compounds in the syntheses of complex and organometallic derivatives, precursors for the production of borides, hydrides and other inorganic materials, and as catalysts of hydrogenation, isomerisation, oligomerisation, polymerisation, *etc.* In addition, these complexes exhibit unusual structural and dynamic properties such as the ability to form metal–hydrogen–boron multicentre bonds and exceptionally low barriers to

the intramolecular exchange of bridging and terminal hydrogen atoms in the tetrahydroborate ligand.

In mononuclear complexes, a tetrahydroborate ligand either exists as the BH₄[−] ion or is linked to the metal through one, two or three M–H–B bridges (η^1 , η^2 and η^3 coordination, respectively). The forms of coordination of tetrahydroborate ligands in polynuclear complexes are even more diverse. The BH₄[−] anion is isoelectronic with a methane molecule. Therefore, it has been suggested that tetrahydroborates can serve as structural models for some steps in the activation of C–H bonds in saturated hydrocarbons. The existence of complexes with η^1 -, η^2 - and η^3 -BH₄ ligands has been proven by various structural methods. However, the NMR spectra of many tetrahydroborate complexes point to the equivalence of the four protons in the BH₄ group, which indicates that these compounds are fluxional, *i.e.* bridging and terminal protons of the tetrahydroborate ligands are able to undergo fast (on the NMR time scale) intramolecular exchange.^{1–5} Thus, most of tetrahydroborate complexes constantly exist in the state of fast dynamic transformation, resulting in the change of the mutual orientation of the complex-forming ion and the tetrahydroborate ligand.

Numerous attempts have been made to explain the unusual properties of tetrahydroborate complexes by such factors as the influence of the Coulomb interaction between the metal ion and the anion, the tendency of the central atom to fill its outer electron shell, the influence of stabilising ligands and so on. A great deal of information on the structures of tetrahydroborates of light elements was provided by *ab initio* quantum-chemical calculations. For transition metal complexes, these calculations are quite cumbersome and have now been performed for only a few objects. It is often impossible to determine unambiguously the most favourable configuration of the complex on the basis of calculations because the energies of different types of coordination of BH₄ ligands differ only slightly; therefore, the results of calculations need to be compared with experimental data (see several papers^{6–10} and references therein).

Tetrahydroborate complexes of various metals have been studied to different extents. The structures of tetrahydroborates of Group III and IV transition metals, especially uranium derivatives, and titanium and zirconium compounds have been studied in most detail. Complexes formed by Group I and V–VIII transition metals and by alkali, alkaline earth and post-transition metals are less studied. Therefore, this review starts with a brief characterisation of the physical properties of tetrahydroborate

complexes and methods for their investigation; the ability of various ligands to stabilise transition metal tetrahydroborates is also considered. This is followed by discussion of the structural and dynamic properties of tetrahydroborates of Group III and IV transition metals with terminal BH_4 ligands and comparison of these properties with the properties of Group I and V–VIII transition metal complexes. An attempt is made to interpret the regularities observed. Data on the structure of alkali, alkaline earth and post-transition metal tetrahydroborates and polynuclear complexes with bridging BH_4 groups are used to verify and refine the correlations found. The results of determination of the structures of tetrahydroborate complexes by electron, X-ray and neutron diffraction analyses and by IR spectroscopy as well as the data on the complexes of Group IV–VIII transition metals, for which the type of coordination of tetrahydroborate ligands has been characterised by NMR spectroscopy, are summarised in tables. Less reliable data on the ligand denticity based only on the results of IR spectroscopy and not confirmed by diffraction methods are cited as little as possible, only where it is necessary to complete the picture.

Hundreds of studies dealing with the investigation or application of tetrahydroborate complexes are published annually. About 200 of these complexes have been structurally characterised; new experimental results have been obtained for them in recent years. However, the questions of what factors determine the structural (type of coordination) and dynamic (stereochemical rigidity or fluxionality) properties of the BH_4 ligands in the complexes and whether or not these properties are related to one another (if they are related, what is the type of relationship) still remain to be answered.

In this review, we analyse the results of experimental determination of the type of coordination of BH_4 groups in different types of complexes by electron, neutron and X-ray diffraction analyses and by NMR spectroscopy. The results are used to make an assumption about the main factors determining the structural and dynamic features of tetrahydroborate complexes.

II. General characteristics of tetrahydroborate complexes

Compounds containing tetrahydroborate ligands are known for all Group IA, IIA and IIIA metals and for all transition metals, except for technetium, promethium, platinum, gold, francium, radium and some actinides, mainly of the berkelium subgroup.^{1–5} The results of studies of metal tetrahydroborate complexes by various methods are summarised in Tables 1–3. The formal oxidation numbers of metal atoms in these complexes vary from 0 to +4. Some metals can form the complexes in two different oxidation states [for example, Cu(I) and Cu(II), Yb(II) and Yb(III), U(III) and U(IV), *etc.*]; for titanium, complexes containing the central atoms in four different oxidation states (0, +2, +3, +4) have been structurally characterised. The ion radii of metal cations (r_i) in tetrahydroborates can differ by a factor of more than six [for example, for Be(II), $r_i = 0.27 \text{ \AA}$, and for Cs(I), $r_i = 1.67 \text{ \AA}$],²²² the surface area of the coordination sphere can differ by a factor of ~ 40 and the volume of the central atom, by a factor of 200. The BH_4^- ($r_i = 2.04 \text{ \AA}$) anion markedly exceeds in size any metal cation which forms complexes with it.¹ Depending on the nature of the central atom, the stabilising ligands and conditions, the compounds in question can be solid, liquid, or gaseous. In the crystalline state, tetrahydroborates having ionic, molecular, islet (ion-molecular) and polymeric (oligomeric) structures are known. Diamagnetic and paramagnetic tetrahydroborate complexes, both low- and high-spin ones, for example $(\text{TMEDA})\text{Cr}(\eta^2\text{-BH}_4)_2$ with $\mu_{\text{eff}} = 4.8 \mu_{\text{B}}$,⁹³ are known. Some tetrahydroborates are stable in air but most of them are unstable and decompose, often with an explosion, in the presence of air or moisture.

An important characteristic of tetrahydroborate complexes is the manner in which the BH_4 ligand is attached to the central atom. The structures of these complexes are determined most often using X-ray diffraction analysis. In many instances, this method can be used to determine the position of hydrogen atoms and establish the type of ligand coordination. The range of structurally characterised compounds includes complexes with

Note. The following designations are used: TMTA is trimethylhexahydrothiazine; bipy is bipyridine; TMTCN is 1,4,7-trimethyltriazacyclononane; *ansa*-Cp' is methylenebis(3-trimethylsilylcyclopentadienyl), CH₂(Me₃SiC₅H₃)₂; DPPP is 1,5-bis(diphenylphosphino)pentane, Ph₂P(CH₂)₅PPh₂.

tetrahydroborate complexes are usually close to the sum of the Shannon ion radius of the metal²²² and the radius of the BH₄

Figure 1. Coordination of terminal tetrahydroborate ligands in covalent complexes;

(a) monodentate η¹; (b) bidentate η²; (c) tridentate η³.

ligand with the corresponding denticity [for η³-BH₄, $r_i \approx 1.36(6) \text{ \AA}$ and for η²-BH₄, $r_i \approx 1.6(1) \text{ \AA}$].²²³ In most cases, the results of this summation are in good agreement with experimental results. For example, for La(III) with a coordination number of 12 ($r_i = 1.36 \text{ \AA}$),²²² the lanthanum–boron distances calculated in this way (2.72 and 2.96 Å) are close to the values found experimentally (2.76 and 2.90 Å) in [La(η²-BH₄)₂(η³-BH₄)₂(THF)₂][–] (see Ref. 18). However, when the coordination number is low and the complex contains bulky ligands, the calculated metal–boron distances deviate substantially from those found experimentally. In our opinion, these deviations point to a considerable influence of steric factors on the structural properties of the BH₄ ligands in the complexes. The use of so-

Figure 2. Coordination of bridging tetrahydroborate ligands in polynuclear complexes; (a–j) see the text.

called effective coordination numbers, instead of the true values, has been proposed for compounds of this type.²²³

Valuable information concerning the type of the metal–ligand bond in the compounds under consideration can be gained using vibrational (IR and Raman) spectroscopy.^{2,3} The observed absorption bands of BH_4 ligands with different denticities were assigned resorting to the studies of model compounds with known structures. Certain correlations between the spectral characteristics and structures of complexes were established. The most characteristic spectral region for the compounds in question is the region of stretching vibrations of the B–H bonds ($\sim 1650\text{--}2600\text{ cm}^{-1}$). As a rule, a tridentate BH_4 group is responsible for an intense absorption band at $\sim 2450\text{--}2600\text{ cm}^{-1}$ [stretching vibrations of the terminal B–H bonds, $\nu(\text{B-H}_t)$] and for an intense doublet of bands at about $2100\text{--}2200\text{ cm}^{-1}$ [stretching vibrations of the B–H bridging bonds, $\nu(\text{B-H}_b)$]. A bidentate type of coordination shows itself as an intense doublet of bands in the region of $2400\text{--}2600\text{ cm}^{-1}$ and an intense band (perhaps, with a shoulder) at $\sim 1650\text{--}2150\text{ cm}^{-1}$. Monodentate complexes are characterised by two broadened absorption bands, $\sim 2300\text{--}2450$ and $\sim 2000\text{ cm}^{-1}$ (see Refs 2–5). Complexes in which the BH_4 group is bound to the metal ion *via* one or several M–H–B bonds have been named covalent tetrahydroborates.²

Unlike X-ray diffraction and IR spectroscopy data, the data of NMR spectroscopy for many tetrahydroborate complexes, both ionic and covalent, point to the equivalence of the four protons in the BH_4 ligand. The disagreement between the results obtained by different methods is due to the difference between the time scales of X-ray diffraction analysis and IR spectroscopy (characteristic time $\sim 10^{-18}\text{--}10^{-20}\text{ s}$), on the one hand, and NMR (characteristic time $\sim 10^{-2}\text{--}10^{-9}\text{ s}$), on the other hand, and to the fluxionality of these compounds on the NMR time scale, *i.e.*, the ability of the bridging and terminal protons of tetrahydroborate ligands to undergo fast intramolecular exchange.^{2–5}

In terms of composition, tetrahydroborate complexes can be divided into two groups, homoleptic (containing one type of ligand) and heteroleptic (containing different ligands). Analysis of the vast experimental information accumulated to date permits one to establish the main types of tetrahydroborate complexes formed commonly by metals of each Group. Neutral homoleptic tetrahydroborates $\text{M}''(\text{BH}_4)_n$ are typical of alkali and alkaline earth metals, beryllium, magnesium and aluminium. Among transition and post-transition metals, these complexes are known only for some lanthanides in the oxidation states +2 or +3, titanium subgroup metals, some actinides, zinc, cadmium and thallium(I).^{1–5,224} Many neutral tetrahydroborates are able to attach additional BH_4 groups to give anionic complexes of the type $[\text{M}''(\text{BH}_4)_{n+k}]^{k-}$ ($k = 1\text{--}3$); however, this anion stabilises noticeably only tetrahydroborates of 3d metals of the beginning of the transition metal row, from Sc to Fe. No homoleptic anionic complexes of cobalt, nickel, copper or Group I and V–VIII 4d or 5d transition metals have been obtained in a pure state.²²⁵

In most cases, in addition to BH_4 groups, tetrahydroborate complexes contain various stabilising ligands; the ligands found most often are ethers and polyethers, amines and polyamines (both cyclic and acyclic), cyclopentadienide anion derivatives and compounds of trivalent phosphorus (tertiary organic phosphines and phosphites). A large number of relatively stable complexes with ethers have been prepared for elements for which non-solvated neutral tetrahydroborates are known. A complex with tetrahydrofuran stable at room temperature is also formed by divalent manganese the ions of which possess a half-filled *d* shell.⁹⁹ For other transition metals, these complexes are either unstable [for example, the chromium complex $\text{Cr}(\text{BH}_4)_2(\text{THF})_2$ decomposes at -20°C] or unknown.³

Complexes with ligands such as halide, alkoxy or aryloxy anions and NO are rather rarely encountered in the chemistry of tetrahydroborates. Complexes with CO molecules as ligands are quite numerous but are mainly formed for Group VI–VIII metals. Anionic ligands (amides, alkoxides, aryloxides, *etc.*) stabilise effectively only tetrahydroborates formed by 3d metals of the beginning of the transition metal row. Examples of stabilisation of platinum metal complexes by cyclopentadienyl ligands are also documented. Unlike the above-mentioned ligands, amines and polyamines stabilise more efficiently complexes of metals from the middle to the end of each transition metal row.

Organic tertiary phosphines are the most efficient stabilising ligands for tetrahydroborates. In many cases, complexes contain hydride ligands together with phosphines. Tetrahydroborate complexes with these ligands are known for most transition metals but not for rare earth elements. The broad range of stabilising capacity of phosphines is stipulated by the broad range of variation of steric and electronic properties of these compounds. To fill the valence shells of metal atoms of the beginning of a transition metal row, a large number of electron-donating ligands are needed; in this case, strong electron donors having relatively small sizes such as trimethylphosphine and bis(dimethylphosphino)ethane are effective. On the contrary, to stabilise Group VIII metal complexes, a few ligands should shield the central atom having many valence electrons from contacts with the outer-sphere electron acceptors. In this case, the stability of complexes increases when they contain bulky ligands $[\text{P}(\text{cyclo-C}_6\text{H}_{11})_3, \text{PBu}_3]$.

The most diverse types of tetrahydroborate complexes are formed by Group I, III and IV transition metals, although no complexes with CO ligands have been found for Group III metals and no complexes with CO or Cp ligands have been described for Group I transition metals. The tetrahydroborate complexes of nickel and palladium are least diverse (no complexes of this type are known for platinum), which is in sharp contrast with the extremely varied chemistry of coordination compounds of these metals with many other ligands (Ni, Pd, Pt are typical complex-forming elements). The typical stabilising ligands vary depending on the position of the metal in the Periodic Table. Whereas for

Note. A plus sign means that for the given group of metals, tetrahydroborate complexes with ligands of this particular type are known, while a minus sign means that these complexes are unknown; the metal (or ion) to which the plus sign refers is given in parentheses.

complexes of Group III and IV transition metals, ethers and amines are commonly found ligands, in the case of Group I and V–VIII metal tetrahydroborates, compounds with these ligands are unusual. The ligands found most often for the latter type of metals are derivatives of tertiary organic phosphines, which are represented by only a few examples in the case of Group III and IV transition metal complexes.

The dependence of the types of stabilising ligands and complexes they form on the nature of the central transition metal atom can be followed by analysing the data of Table 4. It can be seen that the number of ligand types capable of efficient stabilisation of tetrahydroborate complexes decreases on passing from Group III and IV transition metals to Group VIII metals, especially to nickel and palladium for which only few examples of tetrahydroborate complexes are known. The decrease in the stability of tetrahydroborate complexes is even more pronounced on passing from 3d to 4d and 5d metals. As a result of these two trends, no tetrahydroborate complexes of 5d metals of the end of the transition row, *viz.*, platinum or gold, have been characterised.

III. Transition metal complexes with terminal BH_4 ligands

The complexes of Group III and IV transition metals are most diverse regarding the mode of addition of the BH_4 ligands to the central atom (see Table 1). Compounds with any of the main types of coordination (see Fig. 1) can be found among complexes of these metals. Molecules containing BH_4 ligands coordinated to the same metal atom in two different modes are also known, for example, $\text{Sc}(\eta^2\text{-BH}_4)(\eta^3\text{-BH}_4)_2(\text{THF})_2$,¹¹ $\text{Y}(\eta^2\text{-BH}_4)(\eta^3\text{-BH}_4)_2\cdot(\text{THF})_3$,¹⁴ $(\text{BP})\text{Zr}(\eta^3\text{-BH}_4)(\eta^2\text{-BH}_4)\cdot(\text{THF})$.⁶⁴ The $\text{Hf}_2\cdot(\text{NPP})_2\text{H}_2(\text{BH}_4)_3$ complex contains simultaneously mono-, bi- and tridentate BH_4 groups.⁸³

The structures of Group I and V–VIII metal complexes are much less studied (see Table 1); this can be explained by the sensitivity of many of them to oxygen and moisture and thermal instability and the difficulty of their synthesis and investigation arising thereupon. The structural chemistry of the tetrahydroborates of Group I and V–VIII transition metals is much scantier than that for Group III and IV metals. No complexes with tridentate BH_4 groups have been found for them; in the majority of their compounds, the BH_4 groups are bidentate ligands.

Among compounds of Group I and V–VIII transition metals, there are quite a few complexes with a monodentate coordination of tetrahydroborate ligands ($\sim 25\%$ of the total number of structurally characterised complexes of the metals in question); this type of coordination is rather poorly studied. Nowadays, the

existence of complexes with $\eta^1\text{-BH}_4$ groups has been reliably established by X-ray diffraction analysis and neutron diffraction. Structures of about 10 compounds of this type determined by X-ray diffraction analysis are documented; one of these compounds has also been studied by neutron diffraction. Taking into account the data of NMR spectroscopy, we would like to note that for Group I and IV–VIII transition metals, at least one example of an η^1 -complex can be given for each group.

It is noteworthy that all η^1 -complexes incorporate P-, N- or S-donor ligands (tertiary organic phosphines, amines and thia- and aza-macrocycles) possessing strong electron-donating properties. In most of these compounds, the central atom is linked to three or more phosphorus, nitrogen, or sulfur atoms.

In terms of the type of the stabilising ligand, the compounds considered can be divided into two groups, namely, complexes with P- and N-donor ligands, which differ markedly in physico-chemical characteristics. The length of the $\text{M}-\text{H}_b$ bond in the former type of compound varies from 1.60 to 1.88 Å and the $\text{M}-\text{B}$ distance ranges from 2.44 to 2.84 Å. The $\text{M}-\text{H}-\text{B}$ bond is bent, the MHB angle ranging from 121 to 164°. The IR spectra of these compounds exhibit broad absorption bands in the ranges of 2300–2350 cm^{-1} [$\nu(\text{BH}_t)$] and $\sim 2000\text{--}2100\text{ cm}^{-1}$ [$\nu(\text{BH}_b)$], which is consistent with the values predicted for η^1 -complexes.³ Resorting to the above-mentioned correlation between the structures and spectroscopic properties, the presence of monodentate BH_4 groups in L_3CuBH_4 type complexes [$\text{L} = \text{P}(\text{HPh})_2$, $\text{P}(\text{OPr}^i)_2\text{Ph}$, $\text{P}(\text{Me}_2\text{Ph})$] was demonstrated by IR spectroscopy. Study of the relationship between the structure of the copper compounds L_nCuBH_4 and the electronic and steric properties of phosphine ligands L showed that the complexes $\text{L}_3\text{Cu}(\eta^1\text{-BH}_4)$ with monodentate tetrahydroborate ligands are formed only when the electron-donating ligands L have a moderate size. A decrease in the electron-donating ability of the ligands, as well as an increase in their size, result in the complexes $\text{L}_2\text{Cu}(\eta^2\text{-BH}_4)$.¹¹⁸

However, compounds with N-donor ligands follow a different type of regularities. X-ray diffraction data point to an unusually long metal–boron distance (3.09–3.31 Å) in these compounds and IR spectra attest to the presence of BH_4^- anions.^{130,131} In solutions, these complexes appear to have ionic structure.¹³²

For compounds with P-donor ligands, the difference between the experimentally determined metal–boron distance and the ion radius of the central atom is 2.0 ± 0.2 Å. In the complexes with N-donors, this difference is close to 2.4 Å, *i.e.* it substantially exceeds the radius of the BH_4^- anion (2.04 Å). This long metal–boron distance implies apparently the absence of covalent interaction between the central atom and the ligand, the monodentate

coordination of the BH_4 ligand in the crystals of these compounds being related to packing effects.

The NMR spectra of some monodentate complexes exhibit separate signals for the terminal and bridging protons, *i.e.* these compounds are less fluxional than complexes with tridentate BH_4 groups. It was shown in relation to iron compounds that an increase in the size of stabilising ligands increases the stereochemical rigidity of complexes, *i.e.* stabilises the η^1 -coordination.¹²³ However, comparison of the structures of $\text{Ti}(\eta^2\text{-BH}_4)_2\text{.(DMPE)}_2$ (d^2 -configuration of titanium) with $\text{V}(\eta^1\text{-BH}_4)_2\text{.(DMPE)}_2$ (d^3 -configuration of vanadium)^{53,54} and $\text{CrH}(\eta^2\text{-BH}_4)(\text{DMPE})_2$ (d^4 -configuration of chromium) with $\text{FeH}(\eta^1\text{-BH}_4)(\text{DMPE})_2$ (d^6 -configuration of iron),^{94,123} which contain Ti(II) or V(II) and Cr(II) or Fe(II) ions with closely similar radii, demonstrates that η^1 -coordination is not determined by steric factors alone. The η^1 -coordination may also be facilitated by the d^3 -configuration of V(II) and the d^6 -configuration of Fe(II) , which are favourable for the formation of octahedral complexes. The tetrahedral geometry, preferred for d^{10} ions for energy reasons, stipulates apparently the formation of the monodentate complexes $\text{Cu}(\eta^1\text{-BH}_4)(\text{PMePh}_2)_3$ and $\text{Ag}(\eta^1\text{-BH}_4)(\text{PMePh}_2)_3$, despite the fact that the ionic radius of Ag(I) is greater than that of Cu(I) and the volume of the silver coordination sphere is sufficient for η^2 -coordination.^{125,129} A η^1 -coordination of BH_4 has been suggested previously for $\text{RuH}(\eta^2\text{-BH}_4)(\text{PPh}_3)_3$,¹⁸³ however, the fact that its IR spectrum differs from the IR spectra typical of η^1 -complexes and resembles the spectrum of the complex $\text{RuH}(\eta^2\text{-BH}_4)(\text{PMe}_3)_3$, which has been characterised by X-ray diffraction analysis (see Table 1), points to a bidentate coordination of the BH_4 group in this complex.

Thus, in all the known cases, monodentate coordination of the BH_4 groups is due to the presence of stabilising ligands possessing definite properties (strong electron donors having a large size), *i.e.* this type of coordination is forced. Complexes with η^1 -coordination of BH_4 groups might also be possible for ions with a different electron configuration provided that the coordination sphere contains a sufficient number of bulky electron-donating ligands. However, the currently available data do not allow one to predict unambiguously the appearance of η^1 -coordination in each particular case.

The IR spectroscopic studies show that in most cases, experimental results are in good agreement with those predicted theoretically for the BH_4 groups of the corresponding coordination;^{2–5} however, in some cases, the absorption bands due to the stretching vibrations of terminal B–H bonds occur at a substantially lower frequency than expected (see Tables 1, 2). Experimental data on the structures of tetrahydroborate complexes show that the idea of the three main types of coordination of the BH_4 ligands in so-called covalent tetrahydroborates is an idealisation. Among complexes of both Group III, IV and Group I, V–VIII transition metals, there are compounds with a distorted geometry of coordinated BH_4 ligands (unequal M–H_b distances and MH_bB angles), which hampers unambiguous identification of the type of coordination. For example, in the structure of $\text{Ti}(\eta^2\text{-BH}_4)(\eta^3\text{-BH}_4)_2(\text{PMe}_3)_2$, the tridentate coordination of the two BH_4 ligands is so distorted that these groups can be regarded as being coordinated through the B–H bonds (the Ti–B distance is 2.27 Å, Ti–H_b is 1.73 Å, the MH_bB angle is 112°).⁵²

It has been noted that this coordination can be regarded as being characteristic of a hypothetical transition state in the activation of the methane molecule, isoelectronic with the tetrahydroborate anion. A similar distortion of a symmetrical coordination is also observed for some η^2 -complexes, for example, for $(\text{phen})(\text{PPh}_3)\text{Cu}(\eta^2\text{-BH}_4)$ (the Cu–B distance is 2.29 Å, Cu–H_b is 1.63 Å).¹¹⁴ This type of coordination plays, apparently, an important role in the exchange of bridging hydrogen atoms and hydride ligands in the complexes $\text{MH}_3(\text{BH}_4)\text{L}_2$.¹⁰ It has been noted above that the M–H_b–B bridge in monodentate complexes is bent, and the MH_bB angle varies over wide limits (from 120 to 164°); hence, in some cases [for example, in

$\text{Hf}_2(\text{NPP})_2\text{H}_2(\eta^3, \eta^2, \eta^1\text{-BH}_4)_3$], the coordination of BH_4 groups found experimentally can be considered to be intermediate between mono- and bidentate coordinations.⁸³ The distortion of the geometry of coordinated ligands affects substantially the spectral properties of the complexes; therefore, in some cases, the denticity of the BH_4 groups cannot be identified unambiguously from the data of vibrational spectroscopy; for example, this is true for the copper and titanium compounds considered above.^{52,114}

Compounds of Group III and IV transition metals possess clear-cut fluxionality; therefore, all the protons of the BH_4 ligands are equivalent on the NMR time scale.^{2–5} Until recently, for none of the complexes of this type, were separate signals for the terminal and bridging protons of tetrahydroborate ligands distinguished in the NMR spectra, not even at low temperatures (for some compounds, studies were performed at ~150 K).³ The activation energy for the exchange of terminal and bridging protons in these compounds equals ~5 kcal mol^{–1}, as estimated for $\text{Cp}_3\text{U}(\eta^3\text{-BH}_4)$.³ For compounds of Group IB metals, separate signals for bridging and terminal protons have not been identified either.²²⁶ Only recently, was the first titanium compound reported [the complex $[\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]^-[K(18\text{C}6)]^+$] for which the limit of slow proton exchange was attained at 178 K and individual signals for the terminal and bridging protons of $\eta^3\text{-BH}_4$ were observed.⁶⁵ The fact that the tetrahedral geometry of the BH_4^- anion in this complex is virtually non-distorted indicates a low contribution of the covalent constituent to the interaction of the central atom with this ligand. Note that in the analogous chromium and molybdenum complexes $[\text{M}(\text{CO})_4(\eta^2\text{-BH}_4)]^-$, the tetrahydroborate ligand has a bidentate coordination. The unique structural and dynamic properties of the titanium complex (this is the only example of a tridentate tetrahydroborate group for which individual signals from the terminal and bridging protons were observed) are apparently due to the combination of the carbonyl groups (active π -acceptors and the most 'powerful' strong-field ligands) with an 'early' 3d metal in a low oxidation state in one molecule.

Many tetrahydroborates of Group V–VIII metals are much less fluxional than complexes formed by Group III and IV transition metals (see Table 2). At low temperature, individual signals of the terminal and bridging protons for both η^2 - and $\eta^1\text{-BH}_4$ groups can be distinguished in the NMR spectra of these compounds. It is of interest that in some cases, bridging protons of the $\eta^2\text{-BH}_4$ groups account for two separate signals and the exchange of these non-equivalent bridging protons with terminal protons occurs at different rates.¹⁷¹ In some complexes, this proton exchange does not proceed at a noticeable rate even at room temperature, or at higher temperatures. Thus for one of the least fluxional tetrahydroborates $\text{Os}(\eta^2\text{-BH}_4)\text{H}_3(\text{PPR}_3)_2$, this process cannot be observed even at 360 K. The activation energy for the exchange of the terminal and bridging protons in this compound cannot be determined experimentally because this compound decomposes at higher temperatures. According to estimates,¹⁰ this energy is greater than 20 kcal mol^{–1}. At 300 K, the bridging protons in this compound undergo fast exchange with the hydride ligands ($\text{Os})\text{H}_3$ (activation energy ~13 kcal mol^{–1}). The results of experimental studies and quantum-chemical calculations for $\text{Os}(\eta^2\text{-BH}_4)\text{H}_3(\text{PPR}_3)_2$ provide grounds for suggesting that the exchange of bridging hydrogen atoms (B)H_b with the hydride ligands (Os)H_t without participation of the terminal hydrogen atoms (B)H_t proceeds *via* a transition state in which the metal is coordinated to the B–H bond.¹⁰

The data presented above demonstrate that the existing view about the exceptionally high fluxionality of transition metal tetrahydroborate complexes needs to be corrected. Individual signals for the terminal and bridging protons cannot be observed (with only one exception⁶⁵) only for compounds of Group I, III and IV transition metals. Among Group V–VIII transition metal compounds, many complexes do give rise to separate NMR signals for the terminal and bridging protons of the BH_4 ligands. The fluxionality decreases with an increase in the size of the

stabilising ligands. This has been shown in relation to the iron complex $\text{FeH}(\text{BH}_4)_2$ ($\text{L} = \text{DMPE}$, DEPE , DPrPE) and a niobium complex with the Cp and Cp^* ligands, respectively.^{123, 169} The results of analysis of the activation energy for the exchange of bridging and terminal protons suggest that the fluxionality of the complexes decreases also on passing from Group V metals to Group VIII metals and from $3d$ metals to $4d$ or $5d$ metals (see Table 2). Thus, the decrease in the fluxionality of tetrahydroborates occurs in the same direction as the decrease in their thermal stability mentioned above. The correlation observed between these properties might be due to the fact that a decrease in the fluxionality is indicative of an increase in the degree of covalency of the $\text{M}-\text{H}_b$ bond, which increases the probability of decomposition of tetrahydroborate complexes by the oxidative addition mechanism ($\text{MBH}_4 \rightarrow \text{HMBH}_3$).

IV. Possible reasons for the differences in the structural and dynamic properties of tetrahydroborate complexes

What is the reason for the so sharp differences in the types of ligand coordination and in the structural and dynamic properties of the complexes formed by Group III and IV transition metals and those formed by Group I, V–VIII transition metals? The attempts to rationalise the structure of tetrahydroborate complexes in terms of the Coulomb interaction between the BH_4^- anions and metal cations (with the assumption that enhancement of the Coulomb forces should increase the degree of covalence of the metal–boron bond and the denticity of the BH_4 ligand²²⁷) do not provide satisfactory results. The attractive force between the anion and the central atom in many complexes of Group I, V–VIII transition metals should be greater than that in Group III and IV metal complexes because the ratio of the ion charge to the ionic radius squared (z/r^2) for, for example, $\text{Fe}(\text{II})$, $\text{Co}(\text{II})$ and $\text{Ni}(\text{II})$ is greater than this ratio for $\text{U}(\text{III})$ or cerium subgroup lanthanides. Nevertheless, the denticity of the BH_4 ligand is lower in the former type of complexes.

Since the oxidation number of the central atoms in most of the Group I, V–VIII transition metal tetrahydroborates is +2, while that in the complexes of Group III and IV transition metals is +3 or +4, one can suggest that the difference in the ligand denticity is related to the oxidation state of the central atom. However, this suggestion is at variance with the existence of a number of bidentate complexes of Group V–VIII transition metals containing the central atom in the +3 and +4 oxidation state [for example, $\text{Ir}(\eta^2\text{-BH}_4)_2\text{H}_2(\text{PBu}_3)_2$, $\text{WH}_3(\eta^2\text{-BH}_4)(\text{PMe}_3)_3$, $\text{OsH}_3(\eta^2\text{-BH}_4)(\text{PPr}_3)_2$]; conversely, complexes of divalent ytterbium contain tetrahydroborate groups coordinated in the tridentate manner (see Table 1).

The most widespread hypothesis states that the tetrahydroborate ligand in the complexes is linked to the central atom *via* covalent two-electron three-centre $\text{M}-\text{H}-\text{B}$ bonds and is isolobal to the chloride, allyl or cyclopentadienyl anion, *i.e.* it acts as a two-, four- or six-electron donor, depending on the denticity. According to this hypothesis, the type of coordination (η^n) of the BH_4 ligand corresponds to the number n of electron pairs provided by this ligand and the ligand denticity is determined by the tendency of the central atom to fill the outer electron shell and can be predicted using the effective atomic number (EAN) rule.^{228–230}

However, the attempts to apply this approach to a broad range of objects showed that predictions based on this hypothesis often do not comply with experimental data regarding both chemical and physical properties of tetrahydroborate complexes, or with the EAN rule. For example, in conformity with this hypothesis, $\text{Cu}(\eta^2\text{-BH}_4)(\text{phen})(\text{PPh}_3)$ and $\text{Cp}_2\text{M}(\eta^2\text{-BH}_4)_2$ ($\text{M} = \text{Zr}$, Hf) should be 20-electron complexes, $\text{Y}(\eta^2\text{-BH}_4)(\eta^3\text{-BH}_4)_2(\text{THF})_3$ should be 22-electron, $\text{M}(\eta^3\text{-BH}_4)_4$ ($\text{M} = \text{Zr}$, Hf) should be 24-electron, and $[\text{Zn}(\eta^2\text{-BH}_4)_4]^{2-}$ should even be a 26-

electron complex.²³¹ This hypothesis cannot also interpret the change in the type of coordination in the pairs of isoelectronic complexes $\text{Sc}(\eta^2\text{-BH}_4)(\eta^3\text{-BH}_4)_2(\text{THF})_2$, $\text{Y}(\eta^3\text{-BH}_4)_3(\text{THF})_2$ and $(\text{MeOCH}_2\text{CH}_2\text{C}_5\text{H}_4)_2\text{Pr}(\eta^3\text{-BH}_4)$, $(\text{MeOCH}_2\text{CH}_2\text{C}_5\text{H}_4)_2\text{Yb}(\eta^2\text{-BH}_4)$. The paramagnetism of the vanadium $\text{V}(\eta^2\text{-BH}_4)_3(\text{PMe}_3)_2$ ($\mu_{\text{eff}} = 2.5 \mu_{\text{B}}$),⁸⁴ chromium $(\text{TMEDA})\text{Cr}(\eta^2\text{-BH}_4)_2$ ($\mu_{\text{eff}} = 4.8 \mu_{\text{B}}$),⁹³ and cobalt $\text{Co}(\eta^2\text{-BH}_4)[\text{MeC}(\text{CH}_2\text{PPh}_2)_3]$ ($\mu_{\text{eff}} = 3.1 \mu_{\text{B}}$)¹⁰⁹ complexes considered in terms of this hypothesis does not agree with the denticity of the BH_4 ligands found for these complexes. The Lewis acidity of the allegedly 18-electron complex $\text{Zn}(\eta^2\text{-BH}_4)_2$ (see Ref. 231) and the 24-electron complexes $\text{M}(\eta^3\text{-BH}_4)_4$ ($\text{M} = \text{Zr}$, Hf) cannot be explained either.^{232, 233} When the number of electrons is calculated in this way, deviations from the EAN rule are observed for many structurally characterised transition metal tetrahydroborates; the deviation increases with an increase in the number and denticity of the BH_4 ligands in the complex, which indicates that this method overestimates the number of electrons donated by the tetrahydroborate ligand.

It should also be noted that, in accordance with the views considered above,^{222–230} the strength of the metal–tetrahydroborate ligand bond should increase with an increase in the number of $\text{M}-\text{H}$ ‘covalent’ bonds, *i.e.* with an increase in the ligand denticity. This, in turn, should result in an increase in the stereochemical rigidity of complexes on passing from monodentate to bi- and then to tri-dentate coordination of BH_4 groups. However, experimental results point to an opposite trend, namely, complexes with η^2 - and even η^1 - BH_4 groups are stereochemically more rigid than complexes with η^3 - BH_4 ligands.

Thus, the hypothesis that, depending on its denticity, the BH_4 group is isolobal to chloro, allyl or cyclopentadienyl ligand cannot explain and predict correctly the chemical, physical or structural properties of transition metal tetrahydroborates. Data on a decrease in the fluxionality of complexes with η^3 - BH_4 groups with respect to the complexes with η^2 - BH_4 and η^1 - BH_4 groups point to a low contribution of covalent interaction to the bond of the metal with the BH_4^- anions, at least, for Group III and IV transition metals. This conclusion is in agreement with the results of calculations carried out for the $\text{L}_{4-n}\text{Cu}-\text{H}_n-\text{BH}_{4-n}$ complexes ($n = 1, 2, 3$), which showed a largely ionic character of the $\text{Cu}-\text{H}_n-\text{BH}_{4-n}$ bond and electrostatic nature of the interaction between the coordinated copper atom and the BH_4^- anion with a relatively small contribution of the covalent bond.²³⁴ This conclusion is also consistent with the results of a study of copper tetrahydroborate complexes by mass spectrometry with extraction of ions from the solution (electro-spray mass spectrometry).^{235, 236}

The change in the type of coordination of the BH_4 ligands in Group III and IV transition metal complexes is much better explained by the influence of purely steric properties of ligands if one assumes that these complexes tend to fill the coordination sphere of the central atom as fully as possible and that a tridentate coordination of the BH_4 group to the metal atom, which implies the largest volume occupied by this group, is the most favourable. It is assumed that this type of coordination is always realised whenever it is allowed by the spatial conditions in the complex and that transition to other types of coordination is induced by the influence of steric factors. On this basis, a procedure for the calculation of the degree of occupancy of the metal coordination space was developed and convincing examples confirming the efficiency and predictive capacity of this approach were cited.^{237 †} The trend to fill the coordination sphere of the central atom as fully as possible and the high coordination numbers typical of tetrahydroborates of Group III and IV transition metals attest to a high degree of ionicity of the $\text{M}-\text{BH}_4$ bond, which is consistent with the substantial fluxionality of these compounds.

Nevertheless, several examples demonstrate that the scope of this approach is also limited. It is mainly applicable to Group III

† Unfortunately, only few steric constants of ligands are given in the study cited,²³⁷ which narrows down the scope of application of this method.

and IV transition metal compounds, although with exceptions. For example, only half of the BH_4 groups in the $[\text{La}(\eta^3\text{-BH}_4)_2(\eta^2\text{-BH}_4)_2(\text{THF})_2]^-$ anion are coordinated as η^3 -ligands, despite the fact that the metal coordination sphere is filled only to 86%.¹⁸ This approach cannot be used to interpret the structure of complexes formed by transition metals of other groups. For example, in the $[\text{Mn}(\eta^2\text{-BH}_4)_3(\text{THF})]^-$ and $[\text{Zn}(\eta^2\text{-BH}_4)_3]^-$ anions, the BH_4 ligands have η^2 -coordination,^{100, 101, 134} although the coordination spheres of the central atom are filled only to 86% and 75%, respectively.

Thus, in the general case, the difference between the types of coordination of the BH_4 ligands in transition metal compounds cannot be explained by either the influence of the oxidation state of the central atom, or the different electrostatic interaction of the metal with the ligands, or by the 'tendency' of the central atom to fill the outer electron shell, or by the influence of spatial factors.

Analysis of the data presented in Tables 1, 2 suggests that the main factor determining the differences between the structures and dynamics of the tetrahydroborate complexes of Group III and IV transition metals, on the one hand, and Group I, V–VIII metals, on the other hand, is the difference between the electronic configurations of the central atoms.

The electronic configuration of Group III and IV transition metals in compounds with tridentate tetrahydroborate ligands (except for the complex of zerovalent titanium with carbonyl groups⁶⁵) is d^0 (or d^1 in the case of complexes of trivalent titanium). In the complexes of Group I, V–VIII transition metals, the central atom with the d^n -configuration ($n = 2–10$) has at least two electrons not involved in the formation of the chemical bonds in the outer d shell. The fact that no examples of structurally characterised complexes of these metals with tridentate BH_4 ligands are available suggests that the presence of two or more electrons in the outer d shell destabilises the η^3 -coordination and, therefore, the η^2 -coordination becomes more favourable from the energy standpoint. Thus, whereas the bidentate coordination is sterically forced in complexes with central atoms having the d^0 - and d^1 -configuration, in the case of ions with d^n -configurations ($n = 2–10$), it is the η^2 -coordination that is realised without steric restrictions.

The increase in the stereochemical rigidity of complexes on passing to compounds of Group V–VIII metals can be accounted for by the presence of electrons in the outer d shell which do not participate in the formation of chemical bonds and decrease the energetic profitability of the most probable rearrangement pathway $\eta^2-\eta^3-\eta^{2'}$.⁵⁷ Indeed, quantum-chemical calculations¹⁰ showed that $\eta^2-\eta^1-\eta^{2'}$ is an energetically more favourable pathway for the exchange of the bridging and terminal protons of the BH_4 group in the complex $\text{Os}(\eta^2\text{-BH}_4)_3(\text{PPt}_3)_2$.

In conformity with the above-noted crucial influence of the electronic configuration of the central atom on the structural and dynamic properties of the tetrahydroborate ligands in the complex, derivatives of titanium group metals with the oxidation number +2 should contain bidentate BH_4 ligands. In fact, no examples of Ti(II) compounds with tridentate BH_4 groups are available; in the d^2 -complexes, $\text{Cp}^*\text{Ti}(\eta^2\text{-BH}_4)[(\text{Me}_2\text{PCH}_2)_3\text{SiBu}^t]$ and $\text{Ti}(\eta^2\text{-BH}_4)_2(\text{DMPE})_2$, the BH_4 groups are coordinated as bidentate ligands.^{54, 55} However, in the d^0 -complex $\text{Yb}(\eta^3\text{-BH}_4)_2(\text{Py})_4$, these ligands are tridentate,²² despite the substantially greater ionic radius of the central atom, which decreases the Coulomb interaction.

In this connection, we would like to mention the well-known influence of lone electron pairs on the structure of coordination compounds explained by repulsion of the coordinated ligands from non-bonding electrons.²³⁸ It was noted that, when the number of non-bonding d electrons is 1 to 3, their effect on the structural properties of molecules is normally too low to be detected experimentally. However, the examples considered above demonstrate that the type of coordination and the dynamic behaviour of the BH_4 ligand change crucially even in the presence of two non-bonding outer d electrons.

As any other corollary based on the generalisation of experimental data, this assumption leaves room for exceptions the discovery and analysis of which would result in further development of the views on the structures of the compounds considered. To verify the assumption concerning the reasons for the differences in the modes of coordination and dynamic properties of BH_4 ligands, it is necessary, in particular, to study complexes of Group IV transition metals with the central atom in a low oxidation state and to develop methods for the synthesis and study of compounds of Group V–VIII metals in high oxidation states.

V. Complexes of post-transition metals with terminal BH_4 ligands

The assumption that metal d electrons destabilise the η^3 -coordination of the BH_4 groups more significantly than the η^2 -coordination relied on analysis of the results of quantum-chemical calculations for complexes with central d^{10} ions.^{239, 240} It was suggested that this destabilisation should decrease the difference between the energies of η^2 - and η^3 -coordinated groups and thus enhance the fluxionality of tetrahydroborate complexes. Indeed, no data about non-equivalence of the terminal and bridging protons in the tetrahydroborate complexes with d^{10} -configuration of the central atom can be found in the literature. Moreover, experimental data point to specific properties of the complexes in which the outer d shell of the metal ions is either half or completely filled (d^5 or d^{10}). Thus Mn(II) , Cu(I) and Zn(II) complexes are much more numerous and thermally stable than complexes of other Group V–VIII transition metals or post-transition metals.

It could be suggested that the presence of a filled d shell influences not only the thermal stability of the complex but also the mode of coordination of the BH_4 groups. However, it can be seen that both post-transition metals (Zn , Cd , Hg , Ga , In) having a closed outer d^{10} shell and Group I and V–VIII transition metals having d^n -configurations ($n = 2–10$) tend to be coordinated by BH_4 in a bidentate fashion even in those cases where steric factors are favourable for η^3 -coordination (see Table 1). Indeed, the complexes $\text{Zn}(\eta^2\text{-BH}_4)_2$ and $[\text{Zn}(\eta^2\text{-BH}_4)_3]^-$ contain bidentate BH_4 ligands, despite the fact that the metal coordination sphere is not 100% full {in $[\text{Zn}(\eta^2\text{-BH}_4)_3]^-$, it is only 75% full}. Apparently, even a closed outer d -shell destabilises η^3 -coordination, although, due to its higher symmetry, a less pronounced destabilisation of the complex should be expected in this case.

The paucity of post-transition metal complexes the structures of which are known can be explained by their low thermal stability (see Table 1). The complex $\text{Cp}(\text{CO})_2\text{FeGa}(\eta^2\text{-BH}_4)[(\text{CH}_2)_3\text{NMe}_2]$ is the only example, among gallium tetrahydroborate complexes with terminal BH_4 groups, the structure of which has been established by X-ray diffraction analysis.¹⁴³ The structural data for other gallium complexes presented in Table 1 have been obtained by gas phase electron diffraction analysis. No examples of structurally characterised tetrahydroborate complexes of mercury, indium or thallium can be found in the literature. However, the conclusion about bidentate coordination of the BH_4 ligand in $\text{Me}_2\text{In}(\eta^2\text{-BH}_4)$ has been drawn on the basis of IR-spectroscopic data.¹⁴⁴ The IR spectra of the tetrahydroborate complexes of post-transition metals reported in the literature generally comply, in the region of stretching B–H vibrations, with those expected for bidentate BH_4 groups (see Table 1).

The synthesis of tetravalent germanium and tin tetrahydroborates $\text{M}(\eta^3\text{-BH}_4)_4$ ($\text{M} = \text{Ge}$, Sn) has been reported;²⁴¹ they were obtained as solid compounds stable in air up to 473 K and containing tridentate (according to IR spectroscopy) tetrahydroborate ligands. An estimate of the degree of filling of the coordination sphere in these compounds, which we performed using published data,^{223, 237} showed that in the case of Ge(IV) , η^3 -coordination of the four BH_4 groups is unlikely because the coordination sphere of the central atom is overcrowded, while the Sn(IV) coordination sphere in $\text{Sn}(\eta^3\text{-BH}_4)_4$ should be filled to 100%. Covalent tetrahydroborates with filled coordination

spheres of the metal atoms should be volatile compounds unstable in air, like $\text{Zr}(\eta^3\text{-BH}_4)_4$. Therefore, the properties described for tetravalent germanium and tin tetrahydroborates, and even the mere fact of existence of these compounds, appear doubtful. It is noteworthy that reports concerning the syntheses of unusual tetrahydroborate complexes of transition metals, such as Cp_3CeBH_4 ²⁴² and $\text{Cp}_2\text{MO}(\eta^2\text{-BH}_4)_2$ ($\text{M} = \text{Mo}, \text{W}$),²⁴³ have been published and repeatedly cited, although subsequent attempts to reproduce them failed.^{244, 245}

VI. Complexes of Group IA and IIA metals and aluminium with terminal BH_4 ligands

The structures of alkali and alkaline earth tetrahydroborate complexes are little studied. Among alkali metal complexes, lithium compounds have been studied most comprehensively. Table 1 presents several examples of complexes of univalent lithium with η^2 - and η^3 -coordinated BH_4 ligands. Antsyshkina *et al.*¹⁴⁶ believe that the complex $\text{LiBH}_4(18\text{C}6)$ in the crystalline state contains a η^1 -coordinated BH_4 group. The same structure was proposed¹⁴⁶ for $\text{NaBH}_4(15\text{C}5)$.¹⁵⁰ However, the conclusions about the monodentate coordination of the tetrahydroborate ligands are inconsistent with the experimental data on the $\text{M}\cdots\text{B}$ distances in these complexes, which are close to the value expected for $\eta^2\text{-BH}_4$.²²³ Despite the fact that no data on the structures of tetrahydroborates of heavier metals ($\text{K}, \text{Rb}, \text{Cs}$) are available to date, it can be suggested that these metals, like lithium, form compounds with all the main types of coordination of BH_4 . The difference between the structures of $\text{Li}(\eta^3\text{-BH}_4)[\text{HC}(3,5\text{-Me}_2\text{pz})_3]$ and $\text{Cd}(\eta^2\text{-BH}_4)[\text{HB}(3,5\text{-Me}_2\text{pz})_3]$, noted by Reger *et al.*,¹⁴⁵ namely, the fact that the BH_4 group is coordinated in the bidentate fashion to the $\text{Cd}(\text{II})$ ion having a greater size and a higher charge, whereas it is coordinated as a tridentate ligand to the $\text{Li}(\text{I})$ ion, can be understood in view of the assumption about destabilising influence of outer d electrons.

The similarity of the structural and spectral properties of TiBH_4 to those of alkali metal tetrahydroborates^{1, 2} is also consistent with this assumption because the closed $5d^{10}$ shell of the $\text{Ti}(\text{I})$ ion is shielded by the filled $6s^2$ shell, which diminishes the destabilising influence.

The type of BH_4 coordination in $\text{CpBe}(\eta^2\text{-BH}_4)$ could not be established unambiguously from electron diffraction data. The conclusion about the bidentate coordination of this ligand to the beryllium atom was drawn resorting to the data of IR spectroscopy.^{151, 152} The denticity of BH_4 ligands in alkaline earth metal complexes ($\text{Ca}, \text{Sr}, \text{Ba}$) corresponds to that expected on the basis of steric considerations — BH_4 groups accomplish tridentate coordination whenever the spatial possibility exists. No structural data pointing to the possibility of η^3 -coordination of BH_4 groups in magnesium or aluminium complexes are currently available. In this connection, recall that the ionic radii of $\text{Al}(\text{III})$ and, especially, $\text{Be}(\text{II})$ are much smaller than those of transition metals.²²²

The type of coordination of tetrahydroborate ligands in the metal complexes in question cannot be determined from the data of NMR spectroscopy; these data attest to equivalence of all the four protons in the BH_4 ligand.^{145, 147, 148, 157, 161} The data of IR spectroscopy for alkali and alkaline earth metal complexes do not conform to any particular type of coordination of the tetrahydroborate groups either.^{145, 147, 148, 157}

The structures of the tetrahydroborate complexes with the central d^0 -metal ions in the oxidation state +1 as well as complexes with the d^n -metal central ions ($n = 2-10$) cannot be explained in terms of the principle of the maximum occupancy of the coordination sphere. Calculations using this principle²³⁷ provide the best results in the case of complexes with $d^0(d^1)$ -metal central ions in the oxidation states +3 or +4 and with ionic radii ranging from 0.7 to $\sim 1 \text{ \AA}$. Calculations performed in conformity with the data reported by Edelstein²²³ show that tridentate coordination of BH_4 groups in tetrahydroborates of metals with ionic radii of less than 0.68 $\text{\AA}$ (the difference between

the radii of the ionic and tridentate forms of BH_4) requires that the metal—boron distances be smaller than the radius of the BH_4^- anion. Therefore, the deviations from the principle of the maximum occupancy of the coordination sphere observed for these ions can be attributed to the mutual repulsion of ligands. For d^0 -metal ions in the oxidation state +2, this principle can be used to estimate the probable denticity of the BH_4 ligands; however, the maximum occupancy of the metal coordination sphere is seldom encountered. Apparently, under normal conditions, the number of neutral ligands (for example, ethers) these ions can hold is insufficient to fill completely their coordination sphere. Thus, the scope of application of the principle of the maximum occupancy of the coordination sphere of the central atom for predicting the structures of tetrahydroborate complexes is mainly limited to complexes with central d^0 -metal ions in the oxidation states +3 and +4.

VII. Tetrahydroborate complexes with bridging BH_4 ligands

The structurally characterised compounds with bridging tetrahydroborate groups are presented in Table 3. Comparison of the data of Tables 1 and 3 shows that alkali metal complexes with bridging BH_4 ligands are as prevalent as complexes with terminal tetrahydroborate ligands. On passing to alkali earth metals, lanthanides and actinides, the proportion of compounds with bridging BH_4 groups in the whole set of structurally characterised compounds gradually decreases; no structurally characterised bi- or polynuclear complexes of Group IV and V transition metals with tetrahydroborate bridges between the metal atoms are known. The trend to form complexes with bridging BH_4 groups then starts increasing again and, for Group VIII metals, the fractions of complexes with known structures containing terminal and bridging BH_4 groups are nearly equal. These data suggest that the formation of bridged compounds is facilitated by a decrease in the charge and an increase in the radius of the complex-forming ion.

The most frequently encountered polynuclear complexes (14 of 39, see Table 3) are those in which two metal atoms are bound in the η^2 -fashion to the opposite edges of a BH_4 tetrahedron (see Fig. 2a). None of the tetrahedron vertices belong simultaneously to both metal atoms. Each hydrogen forms μ_2 -bridges between boron and the metal, *i.e.* the BH_4 groups are generally tetradentate. Depending on the oxidation state of the metal, the number of BH_4 tetrahedra, the nature of the stabilising ligands and crystallisation conditions, this type of coordination of bridging groups results in the formation of dimers,^{189, 212, 213, 216} infinite polymer chains,^{160, 200, 202, 217} a two-dimensional network,²¹⁰ or a three-dimensional network.^{147, 207, 208} Apparently, three-dimensional structures of this type are also formed in some non-solvated compounds $\text{M}^n(\text{BH}_4)_n$ ('ionic' tetrahydroborates).

In a less abundant (six complexes) type of coordination, the BH_4 group is bound by two edges to two metal atoms and the edges participating in the coordination share a vertex ($\mu_3\text{-H}$). One hydrogen remains free from binding to the metal atoms; thus, the BH_4 groups are in total tridentate (see Fig. 2b). This pattern of coordination results most often in the formation of dimeric complexes^{145, 148, 198, 214} and in some cases, polymer chains.¹⁹⁹

There is only one compound ($\text{LiBH}_4 \cdot \text{Et}_2\text{O}$) in which the BH_4 group is coordinated to three metal atoms (to each of them, by an edge); these three edges share a vertex ($\mu_4\text{-H}$, see Fig. 2c).^{147, 197} In the crystals of $\text{LiBH}_4(\text{MeOBU})$, the BH_4 group is also coordinated by its edges to three metal atoms; however, there is no vertex common to these three edges (see Fig. 2d). In these cases (see Fig. 2c,d), all the four hydrogen atoms are involved in the formation of bridging bonds, *i.e.* the BH_4 group is tetradentate.

The η^1, η^2 -bridging coordination is represented by two examples, $\text{Mn}_2(\text{CO})_5(\text{DPPM})\text{H}(\text{BH}_4)$ and $\text{GaH}_2(\text{BH}_4)$; in this case, one metal atom is coordinated to an edge of the tetrahedron, while the other one is bound to the opposing vertex (see Fig. 2e).^{174, 221} The

η^1, η^1 -coordination according to which each of the two metal atoms is bound to one tetrahedron vertex (see Fig. 2f) is represented by six examples.^{93, 173, 178, 196, 221} This gives rise to a chain or a ring with the $M-H-BH_2-H-M$ sequence of bonds; two hydrogen atoms remain in the terminal positions.

The complex $GaH_2(BH_4)$ in the crystalline state forms a polymer chain consisting of alternating BH_4 tetrahedra with the types of coordination shown in Fig. 2e,f, so that the coordination numbers of the gallium ions are 4 and 6.²²¹

There exists one example, $HFe_3(CO)_9(BH_4)$, of η^1, η^1, η^1 -coordination of the BH_4 ligand where three metal atoms of the cluster are bound to three vertices of the BH_4 tetrahedron (three μ_2 -H bonds; the overall denticity of the tetrahydroborate ligand is η^3 , see Fig. 2g).¹⁷⁷ Conversely, in the Na_4B_4 heterocubane core of the $[NaBH_4(TMTCN)]_4$ tetramer, each three neighbouring sodium atoms are linked to the same vertex of the BH_4 tetrahedron (μ_4 -H bond; the total denticity of the BH_4 group is η^1 , Fig. 2h).¹⁴⁸

Among mercury complexes, two compounds, $[cyclo-(o-C_6F_4Hg)_3] \cdot (BH_4)_2(Bu_4N)_2$ and $[cyclo-(o-C_6F_4Hg)_3]_2(BH_4) \cdot (Bu_4N)$, have been isolated in an individual state.²¹⁹ Their structures have not been determined. Relying on the results of quantum-chemical calculations, it was assumed that the BH_4 ligand in $[cyclo-(o-C_6F_4Hg)_3] \cdot (BH_4)(Bu_4N)$ is linked to one mercury macrocycle as shown in Fig. 2g and to one more macrocycle as shown in Fig. 2h,²²⁰ i.e. this group is supposed to be connected simultaneously to six metal atoms.

A type of coordination in polynuclear complexes represented rather widely (six structures) is the coordination according to which one or two metal atoms are bound to a face of the BH_4 tetrahedron, which corresponds to η^3 -coordination in mononuclear complexes (see Fig. 2i, total denticity η^4 , and Fig. 2j, total denticity η^3). However, as in the case of mononuclear complexes, this coordination pattern is encountered only for metal ions having no outer *d* electrons, i.e. sodium,¹⁴⁸ strontium(II), barium(II),¹⁵⁷ cerium(III),²⁰³ samarium(III),²⁰⁴ and neodymium(III),²⁰⁵ whereas no examples of face coordination (η^3) are known for *dⁿ* ions ($n = 2-10$) (see Table 3).

In the NMR spectra of complexes of Group I, II, III and IV metals with BH_4 bridges, separate signals for the terminal and bridging protons have not been detected. The non-equivalence of protons of the bridging BH_4^- ligands has been observed in the NMR spectra of complexes of Group VII–VIII transition metals.^{173, 174, 177, 178, 188, 196} Thus, the structure and the dynamic behaviour of polynuclear compounds with BH_4 bridging groups also does not contradict the assumptions made in this study.

The data presented in Table 3 demonstrate a fundamental difference between the complexes with central *d⁰*-metal ions and the complexes with *dⁿ* transition metal ions ($n = 2-10$), namely, in the case of alkali and alkaline earth metals, lanthanides and uranium, the tetrahydroborate bridges connect neutral mononuclear molecular units, which results in a fuller occupancy of the metal coordination sphere and corresponds to the non-directionality and non-saturability of the mainly ionic $M-BH_4$ bond in these compounds. In the case of Group I and V–VIII transition metals, the tetrahydroborate bridges are formed between cationic species or, in most cases, between metal atoms bound into a cluster and located close to each other. The example of the cobalt complex $[Co(DPPP)(BH_4)]_2$ seemingly contradicts this conclusion. However, the low magnetic moment of this complex points to the presence of a metal–metal bond.²¹⁴ Hence, in this case, too, the formation of the tetrahydroborate bridges is favoured by the presence of a bond between transition metal atoms. Among post-transition metal complexes, there are compounds with polymer chains consisting of neutral molecules connected *via* tetrahydroborate bridges, for example, $[MeZnBH_4]_\infty$ ^{217, 218} and $[GaH_2(BH_4)]_\infty$.²²¹

The fluxionality, η^3 -coordination and the trend for the maximum occupancy of the coordination sphere are as typical of lanthanide and actinide complexes as of complexes formed by *d* metals with *d⁰* central ions. Therefore, it can be concluded that *f*

electrons do not influence the properties of tetrahydroborate complexes as substantially as outer *d* electrons. It has been suggested^{5, 207} that *f* orbitals participate in the formation of the bonds of the central atom with the BH_4 groups. However, in our opinion, the available data do not provide grounds for this suggestion.

In the structures which have now been determined, one to three metal ions are connected to one BH_4 group *via* its vertices or edges, or one or two metal ions are coordinated to this BH_4 group *via* faces. The metal ions in one structure can be coordinated both in the same way and in different ways; however, not all the possible combinations of various types of coordination have been confirmed experimentally. Thus a complex in which three metal ions are bound to the same vertex of the BH_4 tetrahedron in the monodentate fashion is known but there are no examples of complexes in which two or more metal ions are coordinated in the bidentate fashion to the same edge or in the tridentate fashion to the same face of the tetrahedron. Examples of structurally characterised complexes in which four or more metal ions are linked to one BH_4 group or examples of heteronuclear complexes in which this group serves as a bridge between ions of different metals cannot be given either. In the majority of polynuclear complexes ($\sim 60\%$ of the total number), all the four hydrogen atoms of the BH_4 groups are involved in coordination, i.e. they are formally tetradentate ligands (see Fig. 2a,c,d,f). About one-fourth of the complexes studied (see Fig. 2b,e,g) contain BH_4 ligands with one non-coordinated hydrogen atom. There are only a few polynuclear complexes with tetrahydroborate bridges formed by one (see Fig. 2h) or two (see Fig. 2f) hydrogen atoms.

Unlike compounds with terminal tetrahydroborate ligands, for bridging complexes, no correlation has been found between the data of IR spectroscopy and the types of coordination of bridging groups.

It has been noted¹⁹⁸ that the hypothesis of three-centre two-electron type of the $M-H-B$ bond is inapplicable for calculation of the EAN in the compounds with bridging BH_4 groups.

VIII. Conclusion

Analysis of experimental data on the structure of tetrahydroborate complexes makes it possible to elucidate a series of correlations between the structural or dynamic properties of these compounds and the nature of the central atom and stabilising ligands.

Compounds of Group III and IV transition metals (lanthanides, U, Ti, Zr, Hf) have been studied most comprehensively. In addition to the diversity of stabilising ligands, these complexes are characterised by diverse modes of coordination of tetrahydroborate ligands (η^1 -, η^2 - and η^3 - BH_4 , various types of BH_4 bridges between neutral species); complexes with BH_4 ligands of different denticities at one metal atom are also known. Most of complexes containing these metals in the oxidation states +3 and +4 comply with the principle of the maximum occupancy of the metal coordination sphere. The known tetrahydroborates of these metals possess clear-cut fluxionality (the protons of the BH_4 group are equivalent on the NMR time scale). Only for the complex $[Ti(CO)_4(\eta^3-BH_4)]-[K(18C6)]^+$, were the signals of the terminal and bridging protons of η^3 - BH_4 distinguished in low-temperature NMR spectra.

The structures of alkali and alkaline earth metal tetrahydroborates have not been adequately studied. As indicated by the available data, characteristic features of these compounds include fluxionality, diversity of the modes of coordinations of tetrahydroborate ligands to metals, formation of BH_4 bridges between neutral molecular units; the principle of the maximum occupancy of the coordination sphere is often violated.

The structural chemistry of Group I and V–VIII transition metal tetrahydroborates is much less plentiful than that for the Group III and IV transition metals; the range of stabilising ligands is more limited; no complexes with η^3 - BH_4 groups or with BH_4

bridges between neutral molecular units have been found. The principle of the maximum occupancy of the coordination sphere is not obeyed for these compounds.

In the complexes of Group I and V–VIII transition metals, BH_4 groups tend to be coordinated as mono- and bidentate ligands. Monodentate coordination is found only when the coordination sphere contains bulky ligands having strong electron-donating properties (phosphines, macrocyclic compounds), *i.e.* it is a forced type of coordination. The factors inducing the formation of complexes of these metals with mono- and bidentate coordination of the BH_4 ligands are not entirely clear yet. Whereas alkali, alkaline earth and rare earth metals and uranium tend to form polynuclear complexes due to tetrahydroborate bridges between neutral mononuclear molecules, in the case of Group I and V–VIII metals, the BH_4 bridges connect either cationic species or metal atoms bound into a cluster and located close to one another.

Tetrahydroborates of Group V–VIII transition metals possess higher stereochemical rigidities than complexes of Group IA, IIA, IIIB and IVB metals. For many of them, separate signals for terminal and bridging protons of mono- and bidentate BH_4 groups can be detected in low-temperature NMR spectra. In some of the compounds considered, the exchange of terminal and bridging protons does not proceed at a noticeable rate even at room or higher temperature. In some cases, bridging protons give rise to two separate NMR signals and the exchange of non-equivalent bridging protons with terminal protons occurs at different rates.

The absence of a trend for the maximum occupancy of the coordination sphere, the low coordination numbers and an increase in the stereochemical rigidity indicate that the degree of covalence of the $\text{M}-\text{BH}_4$ bond in Group V–VIII metal tetrahydroborates is higher than that in the Group IA, IIA, IIIB and IVB metal complexes.

Neither resorting to the views on the three-centre two-electron $\text{M}-\text{H}-\text{B}$ bond, widely employed now, nor allowing for steric factors can substantiate in the general case the observed structures and some physical and chemical properties of tetrahydroborate complexes.

Analysis of the experimental data presented above led to the assumption that the crucial factor determining the differences in the structures and the dynamic properties of transition metal tetrahydroborate complexes is the electron configuration of their central ions, which is d^0 (d^1) for most of the Group III and IV metal compounds considered or d^n ($n = 2-10$) for Group I and V–VIII metal complexes. High coordination numbers, the trend for the maximum occupancy of the coordination sphere and fluxionality of the tetrahydroborates of Group IA, IIA, IIIB and IVB metals indicate that the $\text{M}-\text{BH}_4$ bonds in these compounds are mostly ionic. The fluxional behaviour of these compounds is apparently related to the fact that the spherically symmetrical electron shell of d^0 ions does not create barriers to free rotation of the BH_4^- anion in the metal coordination sphere. In the complexes with central d^n ions ($n = 2-8$), the mutual repulsion of the non-bonding d -electrons and coordinated BH_4^- anions destabilises the η^3 -coordination of the BH_4 groups, which makes the most probable rearrangement pathway ($\eta^2-\eta^3-\eta^2$) energetically less favourable and results in an increase of the stereochemical rigidity of complexes of Group V–VIII metals. In addition, this factor prevents the formation of tetrahydroborate bridges between neutral mononuclear molecules in d^n -metal tetrahydroborates ($n = 2-8$). Complexes with central d^{10} ions, possessing completely filled d -electron shells, occupy an intermediate position — there are no complexes with η^3 -groups among them but stereochemically rigid complexes have not been found either.

The similarity of the structural and dynamic properties of tetrahydroborate complexes formed by f elements and those with central d^0 ions (η^3 -coordination, fluxional behaviour and the trend for maximum occupancy of the metal coordination sphere) leads to the conclusion that f electrons do not influence the properties of

tetrahydroborate complexes as significantly as outer d electrons and they apparently do not participate in the formation of bonds of the central atom with the BH_4 ligand.

The data considered above provide information not only on the dependence of the structural and dynamic properties of the tetrahydroborate ligand on the electronic configuration of the central atom but also on the dependence of the coordination and, correspondingly, catalytic properties of the central atom on the structure of its outer electron shell.

Since the tetrahydroborate anion is isoelectronic with the methane molecule, tetrahydroborates can be regarded as models of some steps of $\text{C}-\text{H}$ bond activation in saturated hydrocarbons.³ It is noteworthy in this connection that the sharp difference between the coordination (and, hence, catalytic) properties of the complexes with central d^0 and d^n ions ($n = 2-10$) is also manifested in many systems related to the transformations of hydrocarbon ligands. Thus activation of methane and cyclo-metallation reactions with participation of d^0 -ion complexes follow a mechanism which includes a multicentre transition state,²⁴⁶ whereas activation of $\text{C}-\text{H}$ bonds involving complexes with central d^n ions often proceeds according to an oxidative addition mechanism, similar to the exchange of hydride ligands and bridging hydrogen atoms in $\text{OsH}_3(\text{BH}_4)(\text{PPr}_3)_2$.¹⁰

It is also known that transition metal metallocene complexes with central d^0 ions act, under certain conditions, as active catalysts for polymerisation of α -olefins according to the so-called metallocene catalysis mechanism.²⁴⁷ Similar complexes with d^n ions do not exhibit pronounced catalytic activity under the same conditions; the catalysts of α -olefin polymerisation based on d^n ions have a different composition, 'work' under different conditions and by a different mechanism.²⁴⁸ By analogy with the BH_4 ligand, hydrocarbon ligands might possess different stereochemical rigidities and different denticities in the coordination with d^0 or d^n ions.

Further studies of structural and dynamic properties of the tetrahydroborate complexes with central d^0 and d^n ions are needed to understand the nature of the metal–ligand bond in these complexes. They are also required for development of the general views on the fluxional behaviour, for more extensive investigations of the dependence of the coordination and catalytic properties of metals on the electronic structures of their atoms and for modelling of the transition states in hydrocarbon activation processes.

Abstract. Data on the interpretation of the IR and Raman spectra based on normal coordinate analysis, on the force constants and on the conformations of the molecules of trivalent tricoordinate phosphorus compounds are summarised. The existing correlations between the spectra and molecular structures are refined and some new correlations are proposed. The bibliography includes 171 references.

I. Introduction

Vibrational spectroscopy is widely used in the chemistry of organophosphorus compounds for the identification of functional groups, determination of the molecular structure and studies on the molecular conformations, inter- and intramolecular interactions. Monographs by Thomas^{1,2} and atlases by Shagidullin *et al.*^{3–5} are devoted to the interpretation of IR spectra of organophosphorus compounds. Unfortunately, Raman spectroscopy has not become a routine method in phosphorus chemistry as yet, though the scope of possible application of this experimental technique in structural studies is as large as that of IR spectroscopy. This is to a great extent due to the lack of studies devoted to the generalisation of scarce information on the Raman spectra of different organophosphorus compounds. In this review, a comparative analysis is given of a continuously growing body of data on both the IR and Raman spectra of phosphorus-containing molecules. An attempt to summarise information on the ‘fingerprints’ of rotational isomerism in the molecules of tricoordinate phosphorus compounds as manifested in vibrational spectra is also undertaken.

A distinctive feature of the review is that here we consider only those molecules the spectra of which have been interpreted on the basis of normal coordinate analysis. A normal coordinate analysis

makes it possible to calculate the eigenvectors of normal vibrations, *i.e.*, to assess the contribution of each valence bond and each bond angle to a particular molecular vibration.^{6,7} This allows unambiguous assignment of the frequencies to the vibrations of particular structural fragments. Knowledge of the eigenvectors of normal vibrations is also necessary for the analysis of the interactions between vibrations of particular bonds in a molecule. It is known that effective coupling of vibrations of two molecular fragments is achieved if their individual frequencies are close ($\nu_1 \approx \nu_2$) and the fragments either share a number of atoms or are connected by a valence bond.⁸ For the coupling of vibrations to occur, they should also be of the same symmetry.⁹ As a result, coupling of two individual vibrations gives rise to two new coupled vibrations. Each fragment of the molecule makes a contribution to each of the new vibrations. Their frequencies (ν'_1 and ν'_2) can differ appreciably from the frequencies of the ‘old’ vibrations; as a rule, $\nu'_1 < \nu_1 \approx \nu_2 < \nu'_2$.

Thus in the molecule of methylphosphine (**1**), vibrations with a predominant contribution of the P–C bond occur at a frequency of about 670 cm^{–1}. Vibrations of two P–C bonds in the molecule of dimethylphosphine (**2**) give rise to two new vibrations, *viz.*, a symmetric stretch of both bonds at a frequency $\nu'_1 \approx 660$ cm^{–1} and an antisymmetric vibration at a frequency $\nu'_2 \approx 700$ cm^{–1}. These changes in the $\nu(\text{P–C})$ frequencies on going from molecule **1** to the molecule **2** are mainly due to the coupling of two individual oscillators sharing the phosphorus atom.

Vibrations of the PCl₂ group in the molecule of methyl phosphorodichloridite, CH₃OPCl₂ (**3**), are characterised by strong IR absorption bands at ~ 460 and ~ 500 cm^{–1}. The frequencies of bending vibrations of the butyl group lie in the same spectral region. However, analysis of the molecular structure of butyl phosphorodichloridite, C₄H₉OPCl₂, shows that these two vibrations cannot interact, since the structural fragments under consideration share no atoms and are not connected by a covalent bond. Therefore, vibrations of the PCl₂ group have identical patterns in the IR spectra of both C₄H₉OPCl₂ and CH₃OPCl₂.

These examples show that, strictly speaking, the lack of information on the eigenvectors of some vibrations makes it impossible to conclude whether they will be characteristic on going from one molecule to another. Therefore, spectral–struc-

tural correlations become much more reliable if they are based on theoretical interpretation of the spectra.

A normal coordinate analysis also makes it possible to calculate the force constants of chemical bonds and bond angles in molecules. The force constants are primarily of interest as transferable parameters, which are used for calculating the vibrational spectra of related molecules.⁶ At the same time, they are also numerical characteristics of the potential surface of a molecule. It should be noted that for several reasons^{6,10} the force constant values depend on the type of computational procedures employed, so that small differences between the estimates of the force fields obtained by different authors for the same molecule are virtually inevitable. Because of this, here we compared the force constants assessed using the same approximations for series of related compounds. This makes it possible to judge the changes in the electronic structure of the molecules if analysis of their force fields reveals large and systematic deviations. The notations are given according to monograph⁶ and the values of force constants are given in 10^2 N m^{-1} .

Compounds of trivalent tricoordinate phosphorus were chosen to be the subject of this review primarily since they are most widely used in the syntheses of organophosphorus compounds. Additionally (probably, because of relatively low stability of tricoordinate phosphorus compounds), their vibrational spectra have been less studied than those of tetracoordinate phosphorus compounds. Virtually all results of normal coordinate analyses of vibrational spectra of organophosphorus compounds reported to date have been analysed. The exceptions are the results of studies on the simplest tetraatomic molecules of phosphine (PH_3) and its halogen derivatives ($\text{H}_n\text{PHal}_{3-n}$).

Spectral characteristics of all the compounds under discussion are listed in Tables. Each fundamental vibration was assigned a number as follows. The whole set of vibrations was divided into groups according to particular symmetry types of the vibrations. Within each symmetry type, the vibrations were numbered in descending order of their frequencies.

The frequencies assigned to overtones and combination bands are omitted. The notations of vibrations are ν for stretching, δ for bending, r for rocking, w for wagging, t for twisting and χ for torsional vibrations; γ denotes vibrations associated with the out-of-plane deviation of particular bonds. These notations describe the type of motion of particular structural fragments of molecules. In discussing any vibration of the entire molecule, that is, a simultaneous motion of several individual oscillators, the above-mentioned notations have a somewhat different meaning. For instance, the totally symmetrical fundamental vibration of the molecule **1** is composed of the contributions from not only the stretching vibrations $\nu(\text{P}-\text{C})$ of the $\text{P}-\text{C}$ bond, but also the wagging vibrations of the phosphino group, $w(\text{PH}_2)$. However, the major contribution to the energy of the resultant vibration is made by the $\text{P}-\text{C}$ bond; therefore, such a vibration is denoted below as $\nu(\text{P}-\text{C})$.

All frequencies are given in cm^{-1} . The intensities (I) and shapes of spectral bands, as well as the degree of depolarisation of the Raman lines (ρ), are qualitatively described using the following notations: w for weak, m for medium, s for strong, ms for medium strong, br for broad, v for very, sh for shoulder, p for polarised and dp for depolarised.

Spectral data listed in Tables are presented in the following order: the vibrational frequency (in cm^{-1}), a qualitative or quantitative description of the intensity (in the latter case, the intensity of a line with respect to that of the strongest Raman peak, taken as 100) and a qualitative or quantitative description of the degree of depolarisation.

II. Alkylphosphines

Vibrational spectra and conformations of primary alkylphosphines have been studied in most detail. Interpretation^{11–13} of the IR spectra¹¹ and the Raman spectra¹⁴ of methylphosphine

Table 1. Interpretation of vibrational spectra of methylphosphine.

Note. Hereafter, l stands for liquid and g for gas. Totally symmetric fundamental vibrations of the A' type were labelled with figures from 1 to 9 and antisymmetric vibrations of the A'' type were labelled with figures from 10 to 15. Vibrations with the highest frequency and belonging to the A' type (Nos 1 and 2) and A'' type (No. 10) and vibration No. 15 are not included, since they correspond to the $\text{C}-\text{H}$ stretching vibrations of the bonds, which are insignificant for analytical purposes. For the same reason, some vibrations are also not included in Tables 2–25.

^a Appears only in the spectrum of crystals.

(Table 1) and its D-isotopomers CH_3PD_2 , CD_3PH_2 and CD_3PD_2 has been given and the force constants have been estimated. Vibrational spectra of ethylphosphine (**4**) have been investigated in a number of studies.^{15–21} Using vibrational¹⁵ and microwave^{16,17} spectroscopy, the molecules of compound **4** were shown to exist in the liquid and gas phases in two rotameric forms, as *trans* (*T*) and *gauche* conformers (*G*) (Fig. 1; $\text{X} = \text{H}$,

Figure 1. Conformers of molecules X_2PYZ : *trans* (*T*) and *gauche* (*G*).

$\text{Y} = \text{CH}_2$, $\text{Z} = \text{CH}_3$). Crystals of this compound are built of the molecules of the *trans* conformer only, so that the spectra are simplified owing to the disappearance of the bands of the *gauche* isomer. Interpretation of the spectra of ethylphosphine was based on the results of normal coordinate analysis²² performed simultaneously for both $\text{C}_2\text{H}_5\text{PH}_2$ and $\text{C}_2\text{H}_5\text{PD}_2$ molecules (Table 2). In studies of vibrational spectra of n-propylphosphine (**5**)²³ (Table 3) it has been shown that this compound exists in the liquid phase as a mixture of five conformers (Fig. 2; $\text{X} = \text{H}$, $\text{Y} = \text{CH}_2$). Vibrational and microwave spectra of isopropylphos-

Note. The number of vibration, symmetry type and assignment are given for the *T* conformer (see Fig. 1). Lines of the *G* conformer were interpreted only if they did not coincide with the corresponding lines of the *T* conformer (their assignments are denoted by the character 'G').

phine (**6**) and its D-isotopomer, iso- $\text{C}_3\text{H}_7\text{PD}_2$, have been studied.^{24,25} It was shown that the *G* and *T* conformers of these molecules are stable in the liquid and gas phases.

The calculated assignments²² for isopropylphosphine **6** (see Table 4) are somewhat different from the empirical ones.²⁴

Compared with the spectra of primary alkylphosphines, the interpretation of the spectra of secondary and tertiary alkylphosphines is more complicated because of the necessity to take into account the coupling of vibrations of adjacent alkyl groups at the phosphorus atom. Therefore, it is not surprising that the spectra of such simple representatives of organophosphorus compounds as dimethylphosphine and its isotopomers have been interpreted in different ways.^{26–29} The problem of contradictory assignments was alleviated only after performing a normal coordinate analysis.^{12,13,29} Different versions of empirical interpretation of the vibrational spectra of phosphirane $(\text{CH}_2)_2\text{PH}$ (**7**) and its deuterio derivatives have also been suggested.^{30,31} Calculations³² made it possible to refine the vibrational assignments and to assess the force constants of the molecule, its thermodynamic functions and the barrier to inversion of the phosphirane ring.

Trimethylphosphine (**8**) is the first organophosphorus compound for which a normal coordinate analysis has been performed.³³ The data on both the eigenvectors of molecular vibrations of $(\text{CH}_3)_3\text{P}$ and $(\text{CD}_3)_3\text{P}$ and the force fields of the molecules have been repeatedly revised.^{13,14,34–40} These molecules have a C_{3v} symmetry, therefore the A_2 modes are optically inactive and not observed in the spectra. Some of the modes were observed owing to the reduction of symmetry of the molecule as a result of crystallisation of the substance.³⁹ Nevertheless, a number of vibrational assignments had to be revised after the spectra of low-symmetric D-isotopomers, $(\text{CH}_3)_2\text{CD}_3\text{P}$ and $\text{CH}_3(\text{CD}_3)_2\text{P}$, had been reported.⁴¹ The force constants of the molecule **8** have

Note. The number of vibration, symmetry type and assignment are given for the *T* conformer. The lines of the *G* conformer (denoted by character 'G') were interpreted only if their frequencies did not coincide with the corresponding lines of the *T* conformer.

^a The frequency was suggested after normal coordinate analysis²² (was not observed experimentally).

The *GGG* and *TG'G* conformers are present simultaneously in the crystalline phase.^{45,46} Theoretical interpretation of the spectra^{46,47} of triethylphosphine **9** was based on the results of normal coordinate analysis⁴⁵ performed using the force constants for molecules **8** and **4**.

Comparison of the spectra of primary alkylphosphines reveals three vibrations, *viz.*, the $\nu_{as}(\text{PH}_2)$, $\nu_s(\text{PH}_2)$ and $\delta(\text{PH}_2)$ ones, which seem to be the most characteristic vibrations of these compounds. The first two vibrations appear as two very strong bands with similar frequencies near $\sim 2300 \text{ cm}^{-1}$ in the gas-phase spectra. On going from gases to liquids, these bands usually coalesce into one band observed in the frequency range $2275\text{--}2300 \text{ cm}^{-1}$ (see, *e.g.*, Refs 15, 18–20, 23, 24, 48, 49). A normal coordinate analysis shows that the vibrations $\nu_{as}(\text{PH}_2)$ and $\nu_s(\text{PH}_2)$ are the characteristic vibrations, *i.e.*, that the frequencies and intensities of the corresponding spectral peaks are determined solely by the properties of the $\text{P}-\text{H}$ bonds.

Scissoring vibrations of the phosphino group, $\delta(\text{PH}_2)$, can mix to a certain degree with vibrations of the alkyl radical (see, *e.g.*, Table 2), which affects mainly the intensities of corresponding bands. At the same time, the frequency of the $\delta(\text{PH}_2)$ vibration depends only slightly on the vibration of the alkyl fragment of the molecule and lies in a relatively narrow frequency range between 1073 and 1097 cm^{-1} (for liquids).^{15, 18–20, 23, 24, 48, 49} Mixing of the

scissoring deformation vibration $\delta(\text{PH}_2)$ with the wagging vibration $w(\text{PH}_2)$ also occurs (see Table 2). Probably, that is why the former vibration has been interpreted²⁰ as $w(\text{PH}_2)$.

The structure of the alkyl fragments of the molecules of primary alkylphosphines strongly affects the frequency of vibration with predominant contribution of the $\text{P}-\text{C}$ bond (Tables 1–5). For instance, the frequency of the vibration

Table 5. Stretching vibrations of $\text{P}-\text{C}$ bonds in the spectra of alkylphosphines and their substituted derivatives.

Note. Notations: cr stands for crystal and s for solution (in Kr).

^a Ring 'breating' vibration accompanied by synchronous changes in the $\text{P}-\text{C}$ and $\text{C}-\text{C}$ bond lengths.

^b Symmetric ring deformation accompanied by synchronous lengthening of two $\text{P}-\text{C}$ bonds and shortening of the $\text{C}-\text{C}$ bond.

^c Non-symmetric ring deformation associated with $\nu_{as}(\text{PC}_2)$.

^d Vibrations of the *A'* symmetry type.

^e Vibrations of the *A''* symmetry type.

$\nu(\text{P}-\text{C})$ decreases by $\sim 70 \text{ cm}^{-1}$ on going from the molecule **1** to the molecule **6** (see Tables 1 and 4). According to calculations, this is due to not only the 'weighting' of the alkyl group, but also a decrease in the force constant $K_{\text{P}-\text{C}}$.

The $\nu(\text{P}-\text{C})$ vibration can mix with deformation vibrations of the phosphino group and alkyl radical. Because of the changes in the contributions of particular groups to the vibrations, the intensities of the corresponding bands in the IR spectra can vary over a wide range on going from one alkylphosphine to another, which severely hampers their assignment. It is much easier to use the Raman spectra for identification of the vibration $\nu(\text{P}-\text{C})$, since the corresponding lines in the spectra of compounds in question always are the most intense and polarised in the frequency range $550-705 \text{ cm}^{-1}$. Thus, it is the Raman spectra that should be used for easy discrimination between different primary alkylphosphines.

When assigning the $\nu(\text{P}-\text{C})$ vibration, it should be remembered that the corresponding frequency can be 'sensitive' to molecular conformations. Therefore, a number of 'extra' peaks is often observed in the vibrational spectra of compounds, whose molecules can adopt several conformations (see, e.g., Tables 2 and 5). Some of the 'extra' peaks disappear as a result of crystallisation of the specimens.

Like the $\nu(\text{P}-\text{H})$ vibrations of primary alkylphosphines, those of the secondary alkylphosphines are observed in nearly the same spectral region $2270-2298 \text{ cm}^{-1}$. On the other hand, lines corresponding to two (rather than one) stretching vibrations of the $\text{P}-\text{C}$ bonds are observed in the spectra of secondary phosphines (see Table 5). An intense, strongly polarised Raman line observed in the region $550-670 \text{ cm}^{-1}$ is associated with symmetric $\nu_s(\text{PC}_2)$ vibrations, while a somewhat weaker and weakly polarised line in the region $600-710 \text{ cm}^{-1}$ is attributed to antisymmetric $\nu_{as}(\text{PC}_2)$ vibrations. In the IR spectra, the latter band is usually stronger than the former. As for the primary phosphines, the $\nu(\text{P}-\text{C})$ frequencies are, as a rule, 'conformationally sensitive' and decrease substantially as the chain length of alkyl radicals increases. All the aforesaid refers to acyclic dialkylphosphines and unstrained cyclic systems. Closure of three-, four- and five-membered strained rings leads to an increase in the $\nu_s(\text{PC}_2)$ frequencies, so that they become higher than the $\nu_{as}(\text{PC}_2)$ frequencies and lie beyond the upper bounds of the corresponding spectral regions.

The $\nu_s(\text{PC}_3)$ and $\nu_{as}(\text{PC}_3)$ stretching vibrations of the $\text{P}-\text{C}$ bonds in the molecules of tertiary phosphines have spectral features similar to those mentioned above (see Table 5). Since the lines corresponding to some characteristic vibrations such as $\nu(\text{P}-\text{H})$ or $\delta(\text{PH}_2)$ are absent in this case, identification of the spectra of tertiary phosphines should be performed using both the $\nu_s(\text{PC}_3)$ and $\nu_{as}(\text{PC}_3)$ lines and the alkyl group bands. The frequencies of some vibrations of the methyl or ethyl radicals at the phosphorus atom are sufficiently characteristic, which makes it possible to use them in the spectral analysis. For instance, the bands associated with symmetrical $\delta_s(\text{CH}_3\text{P})$ and antisymmetrical $\delta_{as}(\text{CH}_3\text{P})$ deformation vibrations are observed in the IR spectra of any liquid alkylphosphines in the regions $\sim 1280-1295$ and $\sim 1410-1445 \text{ cm}^{-1}$, respectively. The $\nu(\text{CH}_3\text{P})$ rocking vibrations mix with vibrations of other groups at the phosphorus atom (see Table 1). Changes in the environment around the P atom lead to substantial changes in the frequency and eigenvector of the resultant complex vibration. Therefore, the corresponding bands in the IR spectra of liquid alkylphosphines are observed in a rather wide region between 940 and 985 cm^{-1} and their intensities can vary from weak to strong. In the Raman spectra of alkylphosphines, the lines attributed to all the three vibrations are usually of weak or medium intensity.

If the ethyl radical is bound to the phosphorus atom, the $\delta(\text{CH}_2)$ bending and $\nu(\text{CH}_2)$ twisting vibrations of the methylene group can be considered characteristic. The corresponding peaks in vibrational spectra are usually of medium intensity and observed in the spectral regions $\sim 1410-1430$ and

$\sim 1230-1250 \text{ cm}^{-1}$, respectively. A complex vibration with predominant contribution of the wagging motion, $w(\text{CH}_2)$, is characterised by a slightly higher frequency ($\sim 1240-1280 \text{ cm}^{-1}$). Since this vibration is strongly coupled, the intensity of the corresponding peak can vary from very weak to medium. On the contrary, vibrations of the $\text{C}-\text{C}$ bond are characteristic and associated with rather strong peaks in the region $\sim 1020-1065 \text{ cm}^{-1}$. Rocking and wagging vibrations of the methylene group mix with the motions of other atoms constituting the alkylphosphine molecule and usually give rise to several peaks in the spectral region $\sim 690-820 \text{ cm}^{-1}$. At least one of the peaks is of rather high intensity.

It should be noted that the above-mentioned frequencies are specific to not only alkylphosphines, but also other organophosphorus compounds,¹⁻⁵ the molecules of which contain the CH_3P or $\text{C}_2\text{H}_5\text{P}$ fragments. This specificity is due to both the mass of the phosphorus atom and the peculiarities of the electronic structure of these fragments, which affect the force constant values. Bands corresponding to the bending and twisting vibrations of the methylene group at the phosphorus atom of an arbitrary coordination are observed in the spectral regions $\sim 1430-1380$ and $\sim 1190-1220 \text{ cm}^{-1}$, respectively, and can be used for the identification of non-branched alkylphosphorus groups. It is more convenient to use the Raman spectra for identification of twisting vibrations, since the corresponding bands in the IR spectra are often weak.

The above-mentioned frequency ranges for the 'fingerprint' bands are given for the liquid-phase spectra, since they are most widely used in routine studies. However, these spectral regions are only slightly shifted on going to the spectra of gases and crystals. For alkylphosphines, the shifts of spectral peaks due to the change in the state of aggregation usually do not exceed $10-15 \text{ cm}^{-1}$. The band intensities also vary only slightly, which indicates the absence of strong intermolecular interactions in the condensed phases. It should be taken into account that crystallisation of alkylphosphines, whose molecules can adopt several conformations, can lead to disappearance of some spectral bands.

III. Alkyl(halogeno)phosphines

Almost no interactions between the vibrations involving relatively heavy halogen atoms and light hydrogen atoms occurs in the molecules of alkyl(halogeno)phosphines. Therefore, skeletal vibrations in these compounds are much less 'sensitive' to substitution of deuterium atoms for hydrogen atoms, so that deuteration, which often facilitates the interpretation of the spectra, appears to be ineffective. Strengthening of intermolecular interactions due to the presence of halogen atoms in the molecules is yet another objectionable circumstance. This can cause shifts of spectral peaks comparable in magnitudes with those caused by structural rearrangement, which precludes the interpretation of experimental results.

Comparison of the spectral characteristics of the $\text{P}-\text{F}$ stretching vibrations for different states of aggregation of difluoro(methyl)phosphine (**10**)^{50,51} makes it possible to assess the effect of intermolecular interactions on these vibrations (Table 6). Vibrational spectra of compound **10** and dichloro(methyl)phosphine (**11**)⁵²⁻⁵⁶ have been interpreted.^{51,56,57} The results obtained in the two last-mentioned studies differ mainly in the assignment of the ν_8 and ν_9 frequencies. In Ref. 57, they were assigned to the vibrations $\delta(\text{PCl}_2)$ and $w(\text{PCl}_2)$, respectively, while the opposite assignment has been given in Ref. 56. The latter attribution is in better agreement with the vibrational assignments for the molecule $\text{C}_2\text{H}_5\text{PCl}_2$ (**12**) based on the results of *ab initio* quantum-chemical calculations.⁵⁸

Difluoro(ethyl)phosphine (**13**) and dichloro(ethyl)phosphine exist in the gas and liquid phases as mixtures of the *T* and *G* conformers^{21,56,58-60} (see Fig. 1; $\text{X} = \text{F}, \text{Cl}$; $\text{Y} = \text{CH}_2$; $\text{Z} = \text{CH}_3$). Vibrational spectra of the former substance and its deuterio derivative have been interpreted⁶⁰ and it was shown that

crystallisation of the specimens leads to the 'freezing out' of the *gauche* conformers. Unlike difluoro(ethyl)phosphine, both conformers of dichloro(ethyl)phosphine exist in the crystalline state.^{21, 56} Vibrational spectra of C₂H₅PCl₂ (see Refs 21, 56) and C₂D₅PCl₂ (see Ref. 21) have been analysed repeatedly.^{21, 56, 58} It is believed that comparison of the results obtained in the *ab initio* calculations⁵⁸ of the vibrations of heavy atoms of molecule C₂H₅PCl₂ with assignments²¹ of the vibrations with predominant contribution of hydrogen atoms provides a version of the interpretation of the spectra of compounds **12**, which does not contradict experimental results^{21, 56, 58} (Table 7).

The molecule of dichloro(propyl)phosphine, n-C₃H₇PCl₂ (**14**), can adopt five stable conformations (see Fig. 2; X = Cl, Y = CH₂). Analysis of the vibrational spectra of compound **14** showed⁶¹ that the *Tt*, *Gt* and *Gg'* conformers exist in the liquid phase. The interpretation of the spectra of dichloro(propyl)phos-

Note. The number of vibration, symmetry species and tentative vibrational assignments are given for the *T* conformer only. Detailed assignment is given for the *G* conformer only.

phine was based on the results of *ab initio* quantum-chemical calculations.⁶¹

The molecules of (chloromethyl)difluorophosphine ClCH₂PF₂ (**15**) and (chloromethyl)dichlorophosphine ClCH₂PCl₂ (**16**) exist^{62–65} both in the liquid and gas phases as mixtures of the *T* and *G* conformers (see Fig. 1; X = F, Cl; Y = CH₂; Z = Cl). Crystallisation of these substances leads to the 'freezing out' of one isomeric form, so that the crystals of compound **16** comprise the molecules of only the *gauche* conformer,⁶⁴ while the molecules of compound **15** comprise the *trans* conformer.⁶³ The spectra of both compounds were interpreted using the force fields obtained from normal coordinate analysis for the corresponding deuterio derivatives.^{63, 64} The assignments suggested⁶⁴ for compound **16** (Table 8) differ from those given earlier,^{56, 66} which is likely due to impurities present in the specimens studied.^{56, 66}

In studying the vibrational spectra of (CH₃)₂PCl (**17**) it has been shown^{49, 67} that the molecules of this compound form asymmetrical dimers in the crystals. This leads to the doublet splitting of a large number of singlet (in the spectra of liquid) bands and lines (Table 9). The components of the doublets

correspond to the in-phase and antiphase molecular vibrations in the dimers. Normal coordinate analysis for the molecule **17**⁵⁷ was based on the known experimental data,⁶⁷ which are somewhat different from those reported earlier.⁴⁹

Since vibrational spectra of CF₃PH₂ (**18**) and its deuterium-substituted analogue revealed no reduction of the C_{3v} local symmetry of the CF₃ group due to the addition of the PH₂ group, a normal coordinate analysis for this molecule was performed assuming this symmetry. An interpretation of the vibrational spectra of molecule **18**, based on the results obtained by Bürger *et al.*,⁶⁸ is given in Table 10; however, the description of the vibrations of the PH₂ fragment is somewhat changed to accord with the true C_s symmetry of the entire molecule.

Table 10. Interpretation of vibrational spectra of (trifluoromethyl)phosphine.

Spectra of (CF₃)₂PH (**19**) and its deuterio analogue, as well as those of (CF₃)₃P (**20**) have been interpreted on the basis of normal coordinate analysis.^{69,70} Vibrational spectra^{54,71} of compounds CF₃PF₂ (**21**), CF₃PCl₂ (**22**), CF₃PBr₂ (**23**) and CF₃PI₂ (**24**) have been analysed.⁷²

Unlike vibrational spectra of unsubstituted alkylphosphines, those of alkyl(halogeno)phosphines are strongly dependent on the state of aggregation of the substances (see Tables 1–10). This can be rationalised by self-association of the molecules. Since routine spectral experiments usually do not include strong heating or cooling of specimens, the spectral indications of particular vibrations presented below are given for those states of aggregation, in which the compounds under study exist at ambient temperature.

Compared to unsubstituted compounds, spectral regions corresponding to vibrations of structural fragments constituting the molecules of alkyl(halogeno)phosphines become much wider. This is due to not only intermolecular interactions, but also relatively strong coupling of vibrations and strong substituents effects. Mention has been made¹ that the IR spectra of compounds of the type RPF₂ reveal two strong bands in the frequency ranges 806–869 and 860–947 cm⁻¹, which correspond to the vibrations $\nu_{\text{as}}(\text{PF}_2)$ and the $\nu_{\text{s}}(\text{PF}_2)$, respectively (see Table 6). As can be seen in Table 6, only the frequencies in the spectra of molecule **21** fall within the above-mentioned limits. Probably, a tendency of compounds containing the PF₂ group to undergo an autocatalytic disproportionation^{73,74} can be a reason for violation of the known correlations.¹ Analysis of the IR spectra of alkyl(difluoro)phosphines showed that both stretching vibrations of the PF₂ group are observed in the same characteristic region ~ 780–830 cm⁻¹. When assigning the vibrations, one should take into account that the $\nu(\text{PF}_2)$ frequencies can increase substantially on going from the liquid to vapour phase. In addition, our experience suggests that in the Raman spectra the $\nu_{\text{s}}(\text{PF}_2)$ lines are of medium or weak intensity and are polarised, while the $\nu_{\text{as}}(\text{PF}_2)$ lines are weak and depolarised (though quantitative

differences between the degrees of depolarisation of these lines can be rather small). Introduction of halogen atoms into molecules causes an increase in the force constants of the P–F bonds, so that the $\nu(\text{PF}_2)$ frequencies can be as high as 870 cm⁻¹.

The frequencies of stretching vibrations of the PCl₂ groups lie in the region 420–526 cm⁻¹ (see the monograph¹). For alkyl(halogeno)phosphines, they are usually close to the upper bound of this spectral region (~ 450–526 cm⁻¹). The frequencies of the vibrations $\nu_{\text{s}}(\text{PCl}_2)$ of alkyl(dichloro)phosphines are somewhat higher than those of the vibrations $\nu_{\text{as}}(\text{PCl}_2)$ [the opposite is observed for molecules **16** and **22** (see Table 9)]; in the spectra of liquids the corresponding peaks usually coalesce into an unresolved contour. These compounds are characterised by an increase in the frequencies of stretching vibrations of the PCl₂ group on going to the gas phase. However, both the IR spectral bands and the Raman lines remain very strong, which facilitates the identification of these $\nu(\text{PCl}_2)$ vibration in spite of their strong coupling with other vibrations (see Table 9).

The vibrations $\nu(\text{P}-\text{Cl})$ of the molecule **17** are strongly mixed with the rocking vibrations of the (CH₃)₂P group, which gives rise to two co-operative vibrations. Among them, the vibration with the higher frequency can be rather arbitrarily associated with the $\nu(\text{P}-\text{Cl})$ stretch (see Table 9). Analysis of scarce spectral data for dialkyl(chloro)phosphines suggests that the frequencies of the vibrations $\nu(\text{P}-\text{Cl})$ of these compounds lie in nearly the same spectral region as those of the vibrations $\nu(\text{PCl}_2)$ (see above). Therefore, the most pronounced distinction between the corresponding spectra is reduced to the appearance of two vibrations, *viz.*, $\nu_{\text{s}}(\text{PCl}_2)$ and $\nu_{\text{as}}(\text{PCl}_2)$, in the spectra of dialkyl(chloro)phosphines instead of one $\nu(\text{P}-\text{C})$ vibration in the spectra of alkyl(dichloro)phosphines. The frequencies of the vibrations $\nu(\text{PCl}_2)$ and $\nu(\text{P}-\text{C})$ in the spectra of alkyl(halogeno)phosphines (see Table 5) are observed near the upper bounds of the corresponding spectral regions (see Section II) for alkylphosphines. (The molecules containing the CH₂Cl and CF₃P groups are exceptions to this rule. Their spectra are discussed below.) The intensities of the corresponding bands in the IR spectra of alkyl(halogeno)phosphines are usually higher than those in the spectra of unsubstituted analogues. Other parameters of these spectral peaks are similar to those discussed above (see Section II).

Spectral indications of the CH₃P and C₂H₅P groups are nearly identical for alkylphosphines and their halogeno-substituted derivatives. The exceptions are the vibrations with predominant contribution of the $r(\text{CH}_3\text{P})$ vibration, since their frequencies decrease from ~ 940–985 down to ~ 880 cm⁻¹ upon introduction of halogen atoms to the phosphorus atom in the last-named molecules. The intensities of the corresponding bands in the IR spectra are rather high.

The peaks in the region 1380–1410 cm⁻¹, corresponding to the $\delta(\text{CH}_2)$ vibrations, are characteristic of the CH₂Cl group. (This spectral region is characteristic of the vibrations of CH₂X groups, where X is a rather heavy atom; *e.g.*, X = P or S). Stretching vibrations of the C–Cl bond of the CH₂Cl group strongly interact with the vibrations $\nu(\text{P}-\text{C})$ and give rise to two new vibrations. Among them, the vibration with the lower frequency is observed in the region typical of the vibration $\nu(\text{P}-\text{C})$ and has all the specific spectral indications (see Section II). The peaks corresponding to the second stretching vibration of the PCCl group are observed in the region ~ 740–790 cm⁻¹ and have variable intensities.

The vibrations of the CF₃P group are readily identified in the spectra of any organophosphorus compounds. Mention has been made⁴ that very strong IR absorption bands in the region 1100–1300 cm⁻¹ correspond to the stretching vibrations of trifluoromethyl groups. For phosphines, this correlation has specific details.

Two very strong bands in the region 1140–1235 cm⁻¹ of the IR spectra of phosphines can be arbitrarily assigned to the vibrations $\nu_{\text{as}}(\text{CF}_3)$ (Table 11), which result from the mixing of the stretching and deformation [$\delta_{\text{as}}(\text{CF}_3)$] vibrations. They are

	$\nu_{\text{as}}(\text{CF}_3), \nu(\text{CF}_3)$		1180, vs (g)
$(\text{CF}_3)_3\text{P}$	$\nu_{\text{as}}(\text{CF}_3), \delta_{\text{as}}(\text{CF}_3) (\parallel)$		1235, s (g)
	$\nu_{\text{as}}(\text{CF}_3), \delta_{\text{as}}(\text{CF}_3) (\perp)$	1176, w, br (g)	1189, s (g)

Note. Hereafter ($\parallel$) and ($\perp$) respectively denote the vibrations, which occur parallel and perpendicular to the molecular symmetry plane.

localised within one CF_3P group and do not interact kinematically with the motions of adjacent fragments. Therefore, variations of the frequencies of the vibrations $\nu_{\text{as}}(\text{CF}_3)$ are due to dynamic reasons alone and, hence, reflect the changes in the electronic structure of the phosphorus-containing fragment of the molecule. The $\nu_{\text{as}}(\text{CF}_3)$ frequencies increase as the electronegativities of substituents at the phosphorus atom increase (see Table 11).

Symmetrical stretching vibrations $\nu_s(\text{CF}_3)$ mix with the bending vibrations $\delta_s(\text{CF}_3)$ and the vibrations $\nu(\text{P}-\text{C})$ (see Table 10). The involvement of the phosphorus atom in the vibrations provides the possibility for kinematic interactions between adjacent groups to occur, which is particularly effective in the case of equal 'individual' frequencies. That is why the number of bands corresponding to the vibration $\nu_s(\text{CF}_3)$ in the IR spectra of compounds with one CF_3P group and with two (or three) CF_3P groups is different, namely, one very strong band in the region $1100-1160\text{ cm}^{-1}$ vs. two bands in the same spectral region, respectively.

Previously (see Section II), particular attention was paid to the vibrations $\nu(\text{P}-\text{C})$ and it was shown that the corresponding Raman lines have distinctive spectral indications, which are common to various organophosphorus compounds with the $\text{P}-\text{C}(\text{sp}^3)$ valence bonds. Unfortunately, compounds with the CF_3P group are exceptions to this rule, since all attempts to discriminate between the vibrations with predominant contribution of the $\text{P}-\text{C}$ bond and other normal coordinates have failed. The vibrations denoted ⁴ as $\nu(\text{P}-\text{C})$ are in fact coupled vibrations with nearly equal contributions of the vibrations $\delta_s(\text{CF}_3)$ and $\nu_s(\text{CF}_3)$ and with a some contributions of the vibrations $\nu(\text{P}-\text{C})$ (see Table 10). The corresponding bands in the vibrational spectra of organophosphorus compounds are observed in the region between 650 and 750 cm^{-1} . For phosphines, this region is much narrower, namely, one or two strong IR absorption bands are observed in the frequency range $\sim 720-750\text{ cm}^{-1}$. The corresponding Raman lines are polarised and intense.

Vibrations of the $\text{P}-\text{C}$ bonds make somewhat greater contributions to the coupled vibrations denoted ⁴ as $\delta(\text{C}-\text{F})$. The corresponding IR absorption bands and Raman lines ($\sim 410-470\text{ cm}^{-1}$) are rather strong, the latter being polarised, which facilitates vibrational assignments.

We suggest that the Raman lines of medium or weak intensity, which are observed in the region $520-570\text{ cm}^{-1}$ and correspond to the vibrations with the predominant contribution of the vibrations $\delta_{\text{as}}(\text{CF}_3)$, can also be used for identification of compounds under consideration. The intensities of the $\delta_{\text{as}}(\text{CF}_3)$ bands in the IR spectrum can vary from very weak to strong.

IV. Phosphines with unsaturated groups at the phosphorus atom

To date, a normal coordinate analysis has been performed only for three groups of the trivalent phosphorus compounds with unsaturated fragments. These are the molecules with the $\text{P}-\text{C}=\text{C}$ fragment, ethynylphosphines and cyano derivatives of phosphines.

The first group comprises alkenyl(dichloro)phosphines. Their molecules can adopt both the *cis* (*C*) and *anti,gauche* (*aG*) conformations.

According to the vibrational spectroscopy data,⁷⁵ the *cis* conformers of the molecules $\text{CH}_2=\text{CHPCl}_2$ (**25**) and $(\text{CH}_3)_2\text{C}=\text{CHPCl}_2$ (**26**) are dominant in the condensed phase, whereas liquid dichloro(styryl)phosphine (**27**) is a mixture of both conformers. Because of steric hindrances, in the molecule of *S*-ethyl *tert*-butyl(1,2-dichlorovinyl)phosphinothioite (**28**) the $\text{C}=\text{C}$ bond is in *cis* position with respect to the lone electron pair (LEP) of the phosphorus atom.⁷⁶ However, it is believed that a mixture of conformers can exist in the liquid owing to internal rotation of the $\text{C}_2\text{H}_5\text{S}$ fragment

The interpreted vibrational spectra⁷⁵ of the simplest representative of this group of compounds, *viz.*, compound **25**, are listed in Table 12.

Triethynylphosphine (**29**) is a representative of the second group of the trivalent phosphorus compounds with unsaturated fragments. Its molecule has a C_{3v} symmetry and the vibrations of the A_2 type are optically inactive and not observed in vibrational spectra. Table 13 lists the experimental⁷⁷ vibrational spectra of compound **29** and the assignments⁷⁸ based on the results of normal coordinate analysis. Unfortunately, neither the eigenvectors of the vibrations nor the potential energy distribution over the

vibrational coordinates have been reported,⁷⁸ therefore the assignments listed in Table 13 seem to be tentative.

Vibrational spectra of dicyano(methyl)phosphine (**30**)⁷⁹ and tricyanophosphine (**31**)^{80–82} have been studied. The spectra reported by Goubeau, Haeberle and Ulmer⁸⁰ differ appreciably from those reported in the other studies.^{81,82} This is probably due to chemical transformations of the substances during the preparation of the samples.⁸² In the condensed phase, both compounds can be involved in strong intermolecular interactions, which can cause rather large shifts of the spectral peaks (Table 14) and even be responsible for the appearance of new bands as compared to the gas-phase spectra. For instance, an intense peak at $\sim 630\text{ cm}^{-1}$ (see Refs 79, 81, 82) in the spectra of liquid and crystalline cyanophosphines and their solutions in CH₃CN is not observed in the spectra of vapours or solutions in other solvents. This peak results from intermolecular interactions involving the cyano groups.^{79,82} Such strong effects hamper the interpretation of the spectra of these molecules in the liquid or crystalline phase. It should be noted that the molecule **31** has a C_{3v} symmetry and vibrations belonging to the A₂ type are optically inactive and not observed in vibrational spectra. The force field of the molecule **31** has been first evaluated by Unnikrishnan and Aruldas.⁸³ How-

ever, calculations performed using this force field have led to unrealistic values of the root-mean-square vibrational amplitudes.⁸⁴ Therefore, Table 14 lists the theoretical interpretation of the spectra of compound **31** according to other studies.^{84,85} The results of normal coordinate analysis for the spectra of dicyano(methyl)phosphine **30** have been reported.⁸⁶

A common feature of the spectra of the three groups of compounds considered in this Section is that the frequencies of stretching vibrations of the multiple bonds at the trivalent phosphorus atom are lower than those for the corresponding organic molecules. For instance, the frequencies of stretching vibrations of the C=C(P) group (see Table 12) are lower than the lower bound of the spectral region 1620–1680 cm^{−1} typical of alkenes.⁸⁷ As is known, the introduction of halogens also leads to a decrease in the frequency of the stretching vibrations $\nu(\text{C}=\text{C})$; however, this effect is not so strong as that observed after introduction of the phosphorus atom. For instance, the frequency of the vibrations $\nu(\text{C}=\text{C})$ in CCl₂=CHCl is 1589 cm^{−1} (cf. 1539 cm^{−1} for the molecule **28**). The same is also observed for the frequency of the vibrations $\nu(\text{C}\equiv\text{C})$ in compound **29** (see Table 13), which is lower than the corresponding frequencies in acetylene and haloacetylenes ($\sim 2085\text{--}2270\text{ cm}^{-1}$).^{87,88} The frequencies of the stretching vibrations $\nu(\text{C}\equiv\text{N})$ of molecules **30** and **31** also lie far below the spectral region 2215–2260 cm^{−1} typical of organic cyanides.⁸⁷ It should be noted that the peaks at $\sim 2180\text{--}2217\text{ cm}^{-1}$ are ‘fingerprint’ of the PCN groups in the spectra of neat liquids or crystals (see monograph¹). A small overlap of the two spectral regions^{1,87} is of no concern for trivalent phosphorus compounds, since the corresponding frequencies of stretching vibrations of the PCN group always lie below 2215 cm^{−1}. At the same time, it should be remembered that the $\nu(\text{C}\equiv\text{N})$ frequencies of halonitriles⁸⁹ lie nearly in the same region as the $\nu(\text{PCN})$ frequencies. The $\nu(\text{C}=\text{C})$, $\nu(\text{C}\equiv\text{C})$ and $\nu(\text{C}\equiv\text{N})$ bands in the IR spectra can be of weak intensity, therefore it is more convenient to identify these groups using the Raman spectra in which the corresponding lines always are sufficiently strong and polarised.

Raman spectroscopy can also be used to assign the vibrations denoted⁸⁷ as $\delta(\text{CH}_2)$ and $\delta(\text{C}-\text{H})$, since the lines associated with them are polarised and are of medium intensity. The frequency of the vibration $\delta(\text{CH}_2)$ of the vinyl radical at the phosphorus atom is observed in the region 1390–1410 cm^{−1} (cf. 1410–1420 cm^{−1} in the spectra of terminal alkenes). The frequencies of the vibrations $\delta(\text{C}-\text{H})$ of monosubstituted styrenes⁸⁷ lie in the region 1295–1310 cm^{−1} [cf. 1335 cm^{−1} for dichloro(styryl)phosphine **27**]. The $\delta(\text{C}-\text{H})$ vibrations in the molecules of terminal alkenes are observed in the spectral region 1290–1300 cm^{−1} (see Ref. 87), while the frequency of the vibration $\delta(\text{PCH})$ of the vinyl group at the phosphorus atom varies between 1250 and 1260 cm^{−1} (see Table 12). The $\gamma(\text{CH}_2)$ and $\chi(\text{C}=\text{C})$ frequencies also ‘drop out’ of the corresponding spectral regions typical of alkenes.⁸⁷ Changes in the ‘fingerprint’ vibrational frequencies of alkenylphosphines as compared to those of alkenes are due to the effect of the phosphorus atom on the force constants of the alkenyl fragment rather than kinematic effects.

V. Alkoxy derivatives of trivalent phosphorus

The spectra of both cyclic and acyclic alkoxy derivatives of trivalent phosphorus have been studied. According to *ab initio* calculations,^{90–92} the simplest acyclic molecules such as methyl dimethylphosphinite (**32**), methyl phosphorodifluoridite (**33**) and methyl phosphorodichloridite (**3**) can adopt both the *T* and *G* conformations (see Fig. 1; X = CH₃, F, Cl; Y = O; Z = CH₃). Studies of the vibrational spectra of molecule **32** and its isotopomers CD₃OP(CH₃)₂, CH₃OP(CD₃)₂ and CD₃OP(CD₃)₂ showed that both conformers were present in the liquid and gas states,⁹³ while only the *trans* conformer was retained in crystals. It should be noted that the interpretation of incomplete spectra of methyl dimethylphosphinite **32** (see Seel and Velleman⁹⁴) is in agreement

Table 15. Interpretation of vibrational spectra of methyl phosphorodichloridite.

with the assignments suggested on the basis of *ab initio* quantum-chemical calculations.^{90,93}

Both vibrational^{91,95} and microwave⁹⁶ spectral studies as well as a gas-phase electron diffraction study⁹⁷ revealed no indications of the *gauche* conformers of the molecule of methyl phosphorodichloridite **33**. Therefore, the interpretation of the IR absorption bands and Raman lines in the spectra of compound **33** (Table 15) is based on the results of *ab initio* calculations of the vibrations of the *trans* conformer.⁹¹

Data on rotational isomerism in the molecule of methyl phosphorodichloridite **3** are contradictory.^{92,98–103} In spite of this, the existence of *trans* conformers of molecule **3** is doubtless,^{92,102,103} and the interpretation of the spectra of *trans* conformer was based on the results of *ab initio* calculations of the vibrations.⁹²

The molecule of ethyl phosphorodichloridite (**34**) can adopt five stable conformations¹⁰⁴ (see Fig. 2; X = Cl, Y = O); however, this has not been confirmed experimentally. Using normal coordinate analysis, it has been shown¹⁰⁴ that the observed spectra can be attributed to the *Tt* and/or *Gt* conformers. The interpretation of the spectra (see Table 16) is based on the results of normal coordinate analysis for the *Tt* conformer.²⁶

The molecule of β -thiocyanatoethyl phosphorodichloridite (**35**) can adopt twenty-three stable conformations. In the liquid state, compound **35** exists as a mixture of at least three conformers, while in the crystalline state (at low temperatures) the

number of conformers equals at least two.¹⁰⁵ Since conformational analysis of compound **35** is too complicated, attempts to determine unambiguously the number and type of observable conformers of molecule **35** have failed. It has only been shown¹⁰⁵ that the mutual *gauche*-orientation of the O–C and C–S bonds is energetically favourable. The interpretation of the IR absorption bands and Raman lines in the spectra of β -thiocyanatoethyl phosphorodichloridite **35** is based on the results of normal coordinate analysis for all possible conformers.¹⁰⁵

A few studies devoted to the normal coordinate analysis of cyclic alkoxy derivatives of trivalent phosphorus has been reported. Five-, six- and seven-membered phosphacycles with the P–O–C fragment have been studied. First, consider the spectra and conformations of five-membered organophosphorus compounds. According to the vibrational spectroscopy data,¹⁰⁶ the molecule of 2-chloro-1,3,2-dioxaphospholane (**36**) adopts a single conformation. Gas-phase electron diffraction study¹⁰⁷ of compound **36** revealed a stable (in the gas phase) conformation of molecule **36** shown in Fig. 3 (*a-E_O*, X = Y = O). Earlier, a normal coordinate analysis for 2-chloro-1,3,2-dioxaphospholane **36** has been performed for a symmetrical 'envelope' conformation in which the phosphorus atom deviates from the plane passing through the other ring atoms¹⁰⁶ (*a-E_P*). Next to the publication cited,¹⁰⁷ a normal coordinate analysis for the non-symmetrical *a-E_O* conformer (see Fig. 3) has been reported.¹⁰⁸ It is this version of the interpretation of the spectra that is listed in Table 17.

**Figure 3.** The 'envelope' conformations of the molecules of 2-chloro-1,3,2-dioxathia(phospholane)s: with apical Y atom and pseudoaxial orientation of the P–Cl bond (*a-E_Y*), with apical C atom and axial orientation of the P–Cl bond (*a-E_C*) and with apical C atom and equatorial orientation of the P–Cl bond (*e-E_C*).

2-Chloro-1,3,2-oxathiaphospholane (**37**) exists in the liquid state and in solutions as a mixture of two non-symmetrical conformers shown in Fig. 3 (*a-E_C* and *e-E_C*; X = O, Y = S).^{108,109} Their vibrational spectra^{108,109} have been interpreted theoretically.¹⁰⁸

The molecule of 2-chloro-1,3,2-dioxaphosphorinane (**38**) adopts a single conformation.¹¹⁰ Based on the results of the gas-phase electron diffraction study,¹¹¹ the conformation *a* was suggested for its molecule; at the same time, the band-shape

analysis of the IR spectra of compound **38** in the vapour phase counts in favour of conformation *e*.¹¹⁰

A normal coordinate analysis for both conformers of the molecule of 2-chloro-1,3,2-dioxaphosphorinane **38** has been performed.^{110, 112}

The molecule of 4,7-dihydro-2-dimethylamino-1,3,2-dioxaphosphin (**39**) adopts mainly a non-symmetrical conformation.¹¹³

for which theoretical interpretation of the vibrational spectra has been carried out.¹¹³

Based on the results of normal coordinate analyses (see Tables 15–17), it is possible to establish the origin of the bands used as spectral indications of the presence of different AlkOP groups in the molecules under study. It is known that the methoxy group at the phosphorus atom is responsible for the appearance of a strong band at $\sim 1010\text{--}1050\text{ cm}^{-1}$, a strong or medium band in the region $\sim 700\text{--}800\text{ cm}^{-1}$ and a medium or weak (often multiplet) band in the region $\sim 1150\text{--}1200\text{ cm}^{-1}$ in the IR spectra. The first two bands are associated with the antiphase and in-phase stretching vibrations of the P–O and O–C bonds, respectively. The former bond makes the major contribution to the symmetric vibration $\nu_s(\text{POC})$, while the latter contributes largely to the antisymmetric vibration $\nu_{as}(\text{POC})$. Mention may be made that the vibrations $\nu_s(\text{POC})$ can also be readily identified using the Raman spectra, since the corresponding line is of rather high intensity and polarised. Weak Raman lines and IR absorption bands in the spectral region $\sim 1150\text{--}1200\text{ cm}^{-1}$ are mainly due to the rocking vibrations of the methyl group.

Spectral ‘fingerprints’ of the $\text{C}_2\text{H}_5\text{OP}$ group are well known.^{1–5} These are the strong bands in the IR spectra in the regions $\sim 900\text{--}970$, $\sim 1010\text{--}1040\text{ cm}^{-1}$ and the bands of medium or weak intensity in the regions $\sim 1090\text{--}1110$ and $\sim 1150\text{--}1170\text{ cm}^{-1}$. All of them are due to strongly coupled vibrations (Table 16). The vibration with the highest frequency is associated with the rocking motion $\nu(\text{CH}_2)$. The frequencies of stretching vibrations of the OCC fragment usually lie in the range $\sim 1090\text{--}1110\text{ cm}^{-1}$. Strong bands in the IR spectrum are to a certain degree due to the antiphase stretching vibrations of the P–O, O–C and C–C bonds (see Table 16, stretching vibrations Nos 9 and 10). The vibration $\nu_s(\text{POC})$ gives rise to the appearance of rather intense spectral peaks both in the IR and Raman spectra (stretching vibration No. 11). They are observed in the region $\sim 700\text{--}800\text{ cm}^{-1}$, the corresponding Raman line being polarised.

This spectral region is characteristic of the frequencies of the vibrations $\nu_s(\text{POC})$ for not only the ethoxy group, but almost any alkoxy groups at the trivalent phosphorus atom. Only for cyclic alkoxy derivatives does the region extend to $\sim 690\text{--}820\text{ cm}^{-1}$. Because of the possibility that the molecules of compounds under study adopt several conformations owing to internal rotation about the P–O bond, the bands corresponding to the vibrations $\nu_s(\text{POC})$ can split into doublets. It should be noted that if a molecule contains two POC groups at the phosphorus atom, their stretching vibrations effectively interact through this atom (see Section I). For instance, the frequencies of the ring ‘breathing’

vibrations corresponding to the synchronous stretch or contraction of the bonds in both POC groups (see Table 17, vibrations No. 15) and to the antiphase vibrations of these fragments (vibrations No. 16) are observed in this region of the spectra of 2-chloro-1,3,2-dioxaphospholane. The IR absorption bands associated with the antiphase vibrations $\nu_s(\text{POC})$ are usually more intense than those corresponding to the in-phase vibrations. At the same time, the lines of the in-phase vibrations in the Raman spectra are symmetrical, very strong and strongly polarised, while those of the antiphase vibrations are, as a rule, of weak intensity.

It should be noted that the ring ‘breathing’ vibrational frequencies of 1,3,2-dioxaphospholanes are always higher than the frequencies of the in-phase vibrations $\nu_s(\text{POC})$ of related acyclic organophosphorus compounds, as well as those of the ring ‘breathing’ vibrations of 1,3,2-dioxaphosphorinanes¹¹² and other related unstrained phosphacyclanes (provided that the exocyclic groups in the dioxaphospholane and in the larger ring to be compared are the same). A remarkable feature of 1,3,2-dioxaphospholanes is that the frequencies of the ring ‘breathing’ vibrations are higher than those of the antiphase vibrations $\nu(\text{POC})$. The opposite is observed for 1,3,2-dioxaphosphorinanes and acyclic dialkoxy derivatives. These distinctions can be used for analytical purposes. If the molecules under study have exocyclic P–Cl bonds, then the strong IR absorption bands and very strong polarised Raman lines in the spectral region $\sim 440\text{--}460\text{ cm}^{-1}$ provide reliable spectral indications of the 1,3,2-dioxaphospholane rings. These spectral bands and lines are due to the stretching vibrations of the P–Cl bond. In the molecules of 1,3,2-dioxaphosphorinanes, the vibrations $\nu(\text{P–Cl})$ interact with the ring deformation vibrations. Two resultant vibrations appear in the spectra as the intense IR absorption bands and Raman lines in the regions $\sim 400\text{--}430$ and $\sim 460\text{--}490\text{ cm}^{-1}$. The most characteristic of the spectra of acyclic phosphorochloridites are intense IR absorption bands in the region $\sim 490\text{--}510\text{ cm}^{-1}$. Thus, the readily identifiable vibrations $\nu(\text{P–Cl})$ can be used for the discrimination not only between 1,3,2-dioxaphospholanes and 1,3,2-dioxaphosphorinanes, but also between these cyclic and corresponding acyclic compounds.

The vibrations of the PCl_2 group (see Table 16) have marked spectral indications. Symmetrical stretching vibrations $\nu_s(\text{PCl}_2)$ of the molecules of alkyl phosphorodichloridites appear as very strong IR absorption bands and Raman lines in the region $\sim 490\text{--}510\text{ cm}^{-1}$. The less intense peaks in the region $\sim 440\text{--}480\text{ cm}^{-1}$ are associated with antisymmetric vibrations. Identification of these vibrations using the Raman spectra is facilitated by the fact that the lines corresponding to $\nu_s(\text{PCl}_2)$ are strongly polarised while those corresponding to $\nu_{as}(\text{PCl}_2)$ are depolarised or nearly depolarised. It should be noted that the appearance of additional intense peaks in these spectral regions, which are due to the deformation vibrations of non-branched alkoxy groups at the phosphorus atom (see Table 16) prevents easy interpretation.

The deformation vibration of the PCl_2 group is also characteristic of alkyl phosphorodichloridites. The corresponding line is observed in the region $\sim 190\text{--}220\text{ cm}^{-1}$ and can be identified with ease in the Raman spectra, since it is always strong and has a depolarisation ratio of about 0.6.

It should be noted that vibrational spectra of phosphorochloridites change as the state of aggregation of compounds under study changes or on dissolution, which is mainly due to intermolecular interactions. The frequencies of the vibrations involving the P–Cl bonds change to the greatest extent. All the above-mentioned characteristic spectral regions refer to the spectra of neat liquids at room temperature.

VI. Dialkylphosphoramidites

To date, a normal coordinate analysis has been performed only for four compounds containing $\text{Alk}_2\text{NP}^{\text{III}}$ groups. The simplest molecules, such as dimethylphosphoramidodifluoridite

(**40**)^{114–116} and dimethylphosphoramidodichloridite (**41**),¹¹⁷ adopt single conformations. The structure of molecule **40** was studied by X-ray analysis,¹¹⁸ gas-phase electron diffraction,¹¹⁹ and microwave spectroscopy.^{116,120} However, two structures of the (CH₃)₂NP fragment were proposed, a planar¹¹⁸ and a pyramidal one.¹¹⁹ Later, the results obtained in the former study¹¹⁹ were critically reviewed^{116,120} since structural parameters of the molecule **40** obtained in more recent studies appeared to be in agreement with the data of the X-ray study.¹¹⁸ The results of gas-phase electron diffraction investigations^{121–123} of molecules **41**, [(CH₃)₂N]₂PCl (**42**) and 2-chloro-1,3-dimethyl-1,3,2-diazaphospholane (**43**) also suggested that the dialkylamino group at the trivalent phosphorus atom has a nearly planar structure. It was found that this group in the molecule **40** is oriented parallel to the LEP of the phosphorus atom.^{116,118,120} Based on the results obtained in studies on the vibrational¹¹⁷ and NMR spectra,¹²⁴ a similar conformation was suggested for the molecule of compound **41**. At the same time, it was stated¹²¹ that the (CH₃)₂NP group is oriented perpendicular to the LEP of the phosphorus atom. Spectra of molecules **40**, **41** and fully deuterated derivative of compound **41** have been studied^{114,117} and a normal coordinate analysis was performed¹²⁵ for the conformations with eclipsed arrangement of the plane of the dimethylamino groups and the LEP of the phosphorus atom. It was also assumed that the molecules have no symmetry elements because of the non-symmetrical orientation of methyl groups.

The initial empirical interpretation of the spectra of dimethylphosphoramidodifluoridite **40** (see Ref. 117) was essentially different from that based on the results of normal coordinate analysis (see Ref. 125). In addition, the experimental vibrational spectra reported by Durig and Casper¹¹⁷ contained some 'extra' Raman lines and IR absorption bands as compared with the spectra reported earlier.¹¹⁴ Probably, they are due to impurities formed as a result of partial hydrolysis. Because of this, Table 18 lists the experimental results¹¹⁴ interpreted on the basis of normal coordinate analysis.¹²⁵ After publication of the study cited (Ref. 125), new spectra of dimethylphosphoramidodifluoridite **40** and its

D-isotopomers have been reported,¹¹⁶ which are somewhat different from those published previously.¹¹⁴

The molecules of tetramethylphosphorodiamidochloridite and 2-chloro-1,3-dimethyl-1,3,2-diazaphospholane adopt single conformations.^{126,127} The equilibrium conformation of the molecule **43** has a C_s symmetry (see Refs 123, 127).

The vibrational spectra of compound **42** (Table 19) have been interpreted¹²⁷ assuming that both dimethylamino groups in the molecule are arranged so that they are nearly eclipsed by the LEP of the phosphorus atom. The results of normal coordinate analysis for this conformer with C_s symmetry are in good agreement with experimental data.¹²⁷ At the same time, it should be noted that, according to the electron diffraction data,¹²² molecule **42** has a non-symmetrical conformation. The spectra of compound **43** listed in Table 20 are given in accordance with the known interpretation.¹²⁷

Analysis of the spectra of phosphoramides based on the results of normal coordinate analysis (see Table 18–20) made it possible to establish the nature of the bands characteristic of the (CH₃)₂NP group. It is known^{1–5} that the bands of medium or high intensity in the frequency range ~ 1260–1320 cm^{–1} are observed in the IR spectra of compounds with these groups. These bands are associated with the vibration in which a symmetric stretch of both N–C bonds [the ν_s(NC₂) vibration] is accompanied by contraction of the P–N bond [the ν(P–N) vibration]. The frequency of synchronous stretch of the three bonds lies in the range ~ 650–700 cm^{–1}. The corresponding IR absorption bands

^a Spectral region below 400 cm^{-1} has not been recorded.

are, as a rule, rather weak, while the Raman lines are intense and strongly polarised.

The vibration $\nu_{\text{as}}(\text{NC}_2)$ with predominant contributions of the antiphase stretch and tension of the N—C bonds interacts with the stretching vibration $\nu(\text{P}-\text{N})$. One of the two resultant vibration appears as a band of strong or medium intensity in the IR spectrum in the region 1140–1210 cm^{-1} . For the trivalent phosphorus compounds, this band is shifted towards high frequencies in this spectral region. The other resultant vibration gives rise to a strong IR absorption band¹ in the region ~ 935–1008 cm^{-1} (a narrower spectral region ~ 940–980 cm^{-1} has also been reported^{4,5}). The corresponding Raman lines are usually weak, as are the lines corresponding to the $\nu(\text{CH}_3)$ rocking vibrations, which appear in the IR spectra of molecules containing the $(\text{CH}_3)_2\text{NP}$ groups as bands of medium intensity in the frequency range ~ 1050–1080 cm^{-1} .

Two or even three peaks can be observed in these spectral regions for diamides and triamides (see Tables 19, 20). The bands due to the vibrations with the contributions of the vibrations $\nu(\text{P}-\text{N})$ and $\nu_{\text{as}}(\text{NC}_2)$ in the frequency range 1140–1210 cm^{-1} or the vibration $\nu_{\text{as}}(\text{NC}_2)$ in the frequency ranges 935–1008 and 650–700 cm^{-1} are mainly split. The splitting is to a great extent caused by the kinematic interaction between the dimethylamino groups through the shared phosphorus atom.¹²⁷

It is of interest to compare the spectra of acyclic compound **42** (see Table 19) and its cyclic analogue **43** (see Table 20). A distinctive feature of the vibrational spectra of 2-chloro-1,3-dimethyl-1,3,2-diazaphospholane **43** is that they contain the lines at 1370, 1342 and 830 cm^{-1} corresponding to the methylene groups, as well as the lines at 855 and 597 cm^{-1} caused by the ring vibrations. As in the case of acyclic compound **42**, the strongest line in the Raman spectrum of the phospholane **43** is associated with the totally symmetrical vibration with the contribution of the P—N bonds. However, for compound **43** the frequency of this line (710 cm^{-1}) is shifted as compared with that of tetramethylphosphoramidochloridite **42** (670 cm^{-1}), whereas

the frequencies of the corresponding antisymmetrical vibrations (692 cm^{-1}) remain virtually unchanged.

VII. Phosphorothioites

A rather large number of studies dedicated to the interpretation of the spectra of phosphorothioites has been reported. Normal coordinate analyses were performed for cyclic and acyclic molecules with one, two and three RSP groups, where R are various alkyl, dithiocarbamoyl and dithiophosphoryl radicals. The simplest representative of phosphorothioites, methyl phosphorodichloridithioite (**44**), exists in the liquid and gas phases as a mixture of the *T* and *G* conformers (see Fig. 1; X = Cl, Y = S, Z = CH₃).^{103, 128} Vibrational spectra of compound **44** have been interpreted¹²⁹ assuming that the molecule adopts a single conformation. Then, it was established¹⁰³ that the molecule adopts several conformations, the previous assignments¹²⁹ were refined and a normal coordinate analysis was performed for the spectrum of compound **44**. These results are listed in Table 21.

Table 21. Interpretation of vibrational spectra of methyl phosphorodichloridithioite.^a

^a See note to Table 2. ^b Spectral region below 400 cm^{-1} has not been recorded.

The molecule of ethyl phosphorodichloridithioite (**45**) can adopt five stable conformations¹³⁰ (see Fig. 2; X = Cl, Y = S). Vibrational spectra of compound **45** have been interpreted using the results of normal coordinate analysis.¹³⁰ It has been shown that internal rotation about both the P—S and S—C bonds occurs in the neat liquid and in solutions. However, it was not established whether the *Gg* and *Gg'* conformations or at least one of them do exist (we only can say that the existence of these conformers does not contradict experimental data). Keeping this in mind, the spectra of ethyl phosphorodichloridithioite **45** can be interpreted in different ways, since some of the frequencies can be attributed to either the *Tg* conformers or the *Tg*, *Gg* and *Gg'* conformers simultaneously. These frequencies are denoted by a character 'g'. The bands, which can be attributed to the *Gt*, *Gg* and *Gg'* conformers are denoted by a character 'G'. A version^{130, 131} of the interpretation of the spectra of compound **45** is listed in Table 22.

The molecule of propyl phosphorodichloridithioite (**46**) can adopt 14 spectroscopically discernible conformations, of which three are shown in Fig. 4. It was established that the *T*, *G*, *gt'*, *tt'*, *gg'* and *tg'* conformers of the molecule **46** (for the meaning of notations, see Fig. 4) exist in the liquid and in solutions and a normal coordinate analysis was performed for all possible conformers.¹³² Attempts to establish exact composition of such a complex mixture of conformers have failed.

The molecule of isopropyl phosphorodichloridithioite (**47**) can adopt five spectroscopically discernible conformations (Fig. 5). The bands associated with internal rotation about the P—S and S—C bonds of the molecule are observed in the vibra-

^a See note to Table 3.^b Spectral region below 400 cm⁻¹ has not been recorded.**Figure 4.** Conformers of the molecule of propyl phosphorodichloridothioite:

Ttg' stands for *trans,trans,gauche*, *Tgt'* for *trans,gauche,trans* and *Gtt'* for *gauche,trans,trans*; *T* and *G* denote the *trans* and *gauche* conformers formed owing to rotation about the P-S bond; *t* and *g* denote the *trans* and *gauche* conformers formed owing to rotation about the S-C bond and *t'* and *g'* denote the *trans* and *gauche* conformers formed owing to rotation about the C-C bond.

**Figure 5.** Conformers of the molecule of isopropyl phosphorodichloridothioite:

Tt stands for *trans,trans*, *Tg* for *trans,gauche*, *Gt* for *gauche,trans*, *Gg* for *gauche,gauche* and *Gg'* for *gauche,gauche'*.

tional spectra of liquid **47**.¹³² Only the *Tg* conformer is retained upon crystallisation.

The number of possible conformers of the molecule of triethyl phosphorothioite (**48**) is as large as 36. Nevertheless, experimental spectra of neat (liquid) compound **48** and its solutions can be interpreted¹³⁰ assuming that its molecule has only two conformers.

Here, the first two characters denote the conformation of one C₂H₅SP group of the molecule **48**, while the next two pairs of characters denote the conformations of the other two identical groups. It has been reported that only the *TtGgG'g'* conformer is retained upon crystallisation.¹³⁰

In the crystalline phase, the equilibrium conformation of the molecule of *S,S',S''*-tris(dimethoxythiophosphoryl) phosphorotrithioite (**49**) has a C₃ symmetry (see Ref. 133)

Other, non-symmetrical conformers appear in the liquid phase (either in a neat liquid or in solutions).¹³⁴

This gives rise to additional peaks in the spectra. Normal coordinate analysis for all possible conformers of the molecule **49** shows¹³⁴ that additional bands can be attributed to the non-symmetrical conformers. Some bands were assigned to those conformers which can be formed from all the three conformers shown above by changing the arrangement of the methoxy groups of the (CH₃O)₂P(=S) fragment from *gauche'*, *gauche* with respect to the P= S bond to the *gauche,gauche* or *gauche,trans* with respect to the same bond. The presence of other conformers also does not contradict the results of spectral experiments.¹³⁴

The equilibrium conformation of the molecule of *S,S',S''*-tris(*N,N'*-dimethylthiocarbamoyl) phosphorotrithioite (**50**) in the crystalline phase has a C₃ symmetry group (see Ref. 135).

According to the vibrational spectroscopy data,¹³⁶ the molecule of compound **50** in solutions retains a single conformation.

According to the results of the gas-phase electron diffraction study,¹³⁷ the molecule of 2-chloro-1,3,2-dithiaphospholane (**51**) adopts a symmetrical 'envelope' conformation with an apical phosphorus atom and an axial P-Cl bond. On the other hand, data obtained in the NMR¹³⁸ and vibrational spectroscopic¹⁰⁸ studies indicate that the molecule of compound **51** adopts a non-symmetrical conformation. Calculations by the molecular mechanics method predict the *a-E_C* conformation of molecule **51**

^a Spectral region below 400 cm^{-1} has not been recorded.^b Nonplanar vibration.

(see Fig. 3; $\text{X} = \text{Y} = \text{S}$). Table 23 lists the interpretation of the vibrational spectra of 2-chloro-1,3,2-dithiaphospholane **51** for this conformation.¹⁰⁸ Experimental spectral parameters¹⁰⁸ of liquid compound **51** coincide with previously reported data,¹³⁹ except for the degrees of depolarisation of the Raman lines.

Stretching vibrations of the $\text{P}-\text{S}$ and $\text{S}-\text{C}$ bonds are most pronounced in the spectra of all the above-mentioned alkyl phosphorothioites. The vibrations $\nu(\text{S}-\text{C})$ can mix with the deformations of the alkylthio group and PSC fragment (Table 24), which is responsible for the variations in the intensities of the corresponding IR absorption bands (from weak to medium) and Raman lines (from medium to strong). The phosphorus-containing fragment of the molecule contributes negligibly to the potential energy of this vibration, therefore its frequency depends on the structure of the alkylthio group. Because of this, the $\nu(\text{S}-\text{C})$ 'fingerprint' spectral regions⁸⁷ of phosphorothioites nearly coincide with those of different organosulfur compounds. It is more convenient to identify stretching vibrations of the $\text{S}-\text{C}$ bond using the Raman spectra, since the corresponding lines are rather strong and polarised. If internal rotation of the alkylthio groups about the $\text{S}-\text{C}$ bond can lead to inequivalent orientations of these groups with respect to the $\text{P}-\text{S}$ bond, the Raman lines become multiplets.

It is also desirable to identify the $\text{P}-\text{S}$ bonds using the Raman spectroscopy. The stretching vibrations $\nu(\text{P}-\text{S})$ in the molecules of alkyl phosphorodichloridothioites are strongly coupled with symmetrical stretching vibrations of the PCl_2 group. One of the two resultant vibrations appears as strong bands in the IR spectrum and polarised Raman lines of medium or strong intensity in the region $\sim 490-530 \text{ cm}^{-1}$. The second vibration is associated with very strong polarised Raman lines and strong IR absorption bands in the region $\sim 460-480 \text{ cm}^{-1}$. If the molecules of compounds under study can adopt several conformations, all these bands are, as a rule, multiplets; it is noteworthy that polarised Raman lines can have depolarised 'shoulders'.

The vibrations $\nu(\text{P}-\text{S})$ can also interact with vibrations of other groups at the phosphorus atom (see Table 24). Nevertheless, the presence of both a strong polarised Raman line and an IR absorption band of medium or strong intensity in the region $\sim 470-540 \text{ cm}^{-1}$ can be considered to be a reliable spectral indicator of the single $\text{P}-\text{S}$ bond, while multiplet IR and Raman spectra in this spectral region can be regarded as an indicator of the existence of different conformers due to the internal rotation about this bond. This spectral region is characteristic of acyclic molecules. For cyclic phosphorothioites, the frequencies of the stretching vibrations $\text{P}-\text{S}$ can be substantially lower.

Table 24. Vibrations of fragments of the molecules with contributions of the $\text{P}-\text{S}$, $\text{P}-\text{Cl}$ and $\text{S}-\text{C}$ bonds in the spectra of organophosphorus compounds.

Effective coupling of the stretching vibrations of three $\text{P}-\text{S}$ bonds in the molecules of trialkyl phosphorotrithioites gives rise to three new resultant motions (see Table 24). Symmetrical

stretching vibrations of all the three P–S bonds of the PS₃ group appear in the spectral region $\sim 430\text{--}470\text{ cm}^{-1}$. The corresponding Raman lines are very intense and strongly polarised and the IR absorption bands are of medium or strong intensity. Two antisymmetric vibrations $\nu_{\text{as}}(\text{PS}_3)$ appear as very strong bands in the IR spectrum and strong Raman lines in the region $\sim 460\text{--}500\text{ cm}^{-1}$ and as peaks of medium intensity in the region $\sim 500\text{--}570\text{ cm}^{-1}$. All the above-mentioned vibrations can be ‘conformationally sensitive’, therefore some ‘extra’ peaks can be observed in these regions of the spectra of those trialkyl phosphorotrithioites which can exist as a mixture of conformers.

If the molecules of trialkyl phosphorotrithioites have a C_3 symmetry, both antisymmetric vibrations $\nu_{\text{as}}(\text{PS}_3)$ become degenerate, *i.e.*, have equal frequencies. This is the case for *S,S',S''*-tris-(*N,N*-dimethylthiocarbamoyl) phosphorotrithioite **50** (see Table 24), for which a singlet IR absorption band and a singlet Raman line corresponding to the vibration $\nu_{\text{as}}(\text{PS}_3)$ are observed. Unlike the spectra of trialkyl phosphorotrithioites, the frequency of symmetric vibration $\nu_s(\text{PS}_3)$ in these spectra is higher than that of antisymmetric vibration $\nu_{\text{as}}(\text{PS}_3)$ (~ 485 vs. $\sim 465\text{ cm}^{-1}$, respectively).

This also holds for compound **49** (see Table 24) that is, the $\nu_s(\text{PS}_3)$ frequency is as high as nearly 500 cm^{-1} , while the $\nu_{\text{as}}(\text{PS}_3)$ frequency is 485 cm^{-1} . According to Thomas,¹ the IR absorption bands and Raman lines characteristic of compounds with the P^{III}SP group are usually observed in nearly the same spectral region ($\sim 480\text{--}510\text{ cm}^{-1}$). As can be seen from the data listed in Table 24, they should be attributed to the stretching vibrations of this group.

VIII. Compounds with Si–P, Ge–P and P–P bonds

Silylphosphine (**52**), (trifluorosilyl)phosphine (**53**) and germlylphosphine (**54**) are rare examples of the trivalent phosphorus compounds with Group IV elements for which normal coordinate analysis has been performed. The spectra of compound **52** and its fully deuterated analogue have been interpreted.^{140, 141} Analysis of the spectra of both these molecules¹⁴¹ has led to some changes in the vibrational assignments suggested earlier.¹⁴⁰ Vibrational spectra of compound **53** and its fully deuterated analogue were interpreted using the results of normal coordinate analysis¹⁴² and the spectra of phosphine **54** and its three D-isotopomers were studied.¹⁴³

A salient feature of the vibrational spectra of silyl- and germlylphosphines is that they contain the peaks which correspond to the stretching vibrations $\nu(\text{Si–P})$ and $\nu(\text{Ge–P})$. The vibration $\nu(\text{Si–P})$ appears in the region $\sim 300\text{--}530\text{ cm}^{-1}$, while the vibration $\nu(\text{Ge–P})$ appears in the region $\sim 290\text{--}410\text{ cm}^{-1}$. Both stretching vibrations can mix with skeletal deformations of the molecules (Table 25). This probably results in substantial variations of the intensities of the corresponding peaks. The vibrations $\nu(\text{Si–P})$ in the molecules of acyclic organophosphorus compounds appear in a somewhat narrower spectral region $\sim 380\text{--}530\text{ cm}^{-1}$. The vibrations $\nu_{\text{as}}(\text{PH}_2)$, $\nu_s(\text{PH}_2)$, $\delta(\text{PH}_2)$, characteristic of all primary phosphines, appear in the spectra of compounds under consideration in nearly the same way as in the spectra of alkylphosphines. For primary phosphines, the $\nu(\text{PH}_2)$ frequencies are somewhat higher while the $\delta(\text{PH}_2)$ frequencies are somewhat lower than those indicated in Section II.

In Table 25, the frequencies of these characteristic vibrations of the phosphino group are also given for the molecule of diphosphane (**55**). As can be seen, the frequencies of stretching and deformation vibrations of the PH₂ groups of the molecule **55** lie far beyond the limits of the spectral regions characteristic of alkyl-, silyl- and germlylphosphines and their halogen-substituted derivatives.

Only the *G* conformers have been detected in diphosphane **55** (see Refs 144–146). Vibrational spectra of diphosphane have been studied.^{144, 147–149} Table 25 lists the interpretation¹⁴⁴ of the

^b The meaning of notation H' is clearly seen from the Newman projections of possible conformations of diphosphane and its derivatives:

^c Symmetry species of vibrations.

spectra, which is based on the results of normal coordinate analysis for molecules **55** and P₂H₂D₂. Vibrational assignments made in the framework of *ab initio* calculations¹⁴⁶ of the force field of the molecule **55** differ only slightly from those listed above.

Initially, the spectra of solutions of tetraiododiphosphane (**56**) were interpreted assuming the *gauche* conformation of the molecule.¹⁵⁰ However, it was shown later¹⁵¹ that the *trans* conformation exists in fact both in the crystal and in solutions. Taking into account the results of normal coordinate analysis of the molecule **56** (see Ref. 152), some vibrational assignments in the low-frequency region were changed compared to those reported earlier.¹⁵⁰

Vibrational spectra of tetrakis(trifluoromethyl)diphosphane (**57**) have been interpreted¹⁵³ assuming that the molecule **57** has only the *trans*-conformation with a C_{2h} symmetry. Under this symmetry group, the vibrations of the A_g and B_g types should be Raman active while the vibrations of the A_u and B_u types should be IR active (the so-called principle of alternative exclusion). However, the results of spectroscopic studies¹⁵³ indicate that this principle is not obeyed. The fact that the IR absorption band corresponding to the vibration $\nu(\text{P–P})$ (see Table 25) is weak is not always a consequence of alternative exclusion. It is known that these bands can also be of weak intensity if the molecules with the P–P bond adopt non-symmetrical conformations. Therefore, the conclusion¹⁵³ that the molecule **57** has a C_{2h} symmetry, which is based on the weak intensity of the $\nu(\text{P–P})$ band, casts some doubts. Correspondingly, the results of theoretical interpretation of the spectra¹⁵³ can appear to be not sufficiently rigorous.

It is convenient to identify the P–P bond in diphosphanes using Raman spectra where the line corresponding to the vibration $\nu(\text{P}–\text{P})$ is observed in the region $\sim 300–530\text{ cm}^{-1}$, has a medium or strong intensity and is polarised (for gases, liquids or solutions).

IX. Rotational isomerism of trivalent phosphorus compounds and its manifestation in vibrational spectra

1. General

If interconversions between stable conformations of a molecule can occur owing to hindered internal rotation and if the conformers are not mirror images, their vibrational frequencies can differ from one another. Because of this, the number of bands and lines in the vibrational spectra of organophosphorus compounds, whose molecules can adopt several conformations, is larger than it should be expected for a single molecular conformation. As a rule, the ‘sensitivity’ to rotations of a particular molecular fragment about an X–Y bond with respect to another molecular fragment is characteristic of those vibrations to which the bond in question contributes. Usually, the frequencies of other vibrations depend only slightly on the molecular conformation, so that the corresponding IR absorption bands or Raman lines in the spectra of different conformers coincide. Therefore, an equilibrium between N conformers rarely, if ever, leads to the N -fold increase in the number of spectral peaks; rather, it causes multiplet splittings of particular peaks, e.g., the $\nu(\text{X}–\text{Y})$ or $\delta(\text{XYZ})$ peaks. However, the frequencies of vibrations with predominant contribution by a particular molecular fragment can also be dependent on the conformation of another molecular fragment. This dependence is due to changes in either or both the spatial mass distribution and the force constants of the molecule on interconversions between different conformations. Sometimes, the effect of conformations on the vibrational frequencies is so weak that it can be detected only in the low-temperature experiments. In this case, the spectral contours become much narrower and the peaks of different conformers which have been unresolved at room temperature, can be observed as multiplets or as separated bands. In other cases, shifts in the vibrational frequencies due to conformational effects are as large as tens of cm^{-1} . Usually, crystallisation leads to simplification of the conformational composition of most compounds and disappearance of particular spectral bands. The conformational composition depends also on the temperature and polarity of the medium. Therefore, the conditions of spectroscopic experiments can strongly affect the spectra of organophosphorus compounds, whose molecules can adopt several conformations. This should be taken into account when interpreting the spectra.

For instance, the intensities of the bands of conformers of greater polarity usually increase in polar media and decrease on going to non-polar solutions. This correlation can be used for the assignment of spectral peaks to the conformers of different polarities. However, the assignments based on both the experimental results and the results of normal coordinate analysis for possible conformers are the most reliable. It is these vibrational assignments that are generalised in this review and serve as the basis for simple empirical rules which facilitate the interpretation of the spectra of organophosphorus compounds, whose molecules can adopt several conformations.

2. Internal rotation of Alk–P fragments

Alkylphosphines and their derivatives with the general formula AlkPX_2 (Alk = C_2H_5 , $n\text{-C}_3\text{H}_7$, $\text{iso-C}_3\text{H}_7$; X = H, F, Cl, CH_3), which are liquids or gases at room temperature, are characterised by the existence of an equilibrium between the G and T conformers formed owing to internal rotation about the P–C bond (see Figs 1, 2). The T conformers are more energetically favourable than the G conformers,^{15–21, 23, 56–61} except for the molecule of ethyl(dimethyl)phosphine;^{46, 154, 155} the energy ‘gain’ is nearly

1.6 kJ mol^{-1} in the liquid phase and 0.8 kJ mol^{-1} in the gas phase. It should be noted that the enthalpy differences (ΔH) between the T and G conformers are small: they vary from ~ 0.4 to $\sim 4.2\text{ kJ mol}^{-1}$ and decrease on going from the liquid to the gas phase. Therefore, liquid or gaseous alkylphosphines exist at room temperature as mixtures of the G and T conformers in comparable proportions.

Many of the vibrations of the T and G conformers have different frequencies (see Tables 2–4). The simplest rule is valid for the conformational ‘sensitivity’ of the P–C stretching vibrations (Alk = C_2H_5 , $\text{iso-C}_3\text{H}_7$): the frequency of the vibrations $\nu[\text{P}–\text{C}(T)]$ is always lower than that of the vibrations $\nu[\text{P}–\text{C}(G)]$. The $\nu[\text{P}–\text{C}(G)]–\nu[\text{P}–\text{C}(T)]$ difference for compounds $\text{C}_2\text{H}_5\text{PX}_2$ (X = CH₃, Cl, F) varies between ~ 30 and 60 cm^{-1} . For the molecule **6**, this value decreases to $\sim 20\text{ cm}^{-1}$ and is only 7 cm^{-1} for ethylphosphine **4**, so that the doublet band corresponding to the vibrations $\nu(\text{P}–\text{C})$ can only be observed in the spectra of a solution of ethylphosphine **4** in liquid xenon.²⁰

The appearance of *gauche* and *trans* conformers in $n\text{-C}_3\text{H}_7\text{PX}_2$ is due to not only internal rotation about the P–C bond (the G and T conformers, respectively, see Fig. 2; Y = CH₂), but also the rotation with respect to the C–C bond (the g and t conformers, see Fig. 2). The t conformers are ~ 1.3 to 2.9 kJ mol^{-1} more energetically stable than the g conformers, the ΔH values decrease on going from the liquid to the gas phase or to solutions in liquid xenon. It is noteworthy that the enthalpy difference between the *gauche* and *trans* conformers of butane measured in the gas phase [$\sim 4.2\text{ kJ mol}^{-1}$ (see Ref. 156)] is much larger than the ΔH values for the corresponding n -propylphosphine conformers. Thus, substitution of a methyl group in the butane molecule by a bulky PX_2 group causes a decrease rather than an increase in the probability of the appearance of the *trans* conformers owing to internal rotation about the C–C bond.

The frequencies of the vibrations $\nu(\text{P}–\text{C})$ of propylphosphines are ‘sensitive’ to conformational transitions of both the $G \rightleftharpoons T$ and $g \rightleftharpoons t$ types. For $G \rightarrow T$ transition, the $\nu(\text{P}–\text{C})$ frequency decreases, as is the case of $\text{C}_2\text{H}_5\text{PX}_2$, whereas the $g \rightarrow t$ transition leads to an increase in this frequency. As a result, the highest-frequency IR absorption band (or Raman line) in the spectra of propylphosphines, corresponding to the vibrations $\nu(\text{P}–\text{C})$, is characteristic of the Gt conformers, while the frequencies of the peaks of the Tt conformers are $\sim 20–50\text{ cm}^{-1}$ lower and the peaks of the Gg and Tg conformers are even more shifted towards the low-frequency region (see Table 5). All these correlations between the changes in the frequency of the vibrations $\nu(\text{P}–\text{C})$ and the conformations of the ethylphosphino and propylphosphino groups are caused mainly by kinematic factors.

Orientations of alkyl groups (*gauche* and *trans*) with respect to the lone electron pair of the phosphorus atom are also characteristic of the molecules of the Alk_2PX or Alk_3P types. In the liquid or gas phase, the molecules of secondary and tertiary phosphines adopt usually several conformations, which is responsible for the appearance of multiplet IR absorption bands and Raman lines corresponding to the symmetrical and antisymmetrical stretching vibrations of the P–C bonds and to some other vibrations (see Table 5). However, all attempts to find general correlations between the molecular conformations and frequencies of any vibrations have failed.

3. Internal rotation of AlkOP fragments

The molecules of compounds with the general formula ROPX_2 can adopt either *trans* or *gauche* conformations, which is due to internal rotation about the P–O bond (see Fig. 1; X = CH₃, F, Cl; Y = O; Z = R). The *gauche* conformers are more favourable for X = CH₃, though a detectable amount of *trans* conformers is also present in the liquid phase. On the contrary, the *trans* conformers of alkyl phosphorodichloridites or alkyl phosphorodifluoridites are much more stable. According to the data of *ab initio* quantum-chemical calculations,^{91, 92} the energy difference between the G and T conformers for X = F is larger than for

X = Cl. In the former case, it is so large that the *G* conformer cannot be detected experimentally.^{91, 95–97}

No spectral indications of the existence of several conformers was observed for alkyl phosphorodichloridites ROPCl₂ (R = CH₃, C₂H₅) in the liquid or gas phase at room temperature.^{98–100, 103, 104} Based on the results of a gas-phase electron diffraction study¹⁰¹ and measurements of the dipole moments,⁹⁹ it was assumed that the molecule **3** adopts a nearly *gauche* conformation. However, a more detailed gas-phase electron diffraction study showed that this molecule adopts the *trans* conformation in the gas phase.¹⁰² Later, additional bands which cannot be attributed to the *trans* conformer were found in the spectra of glassy films of compound **3** and its solutions.¹⁰³ The high-frequency component of the doublet at 748/754 cm^{−1} corresponding to the vibrations $\nu_s(\text{POC})$ was attributed to the *gauche* conformer. The enthalpy difference between the *gauche* and *trans* conformers determined in CS₂ from the temperature dependence of the relative intensities of the bands at 748 and 754 cm^{−1} was found to be ~ 0.8 kJ mol^{−1} in favour of the latter. However, studies of methyl phosphorodichloridite **3** dissolved in liquid xenon revealed⁹² disappearance of some of the bands attributed to the *gauche* conformer.¹⁰³ Probably, these bands belong to molecular associates. However, the doublet band at 773/754 cm^{−1} corresponding to the stretching vibrations $\nu_s(\text{POC})$ retained in the solution in liquid xenon. It was suggested that this doublet is due to the Fermi resonance, since the relative intensities of the bands at 773 and 754 cm^{−1} were found to be temperature-independent.⁹²

It should be emphasised that the enthalpy differences between the *G* and *T* conformers of molecules AlkOPX₂ (X = CH₃, F, Cl) have not been measured as yet. The same is also true for the enthalpy differences between the *g* and *t* conformers, which are formed due to internal rotation about the O–C bond in this type of molecules (see Fig. 2, Y = O). These differences seem to be so large that only *t* conformers are observed in the liquid phase at room temperature.¹⁰⁴ This is also typical of the dialkyl ether molecules for which the *trans* conformers formed by internal rotation about the O–C bond are much more energetically favourable ($\Delta H \simeq 4.6\text{--}6.3$ kJ mol^{−1}).^{157–160} However, their *gauche* conformers are also present in detectable amounts both in the liquid and gas phase at room temperature.

Relative stabilities of the *gauche* and *trans* conformers change drastically upon introduction of the SCN group into the alkyl substituent of the ROPCl₂ molecules. The enthalpies of the *G* and *g* conformers of the molecule **35** become much lower than those of the *T* and *t* conformers, respectively.¹⁰⁵ The fact that the ‘twist’ conformers of the molecule **35** are more energetically favourable was attributed¹⁰⁵ to the effects of hypervalent intramolecular 1–5-attraction between the phosphorus and sulfur atoms. It should be noted that a doublet at 730 to ~ 715 cm^{−1} is observed in the spectra of liquid β -thiocyanatoethyl phosphorodichloridite **35** in the region characteristic of vibrations with predominant contribution of the $\nu_s(\text{POC})$ vibration and that the low-frequency line of the doublet disappears upon crystallisation.

Doublet IR absorption bands and Raman lines, assigned to the P–O stretching vibrations, are also observed in the spectra of liquid 2-chloro-1,3,2-oxathiaphospholane **37** (~ 760 to ~ 750 cm^{−1}), whose molecule can adopt several conformations owing to internal rotation about the P–O bond (see Fig. 3; conformers *a-E_C* and *e-E_C*, X = O, Y = S).¹⁰⁸ The *a-E_C* conformer, which is an analogue of the *T* conformers of acyclic alkoxy derivatives of the trivalent phosphorus compounds, was found to be ~ 2 kJ mol^{−1} more stable than the *e-E_C* conformer (an analogue of the *G* conformers).

Thus, despite some uncertainty in the data on the spectral indications of interconversions of the molecules containing one Alk–O–P group, one can say that they can be detected using the readily identifiable band corresponding to the POC stretching vibrations. However, the corresponding effects are weak and often remain unnoticed in the spectra of liquids measured at room

temperature. These effects can be observed if the spectral resolution is improved compared to that of the routine experiments. This can be attained in the low-temperature experiments. The kinematic effect of the *G* $\rightarrow$ *T* transition results in a decrease in the $\nu_s(\text{POC})$ frequency. However, for 2-chloro-1,3,2-oxathiaphospholane **37** an increase rather than a decrease in this frequency was observed, which is probably due to changes in the force field of the molecule in the course of interconversion of its conformers.

4. Internal rotation of AlkSP fragments

Alkyl phosphorodichloridothioites AlkSPCl₂ exist in the liquid and gas phases as mixtures of *T* and *G* conformers^{103, 128, 130–132} which are formed owing to internal rotation about the P–S bond (see Fig. 1; X = Cl, Y = S, Z = Alk). In the liquid phase, the *T* conformers are more energetically favourable^{130–132} (e.g., $\Delta H \sim 3.3$ kJ mol^{−1} for Alk = C₂H₅). Nevertheless, the amount of the *G* conformers at room temperature is comparable with that of the *T* conformers. For the molecule **28**, it is possible that great steric hindrances to the formation of the *trans* conformers (conformer A, see Section IV) lead to a decrease in their concentration in the equilibrium mixture. This can be assessed from the intensity ratio of the Raman lines corresponding to the vibrations $\nu(\text{P–S})$ of the *gauche* and *trans* conformers (see Table 25).

Rotation about the S–C bond can also be responsible for the formation of the *g* and *t* conformers (see Fig. 2; Y = S; Fig. 4, 5), the *trans* arrangement of the P–S and C–C bonds being more favourable for liquid alkyl phosphorodichloridothioites^{130–132} (e.g., $\Delta H_{g-t} \simeq 1.6$ kJ mol^{−1} for Alk = C₂H₅). For Alk = *n*-C₃H₇, the *g'* and *t'* conformers were also detected in the liquid phase¹³² which appear due to internal rotation about the C–C bond (see Fig. 4).

The molecules of alkyl phosphorodichloridothioites can adopt several conformations. A distinctive feature of their spectra is that the number of the IR absorption bands and Raman lines is much larger than one could expect. In particular, a complicated spectrum is observed in the region characteristic of the ‘co-operative’ stretching vibrations of the Cl₂PS fragment at $\sim 450\text{--}530$ cm^{−1}. The totally symmetric stretching vibration $\nu_s(\text{Cl}_2\text{PS})$ is ‘sensitive’ only to rotation about the P–S bond and the frequencies of this vibration for the *T* conformers are always lower than those of the *G* conformers ($\sim 495\text{--}505$ vs. $\sim 510\text{--}530$ cm^{−1}, respectively). A similar type of conformational ‘sensitivity’ was also observed for the frequencies of the vibrations $\nu(\text{P–S})$ of the molecule **28** (see Table 25). A decrease in the frequencies of vibrations with contribution of the P–S bond on going from the *G* to *T* conformers is mainly due to changes in the kinematic interactions in the molecule upon this transition.

The frequencies of the antisymmetric vibrations $\nu_{as}(\text{PCl}_2)$ of alkyl phosphorodichloridothioites depend on the conformations of the Cl₂PSC and PSCC fragments. The conformation in which the lone electron pair of the phosphorus atom lies in the plane of the PSCC fragment (the *Tt* conformation, see Figs 2 and 4; or the *Tg* conformation, see Fig. 5) is characterised by a frequency in the range between ~ 450 and 460 cm^{−1}. For all other conformations, the characteristic frequency $\nu_{as}(\text{PCl}_2)$ is observed at ≈ 490 to 495 cm^{−1} (see Table 25). The corresponding bands in the IR spectrum are masked by a very strong band corresponding to the antiphase stretching vibration of the P–S bond and PCl₂ fragment ($\sim 460\text{--}480$ cm^{−1}), which is conformationally ‘insensitive’. Because of this, the vibrations $\nu_{as}(\text{PCl}_2)$ of different conformers can be identified only in the Raman spectra in which they appear as depolarised shoulders on either side of a very strong polarised line at $\sim 460\text{--}480$ cm^{−1} corresponding to the above-mentioned antiphase stretching vibration of the P–S bond and PCl₂ group.

It is also convenient to use the Raman spectra for the attribution of the lines corresponding to the stretching vibrations S–C, the frequency of which depends on not only the structure of the alkyl radical at the sulfur atom, but also the conformation of the PSCC fragment. The conformer with *trans* arrangement of the P–S and C–C bonds (*t*, see Figs. 2 and 4; *g*, see Fig. 5) is

characterised by a higher frequency $\nu(\text{S}-\text{C})$ than the *gauche* conformer (*g*, see Figs. 2 and 4; *t*, see Fig. 5). Therefore, in the case of a mixture of the *g* and *t* conformers, the vibrations $\nu(\text{S}-\text{C})$ appear as doublets. For *S*-propyl phosphorodichlorodithioite, a triplet rather than a doublet corresponding to the vibrations $\nu(\text{S}-\text{C})$ is observed (see Table 25). This may be due to the fact that the frequency of this vibration depends on internal rotation about not only the $\text{S}-\text{C}$ bond, but also the $\text{C}-\text{C}$ bond. Nevertheless, the high-frequency components of the triplet correspond to the *t* conformation of the PSCC fragment.

The molecules of S,S',S'' -trialkyl phosphorotrithioites $(\text{AlkS})_3\text{P}$ are also characterised by the *G* and *T* orientations of the $\text{S}-\text{C}$ bonds with respect to the LEP of the phosphorus atom and either a *g* or *t* arrangement of the $\text{C}-\text{C}$ bonds with respect to the $\text{P}-\text{S}$ bonds. Usually, S,S',S'' -trialkyl phosphorotrithioites exist in the liquid or gas phase as mixtures of the *TGG* and/or *TGG'* conformers with the *GGG* conformers.^{130, 131, 161} The latter are less energetically favourable, but are present in considerable amounts at room temperature. Since the molecules of S,S',S'' -trialkyl phosphorotrithioites can adopt several conformations, some of the bands in their vibrational spectra become split into multiplets. However, only correlations between the conformations of the $\text{C}_2\text{H}_5\text{SP}$ fragments and the frequencies of the CH_2 rocking vibrations were found.^{130, 131} The *g* arrangement of the $\text{C}-\text{C}$ bond with respect to the $\text{P}-\text{S}$ bond corresponds to the $\nu(\text{CH}_2)$ frequency $\approx 780\text{ cm}^{-1}$, while the *t* arrangement corresponds to the $\nu(\text{CH}_2)$ frequency $\approx 760\text{ cm}^{-1}$. The same is also true for the molecule **45** (see Table 22).

X. Force constants of molecules containing trivalent phosphorus atoms

Among different classes of organophosphorus compounds, the force constants of alkylphosphines and their halogen-substituted derivatives have been studied in most detail. The potential fields of all these molecules share the common property that the effect of the phosphorus atom is confined to the distance to the α -C atom. For instance, the force constants of the CH_3 group of ethyl radical at the phosphorus atom remain virtually the same as in the ethane molecule. Because of this, only frequencies of the vibrations with predominant contribution of the $\text{P}-\text{C}$ bonds, and those of the methyl and methylene groups bound to the phosphorus atom are specific to alkylphosphines and, hence, can be regarded as having an analytical value.

On the other hand, variation of the alkyl radical in the AlkPX_2 molecules affects not only the force constants of the AlkP group, but also the parameters of the potential field of the PX_2 fragment. For instance, the force constants of the $\text{P}-\text{C}$ and $\text{P}-\text{X}$ bonds decrease simultaneously as the chain length of the alkyl radical increases.

Force constant	CH_3PF_2	$\text{C}_2\text{H}_5\text{PF}_2$	CH_3PCl_2	$\text{C}_2\text{H}_5\text{PCl}_2$
K_{PC}	2.76	2.54	2.94	2.65
K_{PF}	4.34	4.15		
K_{PCl}			2.08	1.94

For $\text{X} = \text{H}$, this dependence can be expressed quantitatively in the form of linear relationships (recall that the force constants are given in 10^2 N m^{-1})²²

$$K_{\text{PH}} = 0.126\sigma^* + 3.063,$$

$$K_{\text{PC}} = 0.235\sigma^* + 2.664,$$

where σ^* is the Taft constant of the alkyl group.¹⁶²

Introduction of halogens into the AlkP fragment leads to a pronounced decrease in the force constant K_{PC} and simultaneous increase in K_{PX} . For instance, the K_{PC} and K_{PCl} values respectively change from 2.94 and 2.08 for CH_3PCl_2 ⁵⁷ to 2.34 and 2.20 for $\text{ClCH}_2\text{PCl}_2$.⁶⁴

For the same alkyl radical, the force constant K_{PC} depends on the type of substituents X at the phosphorus atom; however, its

magnitude changes only slightly and does not obey simple rules. Thus for the CH_3PX_2 molecules the K_{PC} value increases from 2.66 to 2.94 on going from $\text{X} = \text{H}$,^{13, 14} to CH_3 ,^{13, 14, 43} F ⁵¹ and Cl .⁵⁷

The force constants of phosphorus-containing molecules can also be conformation dependent. For instance, the *gauche* $\rightarrow$ *trans* transition in the molecule **6** causes a decrease in the force constant K_{PH} from 3.05 to 3.01.²² Despite the small difference between these values, it was found to be reliable, since the $\text{P}-\text{H}$ stretching vibrations are known to be characteristic.²² Changes in the conformation of the polar ClCH_2P group has a more pronounced effect on the potential field of the molecule **15**: $K_{\text{PF}}(\text{gauche}) = 4.43$; $K_{\text{PF}}'(\text{gauche}) = 4.51$; $K_{\text{PF}}(\text{trans}) = 4.08$; $K_{\text{PC}}(\text{gauche}) = 2.81$; $K_{\text{PC}}(\text{trans}) = 2.84$; $K_{\text{CCl}}(\text{gauche}) = 3.09$; $K_{\text{CCl}}(\text{trans}) = 2.97$.

Thus, analysis of the force constants of the molecules of alkylphosphines and their halogen-substituted compounds suggests that the potential field of the phosphorus-containing fragment of the molecule strongly depends on the type and spatial orientation of each substituent at the phosphorus atom. On the other hand, the effect of the phosphorus-containing fragment on the force constants of adjacent groups is confined to the nearest environment of the phosphorus atom.

For phosphines with unsaturated groups at the phosphorus atom, the effect of the latter can likely extend to distances longer than the distance to the α -C atom. The force constants of the fragment $=\text{C}(\text{CH}_3)_2$ of molecules $\text{Cl}_2\text{PCH}=\text{C}(\text{CH}_3)_2$ (see Ref. 75) and $\text{CH}_2=\text{C}(\text{CH}_3)_2$ (see Ref. 160) differ appreciably, thus providing an explanation for the specific values of the characteristic vibrational frequencies of the alkenyl groups at the phosphorus atom. The potential fields of all these molecules share the common property that the force constants of the multiple carbon-carbon bonds at the trivalent phosphorus atom are smaller than those for the corresponding hydrocarbon molecules. The force constant $K_{\text{C}=\text{C}}$ for the molecules of alkenyl(dichloro)-phosphines is much smaller than those for ethylene and various alkenes and halogen-substituted alkenes [7.9 (Ref. 75) vs. 8.3–10.0 (Ref. 163), respectively]. On the other hand, the constants $K_{\text{PC}} \approx 3.1$ –3.5 (see Ref. 75) and $K_{\text{PCl}} \approx 2.3$ (see Ref. 75) are larger than the corresponding force constants of alkyl(dichloro)-phosphines [e.g., $K_{\text{PC}} = 2.94$ and $K_{\text{PCl}} = 2.08$ for the molecule **11** (see Ref. 57)].

A similar situation is also observed for the molecule **29**: the value of the constant $K_{\text{C}\equiv\text{C}} = 13.85$ (see Ref. 78) 'drops out' of the range between 14.22 and 15.62 (see Refs 164–167), which is characteristic of acetylene and its alkyl- and halogen-substituted derivatives; while the value of the constant $K_{\text{PC}} \approx 3.3$ (see Ref. 78) far exceeds the corresponding value [2.9 (see Ref. 43)] for the molecule **8**.

On the other hand, numerical values of the force constants K_{PC} and $K_{\text{C}\equiv\text{N}}$ for molecules **30** (see Ref. 79) and **31** (see Refs 84, 85) lie within the limits of conventional ranges, which are characteristic of trialkylphosphines and cyanogen halides.¹⁶⁷ Probably, this indicates that the phosphorus atom affects the electronic systems of adjacent $\text{C}\equiv\text{N}$ and $\text{C}\equiv\text{C}$ groups in a different manner.

For the AlkOP groups, this effect is most likely confined to the distance to the α -C atom of the ester group. In any case, the force constants of the ethyl fragments of molecules $\text{C}_2\text{H}_5\text{OPCl}_2$ (see Ref. 104) and $\text{C}_2\text{H}_5\text{OC}_2\text{H}_5$ (see Ref. 168) are nearly equal. On the other hand, the force constant K_{PO} increases by about one unit on going from the ethyl to the methyl substituent.^{103, 104} Usually, variation of the nearest environment of the trivalent phosphorus atom has little effect on the force field of the AlkOP groups. For instance, $K_{\text{PO}} = 5.97$ and $K_{\text{OC}} = 4.91$ for CH_3OPCl_2 ,⁹² while for CH_3OPF_2 these values are $K_{\text{PO}} = 5.99$ and $K_{\text{OC}} = 4.51$.⁹¹

For the molecules of dialkylphosphoramides, the dependence of the force constant K_{PN} on the nature of substituents at the phosphorus atom is much more pronounced; for instance, the K_{PN} value increases from 4.5 to 5.1 on going from $(\text{CH}_3)_2\text{NPCl}_2$ to $(\text{CH}_3)_2\text{NPF}_2$.¹²⁵

Analysis of the force fields of the molecules of S-alkyl phosphorothioites shows that the phosphorus atom has no effect not only on the alkyl fragment of the molecule, but also on the force constant of the S—C bond. This seems to be reason why the spectral characteristics of the AlkS groups in the molecules of organophosphorus compounds coincide with the spectral indications of these groups in organosulfur compounds. Alkyl phosphorothioites are also characterised by the absence of pronounced effect of the alkyl radical on the force field of the phosphorus-containing fragment of the molecule. All acyclic compounds studied belonging to this class are characterised by the same force constant $K_{PS} = 2.0$.^{130–132} It should be noted that even passage to strained five-membered rings with endocyclic P—S bond¹⁰⁸ or replacement of the alkyl radical in the AlkSP group by the dimethoxythiophosphoryl fragment^{133, 134} decrease the K_{PS} value by only $\sim 10\%$.

As for the force fields of the molecules with the Si—P, Ge—P and P—P bonds, the corresponding data are too scarce to be used as a basis for any generalisation.

Closing the discussion of the force constants of the molecules of organophosphorus compounds, it should be emphasised that they can be used to predict the molecular spectra of related compounds for which studies by conventional methods of vibrational spectroscopy give no unambiguous solutions.¹⁶⁹ Additionally, rapid progress of computer industry opened the way to routine quantum-chemical calculations of the force constants. The first systematic studies of the so-called scaled 'quantum-chemical' potential fields of phosphines gave encouraging results.¹⁷⁰ Taken together, this allows one to hope that computer-assisted predictions of vibrational spectra of various organophosphorus compounds will become a routine procedure already in the near future.

XI. Conclusion

Trivalent tricoordinate phosphorus compounds contain no structural elements with such distinct spectral indications as, e.g., the phosphoryl group. However, analysis of the published data shows that the efficiency of vibrational spectroscopy in studying the structure of trivalent phosphorus compounds can be as high as in the case of pentavalent phosphorus compounds. This requires that the following salient features of the vibrational spectra of organophosphorus compounds be taken into account.

The effect of the phosphorus-containing fragment of the molecule is confined to the force constants of adjacent molecular fragments. This leads to a nearly complete additivity in that part of the spectral region which is due to the vibrations of more distant groups. For instance, the spectra of molecule $[(CH_3O)_2P(S)S]_3P$ nearly coincide with those of the corresponding *O,O'*-dimethyl phosphorodithioate $(CH_3O)_2P(S)SH$ (see Ref. 171) in the whole frequency range, except for the region corresponding to the stretching ($485\text{--}585\text{ cm}^{-1}$) and bending vibrations ($108\text{--}150$ and $350\text{--}405\text{ cm}^{-1}$) of the PSP fragments. Therefore, the spectrum of a phosphorus-containing molecule can be represented as the sum of the spectra of the fragments constituting the molecule minus the region corresponding to the vibrations of the nearest environment of the phosphorus atom. Therefore, the use of the data listed in Tables 1–25 can make the interpretation of vibrational spectra of trivalent phosphorus compounds much easier. For instance, spectral parameters of the C_2H_5OP fragment of an arbitrary molecule will coincide with the corresponding parameters of the *O*-ethyl fragment of ethyl phosphorodichloridite **34**. Vibrations of the POC fragment can appear to be an exception to this rule, since they can interact with vibrations of some other substituents through the shared phosphorus atom.

This example shows that consideration of the interactions between individual oscillators is of great importance to the analysis of the 'fingerprint' spectral regions. The data on the characteristic vibrations of different phosphorus-containing groups collected in this review will also help in predicting these

effects correctly. Stretching vibrations of the C—C bond in the C_2H_5P fragment of dichloro(ethyl)phosphine may serve as an example. This bond is connected to the PCl_2 group through the P—C valence bond. Nevertheless, no interaction between the vibration $\nu(C-C)$ and the vibrations of the PCl_2 group occurs (see Table 7). The reason is that the vibrational frequencies of the PCl_2 fragment are much lower than the frequency of the vibrations $\nu(C-C)$. A similar situation will be observed for any other molecules with heavy substituents at the phosphorus atom. Therefore, the frequencies of the vibrations $\nu(C-C)$ in the molecules **9**, **12** and **13** are equal. On the other hand, this frequency can vary on introduction of the C_2H_5P fragment into a molecule with light substituents at the phosphorus atom, since the character of the interaction between vibrations in the new molecule may be different. For instance, characteristic frequencies of the bending vibrations of the PH_2 group ($1073\text{--}1097\text{ cm}^{-1}$) are close to the frequency of the vibrations $\nu(C-C)$. Therefore, one can expect that in the molecule of ethylphosphine **4** these individual oscillators will interact, thus changing the frequency of the vibration $\nu(C-C)$ as compared to those of the same vibrations of molecules **9**, **12** and **13**. The data listed in Table 2 confirm this assumption.

Vibrations with contributions of the nearest environment of the phosphorus atom can change on going from one compound to another since the force constants of the phosphorus-containing molecular fragment depend on the types and conformations of all substituents at the phosphorus atom. Turning our attention to the above-mentioned example with the C_2H_5P fragment, one can say that the frequency of the stretching vibrations $\nu(P-C)$ will change from 636 cm^{-1} for ethylphosphine **4** to $631/663\text{ cm}^{-1}$ for the molecule **12** or to $655/682\text{ cm}^{-1}$ on going to ethyldifluorophosphine **13**.

Reliability of spectral–structural correlations for the 'fingerprint' region increases substantially, if the Raman spectra are used in combination with the IR spectra. For instance, several IR absorption bands in the region $550\text{--}710\text{ cm}^{-1}$ can indicate two or three P—C bonds in the molecule under study. However, if the molecules of compounds under study contain one P—C bond but can adopt several conformations, more than one IR absorption band will be observed in the above-mentioned spectral region. It is easy to discriminate between these two variants using the Raman spectrum. In the first case, an intense, strongly polarised Raman line will correspond to only one of the bands in the IR spectrum [see, e.g., $(CH_3)_2PCl$ or $(CH_3)_3P$ in Table 5], while the number of polarised lines in the Raman spectrum of the second compound will be equal to the number of peaks in the IR spectrum (e.g., $n-C_3H_7PCl_2$ or $n-C_3H_7PH_2$, see Table 5).

In conclusion, the author expresses his gratitude to Prof. R R Shagidullin, Prof. V A Al'fonsov, Prof. B V Lokshin and Prof. B J van der Veken for valuable comments which were taken into account in the course of preparation of the manuscript.

Crown ethers in radiochemistry. Advances and prospects

S V Nesterov

Contents

I. Introduction	769
II. Methods for immobilisation of crown ethers	769
III. Radiation-chemical transformations in extraction systems based on crown ethers	772
IV. Areas of application of crown ethers	775
V. Conclusion	780

Abstract. Methods for the immobilisation of dicyclohexano- and non-substituted crown ethers are reviewed. Data on the radiation chemistry of these compounds and on the influence of irradiation on the properties of crown-containing extraction systems published over the last decade are discussed systematically. Examples of the use of crown ethers in different fields of radiochemistry are presented. The bibliography includes 199 references.

I. Introduction

Intense development of nuclear power resulted in the accumulation of huge volumes of liquid and solid radioactive waste, which present serious hazard to the environment.^{1,2} An approach to the reduction of the amount of radioactive wastes consists in upgrading of the existing technologies for the reprocessing of spent nuclear fuel as well as in the decrease in the bulk of waste subject to disposal and utilisation of the already available waste. The major procedure for the reprocessing of spent nuclear fuel is liquid extraction in which the transuranium elements are separated from fission fragments with subsequent regeneration of uranium and plutonium. Organophosphorus compounds used currently in extraction processes, such as tributyl phosphate, have a number of disadvantages, in particular low resistance to radiation and insufficient selectivity in binding radionuclides. In this context, the search for more efficient cation-binding compounds is topical.

Since the mid-1970s, macrocyclic polyethers or the so-called crown ethers have been regarded as promising extractants for the reprocessing of spent nuclear fuel and utilisation of radioactive wastes.³ Their feature is high selectivity of complexation with cations of metals possessing similar chemical properties; in many cases, the magnitude of the complex stability constant is characterised by the ratio of the size of the macrocycle cavity and the cation radius (see, *e.g.*, Refs 4 and 5). The existing methods for the synthesis of crown ethers allow preparation of ligands with the predetermined ability to bind cations of specific metals.⁶ Macrocyclic polyethers are chemically stable and can be easily regenerated. These properties of crown ethers stimulated studies on the

possibility of their use in the reprocessing of spent nuclear fuel, utilisation of radioactive waste in different stages of the nuclear fuel cycle and in radiochemical analysis. The most effective macrocyclic compounds for the separation of plutonium and uranium from fission fragments proved to be non-substituted and dicyclohexanocrown ethers. However, a substantial disadvantage of these extractants is their rather high solubility in water, which leads to their washout from the extraction and sorption systems.⁷ In this connection, studies are underway which are aimed at the development of methods for the synthesis of grafted and polymeric macrocyclic polyethers capable of binding selectively radionuclides and at the elaboration of novel technological processes based on them.

The present review discusses the methods for immobilisation and modification of non-substituted and dicyclohexanocrown ethers and synthesis of polymers based on them, generalises the published data on radiation chemistry of crown ethers and crown-containing extraction systems and presents examples of the use of macrocyclic polyethers in different fields of radiochemistry.

II. Methods for immobilisation of crown ethers

The efficiency of the use of crown ethers in extraction and sorption systems depends, among other factors, on the extent of losses associated with solubility of these compounds in an aqueous phase. The rather high solubility of crown ethers in water leads to the transfer of extractants from the organic to the aqueous phase, to transfer of water to the organic phase in extraction processes⁸ and the washout of complexants from the surface of porous supports in sorption processes.⁹ The necessity of an increase in hydrophobicity of non-substituted and dicyclohexanocrown ethers has been emphasised in the review by McDowell⁷ where he first considered in detail major problems to be solved for practical application of crown ethers in radiochemical technology. Appreciable progress has been achieved in the search for ways of decreasing the solubility of benzo- and azacrown ethers. The methods of immobilisation and synthesis of polymeric aza- and benzo-substituted crown ethers were considered in detail in a number of papers and monographs.^{10–15} A highly promising method for the synthesis of polymeric crown ethers, which can be used for the solution of radiochemical problems, is the anodic oxidation of dibenzocrown ethers on the surface of an electrode, which makes it possible to obtain crown-containing polymers of the type **I** in one step.^{16–19}

In the case of non-substituted and dicyclohexanocrown ethers, immobilisation and synthesis of polymeric compounds is much more difficult,²⁰ since these macrocycles are rather inert

$n, m = 0-2$.

chemically. The basic methods for the reduction of their solubilities in water developed to date can be divided into several groups.

1. Synthesis of macrocyclic compounds with hydrophobic aliphatic substituents.

2. Synthesis of polymers containing fragments of non-substituted and cyclohexanocrown ethers or grafting of crown ethers onto porous supports.

3. Immobilisation (without covalent binding) of crown ethers on a matrix which is inert with respect to metal cations or on the surface of a porous support.

The first group includes the methods of synthesis of dicyclohexanocrown ethers containing branched alkyl and/or other hydrophobic substituents. Introduction of branched alkyl chains into the cyclohexane ring leads to decrease in solubilities of crown ethers in water and simultaneously increases their solubilities in organic solvents. One of the most popular compounds of this type is 4',4'-(5')-di(*tert*-butylcyclohexano)-18-crown-6 (**2**, DTBDCH-18-C-6).^{21,22}

The crown ether **3** (DTODB-18-C-6) containing C₈ tertiary alkyl groups was obtained^{23,24} by cyclisation of alkylated pyrocatechol **4** with 2,2'-dichlorodiethyl ether (**5**, chlorex). Subsequent hydrogenation of dibenzocrown ether **3** leads to substituted dicyclohexanocrown ether **6** (DTODCH-18-C-6).

The crown ether **3** is soluble in all organic solvents (including alkanes) and is virtually insoluble in water and saline solutions. The solubility of the crown ether **6** in water proved to be close to that of ordinary dibenzocrown ethers. It is important that the introduction of *tert*-alkyl substituents did not change the ability

for complexation compared to that of non-substituted dicyclohexanocrown ethers.

McDowell *et al.*²⁵ described a method for the preparation of di-*tert*-butyldibenzo-21-crown-7 (**7**); its hydrogenation gives rise to the corresponding dicyclohexanocrown ether.

A promising method for the modification of non-substituted and cyclohexanocrown ethers was proposed.^{26,27} In the example of 1,4-dioxane and morpholine, which are low-molecular-weight analogues of crown ethers, the possibility of radical-chain addition of an aromatic hydrophobic group was demonstrated. Selective addition of allylbenzene to these cyclic ethers with the formation of compounds **8a,b** takes place upon γ -irradiation of a solution of allylbenzene (0.05–0.15 mol litre⁻¹) in 1,4-dioxane or morpholine. The degree of conversion of allylbenzene exceeds 30% at absorbed doses < 60 kGy.

X = Y = O (**a**), X = NH, Y = O (**b**).

The second group includes methods of synthesis of polymeric crown ethers and methods of grafting of macrocycles on porous polymeric supports. Chauhan and Boudjouk²⁸ developed a one-

Scheme 1

$n = 1, 2$.

Scheme 2

(P) is polymer; R = NH₂, CH(OH)Me, P(O)(OAlk)₂; X = NH, C(Me)O, P(O)OAlk.

Scheme 3

10a,b

step method for the synthesis of polysiloxanes **9** containing fragments of non-substituted crown ethers and their oligomers. This method consists in selective catalytic oxidation of poly(methyl)siloxane and addition of 2-hydroxymethylcrown ether to the siloxane chain (Scheme 1).

The reaction proceeds under mild conditions, oxidation of Si–H bonds occurs without disproportionation and scission of the main chain. The polymers obtained are fairly well soluble in common organic solvents.

A method was proposed^{29–31} for immobilisation of a number of dicyclohexanocrown ethers on a support which is a chloromethylated copolymer of styrene with divinylbenzene (Scheme 2), the content of macrocyclic groups ranging from 0.75 to 1.6 mg-equiv g^{−1}. It is presumed that the groups X through which grafting is effected influence insignificantly the distribution of electron density in the crown-ether fragment. The electron-donor properties of the oxygen atoms are not weakened and the capacities for complexation of the grafted and free crown ethers differ insignificantly.

Kurmanaliev *et al.*³² described synthesis of polyimides **10a,b** containing the structural moiety of diaminodicyclohexano-18-crown-6 or diaminodicyclohexano-24-crown-8 and studied the transport of alkali metal cations through thin films of these polymers (Scheme 3). For polymer **10a**, the selectivity of the cation transport changes in the order K⁺ > Cs⁺ > Na⁺ and for polymer **10b** it changes in the order Cs⁺ > K⁺ > Na⁺. The sequences obtained match the binding capacities of free crown ethers.⁴ Thus, polymerisation of crown ethers does not change the selectivity of complexation.

Watanabe *et al.*³³ synthesised a novel crown ether **11** containing the pyrrolidine ring and grafted it onto a chloromethylated copolymer of styrene with divinylbenzene.

$n = 1, 2$.

A method of radical polymerisation in the presence of a larger-size crown ether, *viz.*, 42-crown-14, was employed to synthesise poly[(styrene)rotaxacrown ether] in which polymeric chains pass through the polyether rings.³⁴ Polyrotaxanes based on polyurathanes and dibenzo-24-crown-8 were obtained and their sorption properties with respect to a number of metals were studied.³⁵

The third group comprises methods for the preparation of compounds in which there are no covalent bonds between the crown ether molecules and the matrix. Solid extraction systems (SESys) and solid extraction solutions (SESol) synthesised by Yakshin *et al.*^{36–40} are characteristic representatives of crown-containing sorbents obtained by this method.

Solid extraction systems based on copolymers of styrene with divinylbenzene containing 40%–43% of a crown ether were obtained by adding a homogeneous mixture of styrene, divinylbenzene, crown ether and a polymerisation initiator to an aqueous solution of starch and subsequent polymerisation of the monomers.³⁶ This resulted in the formation of ball-shaped

granules. Their stability was studied under conditions of contact with water for two days. The losses amounted to 90% for dicyclohexanocrown ethers such as dicyclohexano-18-crown-16 (DCH-18-C-6, **12**), DTBDCH-18-C-6 (**2**), dicyclohexano-21-crown-7 (DCH-21-C-7, **13**) and dicyclohexano-24-crown-8 (DCH-24-C-8, **14**).

2, 12–14

R = Bu^t, $n = m = 1$ (**2**); R = H: $n = m = 1$ (**12**), $n = 1, m = 2$ (**13**), $n = m = 2$ (**14**).

Washout of poorly water-soluble dibenzocrown ethers, *viz.*, dibenzo-18-crown-6 (**15**), dibenzo-21-crown-7 (**16**), dibenzo-24-crown-8 (**17**), dibenzo-30-crown-10 (**18**) and di(*tert*-butylbenzo)-18-crown-6 (**19**), occurred to lesser extent and the losses ranged from 10% to 30%. And finally, the losses of crown ethers

15–19

R = H: $n = m = 1$ (**15**), $n = 1, m = 2$ (**16**), $n = m = 2$ (**17**), $n = m = 3$ (**18**); R = Bu^t, $n = m = 1$ (**19**).

containing hydrophobic iso-octyl substituents in the aromatic and dicyclohexane rings, DTODB-18-C-6 (**3**) and DTODCH-18-C-6 (**4**), did not exceed 5%–10%.

In order to reduce losses of crown ethers, Yakshin *et al.*³⁶ proposed to presaturate the aqueous phase with the corresponding crown ether. Solid extraction solutions containing from 1% to 50% (w/w) of extractants were obtained^{37–39} by heating different liquid and low-melting crown ethers [DB-18-C-6 (**15**), *cis-syn-cis*-DCH-18-C-6 (**12**), DTBDCH-18-C-6 (**2**), DTODCH-18-C-6 (**4**) and others] with naphthalene, biphenyl or paraffin to their melting temperatures with subsequent dispersion of homogeneous melts in an aqueous solution of starch. The ball-shaped granules formed were separated and their sorption abilities were studied.

The onset of equilibrium in solutions in contact with SESys and SESol obtained by the methods described above takes a very long time (from 0.5 h to a few days^{38,40}) since under these conditions the binding of metal cations is limited by diffusion of ions (including anions) to the macrocyclic ligand through an inert matrix. For this reason, the use of these extractants under dynamic conditions is not advisable.

Solid extraction systems and solutions could not absorb metal cations from solutions in nitric acid. It was suggested that the macrocyclic centres are blocked in the nitric acid medium;^{40,41} however, the nature of this effect has not been clarified. It should be noted that such a block does not occur for solutions in hydrochloric acid.

The third group of methods includes also immobilisation of crown ethers on porous supports either by their application onto the surface or by impregnation. The advantage of the specimens obtained by this method is the accessibility of macrocyclic groups localised on the surface of the support for contact with metal ions.

Chuang and Lo⁴² described the preparation of a crown-containing sorbent by application of DCH-18-C-6 (**12**) onto silica gel. Silica gel was preliminarily dried at 110 °C, treated with dichlorodimethylsilane for substitution of free hydroxy groups

and then a solution of the crown ether in chloroform was added. After removal of the solvent, a sorbent was obtained which contained 3.8% of DCH-18-C-6 (**12**) and was sufficiently resistant to washout of the crown ether.

Horwitz *et al.*^{21,22,43,44} proposed a simple and efficient method for the preparation of a crown-containing sorbent which enables isolation of Sr²⁺ from nitric acid solutions. A solution of DTBDCH-18-C-6 (**2**) in octan-1-ol is immobilised on an inert porous support (Amberlite XAD-7 or Amberchrom CG-71 ms). The presence of hydrophobic *tert*-butyl substituents in the crown ether molecule provides good fixation of the macrocycle on the surface of the support on contact with aqueous solutions. This method for immobilisation of crown ethers has been patented; the commercial specimen called Sr-Spec may be purchased from the EICrom Industries Inc. (USA). Another impregnate was prepared at the V I Vernadsky Institute of Geochemistry (Russia) by impregnation of a porous copolymer of styrene and divinylbenzene with a 10% solution of DCH-18-C-6 (**12**) in chloroform or tetrachloroethane.^{2,45}

Nazarenko *et al.*⁴⁶ described a method of synthesis of crown-containing sorbents by coprecipitation of 18-crown-6 and phosphomolybdic heteropolyacid. These authors⁴⁶ also studied the influence of sorbent composition and medium acidity on the sorption properties with respect to rare-earth elements of the cerium group. The capacity of sorbents for the metal was 10–41 mg g^{−1} depending on the specimen composition and the nature of the metal to be sorbed. The data on the resistance of sorbents to washout are not presented.

III. Radiation-chemical transformations in extraction systems based on crown ethers

High resistance of an extractant to irradiation is one of the main factors which determine the efficiency of its use in radiochemical processes. It is presumed^{47,48} that the ionising irradiation initiates radiation-chemical transformations which may result in considerable changes in properties of the extraction system.

1. Decomposition of extractant leads to lower extraction efficiency.
2. The formation of radiolysis products affects unfavourably the selectivity of extraction.
3. The formation of active compounds prevents the partition of phases.
4. A third solid phase precipitates.
5. Formation of corrosive acids is possible.
6. Oligomers may be formed, which will unfavourably affect the extractant regeneration.

It is known⁴⁹ that macrocyclic polyethers form more stable complexes with metal cations in solutions than their non-cyclic analogues having the same number of donor atoms. This phenomenon was called the 'macrocyclic effect'. Upon irradiation of crown ethers, two main processes may occur, *viz.*, abstraction of a hydrogen atom from the methylene group of the polyether ring or from the hydrocarbon substituent (if present) and the cleavage of the ether bond of the macrocycle. The relationship between the extraction ability of a macrocycle and its cyclic structure was confirmed experimentally. Draye *et al.*^{50,51} synthesised products of the ether bond cleavage which can be formed from crown ethers upon irradiation. It turned out that the capacity for complexation of non-cyclic compounds mimicking the radiolysis products of DCH-18-C-6 (**12**) is much lower than that of the initial crown ether. Thus, the cleavage of the ether bond of the macrocycle upon radiolysis leads to a decrease in the efficiency of complexation.

The first studies of the radiation chemistry of macrocyclic polyethers were initiated in the 1980s.^{52–55} The major attention has been paid to the γ -radiolysis products of individual crown ethers in the gas and condensed phases.^{52–54,56} Radiation-chemical yields of molecular hydrogen [$G(\text{H}_2)$] and gaseous hydrocarbons have been calculated (Table 1). The yields obtained by different authors for the same compounds exhibited substantial

differences. Later, papers were published^{60, 61} in which intermediate species formed as a result of interaction of water radiolysis products with 18-C-6 and DCH-18-C-6 were studied by pulsed radiolysis and EPR methods. Based on the experimental results available at that time, it was concluded^{52–56, 60–62} that the abstraction of hydrogen atoms from the methylene groups of the polyether ring is predominant in the radiolysis.

Later, investigators began to give much attention to the identification of intermediate products of radiolysis of crown ethers. The results obtained provided evidence that it is the cleavage of the macrocycle that dominates in the radiolysis of crown ethers and extraction systems based on them.

1. Radiolysis of crown ethers

Information about the nature of the intermediate and final radiolysis products of crown ethers, radiolysis mechanism and radiation-chemical yields is extremely important since this allows assessment of the macrocycle resistance to scission. Unfortunately, at present there are no data on primary radiolysis products (radical cations, excited molecules) or the contribution of ionisation and excitation processes to the mechanism of radiolysis of polyethers. Furthermore, there is no information that studies

along these lines are being carried out systematically. To some extent, this is explained by the complexity of experiments which require investigation of radiolysis of macrocyclic systems under conditions of matrix isolation of crown ethers or in adsorbed monolayers, *e.g.*, on zeolites. An exception are the studies of Kuruc *et al.*^{63, 64} who attempted to identify radicals and radical cations in γ -irradiated crown ethers by the methods of spin traps and isolation in Freon matrices. However, it was impossible to interpret unambiguously the results obtained because of poor resolution of the EPR spectra.

Much attention has been paid to studies of radical products of radiolysis of crown ethers stabilised at the temperature of liquid nitrogen. Schemes of the formation of radicals were proposed and assessment was made of the stability of γ -irradiated (at 77 K) non-substituted crown ethers **20a–d**,^{58, 59, 65} complexes of 15-crown-5 (**20b**) and 18-crown-6 (**20c**) with alkaline-earth metal chlorides,^{66–69} benzo- (**21a–c**) and dibenzocrown ethers (**22a–g**),^{58, 70, 71} aza- and thiocrown ethers (**23–25**), as well as of [2.2.2]-cryptand (**26**).^{72, 73}

It was proposed^{68, 71} to use the values of radiation chemical yields of radicals $G(R)$ as characteristics of the radiation stability (see Table 1). The data presented in Table 1 make it possible to

state that the radiation-chemical behaviour of crown ethers on the whole is similar to that of their low-molecular-weight non-cyclic analogues. Thus the yields of radicals $[G(R)]$ in non-substituted crown ethers are several times higher than those in thiocrown ethers. The same regularity was observed earlier in the radiolysis of aliphatic alcohols, ethers and thiols.⁷⁴ Benzo- and dibenzo-crown ethers show a negative deviation from the additivity rule in the formation of radicals, which is due to the transfer of absorbed energy from the macrocycle to the aromatic group, *i.e.*, a protection effect is observed. In addition, in benzocrown ethers the value of $G(R)$ depends on the size of the macrocycle, number of aromatic groups in the polyether ring and the length of the hydrocarbon chain of the alkyl substituent.⁷¹ The yields of radicals for complexes of non-substituted crown ethers with alkaline-earth metal chlorides are considerably higher than for 'free' polyethers. In this case, a substantial role is played by the matching of the macrocycle cavity size to the radius of the metal cation. Thus the resistance of 15-crown-5 complexes to radiation changes in the sequence $\text{Be}^{2+} \approx \text{Mg}^{2+} > \text{Ca}^{2+}$ (see Refs 67, 68), whereas for 18-crown-6 complexes the sequence is $\text{Be}^{2+} > \text{Mg}^{2+} > \text{Ca}^{2+} > \text{Sr}^{2+} > \text{Ba}^{2+}$ (see Ref. 68).

Apparently, the dominant process of radiolysis of the majority of crown ethers is the cleavage of the ether bond rather than the abstraction of a hydrogen atom, as was believed earlier.⁶² This conclusion is supported by the complexity and multicomponent pattern of the EPR spectra of γ -irradiated (at 77 K) crown ethers, which is explained^{59, 66, 69} by the superposition of signals belonging to several paramagnetic species and also by the absence of correlation between the radiation-chemical yields of radical products and of molecular hydrogen, $G(R) \neq 2G(\text{H}_2)$ (see Table 1).

An exception is hexathia-18-crown-6 where abstraction of hydrogen from the methylene groups of the polyether ring predominates.⁷³

2. Radiolysis of model extraction systems based on crown ethers

Investigation of the behaviour of extraction systems based on crown ethers under irradiation sheds light on the possibility of

their use under real conditions. Under the action of ionising radiation on an extraction system, both the processes of radiolysis of individual components of the system and the reactions of the products of solvent radiolysis (solvated electrons, hydrogen atoms and radicals) with the extractant contribute to the formation of products of radiation-chemical transformations. Due to these processes, the composition and properties of the system may be changed considerably. We will consider below the papers in which changes in the extraction capacity of crown-containing systems under the action of irradiation were studied and the stable products formed in the condensed phase were analysed.

Thus irradiation of DCH-18-C-6 (**12**) and 18-C-6 (**20c**) in chloroform solutions ($c = 0.05\text{--}0.1$ mol litre⁻¹) resulted in a 20% decrease in Sr^{2+} extraction from aqueous solutions of picric acid at absorbed doses of 30–50 kGy.⁷⁴ No new signals were present in the ¹H NMR spectra of irradiated solutions. This fact and the results of experiments in which preirradiated chloroform was used indicate that the coefficient of strontium distribution (D_{Sr} , *i.e.*, the ratio of the concentration of metal ions in the organic phase to that in the aqueous phase) decreases due to formation of chloroform radiolysis products, *viz.*, HCl and C_2Cl_6 . And indeed, the addition of these compounds to the extraction system led to a decrease in D_{Sr} .

Neither UV and IR spectra were changed nor new peaks in a chromatogram were observed following γ -irradiation of a 10% solution of DCH-18-C-6 (**12**) in chloroform to absorbed dose of 168 kGy.⁷⁵ Upon prolonged contact of DCH-18-C-6 with α -emitters (Pu^{4+} and U^{6+}) during which the total absorbed dose corresponded to 1.6 MGy, the extraction capacity of the macrocycle changed within acceptable limits: extraction of Pu^{4+} and U^{6+} decreased by $\sim 2\%$ and 23% , respectively. Irradiation of tributyl phosphate under analogous conditions leads to the formation of considerable amounts of mono- and dibutyl phosphate, due to which the selectivity of plutonium extraction in the process of plutonium and uranium extraction (PUREX) decreased considerably.

Shukla *et al.*⁷⁶ revealed a strong influence of irradiation on the ability of DCH-18-C-6 (**12**) solution in toluene (a mixture of isomers at a concentration ranging from 0.1 to 0.3 mol litre⁻¹) to extract Pu^{4+} and U^{6+} from solutions in nitric acid. Irradiation was carried out in the presence of air up to an absorbed dose of 710 kGy. The distribution coefficients of uranium and plutonium decreased two- and tenfold due to decomposition of the extractant and toluene.

At present, there is no unequivocal answer to the question about the influence of ionising irradiation on the properties of membranes based on crown ethers. On the one hand, preirradiation of a membrane based on 18-C-6 (**20c**) in chloroform ($c = 10^{-3}$ mol litre⁻¹) with a dose of 0.45 kGy in the presence of air results in a three- and twofold increase in the transport of Cs^+ and Sr^{2+} cations, respectively, (see Ref. 77) and the shift of selectivity of cation binding (from K^+ to Cs^+). Vijayavergiya and Mookerjee⁷⁷ explain this effect by the reaction of crown ether **20c** with chlorine atoms which are the radiolysis product of chloroform in the presence of HCl resulting from radiolysis of chloroform in air. These authors note the occurrence of a shift to the longwave region of the UV spectrum; however, they do not indicate to which absorption band this refers. On the other hand, the transport of U^{6+} and Pu^{4+} cations decreases after γ -irradiation of a membrane composed of a 0.2 M solution of DCH-18-C-6 in toluene on a polypropylene support.⁷⁶ The influence of irradiation becomes apparent after absorbed doses of 460 kGy for uranium and 100 kGy for plutonium. Above 710 kGy, the fluxes of U^{6+} and Pu^{4+} are decreased *ca.* twofold and *ca.* sixfold, respectively.

The radiation resistance of DCH-18-C-6 (**12**) immobilised on silica gel (3.8%) is estimated by comparing the sorption capacities of irradiated and non-irradiated samples with respect to Sr^{2+} (see Ref. 42). At absorbed doses ranging from 0 to 1.0 MGy, the sorption ability is virtually unchanged.

Analysis of the final radiolysis products of extraction systems based on crown ethers is a rather complicated task because of low radiation-chemical yields. Successful solution of this problem requires chromatographic separation of the decomposition products from the initial compounds. Thus irradiation (50–400 kGy) of B-15-C-5 (**21b**) in chloroform ($c = 0.001\text{--}0.15\text{ mol litre}^{-1}$) gave rise to the formation of the chloroform radiolysis products and mono- and dichloro derivatives of B-15-C-5 (**21b**) which represented ionic associated complexes $(\text{B-15-C-5})\text{H}^+\text{Cl}^-$ and $(\text{B-15-C-5})\text{H}^+\text{Cl}_2^-$. These were isolated chromatographically and identified by mass-spectrometry.⁷⁸ The products of the reaction of the chlorine atoms, which were derived from radiolysis of chloroform, with the aromatic ring of the crown ether were absent. The IR spectra of the radiolysis products revealed a band at 1740 cm^{-1} which was attributed to the carbonyl group. On this ground, a conclusion was made about the macrocycle opening.

Myasoedova and Dmitrieva⁷⁹ studied radiation-chemical transformations in a system containing $0.1\text{ mol litre}^{-1}$ of DCH-18-C-6 (**12**) in a 1 : 1 mixture of 1,1,2,2-tetrachloroethane and 3M HNO_3 . The organic and aqueous phases were stirred and irradiated in air. The absorbed dose was $\sim 10^5\text{ Gy}$ at a dose rate of 2 Gy s^{-1} . After distillation of tetrachloroethane, the residue was analysed by chromato-mass spectrometry. More than 40 radiolysis products were found. The probable products corresponding to the main peaks in the chromatogram are shown below:

A scheme of radiation-chemical transformations of DCH-18-C-6 (**12**) was proposed. The major processes of radiolysis are presumed⁷⁹ to involve oxidation of the crown ether leading to the macrocycle opening and formation of acyclic products, addition of the products of tetrachloroethane and HNO_3 radiolysis to the initial crown ether, elimination of the oxyethylene fragment from the macrocycle with preservation of the cyclic structure (analogous to the fragmentation observed in the electron-impact mass spectrometry) and dehydrogenation of the cyclohexane ring. It was noted that at least two of the most abundant peaks in the chromatogram ($m/z\ 366$ and 400) were apparently due to the presence of an impurity derived from DB-18-C-6 and intermediate products appearing during its formation.

Draye *et al.*⁸⁰ studied the γ -radiolysis products of a solution of DCH-18-C-6 (**12**) and uranyl nitrate in 1M nitric acid using NMR and IR spectroscopy and chromato-mass spectrometry. Samples were irradiated without preliminary evacuation up to the absorbed dose of 3.29 MGy . New bands corresponding to the OH and C=O groups were observed in the IR spectra. At the same time, the NMR spectra of irradiated and non-irradiated samples remained identical. Of the seven basic peaks, the most prominent were the peaks with $m/z\ 160$ and 204 which are attributed to compounds **27** and **28**, respectively.

Unfortunately, Draye *et al.*⁸⁰ neither presented the experimental NMR and mass-spectra nor reported whether or not the samples were dehydrated before the analysis; therefore, the identification of the radiolysis products of crown ethers remains ambiguous.

Abashkin *et al.*⁴⁸ studied the radiolysis of *cis-syn-cis*- and *cis-anti-cis*-isomers of DCH-18-C-6 (**12**) and their complexes with strontium nitrate. At the absorbed doses below 500 kGy , no radiolysis products were found in free crown ether. Increase in the absorbed dose to 1500 kGy led to the appearance of a radiolysis product with a carbonyl group which was detected by chromatography. Presumably,⁴⁸ radiolysis resulted in a symmetrical scission of the macrocycle over two C–O bonds with the formation of a compound giving a peak at $m/z\ 186$ in the mass spectrum.

It was found that *cis-syn-cis*-**12** is more stable than *cis-anti-cis*-**12**. The complex of DCH-18-C-6 (**12**) with strontium nitrate is less resistant to the radiation than the free crown ether. At 500 kGy , complex decomposition products are formed, which is evidenced by the appearance of the absorption bands of the unbound nitrate in the IR spectrum and by the decrease in the intensity of the absorption bands of the complex. The macrocycle of the complex also undergoes decomposition yielding a product containing a carbonyl group.

Thus, DCH-18-C-6 possesses high resistance to irradiation in the range of doses received by extractants during the spent nuclear fuel reprocessing cycle, and decomposition of the macrocycle may be disregarded. Irradiation of extraction systems based on crown ethers with larger doses leads mainly to macrocycle scission, while the formation of cross-linking or polymerisation products is hardly probable. A decrease in the extraction ability of the systems based on crown ethers under the action of ionising irradiation is associated with the formation of the solvent radiolysis products; for this reason, the use of chlorine-containing solvents is undesirable.

In studies of the radiolysis of dicyclohexanocrown ethers and their complexes with metal cations, the purity of samples is highly important, since even insignificant amounts of dibenzocrown ethers may lead to erroneous identification of the radiolysis products.^{48,79}

IV. Areas of application of crown ethers

1. Reprocessing of spent nuclear fuel and extraction of fission fragments from radioactive waste

Reprocessing of spent nuclear fuel is a stage of the fuel cycle in which uranium and plutonium are separated from fission fragments. The major role in this process is played by liquid extraction. The use of crown ethers as extractants, in particular of dicyclohexanocrown ethers, ensures higher selectivity of the extraction of uranium and transuranium elements compared to that provided by extractants used currently and allows separation of these radionuclides from the fission fragments.^{3,8} New extraction processes based on the use of macrocyclic polyethers were proposed which allow selective isolation of Sr and Tc,^{81–85} U(VI) and Pu(IV)^{51,86} from solutions in nitric acid with high specific activity.

Dicyclohexanocrown ethers are efficient in the utilisation of liquid radioactive waste formed in the processing of nuclear fuel and deactivation of equipment. Depending on their origin, the radioactive wastes can have acidic or alkaline reaction. Concentrates of such wastes possess high activities due to the presence of long-living cesium and strontium isotopes with half-life times ($\tau_{1/2}$) of 28.5 and 30.1 years for ^{90}Sr and ^{137}Cs , respectively.⁸⁷ These concentrates are stored in geological storage pits. Selective extraction of radionuclides from them makes it possible to decrease considerably the bulk of waste, which simplifies further reprocessing and storage. In addition, ^{90}Sr and ^{137}Cs are widely used as

sources of β -radiation and energy generators.⁸⁸ At present, two processes of radioactive waste treatment are under testing in the USA. Thus in the Argonne National Laboratory, a process for selective extraction of ^{90}Sr (the so-called SREX, *i.e.*, Strontium Extraction) from solutions in nitric acid was developed. This method employs DTBDCH-18-C-6 (**2**) ($c = 0.15 \text{ mol litre}^{-1}$) as a selective extractant of Sr^{2+} . The extraction system is supplemented with tributyl phosphate to prevent formation of a third phase and with kerosene Isopar L[®] as the solvent. Pilot technological testing has shown that crown ether **2** allows 99.98% extraction of strontium in a single cycle, the extract containing virtually no Na, Fe, Ca ions and other ballast elements.^{84,85} A disadvantage of the SREX process is co-extraction of Pb^{2+} and K^+ cations, and this fact requires that the process included an additional stage for the separation of these cations. Researchers of the Oak Ridge National Laboratory devised an SRTALK process for the extraction of technetium and strontium from alkaline radioactive waste.^{81–83} The extraction system consists of DTBDCH-18-C-6 (**2**) solution ($c = 0.02 \text{ mol litre}^{-1}$) in a 1 : 1 (v/v) mixture of kerosene Isopar L[®] and tributyl phosphate as a modifier.

Selective ligands with respect to cesium cations are dibenzo-crown ethers and calixarenes containing fragments of crown ethers. At present, intensive studies of extraction and sorption systems based on them and aimed at extracting Cs from radioactive waste are underway.^{89–94} Photosensitive monocrown-6-azobenzocalix[4]arene (**29**) was synthesised.^{89,95} When it is used for the extraction of Cs^+ ions, the distribution coefficient increases threefold under the action of UV light.

29
 $\text{R}^1 = \text{COOH}$, $\text{R}^2 = \text{H}$ (a); $\text{R}^1 = \text{R}^2 = \text{SO}_3\text{Na}$ (b);
 $\text{R}^1 = \text{R}^2 = \text{SO}_2\text{N}(\text{CH}_2\text{CH}_2\text{OH})_2$ (c).

The preparation of water-soluble calix[4]arene-bis(crown ethers) **30a–c** has been described. These compounds were shown⁹¹ to have high affinities for cesium ions. Calix[4]arene[

31
32, 33 $\text{R} = \text{H}$ (**32**);
 $\text{R}_2 = \text{CH}=\text{CHCH}=\text{CH}$ (**33**).

bis(tribenzo)-crown-6] (**31**)⁹⁰ and non-symmetrical calix[4]arene[bis-crown ethers] (**32, 33**)⁹⁶ were synthesised. These were shown to possess high cation-binding abilities for cesium ions and to be virtually inert with respect to sodium ions. High selectivities of compounds **31–33** are determined by the presence of aromatic substituents in the polyether ring resulting in a change in the sp^3 hybridisation of carbon atoms of the oxyethylene moiety to sp^2 hybridisation.⁹⁰

It was proposed to use crown-containing calixarenes as supports in membranes for selective extraction of cesium ions from nuclear waste^{97–99} and in ion-selective electrodes.¹⁰⁰ Lamare *et al.*¹⁰¹ described a method for selective extraction of traces of cesium by calixarene-crown ethers from sodium nitrate solutions.

a. Effect of solution acidity and the crown ether structure on the extraction efficiency

Quantitative parameters of the extraction process are characterised by the distribution coefficient D and the extraction constant K_{ex} . As a rule, extraction of metal ions by a macrocycle from acidic and neutral solutions is described^{102–107} by the scheme

where M is the metal cation, m is the metal oxidation state, CE is a crown ether, k is the number of macrocyclic molecules involved in complexation, A is an anion and n is the anion charge. $\text{M}_n(\text{CE})_k\text{A}_m$ is the complex of the crown ether with the cation.

For most systems, $k = 1$ or 2 . For $k = 2$, a sandwich-like complex is formed.

The extraction constant may be calculated using the following relation:

$$K_{\text{ex}} = \frac{[\text{M}_n(\text{CE})_k\text{A}_m]^*}{[\text{M}^{m+}]^n [\text{CE}]^k [\text{A}^{n-}]^m}, \quad (1)$$

where $[\text{CE}]$ and $[\text{M}_n(\text{CE})_k\text{A}_m]^*$ are the concentrations of a crown ether and its complex in the organic phase, $[\text{M}^{m+}]$ and $[\text{A}^{n-}]$ are the concentrations of a cation and an anion in the aqueous phase.

The distribution coefficient is determined from the relation

$$D = \frac{[\text{M}_n(\text{CE})_k\text{A}_m]^*}{[\text{M}^{m+}]^n}. \quad (2)$$

Substituting K_{ex} from the relation (1) gives

$$D = K_{\text{ex}}[\text{CE}]^k [\text{A}^{n-}]^m \quad (3)$$

or

$$\log D = \log K_{\text{ex}} + k \log [\text{CE}] + m \log [\text{A}^{n-}]. \quad (4)$$

The compositions of crown-containing extraction systems and the distribution coefficients of Cs, Sr, U and Pu ions obtained for them are listed in Table 2.

The dependence of the distribution coefficient of a metal on the concentration of crown ether at a constant concentration of a counterion allows determination of the extraction constant and the composition of the crown ether complexes with metal cations (Table 3).

It should be noted that the above-cited scheme of extraction of metal ions by macrocycles does not take into account a number of factors. As a rule, transition of a metal salt into the organic phase in the absence of a macrocycle and dissociation of a macrocyclic complex in the organic phase may be disregarded,¹¹³ however, the solution acidity is one of the crucial factors determining quantitative parameters and the mechanism of the extraction process. In an acidic solution, complexation is complicated by the involvement of protonated ligands.^{119, 122, 123} In addition, it was found that DCH-18-C-6 (**12**) forms complexes effectively with nitric and picric acids. It is noteworthy that up to 10 molecules of nitric acid per macrocycle can be extracted from the aqueous to the organic phase.^{3, 8, 124, 125} The effect of concentration of nitric and picric acids on the extraction of strontium,^{87, 102–104, 119} uranium,^{105, 107, 114, 126, 127} and plutonium^{8, 105, 106, 120} by dicyclohexanocrown ethers was investigated in numerous studies. It was

^a 5M HCl was added; ^b *cis-syn-cis*-isomer, ^c mixture of isomers, ^d pH = 3, ^e neutral medium, ^f alkaline medium, [OH⁻] = 1.75 g-ion litre⁻¹.

found that the efficiency of the extraction depends on the nature of the solvent, metal, counterion, *etc.* Thus in the extraction of Sr²⁺ by DCH-18-C-6 (**12**) in a butanol–octanol mixture (80:20), the distribution coefficient *D*_{Sr} depends on the concentration of nitric

acid and increases as the HNO₃ concentration is increased from 1 to 8 mol litre⁻¹ (see Ref. 102). When 1,1,2,2-tetrachloroethane⁸⁷ and chloroform¹¹¹ are used as solvents, the distribution coefficient of Sr²⁺ reaches maxima for HNO₃ concentrations of

Table 3. Composition of complexes of crown ethers with metal cations.

Cation	Crown ether	Ratio of components in the complex	Ref.
Sr ²⁺	18-C-6 (20c)	1 : 1	103
	DCH-18-C-6 (12)	1 : 2	102, 119
Pu ⁴⁺	DCH-18-C-6 (12)	1 : 2	3, 105, 120
U ⁴⁺	15-C-5 (20b)	1 : 3	121
	B-15-C-5 (21b)	1 : 2	114
	18-C-6 (20c)	1 : 1	114
	DCH-18-C-6 (12)	1 : 1	105

1.25 and 3.0 mol litre⁻¹, respectively. For the U⁶⁺ ion, the D_U increases as the concentration of HNO₃ is increased and reaches a plateau for its concentration of 5–8 mol litre⁻¹ (Refs 105, 114). The dependence of D_{Pu} on solution acidity has a maximum which is shifted from 4–5 to 3–4 mol litre⁻¹ HNO₃ as the macrocycle concentration is increased from 0.05 to 0.2 mol litre⁻¹ (see Refs 105, 120). Presumably,^{8,105} the initial enhancement of the Pu(IV) extraction is due to salting out of the metal by nitric acid. Subsequent decrease in D_{Pu} as the acidity is increased was explained by the displacement of the metal from the organic phase due to the reaction of the ligand with the acid.⁸ However, an alternative explanation was also proposed:¹⁰⁵ this effect is believed to be related to the formation of less extractable acidic complexes of the type HPU(NO₃)₅ and H₂Pu₄(NO₃)₆.

The structure of crown ether, in particular the size of the polyether ring and the nature of the substituent, exert a strong effect on the efficiency of extraction. Relevant studies were devoted to the investigation of the influence of the crown ether structure on the extraction of cesium,^{118, 128–130} strontium,^{47, 87, 103} uranium and plutonium^{8, 105, 131} and other actinides.⁸ In the extraction of ions of alkali and alkali-earth metals, crown ethers behave in conformity with the concept of geometric correspondence of the size of the cation to the size of the polyether ring cavity. Thus the optimum macrocycles for the binding of strontium are 18-C-6 (**20c**) and DCH-18-C-6 (**12**), whereas dicyclohexano- and dibenzo-21-crown-7 and -24-crown-8 are selective ligands for cesium cations.^{132, 133} The effect of the macrocycle size on the extractability of uranium and plutonium ions is of a more complex character. The extraction ability of crown ethers in toluene¹⁰⁵ or chloroform¹¹⁴ in regard of UO₂(NO₃)₂ and Pu(NO₃)₄ in a nitric acid medium proved to be changed in parallel with the macrocycle size and had the following order: DCH-18-C-6 (**12**) > DB-24-C-8 (**17**) > DB-18-C-6 (**15**) > B-15-C-5 (**21b**).

However, these sequences for U⁶⁺ and Pu⁴⁺ ions do not coincide in the case of extraction with solutions of crown ethers in dichloroethane from nitric acid media. The extractability of U⁶⁺ decreases in the order: DCH-18-C-6 (**12**) > DCH-24-C-8 (**14**) > DB-24-C-8 (**17**) > DB-18-C-6 (**15**) > 15-C-5 (**20b**) > 18-C-6 (**20c**), while that of Pu⁴⁺ decreases in the order: DCH-24-C-8 (**14**) ≈ DCH-18-C-6 (**12**) > 15-C-5 (**20b**) > 18-C-6 (**20c**) > DB-24-C-8 (**17**) > DB-18-C-6 (**15**).³

In the extraction of uranyl ions from solutions in picric acid, the increase in the size of the macrocycle cavity leads to a decrease in $D_{UO_2^{2+}}$ in the order: B-15-C-5 (**20b**) 18-C-6 (**20c**) > DB-18-C-6 (**15**) >> DB-24-C-8 (**17**).¹¹⁵

Neutral inorganic complexes of uranium and plutonium were shown^{134, 135} to be linked to the macrocycle by means of hydrogen bonds through coordinated water molecules. These characteristic features of the structures of uranium and plutonium complexes could explain why the principle of geometric correspondence does not operate in this case.

b. Methods for increasing extraction efficiency and non-conventional extraction systems

The major routes to increasing the distribution coefficients in the extraction systems based on crown ethers are as follows: introduction of an additional extractant in order to achieve an extraction

synergism effect, addition of a complexation agent (EDTA, acetylacetone, *etc.*) to the aqueous phase, addition of a polar water-miscible solvent (acetonitrile, propylene carbonate, dioxane, *etc.*) to the aqueous phase, extraction by crown ethers dissolved in liquid CO₂, the use of biphasic aqueous systems for extraction.

The synergism of extraction is understood as a joint action of two extractants, which results in the distribution coefficients exceeding those for each extractant used separately. Systems involving crown ethers were developed and the synergetic effects in the extraction of ions of cobalt,¹³⁶ manganese,^{137–139} palladium,¹⁴⁰ uranium(VI),¹⁴¹ lanthanides and actinides,^{142–149} strontium and barium,^{150–153} cesium²⁵ and radium^{154, 155} were studied. Unfortunately, in the studies of synergism the major attention has been paid to quantitative parameters of the extraction process (calculation of extraction constants and distribution coefficients), while the reasons for this effect and its mechanism have rarely been discussed. An exception are the studies by McDowell *et al.*¹²⁸ and Meguro *et al.*¹⁴⁸ who investigated the influence of the macrocycle structure on extraction synergism. In the extraction of lanthanides and actinides, which have high coordination numbers, the reason for the synergism seems to consist in the replacement of water molecules of coordination by the first extractant, which facilitates the transfer of the adduct with the second extractant to the organic phase.

In a number of cases, it was possible to increase substantially the distribution coefficients by adding a polar water-miscible organic solvent to the extraction system. It was shown^{106, 107, 156} that organic solvents less polar than water (acetonitrile, propylene carbonate) favour formation of neutral complexes, *e.g.*, of UO₂(NO₃)₂ or Pu(NO₃)₄, with crown ethers, which enhances strongly the extraction efficiency.

Rather recently,¹⁵⁷ liquid CO₂ has been proposed as a solvent for crown ether-assisted extraction. The main advantage of this method consists in a substantial decrease in the amount of liquid waste containing as a rule toxic organic solvents. Furthermore, the high diffusive ability and low viscosity of liquid CO₂ allows direct extraction of dissolved substances from the solid phase (*e.g.*, from samples of ground, soil, sand, *etc.*). In his review, Wai considered the effect of solubility of ligands and metal complexes in CO₂, pH of the aqueous phase, temperature and pressure, the chemical nature of metal compounds and other factors on the extraction efficiency.¹⁵⁷ An interesting feature of this extraction technique consists in the possibility of separation of metal compounds in organic and inorganic forms by selecting appropriate ligands.

Biphasic aqueous extraction systems represent mixtures of water-soluble polymers, inorganic salts and extractants which separate and form immiscible phases.^{158–160} The advantages of these systems reside in the use of inexpensive, non-toxic and easily accessible water-soluble polymers and in the possibility of using novel water-soluble complexants, which is particularly attractive in the case of dicyclohexano- and non-substituted crown ethers. The application of water-soluble 15-C-5 (**20b**) and 18-C-6 (**20c**) as extractants for cations of metals of groups I and II, UO₂²⁺, Pu⁴⁺, Th⁴⁺ and Am³⁺ in a biphasic aqueous system containing poly(ethylene glycol) (PEG-2000) and (NH₄)₂SO₄ has been described.^{135, 160} The distribution coefficient of UO₂²⁺ ($D_{UO_2^{2+}}$) exceeded unity at a rather high concentration of 18-C-6 (**20c**) (1.25 mol litre⁻¹).¹³⁵

2. The use of crown ethers in radiochemical analysis

a. Determination of the content of radionuclides in water, soil and biological materials

Isotopes of uranium and plutonium as well as their fission products, *viz.*, the radionuclides ⁹⁰Sr and ¹³⁷Cs, are extremely toxic. In this connection, the determination of concentrations of these radionuclides in various natural specimens, which can find their way into human and animal organisms, is of great importance. This analysis is difficult to perform due to the presence of a great amount of interfering cations (Na⁺, K⁺, Mg²⁺, Ca²⁺, *etc.*).

From the biological viewpoint, the isotope ^{90}Sr is one of the most hazardous fission products, since it can replace calcium in bones and has a long half-life time. Numerous procedures have been developed to date for the determination of the content of ^{90}Sr in water, soil and biological samples. These include precipitation,¹⁶¹ liquid extraction,¹⁶² ion exchange,^{163–165} thin-layer chromatography¹⁶⁶ and other methods. All these techniques have serious disadvantages, which prevents their wide uses. Thus in the case of inadvertent release of radionuclides resulting from accidents at an atomic energy power plant or from those related to tests and production on nuclear weapons, a fast, simple and efficient method is required. However, most of the above-mentioned methods of analysis are lengthy.¹⁶⁷ The use of macrocyclic compounds allows considerable simplification of the analytical procedure.

Using the sorbent Sr-Spec, Horwitz *et al.*^{21,22} succeeded in developing a number of competitive methods for the determination of strontium against the background of a large amount of cations which are not biologically hazardous. Gjerci¹⁶⁸ proposed an extraction-chromatographic method for the determination of the content of radioactive strontium in soil, grasses, milk and animal bones. A sample under analysis is subjected to extraction, filtered and then strontium is precipitated from the filtrate as oxalate, the precipitate is dissolved in 3M HNO_3 and the resulting solution is passed through a column with Sr-Spec. The strontium sorbed selectively is eluted and quantitated. Vajda *et al.*¹⁶⁹ reported a method which allows determination of up to 80% of radioactive strontium in soil. This method consists in the separation of potassium, sorption of strontium on Sr-Spec and subsequent precipitation of strontium as oxalate. The Sr-Spec sorbent was also used¹⁷⁰ for rapid quantitation of ^{90}Sr in radioactive waste solutions in nitric acid in the presence of radionuclides of Am, Cd, Co, Ce, Sn, Cs and Y with separation factors $> 99\%$. A continuous automated method for the analysis of ^{90}Sr (see Ref. 171) and a procedure for the determination of ^{90}Sr in water and sedimentary rocks based on the sorbent Sr-Spec were proposed.¹⁷² In this case, ^{90}Y (^{90}Sr) is determined by liquid scintillation after separation of strontium on a column packed with Sr-Spec.¹⁷²

The Sr-sorption abilities of two DCH-18-C-6 (**12**)-based solvents prepared by different techniques were compared and a new method for the quantitation of strontium in natural waters was proposed.¹⁷³ One of them, *viz.*, SESys, was obtained by introducing a crown ether into a matrix of a styrene–divinylbenzene copolymer during polymer isolation, while the other sorbent (impregnate) was prepared by impregnating a macroporous styrene–divinylbenzene copolymer with the same crown ether. Higher values of the distribution coefficient D_{Sr} were obtained on this porous polymeric sorbent.

Extraction-chromatographic and extraction methods were proposed^{45, 174, 175} for rapid quantitation of radioactive strontium in water, soil and agricultural products. An impregnate containing a 10% solution of DCH-18-C-6 (**12**) was used as the sorbent,⁴⁵ while the extraction system was composed of 10% solution of the crown ether **12** in chloroform.^{174, 175} The analytical procedure involved drying of the sample, its calcination at 500–600 °C for several hours and subsequent treatment of the ash with HNO_3 or HCl . Then the solution obtained was passed through a sorption column for binding strontium or recourse was made to extraction, strontium was isolated and its β -activity was measured. In this method, analysis of a sample after its pretreatment required no more than 30–50 min, the chemical yield was $> 95\%$ with the product purity $> 98\%$.⁴⁵

A rapid method for the quantitation of Sr in milk was developed.¹⁷⁶ Milk was treated with a chelate-forming resin, Sr was eluted with a dilute nitric acid, separated from Ca by extraction of the eluate with DCH-18-C-6 (**12**) in chloroform with subsequent transfer of Sr to the aqueous solution and removal of Ba by extraction with a solution of 21-C-7 in dichloromethane. This analytical procedure takes about 3 h and more than 90% of strontium is determined.

Separation and concentration of a number of radionuclides based on co-precipitation of metal ions with silicotungstic acid ($\text{H}_4\text{SiW}_{12}\text{O}_{40} \cdot 2\text{H}_2\text{O}$) from 1M HNO_3 in the presence of 15-C-5 (**20b**) and 18-C-6 (**20c**) were carried out.^{177–180} The selectivity of separation of radionuclides depends on the ratio of the stability constants of crown-ether complexes with the metal cations present in the solution. Precipitation was used to separate and concentrate Sr in the presence of Ca;¹⁷⁹ Pb in the presence of Ca, Sr and Ba,¹⁷⁸ Ra in the presence of Ca and Sr.¹⁷⁷ This method allows estimation of the stability constant of a radionuclide complex with a crown ether even at a very low radionuclide content in solution.¹⁷⁷

A method was devised¹⁸¹ for the determination of the content of alkali and alkaline-earth metals in natural water using ion-exchange chromatography with a conductometric detector. Non-modified silica gel was used as the ion-exchange material, and the eluent contained oxalic acid ($0.001 \text{ mol litre}^{-1}$) and 18-C-6 (**20c**) ($0.003 \text{ mol litre}^{-1}$).

Miura *et al.*¹⁸² proposed a method for the determination of ^{210}Pb and ^{210}Po in sedimentary rocks, clay and biological specimens. The analytical procedure includes four stages: sample decomposition, co-precipitation of ^{210}Pb and ^{210}Po with CuS , separation of isotopes on a column with Sr-Spec and quantitation of ^{210}Pb and ^{210}Po .

Calix[4]arene-crown-6 and calix[4]arene-crown-5 containing two allyl groups were synthesised and grafted onto silica gel.⁹² The macrocycle/silica gel ratio was 1 : 10 (w/w). These sorbents were successfully used for the chromatographic separation of Cs^+ from cations of other alkali metals.

Mohite *et al.*¹⁸³ proposed a chromatographic method for the determination of barium in minerals. A copolymer of DB-18-C-6 (**15**) with formaldehyde was used as the sorbent. The absorbed barium was eluted with 1M acetic acid and its content was determined spectrophotometrically with Sulfonazo III. The capacity for barium was equal to $1.475 \text{ mmol g}^{-1}$. This method allows separation of barium from lead, thorium, uranium, cesium, cerium and molybdenum. The procedure is reproducible with an error of $\pm 2\%$.

The last-mentioned authors^{126, 127} have also described the application of extraction and column chromatography for the quantitation of uranium in geological specimens and animal bones. Dibenzocrown ethers were used as the extractants, while the sorbent was a copolymer of DB-18-C-6 (**15**) with formaldehyde with a sorption capacity of 2.5 mmol g^{-1} . Both methods are distinguished by their simplicity, rapidity and good reproducibility and allow separation of uranium from nuclear fission products.

b. Separation of isotopes

In recent years, considerable progress has been observed in the separation of metal isotopes using extraction and sorption systems based on crown ethers. A monograph by Hiraoka¹⁸⁴ published about 15 years ago cited only one report describing a method of separation of calcium isotopes with the aid of crown ethers. A review by Tsivadze *et al.*¹⁸⁵ published in 1996 generalises the results of over 40 similar studies and presents examples of the use of crown-containing systems for the separation of isotopes of hydrogen, lithium, sodium, potassium, strontium, barium, zinc, cerium and uranium. Kim *et al.*¹⁸⁶ reported recently the application of a polymeric resin based on an azacrown ether for the separation of lithium isotopes. Methods are known for the extraction-based separation of potassium isotopes with the aid of DCH-18-C-6 (**12**)¹⁸⁷ and chromatographic enrichment of calcium isotopes using 18-C-6 (**20c**) grafted onto a macroporous solid support.^{188, 189} An anomalous isotope effect for the isotopes with even and odd mass numbers was observed in the extraction of isotopes of zinc,^{190, 191} magnesium,¹⁹² samarium¹⁹³ and strontium¹⁹⁴ with crown ethers.

The development of methods for the isolation of a daughter isotope ^{90}Y from the parent isotope ^{90}Sr is an important and interesting direction. The isotope ^{90}Y has found wide uses in biology and radiotherapy owing to its short half-life time (64 h)

and stability of its daughter isotope ^{90}Zr . From the viewpoint of clinical application of ^{90}Y , its purification from ^{90}Sr is particularly important. It was found that this problem may successfully be solved using certain crown ethers. Thus ^{90}Y with the purity $> 99.9\%$ was obtained by liquid extraction based on benzocrown ethers having a carboxy substituent in their polyether ring.¹⁹⁵ Chuang and Lo¹⁹⁶ studied the extraction of strontium and yttrium cations by solutions of DCH-18-C-6 (**12**), 18-C-6 (**20c**), B-15-C-5 (**21b**) and DB-18-C-6 (**15**) in chloroform and showed that DCH-18-C-6 (**12**) is the most efficient in the separation of these isotopes. This method of separation is remarkable for its simplicity. The separation proceeds with quantitative yields and the purity achieved is above 99.9%. The isotopes ^{90}Y and ^{90}Sr were separated chromatographically on a paper impregnated with carboxy-substituted benzocrown ethers¹⁹⁷ and on a column packed with a dibenzocrown ether–formaldehyde copolymer.¹⁹⁸ A method of extraction-chromatographic separation of ^{90}Y from ^{90}Sr by sorption with DCH-18-C-6 (**12**) immobilised on silica was proposed.⁴² Quantitation of strontium and separation of its daughter isotope Y^{3+} by thin-layer chromatography on SiO_2 with DCH-18-C-6 (**12**) applied on it was described.¹⁹⁹

V. Conclusion

Crown ethers possess high selectivity and complexation efficiency, resistance to irradiation and a number of other advantages. The progress in the chemistry of macrocyclic polyethers made it possible to develop methods of quantitation of highly toxic radionuclides in various mineral and biological specimens, as well as a number of promising processes for the reprocessing of spent nuclear fuel and utilisation of radioactive waste. A new direction of the use of crown ethers in radiochemistry is the extraction with the aid of liquid CO_2 .

Upon irradiation of both free crown ethers and extraction systems based on them, the main process of radiolysis is the macrocycle scission; however, the radiation-chemical yield of the ring opening is insignificant at absorbed doses corresponding to real conditions.

However, the studies of radiation chemistry of crown ethers and the development of methods for their immobilisation on supports face some unsolved problems. Thus details of the mechanism of radiolysis of crown ethers remain virtually obscure, there is no information about the structure and transformations of primary products. The radiation chemistry of calixarene-crown ethers is virtually uninvestigated.

Definite advances have been achieved in the synthesis of impregnates based on dicyclohexanocrown ethers. A number of procedures for the determination of strontium, lead, polonium and other elements have been developed based on the sorbent Sr-Spec. Unfortunately, the high solubility of non-substituted crown ethers in water apparently will not allow creation of impregnates based on them, unless the polyether ring of crown ethers is modified by hydrophobic groups. The methods of chemical immobilisation of dicyclohexano- and non-substituted crown ethers developed to date are mostly based on the condensation of the macrocycles containing reactive groups. These methods are complicated, include many steps and are time-consuming; therefore, their perfection is needed. In this context, of high interest might be the use of methods of radiation-chemical synthesis, which would allow selective single-step formation of active centres and their addition to the reactive groups of a support or a monomer.

Abstract. Data on syntheses, structures and reactivities of scandium, yttrium, lanthanum and lanthanide complexes with π -bonded ligands containing one or several six-membered aromatic rings are surveyed and systematised. The bibliography includes 107 references.

I. Introduction

Early investigations in the field of chemistry of organometallic compounds containing rare-earth metals were aimed at synthesising and studying compounds typical of organometallic chemistry, such as σ -alkyl(aryl), cyclopentadienyl, indenyl, fluorenyl, cyclooctadienyl, *etc.* derivatives. Complexes containing π -bonded arene ligands were studied later.¹ However, the chemistry of these compounds was extensively investigated in the last 12 years after the first benzene derivatives of lanthanides had been synthesized. The accumulated data allow some general conclusions to be drawn about the characteristic features of the synthesis, structures, the character of metal–ligand bonding and reactivity of π -arene lanthanide complexes belonging to a class of compounds unique in many respects. Particular types of π -arene lanthanide complexes were surveyed in the reviews.^{2,3} The present review is devoted to comprehensive and critical consideration of the available data on the synthesis, structures, the character of bonding, reactivity and catalytic activity of rare-earth metal complexes containing π -bonded six-membered aromatic rings, which were published before January 2000. Derivatives of stilbene, tolan and analogous compounds fall outside the scope of this review because π -electrons of multiple bonds of substituents in aromatic rings of these compounds are generally involved in Ln ligand interactions.

II. Complexes of rare-earth metals with derivatives of benzene and its homologues

1. Arene chloroaluminate complexes

The chloroaluminate complex of samarium, $(C_6Me_6)Sm(AlCl_4)_3$, was the first complex of a rare-earth metal with a π -bonded arene ligand synthesised under conditions of the Friedel–Crafts reaction.^{4–6} This procedure for the synthesis was extended to other complexes of the type **1**. The reactions were carried out with 1,3- $Me_2C_6H_4$,⁷ C_6H_6 ,^{8–10} $Me_4C_6H_2$,^{11,12} MeC_6H_5 (see Ref. 13) and a large series of lanthanides (Y, Pr, Nd, Gd,¹² La,⁸ Eu and Yb¹³). The compositions and structures of complexes of the type **1** indicate that the aromatic moiety is η^6 -coordinated to the trivalent metal atom and serves as a neutral π -donor ligand. The average Ln–C distances [2.93 Å (Nd),¹¹ 2.90 Å (Sm),⁷ 2.999 Å (Eu)¹⁴ and 2.978 Å (Yb)¹⁵] are noticeably shorter than the sums of the van der Waals radius of the carbon atom and the ionic radius of the corresponding metal atom, but are substantially longer than the Ln–C contacts in the cyclopentadienyl derivatives (2.60–2.82 Å for the whole series of lanthanides).

Ln = Y, Pr, Nd, Gd, La, Eu, Yb; R = H, Me; $n = 0, 1, 2, 4$.

The replacement of one of the bridging chlorine atoms by the alkyl group, for example, in the complexes $(C_6H_5Me)Ln.(AlCl_3Me)_3$ (Ln = Y or Nd) and $(C_6H_5Me)Nd(AlBr_3Et)_3$,¹² does not lead to a change in the character of the arene–metal bond. The divalent europium complex $(C_6Me_6)Eu(AlCl_4)_2$ has an analogous structure.¹⁴

2. Arene aryloxy complexes

In aryloxides of lanthanides, there are nonvalent interactions between the metal atom and the benzene ring identical to those found in arene chloroaluminate complexes. The presence of the phenyl substituent at the *ortho* position of the aryloxy group [for

M N Bochkarev G A Razuvaev Institute of Organometallic Chemistry, Russian Academy of Sciences, ul. Tropinina 49, 603600 Nizhnii Novgorod, Russian Federation. Fax (7-831) 266 14 97. Tel. (7-831) 266 67 95. E-mail: mboch@imoc.sinn.ru

example, in the complex $\text{Nd}(\text{OC}_6\text{H}_3\text{Ph}_2\text{-2,6})_3$ (**2**) results in an intramolecular η^6 -interaction between the lanthanide atom and one of the phenyl substituents of the phenoxy ligand. The phenyl substituent in the second phenoxy ligand is η^1 -bonded to the Ln atom, whereas the third phenoxy ligand remains monodentate.^{15–17} In the analogous complex $\text{Nd}(\text{OC}_6\text{H}_3\text{Ph}_2\text{-2,6})_3(\text{THF})$ (**3**), which differs by the presence of one THF molecule coordinated to the metal atom, only one $\text{OC}_6\text{H}_3\text{Ph}_2\text{-2,6}$ substituent serves as a chelate ligand, the multiplicity of the Ln–Ph π -bond decreasing (becoming triple).¹⁶

Ar = 2,6- $\text{Ph}_2\text{C}_6\text{H}_3$.

In lanthanide triphenoxides containing the *tert*-butyl substituents at positions 2 and 6, the metal atom is η^6 -bonded to the phenoxide ligand to form the dimers $(2,6\text{-Bu}_2\text{C}_6\text{H}_3\text{O})_2\text{Ln}(\mu\text{-}2,6\text{-Bu}_2\text{C}_6\text{H}_3\text{O})_2\text{Ln}(\text{OC}_6\text{H}_3\text{Bu}_2\text{-2,6})_2$ (**4**).^{18, 19}

Ar = 2,6- $\text{Bu}_2\text{C}_6\text{H}_3$.

The Ln–Arn contacts (Arn is arene) are retained upon dissolution of complexes of the type **4** in nonsolvating solvents. However, π -bonds are cleaved in THF or upon addition of ammonia and the coordination site of the η^6 -arene ligand in the resulting complexes is occupied by solvent molecules, which is indicative of low strength of the Ln–Arn bond. The Ln–C bond lengths in these fragments (the average distances are 2.986–3.061 Å) are virtually identical to the corresponding values in arene chloroaluminate complexes.

3. Bisarene complexes

Co-condensation of benzene and neodymium vapours on a surface cooled to -196°C afforded a binuclear complex with composition $\text{Nd}_2(\text{C}_6\text{H}_6)_3$,²⁰ which was isolated as black insoluble crystals. The magnetic moment ($3.42 \mu_B$) corresponds to the Nd(III) cation ($3.68 \mu_B$ ²¹) and the dianionic form of all three benzene ligands. The complex was not studied by X-ray diffraction analysis, but it is reasonable to suppose that its structure is similar to that of the thulium naphthalene analogue $[(\text{C}_{10}\text{H}_8)\text{Tm}(\text{DME})]_2(\mu\text{-C}_{10}\text{H}_8)$ considered below.

Sandwich bisarene complexes of rare-earth metals of the $(1,3,5\text{-Bu}_3\text{C}_6\text{H}_3)_2\text{Ln}$ type (**5**) analogous to the well-known bisarene complexes of *d* transition metals were prepared by coconden-

Ln = Gd (**a**), Y (**b**), Ho (**c**), Nd (**d**), Tb (**e**), Dy (**f**), Er (**g**), Lu (**h**), Ce (**i**), Eu (**j**), Yb (**l**), La (**m**), Pr (**n**), Sm (**o**), Sc (**p**).

sation of 1,3,5-tri-*tert*-butylbenzene and metal vapours at 75 K.^{22–25} The structures and magnetic moments of the complexes **5** confirm the η^6 -character of the bond between the neutral aromatic ring and the formally zero-valent metal atom.

In gadolinium complex **5a** characterised by X-ray diffraction analysis, the Gd–C distances are in the range of 2.585–2.660 Å (the average distance is 2.630 Å). These distances are virtually identical to the Ln–C bond lengths in cyclopentadienyl complexes of the Cp_2GdBr type (2.635, 2.639 and 2.630 Å²⁶). The yttrium (**5b**) and holmium (**5c**) complexes were found to have analogous structures.^{3, 22}

The stability of the compounds **5** depends on the nature of lanthanide. Thus the Yb, Nd, Gd, Tb, Dy, Ho, Er and Lu complexes are stable (some of them can be sublimed *in vacuo* without decomposition), whereas the Ce, Eu, Tm and Yb complexes do not form stable products. Derivatives of La, Pr and Sm are intermediate in stability. In the synthesis of the scandium complex, the formation of the expected sandwich $(1,3,5\text{-Bu}_3\text{C}_6\text{H}_3)_2\text{Sc}$ (**5p**) was accompanied by the formation of the complex $(\eta^6\text{-Bu}_3\text{C}_6\text{H}_3)[\eta^6, \eta^1\text{-Bu}_2(\text{CMe}_2\text{CH}_2)\text{C}_6\text{H}_3]\text{ScH}$ (**6**) containing Sc(II) due to the insertion of Sc at the C–H bond of the methyl group of the substituent.²⁷

Since a strong arene–lanthanide π -bond can be formed if the metal atom adopts the d^1s^2 configuration, the difference in thermal stability of the complexes **5** was attributed to the difference in energy of promotion of $f^n s^2 \rightarrow f^{n-1} d^1 s^2$ transitions for different lanthanides. Thermodynamic studies²⁵ confirmed the high stability of Ln–Arn bonds in bisarene complexes. Thus the enthalpies of cleavage of these bonds in the Yb, Gd, Dy, Ho and Er complexes are 72, 68, 47, 56 and 57 kcal mol^{–1}, respectively.²⁵

The stability of bisarene complexes increases as the number and size of substituents in the aromatic ring increase as was exemplified by scandium derivatives.³ Calculations by molecular mechanics²⁸ for $(\text{C}_6\text{H}_6)_2\text{Gd}$ and $(1,3,5\text{-Bu}_3\text{C}_6\text{H}_3)_2\text{Ln}$ (**5**) [Ln = Gd (**a**), Y (**b**) or Yb (**l**)] confirmed that the benzene complex is substantially less stable than the complexes **5a, b, l** containing the *tert*-butyl groups in the benzene ring. Quantum-chemical calculations^{29, 30} demonstrated that the metal atoms are bound to the benzene ligands primarily through back donation from the occupied $d_{\pm 2}$ orbitals of the metal atom to the unoccupied π -orbitals of the benzene ligands.

4. Complexes with benzene radical anions and dianions

Reduction of the cyclopentadienyl complex of lanthanum containing two *tert*-butyl substituents in the cyclopentadienyl rings, *viz.*, $\text{Cp}_2^{\text{t}}\text{La}$, where $\text{Cp}^{\text{t}} = \eta^5\text{-C}_5\text{H}_3\text{Bu}_2\text{-1,3}$, with an excess of potassium in benzene in the presence of 18-crown-6 (18-C-6) afforded a dark-red product. Subsequent heating of the latter in benzene at 70°C gave rise to the dark-green ate-complex $[\text{K}(18\text{-C-6})(\eta^2\text{-C}_6\text{H}_6)_2][(\text{Cp}_2^{\text{t}}\text{La})(\mu\text{-}\eta^6\text{:}\eta^6\text{-C}_6\text{H}_6)]$ (**7**).³¹ X-Ray diffraction analysis demonstrated that the bridging six-membered ring in the anionic moiety of the complex **7** is planar and the C–C bond lengths in this ring are almost identical. All La–C(benzene) bond lengths vary over a narrow range (2.75–2.79 Å). Based on these data, the structure of a salt containing two $\text{Cp}_2^{\text{t}}\text{La}(\text{II})$ units η^6 -bonded to the benzene anion was assigned to the complex **7**.

An analogous reaction of potassium with the complexes $\text{Cp}^{\text{ts}}\text{Ln}$ [$\text{Cp}^{\text{ts}} = \text{C}_5\text{H}_3(\text{SiMe}_3)_2$ -1,3; $\text{Ln} = \text{La}, \text{Ce}, \text{Pr}$ or Nd] also afforded dark-red ionic complexes $[\text{K}(18\text{-C-6})][\text{Cp}^{\text{ts}}\text{Ln}(\text{C}_6\text{H}_6)]$ (**8a–d**). However, the cations in these complexes do not contain coordinated benzene molecules and the C_6H_6 ligand in the anionic moiety exists as the dianion of cyclohexa-1,4-diene η^6 -bonded to the $\text{Cp}^{\text{ts}}\text{Ln}$ unit with the trivalent Ln atom.^{32,33} In the complex **8a**, two short $\text{La} - \text{C}(\text{cyclohexadiene})$ distances are 2.617 and 2.652 Å. In analogous complexes of cerium and neodymium **8b,c**, the corresponding bond lengths are 2.588 and 2.612 Å (Ce) and 2.555 and 2.572 Å (Nd).

$\text{Ln} = \text{La}$ (a), Ce (b), Nd (c), Pr (d).

ESR studies demonstrated³³ that reduction of $\text{Cp}^{\text{ts}}\text{La}$ with potassium in benzene in the presence of 18-C-6 afforded at least four metal-centred free-radical species. The authors believed that the latter are $\text{La}(\text{II})$ derivatives. In this stage, the reaction mixture was dark-blue-violet in colour, which then changed to dark-red.

5. Biphenyl complexes

Treatment of the yttrium(III) chloride complex with composition LYCl , where $\text{L} = \text{PhP}[\text{CH}_2(\text{SiMe}_2\text{N}(\text{SiMe}_2)\text{CH}_2)_2\text{PPh}]$, with phenyllithium gave rise to the dark-blue binuclear product $(\{\text{PhP}[\text{CH}_2(\text{SiMe}_2\text{N}(\text{SiMe}_2)\text{CH}_2)_2\text{PPh}\}\text{Y})_2(\mu\text{-PhPh})$ (**9**)[†] containing the biphenyl dianion as the bridging ligand.³⁴ The complex **9** was also prepared by the reaction of the σ -alkyl complex $\text{LYCH}_2\text{SiMe}_3$ [$\text{L} = \text{PhP}[\text{CH}_2(\text{SiMe}_2\text{N}(\text{SiMe}_2)\text{CH}_2)_2\text{PPh}]$] with benzene.³⁴

In the complex **9**, both rings in the biphenyl ligand remain virtually planar and the $\text{Y} - \text{C}$ distances vary over a narrow range (2.675–2.738 Å), which are evidence of η^6 -interaction. These

[†] Hereinafter, the methyl groups at the silicon atoms are omitted.

distances (the average distance is 2.723 Å) are close to the $\text{Y} - \text{C}$ bond lengths in the complex $\text{Cp}_3\text{Y}(\text{THF})$ (the average distance is 2.71 Å)³⁵ and are somewhat larger than those in the complexes $[\text{Cp}_2\text{YCl}]_2$ (2.60 Å)³⁶ and $(\text{C}_5\text{Me}_5)_2\text{YCl}(\text{THF})$ (2.659 Å).³⁷

The reaction of LYCl with $3\text{-MeC}_6\text{H}_4\text{Li}$ also resulted in the formation of a $\text{C} - \text{C}$ bond. According to the data of ^1H NMR and UV spectroscopy, the dark-blue reaction product is structurally similar to the complex **9**. However, $4\text{-MeC}_6\text{H}_4\text{Li}$ under the same conditions gave the dark-brown compound $(\{\text{PhP}[\text{CH}_2(\text{SiMe}_2)\text{N}(\text{SiMe}_2)\text{CH}_2)_2\text{PPh}\}\text{Y})_2(\mu\text{-MePhPhMe})$ (**10**) in which both YL fragments are bound to the same ring of the $[\text{MeC}_6\text{H}_4\text{C}_6\text{H}_4\text{Me}]^{2-}$ anion.³⁴ The average $\text{Y} - \text{C}$ distances in the fragments of **10** (2.676 and 2.699 Å) are somewhat shorter than the corresponding bond lengths in the complex **9**. ^1H NMR spectral studies of the complex **10** demonstrated that slow (within the NMR time scale) migration of one of the YL groups from one benzene ring to another occurs in solution. It was assumed³⁴ that such behaviour in solutions is also typical of other complexes with bridging $\text{Ar} - \text{Ar}$ ligands.

Samarium and ytterbium powders activated with diiodoethane reacted with biphenylene at room temperature to form dark-coloured solutions.³⁸ Attempts to isolate reaction products in the individual state failed. However, their reactions with oxygen (giving rise to 1,1'-biphenyl-2,2'-diol), deuteromethanol (yielding a mixture of biphenyl and dideuterobiphenyl) and Me_2SiCl_2 (forming a mixture of biphenyl and 1,1-dimethylsilafluorene) were carried out. These results testify that the reactions of lanthanides with biphenylene lead to the cleavage of the four-membered ring giving rise to the lanthanide σ -complexes with biphenyl (**11**). It was suggested³⁸ that the first stage involved reduction of biphenylene to form the ionic intermediates $\text{C}_{12}\text{H}_8^{2-}\text{Ln}^{2+}$, which abstracted hydrogen from the solvent to form biphenyl and the complex **11**.

Apparently, an analogous product was formed in the reaction of octamethylbiphenylenedilithium with SmI_2 .³⁸

III. Complexes with naphthalene derivatives

It was found that reduction of anhydrous ytterbium diiodide with two equivalents of lithium naphthalenide in THF or dimethoxyethane (DME) afforded insoluble black pyrophoric powders with composition $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_3$ or $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{DME})$.^{39–44} Based on the facts that the resulting compounds are diamagnetic [$\text{Yb}(0)$ is diamagnetic] and their reactivities are surprisingly high (even for organolanthanides), it was originally conceived that these products are complexes of zero-valent ytterbium π -bonded to the neutral naphthalene ring. However, additional data on tetrahydrofuran complex **12** obtained more recently demonstrated that these compounds in fact contain the naphthalene dianion and the Yb^{2+} cation.

Analogous naphthalene complexes with samarium and europium^{43,45–48} as well as 1-methylnaphthalene complex with ytterbium^{40,48} were synthesised. The naphthalene complexes of samarium, europium and ytterbium, like alkali metal naphthalenides, are powerful reducing agents. However, the former complexes in contrast to naphthalenides do not react with naphthalene [the reactions could form radical-anionic derivatives of the type $(\text{C}_{10}\text{H}_8^-)_2\text{Ln}(\text{THF})_x$].

The reactions of equimolar amounts of LnI_2 ($\text{Ln} = \text{Eu}$ or Yb) and sodium naphthalenide resulted in the replacement of only one iodide anion and afforded binuclear derivatives **13** containing the bridging naphthalene dianion rather than radical-anionic complexes $(\text{C}_{10}\text{H}_8^{\cdot-})\text{LnI}(\text{THF})_x$.^{49,50}

$\text{Ln} = \text{Eu}, \text{Yb}$.

The $\text{Ln}(\mu\text{-C}_{10}\text{H}_8)\text{Ln}$ moiety containing the naphthalene bridging dianion (complex **14**) was also formed in the reaction of sodium naphthalenide with lanthanum iodide.⁴⁹ Analogous complexes were obtained for Ce, Pr, Nd and Gd.⁵⁰

The stability of complexes of the type **14** decreases on going from light to heavy lanthanides. From Tb and onwards, attempts to isolate such complexes failed even at low temperature. The neodymium derivative **15** was synthesised by oxidation of divalent neodymium iodide with naphthalene in a solution in THF.⁵¹

The naphthalene complexes of europium and lanthanum, *viz.*, $[\text{I}_2\text{Eu}(\text{DME})_2]_2(\mu\text{-C}_{10}\text{H}_8)$ (**16**) and $[\text{I}_2\text{La}(\text{THF})_3]_2(\mu\text{-C}_{10}\text{H}_8)$ (**17**), respectively, were studied by X-ray diffraction analysis.⁴⁹ In these complexes, the metal atoms are located on the opposite sides of the plane of the bridging naphthalene ligand and are η^4 -bonded to different rings. The naphthalene moiety is nonplanar and the dihedral angles between the rings are 5.8° and 15.2° in the complexes **16** and **17**, respectively. The shortest La–C and Eu–C distances are in the ranges of 2.782–2.808 and 2.815–2.858 Å, respectively.

With the aim of preparing halogen-free naphthalene complexes of lanthanides, the reactions of triiodides LnI_3 with a threefold excess of $\text{C}_{10}\text{H}_8\text{Na}$ were carried out.^{43,52} After removal of the solvent, solid black or dark-brown amorphous substances were obtained from the resulting dark-brown solutions. Attempts to isolate individual products from these substances failed. The individual compound $[\text{C}_{10}\text{H}_8\text{Tm}(\text{DME})]_2(\mu\text{-C}_{10}\text{H}_8)$ (**18**) was obtained only for thulium starting from the salt $\text{TmI}_2(\text{DME})_3$.⁵³

It is worthy of note that thulium was oxidised in the course of the reaction to the trivalent state in spite of the fact that $\text{C}_{10}\text{H}_8\text{Na}$

is a strong reducing agent. The trivalent state of thulium was confirmed by magnetic measurements and by the fact that the colour of the reaction mixture changed from green to red-brown. The compound **18** has the structure of a triple-decker sandwich. According to the valence balance, all three naphthalene groups in the complex exist as dianions. The central binuclear unit with the η^4 : η^4 -bonded bridging naphthalene ligand is structurally similar to those in the iodine-containing complexes **16** and **17**.

The lengths of the short $\text{Tm}-\text{C}(\text{bridging } \text{C}_{10}\text{H}_8)$ bonds are in the range of 2.59–2.62 Å. The folding angle of the rings along the $\text{C}(1)-\text{C}(4)$ line is 19.28° . Based on the shortest $\text{Tm}-\text{C}$ distances to the terminal naphthalene moieties [2.41 and 2.42 Å for $\text{C}(\alpha)$ and 2.54 and 2.54 Å for $\text{C}(\beta)$], both types of interactions can be considered as η^4 and η^2 . However, the dihedral angle (26.22°) and the redistribution of the C–C bond lengths in the coordinated rings correspond to cyclohexa-1,4-diene. The absolute values of the shortest $\text{Tm}-\text{C}$ distances are identical (taking account of the difference in the ionic radii and coordination numbers of the metal atoms) to the $\text{Ln}-\text{C}$ σ -bonds in the complexes $[\text{Li}(\text{THF})_3] \cdot \{[(\text{Me}_3\text{Si})_2\text{CH}]_3\text{YbCl}\}$ (the average distance is 2.375 Å),⁵⁴ $\text{Cp}^*\text{CeCH}(\text{SiMe}_3)_2$ ($\text{Cp}^* = \eta^5\text{-C}_5\text{Me}_5$, 2.535 Å)⁵⁵ and $\text{Cp}^*\text{NdCH}(\text{SiMe}_3)_2$ (2.517 Å).⁵⁶

It was assumed^{46,57} that black insoluble finely dispersed products formed upon reduction of SmBr_3 and YbBr_3 with sodium naphthalenide are metallic lanthanides. However, there are strong grounds to believe that these reactions, like the analogous reactions with iodides, afforded naphthalene complexes of lanthanides. Apparently, the results of reduction of NdCl_3 with lithium naphthalenide were also misinterpreted.⁵⁸ Reinvestigation⁵⁹ of reduction of NdCl_3 with insufficient lithium in THF in the presence of naphthalene demonstrated that the reaction performed under these conditions gave rise to a mixture of naphthalene complexes with composition $[\text{NdCl}_2(\text{THF})_2\text{LiCl}]_n(\text{C}_{10}\text{H}_8)$ ($n = 4-7$) rather than divalent neodymium chloride $\text{NdCl}_2(\text{THF})_2$ as has been reported previously.⁶⁰

Binuclear complexes of the general formula $\{(\text{PhP}[\text{CH}_2.(\text{SiMe}_2)\text{N}(\text{SiMe}_2)\text{CH}_2]_2\text{PPh})\text{Ln}_2\text{Arn}\}$ (**19a–d**) [$\text{Arn} = \text{C}_{10}\text{H}_8$, $\text{Ln} = \text{Y}$ (**a**) or Lu (**b**); $\text{Arn} = \text{C}_{10}\text{H}_7\text{Me}$, $\text{Ln} = \text{Y}$ (**c**) or Lu (**d**)] containing the $\text{Ln}(\mu\text{-Arn})\text{Ln}$ group were prepared by the reactions of a mixture of potassium-intercalated graphite (KC_8) and naphthalene or 1-methylnaphthalene with the complex $\{(\text{PhP}[\text{CH}_2.(\text{SiMe}_2)\text{N}(\text{SiMe}_2)\text{CH}_2]_2\text{PPh})\text{YCl}_2\}$ (**9**) or its lutetium analogue.⁶¹ X-Ray diffraction analysis demonstrated that the fragments containing the phosphorus ligand bound to Y in the compound **19a**, like those in the complex $[\text{I}_2\text{La}(\text{THF})_3]_2(\mu\text{-C}_{10}\text{H}_8)$ (**17**), are located on the opposite sides of the bridging naphthalene ligand and are η^4 -bonded to the Y atoms. The shortest Y–C(1,2,3,4)(naphthalene) distances are 2.696, 2.684, 2.686 and 2.652 Å, respectively. The rings in the naphthalene ligand are folded along the $\text{C}(1)-\text{C}(4)$ and $\text{C}(5)-\text{C}(8)$ lines. According to the preliminary data, the lutetium analogue has a similar structure.

The $^{31}\text{P}\{^1\text{H}\}$ NMR spectra of all the four compounds are similar (the spectrum of the yttrium derivative has a doublet at

δ 21, $^1J_{\text{YP}} = 60$ Hz), which is indicative of the equivalence of the phosphorus ligands. Based on this fact, it was suggested⁶¹ that intramolecular migration of the $\{\text{PhP}[\text{CH}_2(\text{SiMe}_2)\text{N}(\text{SiMe}_2)\text{CH}_2]_2\text{PPh}\}\text{Ln}$ moieties between the naphthalene rings (structures **A–D**) occurs in solution. Apparently, the moieties migrate independently and, as a consequence, **A** is converted into **B** through the intermediates **C** and **D**.

R = H, Me; Ln = Y, Lu.

The lanthanide complexes $[\text{CpLn}(\text{THF})(\mu\text{-}\eta^4\text{:}\eta^6\text{-C}_{10}\text{H}_8)\text{VCp}]_x$ (**20a–c**) containing the bridging naphthalene ligand were prepared by the reactions of naphthalenytytterbium, -europium or -samarium with vanadocene.^{62,63}

Ln = Sm (**a**), Eu (**b**), Yb (**c**).

According to the data of ESR spectroscopy and magnetic measurements, the bridging naphthalene ligand in the complexes **20a–c** is neutral and the negative charge is located at the vanadium atom as a result of which the latter becomes formally zero-valent. Compounds of this type can be considered as dicyclopentadienyl complexes of lanthanides in which one of the cyclopentadienyl anions is coordinated to the metal atom through the neutral $(\text{C}_{10}\text{H}_8)\text{V}$ group.

Analogous lanthanide–vanadium complexes $[\text{CpV}(\mu\text{-}\eta^6\text{:}\eta^6\text{-C}_{10}\text{H}_8)_2\text{Ln}(\text{THF})(\text{DME})]$ (**21**) were synthesised in THF by the reactions of samarium or europium diiodides with cyclopentadienylnaphthalenevanadium anions prepared *in situ*.⁶³ The reactions in hexane gave rise to monomeric complexes in which the rare-earth atom is coordinated to two $\text{CpV}(\text{C}_{10}\text{H}_8)$ units.

Ln = Sm (**a**), Eu (**b**).

The naphthalene ligands in the complexes **20** and **21** are planar. The $\text{Ln}–\text{C}(\text{naphthalene})$ bond lengths in the complex **20b** [$\text{Eu}–\text{C}(\alpha)$, 2.828 and 2.869 Å; $\text{Eu}–\text{C}(\beta)$, 3.037 and 3.098 Å] are indicative of η^4 -interaction in the $\text{CpLn}(\text{C}_{10}\text{H}_8)\text{VCp}$ moieties. In the quadruple-decker compound **21b**, the $\text{Eu}–\text{C}$ bond lengths are in the range of 2.872–3.084 Å, *i.e.*, η^6 -coordination occurs in the $(\text{C}_{10}\text{H}_8)\text{Eu}(\text{C}_{10}\text{H}_8)$ moieties.

The reaction of lithium naphthalenide with Cp_2LuCl proceeded through another pathway. In this case, the resulting (apparently, unstable) radical-anionic intermediate $\text{Cp}_2\text{Lu}(\text{C}_{10}\text{H}_8^{\cdot-})$ (**22**) underwent rapid conversions involving metallation of naphthalene and formation of hydride and naphthyl derivatives.⁶⁴

Reduction of CpLuCl_2 with sodium naphthalenide afforded the mononuclear complex $(\eta^5\text{-C}_5\text{H}_5)\text{Lu}(\text{C}_{10}\text{H}_8)(\text{DME})$ (**23**).⁶⁵

The molecular geometry of the complex is indicative of the σ -character of the bond between the lutetium atom and the naphthalene ligand whose coordinated ring loses aromaticity.

The $\text{Lu}–\text{C}(\alpha)$ bond lengths (2.406 and 2.397 Å) are comparable with the $\text{Lu}–\text{C}$ σ -bond lengths in the complexes $\text{Cp}_2\text{LuBu}^t(\text{THF})$ (2.47 Å)⁶⁶ and $\text{Cp}_2\text{LuCH}_2\text{SiMe}_3(\text{THF})$ (2.376 Å).⁶⁷ The $\text{Lu}–\text{C}(\beta)$ bond lengths (2.579 and 2.562 Å) are close to the $\text{Lu}–\text{C}(\text{Cp})$ bond lengths (2.65 Å), which suggests the presence of additional π -interaction of the lutetium atom with the double bond (1.36 Å) between the $\text{C}(\beta)$ atoms of the coordinated ring. The folding angle in the coordinated ring is 31.5°. Therefore, the bond between the naphthalene ligand and the metal atom in this case may be characterised as $2\eta^1\text{:}\eta^2(2\sigma,\pi)$ interaction.^{64,65,68} Analogous Y, Gd, Er and Tm complexes were also prepared.⁶⁹

In the reactions with $\text{C}_{10}\text{H}_8\text{Na}$ performed under comparable conditions, lanthanide derivatives characterised by lower potentials of $\text{Ln}(\text{II})/\text{Ln}(\text{III})$ transitions (such as Sm and Yb) were reduced to form the binuclear $\text{Ln}(\text{II})$ complexes containing the bridging naphthalene group, *viz.*, $(\text{CpLn})_2(\mu\text{-C}_{10}\text{H}_8)_4$ (**24**).⁶⁹

Ln = Sm, Yb.

The reaction with the use of the pentamethylcyclopentadienyl derivative of lutetium, Cp^*LuCl_2 , as the starting compound yielded the diamagnetic ate-cluster $\{[(\text{Cp}^*\text{Lu})_3(\text{C}_{10}\text{H}_8)(\text{C}_{10}\text{H}_7)]\cdot[\text{Na}(\text{THF})_3]\}^{2+}$ (**25**) whose trinuclear cation contains the naphthalene dianion and the naphthyl group with a charge of -3 .⁷⁰

The naphthalene dianion, which is not coordinated to the metal atoms, represents the anionic moiety of the complex. The ring *A* of one of the naphthalene ligands in the cationic moiety is η^4 -bonded to the $\text{Lu}(1)$ atom. As in the complex **23**, the $\text{Lu}–\text{C}$

bond lengths of this fragment in **25** [Lu–C(α), 2.58 and 2.60 Å; Lu–C(β), 2.67 and 2.77 Å] and the folding angle along the C(α)–C(α) line (the dihedral angle is 172.5°) correspond to $2\eta^1 : \eta^2$ -interaction. The *B* ring remains planar and is η^6 -bonded to the Lu(2) atom (the Lu–C bond lengths are in the range of 2.61–2.88 Å). The $2\eta^1 : \eta^2$ -interaction is most pronounced in the Lu(3)–C₁₀H₇ group. In this case, the dihedral angle along the C(α) line is 142.5°. The Lu(3)–C(α,β) distances are 2.44, 2.47, 2.54, and 2.59 Å, respectively. The naphthyl ring *C* is σ -bonded to the Lu(2) atom. The short Lu(1)–ring *C* (2.81 Å) and Lu(3)–ring *A* (2.72 Å) distances are, apparently, indicative of some degree of bonding in these fragments. It is not inconceivable that the anionic cluster contains a bridging proton bound to the Lu(1) and Lu(2) atoms. However, the presence of this proton has not been unambiguously established.

It was reported⁷¹ that thin films of cerium and europium readily reacted with naphthalene in diethyl or dipropyl ethers at room temperature to form colourless solutions. Based on the spectral characteristics, it was concluded that pale-brown substances obtained after removal of the solvent and excess naphthalene are bis(naphthalene) π -complexes of zero-valent lanthanide of the bis(naphthalene)chromium type. However, this conclusion is in contradiction with the following facts: the products are pale in colour, which is untypical of neutral and charged arene complexes; under these conditions, naphthalene does not react with other lanthanides (Pr, Nd, Gd, Tb, Dy, Ho or Er); the reaction does not proceed in THF; the reaction with anthracene proceeds more slowly than that with naphthalene.

The reaction of acenaphthylene with permethylsamarocene readily proceeded in benzene giving rise to a dark-blue compound. According to the data of NMR and IR spectroscopy and elemental analysis, the compound can be described by the chemical formula (Cp^{*}Sm)₂(C₁₂H₈).⁷² The structure of the product was not established.

IV. Complexes with anthracene

Anthracene which possesses the higher electron affinity than naphthalene forms complexes with lanthanides in the direct reactions with ytterbium, samarium and cerium activated with diiodoethane.^{73–75} Attempts to isolate these complexes in an individual state failed. However, structure **26** was assigned to the resulting complexes by reasoning from the products of reactions with MeOD, MeI and Me₃SiCl.

A film of metallic ytterbium prepared by concentrating a solution of the metal in liquid ammonia also reacted with anthracene in the presence of LiCl, NaBr, LiI, KI or Bu₄NI.⁷⁶ The authors believed that the reactions gave rise to complexes containing the anthracene radical anion with composition Yb(C₁₄H₁₀^{•−})₂·*n*MX. However, attempts to identify the reaction products were also unsuccessful. After washing of the substance with benzene, a violet powder containing the anthracene dianion, ytterbium and NaI in a ratio of 1 : 1 : 6 was obtained.

Anthracene complexes were prepared by the reactions of anthracene with naphthaleneytterbium in THF in the presence of alkali metal halides or by the reaction of YbI₂ with C₁₄H₁₀Na.^{40, 77} These complexes were isolated as black insoluble powders, which are similar in properties to naphthalene analogues. ESR spectral studies of these compounds and their hydrolysis products suggested the existence of an equilibrium between the radical-anionic (**A**) and dianionic (**B**) forms, with the latter predominating:

Since the resulting complexes are poorly soluble, their high-quality crystals were not prepared and the structures could not be established by X-ray diffraction analysis. However, analogous investigations were successfully performed by the use of cyclopentadienyllanthanide derivatives. It appeared that rare-earth metals form two types of anthracene complexes through addition at either an edge or a plane; however, the arene ligand in both cases carries a negative charge –2.

The reaction of CpLuCl with the dianion or two radical anions of anthracene gave rise to heterobimetallic ate-complex **27** containing the anthracene dianion.⁷⁸

Neutral complexes of samarium (Cp^{*}Sm)₂(μ - $\eta^3 : \eta^3$ -C₁₄H₁₀) (**28**) and lanthanum (Cp^{*}La)₂(μ - $\eta^3 : \eta^3$ -C₁₄H₁₀)·2PhMe (**29**) with the anthracene dianion were prepared by oxidative addition of decamethylsamarocene to anthracene⁷² or by metathesis of the lanthanum potassium complex with disodium anthracene.⁷⁹

Both products are structurally similar. The planar anthracene dianion is $\eta^3 : \eta^3$ -bonded to two Cp^{*}Ln units located on the opposite sides of its plane. Apparently, the product of the reaction of Cp^{*}Sm with 9-methylanthracene, *viz.*, (Cp^{*}Sm)₂C₁₅H₁₂, has an analogous structure.⁷²

The reaction of C₁₄H₁₀^{2−} with CpLuCl₂ afforded a complex with different composition and structure, *viz.*, CpLu(C₁₄H₁₀^{2−})·2THF (**30**).^{80, 81}

In the complex **30**, the character of the bond between the Lu atom and the arene ligand is analogous to that observed in the complex **23**, *i.e.*, it can be interpreted as σ, σ -interaction although

the Lu–C(9,10) distances (2.44 and 2.45 Å, respectively) are somewhat longer than the analogous contacts in the naphthalene derivative **23**, but are substantially shorter than those in the binuclear anthracene compound (2.683, 2.850 and 2.882 Å). The folding angle of the anthracene molecule along the C(9)–C(10) line is 38.7° (29.9° for the second symmetrically independent molecule in the crystal).

The complex **30** containing the anthracene dianion was also synthesised by the reaction of CpLuCl₂ with the anthracene radical anion. In this case, free anthracene was detected in the reaction mixture.^{80,81}

Unlike the lanthanum and samarium complexes, lutetium dicyclopentadienyl chloride gave the ate-complex [CpLu(C₁₄H₁₀²⁻)]·[Na⁺(THF)] in the reactions both with C₁₄H₁₀^{·-} and C₁₄H₁₀²⁻.⁸¹ The replacement of coordinated THF by diglyme afforded complex **31**. The authors managed to grow perfect crystals of **31** and to establish its structure by X-ray diffraction analysis.⁸¹ It appeared that the character of the bond between anthracene and the lanthanide atom in this compound is similar to that in the complexes CpLu(C₁₀H₈)(DME) (**23**) and CpLu(C₁₄H₁₀²⁻) (**30**). The arene ligand is folded along the C(9)–C(10) line (the dihedral angle is 40.1°). The shortest distances between the anthracene ligand and the lutetium atom [Lu–C(9,10) are 2.473 and 2.482 Å, respectively] are only 0.03 Å larger than the corresponding distances in the complex **30**.

The reaction of the aminophosphine yttrium complex **9** with anthracene in the presence of KC₈ yielded the binuclear complex ((PhP[CH₂(SiMe₂)N(SiMe₂)CH₂]₂PPh)₂(μ-C₁₄H₁₀)) (**32**). The latter, like the anthracene derivatives **30** and **31**, contains the C₁₄H₁₀²⁻ dianion.⁶¹ The metal atoms in the compound **32** are located on the opposite sides of the aromatic ligand and are η⁴-bonded to the central ring and one terminal ring.

The coordinated rings are folded along the C(1)–C(4) and C(9)–C(10) lines. The shortest Y–C distances (the average values are 2.694 and 2.751 Å) are virtually identical to the corresponding distances in the naphthalene analogue **19a**. Based on the data of ¹H and ³¹P{¹H} NMR spectroscopy, it was assumed⁶¹ that in solution the metal-containing moieties in the

complex **32**, as those in the naphthalene derivative **19a**, migrate along the arene plane. It is significant that intermolecular migration of the {PhP[CH₂(SiMe₂)N(SiMe₂)CH₂]₂PPh}Ln moieties in the anthracene complexes or in mixtures of anthracene and naphthalene analogues does not occur. This is evidence that the complexes do not dissociate in solution in spite of the ionic character of the Ln–Arn bond.

V. Pyrene and benzoanthracene derivatives

Pyrene can form three types of complexes with rare-earth metals.⁸² The reaction of Cp₂*La(μ-Cl)₂K(THF)₂ (**33**) with the pyrene dianion in THF afforded red crystals with composition [Cp₂*La(THF)₂](C₁₆H₁₁) (**34**) in low yield. The ¹H NMR spectrum of **34** has nine signals with equal intensities and one double-intensity signal (at δ 4.12). The authors believed⁸² that these signals are indicative of the presence of the hydropyrene anion C₁₆H₁₁⁻, which was, apparently, formed as a result of detachment of protons from the solvent.

It was assumed⁸² that the [Cp₂*La(THF)₂]⁺ cation does not form a strong bond with the aromatic anion, *i.e.*, the complex in solution exists as a solvent-separated ion pair.

The reaction of the ate-complex **33** with pyrene and potassium in toluene taken in a ratio of 2:2:1 gave rise to black-green crystals. The NMR spectrum of these crystals corresponds to the binuclear complex (Cp₂*La)₂(μ-η²:η²-C₁₆H₁₀) (**35**). It was suggested⁸² that the Cp₂*La units in **35**, like those in the anthracene derivatives **29**, are located on the opposite side of the plane of the aromatic ligand and are bound to the opposite rings.

The samarium analogue (Cp₂*Sm)₂(μ-η³:η³-C₁₆H₁₀) (**36**), which was prepared by the reaction of free pyrene with Cp₂*Sm, differs in structure (according to the X-ray diffraction data) from **35**.⁷² Both metallocene moieties in **36** are coordinated at the edge of pyrene and are located above and below its plane, but they form three short contacts each with the adjacent rings rather than with the opposite rings.

The angles between the samarium atoms and the plane of the polycyclic ligand are 117° and 120°. The Sm–C distances are in the range of 2.660–2.806 Å, which is somewhat larger than the

corresponding distances in the allylic complexes $\text{Cp}_2^*\text{Sm}(\eta^3\text{-CH}_2\text{CHCHR})$ (2.551–2.643 Å),⁸³ but are substantially shorter than the $\text{Sm}-\text{C}$ bonds in the arene chloroaluminate compounds $[\text{ArnSm}(\text{AlCl}_4)_3]$ (2.89–2.91 Å).^{5, 7, 11}

In the reaction with the use of the reagent ratio $\text{Cp}_2^*\text{Sm}:\text{pyrene}:\text{THF} = 3:3:1$ or in the reaction of pyrene and potassium with the monocyclopentadienyl complex $\text{Cp}^*\text{LaCl}(\mu\text{-Cl})_2\cdot\text{Li}(\text{THF})_2$, pyrene was reduced to the trianion yielding the red-violet trinuclear complex $(\text{Cp}^*\text{LaCl})_2[\text{Cp}^*\text{LaCl}(\text{THF})](\text{C}_{16}\text{H}_{10})$ (**37**).⁸² According to the X-ray diffraction data, all three Cp^*LaCl moieties are located above the plane of the pyrene ligand. Two of these moieties are η^6 -bonded to the arene ligand, whereas the third moiety containing an additional coordinated THF molecule forms only two short $\text{La}-\text{C}(\text{pyrene})$ contacts.

The lengths of the $\text{La}-\text{C}$ bonds with the participation of the η^6 -coordinated rings are in the range of 2.766–3.072 Å and the lengths of the $\text{La}-\text{C}$ bonds with the participation of the η^2 -coordinated rings are 2.823 and 2.841 Å, which are 0.1 Å larger than the corresponding contacts in the naphthalene complex $[\text{I}_2\text{La}(\text{THF})_3]_2(\mu\text{-C}_{10}\text{H}_8)$ (**14**).

2,3-Benzoanthracene, like pyrene, readily reacts with Cp_2^*Sm to give green crystals of the complex $(\text{Cp}_2^*\text{Sm})_2(\mu\text{-}\eta^3:\eta^3\text{-C}_{18}\text{H}_{12})$ (**38**),⁷² which is structurally similar to the pyrene complex **36**. Two Cp_2^*Sm fragments are coordinated at the edge of the arene ligand and are located on the opposite sides of its plane. The distance from the Sm atoms to this plane is 2.063 Å. Both metal atoms are bound to the same central ring. The $\text{Sm}-\text{C}(\text{Arn})$ bond lengths (2.688–2.828 Å) are similar to those in the pyrene analogue **36**.

Interestingly, all permethylsamarocene complexes with arenes, unlike other arenelanthanides, are readily decomposed upon dissolution in THF to form $\text{Cp}_2^*\text{Sm}(\text{THF})_2$ and the corresponding polycyclic hydrocarbon.⁷² This lability of the $\text{Sm}-\text{Arn}$ bond may be evidence for its nonvalent character, *i.e.*, the formation of these derivatives is not accompanied by redox processes and the coordination complexes $[\text{Cp}_2^*\text{Sm}(\text{II})]_2(\text{Arn}^0)$ are formed. However, the ^1H and ^{13}C NMR spectra of the reaction products are unambiguously indicative of the change in the valence state of the metal atom from $\text{Sm}(\text{II})$ to $\text{Sm}(\text{III})$ in the course of the reaction and, consequently, the arene ligand in the complexes exists as the dianion. The $\text{Sm}-\text{Cp}^*$ distances in these complexes and their electronic spectra also correspond to trivalent samarium. The characteristic feature of the permethylsamarocene complexes with arenes is the allylic type of bonding between the arene ligand and the Cp_2^*Sm unit.⁷²

VI. Complexes with heterocyclic aromatic ligands

The great majority of complexes of rare-earth metals with heterocyclic aromatic ligands are formed through coordination interaction between the lone electron pair of the heteroelement and the Ln atom.¹ In these complexes, the ligands can be either neutral or charged (-1 or -2). The charges are localised primarily on heteroatoms. However, examples of compounds similar in nature to typical bisarene complexes are also available. One of them, *viz.*, $(2,4,6\text{-Bu}_3\text{C}_5\text{H}_2\text{N})_2\text{Sc}$, was prepared under conditions of the cryogenic synthesis.³ It was suggested that this compound contains the formally zero-valent scandium atom and the neutral *tert*-butyl-substituted pyridine ligands. The molecule was represented as a planar-parallel sandwich.

The reaction of Cp_2^*Sm with phenazine, like that with anthracene, afforded the binuclear complex $(\text{Cp}_2^*\text{Sm})_2(\mu\text{-}\eta^3:\eta^3\text{-C}_{12}\text{H}_8\text{N}_2)$ (**39**) in which the samarocene fragments are in the transoid orientation with respect to the $[\text{C}_{12}\text{H}_8\text{N}_2]^{2-}$ dianion.⁷² The presence of three short contacts between the samarium atoms and the phenazine ligand are indicative of the allylic type of bonding.

The $\text{Sm}-\text{N}$ bond length (2.360 Å) is slightly larger than the $\text{Sm}-\text{N}$ σ -bond length in the complex $\text{Cp}_2^*\text{SmN}(\text{SiMe}_3)_2$ (2.306 Å),⁸⁴ which is evidence for substantial localisation of the charge on the nitrogen atoms, as in the complexes of the $\text{Cp}_3\text{Ln}(\text{py})$ ¹ and $\text{Ln}(\text{bipy})_4$ types (bipy is 2,2'-bipyridyl).⁸⁵

The reaction of permethylsamarocene with acridine was accompanied by dimerisation of the latter to form a $\text{C}-\text{C}$ bond.⁷³

The character of the metal–arene bond in the complex **40** is analogous to that in the phenazine derivative, *i.e.*, corresponds to η^3 -interaction, with the $\text{Sm}-\text{N}$ component predominating.

Arene lanthanide complexes of an unusual type were prepared by cocondensation of vapours of scandium and *tert*-butylphosphoalkyne $\text{Bu}^t\text{C}\equiv\text{P}$ at 77 K.⁸⁶ The reaction was accompanied by cyclisation of the phosphoalkyne giving rise to two products, *viz.*, dark-violet scandocene $(\eta^5\text{-Bu}_3\text{C}_3\text{P}_2)_2\text{Sc}$ containing divalent scandium and the green triple-decker complex $[(\eta^5\text{-Bu}_3\text{C}_2\text{P}_3)\text{Sc}]_2$ (**41**) containing formally monovalent scandium. The valence states of the scandium atoms in both complexes were unambiguously established by UV and ESR spectroscopy and magnetic measurements. The structure of the triple-decker complex was confirmed by X-ray diffraction analysis.⁸⁷ The central six-membered ring in the complex **41** is located on a crystallographic mirror plane. All $\text{P}-\text{C}$ bond lengths in this ring have closely similar values (1.793–1.807 Å).

It is worthy of note the distance from Sc to the central ring in the compound **41** is noticeably shorter (1.787 Å) than the analogous distance in the bisarene complex $(\text{Bu}^t_3\text{C}_6\text{MeH}_2)_2\text{Sc}$ (1.983 Å).⁸⁷ In spite of the valence state +1 untypical of scandium, the compound **41** is quite stable and can be even sublimed *in vacuo* at 250 °C. The magnetic moment (3.98 μ_B) of **41** is somewhat smaller than the value calculated for four unpaired electrons, which was attributed to the presence of an orbital contribution.⁸⁷

VII. Reactivity of arene lanthanide complexes

The chemical properties of complexes of rare-earth metals with π -bonded arene ligands were studied primarily using naphthalene derivatives as examples. For compounds with other aromatic hydrocarbons, only the most common characteristics are known. All arene lanthanide complexes exist as dark-coloured solids, which are readily oxidised in air (often with ignition). It was found that bisarene complexes of formally zero-valent Sc, Y, Nd, Gd, Tb, Dy, Ho, Er and Lu are thermally stable under an inert atmosphere or *in vacuo*. Some of them can even be sublimed with insignificant decomposition at 100 °C (at 10^{-4} mm Hg). These complexes are readily soluble in aromatic and aliphatic hydrocarbons. Complexes with arene dianions are virtually insoluble.

The yttrium complex $(1,3,5\text{-Bu}^t_3\text{C}_6\text{H}_3)_2\text{Y}$ (**5b**) readily reacted with phenol, 2,4,6- $\text{Bu}^t_3\text{C}_6\text{H}_2\text{OH}$ and hexamethyldisilazane to form tri(aryloxyde) (**42**) and yttrium tris(trimethylsilyl)amide (**43**) in good yields. The reaction of the holmium complex **5c** with bi-*tert*-butyl-1,3-diazabuta-1,3-diene (DAD) also resulted in complete replacement of the arene ligands.³

Ln = Y (**b**), Ho (**c**); DAD = $\text{Bu}^t\text{N}=\text{CHCH}=\text{NBu}^t$.

All $(\text{Ar}_n)_2\text{Ln}$ complexes are efficient catalysts of ethylene polymerisation.

Naphthalene lanthanide complexes of all types exhibit very high reactivities with respect to many inorganic, organic and organometallic compounds. Essentially in all cases, these complexes act as strong reducing agents comparable in reducing ability to alkali metal naphthalenides. The reactions were carried out in THF or DME at room or lower temperature. Generally, the yields of the products many of which were characterised by X-ray diffraction studies are higher than 60%–70%. Hence, these reactions may be recommended as preparative (often the only

possible) procedures for the synthesis of organolanthanide compounds. The important advantage of these syntheses is the fact that the second product, *viz.*, naphthalene, is unreactive and can be readily separated from the target compound. The reactions with the participation of the complexes $(\text{C}_{10}\text{H}_8)\text{Ln}(\text{THF})_x$ are listed in Table 1.

The compounds $(\text{C}_{10}\text{H}_8)\text{Ln}(\text{THF})_x$ also exhibit high reactivity in catalytic processes. Thus the complex $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_3$ catalyses hydrogenation of hex-1-ene, stilbene, isoprene and piperylene at room temperature under atmospheric pressure of H_2 yielding the corresponding hydrocarbons.⁴¹ Tolan was hydrogenated to form *trans*-stilbene and diphenylethane. In the presence of 1%–5% of $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_3$, styrene, methyl methacrylate, ethyl acrylate, isoprene and piperylene formed polymers at room temperature.⁴⁸ The conversion reached 100% in several hours. Piperylene produced more than 80% of the *trans*-polymer, whereas polyisoprene was obtained as a mixture of virtually equal amounts of *cis* and *trans* forms. Naphthaleneytterbium catalyses polymerisation of epoxides and their reactions with CO_2 . In the latter case, a mixture of monomeric and polymeric alkyl carbonates was obtained.⁴⁸ It is interesting to note that naphthalene complexes of 'trivalent' lanthanides, which were not isolated in the individual state, appeared to be efficient catalysts of polymerisation of conjugated dienes.⁴³ The reactions of the latter [like that of $(\text{C}_{10}\text{H}_8\text{Tm})_2(\text{C}_{10}\text{H}_8)$] with cyclopentadiene afforded the corresponding Cp_3Ln in 15%–60% yield depending on the metal.^{52, 53}

It was found⁵⁸ that the products of the reaction of NdCl_3 with $\text{C}_{10}\text{H}_8\text{Li}$ (apparently, the reaction afforded naphthalene neodymium complexes rather than finely dispersed neodymium as has been suggested in Ref. 58) readily reacted with ketones and aldehydes to yield the corresponding diols or ethylene derivatives as a results of coupling of the substrate.

Generally, mixed-ligand complexes containing naphthalene as well as the iodine atom, the cyclopentadienyl substituent or the double-decker $\text{CpV}(\text{C}_{10}\text{H}_8)$ moiety bound to the rare-earth element react analogously to compounds of the $(\text{C}_{10}\text{H}_8)\text{Ln}(\text{THF})_3$ type, *i.e.*, the attack occurs primarily on the $(\text{C}_{10}\text{H}_8)\text{Ln}$ group. Due to the presence of the LnI or LnCp groups along with the $\text{Ln}(\text{C}_{10}\text{H}_8)$ moiety, these complexes are convenient starting compounds for the preparation of complexes of the RLnI or RLnCp types. The most typical reactions are given in Table 2.

The chemical properties of anthracene lanthanide complexes are analogous to the properties of their naphthalene analogues. However, the activities of the former are substantially lower. Thus the reactions of anthraceneytterbium with cyclopentadiene, fluorene, 9-*tert*-butylfluorene, tetraphenylpropene and 9-phenylxanthene in solutions afforded the corresponding anions, *i.e.*, the R_2Ln compounds apparently formed, but the reaction rates were low (from several days to weeks). Triphenylmethane did not enter into the reaction at all.⁷⁶ Deuterolysis of the complexes $(\text{C}_{14}\text{H}_{10})\text{Ln}(\text{THF})_x$ ($\text{Ln} = \text{Sm}$ or Yb) gave rise to 9,10-dideutero-9,10-dihydroanthracene,^{48, 74} whereas their reactions with MeI afforded a mixture of 9,10-dimethyl-9,10-dihydroanthracene (14%–20%), $\text{MeC}_{14}\text{H}_9$ (1%–4%) and 9,10-dihydroanthracene (13%–25%). It is noteworthy that attempts to alkylate naphthalene in the reactions of naphthaleneytterbium with different alkyl halides have not met with success. In all cases, only unsubstituted naphthalene was obtained.[‡]

For anthracene mixed-ligand complexes of lanthanides, only the reaction of $\text{CpLu}(\text{C}_{14}\text{H}_{10})(\text{THF})_2$ with iron pentacarbonyl giving rise to the heterobimetallic product with composition $[\text{CpLu}(\text{THF})]\text{Fe}(\text{CO})_4$ was reported.¹⁰⁶

‡ Unpublished data of the author of the present review.

Table 1. Reactions of the naphthalene complexes $(C_{10}H_8)Ln(B)_x$ ($Ln = Sm, Eu$ or Yb ; $B = THF$ or DME , $x = 2$ or 3).

Substrate	Products	Ref.
O_2	$Ln_2O_3 + C_{10}H_8$	48
H_2	$LnH_2 + C_{10}H_8$	88, 89
H_2O	$C_{10}H_{10} + Ln(OH)_3$	48
Bu^tOH	$(Bu^tO)_2Ln + C_{10}H_8$	see ^a
R_2NH [$R = Et, N(SiMe_3)_2$]	$(R_2N)_2Ln + C_{10}H_8 + C_{10}H_{10} + H_2$	48
CpH	$Cp_2Ln + C_{10}H_8 + H_2$	48
$IndH^b$	Ind_2Yb	see ^a
$FluH^c$	Flu_2Yb	see ^a

^a For Eu and Yb.

VIII. Conclusion

Based on analysis of the available data, the characteristic features of complexes of rare-earth metals with π -bonded arene ligands were revealed. First, it should be noted that these compounds exist in the two major forms, *viz.*, with neutral arene or with the arene dianion. Forms with arene carrying a charge -1 or -3 are untypical of these complexes. Apparently, these forms can be obtained and exist only under particular conditions. It should be noted that the tendency of lanthanides to form complexes of the $[\text{Ln}]^{2+}[\text{L}]^{2-}$ type even in the presence of the free uncharged ligand is also observed in the case of other ligands (such as bipy[§] or DAD) exhibiting polyvalence.¹⁰⁷ The mode of bonding of lanthanide with arene ligands can vary from η^2 to η^6 . The Ln atom can be coordinated both at the plane of the arene ligand and at its edge. The character of the Ln–Arn bond in complexes with neutral arene and formally zero-valent lanthanide is similar to the character of the metal–arene bond in complexes of *d* metals, *i.e.*, the bond is determined by back donation of the electron density from the occupied d_{xy} and $d_{x^2-y^2}$ orbitals of lanthanide to the unoccupied π -orbitals of arene. In compounds with neutral ligands coordinated to the Ln^{3+} cation {complexes of the $(\text{Arn})\text{Ln}[(\mu\text{-Cl})_2\text{AlCl}_2]_3$ or $\text{Ln}(\text{OC}_6\text{H}_3\text{Ph}_2\text{-2,6})_3$ types}, the *d* orbitals of the metal atoms are unoccupied and interactions occur, apparently, through donation of the electron density from the π -orbitals of the arene ligand to the unoccupied orbitals of the metal atom. The metal–arene bonds in these compounds are substantially weaker as evidenced by the noticeably elongated Ln–C(arene) bonds. In complexes containing Ln^{2+} , $(\text{XLn})^{2+}$ or $(\text{X}_2\text{Ln})^+$ cations and the arene dianion (naphthalene lanthanide complexes and related derivatives) bonding occurs, apparently primarily through Coulomb interactions between the positively and negatively charged moieties of the molecule. However, the structures of the complexes and the fact that these complexes contain the shortest Ln–C(arene) bonds of all arene lanthanide complexes are indicative of the presence of the second bonding component, *viz.*, of donation of electron density from the π -orbitals of arene to the unoccupied orbitals of the metal atom. In spite of the high (judging from the geometric parameters of the molecules) energy of the metal–arene bond, naphthalene lanthanide complexes exhibit very high reactivity. At the same time, these complexes are readily accessible owing to which they show promise as a source of lanthanides or lanthanide-containing fragments in the synthesis of other derivatives of rare-earth metals.

The review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 00-03-32875).

Solid-phase synthesis of oligosaccharides and glycoconjugates

N K Kochetkov

Contents

II. The methodology of synthesis of oligosaccharide chains on solid supports	795
III. Model syntheses of di- and trisaccharides	798
IV. Synthesis of higher oligosaccharides	801
V. Synthesis of glycopeptides	811
VI. Synthesis of phosphoglycans	817
VII. Conclusion	819

Abstract. The use of polymeric supports for directed regiospecific assembly of oligosaccharides, glycopeptides and phosphoglycans is considered. In some cases, synthesis of oligosaccharides on supports is more efficient than the corresponding synthesis in solution, although this cannot still compare favourably with the latter. Examples of successful solid-phase syntheses of complex oligosaccharides and glycoconjugates are given. Special emphasis is laid on the choice of optimum supports, linkers and glycosylation methods. The bibliography includes 105 references.

I. Introduction

The explosive development of molecular biology is closely connected with recent advances in the chemistry and biochemistry of biopolymers including the development of efficient techniques for their targeted chemical synthesis. The recently developed approaches to the synthesis of biopolymers are based on essentially new principles for elongation of the polymeric chains including their assembly on polymeric supports.

This method was first employed by Merrifield for the synthesis of peptides.¹ After solution of numerous methodological problems, this protocol, which is sometimes improperly referred to as 'solid-phase synthesis', was successfully automated and became the main routine procedure in peptide synthesis.

An enormous body of experimental evidence published in the past two-three decades point to the prominent role of biopolymers, such as polysaccharides and glycoconjugates (glycoproteins, glycolipids) in vital processes. These polymers are indispensable participants in many biological processes (*e.g.*, antigen–antibody, enzyme–substrate and ligand–receptor interactions) as well as in some other interactions of carbohydrates with proteins.^{2,3}

The first attempts aimed at synthesising oligosaccharide chains on solid supports were undertaken in the early 1970's;^{4,5} however, it became clear that rapid progress in this area was hardly possible, since chemical synthesis of oligosaccharides with

a strictly determined sequence of monomeric units presented a serious problem due to the polyfunctionality of monosaccharides and the stereochemical ambiguity of intermonomeric glycosidic bond formation.

At present, synthesis of oligosaccharides on polymeric supports still cannot compete with the classical synthesis in solution, but its development is in progress and the methodology is improved. This is associated with the fact that in many cases syntheses on supports are more advantageous. Numerous examples of successful application of the solid-phase approach in the synthesis of complex oligosaccharides and glycoconjugates are currently known.

A vast body of experimental material accumulated thus far highlights the major problems and advances in solid-phase synthesis of carbohydrate-containing compounds and allows estimation of its possible application for realistic syntheses. It seems therefore expedient to sum up these data in order to inform all those who are concerned with this subject about the potential of the method and the problems it may involve.

The review covers the publications appearing up to 1999 inclusive.

II. The methodology of synthesis of oligosaccharide chains on solid supports

The synthesis of oligosaccharides on solid supports includes immobilisation of the first unit from which elongation of the oligosaccharide chain begins on a specially selected optimum support followed by elongation of the oligosaccharide chain using specific methods for the formation of interglycosidic linkages (*viz.*, by glycosylation) and removal of the oligosaccharide molecules thus synthesised from the polymeric support without any sacrifice of their structures. The peculiarity of carbohydrate chemistry is manifested in all steps of the solid-phase oligosaccharide synthesis, which makes it different from peptide and nucleotide syntheses.

1. Supports

Oligosaccharide syntheses are carried out both on insoluble solid supports and on soluble polymers. In the former case, the reaction proceeds in heterogeneous media, in the latter case, in homogeneous media.

The obvious advantage of insoluble solid supports is that the isolation and purification of the reaction products after each step is achieved by simple filtration and washing with a solvent.

Furthermore, the reaction rate can be increased if one of the reagents, which can be regenerated following the reaction, is taken in a large excess. The main disadvantage of insoluble supports is that the reaction occurs on a solid surface, which hampers the access of the reagent to the reaction centre and poses additional difficulties in regulation of regio- and stereoselectivity of the reaction.

Syntheses of oligosaccharide chains anchored to soluble polymeric supports are partly devoid of this drawback but purification of the reaction product becomes more difficult. In this case, the polymer-bound reaction product has to be precipitated by addition of another solvent and purified by repeated precipitations. The use of an excess of a reagent for acceleration of the reaction is also undesirable, since in this case its complete removal, which is necessary to ensure the desired sequence of the monomeric units in the 'growing' chain, faces difficulties. On the other hand, glycosylation in a homogeneous medium offers better opportunities for regulation of regio- and stereospecificity of the reaction.

Currently, both types of supports for the synthesis of oligosaccharides are employed; however, synthesis on soluble polymers (especially, synthesis of glycoconjugates) has acquired ever increasing importance in recent years.

a. Insoluble solid supports

The efficiency of solid-phase synthesis strongly depends on the physicochemical properties of solid supports, such as porosity and swelling capacity in different solvents. These characteristics are very important, since they determine the accessibility of immobilised molecules to the reagent present in the solution. The number of moles of the first monomeric unit from which elongation of the chain begins, which can be immobilised per g of the polymeric support (the so-called 'loading'), is yet another factor of considerable practical importance.

In the early period of solid-phase oligosaccharide synthesis, polystyrene-based resins prepared by copolymerisation of styrene with *p*-divinylbenzene were predominantly employed. Commercial resins of this type are now available as powders with particles having spherical shapes ('beads') and differing in the degree of cross-linking, porosity, swelling capacity and particle size.[†] Modified polystyrenes containing reactive chloromethyl (Merrifield's polymer), phenolic hydroxy groups,⁷ mercaptomethyl,⁸ sulfonylmethyl,⁹ diphenyl- and diisopropylchlorosilyl,¹⁰ (3-mercaptopropyl)oxy(thio)methyl^{11,12} and some other groups are most commonly used as supports. The choice of a particular polystyrene resin as a solid support is determined by the strategy of a realistic synthesis, the mode of attachment of the first monomer to the solid phase and the structure of the linker. Sometimes, the role of a linker is played by the functional group of the polystyrene resin.

A main disadvantage of polystyrene resins used in solid-phase oligosaccharide synthesis is their poor compatibility with biomolecules. For example, the yields of oligosaccharides in enzymic solid-phase synthesis catalysed by glycosyl transferases were low to such an extent that this method had to be abandoned as being impractical.

Attempts were undertaken aimed at using polyacrylamide gels as supports. Prior to the use, the gels were modified, *e.g.*, by incorporation of aminoethyl groups.¹³

Controlled-pore glasses (CPG) with a modified surface, *e.g.*, with grafted 3-aminopropyl groups serving to attach the first monomer (see, *e.g.*, Refs 14 and 15), are currently employed with increasing frequency. The surface of CPG-based supports can be modified by silanisation with prior zirconation.¹⁶ The use of CPG has a number of advantages, since they offer broad opportunities in the selection of supports of desired porosity and allow appropriate modification of the surface.

[†] A brief survey of polymeric substrates for solid-phase syntheses is given in Ref. 6.

b. Soluble supports

These types of supports have currently acquired wide popularity. The simplest soluble support is polyethylene glycol (PEG) ($M_r \sim 5,000$ Da) in which one of the terminal hydroxy groups is methylated and the other one is free and serves to immobilise the first monomer (either directly or through a linker).¹⁷ Commercially available PEG is easily soluble in many solvents.

Polymers of a hybrid type, containing both hydrophobic and hydrophilic fragments, have received considerable attention in the last few years. The synthesis on such materials is carried out in a 'micromedium', *i.e.*, under conditions mimicking those of a homogenous reaction, and at the same time allows easy isolation of the reaction products after each step. These polymers include a copolymer of acrylamide or its N-substituted derivatives with polyethylene glycol (PEGA) possessing terminal amino groups¹⁸ and a copolymer of polystyrene with polyethylene glycol (Tentagel).¹⁹ Other more sophisticated copolymers are also used and will be discussed below.

2. Linkers

In solid-phase syntheses of oligosaccharides, the first monomer is usually attached to the support through a bifunctional group (the so-called linker) rather than directly. The linker serves both to bind the monomer to the polymer and to make the monomer and the growing chain remote from the support in order to minimise the influence of the solid surface on the course of the reaction. The latter circumstance is especially important, since heterogeneity of the medium has a specific, sometimes rather obscure effect on the stereochemistry of the newly formed glycosidic linkage.

In deciding upon a linker, allowance should be made for the possibility of selective cleavage of one of its linkages in the release of the oligosaccharide synthesised from the solid support without affecting labile glycosidic bonds.

In early oligosaccharide syntheses, the first monosaccharide was immobilised on chloromethyl-polystyrene without linkers. However, later the use of linkers differing in structures and chemical properties became common practice.

It should be noted that in contrast with the conventional solid-phase peptide and oligonucleotide syntheses, diverse linkers are utilised in solid-phase syntheses of carbohydrates. The choice of a suitable linker for a realistic purpose is an indispensable step in the design of a synthesis. In the synthesis of glycopeptides, the peptide chain is often used as a linker which also removes the growing carbohydrate chain from the surface of the support. A more detailed description of linkers will be given further below in relation to particular syntheses.

3. Elongation of the oligosaccharide chain

This step is crucial in oligosaccharide synthesis, therefore the choice of a method for the formation of glycosidic bonds between the monosaccharides (*i.e.*, method of glycosylation) determines the overall strategy of the synthesis. The predetermined sequence of monosaccharides necessitates that the formation of glycosidic linkages is strictly regio- and stereospecific. A prerequisite for the preparation of homogeneous oligosaccharides with a predetermined structure, which should not require any additional purification (it is this that makes solid-phase synthesis advantageous in comparison with the classical synthesis in solution), is that the yields were close to quantitative in all steps. The lack of a versatile glycosylation procedure (optimal for all monosaccharides) makes the implementation of these requirements extremely difficult, which is the main reason for the relatively slow progress in the solid-phase synthesis of oligosaccharides.

Two problems seem to be especially difficult to overcome. The first of them is that successful synthesis of any biopolymer consisting of 40–50 monomeric units with a predetermined sequence (without deletions or 'erroneous' units) requires that the yield in each elongation step is no less than 97%–98%. Meanwhile, even the most advanced glycosylation methods do not ensure such high yields, which in addition vary strongly

depending on the nature of the monosaccharide and the type of the newly formed glycosidic linkage. The second problem is related to stereochemical ambiguity of the glycosylation reaction,[‡] which makes the oligosaccharide synthesis different in principle from the peptide and oligonucleotide syntheses, although it is known, for example, that the synthesis of the 1,2-*trans*-glycosidic bond is usually stereospecific. So far, the use of solid-phase synthesis is effective only for the preparation of relatively short oligosaccharides.

Yet another problem inherent in the solid-phase synthesis of oligosaccharides is related to the polyfunctionality of monosaccharides. The formation of (1-2), (1-3), *etc.*, intermonomeric glycosidic linkages requires temporary protection of hydroxy groups which are not involved in the glycosylation reaction. In the general case, synthesis of irregular oligosaccharides (*viz.*, those in which the monosaccharide components are either different or identical but differ in the type of bonding) requires specific protection depending on the type of the glycosidic bond for each monosaccharide. After the glycosylation step, the type of protection of hydroxy groups must be changed up to complete removal of the existing and introduction of new protecting groups. This sophisticated procedure makes oligosaccharide synthesis technically cumbersome in comparison with peptide and oligonucleotide syntheses. Sometimes, as in the case of homopolysaccharide synthesis, elongation of the oligosaccharide chain involves the same set of procedures, but even in these cases the passage from attachment of one monomeric fragment to the other is complicated and automation of the synthetic protocol presents a problem.

In designing a general strategy for oligosaccharide synthesis with any combination of protecting groups, it is necessary, first of all, to define the order in which the oligosaccharide chain has to be elongated. The elongation is typically carried out in two directions, *viz.*, from the reducing end of the chain to the non-reducing one (route **A**) or *vice versa* (route **B**) (Scheme 1). In the former case (route **A**), the monosaccharide immobilised on a solid support through a glycosidic hydroxyl is used as a glycosyl acceptor and

the second monosaccharide present in the solution plays the role of a glycosyl donor. In the latter case (route **B**), the first monosaccharide is attached to the support through one of the hydroxy (non-glycosidic) groups and serves as a glycosyl donor, whereas the second monosaccharide remains in the solution and fulfils the function of a glycosyl acceptor. Naturally, the protecting groups and manipulations with them in each stage of the solid-phase synthesis are different in these two routes. If the synthesis is to be performed *via* the route **A**, it is in the terminal monosaccharide of the glycosyl acceptor that the protection of the hydroxy groups should be changed or selectively removed, whereas in the case of the route **B** it is necessary to introduce or establish a group activating the glycosidic centre in the terminal monosaccharide of the glycosyl donor. Obviously, the reagents present in a solution, *e.g.*, a glycosyl acceptor (route **B**) or a glycosyl donor (route **A**), should also contain appropriate protecting groups.

Glycosylation can be carried out by chemical methods or using specific enzymes (most often, glycosyl transferases), which changes the whole strategy of the solid-phase synthesis and eliminates the problem of temporary protection of the monosaccharide units.

a. Chemical glycosylation methods

The pioneering studies of solid-phase oligosaccharide synthesis utilised classical glycosylation with glycosyl halides (predominantly, per-*O*-acetylglycosyl bromides)[§] under conditions of the Koenigs–Knorr or the Helferich reaction⁴ as well as the ortho-ester glycosylation method.²² However, insufficiently high yields and the lack of complete stereospecificity in the formation of glycosidic bonds devalue these methods for use in solid-phase synthesis. Other glycosylation methods based on the use of thio-glycosides (in the presence of activators), glycosyl tosylates,²³ glycosyl sulfoxides,²⁴ *etc.*, as glycosyl donors, have also been explored.

Glycosylation with sugar *O*-trichloroacetimidates proved to be especially efficient.²⁵ This procedure provides sufficiently high yields for a wide variety of monosaccharides. Unfortunately, the stereospecificity of this reaction and the effect of the configuration of the trichloroacetimidate on the steric outcome of the reaction still present a problem; therefore, the practical utility of this reaction in solid-phase synthesis of relatively high-molecular-weight oligosaccharides still remains to be elucidated.

Recently, Danishefsky *et al.*²⁶ proposed to use the so-called glycal approach²⁵ for the synthesis of relatively short oligosaccharides and glycoconjugates with more complex structures where 1,2-anhydrosugars were used as donors. This procedure has not received wide application in conventional oligosaccharide syntheses yet, but has been used to develop a convenient scheme for a solid-phase synthesis (see below).

b. Enzymic glycosylation

The elongation of the oligosaccharide chain immobilised on a support can also be carried out by biochemical methods,[¶] *i.e.*, using enzymes which transfer a monosaccharide residue from the corresponding nucleoside diphosphate sugar (NPPSug) to the end of the growing chain (Scheme 2).

The main advantages of the enzymic approach are good yields and, which is more important, high regio- and stereospecificity of

‡ A critical review of the stereospecificity of the main glycosylation reactions is given in Ref. 20.

§ An overview of various glycosylation methods is given in Ref. 21.

¶ The biosynthesis of oligosaccharides is described in a review.²⁷

glycosylation. Moreover, in this case no protection of the monosaccharide hydroxy groups is necessary, which significantly simplifies the synthetic procedure. However, sometimes the high specificity of enzymic glycosylation may have a negative effect, *viz.*, where different monosaccharides are to be introduced or different types of glycosidic bonds are to be formed. The reason is that in these cases each elongation step would require its own, specific enzyme because of the normally narrow specificities of glycosyl transferases. Moreover, the specificities of enzymes can depend both on the nature of the monosaccharide donor and the monosaccharide acceptor and on the nature of adjacent monosaccharides in the fragment of the oligosaccharide chain synthesised.

Yet another characteristic feature of enzymic glycosylation which should be taken into consideration in conducting solid-phase synthesis is a noticeable dependence of the outcome of the reaction on the nature of the support and the structure of the linker. This can be explained by the fact that the accessibility of the reaction centre of the oligosaccharide chain, which is immobilised on a solid support, for the enzyme, which itself represents a macromolecule, and the formation of an enzyme–support complex are impeded in comparison with enzymic reactions carried out in a solution. Therefore, the requirements for supports and linkers, which enable contact between the reacting molecules, are more stringent. This is the main reason why soluble and conformationally flexible polymers and structurally complex linkers are employed where enzymic methods are used for oligosaccharide synthesis on polymeric supports. (As noted above, glycosyl transferases cannot be used for enzymic oligosaccharide syntheses on polystyrene-based resins due to incompatibility of these structurally different macromolecules).

Although the first attempts to use enzymes in solid-phase syntheses of oligosaccharide date back to the 1980's, it was not until recently that this method received wide application.

III. Model syntheses of di- and trisaccharides

The pioneering studies on solid-phase oligosaccharide synthesis were aimed at elucidating the feasibility of this technique for preparing this class of compounds. The simplest di- and trisaccharides were the first to be synthesised.

Thus Frechet and Scheurch⁴ carried out the synthesis of D-glucopyranosyl-(1-6)-D-glucose and the corresponding trisaccharide with 1-6-bonds using elongation of the oligosaccharide chain immobilised on an insoluble support from the reducing end (Scheme 3). Treatment of a polystyrene resin modified by introduction of allyl alcohol residues²⁸ with 2,3,4-tri-*O*-benzyl-6-*O*-(*p*-nitrobenzoyl)-D-glucopyranosyl bromide (**1**, R = NO₂) or its *p*-methoxybenzoyl analogue (**1**, R = MeO) resulted in immobilisation of a protected glucose residue after which the acyl protection of the hydroxy group at position 6 was removed. The glucose residues in the polymer **2** were glycosylated with the same bromides. The immobilised disaccharide residues in the polymer **3** were subjected to repeated deacylation and glycosylation to obtain a trisaccharide. The polymer **3** containing disaccharide residues (or its analogue containing trisaccharide residues) was subjected to ozonolysis in order to detach the reaction product, *viz.*, the corresponding di- or trisaccharide. After reduction, the reaction products were isolated as the corresponding 2-hydroxyethyl glycosides. The disaccharide **4** represented an anomeric mixture of derivatives of α - and β -D-glucopyranosyl-(1-6)-D-glucose (*i.e.*, isomaltose and gentiobiose). Thus, the solid-phase synthesis was not stereospecific and did not differ in this respect from the corresponding reaction in solution.

An alternative scheme for the solid-phase synthesis of β -D-glucopyranosyl-(1-6)-D-glucose (gentiobiose) was proposed by Guthrie *et al.*⁵ who used an orthoester glycosylation method[†]

for the elongation of the chain (Scheme 4). The linear polymer **5**, which contained glucose residues linked through a 6-hydroxy group, was prepared by copolymerisation of styrene with 1,2,3,4-tetra-*O*-acetyl-6-*O*-(*p*-vinylbenzoyl)-D-glucopyranose or its 6-*O*-(*p*-vinylphenyl)sulfonyl analogue. The glucose residues immobilised on the polymer were converted into the corresponding 1,2-orthoester residues. The resulting polymer **6** was used as a glycosyl donor. Its reaction with methyl 2,3,4-tri-*O*-benzoyl- α -D-glucopyr-

[†] For a review on the orthoester glycosylation method, see Ref. 22.

anoside under standard conditions of orthoester glycosylation afforded the gentiobiose derivative **7** (yield 64%) which was detached from the polymer by treatment with sodium methoxide. Since glycosylation of primary alcohols with orthoesters is stereospecific, this solid-phase synthesis was also stereospecific and yielded exclusively gentiobiose.

These two studies demonstrated that glycosidic bonds can be formed in heterogeneous reactions and that the value of solid-phase oligosaccharide syntheses does not exceed that of conventional syntheses in solution. Further developments in this field were aimed at overcoming some of the methodological problems, such as the choice of supports, construction of linkers suitable for support immobilisation, intermittent treatment of the polymer, *etc.* The applicability of the solid-phase approach to the synthesis of other simplest oligosaccharides was studied in parallel.

Thus the solid-phase synthesis of D-glucopyranosyl-(1-3)-D-glucose²⁹ was carried out with the aim of examining the possibility of glycosylation of a less reactive secondary hydroxy group (Scheme 5). To this end, 2,4,6-tri-*O*-acetyl-D-glucopyranose was immobilised on a polystyrene-based resin through a linker (succinic acid residue). The glycosyl acceptor **8** thus immobilised was glycosylated with 2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl bromide under conditions of the Helferich reaction (48 h, 30 °C). The polymer **9** was separated and washed, after which glycosylation was repeated two more times. The acylglycosidic linkage in the polymer **9** was cleaved with hydrazinium acetate. The yield of the disaccharide, which represented a mixture of an α - (nigerose) and a β -isomer (laminaribiose) ($\sim 3:2$), was 81%.

Scheme 5

Glycosylation with 3,4,6-tri-*O*-acetyl-2-*O*-benzyl- α -D-glucopyranosyl bromide was stereospecific; the yield of the α -linked disaccharide was 55%. Thus, the feasibility of glycosylation of immobilised monosaccharides at a less reactive secondary hydroxy group under conditions of a solid-phase synthesis has been demonstrated.

In more recent studies, a succinic acid-based linker has been applied for chemical and enzymic syntheses of oligosaccharides on soluble supports. Krepinsky *et al.*³⁰ were the first to use this linker for immobilisation of the first monosaccharide on the monomethyl ether of PEG. Glycosylation of the thus immobilised monosaccharide derivatives (*e.g.*, methyl galactopyranoside, methyl 2-deoxy-2-phthalimido- β -D-glucopyranoside or 1,6-anhydro- β -D-glucopyranose) was carried out with glycosyl bromides or *O*-glycosyltrichloroacetimidates in the presence of the corresponding promoters. The resulting disaccharides[‡] were easily split off the support after completion of the synthesis. At the same time, there were some difficulties associated with the separation of the immobilised product from an excess of the glycosylating reagent

present in the solution which, as was mentioned above, is a disadvantage of the use of soluble polymers as supports.

A similar approach was used in the synthesis of β -D-glucopyranosyl-(1-6)-D-galactose. In this case, the glycosyl acceptor (*viz.*, selectively protected methyl α -D-galactopyranoside with a free primary hydroxy group) was immobilised on a soluble support (Tentagel) through an OH group at position 2 or 3 using succinic acid as the linker. Glycosylation of the immobilised monosaccharide with *O*-(2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl) trichloroacetimidate was stereospecific; the yield of the disaccharide liberated from the polymer by treatment with aqueous ammonia varied from 50% to 70% depending on the promoter.¹⁹

In order to facilitate detachment of oligosaccharides from the supports, it was proposed⁸ to use the thioglycoside linkage for the binding of the first monosaccharide. This linkage was formed either in a reaction of 1-thio sugars with chloromethylated polystyrene or in a reaction of acylglycosyl halides with polystyrene containing HSCH₂ groups. A model synthesis was that of gentiobiose. The resulting disaccharide was split off the polymer as benzyl glycoside by boiling in benzene containing methyl iodide and benzyl alcohol.

Zehavi *et al.*^{32–34} proposed to use 4-hydroxymethyl-3-nitrobenzoic and 4-hydroxymethyl-6-methoxy-3-nitrobenzoic acid derivatives as photosensitive linkers. The hydroxy groups of these linkers are glycosylated with monosaccharides, while the carboxy group is used for the binding to the polymeric support. The presence of an *o*-nitrobenzyl alcohol fragment enables smooth decomposition of these linkers upon photolysis in neutral media, which results in the liberation of the oligosaccharides.

These linkers were used for the first time in the synthesis of α -D-glucopyranosyl-(1-6)-D-glucose (isomaltose) (Scheme 6).³² The 2,3,4-tri-*O*-benzyl-6-*O*-(*p*-nitrobenzoyl)-D-glucopyranose residue was immobilised as an *O*-glycoside on a polystyrene-based resin (**10**) through the linker. The 6-OH group was deprotected by treatment with MeONa after which the polymer **11** containing partially substituted glucose residues was glycosylated with 2,3,4-tri-*O*-benzyl-6-*O*-(*p*-nitrobenzoyl)- α -D-glucopyranosyl bromide. In order to liberate the target product, which represents an isomaltose derivative, the polymer **12** was irradiated in dioxane for 32 h (yield 80%).

Scheme 6

[‡] For the 'methathesis' of oligosaccharides occurring in this glycosylation technique, see Ref. 31.

In more recent studies, the photosensitive linker based on 4-hydroxymethyl-3-nitrobenzoic acid was used for the enzymic synthesis of oligosaccharides on other supports. The reaction of 2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl bromide with alkyl 4-hydroxymethyl-3-nitrobenzoate followed by *O*-deacetylation and saponification gave the glycoside **13** (Scheme 7), which was then immobilised on modified polyacrylamide containing 2-aminoethyl groups¹³ or on modified polyvinyl alcohol bearing amino groups.³³ The glucose residues in the resulting polymers **14** were linked by glycosidic bonds and served as acceptors in enzymic syntheses. These polymers were incubated with galactosyl transferase in the presence of uridine diphosphate galactose (UDPGal) as a galactosyl donor. β -D-Galactopyranosyl-(1-4)-D-glucose (lactose) formed was split off by irradiation of the polymer **15** in aqueous solution for 20 h. This synthesis was the first to demonstrate the usefulness of glycosyl transferase in regio- and stereo-specific synthesis of a disaccharide using glycosylation of an immobilised monosaccharide residue devoid of protecting groups.

Scheme 7

Similarly, the glycosylation of 4-hydroxymethyl-3-nitrobenzoic acid immobilised on polyacrylamide with cellobiose 1,2-orthoester and subsequent deacetylation afforded a polymer containing cellobiose residues with free hydroxy groups. These played the role of acceptors in the enzymic reaction with galactosyl transferase and UDPGal which gave the trisaccharide β -Galp(1-4)- β -Glc(1-4)Glc. Cellobiose immobilised on polyacrylamide was also used in the synthesis of oligosaccharides containing *N*-acetyl- β -D-glucosamine residues which were transferred from chitin in the presence of lysozyme.¹³

Maltose [α -Glc(1-4)Glc], maltotriose [α -Glc(1-4)- α -Glc(1-4)Glc] and panose [α -Glc(1-6)- α -Glc(1-4)Glc] were immobilised on *N*-(2-aminoethyl)polyacrylamide through the same photosensitive linker in order to investigate the specificity of glycogen synthase, which transfers glucose residues from uridine diphosphate glucose (UDPG) to glucooligosaccharides, and to elucidate the role of primers in the biosynthesis of glycogen.³⁴ Oligosaccharide derivatives were attached to 4-hydroxymethyl-3-nitrobenzoic acid; the resulting glycosides were deacylated and immobilised on a polymer through the carboxy group of the linker by treatment with water-soluble carbodiimide. Reactions of these immobilised acceptors with UDPG in the presence of glycogen synthase shed additional light on some essential details of the mechanism of glycogen biosynthesis, *e.g.*, the role of primers, the appearance of branching, *etc.*

In the enzymic synthesis of *N*-acetylglucosamine [2-acetamido-4-*O*-(β -D-galactopyranosyl)-2-deoxy-D-glucose],³⁵ the *N*-acetylglucosamine residue was immobilised on a water-soluble copolymer of acrylamide and *N*-acryloyloxysuccinimide modified by incorporation of 2-aminoethyl groups through its glycosidic centre and a photosensitive linker (*viz.*, 4-hydroxymethyl-3-nitrobenzoic acid). After *O*-deacetylation of the glucosamine residue, the polymer was incubated with UDPG in the presence of the UDPG epimerase–galactosyl transferase system which provided epimerisation of the glucose residue and transfer of the galactose residue to the acceptor. The *N*-acetylglucosamine thus formed was liberated from the polymer by photolysis.

Copolymerisation of acrylamide with its derivative **16** (Scheme 8) gave rise to polyacrylamide **17** bearing glucosamine residues glycosidically linked to a benzyl-type linker. After *O*-deacetylation, the polymer **18** was incubated with UDPGal and galactosyl transferase. The resulting *N*-acetylglucosamine **19** was split off the polymeric carrier by hydrogenolysis in the presence of Pd/C.³⁶

Scheme 8

These examples illustrate that the use of enzymes in solid-phase synthesis of oligosaccharides is promising. The efficacy of enzymic elongation of oligosaccharide chains depends on the distance between the monosaccharide acceptor and the surface of the support. This distance and, as a consequence, the optimum size of the linker, are determined by the molecular mass of the enzyme. If the galactose residue is transferred by galactosyl transferase, it can be attached to the polymer by a chain containing only two methylene units, whereas successful glucose transfer effected by glycogen synthase with a higher molecular mass requires that the chain contained at least six methylene units.

The solid-phase syntheses of di- and trisaccharides described above do not have any obvious advantages over the corresponding syntheses in solution. However, they provided a clue to the solution of some urgent methodological problems in order to pass to targeted synthesis of fragments of homo- and heteropolysaccharides and glycopeptides and contributed also to progress in the combinatorial chemistry of carbohydrates.

IV. Synthesis of higher oligosaccharides

Several solid-phase syntheses of regular homooligosaccharides containing up to 10 monosaccharide units have been carried out to date. Although some of compounds of this type can be prepared by polymerisation of monosaccharide derivatives,^{37,38} their synthesis on solid supports made it possible to develop a standard procedure for stepwise elongation of an oligosaccharide chain suitable for concrete method of glycosylation.

Gluco- and manno oligosaccharides were prepared by the Schmidt trichloroacetimidate method,³⁹ which is the most popular. The synthesis of (1-6)-D-gluco oligosaccharides is shown in Scheme 9. The polymer **20** modified with 3-mercaptopropylthiomethyl groups was prepared by the reaction of the Merrifield polymer with propane-1,3-dithiol. The substituted glucose residue was attached to the free thiol group of the polymer to form the thioglycosidic bond using *O*-(6-*O*-acetyl-2,3,4-tri-*O*-benzyl-D-glucopyranosyl) trichloroacetimidate (**21**). The 6-*O*-acetyl group in the resulting polymer **22** was removed and the polymer **23** formed was treated with a threefold excess of the imidate **21** in the presence of trimethylsilyl triflate. The *O*-acetyl group in the polymer **24** was removed again, the polymer **25** was glycosylated by treatment with the glycosyl donor **21**, and the whole procedure was repeated as many times as required. After termination of the synthesis, the oligosaccharide was split off from the polymer **26** with a thiophilic reagent [e.g., dimethyl(methylthio)sulfonium triflate] in the presence of a base. This approach was used in the synthesis of di-, tri-, tetra- and pentasaccharides. The yields of the products in each step of the chain elongation were determined by the increase in the polymer mass. In addition, this reaction was monitored by a mass-spectrometric procedure which had been specially developed for this purpose. An aliquot of the polymer was treated with dimethyl(methylthio)sulfonium tetrafluoroborate in a dichloromethane–methanol mixture in the presence of

the Hünig base and the oligosaccharides liberated were analysed by mass spectrometry, which made it possible to judge the completeness of glycosylation in each step. According to mass spectrometric data (MALDI–TOF), the yield was 95%.

Each glycosylation step afforded a mixture of α - and β -anomers in an α : β ratio of 1:1; thus, the pentamer represented a mixture of 32 diastereomers. Hence, this methodology is well-suited for combinatorial syntheses.

A similar approach was used in the synthesis of α -1,2-linked oligomannosides.¹¹ 2-*O*-Acetyl-3,4,6-tri-*O*-benzyl-D-mannopyranose residues were incorporated into the polystyrene resin $(\text{P})\text{-CH}_2\text{OCH}_2\text{CH}_2\text{CH}_2\text{SH}$ prepared in an analogous way. After deacetylation and glycosylation of the deacetylated product with *O*-(2-*O*-acetyl-3,4,6-tri-*O*-benzyl-D-mannopyranosyl) trichloroacetimidate and reiteration of the reaction cycle, the immobilised oligomannosides **27** (up to the hexasaccharide) were split off the support by treatment with *N*-bromosuccinimide in THF–MeOH in the presence of 2,6-di-*tert*-butylpyridine. The elongation of the chain was monitored by mass spectrometry. The yields of di-, tri- and tetramannosides were 75%, 54% and 34%, respectively.

Glycosylation of the first mannose residue with an L-fucose analogue instead of *O*-mannosyl trichloroacetimidate yields the disaccharide **28** containing an α -L-fucosidic (1,2-*cis*-glycosidic) bond.

This approach was also used in the synthesis of a well-known core of *N*-glycoproteins, which represents a branched pentasaccharide (Scheme 10).¹² Mannose residues were immobilised on the same polymer, viz., $(\text{P})\text{-CH}_2\text{OCH}_2\text{CH}_2\text{CH}_2\text{SH}$, by treatment with *O*-(2,4-di-*O*-benzyl-3,6-di-*O*-benzoyl- α -D-mannopyranosyl) trichloroacetimidate. Both benzoyl groups in the resulting polymer were removed, and the diol **29** formed was glycosylated with an excess of *O*-(2-*O*-acetyl-3,4,6-tri-*O*-benzyl- α -D-mannopyranosyl) trichloroacetimidate (**30**). The acyl groups in the polymer **31** were removed again, and the immobilised trisaccharide **32** was glycosylated with *O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trichloroethoxycarbonylamino- α -D-glucopyranosyl) trichloroacetimidate

Scheme 10

(33), which afforded a polymer with an immobilised pentasaccharide (34). The thioglycosidic linkage was cleaved with *N*-bromosuccinimide in the presence of methanol and 2,6-di-*tert*-butylpyridine resulting in the pentasaccharide 35 in 20% yield; hence, the yield of glycosylation was 85% in each step. The yields of the reaction products were monitored by mass spectrometry, while the stereochemistry of the glycosidic bonds was established by NMR spectroscopy.

Analogous syntheses of α -(1-2)-linked manno oligosaccharides were performed on other supports as well, *e.g.*, on porous glasses with grafted mercaptopropyl groups.⁴⁰ The 3,4,6-tri-*O*-benzyl-2-*O*-phenoxyacetyl-D-mannose residues were attached to the support modified by treatment with 3-mercaptopropyltrimethoxysilane. The phenoxyacetyl group in the immobilised saccharide 36 was removed with guanidine and the next mannose residue was attached to the liberated hydroxy group after which the whole reaction cycle was reiterated. The oligomannoside synthesised was split off the support by treatment with *N*-bromosuccinimide in the presence of methanol and 2,6-di-*tert*-butylpyridine. Mass-spectrometric analysis revealed that the resulting trisaccharide contained only trace amounts of the mono- and the disaccharide, which suggests that glycosylation occurred with high yields in each step.

Synthesis of this type of oligomannosides have also been carried out on a soluble support, *viz.*, monomethyl ether of polyethyleneglycol.¹⁷ 1,4-Bis(hydroxymethyl)benzene⁸ has been used as a linker and 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-D-mannopyr-

anose residue was attached through this linker. The elongation of the oligosaccharide chain was carried out as described above. A scandium(III) triflate-acetic anhydride system was recommended for the splitting of the reaction product from the polymer.⁴¹

In all these oligomannoside syntheses, the chain was elongated from the reducing end to the non-reducing one. However, an alternative route is documented, which utilises an opposite strategy, *i.e.*, the elongation is performed from the non-reducing end of the chain to its reducing end. The synthesis on the soluble support (PEG) was carried out according to the following scheme.⁴² The linker used was a 6-(4-hydroxymethylphenoxy)-hexanoic acid derivative, which alkylated methyl 3,4,6-tri-*O*-benzyl-1-thio- α -D-mannopyranoside at position 2 and esterified PEG (Scheme 11). The substituted methyl 1-thiomannopyranoside residue in the polymer 37 served as the glycosyl donor, reacted with 3,4,6-tri-*O*-benzyl-D-mannopyranosyl fluoride in the presence of methyl triflate to give the disaccharide derivative 38 which also played the role of a glycosyl donor. The Suzuki glycosylation⁴³ of 2-(trimethylsilyl)ethyl 3,4,6-tri-*O*-benzyl- α -D-mannopyranoside resulted in the immobilised trisaccharide 39; the free trisaccharide was split off the polymer by treatment with a base and deprotected by hydrogenolysis.

The target product (yield 40%) was easily separated from by-products owing to the presence of a hydrophobic trimethylsilyl-ethyl group.

Incorporation of hydrophobic groups to facilitate isolation of the target product was also used⁴² in the synthesis of a structurally more complex heterooligosaccharide 40, which is a fragment of glycosphosphatidylinositol. The latter was prepared by a reaction of the disaccharide 41 with the glycosyl donor 38. The tetrasaccharide 40, which was cleaved from the polymer 40p by hydrogenolysis, could easily be purified by reversed-phase chromatography owing to the presence of hydrophobic phthalimido- and methoxyphenyl groups. This methodology is an interesting example of modification of carbohydrate synthesis on solid phase supports.

From the oligomannoside syntheses described above one cannot draw any final conclusion in favour of one or another synthetic procedure, but the flexibility and high potential of the solid-phase method have been demonstrated.

§ It should be noted that this type of linker has also been used in some other syntheses on soluble supports, *e.g.*, in the synthesis of model disaccharides.

$$\beta\text{-Gal}f(1\text{-}5)[\beta\text{-Gal}f(1\text{-}5)]_5\beta\text{-Gal}f\text{OCH}_2\text{CH}_2\underset{\text{NH}_2}{\underset{|}{\text{CH}}}\text{COOH}$$

42

Further developments in solid-phase oligosaccharide synthesis were aimed at a search for novel methods of glycosylation. The

so-called glycal method (Scheme 13) ¹⁰ offers the most interesting opportunities for the synthesis of complex (including branched) oligosaccharides. After treatment with a mild epoxidising reagent (*viz.*, 3,3-dimethyldioxirane), the glycal **48** immobilised on a support through a hydroxy group is converted into the 1,2-anhydrosugar **49**. The latter reacted with the glycal **50** with a free

Tr = Ph₃C; Z = PhCH₂OCO; Piv = Me₃CCO; Lev = MeCO(CH₂)₂CO.

The reaction scheme illustrates the synthesis of phosphonate-protected nucleosides. It begins with nucleoside **48**, which has a phosphate group at the 5' position and a double bond between the 2' and 3' carbons of the sugar ring. Oxidation ([O]) of **48** yields intermediate **49**, where the double bond has been converted to an epoxide ring. Intermediate **49** then reacts with nucleoside **50** (a nucleoside with a 2,6-dimethyl-4-hydroxyphenyl group at the 1' position) to form intermediate **51**. Intermediate **51** is a dimeric structure where the 3' carbon of the sugar in **49** is linked via an oxygen atom to the 5' carbon of the sugar in **50**. Finally, oxidation ([O]) of **51** yields intermediate **52**, where the double bond in the sugar of **50** has been converted to an epoxide ring. Intermediate **52** then reacts with nucleoside **53** (a nucleoside with a 2,6-dimethyl-4-hydroxyphenyl group at the 1' position and a hydroxyl group at the 3' position) to form the final product **54**. Intermediate **54** is a dimeric structure where the 3' carbon of the sugar in **52** is linked via an oxygen atom to the 5' carbon of the sugar in **53**.

hydroxy group in the presence of ZnCl_2 to yield the disaccharide glycal **51** which is further converted into the 1,2-anhydrosugar **52**. Its reaction with the monosaccharide glycal **53** afforded the immobilised trisaccharide glycal **54**, and so on. The yields in each glycosylation step amounted to 90%–95%. High stereospecificity of glycosidic linkage formation is governed by well-established regularities in the epoxide ring opening. As can be seen, the main characteristic feature of this approach is the reconstruction of a reactive epoxide group (*i.e.*, a glycosyl donor group) at the reducing end of the growing chain under standard mild conditions. By varying the structure of the glycal acceptor, one can obtain both regular and irregular homo- and heterooligosaccharides. Immobilised glycals with free hydroxy groups resulting either from the reaction or after selective removal of protecting groups can also play the role of glycosyl acceptors which permits their glycosylation leading to branched oligosaccharides.

It should be emphasised that the use of the glycal method simplifies the purification of the reaction product, since possible admixtures formed as a result of incomplete glycosylation in the intermediate steps of the synthesis become more polar after final treatment and can easily be separated from the target oligosaccharides by chromatography.

The high potentials and flexibility of the glycal method can be exemplified in the convergent synthesis of several oligosaccharides on an insoluble support (Scheme 14).¹⁰ Here, R_2SiCl groups ($\text{R} = \text{Ph}$, Pr^i), which are used as linkers for binding the first monomer to the polymeric support, were incorporated into a polystyrene resin by sequential treatment with butyllithium and diphenyl- or diisopropyldichlorosilane. The use of such linkers allows easy cleavage of the $\text{O}-\text{Si}$ bond upon treatment with Bu_4NF , which enables detachment of the synthesised product from the support under mild conditions.

Treatment of the thus modified polystyrene **55** with a D-galactal derivative **56** in the presence of a base followed by oxidation with dimethyldioxirane (**57**) affords the polymer **58**, which contains the immobilised anhydrosugar residue, which is employed as the glycosyl donor for the elongation of the chain. Glycosylation of the polymer **58** with D-galactal **56** in the presence of anhydrous ZnCl_2 yields the disaccharide glycal derivative **59**. Reiteration of the reaction cycle results in the trisaccharide glycal **60**; its reaction with 3,4-di-*O*-benzyl-D-glucal (**50a**) yields the tetrasaccharide glycal **61** with (1-6) glycosidic linkages. The introduction of a structurally different glycal acceptor (*e.g.*, 4,6-*O*-benzylidene-D-glucal **62**) into the reaction with an immobilised glycosyl donor prepared from the trisaccharide glycal **60** results in the formation of the tetrasaccharide glycal **63** of irregular structure. After

conversion into the glycosyl donor, the glycal **63** reacts with 3,4-di-*O*-benzyl-D-glucal as described above to yield the irregular pentasaccharide derivative **64**. Finally, oxidation of the trisaccharide glycal **60** and subsequent reaction with the disaccharide glycal **65** afforded the pentasaccharide glycal **66**. Conversion of the tetrasaccharide glycal **63** into a glycosyl donor using the conventional scheme and reaction of the latter with the disaccharide glycal **65** result in the hexasaccharide derivative **67**.

In each step of this convergent synthesis, the oligosaccharides can be split off the polymer by treatment with Bu_4NF and protecting groups can be removed by standard methods. The yields of the oligosaccharides are 80%–90% in each step, which gives the final yields of the order of 20% to 40%. The stereochemistry of glycosidic linkages in all steps of this synthesis was established by NMR spectroscopy.

The usefulness of two other, recently proposed glycosylation methods for solid-phase synthesis, *viz.*, those utilising glycosyl sulfoxides²⁴ and pent-4-enyl glycosides⁴⁵ as glycosyl donors, is more difficult to evaluate.

Several examples of solid-phase syntheses with the use of these glycosylating reagents are considered below.

p-Hydroxyphenyl 2,3,4-tri-*O*-pivaloyl-6-*O*-trityl-1-thio- β -D-galactopyranoside (**68**) was immobilised on Merrifield's resin (Scheme 15).²⁴ After removal of the trityl group from the immobilised monosaccharide, the hydroxy group in the polymer **69** was glycosylated with the sulfoxide **70** in the presence of trifluoromethanesulfonic acid anhydride and 2,4,6-tri-*tert*-butylpyridine. After removal of the trityl group from the immobilised disaccharide, the reaction sequence was repeated. The resulting derivative of the corresponding trisaccharide **71** was split off the support by treatment with mercury trifluoroacetate in a dichloromethane–water mixture. The glycosylation occurred stereospecifically with formation of a β -galactosidic bond. The yield of the trisaccharide was 52%. Taking into account the fact that only 70% to 75% of the oligosaccharide is liberated from the polymer, the yields of di- and trisaccharides in the glycosylation step were no less than 94%–95%.

Glycosyl sulfoxides can be used as glycosyl donors in the glycosylation of secondary hydroxy groups as is exemplified in the synthesis of two synthetic precursors of Lewis antigens of group-specific blood glycoproteins.

Glycosylation of 2-azido-4,6-*O*-benzylidene-2-deoxy-1-thio-D-glucoside immobilised in an analogous way (**72**) with sulfoxides based on 2,3,4-tri-*O*-benzyl-L-fucose and 2,3,4,6-tetra-*O*-pivaloyl-D-galactose afforded the disaccharides **73** and **74** (yields 67% and 64%, respectively); these reactions were stereospecific.

Scheme 15

The stereospecificity of these reactions, which is particularly emphasised by the authors,²⁴ is quite obviously governed by the nature of a substituent at the O(2) of the glycosyl donor. The same regularity is observed when glycosylation is carried out in solution.

Further utilisation of glycosyl sulfoxides in solid-phase syntheses of oligosaccharides is still not documented.

Rather specific experimental conditions and uncertainty of the problem of stereospecificity in the case of other monosaccharides seem to preclude the widespread application of glycosylation based on the use of glycosyl sulfoxides.

Pent-4-enyl glycosides act as glycosylating agents following generation of a carbocation at the glycosidic centre of the sugar as a result of treatment with *N*-iodosuccinimide and triethylsilyl triflate. The glycosylation with *n*-pent-4-enyl glycosides has been described in detail;⁴⁵ some general considerations concerning the applicability of this reaction to solid-phase syntheses on different

supports, with different linkers and monosaccharides were briefly surveyed in Ref. 46. According to Fraser-Reid *et al.*,⁴⁶ solid-phase glycosylation gives satisfactory yields. Since the stereoselectivity of this reaction is not very high, it is recommended for use in combinatorial chemistry for the acquisition of 'libraries' of immobilised oligosaccharides designed for direct activity assays. The principles common to combinatorial chemistry have been applied for the acquisition of a library of deprotected oligosaccharides concomitant with the synthesis of the trisaccharide β -Galp(1-2)- α -Glc(1-6)GlcNAc (no experimental details were given).

The advantages of solid-phase oligosaccharide synthesis are most conspicuous in the directed synthesis of complex fragments of natural biopolymers. Thus, the glycal method was used in the synthesis of a series of biologically important oligosaccharides which play an essential role in carbohydrate-protein interactions and represent antigenic determinants. Some steps of this synthesis were carried out on a polystyrene support.

The synthesis of the blood-group H-determinant (type 2) is shown in Scheme 16.⁴⁷ 3,4-*O*-Carbonyl-D-galactal **75** immobilised on a polystyrene resin through a diisopropylsilyl linker was oxidised with dimethyldioxirane into the corresponding 1,2-anhydrosugar which was then introduced into a reaction with 3,6-di-*O*-benzyl-D-glucal in the presence of ZnCl_2 . The resulting immobilised disaccharide glycal **76** was glycosylated at the free OH group at position 2' with 2,3,4-tri-*O*-benzyl-L-fucopyranosyl fluoride in the presence of tin triflate and 2,6-di-*tert*-butylpyridine. The immobilised trisaccharide **77p** was treated with Bu_4NF to liberate the trisaccharide **77** (overall yield was 50%) after which the synthesis was continued in the solution. The hydroxy group at C(6) of the galactose residue in the trisaccharide **77** was protected with a triisopropylsilyl group and treated with benzenesulfamide in the presence of iodonium(dicollidine) perchlorate. The resulting 2-deoxy-2-iodo-*N*-phenylsulfonylglycosylamine **78** (*cf.* Ref. 48) underwent rearrangement in a reaction with 3-*O*-tributylstannyl-6-*O*-triisopropylsilyl-D-galactal in the presence of silver tetrafluoroborate.⁴⁹ The resulting tetrasaccharide **79** was subjected to

Scheme 16

TIPS = SiPr_3 .

Scheme 17

deprotection and *N*-acetylation to give the tetrasaccharide **80**, which is a derivative of the H-antigen (type 2) of a blood group-specific glycoprotein.

A similar approach was used in the synthesis of a Le^b -specific hexasaccharide, which was prepared in a form suitable for conjugation with proteins (Scheme 17).⁴⁷ The starting galactal **56** was immobilised on a polystyrene resin; the reaction product was converted into an 1,2-anhydrosugar, which further glycosylated 6-*O*-triisopropylsilyl-D-glucal [its most reactive hydroxy group at C(3) reacts selectively]. The (1-3)-linked disaccharide **81** with two free hydroxy groups was glycosylated with an excess of 2,3,4-tri-*O*-benzyl-L-fucopyranosyl fluoride (**82**). The resulting tetrasaccharide **83p** bearing two L-fucose residues was split off the support, the primary alcohol groups in the tetrasaccharide liber-

ated were silylated after which the synthesis was continued in solution. The tetrasaccharide **83** was converted into tetrasaccharide 2-deoxy-2-iodo-*N*-phenylsulfonylglycosylamine **84**. The latter reacted with 3-*O*-tributylstannyl-L-fucose derivative **85** to give the hexasaccharide glycal **86**, which was converted into an 1,2-anhydro derivative and then made to react with allyl alcohol to obtain the allyl glycoside of the corresponding hexasaccharide **87**. To prepare antibodies against Le^b antigen, the hexasaccharide **87** was converted into the aldehyde **88** suitable for conjugation with proteins.

Halcomb *et al.*¹⁵ performed an enzymic synthesis in solution of the pentasaccharide NeuAc- α -(2-3)-Gal- β -(1-4)-[Fuc- α -(1-3)]-GlcNAc- β -(1-3)-Gal and an enzymic solid-phase synthesis of the tetrasaccharide NeuAc- α -(2-3)-Gal- β -(1-4)-GlcNAc- β -(1-3)-Gal,

Scheme 18

which are known as inhibitors of E-selectin and *Helicobacter pylori*, respectively. A fragment of the pentasaccharide, viz., the tetrasaccharide NeuAc- α -(2-3)-Gal- β -(1-4)-[Fuc- α -(1-3)]-GlcNAc (sialyl-Lewis X, SLe^X), is a tumour-associated antigen; it is involved in processes of cell adhesion, metastasis, inflammation and thrombosis. This antigen contains neuraminic acid; its stereospecific introduction into oligosaccharides by chemical methods presents a problem, therefore the use of enzymic glycosylation is more preferable in this case.

The solid-phase synthesis of the tetrasaccharide NeuAc- α -(2-3)-Gal- β -(1-4)-GlcNAc- β -(1-3)-Gal was performed on CPG modified with iodoacetyl amino groups, which made it possible to conduct the synthetic operations in both aqueous solution and organic solvents as required (Scheme 18).¹⁵ The starting disaccharide, viz., 2-acetamido-2-deoxy- β -D-glucopyranosyl-(1-3)-D-galactopyranose, prepared by chemical synthesis as a glycoside of ω -hydroxyhexanoic acid, was immobilised on the modified CPG. After incubation with UDPGal in the presence of β -(1-4)-galactosyl transferase, the immobilised disaccharide **89** yielded the trisaccharide **90**, which was made to react with cytidine 5'-phospho-*N*-acetylneuraminic acid (CMP-*N*-acetylneuraminic acid) in the presence of α -(2-3)-sialyl transferase. The resulting tetrasaccharide **91** was split off the support with hydrazine and isolated as ω -hydroxyhexanohydrazide glycoside **92** suitable for conjugation with proteins. This synthesis demonstrates again the advantages of the enzymic approach in solid-phase oligosaccharide syntheses

where the regio- and stereospecificity of the glycosidic bonds formed are determined by the specificities of glycosyl transferases.

The synthesis of the phytoalexin elicitor (PAE), which prevents viral and bacterial infections in plants, is yet another example of successful application of the solid-phase methodology in directed synthesis of biologically active and structurally complex oligosaccharides. Synthetic PAE (a branched heptasaccharide) presents substantial practical interest for agriculture, since the natural product is difficultly accessible due to its low concentration in plants. The synthesis of PAE **93** was carried out using two different approaches.

In the first approach (Scheme 19),⁵⁰ the oligosaccharide chain was elongated by sequential addition of blocks on a soluble polymeric support (PEG) using a thioglycoside glycosylation method. The starting monosaccharide, viz., methyl 2,3-di-*O*-benzoyl-6-*O*-dimethoxytrityl- α -D-glucopyranoside (**94**), was attached to the polymer modified with succinic acid through the hydroxy group at C(4) (the support loading was 148 mmol g⁻¹). After mild acidolysis of the dimethoxytrityl group, the polymer was introduced into the reaction with the disaccharide thioglycoside **95** in the presence of *N*-iodosuccinimide and trifluoromethanesulfonic acid. Benzylidene protection was removed by acid hydrolysis after which the immobilised trisaccharide **96** was subjected to regioselective glycosylation with the thioglycoside **97** at O(6'). Subsequent acylation of the hydroxy group at C(4')

Scheme 19

(**98a** → **98b**) and removal of silyl protection resulted in the tetrasaccharide **98c**.

Reiteration of this reaction sequence, *viz.*, the reaction with the disaccharide **95**, debenzilylation and the reaction with the thioglycoside **97**, afforded the protected immobilised heptasaccharide. Purification of the reaction products formed in each step from excess of the soluble reagents was achieved by precipitation of the polymeric material and subsequent washing with diethyl ether. Deprotection by treatment with sodium methoxide was accompanied by splitting of the heptasaccharide from the polymer eventually resulting in the biologically active PAE methyl glycoside (yield 18%).

According to the second scheme, PAE and its lower analogues were synthesised on a hydroxylated polystyrene resin using a photosensitive linker **99** and thioglycoside glycosylation.⁷ Nitrobenzyl alcohol **99** was glycosylated with phenyl-2,3,4-tri-*O*-benzoyl-6-*O*-(*tert*-butyldiphenylsilyl)-1-thio-β-D-glucopyranoside (**100**), and the resulting glycoside was immobilised. This glucose residue served as the origin of the oligosaccharide chain which was elongated by successive treatment with the thioglucosides **100**, **101** and **102** (Scheme 20). The thioglucoside **100** contained a selectively removable *tert*-butyldiphenylsilyl protecting group at O(6), while the thioglucoside **101** contained a 9-fluorenylmethoxycarbonyl (Fmoc) group at O(4). These groups were selectively removed when required, and the hydroxy groups liberated were glycosylated with the corresponding thioglucoside in the presence of dimethyl(methylthio)sulfonium triflate. The resulting heptasaccharide (overall yield 20%) was split off the support by photolysis.

Solid-phase synthesis was also used for the preparation of oligosaccharides containing 6-deoxy- and/or 2,6-dideoxymonosaccharide units which represent carbohydrate chains of some antibiotics.⁹ This synthesis combines ingeniously detachment of the oligosaccharide from the support with nucleophilic substitution of the hydroxy group involved in immobilisation of the sugar on the polymer. The Merrifield's resin modified by introduction of ethanesulfonic acid was used as the solid support. Methyl 4-*O*-

acetyl-2,3-di-*O*-benzyl- and methyl 2-*O*-acetyl-3,4-di-*O*-benzyl-α-D-glucopyranoside **103a(b)** were immobilised on this polymer (Scheme 21) after which *O*-acetyl groups were removed by treatment with guanidine. The immobilised monosaccharides **104a(b)** reacted with the glycosyl donors **105** and **106** in the presence of trimethylsilyl triflate to afford the corresponding immobilised disaccharides **107**–**110**. These disaccharides were split off the support by treatment with NaI in ethyl methyl ketone with simultaneous substitution of iodine for the sulfonyloxy group. The yields of iododeoxysaccharides (**111**–**114**) varied from 85% to 91%. Their treatment with Bu₃SnH gave the corresponding deoxy sugars **115**–**118** in 92% yield.

This method was used in the targeted synthesis of the carbohydrate fragment of the antibiotic olivomycin A (Scheme 22).⁹ Glucal **119** was immobilised on a sulfonylethylated Merrifield's polymer after which it was desilylated and treated with trichloroacetimidate **122**. The immobilised disaccharide **123** formed was desilylated (**123** → **124**) and glycosylated with glycosyl acetate **106** in the presence of trimethylsilyl triflate. The trisaccharide **125** was detached from the polymer with simultaneous substitution of iodine for bromine (yield 67%). The glycal **125** was used for direct incorporation of the carbohydrate fragment into the aglycon of olivomycin A.

An important observation which awaits rationalisation is the fact that the glycosylation of the immobilised acceptor with trichloroacetimidate **122** was stereospecific leading exclusively to β-linkages, whereas the product synthesised in solution contained some proportion of α-linked oligosaccharide.

This example is also interesting in that it illustrates that the solid-phase synthesis of carbohydrates can be combined with simultaneous transformation of the monosaccharide residues. This significantly extends the range of reactions in synthetic chemistry of carbohydrates performed on solid supports. The same approach can be used for the introduction of amino sugar units into oligosaccharides if sodium azide is employed instead of NaI for splitting off the reaction product.⁹

TES = Et_3Si ; TBS = Bu_3Si .

V. Synthesis of glycopeptides

Glycopeptides are compounds in which oligosaccharides are covalently linked to amino acids or peptides by *O*- or *N*-glycosidic bonds. They are structural components of glycoproteins, the important naturally occurring glycoconjugates responsible for a great diversity of vital cell functions and are used as the simplest models in studies of biological activities of glycoproteins. In recent years, glycopeptides have acquired considerable practical importance, since many of them served as the basis for the development of new generations of highly efficient drugs.

Glycopeptides are most commonly prepared by solid-phase synthesis, since their synthesis in solution faces serious problems.

Synthesis of glycopeptides can be performed by elongation of a peptide or an oligosaccharide chain. Those peptides in which an amino acid is glycosylated with a monosaccharide are the simplest representatives of the glycopeptide family.[¶] These can be prepared by direct glycosylation of the corresponding amino acid residue in a presynthesised immobilised peptide chain.[†]

[¶] It is interesting to note that the mode of incorporation of the first monosaccharide residue is a crucial factor which determines the physicochemical characteristics of these peptides.

[†] For direct *O*-glycosylation of peptides containing serine and threonine residues in solution, see Refs 51 and 52.

This method has been briefly described by Hollósi *et al.*⁵³ in the example of the synthesis of a glycosylated fragment 189–207 of tau-protein (**126**), responsible for a certain stage of Alzheimer's disease, and of its simplified analogue.

The immobilised 19-membered peptide **127** possessing the necessary protecting groups in its amino acid residues (with the exception of the hydroxy group of serine-202 which was subject to glycosylation) was prepared by solid-phase peptide synthesis. This peptide was treated with 3,4,6-tri-*O*-acetyl-2-methyl-*D*-gluco-oxazoline[‡] prepared by treatment of per-*O*-acetyl- β -D-glucosamine with trimethylsilyl triflate as described in Ref. 54 (Scheme 23).

The resulting *O*-glycopeptide **128p** (yield 23%) was split off the polymer by treatment with a trifluoroacetic acid–anisole mixture and purified by chromatography. The structure of the glycopeptide **128** was confirmed by mass spectrometry. The glycosylation of the serine residue in its simple peptide analogue AcGly-Ser-Pro-Val-Glu-Lys was carried out in a similar way. The corresponding *O*-glycopeptide was obtained in 33% yield. This synthesis demonstrated the possibility of glycosylation of the serine residue adjacent to the proline residue of immobilised peptides, which normally hardly undergoes glycosylation.

The synthesis of *N*-glycopeptides in which mono- and oligosaccharide residues (including hexasaccharides) are linked to the asparagine residue of the hexapeptide Asn-Tyr-Gly-Phe-Leu by an *N*-glycosidic bond is yet another example of direct glycosylation. In this synthesis, the hexapeptide with *N*-terminal aspartic acid was immobilised on a support and the aspartic acid was converted into the pentafluorophenyl ester. The activated ester was brought into reaction with the corresponding glycosylamines in the presence of hydroxybenzotriazole and amine to afford *N*-glycosylasparagines.⁵⁵

It is necessary to note that direct glycosylation of immobilised peptide chains has not received wide recognition in synthetic practice. It is the classical solid-phase peptide synthesis (see, *e.g.*, Refs 56–90) that is mainly employed for the preparation of glycopeptides bearing a monosaccharide residue or a short oligosaccharide chain, which makes use of the corresponding glycosylated amino acids.

However, implementation of solid-phase glycopeptide synthesis in an automated regime of conventional peptide synthesis required that a number of problems was solved, such as a search for supports and linkers providing both the optimum conditions for the condensation in the elongation of the peptide chain and smooth non-destructive liberation of the target glycopeptide from the support. The most common support is Merrifield's peptide resin⁵⁶ modified by incorporation of benzyl alcohol fragments ($\text{HOCH}_2\text{C}_6\text{H}_4\text{OCH}_2-\text{P}$),⁵⁸ the role of linker is played by a compound with benzhydrylamine and phenoxyacetic acid fragment (the so-called Rink linker),⁶¹ a variety of compounds

containing β -hydroxyallylic groups (Hycron and Hycram linkers)^{62, 63} and nitrobenzophenone oxime.⁶⁵

In parallel with a search for linkers, the general strategy of glycopeptide synthesis required unification of procedures used for incorporation of glycosylated amino acids into the peptide chain.

To this end, efficient methods for incorporation of glycosylated amino acid residues into the peptide chain have been developed and synthesis of such fragments has been proposed.[§]

And, finally, particular attention has been paid to the protection of hydroxy groups of carbohydrates and functional groups of amino acids as well as to protecting group introduction, removal and manipulations as required in the synthesis.

The Fmoc/PfP strategy was found to be the most efficient in the synthesis of *O*-glycopeptides. In this case, the amino group of serine or threonine (**129**) derivatives is protected with a Fmoc group which is easily removed upon treatment with mild bases, while the carboxy group is activated by conversion into the pentafluorophenyl ester (PfP).

R = H, Me.

The use of these derivatives allows incorporation of glycosylated amino acids into the peptide chain in an automated mode of a conventional peptide synthesis.

An alternative approach to the synthesis of glycopeptides with a complex carbohydrate chain consists in the elongation of the oligosaccharide chain starting from the monosaccharide residue that has been incorporated into the immobilised peptide chain. In this case, as in the oligosaccharide synthesis in solution, the choice of protecting groups in the monosaccharide residues and the method of glycosylation which provide the highest regio- and stereoselectivity of glycosylation are of great importance. A factor which largely determines the successful outcome of the glycopeptide synthesis is the proper choice of a support which ensures effective synthesis of both peptide and oligosaccharide fragments within a single system '(support + linker)–solvent'. The conditions for the peptide and oligosaccharide syntheses can differ (*e.g.*, the synthesis of an oligosaccharide fragment should preclude the presence of water or any other hydroxyl-containing components), which may require additional technical manipulations connected with a change of solvents in the course of the synthesis.

Glycopeptide syntheses by chemical elongation of the oligosaccharide chain was described in detail in a fundamental study by Paulsen *et al.*⁹¹

The Rink linker and norleucine (Nle) as the internal standard were used in the synthesis of mucin core fragments, *viz.*, glycopeptides with the peptide chain comprising eight amino acids and a di- or a trisaccharide residue (Scheme 24). One of the threonine residues incorporated into the peptide chain immobilised on a

‡ An attempt to incorporate the first monosaccharide into an immobilised peptide by direct glycosylation with sugar trichloroacetimidates was unsuccessful.

§ These residues include *O*-glycosylated threonine and serine residues in the case of *O*-glycopeptide synthesis and *N*-glycosylated asparagine in the case of *N*-glycopeptide synthesis.

Scheme 24

PEGA support contained a substituted 2-azido-2-deoxy- α -D-galactose residue linked by an *O*-glycosidic bond. The only free hydroxy group at the C(3) atom of the sugar residue in this immobilised glycopeptide (**130**) was glycosylated with the corresponding *O*-glycosyl trichloroacetimidates. As was noted above, this method is used for the formation of β -glycosidic linkages in good yields and with high stereoselectivity. Thus, the reaction of the glycopeptide **130** with *O*-(tetra-*O*-benzoyl-D-galactopyranosyl)- (**131**) and *O*-(perbenzoyl- β -D-galactopyranosyl-(1-3)-D-galactopyranosyl) trichloroacetimidates (**132**) in the presence of trimethylsilyl triflate afforded the glycopeptide derivatives **133** and **134**, respectively. The latter were split off the support with trifluoroacetic acid (yields 67% and 33%, respectively), this was accompanied by removal of *O*-*tert*-butyl protecting groups. The azido groups in the resulting compounds were transformed into acetamido groups with subsequent removal of *O*-benzoyl protection. This procedure afforded the glycopeptides **135** and **136** with the *N*-acetylgalactosamine residue in the carbohydrate-peptide linkage site.

An attempt to perform this synthesis on other supports and substitution of acetyl groups in the trichloroacetimidates **131** and **132** for *O*-benzoyl groups decreased the yields of the resulting glycopeptides **133** and **134**.

The same linker and the support were used in the synthesis of a series of isomeric glycopeptides with (1-3) and (1-6) glycosidic linkages. The starting monoglycosylated peptide comprised a threonine residue glycosylated with 2-azido-2-deoxy-3,4-*O*-isopropylidene- α -D-galactopyranose (Scheme 25). The glycosylation of the peptide **137** with the trichloroacetimidates **131** and **132** gave the glycopeptide derivatives **138** and **139** (yields 69% and 53%, respectively) which were further converted into the corresponding *O*-glycopeptides after transformation of azido groups into acetamido groups with subsequent liberation from the support and deprotection.

This scheme was also used in the synthesis of *O*-glycopeptides having branched oligosaccharide chains. Here, the protecting benzylidene group in the immobilised glycopeptide **133** was

removed by mild acid hydrolysis, and the glycopeptide **140** was selectively glycosylated with the trichloroacetimidate **131** at the primary hydroxy group of the partially protected disaccharide fragment. This procedure afforded the glycopeptide **141** with a branched oligosaccharide chain.

This approach was also used in the preparation of glycopeptides with carbohydrate chains built of amino sugars. The immobilised glyconapeptides **142** and **143** structurally related to compounds **130** and **137** with an additional N-terminal glutamic acid residue were glycosylated with an excess of *O*-(3,4,6-tri-*O*-benzoyl-2-deoxy-2-trichloroethoxycarbonylamino- α -D-glucopyranosyl) trichloroacetimidate **144** (Scheme 26). The *N*-trichloroethoxycarbonylamino- and azido groups in the resulting glycopeptide derivatives **145** and **146** were transformed into *N*-acetylamino groups, the protecting groups in amino acid and sugar residues were removed after which the reaction products were split off the support. The corresponding glycopeptides, which represent mucin core fragments, were obtained in 62% yield.

Obviously, the elongation of an oligosaccharide chain in an immobilised glycopeptide bearing a monosaccharide residue is a flexible and reliable, albeit labour-consuming, method for the synthesis of complex glycopeptides. This procedure can be considerably simplified if glycosylation is performed with the use of glycosyl transferases. The use of enzymes makes monosaccharide protection unnecessary and ensures high regio- and stereoselectivity in the formation of glycosidic bonds. The supports employed in enzymic glycopeptide synthesis involving consecutive elongation of peptide and oligosaccharide chains must provide adequate conditions both for the synthesis of the peptide chain and for the transfer of monosaccharide residues under the action of glycosyl transferases.[¶] This problem was successfully overcome

[¶] In choosing supports for such syntheses, one should take into account the fact that peptide syntheses are performed in organic solvents, while the elongation of the oligosaccharide chain is carried out in aqueous media.

Scheme 25

Scheme 26

Scheme 27

Scheme 28

through the use of complex polymeric supports (PEGA) capable of swelling both in water and in organic solvents, or of mineral supports (*e.g.*, CPG modified by introduction of amino groups).

The synthesis of a model *N*-glycopeptide, *viz.*, { β -D-Galp-(1-4)- β -D-GlcNAc-[1-N(4)]-Asn-Gly, on a PEGA-type support modified by attachment of the Rink linker is shown in Scheme 27.¹⁸ A C-terminal amino acid, *viz.*, *N*-Fmoc-glycine, was immobilised on a modified support. After removal of the Fmoc-group, the immobilised glycine **147** was made to react with *N*(4)-glycosylated *N*(2)-Fmoc-asparagine to give the glycopeptide **148**. Incubation with UDPGal and β -(1-4)galactosyl transferase was carried out after removal of Fmoc- and *O*-acetyl protecting groups. The resulting glycopeptide **149** was split off the polymer with CF₃COOH or used further in the immobilised form. The glycosylation reaction was monitored by ¹H NMR spectroscopy.

The use of CPG modified with 3-aminopropyl groups for solid-phase chemo-enzymic synthesis of glycopeptides was exem-

plified in the preparation of sialyl-Lewis-X glycopeptide (Scheme 28).¹⁴ In this synthesis, the hexaglycin fragment was attached to the amino groups of the modified CPG; the unreacted amino groups of the polymer were 'capped' by acetylation to prevent their involvement in further reactions after which the terminal amino group of the hexapeptide was acetylated with *O*-(*N*-Boc-phenylalanyl)glycolic acid. The ester bond formed is susceptible to hydrolysis with chymotrypsin and is well-suited for splitting the reaction product off the support. Following liberation of the amino group in the ester **150**, glycine and *N*(4)-glycosylated asparagine residues were introduced by conventional methods of solid-phase peptide synthesis. The immobilised glycopeptide **151** was incubated with UDPGal and β -(1-4)-galactosyl transferase to afford the immobilised glycopeptide **152**. The latter was made to react with cytidine 5'-phospho-*N*-acetylneuraminic acid (CMP-*N*-acetylneuraminic acid, the activated form of *N*-acetylneuraminic acid) and α -(2-3)-sialyl transferase to yield the

glycopeptide **153p** containing a trisaccharide chain. The latter is easily split off the support with α -chymotrypsin. After liberation, the *N*-glycopeptide **153** was further glycosylated in solution with thymidine 5'-diphospho-L-fucose (TDP-fucose) in the presence of α -(1-3)-fucosyl transferase eventually resulting in the branched *N*-glycopeptide **154**.

The synthesis of a more complex biologically important *O*-glycopeptide **155** with the same tetrasaccharide moiety, which represents a fragment of the mucin-type glycoprotein MAdCAM-1 (a specific ligand for selectins),⁹² was carried out in a similar way. The problems which arose in its synthesis were connected with the high lability of the *O*-glycosidic bond between *N*-acetylglucosamine and threonine.

The synthesis of the glycopeptide **155** was carried out on PEGA and CPG modified with aminopropyl groups. CPG appeared to be more convenient than organic supports of the PEGA type. The Hycron linker containing an allylic hydroxy group with an attached *N*-Fmoc-alanine as a terminal amino acid was used for the immobilisation of the peptide chain.

After removal of the Fmoc-group in the polymer Fmoc-Ala-HYCron-NH-CPG, the peptide chain was elongated from the alanine residue using a standard *N*-Boc/OBu^t procedure. *N*-Acetylglucosamine linked to threonine served as a carbohydrate-peptide junction. After removal of *N*- and *O*-protecting acid-labile groups (treatment with trifluoroacetic acid in the presence of ethanedithiol) from the immobilised monoglycosyloctapeptide **156**, this

AcLys(Boc)-Pro-Pro-Asn(Trt)-Thr-Thr(Bu^t)-Ser(Bu^t)-Ala-HYCron-NH-CPG

was incubated first with UDPGal in the presence of galactosyl transferase and then with CMP-*N*-acetylneuraminic acid in the presence of α -(2-3)-sialyl transferase. The resulting triglycosyl peptide derivative **157** was split off the support in the presence of

Pd(0) as a catalyst. The yield of the glycopeptide **157** was 9% with respect to the immobilised alanine. The glycopeptide **157** was converted into the glycopeptide **155** by enzymic fucosylation as described above.

The glycopeptide **155** has also been synthesised in a solution. The yield of the target product was higher in this case, but the reaction time increased significantly (up to 9 days). In the authors' opinion,⁹² the shorter duration of solid-phase synthesis may fully compensate for the lower yields of the target product.

The enzymic elongation of oligosaccharide chains was also employed in the synthesis of glycoconjugates which are used in the manufacture of diagnostic preparations (artificial antigens), *e.g.*, in the synthesis of a polymer containing the α -NeuNAc(2-3)- β -D-Galp(1-4)- β -D-GlcNAc chains attached to a polyacrylamide carrier.⁹³ The polyacrylamide carrying monosaccharide residues was obtained by copolymerisation of *n*-pent-4-enyl 2-acetamido-2-deoxy- β -D-glucopyranoside and acrylamide.⁹⁴ This was incubated consecutively with UDPGal in the presence of β -(1-4)galactosyl transferase and *p*-nitrophenyl *N*-acetylneuraminic acid in the presence of Tc-Ts-transsialidase to afford the synthetic glycoconjugate **158**, which contained trisaccharide units together with a small amount of unsialylated units.

Thus, in some cases the solid-phase synthesis is confined exclusively to the preparation of a glycopeptide containing only one monosaccharide residue in the carbohydrate-protein junction, which is followed by enzymic elongation of the carbohydrate chain in solution. The synthesis of a large series of *N*-glycopeptides the chains of which contained different amino acid sequences including two asparagine residues glycosylated with *N*-acetylglucosamine, *N*-acetylglucosamine and sialyl(2-6)-*N*-acetylglucosamine, provides an example.⁹⁵

The solid-phase synthesis of lactosylceramide on a soluble support with a photosensitive linker is yet another, thus far unique example of enzymic elongation of a carbohydrate chain in glycolipids.⁹⁶ Synthetic (2*S*,3*R*,4*E*)-2-amino-1-(β -D-glucopyranosyloxy)-3-hydroxyoctadec-4-ene (**159**, glucosylsphingosine) was converted into a urethane (4-hydroxymethyl-3-nitrobenzoic acid derivative) and immobilised on a copolymer of acrylamide with *N*-acryloyloxysuccinimide (Scheme 29). The immobilised glycolipid **160** was incubated with UDPGal and galactosyl transferase. The resulting disaccharide derivative **161** was purified from low-molecular-weight admixtures by dialysis and the reaction product **162** was split off the polymer by photolysis.

VI. Synthesis of phosphoglycans

Solid-phase synthesis has successfully been used for the preparation of fragments of phosphoglycans, *i.e.*, the regular biopolymers built of repeating carbohydrate units linked through phosphodiester bonds. This class of biopolymers, *e.g.*, teichoic acids, are widespread in microorganisms where they play the role of antigens.

Synthesis of phosphoglycans in solution results exclusively in low-molecular-weight compounds which contain no more than two or three repeating units of the biopolymer. Apparently, solid-phase synthesis is more preferable in the preparation of high-molecular-weight phosphoglycan fragments. Several examples of such syntheses are currently known.

In general, the synthesis of phosphoglycans is very close to the synthesis of polynucleotides and differs in the structure of the repeating units which incorporate more or less complex carbohydrate structures.

The synthesis of a fragment of teichoic acid from *Bacillus licheniformis* is the first example of solid-phase phosphoglycan synthesis. This biopolymer is built of 1-*O*-(β -D-galactopyranosyl)glycerol repeating units linked *via* (6'-3)-phosphodiester bonds. The solid-phase synthesis of the trimer of the repeating unit of this phosphoglycan was performed on a modified CPG; the phosphodiester bond was formed using the phosphoramidite method (Scheme 30).⁹⁷ The galactopyranosylglycerol derivative **163**, which represents a fragment of the repeating unit of this biopolymer, was synthesised in solution and was treated with succinic anhydride to yield the succinic acid monoester **164**, which was then immobilised on the modified CPG. The reaction of the derivative **163** with $\text{Pr}_2\text{NP}(\text{OCH}_2\text{CH}_2\text{CN})\text{Cl}$ gave (galactosylglyceryl) (2-cyanoethyl) *N,N*-diisopropylphosphoramidite **165**, which was used as a phosphorylating agent. The elongation of the oligomeric chain was carried out in an automated mode using

a well-established technique for the synthesis of oligonucleotides. This included reiteration of the following operations: liberation of the primary hydroxy group in the galactose residue of the polymer **164p** by removal of the 6'-dimethoxytrityl group, the reaction with phosphoramidite **165** in the presence of 1*H*-tetrazole, acetylation of unreacted free hydroxy groups in order to prevent their interaction at subsequent steps and oxidation of trivalent phosphorus into pentavalent phosphorus with iodine. The yield in each reaction cycle was 95%. The target product **166** ($n = 3$) was split off the support by ammonolysis with simultaneous removal of *O*-acetyl and cyanoethyl groups. The structure of the teichoic acid fragment thus prepared was confirmed by ¹H NMR spectroscopy and FAB-mass spectrometry.

The synthesis of a fragment of the capsular polysaccharide of *Haemophilus influenza* (type b), which is known to induce meningitis in children, proved to be more difficult. This synthesis was undertaken⁹⁸ with the aim of using this phosphoglycan as an artificial antigen in the preparation of a synthetic vaccine (Scheme 31). This synthesis utilised the methodology of the oligonucleotide synthesis and was carried out on a modified CPG. The substituted ribosylribitol **167** was used as the starting compound. The disiloxanedyl group was removed by treatment with Bu_4NF , the primary hydroxy group was selectively protected by silylation and the secondary hydroxy group at C(3') was converted into the succinic acid monoester. The resulting ester **168** was immobilised on CPG and detritylated to afford the polymer **169**. The ribosylribitol **167** was converted into 2-cyanoethyl *N,N*-diisopropyl phosphoramidite **170**. This was then introduced into reaction with the polymer **169**, which was carried out in an automated synthesiser under conditions of nucleotide synthesis. The reaction cycle was repeated as many times as required after which a (6-aminoethyl) phosphate spacer was attached to the oligomer **171** ($n = 6$) in order to ensure its further transformation into a synthetic antigen following binding to the protein. The reaction product was split off the support by

ammonolysis; the protecting groups were removed by treatment with Bu_4NF and hydrogenolysis. The overall yield of the target oligomer **172** ($n = 6$) was 24%.

DMTr is dimethoxytrityl; BOM is benzyloxymethyl.

Scheme 30

Scheme 31

Synthesis of the phosphoglycan on a soluble support (PEGA)⁹⁹ using an analogous scheme with *O*-benzyl protection, was found to be more efficient and suitable for practical purposes. In this case, the loading of the support was larger (109 mmol g^{-1}) than in the previous synthesis (34 mmol g^{-1}); higher oligomers were synthesised in 35% yield.

The same standard procedure was used in the synthesis¹⁰⁰ of a fragment **173** of the phosphoglycan of *Haemophilus pleuropneumoniae* (serotype 2) which induces swine diseases. This fragment is made up of β -D-glucopyranosyl-(1-6)- β -D-glucopyranosyl-(1-6)- α -D-galactopyranosyl-(1-3)-glycerol repeating units linked through (1-3')-phosphodiester bonds.

The synthesis of the tetrameric fragment of the repeating unit¹⁰⁰ was carried out according to a scheme similar to those used in previous syntheses. CPG modified with aminopropyl groups served as the support and the phosphoramidite method was employed for the formation of the phosphodiester bond.

2-*O*-Benzyl-3-*O*-dimethoxytritylglycerol was converted into a monoester of succinic acid and immobilised on CPG as in the previous syntheses. The resulting product **174** was detritylated and used as an initial unit for the elongation of the chain. The

primary hydroxy group in the glycerol portion of the repeating unit, viz., triglycosylglycerol **175**, was protected with dimethoxytrityl ether, and the hydroxy group at C(3) of the galactose residue was converted into (2-cyanoethyl) *N,N*-diethylphosphoramidite and used as a phosphorylating agent under conditions of automated oligonucleotide synthesis. The immobilised tetramer of the phosphoglycan repeating unit **176** obtained after four reaction cycles was detritylated with subsequent introduction of a phosphorylated spacer. The reaction product was split off the support by ammonolysis with simultaneous removal of protecting ester groups. Subsequent hydrogenolysis gave compound **173** which could be employed for the preparation of a synthetic vaccine.

These results demonstrate the high efficiency of the solid-phase synthesis of phosphoglycans of the teichoic acid type, which utilises well-established techniques of nucleotide synthesis.

VII. Conclusion

The examples of solid-phase carbohydrate syntheses described above demonstrate that advances in this area are modest yet. The problems encountered in solution synthesis of various carbohydrate structures are related to the polyfunctionality of monosaccharides and non-stereospecificity of the formation of glycosidic bonds; these problems persist and preclude automation of the synthesis.

It is quite natural that the 'technology' of solid-phase synthesis of carbohydrates demands further improvement and studies in this area are currently under way. It is desirable that the elongation of the carbohydrate chain by chemical methods should involve standard procedures for the formation of active glycosyl-donor function and for the liberation of hydroxy groups after each elongation step. The solution of this problem would open a way to the automation of the synthetic process.

An example of a successful solution of this problem is described in this review, particularly, in the section devoted to oligosaccharide synthesis by the glycal method. It should be noted that elongation of the oligosaccharide chain is more conveniently performed in the direction from the reducing end of the chain to its non-reducing end, since in this case the elongation of the chain by addition of the next fragment to the immobilised reagent should be preceded only by a selective liberation of the required hydroxy group, which is much easier to perform than to reconstruct the activated glycosidic centre.

Yet another problem which demands urgent solution is the choice of ideal polymeric supports and linkers compatible with them. Their wide availability will significantly simplify the synthesis and open up a way to the automated synthesis.

Obviously, solid-phase synthesis can successfully be employed for the preparation of lower oligosaccharides, but in this case its advantages over syntheses in solution are not so apparent. However, on going to higher-molecular-weight oligosaccharides and glycoconjugates the merits of the solid-phase technique will become more conspicuous as in the case of glycoconjugate (*viz.*, glycopeptide and phosphoglycan) synthesis. It is this trend that has become particularly popular in the last few years. And yet major progress was achieved in those syntheses where the elongation of the carbohydrate chain was carried out by enzymic methods, which made it possible to overcome the problem of selective protection of hydroxy groups and its changes in each step of the synthesis.

The feasibility of modification of immobilised monosaccharides presents particular interest and can be illustrated by several examples.

The use of solid-phase techniques in combinatorial chemistry, particularly in a search for carbohydrate structures possessing the optimum biological activity, is one of the most attractive fields. The use of solid-phase synthesis for the preparation of an immense diversity of the so-called 'libraries' of structurally related polyfunctional oligosaccharide structures, excels other methods in many points.

A search for medicinal drugs and other substances possessing specific biological activities among carbohydrate-containing compounds demanded a rapid synthesis of a vast variety of analogues and fragments of biopolymers aimed at a selection of the most active compounds. This in turn required the acquisition of 'libraries' of compounds synthesised by methods of combinatorial chemistry and their further analysis.

It is known that 'combinatorial chemistry' is based on the principle of simultaneous synthesis of a series of related compounds and includes reactions of structurally similar acceptors with donors analogous to each other. This principle can be used

sequentially in different stages of a multistep synthesis.¹⁰¹ The most active compounds are further selected from such 'libraries'.

This strategy attracts considerable attention of specialists in the chemistry of biopolymers who widely utilise the strategy of solid-phase synthesis in the design of peptide and oligonucleotide 'libraries'. Very often, the selection of active components does not require their splitting off the support. The advantages of this approach in a search for biologically active oligosaccharides are especially apparent against the background of their immense structural diversity, which is due to the polyfunctionality of the constituent monosaccharides. The applicability of solid-phase synthesis to the construction of oligosaccharide 'libraries' has been considered.¹⁰² Acquisition of a 'library' comprising ~ 1300 compounds which represent derivatives of β -D-galactopyranosyl-(1-3)-2-deoxy-2-*N*-acylaminogalactopyranoside and include di- and trisaccharides differing in the nature and sequence of monosaccharides, type of intermonomeric glycosidic bonds and substituents at hydroxy and amino groups is a clear example.¹⁰³ A Tentagel-type polymer was used as a support and glycosyl sulphoxides served as glycosyl donors. The resulting 'library' of immobilised oligosaccharides was examined for the specificity of carbohydrate-protein interactions. The most active components were selected using a lectin test.

At present, the principles of combinatorial chemistry including carbohydrate synthesis have become widely used by large manufacturing companies.¹⁰⁴

Special mention should be made in conclusion of a recent review¹⁰⁵ devoted to solid-phase synthesis of oligosaccharides, which suggests that interest in this method continues.

Abstract. Methods for the preparation of nano-sized metal particles are considered. Theoretical approaches to the analysis of electron behaviour in systems with quantum-size effects are outlined. The results of experimental investigations of the thermodynamic and optical characteristics of small metal particles and thin films are presented. The data of experiments on the electron dynamics in single nanoparticles and nanoparticle ensembles are described. The self-assembly of nanoparticles to form supported ordered structures is considered. The bibliography includes 343 references.

I. Introduction

The interest of researchers in nano-sized systems has markedly enhanced in recent years. Two main lines have taken shape in the research and practical application of systems consisting of elements with sizes from several nanometers to hundred nanometers. The first line includes studies of nano-structured materials. These materials are formed by a large number of nano-sized particles the individual properties of which show themselves in an indirect way — the change in the properties of individual structural units on passing to the nanometer region results in the appearance of new properties of the material. Thus, the ceramics produced from nanometer particles possess enhanced strength, plasticity and wear resistance; alloys of non-compatible metals can be formed; the electrical and magnetic properties of the composites are enhanced, and so on. The achievements concerning imparting new properties to nano-structured materials have been described in the literature fairly comprehensively.^{1,2} Therefore, we do not consider these aspects here.

The second line of research is related to studies of individual nanoparticles. The goals of these studies include both the develop-

ment of methods for the preparation of nanoparticles which would allow one to manipulate them as separate objects and investigation into the physicochemical properties of the nanoparticles synthesised. The history of development of these investigations is fairly long; the results are reflected in monographs.^{3,4}

However, after the publication of these monographs, many new results not reflected yet in review literature have been obtained. The greater part of the experimental data concerning the synthesis and study of the properties of nanoparticles appeared during the last decade. This enhancement of the interest in nanoparticles is due to several reasons

— methods for controlling the size of nanoparticles have been developed;

— new methods for the experimental investigation of nanoparticle structures and electronic and optical characteristics have appeared;

— procedures which enable isolation and stabilisation of individual nanoparticles together with the investigation of their physicochemical properties have been elaborated;

— finally, new properties of nanoparticles were discovered which permit them to be regarded as promising elements of microelectronic devices. The progress attained in the synthesis and study of nanoparticles brought about new problems, which have also stimulated new experimental studies.

In this review, we consider only some of the problems related to the 'quantum-size' colloid metal systems. One should bear in mind the difference between nano-sized (or quantum-size) particles and ultradisperse systems. The latter term has long been used in colloid chemistry. It refers to systems consisting of particles the size of which is smaller than 100 nm; in this case, the contribution of the surface to the thermodynamic characteristics becomes significant, which implies the possibility of changing the surface properties, for example, the surface tension (size corrections). The bulk properties of the particles are usually considered invariant. Meanwhile, the term nano- or quantum-size particles is used to imply colloidal systems of particles, the bulk characteristics of which undergo changes of one type or another caused by particle dimensions. It is this type of systems that is discussed below.

Attention is focused on the preparation of metal nanoparticles in colloidal solutions and on the thermodynamic properties of nanoparticles and metallic films under conditions where quantisation of the electron movement plays a noticeable role. Simulta-

Uspekhi Khimii 69 (10) 899–923 (2000); translated by Z P Bobkova

neously, the main methods used to calculate the electronic structures and thermodynamic characteristics of quantum-size metal systems are outlined. The features of electron dynamics in small metal particles are described and the collective effects in the colloidal ensembles of nanoparticles are considered.

We wittingly restricted consideration to colloidal systems based on metal particles because other nano-sized systems as well as methods for their synthesis and study of properties have already been described in review literature. For example, the results of investigations into the synthesis and encapsulation of nanoparticles in various organic matrices have been reported^{5,6} and various aspects of the physical chemistry of semiconductor nanoparticles have been analysed comprehensively in a review.⁷ In addition, the experimental data concerning nano-sized systems are so numerous that it is impossible to embrace the whole body of information available from the literature in one review.

II. Methods for the synthesis of metal nanoparticles

There exist diverse methods for the preparation of nanoparticles and nanocomposites. In this Section, we shall consider several main methods used to prepare nanoparticles which ensure the possibility of isolating them and separating them from the ensemble. Nanoparticles can present interest as elements of microelectronic devices only when they have been isolated from the ensemble. Therefore, the problem of preparing individual nanoparticles is one of the central problems in today's investigations.

1. Evaporation–condensation method

The evaporation–condensation method has long served as a common method for the preparation of metal nanoparticles.³ According to this method, a metal is evaporated into a flow of an inert gas. Then the flow of the carrier gas with the metal vapour is fed to a chamber, while the temperature of the chamber walls varies according to a previously specified pattern. The pattern of temperature variation is usually calculated taking into account the heat and mass transfer equations and the kinetics of nucleation, in order to attain the necessary rate of condensation of the metal vapour such that the particles have time to grow to the required size before supersaturation is eliminated.

Until recently, the particles thus prepared have been deposited on an inert substrate.^{3,8} The use of a support was necessary in the gas-phase method. Only in this case, were individual particles produced because nano-sized particles are fairly mobile and stick together upon collision; hence, their aggregation has to be suppressed somehow.

Detailed investigations⁹ into the kinetics of aggregation of nanoparticles during their preparation by the evaporation–condensation method have shown that, for example, zinc nanometer particles aggregate over periods of 10–100 ms depending on the conditions of particle growth. They form fractal aggregates with log-normal size distribution, the average size of the aggregates corresponding to the micrometer range.

The evaporation–condensation procedure gives rise to the purest metal particles. This is why it still remains attractive; however, search for the methods that would enable the preparation of nanoparticles without using solid supports is in progress. Methods have been proposed^{10–14} in which the solid support was replaced by frozen argon¹⁰ or by a solvent.^{11,14} According to these (and other similar) techniques, the particles are co-precipitated with the solvent; thus, a composite containing nanoparticles gradually grows. By subsequent heating, the solid composite is converted into a colloidal dispersion of nanoparticles.

Colloidal dispersions obtained in this way are not always stable. In order to obtain stable systems, the methods mentioned above have been modified,^{15,16} namely, surfactants were introduced into the system by co-precipitation (or added subsequently). This gave particles with sizes of up to 1 nm dispersed in

a solvent with a concentration of 10^{20} particles per m^3 . According to the data of electron microscopy, systems prepared in this way contained no particle aggregates.

In early studies,^{15,16} evaporation–condensation experiments were performed with silver particles. This method was studied in more detail in another study in which Ag, Bi, Cu and Te nanoparticles were obtained.¹⁷ It was found that particles with the size from 1 to 10 nm can be obtained in any of the systems tested by varying the pressure and the composition of the carrier gas. The particle size varies as a linear function of pressure. The particles are characterised by a rather narrow size distribution, the corresponding standard deviation being 1.4–1.6.

Particles of Ag/M alloys ($M = \text{Co}, \text{Fe}, \text{Ni}$) with approximately the same characteristics were also prepared by the evaporation–condensation technique.¹⁸

An aerosol method for the preparation of silver nanoparticles coated with a dodecanethiol layer and subsequent introduction of the particles into an organic solvent have been reported.^{19,20} Coating with dodecanethiol was accomplished in the vapour phase immediately after the nucleation of particles by mixing of an aerosol flow with a flow of an inert gas saturated by dodecanethiol vapour. This procedure provided nanoparticles with the best dispersity; however, this was associated with substantial procedural difficulties.

Despite the progress achieved using the evaporation–condensation method, it is mainly employed to produce composite materials and is seldom used to prepare nanoparticles. This is due, first, to the low productivity of the method and, second, to the fact that the size distribution of the resulting particles is too broad, according to the modern criteria. In addition, when using this method, it is difficult to control the size of the nanoparticles formed. As a consequence, standard colloidal methods for the preparation of nanoparticles proved to be more convenient; they have become more attractive owing to the unexpectedly successful use of special surfactants.

2. Reduction from solutions

Chemical reduction is used most widely to synthesise colloidal particles.²¹ Metal salts can be reduced by various reducing agents in the presence of stabilisers (special ligands, polymers, surfactants), which suppress particle aggregation.^{22,23} The reduction yields particles of different sizes. The size cannot be predicted because it is affected simultaneously by several factors: the nature and the concentration of the solvent and the stabilising agent used, reaction temperature, and reaction time. In addition, the particle size is determined to a large extent by the supersaturation developed, higher supersaturation resulting in smaller particles; hence, the size of the particles can be controlled by varying supersaturation.^{21,24}

The degree of supersaturation reached in the experiments is governed by the rate of the chemical reduction, temperature and the amount of the reduced metal spent for the particle formation and growth. The process of particle formation is normally connected with homogeneous (or, perhaps, heterogeneous) nucleation. As a rule, it is limited by the experimental conditions. For this reason, the main way of controlling the particle size is to use growth retardants, which play a dual role. On the one hand, they retard the transfer of the reduced metal from the solution to the particles and thus increase supersaturation. On the other hand, the retardants directly limit the rate of the increase in the particle size. Thus, the choice of the protective shell of the particles appears to be the crucial point in controlling the particle size.

Alkanethiols are known to form dense self-assembled monolayers on the surface of crystalline gold.²⁵ However, until recently, this fact has not been used in the synthesis of nanoparticles. Only in a few publications,^{26,27} were alkanethiols employed in the reduction of gold in a solution of HAuCl_4 by NaBH_4 ; it was found that this process yields virtually monodisperse particles. Originally, so-called two-phase method consisting of two stages has been used for reduction.^{26,27} In the first stage, metal-contain-

ing reagents were transferred from the aqueous phase to the organic phase and then solutions of the surfactant and the reducing agent were added to the organic phase. Subsequently, a single-phase method was developed.^{28–34} According to this method, solutions of the surfactant and the reducing agent were added simultaneously to a metal-containing solution. Presumably, in both cases, gold is reduced to the atomic state, which ends in the nucleation of atoms to give nanocrystals; alkanethiols are adsorbed on the surface of the crystals. The thermodynamics of formation of gold nanoparticles in the presence of alkanethiols has been considered in a study,³⁰ where it was shown that the process of formation of nanoparticles is similar to the process of formation of drops of a water-in-oil microemulsion.

The gold nanocrystals coated by an alkanethiol monolayer, which are formed upon reduction, consist of a metallic core comprising 10 to 5000 atoms and a dense surfactant shell. Almost all the particles exhibit a clear-cut plasmon band in the optical absorption spectrum. The position and the width of the band depend on the particle size and the properties of the adsorbed layer.

The monolayer on nanoparticles is assumed to be self-assembled in the same way as on the surface of bulk samples. The size of nanocrystals depends on the length of the alkyl chain in alkanethiol and on the thiol to gold ratio in the solution.^{27, 32, 35} Examination by electron microscopy shows that gold microcrystals are compact and faceted and have a face-centred cubic (FCC) lattice.³² The crystals are mainly octahedral or icosahedral. The inner area of the microcrystals is pure gold, the sulfur atoms being located on the surface and connected to alkyl chains. These results were obtained from spectroscopy and mass spectrometry.^{32, 36, 37}

Arnold and Reilly³⁷ reported a unique experiment. After the powder of gold nanoparticles coated by alkanethiols had been prepared, it was exposed to powerful laser radiation. As a result, the particles were 'evaporated'. The flow of particles was again irradiated by a laser with the wavelength selected in such a way as to cleave the bond between sulfur and the alkyl chain. This yielded gold nanoparticles with an adsorbed layer of sulfur atoms. The resulting clusters were studied by mass spectrometry. Interpretation of the mass spectra showed that the sulfur atoms form dense monolayers on the surface of gold microcrystals. This result fully confirmed the assumption concerning the formation of dense self-assembled monolayers of alkanethiols on the surface of gold nanoparticles.

A study has been devoted to the dependence of the structure of alkanethiol adlayers coating nanoparticles on the particle size.³⁸ Particles with sizes ranging from 1.2 to 5.2 nm were used in these experiments. The properties of the adlayer were studied by Fourier transform IR spectroscopy, differential scanning calorimetry, wetting and thermal desorption mass spectrometry. The transition from a two-dimensional to three-dimensional packing of alkanethiol molecules was also investigated. It was found that in the case of larger nanoparticles, more ordered conformations of the alkyl chains in the adsorbed alkanethiols are observed. The critical diameter corresponding to the change in the pattern of the adlayer packing was found to be 4.4 nm. For particles with larger diameters, a two-dimensional adlayer is formed, whereas in the case of particles with smaller diameters, elements of a three-dimensional packing show themselves in the adlayer.

In recent years, more complex thiolates have been used for the production of gold nanoparticles,^{39–43} because surfactants with more complicated structures may promote the formation of self-assembled monolayers of nanoparticles (see below). The method is being perfected;⁴⁴ this allows preparation of particles of different metals according to the same procedure.

In particular, alkanethiols have been employed to produce silver nanoparticles^{45–50} (by both single-phase and two-phase procedures). Simultaneous synthesis of gold, silver and platinum nanoparticles has also been accomplished.⁵¹ As for gold, in this case, too, the position of the plasmon band in the optical

absorption spectra depended on the method of preparation and the structure of the environment of metal particles.

3. Reduction in microemulsions

Microemulsions of the 'water-in-oil' type (reverse micelles) have been attracting increasing attention in recent years as micro-reaction media for the preparation of nanoparticles. Microemulsions consist of nano-sized water (or solution) drops dispersed in oil (organic) phase and stabilised by surfactant molecules distributed over the interface. Highly dispersed drops of water are perfect microreactors for the preparation of nanoparticles because the size of drops is a natural restrictor for the dimensions of the growing nanoparticles.

Primarily, microemulsions have been used for the preparation of monodisperse microparticles. The synthesis of Pt, Pd, Rh and Ir particles by the reduction of the corresponding salts in water drops has been described.⁵² Since this publication appeared, microemulsions have been repeatedly used for the preparation of diverse particles of both individual metals and their compounds.

In the 90s, the use of microemulsions to prepare silver,^{53–55} gold,⁵³ platinum, cobalt⁵⁶ and iron⁵⁷ nanoparticles was reported. Nanoparticles were prepared by reduction of the corresponding metal salts by sodium tetrahydroborate or hydrazine. The unique opportunities for controlling the size and shape of nanoparticles from microemulsions have been demonstrated in several studies.^{58–61} The high efficiency of microemulsions in preparing nanoparticles of specified dimensions and shapes was demonstrated most vividly in several studies by Pileni *et al.*^{62–67}. In these works, a functional surfactant, copper bis(2-ethylhexyl)sulfosuccinate Cu(AOT)₂, was used to prepare copper nanoparticles. The surfactant played a dual role — on the one hand, it stabilised drops of water and, on the other hand, it served as a source of copper in the drops.

To prepare nanoparticles, a microemulsion of water drops stabilised by Cu(AOT)₂ and Na(AOT) in isooctane was mixed with a microemulsion of drops of a solution of sodium tetrahydroborate stabilised by Na(AOT). After microemulsions have been mixed, the material exchange between the drops starts and copper is reduced. Due to the presence of natural restrictions, the resulting copper particles are nano-sized.

The size and shape of particles are largely determined by the ratio

$$w = \frac{[\text{H}_2\text{O}]}{[\text{AOT}]}$$

in the microemulsion, because the structure of the microemulsion also depends significantly on this ratio. When $w < 4$, only spherical drops are present, their size being proportional to w . Reduction of copper in such a system gives rise to spherical nanoparticles 1 to 12 nm in diameter; their size is also proportional to w .

Further increase in the content of water ($4 < w < 5.5$) changes the shape of microdrops — they become spheroidal. Correspondingly, reduction in the system affords spherical nanoparticles with diameters of 8.2 and 12 nm and cylindrical particles with a diameter of 12 nm and a length of 18.5 nm. When the relative water content is $5.5 < w < 11$, the microemulsion has a structure of a bi-continuous phase in which nano-spheres with diameters of 6.7 and 9.5 nm and 22.6-nm long nano-rods 9.5 nm in diameter are formed.

When the content of water increases further ($w > 11$), the microemulsion is transformed into a lamellar structure in which only rods with lengths of 300 to 1500 nm and with diameters of 10 to 30 nm are present. According to electron microscopy data, nanoparticles synthesised in microemulsions (including the long rods mentioned above) have defect-free surfaces, which indicates their high quality.

The process of reduction of nanoparticles in microemulsions was studied by numerical modelling by the Monte Carlo method.^{68–70} The modelling data showed that the flexibility of

the surfactant monolayer and the surfactant concentration in the system play an important role in the formation of particles in microemulsions. By varying the monolayer flexibility and the content of the surfactant, one can change appreciably the size distribution of nanoparticles and even prepare ensembles with a bimodal size distribution, which is apparently due to the character of evolution of the supersaturation of microemulsions with metal atoms.²⁴

Since surfactants play an important role in the preparation of nanoparticles in microemulsions, the search for new, in particular, non-ionic surfactants which could be used in the synthesis of metal nanoparticles is currently in progress.⁷¹ Syntheses are carried out using non-traditional microemulsions such as water drops in supercritical carbon dioxide.⁷²

In view of the significant dependence of the size distribution of particles on the character of the exchange of matter between the drops, the use of new methods for the synthesis of nanoparticles in microemulsions which exclude this exchange has started. For example, Revina *et al.*^{73,74} prepared silver nanoparticles by radiation-induced reduction. Studies on the influence of external factors, for example, temperature,^{75,76} on the size and shape of nanoparticles formed in microemulsions have been carried out (in the studies cited, these were gold nanoparticles).

4. Preparation of nanoparticles with a stoichiometric composition

A method yielding metal nanoparticles with a definite composition is most promising as regards investigation of the individual properties of these particles. Primarily, these particles were obtained as metal clusters containing less than ten and, later, more than ten metal atoms (a brief review of the history of preparation of these compounds has been reported⁷⁷). Substantial progress along this line has been achieved by Vargaftik *et al.*,^{78–80} who identified unambiguously palladium clusters containing (in the ideal case) exactly 561 metal atoms. The cluster had the composition $\text{Pd}_{561}\text{L}_{60}(\text{OAc})_{180}$, where L is 1,10-phenanthroline or 2,2'-bipyridine and the OAc groups form the ligand shell. The cluster was produced in a two-stage synthesis^{78–80} including the reduction of $\text{Pd}(\text{OAc})_2$ with hydrogen in an AcOH solution

and subsequent treatment of the high-molecular-weight clusters with oxygen

This cluster belongs to the category of 'magic clusters',[†] *i.e.* those containing strictly definite, 'magic' numbers of metal atoms, namely, 13, 55, 147, 309, 561, ... These numbers correspond to fully occupied atomic layers (shells) of cubooctahedral clusters having a FCC lattice. No clusters with three filled shells have been synthesised up to now;⁸¹ however, clusters with four⁸² ($\text{Pt}_{309}\text{Phen}_5\text{O}_{30}$, Phen is *o*-phenanthroline) and five^{78,83} ($\text{Pd}_{561}\text{Phen}_{36}\text{O}_{200}$) shells have been prepared. The existence of clusters with seven⁸⁴ ($\text{Pd}_{1415}\text{Phen}_{54}\text{O}_{1000}$) and eight⁸⁵ ($\text{Pd}_{2057}\text{Phen}_{38}\text{O}_{1600}$) shells has also been established. The clusters obtained were studied by various methods — high-resolution electron microscopy, EXAFS, Mössbauer spectroscopy, NMR and others. These studies demonstrated that metal atoms actually form a close cubic packing and the distance between the metal atoms virtually coincides with that found for bulk samples. The diameter of the metallic core of the clusters varies from 2.4 to 3.7 nm.

[†] The matter concerns 'magic' numbers in terms of the Mackay–Chini crystal-chemical model. See A L Mackay *Acta Crystallogr.* **15** 225 (1979); P Chini *J. Organomet. Chem.* **200** 37 (1980); B K Teo, N J A Sloan *Inorg. Chem.* **24** 4545 (1985).

The mechanism which provides the synthesis of clusters with a definite number of metal atoms according to the above-described scheme has not been ultimately elucidated. Investigations into the structures of the cluster precursors at different stages of evolution showed that they are shaped like polymeric chains, which are transformed into compact metal particles during heat treatment.⁸⁶ In the case of the cluster with the Pd_{561} core, the metal particle forms a FCC lattice and takes on an icosahedral or twin shape at the final stage.^{87–89}

The methods for the preparation and investigation of clusters with a specified number of atoms are being constantly improved. Modern methods have been employed to perform unique investigations of the thermodynamic and magnetic properties of these nanoparticles. It will be shown below that physical characteristics of 'quantum'-size particles depend essentially on the number of collective electrons they contain.

5. Other methods for the preparation of metal nanoparticles

Among other methods used to synthesise metal nanoparticles, apart from those described above, mention should be made of pulse radiolysis in solutions, which is employed fairly frequently.^{90–97} Under the action of X-ray or ultraviolet radiation or of high-energy electrons, clusters M_2^+ , M_3^+ , ..., M_n^{x+} are formed successively.⁹⁸ Some of these are exceptionally stable. As a result, stable magic clusters are accumulated in the solution. The presence of magic clusters is indicated by the appearance of characteristic bands in the absorption spectra. The contribution of 'non-magic' clusters was found to be insignificant because their lifetimes are fairly short. When using the radiolysis method to prepare nanoparticles, various stabilisers are also added, although in some cases, for example, for aqueous solutions of silver, the use of stabilisers is optional. The nanoparticles formed in the presence of stabilisers are characterised by a higher level of monodispersity and a smaller size. Polymers are used as stabilisers.⁹⁹ The method of radiolysis is also applicable for the preparation of nanoparticles with a mixed composition.^{100,101} This is done either by the reduction of different metal ions present simultaneously in the solution or by preparing first the particles of one metal and coating them subsequently with a shell of a different metal,¹⁰² which is also reduced by radiolysis. By varying radiation doses, one can control the size and the composition of nanoparticles. Apart from the radiation-chemical method, sonochemical preparation of particles is also used.¹⁰³

Metal nanoparticles are often prepared in the presence of polymers.^{104–120} Soluble polymers,^{104–109,118–120} block copolymers^{115,116} or cross-linked matrices are used. The role of the polymeric medium is usually to stabilise the particles. In addition, in the case of solutions of polymers or block copolymers subjected to microphase separation,¹¹⁶ they restrict the particle size. The extent to which the polymer influences the size of nanoparticles depends on the length of the polymer chain¹¹⁹ and on the conditions of synthesis. The synthesis can require a fairly sophisticated procedure; for example, nanoparticles have been prepared using supercritical carbon dioxide.¹¹¹ In another study,¹²⁰ polymers were used to ensure high yields of nanoparticles of noble metals. One more problem was solved simultaneously, namely, transfer of the nanoparticles into a colloidal solution of any concentration, replacement of the solvent being possible.

Various templates are used in the synthesis of nanoparticles in order to impart a specified shape to them and to restrict their size. The materials used for this purpose included polymeric membranes^{121,122} (this permitted the researchers to grow cylindrical particles), high-porosity oxide films¹²³ and specially prepared substrates,^{124–126} which often provided the possibility of preparing catalysts ready for use or ordered structures constructed from nanoparticles. In some cases, nanoparticles and composites based on them are prepared using the 'sol-gel' technology,^{127–132} or by growing particles in biological^{133,134} and liquid-crystalline¹³⁵ systems. A method for the preparation of nanoparticles under electric discharge in solution has been proposed.¹³⁶

III. Methods for calculation of the electronic properties of metal nanoparticles

1. The density functional method

The *ab initio* Hartree–Fock method has found wide use in the calculation of properties of many-electron systems. In this method, the properties of a many-particle system are determined by calculating the orbitals of separate electrons moving in the self-consistent field of other electrons and atomic nuclei. The Hartree–Fock method allows one to find the wave functions of electrons without invoking adjustable parameters. The main obstacle to the use of this method is the complexity of calculations; the time it takes to perform calculations increases as N^4 , where N is the number of electrons in the system. For this reason, the Hartree–Fock method is mainly used to perform calculations for atoms or relatively small molecules and clusters.

The greatest progress in calculations for many-electron systems has been attained in the last decades using the density functional method. The time needed for calculations by this method increases with an increase in the number of electrons much more slowly; at present, this method is widely used for calculations for various systems with a large number of electrons including polyatomic molecules, complexes, clusters, and condensed media.

There are two approaches in the density functional method, namely, integral and local approaches. The former dates from an original study by Hohenberg and Kohn,¹³⁷ while the latter is a modification of the theory proposed by Kohn and Sham.¹³⁸ We shall consider these approaches in relation to a system of N non-relativistic electrons described by a Hamiltonian

$$H = T + V + U. \quad (1)$$

Here T is the operator for the kinetic energy of electrons

$$T = -\frac{1}{2m} \hbar^2 \sum_i \Delta_i, \quad (2)$$

m is the mass of an electron, Δ_i is the Laplacian for an i th particle, V is the potential energy operator for a system of electrons in an external field and U is the operator of the electrostatic repulsion energy of electrons.

It was shown¹³⁷ that the electron density distribution $\rho(\mathbf{r})$ determines unambiguously all the main properties of a many-electron system including the wave function. The energy of a many-electron system in an external field $v(\mathbf{r})$ is a functional of $\rho(\mathbf{r})$

$$E[\rho(\mathbf{r})] \equiv \int v(\mathbf{r})\rho(\mathbf{r})d\mathbf{r} + G[\rho(\mathbf{r})]. \quad (3)$$

The last term depends on the wave function Ψ of the system of electrons, determined by the distribution of their density

$$G[\rho(\mathbf{r})] = \int \Psi^*[\rho(\mathbf{r})](T + U)\Psi[\rho(\mathbf{r})]d\mathbf{r} \quad (4)$$

(the character * means the complex conjugate).

The minimum energy corresponds to the ground state of the system

$$E[\rho(\mathbf{r})] \geq E[\rho_g(\mathbf{r})], \quad (5)$$

where $\rho_g(\mathbf{r})$ is the electron density distribution in the ground state.

However, the fundamentality and simplicity of the Hohenberg and Kohn theorem¹³⁷ are fraught with latent difficulties. Determination of the electronic density and other characteristics of an electron system requires that the explicit form of functional (3) be known. However, the explicit form of this functional is unknown; thus, additional statements are needed to find the form of $E[\rho(\mathbf{r})]$. Functional (3) can formally be represented as follows:

$$E[\rho(\mathbf{r})] = \int v(\mathbf{r})\rho(\mathbf{r})d\mathbf{r} + T_0[\rho(\mathbf{r})] + \frac{1}{2} \int \frac{e^2 \rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}d\mathbf{r}' + E_{xc}[\rho(\mathbf{r})], \quad (6)$$

where e is the charge of an electron, $\mathbf{r}, \mathbf{r}'$ are space coordinates.

The second term is the kinetic energy of non-interacting electrons T_0 , and the third term is the energy of electrostatic interaction between them.

The last term, $E_{xc}[\rho(\mathbf{r})]$, is an electron density functional depending implicitly on $v(\mathbf{r})$. It is usually called exchange correlation energy of electron gas. Actually, equality (6) is the definition of this functional. Thus, a fundamental problem faced by the density functional method is to elucidate the form of the functional $E_{xc}[\rho(\mathbf{r})]$. There are several approximate methods for the calculation of this functional.¹³⁹

Minimisation of functional (3) in a one-electron approximation results in a set of self-consistent equations (Kohn–Sham equations)

$$\left(-\frac{1}{2} \frac{\hbar^2}{m} \Delta_j + v(\mathbf{r}) + \int \frac{e^2 \rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + v_{xc}(\mathbf{r}) - E_j \right) \phi_j(\mathbf{r}) = 0. \quad (7)$$

Here, $\rho(\mathbf{r})$ is the electron density

$$\rho(\mathbf{r}) = \sum_{j=1}^N \phi_j^*(\mathbf{r})\phi_j(\mathbf{r}), \quad (8)$$

$v_{xc}(\mathbf{r})$ is the exchange correlation potential

$$v_{xc}(\mathbf{r}) = \frac{\delta E_{xc}[\rho(\mathbf{r})]}{\delta \rho(\mathbf{r})}, \quad (9)$$

E_j are single-electron energy levels, $\phi_j(\mathbf{r})$ are single-electron wave functions, $j = 1, \dots, N$.

The ground-state energy for a many-electron system is given in this approximation by the relation

$$E = \sum_{j=1}^N E_j - \frac{1}{2} \int \frac{e^2 \rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}d\mathbf{r}' - \int v_{xc}(\mathbf{r})\rho(\mathbf{r})d\mathbf{r}. \quad (10)$$

Formally, the Kohn–Sham equations are exact; however, there exists the problem of the relationship between $v_{xc}(\mathbf{r})$ and electron density. At present, it can be regarded proven that the potential $v_{xc}(\mathbf{r})$ can be determined unambiguously; in this case, the use of single-electron approximation does not play a crucial role.^{140–142} It has also been proven that, by using the potential $v_{xc}(\mathbf{r})$, one can reproduce precisely the distribution of electron density in the system¹⁴³ and that the upper occupied level of an isolated system of electrons in the absence of an external field is related uniquely to the ionisation potential;¹⁴⁴ in addition, the asymptotic variation of the electron density for a system with a finite number of electrons is entirely determined by the upper occupied single-electron function (orbital).

As has already been noted, the use of the density functional method requires at least an approximate way of finding $E_{xc}[\rho(\mathbf{r})]$. For a uniform electron gas, it can formally be written in the local density approximation that

$$E_{xc} = \int \rho \epsilon_{xc} d\mathbf{r}, \quad (11)$$

where ϵ_{xc} is the local exchange correlation energy of electrons, equal to $-9[(3/4\pi)\rho]^{1/3}$. For non-uniform systems, the local energies ϵ_{xc} were found as the gradient expansion^{145–149}

$$\epsilon_{xc} = g[\rho(\mathbf{r}), \nabla \rho(\mathbf{r}), \nabla^2 \rho(\mathbf{r})]. \quad (12)$$

Other attempts to determine the exchange correlation energy as the electron density functional have also been undertaken.^{150, 151} In particular, it has been represented as a non-local functional.¹⁵²

2. The method of statistical functions

In the investigations of many-electron systems including nanoparticles, considered in this review, the method of statistical distribution functions is also used. This method has been used successfully to study the surface properties of various quantum objects^{153–156} and the structures of clusters;¹⁵⁷ it can also be used to investigate the dynamic processes in quantum systems.¹⁵⁶ For this reason, we shall outline briefly the main principles of the distribution functions method.

In quantum mechanics, the role of distribution functions is played by the density matrix¹⁵⁸ for N particles, $\rho_N(t)$ (t is time). In the coordinate representation, the density matrix of a system is a function of coordinates and spin variables of all particles

$$\langle \sigma', R' | \rho_N(t) | \sigma, R \rangle = \sum_i P_i \Psi_i^*(R', \sigma') \Psi_i(R, \sigma), \quad (13)$$

where R and σ are sets of coordinates $R = (\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)$ and spin variables $\sigma = (\sigma_1, \dots, \sigma_N)$, and P_i is the probability that the system occurs in a pure state i with the wave function Ψ_i . By means of the density matrix, the average value of any operator $\hat{T}$ can be written in the form

$$\langle \hat{T} \rangle = \sum_{\sigma} \int dR \hat{T} \langle \sigma', R' | \rho_N | \sigma, R \rangle \Big|_{\substack{\sigma'=\sigma, \\ R'=R}}, \quad (14)$$

the operator $\hat{T}$ acting on the ‘non-primed’ variables of the density matrix. After the action of the operator, the primed and non-primed variables are taken to be equal.

The diagonal elements of the density matrix $\langle \sigma, R | \rho_N | \sigma, R \rangle$ determine the probabilities of distribution of the system over coordinates and spin states of the particles.

The density matrix satisfies the Liouville quantum equation

$$\left(i\hbar \frac{\partial}{\partial t} - \hat{H} + \hat{H}'^* \right) \langle \sigma', R' | \rho_N | \sigma, R \rangle = 0. \quad (15)$$

Here $\hat{H}$ is the Hamiltonian for a system of particles acting on the non-primed variables, while $\hat{H}'^*$ acts on primed variables.

For a system of particles with pair interaction, in the absence of an external field, the Hamiltonian has the form

$$\hat{H} = \sum_i \left(-\frac{\hbar^2}{2m} \Delta_i \right) + \sum_{1 \leq i < j \leq N} u(\mathbf{r}_i - \mathbf{r}_j),$$

where Δ_i is the Laplacian operating on the coordinates of an i th particle and $u(\mathbf{r}_i - \mathbf{r}_j)$ is the energy of pair interaction of particles.

Wigner¹⁵⁹ introduced a special (mixed) representation for a density matrix in which the distributions of particles over coordinates $R = (\mathbf{r}_1, \dots, \mathbf{r}_N)$ and momenta $P = (\mathbf{p}_1, \dots, \mathbf{p}_N)$ appear. The density matrices in the Wigner representation and those in the coordinate representation are related as

$$F(R, P, t) = \frac{1}{(2\pi)^{3N}} \int d\tau [\exp(-i\tau P)] \times \langle \sigma, R - \frac{\hbar}{2}\tau | \rho_N(t) | \sigma, R + \frac{\hbar}{2}\tau \rangle, \quad (16)$$

where $\tau = (\tau_1, \dots, \tau_N)$, $R - \frac{\hbar}{2}\tau = (\mathbf{r}_1 - \frac{\hbar}{2}\tau_1, \dots, \mathbf{r}_N - \frac{\hbar}{2}\tau_N)$ and $\tau P = (\tau_1 \mathbf{p}_1 + \dots + \tau_N \mathbf{p}_N)$.

In the general case, the mixed representation $F(R, P, t)$ can be used to derive separate distributions over coordinates and over particle momenta

$$F_R(R, t) = \int F(R, P, t) dP, \quad (17)$$

$$F_P(P, t) = \int F(R, P, t) dR.$$

Using the Wigner density matrix, the average value of any operator $\hat{T}(R, P)$ depending on R and P is calculated from the formula

$$\langle \hat{T} \rangle = \int dR dP \hat{T}(R, P) F(R, P). \quad (18)$$

Thus, the mixed representation for the density matrix (16) is similar to the ordinary distribution function used in classical statistical mechanics; its standard expressions can be employed to find the average values of physical quantities. There is, however, one fundamental difference between the classical and quantum descriptions: unlike the classical distribution function of particles over coordinates and momenta, the density matrix $F(R, P, t)$ can acquire not only positive but also negative values. This is due to the fact that the function $F(R, P, t)$ has no clear physical meaning because it is known that particle coordinates and momenta cannot be measured simultaneously in quantum mechanics. Only the distribution functions $F_R(R, t)$ and $F_P(P, t)$ have a physical meaning; they are positive.

The Liouville quantum equation (15) in the mixed representation has the form

$$\begin{aligned} & \left(\frac{\partial}{\partial t} + \sum_{i=1}^N \frac{\mathbf{p}_i}{m} \frac{\partial}{\partial \mathbf{r}_i} \right) F_{\sigma', \sigma}(P, R) = \\ & = \frac{1}{i\hbar} \int \frac{d\tau}{(2\pi)^3} \sum_{i \neq j} \int d\mathbf{p}'_i d\mathbf{p}'_j \delta(\mathbf{p}'_i + \mathbf{p}'_j - \mathbf{p}_i - \mathbf{p}_j) \times \\ & \times \exp \left\{ \frac{1}{2} i\tau [(\mathbf{p}'_i - \mathbf{p}'_j) - (\mathbf{p}_i - \mathbf{p}_j)] \right\} \left[u \left(\left| \mathbf{r}_i - \mathbf{r}_j + \frac{1}{2} \tau \hbar \right| \right) - \right. \\ & \left. - u \left(\left| \mathbf{r}_i - \mathbf{r}_j - \frac{1}{2} \tau \hbar \right| \right) \right] \times \\ & \times F_{\sigma', \sigma}(\mathbf{r}_1, \dots, \mathbf{r}_N, \mathbf{p}_1, \dots, \mathbf{p}_{i-1}, \mathbf{p}'_i, \mathbf{p}_{i+1}, \dots, \mathbf{p}_{j-1}, \mathbf{p}'_j, \mathbf{p}_{j+1}, \dots, \mathbf{p}_N, t). \end{aligned} \quad (19)$$

The N -particle equation (19) can be transformed by standard quantum-mechanics methods¹⁶⁰ into a sequence of engaged equations for one-, two- and many-particle distribution functions. Thus, for one-particle distribution function, after integration over coordinates and spin variables of particles 2, 3, ..., N , we have

$$\begin{aligned} & \left(\frac{\partial}{\partial t} + \frac{\mathbf{p}_1}{m} \frac{\partial}{\partial \mathbf{r}_1} \right) F_{\sigma'_1, \sigma_1}(\mathbf{r}_1, \mathbf{p}_1, t) = \frac{1}{i\hbar} \frac{1}{(2\pi)^3} \left(\frac{N}{V} \right) \times \\ & \times \int d\tau d\mathbf{r}_2 d\mathbf{p}'_2 d\mathbf{p}'_1 \sum_{\sigma_2} \exp[i\tau(\mathbf{p}'_1 - \mathbf{p}_1)] \times \\ & \times \left[u \left(\left| \mathbf{r}_1 - \mathbf{r}_2 + \frac{1}{2} \tau \hbar \right| \right) - u \left(\left| \mathbf{r}_1 - \mathbf{r}_2 - \frac{1}{2} \tau \hbar \right| \right) \right] \times \\ & \times F_{2\sigma'_1, \sigma'_2, \sigma_1, \sigma_2}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{p}_1, \mathbf{p}_2, t). \end{aligned} \quad (20)$$

The equation for a two-particle function $F_{2\sigma'_1, \sigma'_2, \sigma_1, \sigma_2}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{p}_1, \mathbf{p}_2, t)$ is more cumbersome.

The possibility of solving Eqn (20) is related to the choice of an appropriate approximation for the two-particle distribution function. Here we consider the simple self-consistent field approximation in which the two-particle function F_2 is represented as a product of one-particle functions

$$F_{2\sigma'_1, \sigma'_2, \sigma_1, \sigma_2}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{p}_1, \mathbf{p}_2, t) = F_{1\sigma'_1, \sigma_1}(\mathbf{r}_1, \mathbf{p}_1, t) F_{1\sigma'_2, \sigma_2}(\mathbf{r}_2, \mathbf{p}_2, t). \quad (21)$$

Let us introduce a density matrix normalised to the density of the number of particles

$$f_{\sigma', \sigma}(\mathbf{r}, \mathbf{p}, t) = \frac{N}{V} F_{1\sigma', \sigma_1}(\mathbf{r}_1, \mathbf{p}_1, t). \quad (22)$$

Then, in the self-consistent approximation, Eqn (20) for a steady-state case acquires a simple form¹⁵³ (the summation is done over spin variables)

$$\frac{\mathbf{p}}{m} \frac{\partial f(\mathbf{r}, \mathbf{p})}{\partial \mathbf{r}} = \frac{1}{i\hbar} \frac{1}{(2\pi)^3} \int_{-\infty}^{\infty} d\tau \int_{-\infty}^{\infty} d\boldsymbol{\eta} [\exp i\tau(\boldsymbol{\eta} - \mathbf{p})] f(\mathbf{r}, \tau) \times \quad (23)$$

$$\times \left[u_{\text{ef}}\left(\mathbf{r} + \frac{1}{2}\tau\hbar\right) - u_{\text{ef}}\left(\mathbf{r} - \frac{1}{2}\tau\hbar\right) \right],$$

where $u_{\text{ef}}(\mathbf{r})$ is the effective self-consistent potential energy

$$u_{\text{ef}}(\mathbf{r}) = u_e(\mathbf{r}) + \int v_{\text{el}}(\mathbf{r} - \mathbf{r}') f(\mathbf{r}', \mathbf{p}') d\mathbf{r}' d\mathbf{p}', \quad (24)$$

u_e is the external potential acting on particles (electrons) and v_{el} is the energy of electron–electron interaction.

Now we consider the metal–vacuum interface. Let us assume that axis z is normal to the metal surface, which coincides with the plane $z = 0$ and that the electron–electron interaction is purely electrostatic (without allowance for exchange and correlation). In this case, the effective potential u_{ef} is determined by the self-consistent Poisson equation the solution of which in the unidimensional variant has the form

$$u_{\text{ef}}(z) = 4\pi e^2 \int_{-\infty}^z d\xi q(\xi) \int_{-\infty}^{\xi} d\zeta q(\zeta), \quad (25)$$

where the electron density $\rho(z)$, appearing in the expression for the charge density

$$q(z) = n_+(z) - \rho(z) \quad (26)$$

is determined from the solutions of Eqn (23), while the density of ions $n_+(z)$ is considered specified. As usual, we shall assume that the density $\rho(z)$ is related to the function $f(z, \mathbf{p})$ by the equation

$$\rho(z) = \int f(z, \mathbf{p}) d\mathbf{p}. \quad (27)$$

Since the effective potential acting on electrons does not depend on the coordinates x and y , then

$$u_{\text{ef}}\left(\mathbf{r} + \frac{1}{4}\tau\hbar\right) = u_{\text{ef}}\left(z + \frac{1}{4}\tau\hbar\right),$$

where $\tau = \tau_z$. The function $f(\mathbf{r}, \mathbf{p})$ does not depend on the coordinates x or y either. Therefore, the left-hand and the right-hand parts of equality (23) can be integrated over the variables $\eta_x, \eta_y, \tau_x, \tau_y, p_x$ and p_y . After integration, we have

$$\frac{p}{m} \frac{\partial f(z, \mathbf{p})}{\partial z} = \frac{1}{2\pi i \hbar} \int_{-\infty}^{\infty} d\tau d\eta [\exp i\tau(\boldsymbol{\eta} - \mathbf{p})] f(z, \eta) \times \quad (28)$$

$$\times \int_{z-\frac{1}{2}\tau\hbar}^{z+\frac{1}{2}\tau\hbar} dy \int_{-\infty}^y q(x) dx.$$

Here, $\tau = \tau_z, \eta = \eta_z$ and $p = p_z$.

Solution of Eqn (28) can be found by standard methods of the kinetic theory, for example, by using the well-developed method of moments. Roldughin and Martynov have shown¹⁵³ how an equation for the electron density near the surface can be derived from Eqn (28). A number of asymptotic dependences can be derived in this way. For example, for the density of electrons in a metal far from the surface, Friedel oscillations were found

$$\rho(z) = n_+ + A \frac{\sin[2p_F(z + z_0)/\hbar]}{(2p_F z/\hbar)^2}, \quad (29)$$

where A is a coefficient, p_F is the Fermi momentum. In a vacuum at $z \rightarrow \infty$, we have

$$\rho(z) = B \exp\left(-\frac{z}{R_s}\right), \quad (30)$$

where B is a coefficient, R_s is a typical length of the attenuation of the electron density near the surface.

Comparison of the results obtained by the method of quantum distribution functions with the results of calculations by the density functional method in the same approximation shows¹⁵³ that the method of quantum distribution functions provides more precise and detailed information on the electron density distribution in metals. In particular, it describes the Friedel oscillations and predicts a steeper decay of the electron density near the metal surface where the simple exponential variation of the charge density vs. distance to the surface is established only asymptotically, which has a clear physical meaning.

3. Phenomenological method

Many properties of electronic systems the thermodynamic characteristics of which are substantially influenced by the surface can be determined using a simpler method which we would conventionally call the phenomenological method. This technique was used to calculate the disjoining pressure (see below) in thin films of liquid metals¹⁶¹ and to determine the chemical potential of electrons in small particles.¹⁶² An interesting feature of this method is the fact that the shift of the chemical potential of electrons is determined, as a first approximation, only by the surface to volume ratio for the object. The geometrical shape of the system and the contribution of the quantisation of energy levels manifest themselves in higher approximations.¹⁶¹

The method is based on the relationship between the density of electronic states $\rho(E)$ (E is the energy of electrons) and the Green function $G(\mathbf{r}, \mathbf{r}', E)$ ¹⁶³

$$\rho(E) = \frac{1}{\pi} \text{Im} \int G(\mathbf{r}, \mathbf{r}', E)_{\mathbf{r} = \mathbf{r}'} d\mathbf{r}. \quad (31)$$

Electrons are considered to move in some self-consistent field. The presence of this field is taken into account by introduction of effective boundary conditions for the electron wave function or the Green function

$$\frac{\partial G(\mathbf{r}_s, \mathbf{r}')}{\partial n} - \lambda_s G(\mathbf{r}_s, \mathbf{r}') = 0. \quad (32)$$

where $\mathbf{r}_s$ is a vector belonging to the particle (or film) surface, $\mathbf{n}$ is an internal normal to the surface, λ_s a parameter of the theory which can be interpreted as the reciprocal of the thickness of the electron cloud near the metal surface. In order to find the parameter λ_s , one has to solve the problem of electron density distribution near the particle or film surface by one of the methods described above.

The Green function can be found from the equation¹⁶⁴

$$\Delta G(\mathbf{r}, \mathbf{r}', E) + k^2 G(\mathbf{r}, \mathbf{r}', E) = -\delta(\mathbf{r} - \mathbf{r}'), \quad (33)$$

where

$$k = \sqrt{\frac{2m}{\hbar^2} (E + i\gamma)},$$

γ is the width of the energy levels of electrons, which can be related to lattice vibrations and other factors, $\delta(\mathbf{r} - \mathbf{r}')$ is a delta function.

A method for finding the Green function $G(\mathbf{r}, \mathbf{r}', E)$ and the density of states $\rho(E)$ has been proposed by Balian and Bloch,¹⁶⁴ who found them as an expansion in terms of ‘multiple scattering’ of electrons by the surface. The Green function was represented as the sum

$$G(\mathbf{r}, \mathbf{r}', E) = G_0(\mathbf{r}, \mathbf{r}', E) + G_1(\mathbf{r}, \mathbf{r}', E). \quad (34)$$

Here $G_0(\mathbf{r}, \mathbf{r}', E) = [\exp(ik|\mathbf{r} - \mathbf{r}'|)]/4\pi|\mathbf{r} - \mathbf{r}'|$ is the Green function for free electron gas and $G_1(\mathbf{r}, \mathbf{r}', E)$ is a correction to this function; it was proposed to determine the correction as the potential of a simple layer

$$G_1(\mathbf{r}, \mathbf{r}', E) = \int_S dS_\alpha G_0(\mathbf{r}, \mathbf{a}, E) \mu_1(\mathbf{a}, \mathbf{r}'). \quad (35)$$

The parameter $\mathbf{a}$ used here and $\boldsymbol{\beta}, \boldsymbol{\gamma}$, and $\boldsymbol{\delta}$ used in the subsequent formulae are the coordinates of points in the layer and $\mu_1(\mathbf{a}, \mathbf{r}')$ is a

function characterising this layer. The derivative of the potential of the simple layer along the normal to the surface satisfies the equation

$$\frac{\partial G_1^{(+)}(\mathbf{b}, \mathbf{r}')}{\partial n_\beta} - \frac{\partial G_1^{(0)}(\mathbf{b}, \mathbf{r}')}{\partial n_\beta} = -\frac{1}{2}\mu_1(\mathbf{b}, \mathbf{r}'), \quad (36)$$

where the subscripts (+) and (0) at the Green function mean that these derivatives are calculated when $\mathbf{r}$ approaches the surface from the inside and directly on the surface (for $\mathbf{r} = \mathbf{b}$), respectively.

From Eqns (32), (34)–(36), one can derive integral equation for $\mu_1(\mathbf{a}, \mathbf{r}')$

$$\begin{aligned} \mu_1(\mathbf{b}, \mathbf{r}') + 2 \int_S \lambda_s dS_x G_0(\mathbf{b}, \mathbf{a}) \mu_1(\mathbf{a}, \mathbf{r}') = 2 \left(\frac{\partial}{\partial n_\beta} - \lambda_s \right) G_0(\mathbf{b}, \mathbf{r}') + \\ + 2 \int_S dS_x \frac{\partial G_0(\mathbf{b}, \mathbf{a})}{\partial n_\beta} \mu_1(\mathbf{a}, \mathbf{r}'). \end{aligned} \quad (37)$$

This equation can be solved rather simply.¹⁶⁴ The Green surface function $\Gamma(\mathbf{a}, \mathbf{b})$ is introduced; it is defined as the solution of the integral equation

$$\Gamma(\mathbf{b}, \gamma) + 2 \int_S \lambda_s dS_x G_0(\mathbf{b}, \mathbf{a}) \Gamma(\mathbf{a}, \gamma) = \delta(\mathbf{b} - \gamma). \quad (38)$$

By multiplying Eqn (37) by $\Gamma(\mathbf{b}, \gamma)$ and integrating over S_β , we obtain an equation for $\mu_1(\mathbf{a}, \mathbf{r}')$ having the following form:

$$\begin{aligned} \mu_1(\mathbf{b}, \mathbf{r}') = 2 \int_S dS_\beta \left(\frac{\partial}{\partial n_\beta} - \lambda_s \right) G_0(\mathbf{b}, \mathbf{r}') + \\ + 2 \int_S dS_\beta \int_S dS_\gamma \Gamma(\mathbf{a}, \mathbf{b}) \frac{\partial G_0(\mathbf{b}, \gamma)}{\partial n_\beta} \mu_1(\gamma, \mathbf{r}'). \end{aligned} \quad (39)$$

This equation is solved by the iteration method; for relatively smooth surfaces, the iterative process rapidly converges.¹⁶⁴ This gives the series

$$\begin{aligned} \mu_1(\mathbf{b}, \mathbf{r}') = 2 \int_S dS_\beta \left(\frac{\partial}{\partial n_\beta} - \lambda_s \right) G_0(\mathbf{b}, \mathbf{r}') + \\ + 4 \int_S dS_\delta \int_S dS_\beta \int_S dS_\gamma \Gamma(\mathbf{a}, \mathbf{b}) \frac{\partial G_0(\mathbf{b}, \gamma)}{\partial n_\delta} \Gamma(\gamma, \mathbf{b}) \left(\frac{\partial}{\partial n_\beta} - \lambda_s \right) G_0(\mathbf{b}, \mathbf{r}') + \dots, \end{aligned} \quad (40)$$

when the λ_s value is constant, the Fourier transform (p -variable) of the function $\Gamma(\mathbf{a}, \mathbf{b})$ can be readily found

$$\hat{\Gamma}(p) = \frac{\sqrt{p^2 - k^2}}{\lambda_s + \sqrt{p^2 - k^2}}, \quad (41)$$

which allows the calculation of every term of the series in expansion (40).

After the Green function $G(\mathbf{r}, \mathbf{r}', E)$ and the density of state $\rho(E)$ have been found, one can determine all thermodynamic characteristics of electrons in small particles and films.

4. Statistics of the electron energy levels in small particles

Yet another method suitable for determination of characteristics of the electrons in small particles is based on analysis of distribution of energy levels. A nanoparticle is never shaped like an ideal sphere. All methods used to prepare nanoparticles imply the presence of impurities on the surface. The distribution of impurities over the particle surface is not ideal either. As a result, it is impossible to calculate the energy levels with an inaccuracy substantially smaller than the distance between the levels. Kubo was the first to notice this.¹⁶⁵ He proposed that the energy levels be regarded as being randomly distributed; the average distance between them was specified to be

$$\Delta_\mu \approx \frac{E_F}{N},$$

where E_F is the energy of Fermi electrons in the particle and N is the number of electrons. The Kubo assumption is matched by the Poisson probability density for the distance Δ between the neighbouring levels

$$P(\Delta) = \frac{1}{\Delta_m} \exp\left(-\frac{\Delta}{\Delta_m}\right). \quad (42)$$

Kubo used this probability density to calculate the heat capacity and the magnetic susceptibility of small particles.

Later, Gor'kov and Elyashberg¹⁶⁶ pointed out that Kubo's results were erroneous. This conclusion was based on the results obtained by Wigner,^{167, 168} who considered the statistics of nuclear energy levels and showed the presence of correlations between them. Wigner's results have been mathematically substantiated and the character of correlations between energy levels has been established.^{169–171}

It was shown^{169, 170} that, in terms of the type of transformations that leave the Hamiltonian for a system of particles invariant, three ensembles can be distinguished, each being characterised by its own statistics of the distribution of levels: (i) orthogonal ensemble — for a system with an integer spin invariant with respect to the inversions of time and space coordinates; (ii) symplectic ensemble — for random interactions of particles invariant with respect to time inversion and for a half-integral spin of the system; (iii) unitary ensemble — for systems not invariant with respect to time inversion.

The orthogonal ensemble appears in the presence of a weak external magnetic field, either weak or strong spin-orbital interaction and with an even number of electrons in the particle. The symplectic ensemble implies strong spin-orbital interaction, able to mix the levels corresponding to different spins of the system; the number of electrons in the system should be odd. The unitary ensemble describes systems occurring in a strong magnetic field.

The normalised distribution of N ordered energy levels for any of the three ensembles is determined from the equation¹⁷²

$$W_\beta(E_1, E_2, \dots, E_N) = C_\beta \exp\left(-\frac{\beta}{2} \sum_i E_i^2\right) \prod_{j < k} |E_j - E_k|^\beta, \quad (43)$$

where C_β is a normalisation factor,

$$\int \dots \int W_\beta dE_1 \dots dE_N = 1, \quad (44)$$

and the parameter $\beta = 1, 2$ and 4 for the orthogonal, unitary and symplectic ensembles, respectively.

The physical properties of small particles depend on the distribution of the electronic energy levels located directly near the Fermi level. The distribution of these levels is found for the limit $N \rightarrow \infty$ by integration over a large number of levels (except for those located in the central region of the energy spectrum)

$$P_\beta(E_i \dots E_{i+n}) = \quad (45)$$

$$= \lim_{N \rightarrow \infty} \int \dots \int W_\beta(E_1 \dots E_N) dE_1 \dots dE_{i-1} dE_{i+n+1} \dots dE_N.$$

In the central part of the spectrum, the absolute position of the level does not play any role, only the distribution of the gaps between the levels being significant

$$\Delta_1 = E_{i+1} - E_i, \Delta_2 = E_{i+2} - E_{i+1} \dots \Delta_n = E_{i+n} - E_{i+n-1}. \quad (46)$$

The role of the distributions¹⁷³ $P_0(\Delta)$, $P_1(\Delta_1, \Delta_2)$, $P_2(\Delta_1, \Delta_2, \Delta_3)$, ... successively decreases because the use of higher approximations in the calculation of thermodynamic properties results only in the refinement of calculations done in the first approximation. Below we restrict our consideration to the first approximation. In this case, the densities of distribution of the levels in the three above-mentioned ensembles at small Δ are given by the expressions

$$\begin{aligned}
P_{\text{ort}}(\Delta) &= \frac{1}{2} \pi \frac{\Delta}{\Delta_m} \exp \left[-\frac{1}{4} \pi \left(\frac{\Delta}{\Delta_m} \right)^2 \right], \\
P_{\text{sym}}(\Delta) &= \left(\frac{8}{3\sqrt{\pi}} \right)^6 \left(\frac{\Delta}{\Delta_m} \right)^4 \exp \left[-\frac{69}{9\pi} \left(\frac{\Delta}{\Delta_m} \right)^2 \right], \\
P_{\text{un}}(\Delta) &= \frac{32}{\pi^2} \left(\frac{\Delta}{\Delta_m} \right)^4 \exp \left[-\frac{4}{\pi} \left(\frac{\Delta}{\Delta_m} \right)^2 \right].
\end{aligned} \quad (47)$$

The corresponding curves are shown in Fig. 1, which also presents the density of probabilities for the Poisson law. It can be seen that real distribution laws substantially differ from the Poisson law; the difference is that the density of distribution of levels for real systems tends to zero when $\Delta \rightarrow 0$. This means that the probability of finding closely located levels in small particles is exceptionally low; it is said that levels ‘repel’ one another. The repulsion of energy levels changes crucially the thermodynamic properties of small particles at low temperatures.

Figure 1. Probability densities for distances between the levels in the Poisson (1), orthogonal (2), unitary (3) and symplectic (4) ensembles.

IV. The electronic and thermodynamic properties of small metal particles and thin films

1. The electronic structure of small particles

As noted above, the density functional method is used most often to calculate the electronic structures of clusters and small particles (see reviews^{174–176}). Even for clusters consisting of several atoms (and even in the absence of ligand shells), various approximations are used. The best known approximation is the jellium model, according to which a cluster is represented as consisting of two subsystems, namely, the positive charge distributed uniformly over the bulk, which models the ion core of the cluster, and delocalised electrons.

Calculations carried out within the framework of this model provide an explanation for the shell character of the electronic structure of atomic clusters of univalent metals. For ‘bare’ spherical clusters, single-electron energy levels correspond to the model of a spherically symmetrical potential well and form the sequence of states $1s, 1p, 1d, 2s, 1f, 2p$, etc. Owing to the spherical symmetry, the energy states of electrons are degenerate, the degeneracy order being equal to $2(2l + 1)$ (with allowance for the electron spin). The numbers of electrons needed for the full occupancy of the shell can be easily found. They are 2, 8, 18, 20, 34, 40, etc. This sequence of filling the shells is matched by local extrema of the ionisation potentials of univalent metal clusters¹⁷⁵ (Fig. 2), although the jellium model does not reproduce the dependence of the ionisation potential of a cluster on its dimensions for a spherically symmetrical core. The mass spectrum of the most stable clusters corresponding to the so-called magic numbers cannot be reproduced in this model either. Note that clusters with closed electron shells, as shown by Brack,¹⁷⁶ are spherically symmetrical. The inadequacy of the spherical model for clusters with open shells is due to the deviation of the shape of these clusters from spherical. Calculations have been carried out^{177, 178}

Figure 2. Ionisation potential (I) vs. the number (N) of atoms in the silver cluster.¹⁷⁵

in which the distortion of the central field acting on the electrons was taken into account in the jellium model for clusters with partially occupied electron shells by replacing the spherical shape of the cluster by a spheroidal shape. The calculated characteristics of clusters, for example, of sodium clusters, such as the total energy, polarisability and ionisation potential follow a more complex dependence on the system dimensions than those in the spherical model and agree better with the experimental data.

A possible reason for the distortion of the spherical shape in the case of particles with non-filled electron shells has been established.¹⁷⁹ It is similar to the Jahn–Teller effect:¹⁵⁸ due to the high degeneracy of the quantum electron levels with respect to l , the energy of electrons in nearly spherical particles becomes a non-analytical function of the surface area of the cluster S . The change in the surface area upon the deformation of a spherical particle increases its surface energy, on the one hand, and decreases the energy of electrons due to splitting of the upper electron level E_{nl} (n is the principal quantum number), on the other hand. The resultant change in energy is found from the equation¹⁷⁹

$$\delta E = \gamma \delta S - g(n, l, m_0)(\delta S)^{1/2},$$

where $g(n, l, m_0) > 0$ is a function of the principal and orbital quantum numbers and of the number of electrons m_0 in the outer shell, and δS is the change of the surface area of the particle upon deformation. The minimisation of the cluster energy determines the equilibrium deformation. According to an estimate made for cesium clusters, in the case of clusters with a size of 5 nm, the relative deformation can reach 10%. The same effect determines the size oscillations of the particle shape.

The possibility of a rearrangement of the ion core (not only of the change in the particle shape) also affects substantially cluster characteristics. Ivanov *et al.*^{180, 181} carried out calculations for clusters in terms of the optimised jellium model they proposed. In this model, the distribution of the positive charge in the jellium was regarded as unknown *a priori* and was determined from the condition of the minimum total energy. The possibility of rearrangement of both the electronic energy spectrum and the ion core was assumed in the calculations. The calculations showed that the internal structure of a jellium-like core is formed in the cluster bulk and the positive charge is distributed non-uniformly in space. As a consequence, regions of maximum and minimum jellium density appear; they correspond to the equilibrium positions of ions in the lattice of a polyatomic cluster. The electron levels also rearrange, this effect being the most pronounced for clusters with filled shells. The magic numbers corresponding to the most stable electronic configurations of clusters with filled shells are also reproduced. For example, $N = 40$ is matched by the configuration $1s^2 1p^6 1d^{10} 2s^2 1f^{14} 2p^6$. The energy difference between optimised and non-optimised cluster models is 0.1 eV per atom and remains nearly constant for clusters with different sizes. The dependence of the average cluster radius on the number of atoms also changes substantially on passing from the non-optimised to the optimised model — this dependence becomes non-monotonic and local minima at $N = 8, 20, 40, 58$, etc. appear on the corresponding curve; *i.e.* clusters with filled shells are more compact.

The method of the density functional, including that as applied to clusters, can easily be extended to non-zero temperatures.^{182–185} When the temperature differs from zero, Eqn (8) has the form

$$\rho(\mathbf{r}) = \sum_i \phi_i^2 f(E_i - \mu). \quad (48)$$

Here,

$$f(E_i - \mu) = \left(1 + \exp \frac{E_i - \mu}{kT} \right)^{-1}, \quad (49)$$

μ is the chemical potential, k is the Boltzmann constant, T is temperature, and the function $f(E_i - \mu)$ should satisfy the condition

$$\sum_i f(E_i - \mu) = N, \quad (50)$$

where summation involves all the single-electron states.

For finite temperatures, Eqns (37)–(39) and (48)–(50) can be used to determine a single-electron energy spectrum of a system (e.g., cluster), the electron density distribution in the system as well as the chemical potential and the occupancy numbers of electron states.

The temperature also influences substantially the structure of clusters. The distribution function of the levels located near μ changes markedly even at relatively low temperatures: it decreases for higher occupied levels and becomes non-zero for levels located above μ . The temperature variation of the occupancy numbers for 3d, 4s and 1k levels closest to the chemical potential level in the Na₁₉₆ cluster has been calculated.¹⁸⁶ It was shown that the transition of electrons to higher energy levels starts even at temperatures appreciably (several times) lower than the values corresponding to the difference in energy between the levels. Moreover, at $T = 300$ K, the occupancy of the 1k level, which lies above the 4s level, proves to be greater than that of 4s. The pattern of variation of the chemical potential vs. temperature is equally complicated. In the clusters with $N = 18$, the chemical potential increases, while in clusters with $N = 40$, it, conversely, decreases with an increase in temperature. The complex temperature dependence of the chemical potential is due to the fact that it is determined by the orbital quantum numbers of the energy levels between which redistribution of electrons takes place.¹⁸⁶

For finite temperatures, the deviation of the cluster shape from spherical is more significant than at $T = 0$ K. In the former case, the loss of sphericity can result not only from deformation of electron shells but also from thermal excitations of the ion core. However, the relevant calculations are associated with substantial procedural difficulties and have not been performed yet.

2. Thermodynamics of electrons in small particles

The thermodynamics of electrons in small particles have been studied fairly comprehensively by Denton *et al.*,¹⁷³ who calculated heat capacities and magnetic susceptibilities of particles for various ensembles. The thermodynamic characteristics of particles were found to depend on the number of electrons in them. The results of standard calculations with allowance for the level statistics are given in Table 1.

It can be seen from the Table that ‘repulsion’ of the energy levels changes in form the pattern of the temperature variation of the heat capacity of small particles. Instead of the linear dependence, typical of bulk samples,¹⁸⁷ a non-linear dependence correlated with the degree of repulsion of the levels is observed. The enhancement of the temperature dependence of heat capacity for low T values is due to the decrease in the probability of close arrangement of levels — the smaller the number of close levels, the smaller the number of electrons able to pass to higher levels on thermal excitation and the lower the heat capacity.

The difference between the heat capacities of particles with even and odd numbers of electrons is not as pronounced as the difference in the magnetic susceptibilities. For even numbers of

Table 1. Heat capacities and magnetic susceptibilities of particles in various ensembles.

Ensemble	N is even	N is odd
Heat capacity (in k units)		
Poisson	$5.02(kT/\Delta_m)$	$3.29(kT/\Delta_m)$
Orthogonal	$3.02 \times 10(kT/\Delta_m)^2$	$1.78 \times 10(kT/\Delta_m)^2$
Symplectic	$3.18 \times 10^4(kT/\Delta_m)^5$	$1.64 \times 10^4(kT/\Delta_m)^5$
Unitary	$5.88 \times 10^2(kT/\Delta_m)^3$	$5.88 \times 10^2(kT/\Delta_m)^3$
Magnetic susceptibility		
Poisson	$3.04 \left(\frac{1}{2} g\mu_B \right)^2 / \Delta_m$	—
Orthogonal	$7.63 \left(\frac{1}{2} g\mu_B \right)^2 kT / (\Delta_m)^2$	$\left(\frac{1}{2} g\mu_B \right)^2 / kT$
Symplectic	$2.02 \times 10^3 \left(\frac{1}{2} g\mu_B \right)^2 (kT/\Delta_m)^4 / \Delta_m$	—

Note. Generally accepted designations: g is the gyromagnetic ratio, Δ_m is the average distance between electron levels.

electrons, the magnetic susceptibility tends to zero at $T \rightarrow 0$ for orthogonal and symplectic ensembles; this is explained by pairing of electrons on separated levels. In the case of the Poisson ensemble, the levels do not repel one another and, with a finite probability, they can be located rather closely; this results in a temperature-independent magnetic susceptibility. For systems with odd numbers of electrons, the magnetic susceptibility of any ensemble, conversely, tends to infinity. This pattern of susceptibility is due to the presence in the upper level of an unpaired electron, which accounts for the sharp increase in the susceptibility on a decrease in temperature.

Until recently, it has been impossible to verify these patterns of temperature dependence of the magnetic susceptibility and heat capacity by direct experiments because the systems prepared contained particles with both even and odd numbers of electrons. As a consequence, only ensemble-average characteristics were observed in experiments. It should be noted, however, that the magnetic susceptibilities of particles with even and odd numbers of electrons have been measured^{3,4} in NMR experiments: the temperature dependence of susceptibility for particles with different numbers of electrons, even when they are present simultaneously in the system, can be determined from the Knight shift.

In recent years, substantial interest in the studies of the heat capacity and magnetic susceptibility of small particles has revived, which is due to the above-mentioned possibility of preparing metallic nanoparticles with a virtually definite number of atoms by the method developed in a series of studies.^{78–89} The advances in the synthesis of nanoparticles permitted experimental verification of the correctness of the theory of their thermodynamic properties. Experiments of this type have been described by Volokitin *et al.*,^{188,189} who carried out a detailed investigation of the thermodynamic characteristics of particles with different numbers of atoms (and, correspondingly, electrons). The experiments were performed with palladium clusters containing 561, 1415, 1740 and 2057 atoms as well as with larger clusters isolated from one another in the samples by ligand shells. The electronic heat capacity and magnetic susceptibility of metal particles were studied as functions of particle size and temperature in the range from 0.05 to 10 K, in which the effects of quantisation of the electron movement should be visible.

Figure 3 shows the temperature dependences of the specific heat capacity (C) of nanoparticles of various sizes and of bulk samples. It can be seen that the plots for nanoparticles of different sizes do not coincide at $T < 2$ K. The deviation from the data for bulk substances increases as the particle size decreases. The results of processing of experimental data by normalisation of the

Figure 3. Temperature dependence of the specific heat capacity (C) for palladium clusters with five (1), seven (2) and eight (3) atomic shells and for clusters containing more than 10^5 atoms (4).¹⁸⁹

dependences to characteristics of the particles of different dimensions are presented in Fig. 4. The same figure shows the theoretical $C(T)$ plot for the orthogonal ensemble. It can be seen from the figure that the theory reliably reproduces experimental data, which point unambiguously to quantisation of the electron levels in small particles.

Figure 4. Normalised temperature dependences of the heat capacity for particles with different sizes.¹⁸⁹ The continuous curve is the calculated dependence for the orthogonal ensemble.

Good agreement between theoretical and experimental results was also obtained for magnetic susceptibility measurements (Fig. 5). These experiments are actually the first studies in which

Figure 5. Normalised temperature dependences of the magnetic susceptibility (χ) for nanoparticles with five (1), seven (2) and eight (3) atomic shells.¹⁸⁹ The continuous curve is the calculated dependence for the orthogonal ensemble with equal percentages (50%) of particles with even and odd numbers of electrons.

the quantum nature of electrons in small particles was demonstrated in an explicit form.

3. Disjoining pressure in liquid metallic films

The stability of free liquid films is due to a positive disjoining pressure $\Pi(H)$,¹⁹⁰ which prevents a decrease in their thickness H . The disjoining pressure $\Pi(H)$ is the difference between the pressure normal to the film surface and the pressure in the bulk phase contacting with the film.¹⁹⁰ The pressure difference arises due to the surface forces when the boundary layers of the two phases overlap.

It is commonly supposed¹⁹⁰ that the disjoining pressure in single-component systems is always negative; therefore, free films of neat substances cannot be stable. However, it has been shown^{61, 191–193} that this rule can be violated for liquid metal films. The appearance of a positive component of disjoining pressure is related to the quantisation of the electron movement in thin films. The physical nature of this component of disjoining pressure is rather simple. According to the Heisenberg uncertainty principle, the component of the electronic momentum directed at the right angle to the surface cannot be smaller than $\hbar/H$. As a consequence, the minimum possible energy of electrons in the film amounts to $\hbar^2/2mH^2$. Owing to this restriction, the energy of each electron in the film increases, due to degeneracy, by a value approximately equal to the above value, even for a continuous spectrum of electron energies. Thus, the change in the density of the total energy of electrons is

$$\Delta E \sim \frac{N\hbar^2}{2mH^2V},$$

where N is the number of electrons in the film and V is the film volume. The pressure of the degenerate electron gas is proportional to the energy density. As a result, the pressure of electrons in thin films increases with respect to the pressure in the bulk by the value

$$\Pi(H) \sim \frac{N\hbar^2}{2mH^2V}.$$

The electron component of the disjoining pressure in thin films was calculated by two methods;^{161, 192, 193} in one method, the model of a potential well with infinitely high walls was used, while the other method was based on the phenomenological model considered above in which the derivative of the electronic wave function on the film surface was specified. In the former case, the film was found to be absolutely stable, while in the latter case, film stability was determined by the nature of the surrounding medium. Let us consider results obtained by Roldughin and Deryagin.^{161, 193} According to these studies,

$$\Pi(H) = E_{0F} \frac{N}{V} R^2 \times \left[\chi_s(\lambda_s) + \frac{2}{R} \exp\left(-\frac{\gamma}{\sqrt{E_{0F}}}\right) \sin\left(2\sqrt{\frac{2mE_{0F}}{\hbar^2}}H + \varphi_0\right) \right], \quad (51)$$

where E_{0F} is the Fermi energy for a bulk sample

$$R = \frac{1}{H} \left(\frac{V}{3\pi^2 N} \right)^{1/3},$$

γ is a value characterising the width of electron levels¹⁷³ and $\chi_s(\lambda_s)$, φ_0 are functions of the parameter λ appearing in the boundary conditions. For the λ value corresponding to a potential well with infinitely high walls, expression (51) for $\Pi(H)$ transforms into the relation derived in another publication.¹⁹² The function χ can be both positive and negative, its sign determining the sign of the disjoining pressure. The last term in relation (51) is insignificant for determination of the film stability because it represents a rapidly oscillating value. This term is due to the discrete character of the electron levels in thin films.

Let us clarify the nature of the change of the sign of disjoining pressure in a thin film following the change in the parameter λ_s , which describes the behaviour of the electronic wave function and, hence, the electron density near the geometrical surface of the film. Actually, λ_s specifies the distance by which electrons are 'allowed' to go out into the external environment. If electrons can easily leave the geometrical surface of the film, their effective density in the film decreases. The decrease in the effective density diminishes the Fermi energy and, as a consequence, the pressure of electrons in the film. Thus, the quantisation effect mentioned above, which ensures a positive disjoining pressure, can be counterbalanced by a decrease in the electron density. This implies that the stability of liquid metallic films is determined to a large extent by the nature of the environment.

Experiments confirm this conclusion. For example, the stability of mercury films adjoining various organic liquids has been studied.^{194, 195} It was found that in octane, mercury films exist for infinitely long periods, whereas in decane, the lifetime of the films does not exceed 1 min; the lifetime in toluene is ~ 1 s.

V. Optical properties of small particles

Nanometer particles have unique optical properties, which are used both for scientific and practical purposes. The optical characteristics of these particles are determined by conventional spectroscopic methods;^{3, 196} therefore, the vast majority of studies devoted to a particular method for the preparation of nanoparticles contain sections devoted to their absorption spectra. Optical spectra provide fundamental information on the electronic structure of small metal particles. In particular, investigation into optical spectra allows one to follow the variation of electronic properties on passing from bulk samples to small particles.

The unique optical properties of small particles are finding application in the design of optical filters, markers of biomacromolecules, reversible photosensitive monochromatic glasses, optical switches and optical traps and for surface enhancement of Raman light scattering spectra.

Absorption spectra of small metal particles have an intense broad band which is missing from the spectra of bulk samples. This band is associated with the collective excitation of the conduction electrons (surface plasmons); its occurrence in the visible region results in a unique colour spectrum of dilute colloidal dispersions of noble, alkaline earth and rare earth metal particles.

The nature of plasmon absorption is fairly simple. Under the influence of the electric field of the incident radiation, the conduction electrons in the particle are displaced with respect to the positively charged ion core. This displacement is cooperative, *i.e.* the movement of electrons is phase matched. The displacement of electrons gives rise to a force which acts to return the electrons to the equilibrium position. The returning force is proportional to the displacement, as for a typical oscillator; therefore, one can speak about the presence of a natural frequency of cooperative oscillations of electrons in a particle. The coincidence of the natural frequency of the cooperative electron oscillations with the frequency of the external field gives rise to a resonance effect related to the excitation of natural oscillations of electrons. In accordance with the symmetry of the spatial size distribution, the resonance cooperative movement of electrons can be represented as an infinite set of separate modes, namely, dipole, quadrupole and other modes. The description of the cooperative movement of electrons in terms of quantum mechanics results in the notion of elementary excitations — plasmons having the energy $\hbar\omega_0$, where ω_0 is the natural frequency of cooperative oscillations. The lifetime of plasmons is short, it is about tens of femtoseconds.

Although the optical properties of nanoparticles are determined by quantum effects, they are well reproduced in terms of the Mie theory,^{3, 196} in which the optical properties of spherical metal particles in dielectric matrices are interpreted within the frame-

work of classical electrodynamics. The response of a particle is described by Maxwell equations and the corresponding boundary conditions. Optical resonance (Mie resonance) also appears in terms of the Mie theory, due to the cooperative excitation of the electron plasma. The properties of the particle material do not appear in the Mie theory in an explicit form; it is assumed that they can be described using the complex dielectric constant, as in the case of bulk solids.

The profile of the absorption band near the Mie resonance for a nanoparticle is a Lorentzian curve characterised by the position and width of the $\hbar\omega_0$ peak. For particles with a size much smaller than the radiation wavelength, the resonance frequency is described by the expression¹⁹⁶

$$\omega_0 = \left(\frac{n e^2}{\varepsilon_0 m_e} \right)^{1/2} (2\varepsilon_m + 1 + \chi_{li})^{-1/2}, \quad (52)$$

where n is the density of electrons, ε_0 is the electric constant, m_e is the effective mass of the conduction electrons, ε_m is the real part of the dielectric constant of the medium, and χ_{li} is its component related to the band–band transitions in the particle.

It can be seen from Eqn (52) that the position of the resonance depends not only on the parameters of the conduction electrons but also on band–band transitions and electron–hole excitations.

The resonance width is determined by the relation¹⁹⁶

$$\Gamma_{r0} = 2\varepsilon_2(\omega) \left[\left(\frac{\partial \varepsilon_1}{\partial \omega} \right)^2 + \left(\frac{\partial \varepsilon_2}{\partial \omega} \right)^2 \right]^{-1/2}, \quad (53)$$

where $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$ are the real and imaginary parts of the dielectric constant of the particle and ω is the current radiation frequency.

According to the Mie theory, starting from some size of the particles (about one-tenth of the radiation wavelength), the position and the width of the absorption band no longer depend on the particle size. However, a substantial shift of the resonance and the broadening of bands following a decrease in the particle size was observed in experiments.

The relevant theoretical models have been considered.¹⁹⁷ The greatest contribution to the variation of the position of the peak as a function of particle size is made by the changes in the average density of electrons in the particles, in the effective mass of electrons and in the susceptibility related to the band–band transitions. However, for typical values of these parameters, the size corrections are usually too small. Therefore, it was assumed that for small particles, collisions of electrons with the surface of particles should be significant (the mean free path in gold is 20 nm). This hypothesis provided an interpretation of the spectra of relatively large particles (> 3 nm for gold) but proved inapplicable to smaller particles. It is clear that the classical views on free electrons become invalid for small particles and quantum size effects should be taken into account. Nevertheless, no demonstrations of these effects have yet been identified unambiguously in the optical properties of small particles, although they show themselves in other properties;^{175, 176} in particular, they are manifested as the change in the conductivity of single particles.^{198, 199} This might be due to the use in experiments of particle ensembles having different sizes and shapes.

An attempt to overcome this difficulty has been undertaken by Alvarez *et al.*,²⁰⁰ who studied the spectra of gold nanocrystals stabilised by *n*-alkanethiolates in toluene. The dimensions of metal particles varied from 1.4 to 3.2 nm (70 to 800 Au atoms); special methods for separation of narrow fractions of particles were used for this purpose. It was found that the absorption spectrum depends slightly on the length of the alkyl chain in the stabilising agent and that the characteristic band (2.4 eV) is broadened upon a decrease in the particle size and virtually disappears for 2 nm particles. A band corresponding to resonance transitions (1.7 eV) was identified and the presence of step structures in the absorption spectrum of small clusters (smaller

than 2 nm) was demonstrated. This spectral feature was attributed to the quantum size effects caused by transitions of electrons from the conduction bands to the discrete levels located above the Fermi level.

It should be noted in this connection that the assumption concerning the change in the optical parameters of gold for particles with a size of 3 nm has also been made previously.²⁰¹ It can be expected that 2 nm is an intermediate size in passing from continuous to atomic structure for particles passivated by thiolates. The transition of a nanoparticle to the metallic state is manifested especially clearly in the absorption spectra (see, for example, Refs 202 and 203).

For the width of the plasmon absorption band for nanoparticles, described by a continuum model, the following expression was obtained:¹⁹⁷

$$\Gamma_r = \Gamma_{r0} + \frac{2\omega_0^2}{\omega^3} v_F \left[\left(\frac{\partial \epsilon_1}{\partial \omega} \right)^2 + \left(\frac{\partial \epsilon_2}{\partial \omega} \right)^2 \right]^{-1/2} \frac{A}{R}, \quad (54)$$

where v_F is the Fermi velocity of electrons, A is a constant, R is the particle radius.

The corresponding dependence of the width of the absorption band on the size of particles has been confirmed experimentally.²⁰⁴ The magnitude of the constant A depends substantially on the nature of the medium surrounding the particles and on the presence and parameters of the adsorbates.²⁰⁵ The medium or adsorbed molecules (electron donors or acceptors) can change markedly the effective concentration of electrons in the particle, resulting in a shift in the resonance and a change in the band width. Apart from this static shift of the resonance and the change in the width of the absorption band, dynamic effects related to the transfer of electrons from the Fermi surface to the adjacent levels of adsorbed molecules or the environment are also possible.

The effects of this type have been studied;^{206–209} effects of adsorption of $S_2O_3^{2-}$ and halide ions on silver particles^{206, 207, 209} and $S_2O_3^{2-}$ ions and pyridine molecules²⁰⁸ on silver particles and on the particles of a copper–silver alloy in an aqueous solution were established. The resulting absorption spectra were processed in terms of the Mie theory; the concentration of conduction electrons in the particles and attenuation coefficients of plasmons were found as functions of adsorption of the corresponding ions. Experiments showed that for 3–5-nm silver and bimetallic particles, the concentration of conduction electrons increases by approximately 10% and 5%, respectively, and the absorption coefficient increases 2- and 1.6-fold, respectively. The increase in the electron density was explained by its movement from the adsorbate to the metal, while the increase in the attenuation coefficient was attributed to the increase in the cross-section of electron scattering on the surface defects which have captured the adsorbate molecules.

It should be mentioned that the Mie theory with appropriate modification of the parameters permits one to describe virtually all the available experimental data on absorption spectra (naturally, except for those for very small particles).²¹⁰ For this reason, theoretical description of the optical characteristics of particles lags substantially behind experimental studies. Simultaneously, the Mie theory has been developed to become more precise and more general in order to go beyond the limits of the approximations used. In particular, investigation into the influence of the shape and the state of the surface of particles on the optical properties have been started. In early studies, simple shapes of particles were chosen — spheres,^{211–213} cylinders or parallelepipeds, because calculations were carried out by quantum-mechanics methods, which imposed certain demands on the shape of particles that enable exact solution of the Schrödinger equation. In these studies, electric absorption, stipulated by the electrical conductivity of particles (determination of which was the object of the studies), was calculated. In the case of particles with a size exceeding the mean free path of electrons, the conductivity is related to the bulk conductivity of the metal; hence, the calcu-

lation of electric absorption is actually reduced to determination of the electric field in the particle.

Magnetic absorption by spherical particles has been studied.²¹⁴ The calculations were based on the solution of the kinetic equation for electrons in terms of the Bhatnagar–Gross–Krook model. The same model was used in another study²¹⁵ to calculate the electronic and magnetic absorption of spheroidal particles. Particles with sizes both larger and smaller than the mean free path of electrons were considered. It was shown that the total absorption and the ratio of electronic to magnetic absorption depend appreciably on the shape of particles and polarisation of the incident electromagnetic wave; these values can change by several orders of magnitude with a fixed particle volume.

In the Mie theory and in other theoretical approaches, the particles are assumed to have a regular shape and smooth surface. However, in practice, this is not always true. In particular, clusters applied on a substrate are shaped like deformed spheroids rather than like spheres.²¹⁶ In addition, on the surface of particles, atoms can occupy positions with different coordination numbers; in particular, they can be rather low, which means roughness at the atomic level. As a result, new channels for light absorption by particles appear.

Experiments^{217, 218} and theoretical calculations²¹⁹ showed that the state of the particle surface is really important for light absorption. Electron resonances localised in the near-surface layer are significant when they overlap with the surface plasmons. In this case, they are excited very rapidly because excitation of a plasmon is accompanied by enhancement of the field on the surface.

Absorption on the surface of small particles has been observed experimentally;²²⁰ for this purpose, a special method for the separation of surface and bulk absorption was used. Metal particles shown²²¹ to have a smooth surface and surface electronic states were applied on a transparent substrate from the vapour phase at 100 K. The particles were exposed to pulse laser radiation, which excited the electrons on the surface and in the bulk. Upon attenuation of the excitations, the temperature of the sample rose, which caused desorption of atoms from the surface. The velocities of the desorbed atoms were measured in order to determine the temperature of the particles. From the difference between the temperatures, the energy absorbed by the particles was found. The surface and bulk excitations were separated by repeating this procedure for particles the roughness of which had been removed by heating and slow quenching. The experiments with sodium particles supported on the surface of quartz glass demonstrated that the surface contribution to the absorption is equal to 32% for clusters with a size of 21 nm.

In recent years, the interest in the optical properties of colloidal dispersions of bimetallic particles has markedly enhanced. Various pairs of metals have been studied.^{222–227} Bimetallic particles containing silver and mercury received particular attention. Both metals are characterised by sharp absorption bands corresponding to surface plasmons and located rather closely together, *viz.* at 380 nm for silver in water and at 300 nm for mercury.²²⁸ Bimetallic particles of this type having different compositions have been prepared.²²⁹ Investigation of their absorption spectra showed that the plasmon resonance bands shift to shorter wavelengths as the content of mercury in the drops increases. The variation of the absorption spectra during the preparation of the colloids was studied. Mercury drops were found to be formed initially during the reduction of metals; silver ions are reduced simultaneously. Then an amalgam is formed in which silver particles occur in the drops of mercury. The colloid is stable if the Hg : Ag ratio is greater than 2. Otherwise, it starts to opalesce and sedimentation occurs. The formation of the amalgam influences the absorption spectrum: the plasmon resonance shifts towards longer wavelengths.

The non-linear optical properties of the nanoparticle ensembles proved unexpected; they are influenced by secondary cooperative effects caused by interaction of excited nanoparticles.

Abnormal enhancement of hyper-Rayleigh scattering in dispersions of gold nanoparticles has been observed.^{230, 231} In a study of the influence of high radiation doses on silver nanoparticles, the presence of a limiting transmission threshold was established;²³² *i.e.* dispersion resulted in an increase in the light absorbance due to non-linear effects. This enhancement was attributed to photochemical processes which have started on the particle surface. Yet another cooperative effect was found in another study.²³³ It was found that the intensity of the surface enhanced Raman scattering increases due to participation of surface ensembles of particles; this effect depends on the composition of particles in a rather complex manner (the experiments were carried out with nanoparticles of gold and silver).

VI. The influence of radiation on the stability of nanoparticles

The optical properties of nanoparticles can be changed by various types of treatment of the colloidal system, for example, by introducing stabilising or destabilising additives, by changing the temperature and also by irradiation of the system. A usual result of this types of treatment is the change in the aggregation state of the colloidal dispersion.

If the particles form aggregates,^{234, 235} the corresponding plasmon band either shifts towards longer wavelengths or becomes broader. However, when the colloidal particles are aggregated, the distribution of particles in the aggregate does not correspond to a close packing. In most cases, aggregation yields fractal structures having one or another fractal dimension, depending on the aggregation conditions.^{236–238} A theory of the optical properties of fractal clusters has been developed;^{239, 240} it was shown that the presence of close neighbours of a particle in the aggregate changes the frequency of optical resonances of the particle and causes band broadening. The change in the frequency and band broadening are due to the dipole–dipole interactions between the light-induced dipole moments of particles. This effect underlies a method for the estimation of the degree of aggregation of colloidal systems, which allows one to monitor the evolution of colloids under complex conditions (see, for example, Ref. 202).

Hasegawa *et al.*²⁴¹ studied the light-induced variations in the stability of colloidal dispersions of ultrasmall particles. They investigated various metal particles dispersed in various organic media. It was found that a sol of gold in chloroform starts to sediment 4 h after irradiation by the light of a mercury lamp, whereas in the dark, it remains stable for a year. Thus, under the influence of light, the rate of coagulation increases by a factor of 1000.

Similar results were obtained for gold particles in water,²⁴² the rate of coagulation being dependent on the radiation frequency. The maximum rate was observed at the frequency corresponding to the Mie resonance. It has been suggested²⁴³ that coagulation is caused by the dipole interaction of particles, which is enhanced by external radiation.

A more detailed study has been performed by Satoh *et al.*¹³ The experiments were carried out with a gold sol prepared by vaporisation followed by deposition from the flow into an organic liquid without using surfactants or stabilisers. Gold sols in acetone, ethanol, propan-2-ol and chloroform as solvents were prepared. The changes in the absorption spectrum on exposure to the light of a mercury lamp and on heating the dispersion were determined. The initial peak (surface plasmon) at a wavelength of 523 nm was found to be broadened and to disappear; the band at 270 nm becomes more intense and a new band at 840 nm appears. The shift of the plasmon peak was attributed to the dipole–dipole interaction of particles in the aggregates.²³⁴ After 20 h of irradiation, complete sedimentation of the aggregates occurred and re-dispersion was impossible. The rate of coagulation depended on the solvent used.

It was found by electron microscopy that nanoparticles form fractal aggregates with a dimension of 1.7, which corresponds to

the diffusion-controlled aggregation model (at an initial stage, unidimensional chains are formed in the system). It was assumed that coagulation is due to the enhancement of the van der Waals attraction caused by the presence of induced dipoles. To verify this assumption, the effect of radiation with different wavelengths on the particles was studied. Coagulation was found to take place even on exposure to visible light. However, UV radiation markedly enhances coagulation. To explain the effect of the radiation wavelength on the rate of aggregation, it was suggested that the instability of the sol (in addition to the increase in the van der Waals interaction mentioned above), can also be related to the change in the Coulomb repulsion as a result of the change of the surface charge due to photochemical processes.

In order to verify this hypothesis, in addition to the measurements of the stability of a dispersion of gold particles in water and propan-2-ol under the action of radiation, their ζ potentials were measured.¹⁴ The coagulation rate was determined not only from the shift of absorption but also by electron microscopy using a special procedure. The relationship between the rate of coagulation and the change in the ζ potential of the particle caused by the addition of a salt was studied. On exposure to radiation, the ζ potential decreased from -45 to -65 mV. The increase in the absolute magnitude of ζ indicates enhancement of the Coulomb repulsion between the particles; thus, this cannot account for the loss of stability of colloidal nanoparticles.

Karpov *et al.*,^{244–246} who studied silver sols, proposed a somewhat different interpretation for photostimulated aggregation. The aggregation of particles was detected from the absorption spectra of colloids. It was established that the rate of aggregation increases by a factor of 10^{10} upon irradiation;²⁴⁷ it was suggested that the acceleration of aggregation was based on the photoeffect.

The proposed mechanism is as follows. Irradiation of a colloid gives rise to oppositely charged particles, due to exchange of the electric charges arising upon photoemission. The exchange proceeds through the dispersion medium; it is due to the fact that the Fermi energy of particles depends on their size and results in equalisation of the electrochemical potentials of particles of different sizes. The long-range electrostatic forces arising after the exchange play a crucial role in the fact that particles approach one another to distances at which van der Waals forces start to show themselves.

The possibility of formation of a contact potential between quantum-size systems of the same nature has been indicated.^{191, 192} This effect was attributed to the shift of the chemical potential under conditions where the movement of electrons is confined by the metal film surface. At the thermodynamic equilibrium, electrons are redistributed between systems of different sizes to ensure equal electrochemical potentials. The effect of this distribution of electrons between nanoparticles has been used¹⁶² to introduce attractive forces between the particles in an equilibrated polydisperse system.

If the process of aggregation of nanoparticles is underlain by photoelectric emission, a 'red boundary' of the process should exist. The variation of the rate of photoaggregation of a silver hydrosol has been studied experimentally by exposure of identical samples to radiation in the range from 366 to 1050 nm.²⁴⁶ The experiments showed that the rate of photoaggregation depends on the radiation wavelength and that a red boundary for the process does exist. However, when the radiation power is rather high, two-photon processes, which shift this boundary, start to play a noticeable role. An interesting feature of photoaggregation has been noted: a higher initial aggregation of particles implies a lower exposure dose required to increase aggregation by the same amount. In a freshly prepared sol, the process of photoaggregation does not start until a threshold radiation intensity is reached, because the sol does not contain spontaneously formed aggregates of two or three particles needed as seeds for photostimulated aggregation.²⁴⁶

The presence of a threshold irradiation dose in the process of destabilisation of colloidal silver sols has also been noted in another study,⁹³ in which irradiation was carried out by electrons (5 MeV) and γ -quanta (^{60}Co as the source). The irradiation by electrons was pulsed (pulse duration 2 μs). The coagulation of particles was indicated by changes in the optical absorption spectra. No changes were detected after 50 pulses. However, in the case of 60–70 pulses, the intensity of the major absorption band sharply decreased, while its width increased. An appreciable increase in the light scattering by the colloidal dispersion was also observed. A critical irradiation dose was also found to exist when γ -quanta were used. The loss of stability of sols in these experiments was attributed to the neutralisation of the particle charge due to the reduction of sorbed silver ions under the action of radiation; this destroys the double electric layer at the particle boundary. The specificity of the electron irradiation was in that it ‘delivered’ electrons, and the charge on the silver particle decreased upon absorption of these electrons. A similar view on the reasons for destabilisation of the nanoparticle sol on exposure to γ -radiation has been expressed in other studies;^{248–251} regularities of the formation of fractal aggregates from silver nanoparticles have been investigated.²⁵¹

VII. Relaxation of electrons in small particles

Direct measurements of the dynamics of electrons in small particles became possible, most of all, owing to the development of ultrafast laser equipment. Absorption spectroscopy is used most often. Short (100 fs) laser pulses are employed to bring electrons into excited states, the relaxation of which is observed by means of the second, probing laser beam. The dynamics of relaxation was determined from the time variation of the absorption between two successive excitations of the system. The variation of transparency with time, related to the restoration of the ground state of the system, is also measured in some cases. The dynamics of electrons in semiconductor particles has been considered in a review;⁷ therefore, we do not discuss it here.

Metal particles differ substantially from semiconductor particles. The main difference is in the structure of electron energy levels. The forbidden gap, which plays a fundamental role in semiconductor particles, is lacking in the case of metals (Fig. 6). At ordinary temperatures, the distance between the electron levels in metal particles can be considered to be relatively small and their optical properties differ little from those of bulk metal samples.¹⁷⁵ Therefore, the electron dynamics in small metal particles markedly differs from that in semiconductor particles.

For small metal particles, only the optical absorption and structural properties have long been studied,^{252–256} whereas the study of electron dynamics has started only recently. The regularities of electron relaxation for times longer than 2 ps have been elucidated.²⁵⁷ The first femtosecond study of relaxation was performed by Roberti *et al.*²⁵⁸ in relation to a dispersion of gold

clusters in water. Subsequently, similar studies^{259, 260} were carried out for silver and platinum nanoparticles in aqueous and organic media.

The investigations showed that for silver and gold particles, relaxation at early stages is determined by the electron–phonon interaction, the relaxation times being 2.5 and 7 ps, respectively. These times are longer than the corresponding relaxation times for bulk samples (670 fs for silver and 1 ps for gold).^{261, 262} The retardation of electron relaxation in nanoparticles was ascribed²⁵⁹ to the decrease in the electron–phonon interaction. This decrease has been predicted theoretically,²⁶³ the relaxation time for gold particles corresponding to that measured for island films.²⁶⁴ Similar femtosecond studies have been carried out for gold^{265–270} and zinc²⁷¹ nanoparticles. Studies of gold particles in glass matrices resulted in a relaxation time of 4 ps.²⁶⁶

It was also demonstrated that the difference between the relaxation times for particles having the same size can be due to the use of different stabilising agents. Thus it was found²⁶⁰ that the relaxation times for the same gold particles (18 nm) in water and cyclohexane are 7 and 3.5 ps, respectively.

For tin particles, the dependence of the relaxation time on the particle size was attributed²⁷¹ to the effect of electron collisions with the particle surface. These results stimulated investigations into this dependence for gold particles with strictly specified dimensions. Thus it was found²⁷² that the relaxation time (τ) for the Au_{55} particle is 1 ps and that for Au_{13} is 300 ps. The electron relaxation for the Au_{55} cluster with a diameter of 2 nm proceeds much faster than that in larger (14–40 nm) particles (Fig. 7), for which the relaxation time is 7 ps. The experimental results are described by a phenomenological formula²⁷³

$$\frac{1}{\tau} = \frac{aR^\alpha}{\tau_b} + \frac{bv_F}{R}, \quad (55)$$

where a , b are constants, τ_b is the bulk relaxation time, v_F is the Fermi velocity, R is the particle radius and α is an integer which can be found from the corresponding theoretical model.²⁶³

According to Eqn (55), as the particle size decreases, the relaxation time first increases, because the first term (normalised electron–phonon interaction) predominates. When the particle size further decreases, the second term starts to predominate and the relaxation time diminishes.

The same pattern of variation follows from the measurements of electron relaxation in platinum particles.²⁷³ However, the data for the Au_{13} clusters do not fit in this regularity. Thus, formula (55) is inapplicable to small clusters, apparently, due to the loss of metallic properties by the clusters (in particular, Au_{13}). This fact is also confirmed by measurements of the absorption spectra of these clusters,^{272, 274} in which many new bands appear. From this it follows that the transition from bulk properties to molecular properties for gold clusters takes place in the range from 55 to 13 atoms.

Deviations from the dependence given by relation (55) are also observed upon an increase in the pumping radiation

Figure 6. Diagrams of energy levels in semiconductors (a) and metals (b). (1) atoms, (2) small particles, (3) bulk samples. Occupied levels are cross-hatched, E_F is the Fermi level.

Figure 7. Change in the optical absorption coefficient (ϵ) vs. time for excited Au_{55} particles (1) and gold particles with a dimension of 15 nm (2).²⁷²

Figure 8. Change in the optical absorption coefficient vs. time for excited gold nanoparticles with a dimension of 15 nm.²⁷⁰

power.^{268, 270, 275} In this case, the time of electron relaxation increases linearly with the intensity of the pumping radiation power, which is due to the heating of electrons and ‘detachment’ of their temperature from the temperature of the ion lattice.

Yet another interesting phenomenon was discovered in the studies cited above, namely, modulation of the absorption of the probing radiation (Fig. 8). The modulation was found for gold particles with a size from 14 to 17 nm. It was found that the modulation frequency did not correspond to the average gap between the electron levels

$$\Delta_m \approx \frac{E_F}{N},$$

the discreteness of which could, at the first glance, account for the modulation. For the particles studied, the modulation frequencies and the widths of energy gaps between the levels differ by an order of magnitude. Therefore, it was suggested²⁷⁵ that these modulations are due to vibrations of the particles. Analysis shows²⁷⁶ that the frequency of the acoustic vibrations of particles is close to the observed modulation frequency of the electron relaxation. The observed changes in the modulation frequencies and acoustic vibrations, depending on the particle size, are also consistent with experimental results.

Acoustic vibrations show themselves in the optical absorption spectra in the following way.²⁷⁵ In conformity with the Mie theory,¹⁹⁶ the absorption coefficient of a particle is

$$\kappa(\omega) \propto \varepsilon_m^{3/2} \frac{\omega \varepsilon_2(\omega)}{[\varepsilon_1(\omega) + 2\varepsilon_m]^2 + \varepsilon_2(\omega)^2}. \quad (56)$$

The resonance absorption takes place when

$$\varepsilon_1(\omega) = -2\varepsilon_m.$$

In the free electron model,

$$\varepsilon_1(\omega) = 1 - \frac{\omega_0^2}{\omega^2 + \Gamma_e^2}, \quad \varepsilon_2(\omega) = \frac{\omega_0^2 \Gamma_e}{\omega(\omega^2 + \Gamma_e^2)}, \quad (57)$$

where Γ_e is the reciprocal relaxation time of electrons.

It can be seen from relations (52) and (57) that the position of the plasmon resonance depends on the density of electrons in the particle (because of a similar dependence of ω_0). As the electron density increases, the resonance shifts to shorter wavelengths; when the density decreases, it shifts to longer wavelengths. The possibility of this change in the position of the plasmon band was shown in experiments on pulse radiolysis²²⁷ of identical silver particles with a size of 6 nm. As a result of vibrations of the ionic lattice, the electron density in the particles changes periodically, which shows itself as the periodic modulation of absorption.

In a study of electron relaxation in experiments similar to those described above,^{266, 277} silver particles 40–60 nm in diameter and gold particles 15–20 nm in diameter were found to be broken to give smaller fragments (5–20 and 5 nm, respectively).

The fragmentation was induced by the radiation from a pumping laser able to cause ionisation of the particles. The radiation power played a minor role. The fragmentation was due to the appearance of an electric charge on the particles upon photoemission.²⁶⁶ This is confirmed by the fact that this effect was especially pronounced when the solution contained molecular traps for electrons.

VIII. Electron transfer through nanoparticles

Metal nanoparticles are unique objects to study the transfer of electrons through point contacts. For contacts between particles, non-linear current–voltage characteristics and (for low voltages) current suppression have been found.^{278–282} In recent years, nanoparticles have started to be used in experiments with point contacts. The tip of a tunnelling microscope normally serves as one of the electrodes in these experiments (Fig. 9).^{283–289} The intensive research along this line started after a single nanoparticle had been isolated and stabilised on a substrate.²⁷

Figure 9. Scheme of the experiment on electron tunnelling through individual particles.

The observed anomalies of current–voltage characteristics were attributed from the beginning²⁷⁸ to the fact that an electron which skips from a particle to an electrode changes the particle charge by the magnitude of the electron charge e and thus increases the electrostatic energy by

$$\Delta E \approx \frac{e^2}{C},$$

where C is the capacitance of the particle. The capacitance of a spherical particle with the radius R coated by a shell with thickness d and having the dielectric constant ε in an electrolyte solution is found from the relation

$$C = 4\pi\varepsilon \frac{R}{d} (R + d).$$

For an electron to be able to skip (tunnel) from the particle to an electrode, the energy of the electron should be greater than ΔE . To ensure that the electron has the required energy, a relatively high voltage should be applied on the electrodes

$$U \approx \frac{e}{C}.$$

In experiments with single nanoparticles,^{27, 289} several steps can be found in the current–voltage characteristics (Fig. 10, curve 1). It was shown²⁸² that in the intervals between the steps, the particle charge does not change and is equal to e , $2e$, $3e$, etc. In addition, the conductivity of the electrode–particle system exhibits several maxima arranged at intervals (Fig. 11).

The maxima are due to degeneration of the electrostatic energy of the particle²⁹⁰

$$E(Q) = \frac{Q^2}{2C} + VQ \quad (58)$$

with respect to the charge Q ; here V is the potential of the particle. The condition of the energy degeneration with respect to charge

Figure 10. Current–voltage characteristics of a nanoparticle–electrode system for particles of different sizes increasing in the sequence $1 < 2 < 3$.

Figure 11. Electrical conductivity of a nanoparticle–electrode system vs. applied voltage.

$$E[(n-1)e] = E(ne)$$

is fulfilled for the potential

$$V_n = -\frac{(2n-1)e}{2C}. \quad (59)$$

The effects of tunnelling through single particles have been studied fairly comprehensively by electrochemical methods.²⁸⁷ Particles of different sizes were considered; in addition to experimental studies, data of numerical modelling of the processes occurring in the system shown in Fig. 9 were presented. In particular, transfer of electrons through the adlayer of the particles characterised by a particular size distribution was studied. It was shown that in the case of a particle ensemble of this type, the steps on the current–voltage characteristics are blurred and disappear with an increase in the particle size (see Fig. 10).

IX. Self-assembly of nanoparticles

Metal nanoparticles meant for the use as elements of electronic devices should finally be deposited on substrates. The properties of ensembles of deposited particles depend appreciably on their distribution over the substrate; this problem has drawn considerable attention. The possibility of deposition of ordered structures consisting of nanoparticles is of special interest; they can serve as miniature electronic devices: memory elements, lasers, screens, switches, *etc.* These ordered structures have been called quantum dots.^{291–293}

The periodic structures based on nanoparticles were initially prepared by deposition of atoms on specially prepared substrates. For example, a procedure for the preparation of ordered islands of silver on the Pt(III) surface has been described.²⁹⁴ The islands were formed as a result of nucleation of silver atoms on a substrate surface with a pre-formed structure of separate silver atoms. It is clear, however, that this procedure is applicable only to a very narrow range of materials; therefore, the search for new, more versatile methods for the preparation of ordered structures from nanoparticles continues. A possible approach is deposition of clusters grown beforehand.

The method of targeted deposition of clusters was apparently implemented for the first time by Fucks *et al.*²⁹⁵ Low-energy monodisperse clusters obtained from the gas phase were deposited *in vacuo* on a substrate. Cluster sub-monolayers containing several

tens to several thousands of atoms were prepared in this way. Observations showed that these clusters are not destroyed when brought in contact with a solid support. For big clusters, diffusion coefficients over the surface are low; therefore, the clusters do not migrate over the surface, their coalescence also being largely suppressed. As clusters are accumulated on the substrate, peculiar structures corresponding to successive deposition of strongly fixed particles are formed.

The resulting films are highly porous and are formed from aggregates of nanoclusters having a fractal structure similar to that found for particles in thin polymeric films.^{237, 238} The fractal dimension and characteristic size of the aggregates are determined by the regime of cluster deposition on the substrate.

It has been proposed²⁹⁶ to deposit energy-charged clusters; in this case, characteristics of the structures formed can be varied over wider limits. The process of formation of structures from deposited clusters was also modelled in numerical experiments. Experimental data and the results of modelling have been surveyed in reviews.^{297, 298}

Ordered structures consisting of nanoparticles supported on substrates are of the greatest interest. These structures were first obtained using self-assembled monolayers of surfactants and resorting to the lithography methods. It has been shown^{299–306} that deposition of surfactant monolayers followed by treating them with beams of low- or high-energy electrons or ultraviolet radiation and the use of scanning tunnelling microscopy affords ordered structured layers of metal particles with characteristic dimensions of up to 20 nm. Periodic structures of metal nanoparticles have also been prepared³⁰⁷ by deposition of a metal on a substrate coated by an ordered adlayer of inert particles with sizes from 50 nm to 30 nm. In this case, the metal is applied on the substrate through the spaces between the inert microparticles.

In recent years, considerable progress has been made in the development of a method that implies formation of ordered nanostructures (colloid crystals) directly from nanoparticles formed in colloidal solutions. The attraction of this method is that it provides the possibility of varying the particle size over wide limits, the structure of the particles being controlled quite reliably by advanced techniques. In addition, the ligand or adsorption shell and, hence, the electronic properties of the particles can be varied as desired. Finally, successful use of this method hardly depends on the nature of the particles.

A method for the preparation of colloid crystals was first realised for CdS nanoparticles.³⁰⁸ The procedure of evaporation of a solution from a colloidal dispersion film was used. During evaporation, either homogeneous or heterogeneous (on the substrate) nucleation of colloid crystals takes place. By this method, one can form both three- and two-dimensional colloid crystals. The scheme of deposition of ordered nanostructures is presented in Fig. 12. The resulting structures were studied by electron microscopy, which showed the presence of nanocrystals with ordering in the range of about 50 μm.

Subsequently, this method has been widely used to prepare ordered structures from metal nanoparticles.^{31, 48, 309–319} Initially, the experiments were carried out with gold nanoparticles because in this case, the composition of the particles was constant and the

Figure 12. Scheme of the formation of ordered structures from nanoparticles by evaporation of the solvent. System: (a) before evaporation; (b) after evaporation.

ligand shell formed from alkanethiols was sufficiently stable to ensure high stability of the colloidal dispersion and a colloid crystal. In addition, gold nanoparticles coated by an alkanethiol adlayer permit easy replacement of the solvent; the nanoparticles can be deposited and again dispersed and exchange reactions with the ligand environment can be carried out.

It has been demonstrated in various studies that nanoparticles form either a planar hexagonal structure or crystals with an FCC lattice. Detailed investigations dealing with the structure of colloid crystals and its dependence on the structure of nanoparticles have been carried out.^{19, 20, 320} It was found that in the case of ordered multilayer structures, a colloid crystal necessarily has the (111) face. This was explained by the important role of the surface forces in the formation of colloid crystals because in ordinary crystals, this face has the minimum surface energy.

The lattice of a colloid crystal formed by gold nanoparticles and stabilised by quaternary ammonium bromides with alkyl radicals of various lengths has been studied.³¹⁹ It was found that the lattice parameter of the colloid crystal depends linearly on the length of the hydrocarbon radical. When the second layer of nanoparticles is deposited, they form either linear or ring structures on the hexagonal lattice formed by the first layer. The particles in the second layer occupy preferentially the sites above the contact points of the first-layer particles.

Characteristic features of the packing of particles have also been studied for the colloid crystals of gold²⁰⁰ and silver³²¹ stabilised by alkanethiols. In this case, too, a correlation was established between the length of the alkyl chain and the lattice parameter of the colloid crystal. In addition, it was found by the method of chemical imaging in transmission electron microscopy with electron energy filtering³²¹ that the alkyl 'tails' of the adlayer of one particle penetrate rather deeply into the adlayers of neighbouring particles and form a sort of chemical bond with them. These experimental data confirm the results of molecular dynamics modelling of the behaviour of long-chain alkanethiols on the surface of nanocrystals.³²²

The interaction between silver nanoparticles coated by thiolates and forming ordered structures has been studied in detail.³²³ The aggregation of nanoparticles and the structural transitions in thin layers and in the bulk of the colloidal solution were investigated. By comparing the experimental data with the results of numerical modelling, parameters of the particle–particle interaction were determined for the van der Waals attraction and for the short-range repulsion. It was shown that model of 'soft spheres' is the most adequate model for nanoparticles. A more comprehensive theoretical study of the characteristic features of nanoparticle structuration at interfaces has been carried out by Gelbart *et al.*³²⁴

For the preparation of colloid crystals by vaporisation, the monodispersity and the shape of particles and the nature of the stabilising shell are significant. Self-assembly of gold, silver and platinum nanoparticles has been studied.⁵¹ Nanoparticles were first prepared in water and then transferred into organic solvents containing thiolates; thus, the particle size and shape could be varied over wide limits. All the systems studied displayed the capability of self-assembly. The effect of the stabilising agent on the preparation of colloid crystals from nanoparticles has been considered by Lin *et al.*,³²⁵ who worked with gold nanoparticles synthesised in reverse micelles using various stabilisers containing thiol, amino and sulfide groups. It was found that the formation of colloid crystals proceeds most readily in the presence of ligands with thiolate groups. The use of dodecanethiol was found to be the most efficient; with this compound, colloid crystals are spontaneously formed, nanoparticles being spontaneously segregated according to their sizes.

Nanoparticles arranged in crystals exhibit new cooperative properties;^{46, 326} in particular, for two-dimensional crystals, the plasmon band shifts towards lower energies with respect to that for isolated nanoparticles. This effect is more pronounced when three-dimensional colloid crystals are formed; in this case the

profile of the absorption band also changes. This change in the band profile is due to the influence of the particle environment and to the tunnelling of electrons between them. The latter factor starts to be significant when the distances between the particles are close to 2 nm; the average distance between nanoparticles coated by, *e.g.*, dodecanethiol is 1.8 nm.

The hypothesis concerning the influence of tunnelling on the absorption spectra has been verified;³²⁷ for this purpose, the energy shift of the plasmon band and the coefficient of light reflection from self-assembled structures consisting of silver particles with various distances between the closest particles were studied. Experimental data were approximated by theoretical curves constructed using the Maxwell–Garnett model. As particles approach one another to distances of several nanometers, the optical characteristics change sharply and the discrepancy between the calculated and experimental data becomes more pronounced. A substantial deviation of the results obtained in terms of classical theory from experimental results was found for the non-linear susceptibility of nanoparticle crystals, which characterises the generation of the second optical harmonics.

The cooperative effects in self-assembled nanoparticles are so pronounced that it is possible to obtain structures exhibiting dichroism by special techniques.³²⁸ It is even possible to control the optical characteristics of ordered layers of nanoparticles.⁴² The relevant experiments were concerned with the regularities of light transmission through and light reflection from multilayer films consisting of isolated gold nanoparticles. The experiments were carried out under conditions where a potential was applied on the film (by injection of electrons). Both the reflectance and the transmittance changed upon application of the potential. It was found that the observed changes in the optical constants cannot be described in terms of the views on the individual behaviour of nanoparticles.

To promote self-assembly of nanoparticles into a supported crystal, special methods are used, for example, pre-treatment of the substrate,³²⁹ which can consist in the preliminary formation of self-assembled monolayers (Fig. 13) the external part of which reacts efficiently with the particles or with their ligand environment; in this case, the nanoparticles are stabilised by complex surfactants having two functional groups selected according to the 'key–lock' principle (Fig. 14).

Langmuir–Blodgett films^{46, 333} and electrophoretic deposition of nanoparticles^{334, 335} have been used to design ordered structures of nanoparticles. Ordered structures of silver nanoparticles have also been prepared by thermal reduction of the

Figure 13. Scheme of the formation of ordered structures from nanoparticles on self-assembled monolayers.³³⁰

Figure 14. Scheme of the design of ordered structures from nanoparticles modified by surfactant vapours selected according to the 'key–lock' principle.^{331, 332}

metal in a solution applied onto the surface of specially pre-treated mesoporous silica.³²⁹ By using block copolymers which allow microphase separation, an ordered distribution of particles in films³³⁶ and the formation of intricate structures from nanoparticles³³⁷ can be attained. These structures can rearrange upon thermal treatment or upon introduction of additives influencing the microphase state of the block copolymer. Ordering of nanoparticles on a molten surface of a polymer the bulk phase of which remains solid has also been observed.³³⁸

Recent years have been marked by vigorous development of the methods for the preparation of self-assembled structures from nanoparticles with the use of biological objects: lipid tubes³³⁹ or oligodesoxyribonucleotides containing terminal thiol groups,^{340–342} which act as efficient organising agents in the case of gold nanoparticles. Biological systems permit several types of self-assembly of nanoparticles;³⁴³ for example, the method found to be efficient for gold nanoparticles includes the use of streptavidin and biotin analogues. Biotin disulfide can be adsorbed on gold nanoparticles, which is followed by introduction of streptavidin; otherwise, biotin disulfide is bound to streptavidin and the complex is then adsorbed on the particles introduced. The complexity of this procedure is justified by the presence of a large number of biotin and streptavidin analogues and by the possibility of controlling the structure of the nanoaggregates synthesised and of preparing ordered structures of nanoparticles directly in solution.

X. Conclusion

The high practical value of nano-sized colloidal systems has stimulated substantial progress in their investigation in the last decade. Modern experimental equipment has enabled the preparation of individual nanoparticles with a specified size and the investigation of their properties. The advances in the synthesis and in the study of nanoparticles confirmed the theoretical models that had been developed decades ago but could not be verified because they were developed for ideal systems. It can be said that the high level achieved in the experiments on the preparation of nanoparticles is now close to the reachable limit. The methods used to investigate the properties of nanoparticles have also substantially improved. Almost exhaustive information on the structures of nanoparticles and on the electron dynamics in them was obtained. All this ensured transition to a new level of understanding of the physicochemical processes taking place in nano-sized colloidal systems.

However, the progress brought out new problems. The crucial role of the surface in the formation of properties of nanoparticles has become obvious. Nevertheless, the possibility of preparing nanoparticles with specified surface characteristics are still limited. The influence of the environment on the properties of nano-sized systems has not been adequately elucidated. There appeared the necessity of the development of theoretical approaches to the description of the properties of nanoparticles with intermediate sizes for which cooperative dynamics of electrons is replaced by the individual dynamics. New theoretical models describing the cooperative effects in nanoparticle ensembles including those taking into account the cooperation of their electronic component are required. At present, there are even no models which take into account the influence of the ligand (adsorption) shells when considering the dynamics of electrons in nanoparticles. In this respect, experimental research goes markedly ahead of the theory. However, experimental data now available constitute a good basis for the development of a more comprehensive theory of nanoparticle ensembles.

The author is grateful to Academician I I Moiseev, who initiated and stimulated writing of this review and to the Corresponding Member of the Russian Academy of Sciences Yu M Polukarov for reading the manuscript and making a number of useful remarks.

IV. Other heterocyclisation reactions	856
V. Conclusion	858

Abstract. Published data on the cyclisation of N^1, N^1 -disubstituted N^2 -aryl- and N^2 -hetaryl-formamidines are analysed, described systematically and generalised. The bibliography includes 147 references.

I. Introduction

Heterocyclisations play an important role in organic chemistry and provide key, sometimes irreplaceable, approaches to the preparation of heterocyclic systems. Since heterocyclic derivatives represent the most numerous class of organic compounds covering about two-thirds of all natural and synthetic products, it is important to describe systematically the methods used to prepare them. At present, the syntheses of heterocyclic compounds are classified using three different approaches: in terms of the cyclisation product (heterocyclic compound or a class of compounds), in terms of the type of ring-forming reaction, and in terms of the functional groups or classes of organic compounds involved in the construction of the heterocycle. The last-mentioned approach attracts special attention because it discloses the synthetic potential and the advantages and disadvantages of heterocyclisation components and represents more vividly the methods suitable for solving sophisticated synthetic problems.

Amidines are important starting compounds in the synthesis of heterocyclic systems of various types. There are several ways of construction of heterocycles with participation of amidines

(a) cyclisation upon the reaction with the NH group of the amidine;

(b) transformation of the reactive CH groups attached to the amidine carbon atoms;

(c) pericyclic reactions;

(d) reaction of the electrophilic amidine carbon atoms with external or internal nucleophiles.

Only routes (a) and (b) have been considered comprehensively in the literature.^{1–5} In this review, we analyse the prospects for using N^1, N^1 -disubstituted N^2 -aryl- and N^2 -hetarylformamidines (hereinafter, referred to as aryl- and hetarylformamidines, respectively) for the construction of simple and fused heterocycles. These

compounds cannot react by routes (a) and (b); therefore, it becomes possible to focus attention on the key reactions of types (c) and (d) and to extend the existing generalisations and views on the role of amidines in the synthesis of heterocyclic systems.

II. Pericyclic and cyclisation reactions initiated by nucleophilic addition to multiple bonds

1. Cycloaddition

N^1, N^1 -Dimethyl- N^2 -arylformamidines and N^1, N^1 -dimethyl- N^2 -hetarylformamidines can play a dual role in cycloaddition: they either provide the imine fragment of the dimethylaminomethylideneamino group $N=CHNMe_2$ (hereinafter, the amidine fragment) for heterocyclisation or act as heterodienes in which the amidine fragment $N=CH$ is conjugated with the double bond of the substituent at the imine nitrogen atom. The latter pathway is realised only for N -hetarylamidines characterised by a high degree of alternation of single and double bonds. In these compounds, the double bond in a heterocyclic substituent is activated by the electron-donating amidine group;⁶ hence, the Michael addition to this bond is possible. The primary reaction products can cyclise to give compounds with the same structure as those formed upon concerted [2+4]-cycloaddition. In these products, recyclisation of heterocyclic fragments is possible, resulting in new heterocyclic compounds.

N^1, N^1 -Dimethyl- N^2 -phenylformamide **1a** and phenyliminopyrrolidinomethane **1b** react with dehydrobenzene according to the [2+2]-cycloaddition pattern⁷ giving rise to unstable benza-zetines **2a,b**, which are converted into 2-phenylaminobenzaldehyde **3** and acridine **4** under the reaction conditions.

The amidine **1a** reacts with sodium azide according to the [2 + 3]-cycloaddition route to give ⁸ 1-phenyltetrazole **5**.

1-Nitrosovinylaryls **6a,b**, generated *in situ* from halooximes, react with *N*¹,*N*¹-dimethyl-*N*²-arylformamidines **1a,c** according to the [3 + 2]-cycloaddition route to give 1,4-diaryl-2-dimethyl-amino-3-oxy-2,5-dihydro-1*H*-imidazoles **7a,b**.^{9,10}

Ar¹ = Ar² = Ph (**1a**, **6a**, **7a**), 4-MeC₆H₄ (**1c**, **6b**, **7b**).

In the case of *N*¹,*N*¹-dimethyl-*N*²-hetarylformamidines containing many alternating single and double bonds, heterocyclisation involves the azomethine fragment of the amidine substituent and the neighbouring vinylene fragment of the heterocycle. The diene reactivity increases in the sequence *N*¹,*N*¹-dimethyl-*N*²-arylformamidines, *N*¹,*N*¹-dimethyl-*N*²-hetarylformamidines and *N*¹,*N*¹-dimethyl-*N*²-vinylformamidines. This is determined by the degree of participation of the vinylene fragment in conjugation. Indeed, *N*¹,*N*¹-dimethyl-*N*²-phenylformamidines derivatives do not participate in cycloaddition reactions as dienes, whereas *N*¹,*N*¹-dimethyl-*N*²-vinylformamidines are quite reactive dienes. On passing from *N*-vinylformamidines to *N*-hetarylformamidines, the diene reactivity decreases. *N*¹,*N*¹-Dimethyl-*N*²-(isopropenyl)formamidine **8a** and *N*¹,*N*¹-dimethyl-*N*²-(cyclohex-1-enyl)formamidine **8b** readily react with alkenes and alkynes¹¹ to give 1,4-dihydropyridine and pyridine derivatives formed as [4 + 2]-cycloaddition products.

R¹ = R² = H (**a**); R¹ - R² = (CH₂)₃ (**b**).

The reactions of *N*¹,*N*¹-dimethyl-*N*²-(1,3-dimethyl-2,6-dioxo-1,2,3,6-tetrahydropyrimidin-4-yl)formamidine **9** with methyl vinyl ketone, methyl acrylate, acrylonitrile and dimethyl or diethyl maleate proceed in a similar way to give 1,3-dimethyl-5,8-dihydropyrido[2,3-*d*]pyrimidine-2,4-diones **10**, which are formed from the products of primary [2 + 4]-cycloaddition **11**.¹² The high regioselectivity observed in the reactions with mono-substituted alkenes is in line with the electron-donating influence of the amidine substituent, which increases the electron density at the 5-position of amidinodimethyluracil **9**. The compounds **10**

were oxidised to the corresponding 1,3-dimethylpyrido[2,3-*d*]pyrimidine-2,4-diones **12** by refluxing in nitrobenzene.

R¹ = H; R² = COMe, CO₂Me, CN; R¹ = R² = CO₂Et, CO₂Me.

*N*¹,*N*¹-Dimethyl-*N*²-5-(1-ethylpyrazolyl)formamidine **13** undergoes [2 + 4]-cycloaddition to (2-nitrovinyl)benzene **14a**, 1-phenyl-3-(2-nitrovinyl)indole **14b** or 2-(2-nitrovinyl)thiophene **14c** on exposure to microwave radiation.¹³ The adducts **15** formed regioselectively are converted *in situ* into a mixture of 4-aryl-1-ethyl-5-nitropyrazolo[3,4-*b*]pyridines **16** and 4-aryl-1-ethylpyrazolo[3,4-*b*]pyridines **17** as a result of abstraction of HNO₂ with aromatisation.

The ratio of the compounds **16** and **17** depends on the nature of the nitroalkene **14** but the nitro derivative **16** predominates in all cases.

Nitroalkene 14	Ar	Yield (%)	
		16	17
a	Ph	64	8
b		60	9
c		84	—

2. Recycling

In the reactions of heterocyclic derivatives of amidines with activated alkynes, Michael addition is the preferred reaction route, as opposed to the reactions of *N*-vinylformamidines. Indeed, the reaction of the compound **9** with dimethyl acetylenedicarboxylate in acetonitrile (20 °C, 36 h) affords a mixture of dimethyl 1,3-dimethyl-2,4-dioxo-1,2,3,4-tetrahydropyrido[2,3-*d*]pyrimidine-5,6-dicarboxylate **18** and methyl 2,5-dimethyl-3-(3-methyl-1,3-diazabut-1-enyl)-1,4,6-trioxo-2,4,5,6-tetrahydropyrrolo-[3,4-*c*]pyridine-7-carboxylate **19** in 1 : 2 ratio. The reaction carried out in toluene (16 h) or chloroform (18 h) gives only the compound **19** in

70% yield. It was suggested¹⁴ that this compound results from recyclisation of the uracil residue in the Michael addition product **20** formed initially.

A reactive dienophile, 4-nitro-2-phenyloxazole **21**, reacts with amidinouracil **9** according to the Michael addition pathway, although its reactions with other dienes follow the [2 + 4]-cycloaddition route.¹⁵ The intermediate **22** is converted into 6-benzamido-7-dimethylamino-1,3-dimethyl-2,4-dioxo-1,2,3,4-tetrahydropyrido[2,3-*d*]pyrimidine **23** through opening of the oxazole ring followed by an electrocyclic reaction accompanied by aromatisation.

3. Reactions with diketene and isocyanates

The reactions of *N*-hetarylformamidines with diketene have been studied in relation to systems containing a pyridine nitrogen atom at the α -position relative to the amidine substituent, namely, *N*¹,*N*¹-dimethyl-*N*²-benzothiazol-2-ylformamidine **24a**, *N*¹,*N*¹-dimethyl-*N*²-benzoxazol-2-ylformamidine **24b** and *N*¹,*N*¹-dimethyl-*N*²-benzimidazol-2-ylformamidine **24c**. These reactions

proved convenient for the construction of fused pyrimidine-containing heterocycles **25a–c**.^{16, 17}

In the general case, *N*¹,*N*¹-dimethyl-*N*²-arylformamidines react with aryl isocyanates to give 1:2 adducts, 1,3,5-triazines **26**.^{18, 19} However, apart from these products, the reactions afford solid substances with high melting points, which have been identified^{20–22} as 1,3,6,8,10-pentaazaspiro[4.5]decane-2,4,7,9-tetraones **27**. Presumably,^{20, 22} they are formed *via* bipolar intermediate **28**, which regioselectively adds isocyanate giving rise to *sym*-triazinedione **26**. Successive insertion of isocyanate into the C–N and C–H bonds results in the spiro compound **27**.

4-Dimethylamino-2,6-dioxo-5-phenyl-4,5-dihydro-1,3,5-triazine-1,3-disulfonyl dichloride **29** is produced in the reaction of the amidine **1a** with Graf's isocyanate **28**.²³

An unusual cycloaddition of methyl isocyanate to *N*¹,*N*¹-dimethyl-*N*²-arylformamidines has been proposed²⁴ as a method for the synthesis of 3-aryl-1,1-dimethyl-3-(1,3,5-trimethyl-4,6-dioxo-1,2-dihydro-1,3,5-triazin-2-yl)ureas **30**, possessing herbicidal properties.

$R_n = \text{H, Cl, Cl}_2, 3\text{-CF}_3, 4\text{-MeO, 4-Me, 3-Cl-4-MeO, 3-Cl-4-Me, 3-CF}_3\text{-4-Cl.}$

Some reactions of *N*-hetarylformamidines with isocyanates differ from the transformations of *N*-arylamidines because either heteroatoms or activated multiple bonds of the heterocycle are involved in the reaction. Thus the reaction of *N*¹,*N*¹-dimethyl-*N*²-2-pyridylformamidines **31** with phenyl isocyanate gave a [2 + 2]-cycloadduct, 4-dimethylamino-1-phenyl-3-pyridin-2-yl-1,3-diazetidin-2-one **32**, in a high yield. At elevated temperature in the presence of phenyl isocyanate, this product is converted into

3-phenylpyrido[1,2-*a*]-1,3,5-triazine-2,4-dione **33**.²⁵ 3-Phenylpyridazino[1,6-*a*]-1,3,5-triazine-2,4-dione is prepared in a similar way.²⁶

Presumably,²⁵ the cycloadduct **32** formed initially undergoes cyclodegradation at elevated temperatures. The subsequent [2 + 4]-cycloaddition of the resulting isocyanates gives rise to the bicyclic adduct **33**.

Depending on the temperature and the reactant ratio, the reactions of *N*¹,*N*¹-dimethyl-*N*²-2-(4,5-dihydrothiazol-2-yl)formamides **34** with phenyl isocyanate afford different products, 2-dimethylamino-3-phenyl-2,3,6,7-tetrahydrothiazolo[3,2-*a*]-1,3,5-triazin-4-one **35**, *N*¹,*N*-dimethyl-*N*²-(2-dimethylamino-4-oxo-1,3-diphenylhexahydrothiazolo[3,2-*a*]-1,3,5-triazin-8*a*-yl)formamidine **36** or 3-phenyl-6,7-dihydrothiazolo[3,2-*a*]-1,3,5-triazine-2,4-dione **37**.²⁷ In the opinion of the researchers cited, phenyl isocyanate reacts with the endocyclic imine nitrogen atom of the hetarylamidine **34** at room temperature; this gives rise to intermediate bipolar compound **A**. This compound either cyclises to yield compound **35** or reacts with a second phenyl isocyanate molecule, resulting in the amidine **36**. At elevated temperatures, the attack by phenyl isocyanate on the exocyclic imine nitrogen atom of the amidine **34** proves to be the preferred reaction pathway; this gives initially intermediate **B**, which is converted into compound **37** upon the reaction with phenyl isocyanate. Apparently, an important stage of this transformation in the latter case is transamination, *i.e.* the exchange by the imine fragments between phenyl isocyanate and the amidine **34**.

4. Electrocyclic reactions

The transformation of phenyliminoaziridinomethane **38** into 1-phenyl-4,5-dihydro-1*H*-imidazoline **39** induced by nucleophiles or acids proceeds similarly to the symmetry-allowed synchronous isomerisation of vinylcyclopropane into cyclopentene. The rearrangement is similar to the isomerization of vinyl ethyleneimine into pyrroline. The researchers suggested^{28,29} that the reaction of aziridine with phenyl isocyanide gives rise to thermodynamically unstable *Z*-isomer **38**, the transformation of which into the imidazoline **39** proceeds *via* initial *Z,E*-isomerization.

On heating or irradiation, *N*-hetarylamidines containing a substituent with an unsaturated fragment in the neighbouring position to the amidine group undergo sigmatropic transformations giving rise to more complicated heterocyclic systems.

Thermolysis of *N*¹,*N*¹-dimethyl-*N*²-6-(5-arylideneamino-1,3-dimethyl-2,6-dioxo-1,2,3,6-tetrahydropyrimidin-4-yl)formamidine **40** is accompanied by the aza Cope reaction. An intramolecular pericyclic reaction followed by isomerisation and elimination of dimethylamine affords 6-substituted 1,3-dimethylpteridine-2,4-dione **41**.³⁰

Transformations of this type are also typical of systems containing an azo fragment in the neighbouring position to the amidine substituent, although they are accompanied by side processes. Thus *N*¹,*N*¹-dimethyl-*N*²-6-(1,3-dimethyl-2,6-dioxo-5-phenylazo-1,2,3,6-tetrahydropyrimidin-4-yl)formamidine **42** is converted at 210–220 °C into a mixture of 3-dimethylamino-5,7-dimethyl-2-phenyl-1,5-dihydro-2*H*-pyrimido[4,5-*e*]-1,2,4-triazine-6,8-dione **43** and 8-dimethylamino-1,3-dimethylpyrine-2,6-dione **44**. Apparently, the latter product is formed from 9-anilino-8-dimethylamino-1,3-dimethylpurine-2,6-dione **45**.³¹

The reactions of amidinouracil **9** with azodicarboxylates proceed similarly to transformations of 6-amino- or 6-alkylamidinouracils to give adducts **46**. These products are converted into pyrine derivatives **44** upon thermal cyclisation.¹⁴

R = Me, Et.

In the photolysis of formamidine **42**, 1,5-cycloaddition is the predominant reaction pathway;^{32,33} 8-phenylamino-1,3-dimethylpurine-2,6-dione **47** is formed upon irradiation. A similar transformation takes place in the reductive heterocyclisation of the compound **42** induced by sodium dithionite.³⁴

The intramolecular 1,5-cycloaddition in *N*¹,*N*¹-dimethyl-*N*²-(5-nitrosopyrimidin-4-yl)formamidine **48** proceeds at room temperature without irradiation.³⁵

III. Intramolecular nucleophilic substitution

1. Reactions with participation of N-nucleophiles

*N*¹,*N*¹-Dimethyl-*N*²-arylformamidines and *N*¹,*N*¹-dimethyl-*N*²-hetarylformamidines are convenient objects for heterocyclisation, provided that a position adjacent to the amidine substituent is occupied by a reactive functional group (amino, carbonyl, ethoxycarbonyl, nitrile, iminophosphorane group and so on).

The reactions in which an N-nucleophile reacts with formamidine in the key stage of ring formation are summarised in Table 1. It should be emphasised that this approach is especially attractive for the synthesis of fused systems which include five-, six- and seven-membered nitrogen-containing heterocyclic fragments. The use of functionalised amidines in the synthesis of various fused pyrimidines has been studied most thoroughly.

Cyclisation can either involve a nitrogen-containing nucleophile present in the molecule or occur upon the addition of ammonia, amines, hydroxylamine, their salts and hydrazine or guanidine. In some cases, the reaction is accompanied by deamination, *i.e.* transformation of the amidine substituent into an amino group.

Aryl- and hetarylformamidines containing a free amino group in the position neighbouring to the amidine substituent are postulated as intermediates in several syntheses of imidazoles from 1,2-diamines. Meanwhile, *N*²-(2,4-diamino-6-hydroxypyrimidin-5-yl)-*N*¹,*N*¹-dimethylformamidine **49** is a stable compound because the electron-donating substituents in the pyrimidine ring decrease the electrophilicity of the formamidine carbon atom.

Formamidines **49** can be converted into 2-amino-6-chloropurine **50** on treatment with HCl and subsequent heating.³⁶

Table 1. Products of heterocyclisation of aryl- and hetarylformamidines formed with participation of N-nucleophiles.

Type of reaction	X	Reagent or reaction conditions	Reaction product
<i>a</i>	NH ₂	Δ	
<i>b</i>	CH ₂ NHPh	Δ	
<i>c</i>	CH(R)CH ₂ NH ₂	Δ	
<i>d</i>	CN	RNH ₂	
<i>e</i>	CN	H ₂ NNH ₂	
<i>f</i>	CN	H ₂ NOH	
<i>g</i>	CN	(H ₂ N) ₂ C=NH	
<i>h</i>	C(O)R	NH ₃	
<i>i</i>	C(O)R ¹	R ² NH ₂	
<i>j</i>	CO ₂ Et	RNH ₂	
<i>k</i>	P ⁺ (Cl)(NR ₂) ₂ Cl ⁻	NH ₃	
<i>l</i>	CHO	NH ₂ OH	

(a) POCl₃, DMF; (b) HCl, H₂O; (c) Δ, -Me₂NH·HCl.

Hetarylamidines containing a free amino group are synthesised by selective reduction of nitro- or cyano-substituted amidines. Under the reaction conditions, they undergo heterocyclisation according to route *a* (see Introduction) giving rise to an imidazole fragment. Thus reduction of *N*¹,*N*¹-dimethyl-*N*²-(2-methyl-3-nitroquinolin-4-yl)formamidine **51** results in *N*²-(3-amino-2-

methylquinolin-4-yl)- N^1,N^1 -dimethylformamide **52**, which undergoes intramolecular cyclisation *in situ* to give 4-methylimidazo[4,5-*c*]quinoline **53**.³⁷

The electron-donating effect of the dimethyluracil moiety accounts for the stability of N^1,N^1 -dimethyl- N^2 -(1,3-dimethyl-2,4-dioxo-6-phenylaminomethyl-1,2,3,4-tetrahydropyrimidin-5-yl)formamide **54**; it is converted into 1,3-dimethyl-7-phenyl-7,8-dihydropyrimido[5,4-*d*]pyrimidine-2,4-dione **55** only on heating in toluene.³⁸

Cyclisation *in situ* of N^1,N^1 -dimethyl- N^2 -[4-(2-amino-1-trimethylsilyloxyethyl)-1-methylpyrazol-5-yl]formamide **56**, prepared by the reduction of N^1,N^1 -dimethyl- N^2 -[4-(cyano-trimethylsilyloxymethyl)-1-methylpyrazol-5-yl]formamide **57**, is a key stage in the synthesis of 1-methyl-1,4,5,6-tetrahydropyrazolo[3,4-*d*]-1,3-diazepin-4-ol **58**.^{39–41}

In the synthesis of 3*H*-2-thia-3,5,6-triazaacanthrylene **59**, the key intermediate, formamide **60**, containing a free amino group, is prepared using the Gewald heterocyclisation of N^1,N^1 -dimethyl- N^2 -(4-methyl-3-cyanoquinolin-2-yl)formamide **61**.⁴²

The reactions of compounds containing cyano-, ester or cabonyl group in the position adjacent to the amidine substituent with ammonia derivatives (see Table 1, reactions *d–j*) are widely used to form a fused pyrimidine fragment. In some cases, the reaction with ammonia is accompanied by deamidation.

On treatment with excess Vilsmeier reagent, reactive amino-substituted heterocyclic compounds are converted into formylhetarylformamides.⁴³ For example, 2-aminoindole **62** was used to synthesise N^1,N^1 -dimethyl- N^2 -(3-formylindol-2-yl)formamide **63**.⁴⁴ Refluxing this product with ammonium salts in ethanol induces cyclisation giving rise to salt **64** the subsequent reduction of which affords 3-substituted 2,3,4,4*a*-tetrahydropyrimido[4,5-*b*]indole **65**. This type of cyclisation has been studied in relation to hetarylformamides derived from 3-aminoindole^{45,46} or 3- and 5-aminopyrazoles.^{47,48}

X = Cl, Br; R = CH₂COOH, Et, Ph, (CH₂)₂NMe₂, (CH₂)₃OH.

The behaviour of hetarylformamides having an acetyl group in the position adjacent to the amidine substituent with respect to low-basicity nitrogen-containing nucleophiles is similar to the behaviour of formyl-substituted derivatives.^{49,50} Thus N^1,N^1 -dimethyl- N^2 -(5-acetyl-6-methylthio-2-phenylpyrimidin-4-yl)formamide **66** is converted into 5-methyl-4-methylthio-2-phenylpyrimido[4,5-*d*]pyrimidine **67** when heated with ammonium acetate in butyl alcohol.⁵¹

1,2-Disubstituted N^1,N^1 -dimethyl- N^2 -(4-benzoyl-1*H*-benzimidazol-5-yl)formamide **68**, containing a low-reactivity carbonyl group, is transformed into substituted 9-phenyl-3*H*-imidazo[4,5-*f*]quinazoline **69** only upon prolonged heating in an ethanol solution of ammonia in an autoclave.⁵²

R¹ = CH₂CH₂OH, Ph; R² = H, Me.

The carbonyl groups of anthraquinone can also be involved in the amidine cyclisations.^{53,54} For example, 1,5-bis(3-methyl-1,3-diazabut-1-enyl)-9,10-dioxo-9,10-dihydroanthracene **70** is converted into 1,3,7,9-tetraazaperylene **71** on refluxing with ammonium acetate in ethylene glycol methyl ether.⁵⁵ This reaction proved convenient for the synthesis of anthrapyrimidine dyes.^{56,57}

The reactions of alkylamines with hetarylformamides containing an ethoxycarbonyl group next to the amidine substituent provide the possibility of constructing a pyrimidone fragment. Thus ethyl 5-(3-methyl-1,3-diazabut-1-enyl)-1*H*-pyrazolyl-4-carboxylates **72** were used to synthesise 5-substituted pyrazolo[3,4-*d*]pyrimidin-4-

ones **73**.⁵⁸ 3-Benzyl-7-methylpyrido[2,3-*d*]pyrimidin-4-one was prepared in a similar way from the corresponding pyridine derivative.⁵⁹

$R^1 = \text{H, Ph; } R^2 = \text{CH}_2\text{Ph, CH}_2\text{CH}_2\text{Ph, MeCHCH}_2\text{Ph.}$

The reactions of nitriles with nitrogen-containing nucleophiles are widely used to synthesise heterocyclic compounds.^{60,61} Thus the reactions of aryl- and hetaryl-formamidines containing a cyano group in the position adjacent to the amidine substituent with ammonia, amines or their salts were found to be convenient for the preparation of fused aminopyrimidines. This approach is used in combinatorial chemistry.⁶²

7-Amino-2-methyl-2*H*-1,2,3-triazolo[4,5-*d*]pyrimidine **74** was obtained by refluxing *N*¹,*N*¹-dimethyl-*N*²-(5-cyano-2-methyl-2*H*-1,2,3-triazol-4-yl)formamidine **75** in an aqueous solution of ammonium acetate.^{63,64}

The same strategy was employed to prepare adenine **76**,⁶⁵ 4-aminopyrazolo[3,4-*d*]pyrimidine **77**,^{66–69} 4-amino-6,8-dimethoxy-5-hydrobenzo[*e*]pyrimido[4,5-*b*]azepin-10-one **78**,⁷⁰ 4-aminopyrrolo[2,3-*d*]pyrimidine **79**,⁷¹ 5,6,7,8-tetrahydro-1,3,5,10-tetraazaphenanthren-4-ylamine **80**,⁷² 4-aminoquinazoline **81**⁷³ and their derivatives.

The transformation of *N*¹,*N*¹-dimethyl-*N*²-(3-cyano-5,6,7-trihydropyrrolo[1,2-*a*]imidazol-2-yl)formamidine **82** into substituted 4-amino-5,6,7-trihydropyrrolo[2,1-*f*]purines **83** has been studied and a mechanism has been proposed for this reaction.⁷⁴ Presumably, the reaction starts with transamination at the formamidine carbon atom, accompanied by evolution of dimethylamine. This is followed by an intramolecular attack by the NH group on the cyano carbon atom giving rise to 5-substituted 4-imino-5,6,7-trihydropyrrolo[2,1-*f*]purines **84**. On treatment with nucleophiles, the products **84** undergo the Dimroth rearrangement; as a result, the aminopyrimidine fragment adds to the initial heterocyclic system.

$\text{Nu} = \text{OH}^-, \text{EtO}^-; \text{NuH} = \text{HOH, EtOH, RNH}_2.$

Partial hydrolysis of hetarylformamidines containing a cyano group in the position adjacent to the amidine group is accompanied by heterocyclisation which gives a pyrimidone fragment. Thus treatment of 5-dimethylaminomethylideneamino-4-cyanopyrazoles substituted at the 1-position yields pyrazolo[3,4-*d*]pyrimidin-4-ones **85**. Apparently, the cyclisation proceeds *via* amides **86**.⁷⁵

Cyclisation of hetarylformamidines can be used to prepare organophosphorus compounds.^{76,77} For example, the phosphorus salts **87** cyclise on treatment with ammonia to yield 3-methyl-4,4-bis(amino)-1-phenylpyrazolo[4,5-*e*]-1,3,4λ⁵-diazaphosphinines **88** *via* intermediate iminophosphonic diamides **89**.⁷⁸

$\text{NR}_2 = \text{N(CH}_2\text{CH}_2\text{O)}_2, \text{NEt}_2.$

When the amidine molecule incorporates two different reaction sites which occupy positions neighbouring the amidine group, the more reactive site participates predominantly in the cyclisation. For instance, *N*¹,*N*¹-dimethyl-*N*²-(1-methoxy-7,8-dimethyl-4-oxo-6-cyanoisochroman-5-yl)formamidine **90** is converted into 6-methoxy-7,8-dimethyl-4*H*,6*H*-5-oxa-1,3-diazaphenylene-9-carbonitrile **91**, the cyano group remaining intact during the reaction.⁷⁹

The same functional groups located in different positions of the heterocycle can differ substantially in reactivity. Thus heterocyclisation of dicyano-substituted 4-dimethylaminomethylideneamino-2-oxo-1,2-dihydropyridines **92** occurs selectively giving rise to 8-cyano-4,7-dioxo-3,4,6,7-tetrahydropyrido[4,3-*d*]pyrimidines **93**.⁸⁰

R = Ph, 4-MeC₆H₄, 4-BrC₆H₄.

The reaction of *N*¹,*N*¹-dimethyl-*N*²-(5,7-dicyano-2,3-dihydro-1*H*-pyrrolizin-6-yl)formamidine **94a** with benzylamine involves the 5-cyano group and results in 8-benzylamino-4-cyano-2,3-dihydro-1*H*-pyrrolo[1',2':5,1]pyrrolo[2,3-*d*]pyrimidine **95a**. The second cyano group does not participate in the reaction. In the case where different functional groups are present in the positions neighbouring the amidine substituent, the cyclisation pathway depends not only on the reactivity of each group but also on their positions in the ring. Indeed, in the cyclisation of *N*¹,*N*¹-dimethyl-*N*²-(5-cyano-7-ethoxycarbonyl-2,3-dihydro-1*H*-pyrrolizin-6-yl)-formamidine **94b**, the more reactive cyano group is involved in the reaction, which affords 8-benzylamino-4-ethoxycarbonyl-2,3-dihydro-1*H*-pyrrolo[1',2':5,1]pyrrolo[2,3-*d*]pyrimidine **95b**.⁸¹

R = CN (a), COOEt (b).

The fact that the reaction follows only this pathway can appear unexpected because the α -position of the unsubstituted pyrrole ring is enriched in electron density, and the cyclisation would rather be expected to involve the electrophilic substituent located in the less electron enriched β -position. However, the presence of two electron-withdrawing groups induces redistribution of the partial charges on the carbon atoms of the ring in both the ground and transition states. As a consequence, the electronic effects of the heterocyclic fragment of the molecule substantially change. In the above example, the reactivity of the nitrile group in the α -position of the pyrrole ring increases and, hence, cyclisation is highly regioselective. The assumption concerning electron density redistribution is supported by the fact that the ester groups at the 4-position of 2,4-pyrroledicarboxylic acid diesters are more stable against hydrolysis than the 2-ester groups.⁸²

In the case of 5-benzoyl-7-cyano-6-(3-methyl-1,3-diazabut-1-enyl)-2,3-dihydro-1*H*-pyrrolizine **96**, the carbonyl group is much more reactive than the nitrile group; therefore, cyclisation affords 4-cyano-8-phenyl-2,3-dihydro-1*H*-pyrrolo[1',2':5,1]pyrrolo[2,3-*d*]pyrimidine **97**. The reaction is accompanied by deamidation, which gives compound **98**.⁸³

Kadushkin *et al.*⁸⁴ have studied the influence of the size of the ring fused to the pyrrole fragment on the pathway of cyclisation of polymethylenepyrrole derivatives, namely, 7-cyano-6-dimethylaminomethylideneamino-5-ethoxycarbonyl-2,3-dihydro-1*H*-pyrrolizine **99a**, 1-cyano-2-dimethylaminomethylideneamino-3-ethoxycarbonyl-5,6,7,8-tetrahydroindolizine **99b** and 1-cyano-2-dimethylaminomethylideneamino-3-ethoxycarbonyl-6,7,8,9-tetrahydro-5*H*-pyrrolo[1,2-*a*]azepine **99c**.

Compound	<i>n</i>	Yield (%)	
		100	101
a	1	< 5	79
b	2	40	42
c	3	95	< 5

In the case of the compound **99a**, pathway *b* predominates, *i.e.* the reaction involves the nitrile group and gives compound **101a**. When the ring size and, hence, steric overcrowding, increases, the heterocyclisation involves the ethoxycarbonyl group activated by the neighbouring heterocyclic fragment. The contribution of pathway *a* increases and, correspondingly, the compounds **100b,c** are formed in higher yields.

Hydrazine hydrate is also used to perform cyclisation of hetarylformamidines containing a nitrile or carbonyl group in the position adjacent to the amidine substituent. Thus 5-cyano-4-dimethylaminomethylideneamino-2-methylthiopyrimidine **102** reacts with hydrazine hydrate being thus converted into 3-amino-4-imino-7-methylthio-3,4-dihydropyrimido[4,5-*d*]pyrimidine **103**.⁸⁵ However, in some cases, only deamidination is observed in these reactions instead of cyclisation.⁸⁶

Since the formation of a pyrimidine ring is more favourable than the formation of a 1,2,4-triazepine ring,⁸⁷ only one nitrogen of the hydrazine molecule participates in the cyclisation.^{88–90} The free amino group can be used in subsequent transformations. Thus the reaction of *N*¹,*N*¹-dimethyl-*N*²-(2-benzoyl-4-chlorophenyl)formamidine **104** with hydrazine hydrate has served as the first stage in the synthesis of *symm*-triazolo[4,3-*a*]-1,4-benzodiazepine derivatives **105**.⁹¹

Treatment with hydroxylamine of hetarylformamidines containing a carbonyl or cyano group neighbouring an amidine group gives rise to pyrimidine *N*-oxides.^{44–47, 92, 93} For instance, 5-chloro-3-dimethylaminomethylideneamino-4-formyl-1-phenylpyrazole **106** was converted into 3-chloro-5-oxy-2-phenylpyrazolo[3,4-*d*]pyrimidine **107**, while 3-cyano-2-dimethylaminomethylideneaminopyrazine **108** was transformed into 4-amino-3-oxypyridine **109**.

It should be emphasised that, unlike the reactions with ammonia, hydrazine or their salts, in this case, the initial product of replacement of the dialkylamino group **110** can be detected and, in some instances, isolated. This difference is due to the fact that the initial reaction product **110** is equilibrated with its tautomer **111**, the latter predominating in the reaction mixture. Compounds of the type **111** do not tend to undergo heterocyclisation, which proceeds more slowly.

N-Hetarylformamidines in which the amidine substituent occupies the neighbouring position with respect to the pyridine-type nitrogen atom⁹⁴ can be used to synthesise fused heterocycles containing a 1,2,4-triazole fragment.⁹⁵ For example, 4-dimethylaminomethylideneamino-1,11,11-trimethyl-3,5,6-triazatricyclo-[6.2.1.0^{2,7}]undeca-2,4,6-triene **112** was converted into 11,14,14-trimethyl-3,4,5,7,9-pentacyclo[9.2.1.0^{2,9}.0^{4,8}]tetradeca-2,5,7,9-tetraene **113** in a high yield.⁹⁶ The triazole fragment (compound **114**) is formed upon nucleophilic attack by a ring nitrogen atom on the nitrogen atom attached to the hydroxy group in the product **113** formed in the reaction with hydroxylamine. The cyclisation occurs on treatment with polyphosphoric acid (PPA) with heating. The high potential of this approach was also demonstrated in relation to derivatives of pyridine,⁹⁷ pyrimidine,⁹⁸ pyridazine,⁸⁹ pyrazine,⁹⁹ *symm*-triazine and some other polycyclic systems.^{73, 100, 101}

Apparently, cyclisation induced by hydroxylaminesulfuric acid follows a similar route.^{102, 103} Thus *N*¹,*N*¹-dimethyl-*N*²-2-pyridylformamidine derivatives **115** are converted into the corresponding 1,2,4-triazolo[1,5-*a*]pyridines **116**. 2-Pyridylcyanoamides **117** are formed as side products. Presumably, the dimethylamino group is initially replaced by hydroxylaminesulfuric acid giving rise to compound **118**, which cyclises. The side product **117** is produced from tautomer **119**.

R = H, 2-Me, 3-Me, 4-Me.

When hetarylformamidines containing a cyano group near the amidine function are subjected to cyclisation on treatment with

guanidine, two amino groups are incorporated simultaneously into the pyrimidine ring formed. This approach was used to prepare 2,4-diaminopyrimido[4,5-*b*]quinoxaline **120** from 3-cyano-2-dimethylaminomethylideneaminoquinoxaline **121**.¹⁰⁴

2. Reactions involving C-nucleophiles

Cyclisations of hetarylamidines in which the substitution of the amidine amino group gives rise to a C–C bond are presented in a general form in Table 2.

As in the case of *N*-nucleophiles, this approach permits the construction of five-, six- and seven-membered heterocycles.

Aryl- and hetarylformamidines containing a methyl group next to an amidine group are converted into heteroannulated pyrroles on heating with sodium phenylmethylamide in methyl-aniline.^{105, 106} Thus 2-dimethylaminomethylideneamino-3-

X = N (a), CH (b).

Table 2. Products of cyclisation of hetarylamidines formed on treatment with C-nucleophiles.

Type of reaction	Hetarylamidine	Reagent or reaction conditions	Reaction product

c		Δ	
d		B:	
e		CF ₃ CO ₂ H	
f		B:	
g		B:	

methylpyrazine **122a** is transformed into 5*H*-pyrrolo[2,3-*b*]pyrazine **123a**. The indole **123b** was prepared from *N*¹,*N*¹-dimethyl-*N*²-2-tolylformamidine **122b** in a similar way. This process can be regarded as a modified Madelung synthesis of indoles.¹⁰⁷ The reaction occurs in the presence of strong bases *via* intermediate carbanions **124a,b**, or under conditions of vacuum flash pyrolysis.¹⁰⁸

Treatment of heterocyclic compounds having methyl and amino groups in the vicinal positions with excess Vilsmeier reagent results in the formation of a pyrrole fragment containing a β-formyl group.^{109, 110} For example, 5-amino-4-hydroxy-2,6-dimethylpyrimidine **125** was converted into 4-hydroxy-2-methyl-5*H*-pyrrolo[3,2-*d*]pyrimidine-7-carbaldehyde **126**.¹¹¹ The first stage gives amidinium salt **127**, which is then formylated at the methyl group by the Vilsmeier reagent. The CH-acidity of the methylene group in intermediate **128** is enhanced, which facilitates heterocyclisation. The amidinium salt **127** does not cyclise when heated in DMF in the absence of POCl₃, which confirms the proposed mechanism.¹¹¹

X = Cl, OP(O)Cl₂.

When hetarylamidines in which the pyridine nitrogen atom occupies an adjacent position to the amidine substituent are made to react with halo ketones, fused imidazole-containing heterocycles are produced. For example, 3-(4-hydroxybenzoyl)-8-methylimidazo[1,2-*a*]pyridine **129** was prepared by the reaction of *N*¹,*N*¹-dimethyl-*N*²-(3-methylpyridin-2-yl)formamidine **130** with 2-bromomethyl 4-hydroxyphenyl ketone. In this process, the pyridine nitrogen atom is alkylated to give intermediate **131**. The high CH-acidity of the methylene group in this compound¹¹² ensures easy cyclisation, which proceeds *via* enolate anion **132**. Therefore, the basicity of the amidine substituent is normally sufficient for the subsequent transformations.

Despite the ambident properties of the enolate anion **132**, the process follows only the route involving the attack of the C-nucleophile on the electron-deficient formamidine centre; after elimination of dimethylamine, this results in the formation of a fused imidazole ring. This reaction has been used to synthesise derivatives of imidazo[1,2-*a*]pyridine,¹¹³ imidazo[1,2-*a*]pyrimidine,¹¹⁴ imidazo[1,2-*b*]-1,2,4-triazine,¹¹⁵ imidazo[2,1-*b*]thiazole,¹¹⁶ imidazo[2,1-*b*]-1,3,4-thiadiazole, pyrrolo[1,2-*a*]imidazole¹¹⁷ and so on.

The enolate anion generated from hetarylamidines having an acetyl substituent in the position adjacent to the amidine fragment also acts as a C-nucleophile. Intramolecular heterocyclisation results in the annelation of a pyridone fragment.¹¹⁸ For example, 4-methylthio-2-phenyl-5-oxo-8*H*-pyrido[2,3-*d*]pyrimidine was prepared from 5-acetyl-4-dimethylaminomethylideneamino-2-phenyl-6-thiomethylpyrimidine.

Cyclisation of 2-(3-methyl-1,3-diazabut-1-enyl)-4-trifluoromethylacetophenone yields 4-dimethylamino-7-trifluoromethylquinoline **134** instead of the expected 4-hydroxy-7-trifluoromethylquinoline **133**.¹¹⁹ This unusual behaviour was explained by assuming that oxygen is replaced by dimethylamine at the stage of enolisation. The decrease in the nucleophilicity on passing from the enolate anion to enamine is counterbalanced, in the opinion of the authors, by the increase in the electrophilicity of the amidine substituent due to protonation.

Phosphonium ylides generated from pyrazolylphosphonium salts **135** undergo intramolecular heterocyclisation *in situ* giving rise to pyrazolo[5,4-*b*]-1,4λ⁵-azaphosphinines **136**.^{76, 78, 120} 4-Nitrobenzylphosphonium salts cyclise much more easily than methylphosphonium salts because of their higher CH-acidity.

$R^1 = \text{H}$, $\text{Hal} = \text{I}$; $R^1 = 4\text{-NO}_2\text{C}_6\text{H}_4$, $\text{Hal} = \text{Br}$; $\text{NR}_2^2 = \text{N} \begin{smallmatrix} \diagup \diagdown \end{smallmatrix} \text{O}$, NEt_2 .

Heating of *N*-methyl-(2-dimethylaminomethylideneamino-5-nitrophenyl)-phenylmethylideneaminoacetamide **137** gives 3-methylaminocarbonyl-7-nitro-5-phenyl-1*H*-benzo[*e*]-1,4-diazepine **138** as the major product.¹²¹ In the opinion of the authors, cyclisation occurs through the substitution of the enolate anion for the dimethylamino group.

The side product, 1-methyl-9-nitro-10*b*-phenyl-1,10*b*-dihydroimidazo[1,2-*c*]quinazolin-2-one **139**, results apparently from an intramolecular cyclisation of the aza-Cope type of the product of rearrangement of the initial compound **137**.

The electrophilicity of the amidine substituent markedly increases upon protonation. This was used to synthesise 7,8-dimethoxy-1-methyl-3-phenylpyrazolo-[3,4-*c*]isoquinoline **140** and 6*H*-pyrrolo[3,4-*c*]carboline-1,3-dione **141** from the corresponding formamidines.^{122, 123} Cyclisation occurs upon refluxing in trifluoroacetic acid over a period of 8–12 h.

3. Reactions involving O- and S-nucleophiles

N,N-Dimethylformamidine hydrochloride and dimethylaminoethoxyacetonitrile are mild reagents used to transform the amino group into the amidine group. However, when they were made to react with 1,2-hydroxyamino or 1,2-sulfanylamino compounds, no amidines were produced; only cyclisation products — annelated oxazoles or thiazoles — were isolated instead. The formation of functionalised amidine intermediates **142** in these reactions was just postulated.² Aminophenols, aminobenzenethiols or the corresponding pyrimidine and pyridazine derivatives were used as the initial compounds.

X = O, S.

The systems containing an *N*-oxide fragment in the adjacent position to the amidine substituent are more stable; however, they undergo recyclisation on heating or on treatment with hydroxylamine salts.^{124, 125} For example, *N*-hydroxy-*N'*-(1,2,4-oxadiazol-3-yl)pyridin-2-yl)benzamidines **143a** and *N*-hydroxy-*N'*-(1,2,4-oxadiazol-3-yl)pyridazin-2-yl)benzamidines **143b** were prepared from the corresponding formamidines **144a,b**.

X = CH (a), N (b).

Treatment of hetarylformamidines containing a nitrile group next to the amidine group with hydrogen sulfide in the presence of bases is used to furnish a pyrimidinethiol fragment.¹²⁶ This method was used, for example, to transform 5-cyano-4-dimethylaminomethylideneamino-2-methyl-2*H*-1,2,3-triazole **145** into 2-methyl-7-thioxo-2*H*-1,2,3-triazolo[4,5-*d*]pyrimidine **146**.

A similar reaction was used⁶⁶ in the synthesis of 3-cyano-4-methylthiopyrazolo[3,4-*d*]pyrimidine **147** from 3,4-dicyano-5-dimethylaminomethylideneamino-1*H*-pyrazole. It was suggested that 4-imino-3-thiocarbamoyl-1,4-dihydropyrazolo[3,4-*d*]-1,3-thiazine **148** undergoes the Dimroth rearrangement to give intermediate **149**. The compound **149** reacts with MeI to give the reaction product **147**.

IV. Other heterocyclisation reactions

This Section surveys transformations of different types in which nucleophilic substitution at the formamidine carbon atom or cycloaddition involving the C = N fragment are not the key stages in the synthesis of heterocyclic compounds. The leading role in these reactions is played by polyfunctional reagents which react with the amidine or by transformations of the heterocyclic fragment of *N*-hetarylformamidines.

In the general case, during cyclisation of trisubstituted aryl- and hetarylformamidines with functionalised nitriles, first, the amidine amino group is replaced and subsequently *N*-nucleophilic heterocyclisation occurs. Thus the reaction of 6-dimethylaminomethylideneamino-9*H*-purine **150** with cyanamide starts with substitution of cyanamide for the dimethylamino group to give derivative **151a**; heterocyclisation resulting in 3-substituted 7-imino-3*H*-1,3,5-triazino[2,1-*i*]purine **152** occurs in the tautomer **151b**. The compound **152** reacts *in situ* with excess cyanamide to be converted into 7-amidinoimino-3*H*-1,3,5-triazino[2,1-*i*]purine.¹²⁷

Trisubstituted formamidines react with aminocyanacetamide according to the transamination pattern. The resulting *N,N'*-disubstituted amidines **153a** are equilibrated with their tautomers **153b**; the latter undergo cyclisation to give imidazole derivatives **154** due to the reaction between the NH and CN groups.¹²⁸ This strategy has also been employed in the synthesis of purine derivatives.^{129, 130}

R = Ph (**1a**), Bn.

Highly basic N^1, N^1 -dimethyl- N^2 -phenylformamidine **1a** performs two functions in the reaction with cyanoacetamide **155**; first, it facilitates the transformation of cyanoacetamide into the carbanion on heating, and, second, it acts as the substrate in which this carbanion substitutes the dimethylamino group. The reaction yields 3-anilino-2-cyanoacrylamide **156**, which is converted into pyrazole derivative **157** on refluxing in an aqueous solution of hydrazine hydrate for 1 h.¹³¹

In this reaction, the amidine, like triethyl orthoformate, acts as a one-carbon synthon for the synthesis of pyrazole derivatives.

When N -hetarylformamidines are heated with hippuric acid in acetic anhydride, nucleophilic substitution at the formamidine carbon atom is accompanied by heterocyclisation. This reaction has been performed for pyridine, pyrimidine, pyrazine, pyridazine, oxazole and benzo-2,1,3-thiadiazole derivatives.¹³² Compounds of the type **158** are the key intermediates in the synthesis of β -hetaryl-amino- α, β -dehydro- α -amino acids.^{133–136}

Aromatic or heteroaromatic compounds containing more than two electron-donating substituents in the ring, including 1,2-diamino derivatives, behave unusually when made to react with dimethylformamide dimethyl acetal. These reactions can give bis- or even tetrakis-amidines, instead of fused imidazoles, for example, 1,2,4,5-tetrakis(dimethylaminomethylideneamino)benzene **159** and 2,4,5-tris(dimethylaminomethylideneamino)benzene **160**. Apparently, the [2-aminoaryl(hetaryl)]amidines formed initially cannot undergo cyclisation because of the low electrophilicity of the formamidine carbon atom. The corresponding fused imidazole-containing heterocyclic compounds — benzo-[1,2- d :4,5- d']diimidazole **161** and 2-dimethylaminomethylideneaminopurine **162** — can be prepared by subsequent pyrolysis in the presence of Al_2O_3 or on heating in diethylene glycol.^{137, 138}

The amidine substituent can also function as a leaving group in heterocyclisation. Thus 5-dimethylaminomethylideneamino-6-(2-dimethylaminovinyl)pyrimidine-2,4-dione **163** is converted into pyrrolo[3,2- d]pyrimidine-5,7-dione **164** on treatment with ammonia.¹³⁹

According to this scheme, ammonia adds to the double bond of the heterocycle, being attached to the more electrophilic carbon atom at the α -position relative to the carbonyl group.

A similar transformation has been used to prepare 5,7-dioxo-6-aza-12,14-dione **165** from 2-amino-4-oxo-4 H -chromenyl-3-carbaldehyde.¹⁴⁰

Partial deamidation occurs during the cyclisation of 4'-dimethylaminomethylideneamino-2,2'-dimorpholino-5-formyl-[4,5'-b]thiazole **166**, giving rise to 2,7-dimorpholinothiazolo[4,5- b]thiazolo[4,5- d]pyrimidine **167**.¹⁴¹

The ease of cleavage of the isoxazole ring at the N—O bond on treatment with nucleophiles or upon reduction accounts for the non-classical behaviour of isoxazolylamidines under heterocyclisation conditions. For example, when 4-cyano-5-dimethylaminomethylideneaminoisoxazole **168** is treated with a hot aqueous solution of ammonia, instead of the expected formation of 4-aminoisoxazolo[5,4- d]pyrimidine **169** or hydrolysis of the amidine substituent, recyclisation occurs giving rise to 4-amino-5-cyanopyrimidin-6-one **170**.¹⁴²

The reduction of 4-dimethylaminomethylideneaminoisoxazol-5-ones **171** catalysed by palladium supported on carbon affords imidazoles **172** in high yields¹⁴³ (90–95%). The key stage of the heterocyclisation is apparently intramolecular transamination at the formamidine carbon atom by the iminocarbonyl function, resulting from reduction of the N–O bond.

Formamidines react with trivalent phosphorus halides in the presence of bases to give molecules with a phosphorus–formamidine carbon bond.^{144, 145} This approach has been used to synthesise phosphorus-containing heterocyclic compounds. For example, treatment of *N*¹,*N*¹-dimethyl-*N*²-arylformamidines **173** with PBr_3 in the presence of bases followed by treatment with secondary amines and heating affords 3*H*-benzaazaphospholes **174**.^{146, 147}

$\text{R}^1 = \text{Me}_2\text{N}, \text{MeO}, \text{Me}, \text{H}, \text{Br}; \text{R}^2 = \text{Me}, \text{Et}, \text{Pr}^i.$

V. Conclusion

The data considered here, which are concerned with heterocyclisation of *N*¹,*N*¹-disubstituted *N*²-aryl- and *N*²-hetarylformamidines, clearly demonstrate the high synthetic potential of these compounds and the prospects for using them to synthesise various heterocyclic systems, including those difficult to prepare otherwise.

However, it should be noted that the synthetic capacities of these compounds are far from being exhausted. The diverse reactivity of amidines is determined by the electrophilicity of the amidine carbon atom, the strong electron-donating ability of the amidine substituent, and the possibility of being involved in nucleophilic reactions and in pericyclic reactions of various types. In general, this allows not only annelation of five-, six- or seven-membered heterocycles to the rings present initially but also one-stage preparation of their functional derivatives by varying the functional substituents in the initial amidines, the reaction conditions and the reagents used for cyclisation.

V. Conclusion	879

Abstract. Data on the synthesis, reactions and structures of monoorganyl derivatives of tellurium(IV) (σ -telluranes) RTeX_3 are systematised and generalised. The use of these compounds in preparative organic chemistry is considered. The bibliography includes 238 references.

I. Introduction

Derivatives of tetracoordinate tellurium RTeX_3 (X is an anionoid substituent) belong to the so-called σ -telluranes. Compounds R_2TeX_2 and tetraorganyltelluranes R_4Te are also σ -telluranes. σ -Telluranes RTeX_3 are important starting compounds in the synthesis of various organic derivatives of tellurium. Thus cyclisation of aryl- and arylvinyltellurium trichlorides is a method for the preparation of various tellurium-containing heterocycles, which is specific to the chemistry of organotellurium compounds. In addition, detelluration and halodetelluration of σ -telluranes RTeX_3 are used in organic synthesis. The two last-mentioned fields of application of monoorganyl derivatives of tellurium(IV) are based on the electrophilic properties of the trichlorotellurium group and a low (compared to other chalcogens) energy of the C–Te bond. σ -Telluranes are also characterised by higher stabilities compared to analogous sulfur and selenium derivatives because the higher energy levels of the p orbitals of tellurium are favourable for bonding.^{1,2} Thus sulfur compounds RSCl_3 decompose to give RSCl and Cl_2 even at very low temperature, RSeCl_3 are stable at room temperature but decompose to RSeCl and Cl_2 on heating, whereas RTeCl_3 are stable up to their melting points.³

Previously, σ -telluranes RTeX_3 have been considered in a review (see Ref. 4) and in the corresponding sections of monographs (see Refs 3 and 5–7).

II. Methods of synthesis

Most compounds of the RTeX_3 type have been prepared from tellurium tetrachloride and diorganyl ditellurides as the starting compounds. Various derivatives of RTeX_3 can also be synthesised by anion exchange in organyltellurium trihalides. Approaches

based on the use of hexahalotellurates, complexes of tellurium tetrachloride with aromatic amines, tellurinic acids and their anhydrides have been studied to a substantially lesser extent. The corresponding reactions were either examined for a few compounds or afforded a limited number of compounds.

1. Reactions of tellurium tetrahalides with heteroorganic compounds

The most important preparative procedures for the synthesis of organyltellurium trihalides involve exchange reactions of tellurium tetrahalides with heteroorganic compounds. These reactions were used primarily for the preparation of aryltellurium trichlorides and aryltellurium tribromides. Poor solubility of TeI_4 in non-polar solvents and its decomposition in polar solvents prevent its use in the synthesis of tellurium triiodides.

In principle, a general procedure for the synthesis of organyltellurium trihalides could involve reactions of equimolar amounts of tellurium tetrahalides with organolithium or -magnesium compounds.

M = Li, MgX; X = Cl, Br.

However, these reactions afford complex mixtures of products due to a more profound exchange. Nevertheless, the reaction of 2-biphenyllithium with TeCl_4 gave rise to 2-biphenyltellurium trichloride, albeit in low yield (16%).⁸

(*N,N*-Dimethylcarbamoyl)tellurium trichloride **1** was prepared by the reaction of TeCl_4 with dimethylaminocarbonylsodium and isolated as a complex with DMF.⁹

Organyltellurium trihalides can be synthesised by the reactions of tellurium tetrahalides with organic derivatives of Hg, Si, Sn or Pb. The procedure most generally employed involves the reaction of TeCl_4 with organomercury compounds. This procedure has been used for the synthesis of aryltellurium trichlorides **2**. Unlike telluration (see below) which yields *p*-substituted aryltellurium trichlorides, this procedure is more versatile because it allows one to synthesise compounds with any substituents (including electron-withdrawing groups) at any position.^{8, 10–21}

The above-mentioned reaction is best carried out in anhydrous dioxane (sometimes CHCl₃ is used) because the resulting mercury(II) chloride forms a 1 : 1 complex with dioxane, which is poorly soluble at room temperature. Generally, the aryltellurium trichlorides formed in admixture with HgCl₂ and, hence, it is necessary to purify the reaction products by recrystallisation or to reduce them to diaryl ditellurides followed by chlorinolysis.

Arylmercury chlorides were used as the starting compounds in the synthesis of aryltellurium tribromides **3**. If molecules of the initial organic substrates contain amino groups²² or the substrates represent pyridine^{23, 24} or quinoline derivatives,²⁴ their reactions with TeCl₄ afford mixtures of unidentified compounds due apparently to side complexation reactions. In this case, TeBr₄ is more suitable.

	23, 24		

Organyltellurium trihalides can also be synthesised from silicon or tin derivatives or, less often, lead or germanium derivatives. The reactivities of heteroorganic derivatives R₄E (E = Si, Ge, Sn or Pb) and R₃EX (X = Cl or Br) increase as the atomic weight of the element increases. The derivatives of the R₄E type are more reactive than R₃EX. Compounds R₂EX₂ and R₃EX do not react with tellurium tetrahalides. The Ar–E bond in mixed derivatives ArEAlk₃ is cleaved under the action of electrophilic tellurium tetrahalides. Thus aryltellurium trichlorides **2** were prepared in 65%–80% yields upon refluxing a mixture of

equimolar amounts of aryltrimethylsilanes and TeCl₄ in toluene for 1 h.^{25, 26}

Ar = 4-BrC₆H₄, Ph, 4-MeC₆H₄, 3-MeC₆H₄, 2-C₆H₄CH₂Ph.

In benzyltrimethylsilane, the C_{sp³}–Si bond is inert with respect to TeCl₄. Refluxing of equimolar amounts of these compounds in toluene afforded a mixture of 4-Me₃SiCH₂C₆H₄–TeCl₃ and (4-Me₃SiCH₂C₆H₄)₂TeCl₂.²⁷

The corresponding aryltrimethylsilanes were used for the synthesis of bis(trichlorotelluro)benzenes. Thus 1,4-bis(trichlorotelluro)benzene²⁸ and 1,2-bis(trichlorotelluro)benzene²⁹ were prepared in ~ 50% yields upon refluxing equimolar amounts of TeCl₄ and 1,4-bis(trimethylsilyl)benzene or 1,2-bis(trimethylsilyl)benzene, respectively, in 1,2-dichlorobenzene.

4-Hydroxyaryltellurium trichlorides **4** were synthesised by the reactions of aryl trimethylsilyl ethers with TeCl₄ in boiling toluene in yields higher than 80%.³⁰

R = H (**a**), Me (**b**).

It was assumed³⁰ that the reaction proceeded *via* intermediate aryloxytellurium trichlorides **5** followed by rearrangement into compounds **4**. This mechanism was supported by the synthesis of aryloxytellurium trichloride **5c** from TeCl₄ and the trimethylsilyl ether of 5-bromosalicylaldehyde.³⁰ Apparently, this compound is stabilised due to coordination of tellurium to the carbonyl oxygen atom.

The reactions of TeF₄ with silylated perfluoroalkanols **6** afforded aryloxytellurium trifluorides **7** in 76%–82% yields.³¹

N-Trichlorotellurioamines **8**,³² **9**³³ and **10**³⁴ were synthesised by the reactions of the corresponding *N*-trimethylsilyl derivatives with TeCl₄.

Organotin compounds react with tellurium tetrahalides at room temperature.^{35–38} The yields of organytellurium trihalides vary from moderate to very high.

The reaction of tributylphenylstannane with TeCl₄ resulted in the cleavage of the C(Ar)–Sn bond to form phenyltellurium trichloride in 80% yield.³⁷

Tetraarylgermanes react with tellurium tetrachloride like organotin derivatives.³⁷

2

Ar = Ph, 4-MeC₆H₄.

Germanium derivatives Ar₃GeCl do not react with TeCl₄.³⁷

Tetraarylplumbanes react with TeCl₄ to form diaryltellurium dichlorides even under mild conditions.³⁹ Phenyltellurium trichloride was prepared with the use of Ph₃PbCl.³⁹

2. Reactions of TeCl₄ with activated arenes

The salt-like structure of tellurium tetrachloride, *viz.*, [TeCl₃]⁺Cl[−] (see Refs 40–44) or [TeCl₃]⁺[TeCl₅][−] (see Ref. 45), both in the solid state and in solutions was confirmed by IR and Raman spectroscopy^{40–45} and the data on conductivity.^{41,42} This compound exhibits moderate electrophilicity and can be involved in electrophilic substitution (telluration) with arenes containing electron-donor substituents. The telluration is highly regioselective. The trichlorotellurio group enters exclusively into the *para* position with respect to the electron-donor substituent in the ring.^{13,16,27,46–56} Heating of azobenzene with TeCl₄ afforded 2-trichlorotellurioazobenzene.⁵⁷ The yields of aryltellurium trichlorides **2** vary over a wide range.

Morgan and Drew⁵⁵ were the first to demonstrate the high selectivity of telluration. He prepared bis(4-ethoxyphenyl) ditelluride by reduction of the product of the reaction of TeCl₄ with phenetole and demonstrated that the reaction of the ditelluride with nitric acid afforded exclusively 4-nitrophenetole. This selectivity was also proved by IR and ¹H NMR spectroscopy for a large number of compounds.

However, C-telluration does not occur if the benzene ring of compounds contains such a strong electron-donor substituent as the dimethylamino group; instead, the complex 2Me₂NPh · TeCl₄ is formed.^{58,59} Analogous complexes were also obtained from other aromatic amines.^{59–62} The corresponding tellurium trichlorides can be isolated from these complexes by subsequent treatment (see below). A decrease in the basicity of nitrogen prevents complexation with TeCl₄. For example, acetanilide underwent telluration in the *para* position.⁴⁶ Organyltellurium trichlorides **11–13** were synthesised from the corresponding derivatives of acridine or quinoline and TeCl₄ in CCl₄.⁶³

However, other quinolines and acridines,⁶³ various pyridines,^{42,45,60,63–65} indoles, carbazoles,⁶³ Schiff's bases^{66–69} and hydrazones⁷⁰ react with tellurium tetrachloride to form only molecular complexes.

Aromatic compounds containing electron-withdrawing substituents (nitrobenzene or 4-nitroanisole) do not react with TeCl₄,⁵⁰ whereas refluxing of TeCl₄ with benzonitrile led to trimerisation of the latter yielding 2,4,6-triphenyltriazine.⁴⁷

Under ordinary conditions, benzene does not react with TeCl₄ due to which it can be used in telluration as the solvent along with CHCl₃ and CCl₄. The introduction of one methyl group into the benzene ring leads to only weak activation of the ring with respect to telluration. Although prolonged boiling (20 h) of a solution of TeCl₄ in toluene afforded 4-methylphenyltellurium trichloride in 83% yield,⁴⁹ toluene can be used as the solvent in certain reactions of TeCl₄ with sufficiently reactive arenes.¹⁶

The TeCl₃ group possesses strong electron-withdrawing properties (see Section IV). Only one trichlorotellurium group can be introduced into the ring by telluration, unlike mercuration, which often gives rise to polymercurated compounds.

Polynuclear hydrocarbons, for example, naphthalene, react with TeCl₄ without additional activation of their nuclei by introducing electron-donor substituents. The reaction of TeCl₄ with naphthalene in toluene under conditions of kinetic control afforded 1-trichlorotellurionaphthalene in 24% yield,¹⁶ which agrees with the usual direction of electrophilic substitution in naphthalene. However, prolonged heating of naphthalene with TeCl₄ at 110 °C without a solvent (under conditions of thermodynamic control) gave rise to 2-trichlorotellurionaphthalene in 54% yield.⁷¹ The reaction of anthracene with TeCl₄ afforded a mixture of 9-chloro- and 9,10-dichloroanthracenes.⁷²

In the case of arenes containing two substituents, the TeCl₃ group is introduced in the *para* position with respect to the stronger electron-donor substituent.^{16,48,50,55,73–75} If this position is occupied, the introduction occurs in the *ortho* position to this substituent.⁵⁰

Telluration of dialkylphenols occurs in the *para* position with respect to the hydroxy group.⁷⁵

R = Me, Bu^t.

The reactions of TeCl₄ with 4-bromoanisole and 3-methoxytoluene also gave rise to aryltellurium trichlorides.⁵⁰ However, the position of the introduction of the trichlorotellurium group into the ring was not established.⁵⁰

Acetamidophenyltellurium trichlorides **15** were synthesised by telluration of 3-mono- and 3,4-disubstituted acetanilides.¹⁹

R¹ = R² = Me; R¹ = Me, OH, OMe, SMe; R² = H.

Aryltellurium tribromides and triiodides cannot be prepared by telluration of arenes with tellurium tetrabromide or tetraiodide, respectively, even in the case of such active compounds as anisole, phenetole or veratrole. Apparently, this is associated with a decrease in electrophilicity of tellurium tetrahalides TeX₄ on going from chlorine to iodine. The electrophilicity of tellurium tetrachloride can be increased by forming complexes of TeCl₄ with Lewis acids. In particular, the complex [TeCl₃]⁺[AlCl₄][−] was formed with AlCl₃.^{43,76} Bergman⁴⁷ was the first to use this approach. However, prolonged boiling of the components in the presence of catalytic amounts of AlCl₃ afforded a mixture of aryltellurium trichlorides and diaryltellurium dichlorides. A more convenient procedure was proposed by Gunther *et al.*⁷⁷ The reactions are carried out with a two-to-threefold excess of AlCl₃. The course of the reaction is monitored by measuring the amount of hydrogen chloride evolved, and the reaction is stopped after evolution of one equivalent of HCl.

As mentioned above, direct telluration of arenes containing NR₂ substituents (R = H or Alk) cannot be performed because these compounds form 2 : 1 complexes with tellurium tetrahalides, which are poorly soluble in ordinary solvents (benzene, toluene or chloroform). Prolonged boiling of these complexes in anhydrous MeOH under an inert atmosphere did lead to electrophilic substitution at the *para* position with respect to the NR₂ group.⁶¹

R = H, Me; X = Cl, Br.

However, attempts to synthesise 4-dimethylaminophenyltellurium trichloride by this procedure failed.⁵⁹ It is believed⁵⁹ that 2 : 1 complexes of aromatic amines with TeCl₄ can have different structures depending on the nature of the amines. In the complexes with *N*- and *ortho*-substituted amines **16**, the tellurium-containing group is located at position 4 with respect to the NR¹R² group. Reduction of these complexes affords mixtures of

4-amino-substituted diaryl tellurides **17** and the corresponding diaryl ditellurides **18**. The ditellurides **18** can be converted into the tellurides **17** by treatment of the reaction mixture with a copper powder or Pd/C. The yields of the diaryl tellurides **17** vary over a wide range (8% – 72%).⁵⁹

R¹R²NAr = 4-Me₂NC₆H₄, 4-MeNHC₆H₄, 4-PhNHC₆H₄, 4-H₂NC₆H₄, 4-H₂N-3-MeC₆H₃, 4-H₂N-3,5-Me₂C₆H₂, 4-H₂N-3-EtOC₆H₃, 4-H₂N-3-CF₃C₆H₃, 4-H₂N-3-MeOCOC₆H₃.

Reduction of 2 : 1 complexes of substituted anilines with TeCl₄ (**19**) gives rise to elemental tellurium and the corresponding anilines.⁵⁹

ArNH₂ = 4-MeC₆H₄NH₂, 3,5-Me₂C₆H₃NH₂, 3-O₂NC₆H₄NH₂, 2,4,6-Br₃C₆H₂NH₂.

The synthesis of *p*- or *o*-substituted aminophenyltellurium trihalides was carried out also with the use of hexahalotellurates of amines, which have been prepared in high yields from amines and solutions of tellurium tetrahalides in hydrohalic acids.^{61,62} Refluxing of these salts in anhydrous methanol was accompanied by elimination of HX to form the corresponding aminoaryltellurium trihalide. It was believed⁶² that hexahalotellurates in methanolic solutions exist in equilibrium with free amines and tellurium tetrahalides and the electrophilic substitution occurs at the nucleus of the free amine.

R₂NAr = 4-H₂NC₆H₄, 4-MeNHC₆H₄, 4-Me₂NC₆H₄, 4-H₂N-3-MeC₆H₃, 2-H₂N-5-MeC₆H₃, 2-H₂N-3,5-Me₂C₆H₂, 4-H₂N-3,5-Me₂C₆H₂; X = Cl, Br, I.

3. Reactions of TeCl₄ with compounds containing active methylene groups

The reactions of aliphatic compounds containing activated methyl or methylene groups with TeCl₄ can proceed as electrophilic substitution at the saturated carbon atom.

Generally, ketones containing at least one methylene group at the α position with respect to the carbonyl group react with TeCl₄ (a solution in CHCl₃) in a molar ratio of 2 : 1 to form mixtures of organytellurium trichlorides **20** and diorganytellurium dichlorides **21**. The trichlorides can be isolated provided that they are poorly soluble and form precipitates.^{78–82} In some cases, the trichlorides were obtained as the only reaction products in high yields.^{81,82} It was suggested⁷⁸ that the reaction proceeded through the addition of TeCl₄ at the double bond of the enol followed by elimination of HCl. Diisopropyl ketone did not react with TeCl₄.^{78,79}

R ¹	R ²	Ref.	R ¹	R ²	Ref.
Pr	Et	78–80	3-MeOC ₆ H ₄	H	82
Bu ^t	H	78, 80	(CH ₂) ₆		81
Ph	Et	78	(CH ₂) ₇		81

The reactions of TeCl₄ with some polyfunctional ketones gave rise to organytellurium trichlorides of the type **20** as the only products.⁸³ Thus telluration of 2-acetylcyclohexanone, 3-acetyl-7-methoxycoumarin and 2,6-diacetylpyridine afforded trichlorides **22–24**, respectively. Apparently, the trichlorotellurium group in the compounds **22–24** exhibits low electrophilicity due to the formation of intramolecular O → Te coordinate bonds, and the reaction stops at this stage. The presence of intramolecular coordinate bonds was confirmed by IR and NMR spectroscopy and X-ray diffraction study of the trichloride **24** (see Section IV). The ketones **22–24** are more stable to hydrolysis than other organytellurium trichlorides, which was also attributed to intramolecular O → Te coordinate bonds.⁸³

The compounds **22–24** have been used for the preparation of thermo- and photothermographic materials.⁸⁴

Trichlorotellurium ketones **25** and **26** containing the trichlorotellurium group at the β position with respect to the carbonyl group were prepared by the reactions of trimethylsilyloxycyclopropanes **27** and **28**, respectively, with TeCl₄ (the yields were 71%–93%).⁸⁵ The compounds **25** and **26** were subjected to dehydrotelluration without isolation from the reaction mixture (see Section III). Based on the IR spectral data, Nakahira *et al.*⁸⁵ assumed the presence of intramolecular O → Te coordinate bonds in the ketones **25** and **26**.

R¹ = R² = H, *n* = 2, 5; R¹–R² = (CH=CH)₂, *n* = 1.

In β-diketones, the most acidic hydrogen atoms of the methylene group are replaced by the TeCl₃ group only if the carbonyl groups bear aryl substituents. Thus the reaction of dibenzoylmethane with TeCl₄ afforded very unstable (dibenzoylmethyl)tellurium trichloride (PhCO)₂CHTeCl₃.⁸⁶ The reactions of TeCl₄ with β-diketones containing at least one hydrogen atom at each of the α- and α'-carbon atoms give rise to 1,1-dichloro-1-telluracyclohexane-3,5-diones **29** as the major products. Diorganytellurium dichlorides and organytellurium trichlorides **30** can be isolated in rare cases and only in reactions carried out in ethanol-free CHCl₃ as the solvent.^{87–89}

R¹, R² = Alk.

R ¹	R ²	Ref.
H	C ₆ H ₁₃	87
H	C ₈ H ₁₇	88
Pr	Pr	89

The formation of organytellurium trichlorides is favoured by the presence of two or three alkyl substituents at one of the α-carbon atoms and the presence of at least one hydrogen atom at the α'-carbon atom. If the organytellurium trichlorides formed bear at least one hydrogen atom at position 3 and chloroform used as the solvent has not been freed from EtOH, the reactions yielded tellurium trichlorides of ethyl enolates **31**.^{86–90} The position of the ethoxy group in these compounds has not been established unambiguously. However, taking into account the strong electron-withdrawing properties of the trichlorotellurium group, it can be assumed that the ethoxy group is located at the β position with respect to the TeCl₃ group.²²

The reactions of tellurium tetrachloride with acetic or propionic anhydrides taken in a ratio of 1:2 in CHCl₃ afforded mixtures of the corresponding α-trichlorotellurocarboxylic acids and anhydrides.^{50,91} However, these trichlorides were converted without isolation into ditellurides **32** under the action of an aqueous solution of K₂S₂O₅.

R = H, Me.

Methylenebis(tellurium trichloride) was isolated in low yield from the mixture obtained by the reaction of TeCl₄ with acetic anhydride.⁹¹ Later, this compound was prepared by refluxing a mixture of TeCl₄ with Ac₂O (taken in a molar ratio of 3:1) in CHCl₃ in 52% yield.⁹² The mechanism of formation of methylenebis(tellurium trichloride) was proposed.⁹²

Attempts to perform telluration of anhydrides of higher aliphatic acids resulted only in elimination of tellurium to form resinous products.

Of other compounds containing the active methylene group, nitromethane was subjected to telluration.⁹³

4. Addition of tellurium tetrachloride to multiple bonds

The major and, apparently, the only procedure for the preparation of alkanes and alkenes containing the TeCl_3 groups and the chlorine atoms at the vicinal positions involves the electrophilic addition of TeCl_4 to double or triple bonds.

a. Reactions of TeCl_4 with alkenes

Under mild conditions (0–60 °C), TeCl_4 adds to the double bond of acyclic or cyclic alkenes to form β -chloroalkyl- and β -chlorocycloalkyltellurium trichlorides **33**.^{94–104} The reactions are generally performed in CHCl_3 , CCl_4 or MeCN . In some cases, bis(β -chloroalkyl)- and bis(β -chlorocycloalkyl)tellurium dichlorides are formed along with the corresponding trichlorides. The addition of TeCl_4 proceeds regioselectively. Thus the reactions of TeCl_4 with terminal alkenes occur as a Markovnikoff addition.

R^1	R^2	Ref.	R^1	R^2	Ref.
H	H	97	Me	Me	99, 100
H	Me	96, 98	$(\text{CH}_2)_3$		99, 100
H	Et	96	$(\text{CH}_2)_4$		94–96, 100, 102–104
H	Bn	101	$\text{CH}_2\text{CH}(\text{Me})(\text{CH}_2)_2$		103, 104
H	C_8H_{17}	99, 100	$(\text{CH}_2)_6$		99, 100
D	C_8H_{17}	99, 100			

The direction of the reactions of TeCl_4 with alkenes and primarily with cycloalkenes depends substantially on the temperature. Thus the reactions of cyclohexene and 4-methylcyclohexene with TeCl_4 in CHCl_3 , CCl_4 or MeCN at 25 °C gave rise to the adducts **33**, whereas the reactions carried out with boiling afforded benzene and toluene, respectively, as the major products.^{103, 104}

Dienes containing isolated double bonds, *viz.*, 1,4-cyclohexadiene¹⁰⁴ and 1,5-cyclooctadiene,^{104, 105} also react with tellurium tetrachloride. In these cases, TeCl_4 adds to only one double bond to form organytellurium trichlorides **34** and **35** in 49% and 64% yields, respectively. Diallyl sulfide reacts analogously to give the trichloride **36**, which is stabilised by an intramolecular S–Te coordinate bond (2.763 Å).¹⁰⁶

Unlike dienes containing isolated double bonds, cyclic dienes with conjugated double bonds (1,3-cyclohexadiene and 1,3-cyclooctadiene) react with TeCl_4 to form primarily dichlorocycloalkenes.¹⁰⁴

The stereochemistry of the addition of TeCl_4 to alkenes has been studied.¹⁰⁰ Thus the reactions of (*Z*)- and (*E*)-but-2-enes generally give rise to mixtures of isomers due to competitive *syn*- and *anti*-addition. *p*-Benzoquinone as a substrate favours the formation of a *syn*-addition product. It is believed that the stereospecific *syn*-addition occurs more or less according to a concerted mechanism. The free-radical reaction competes with this addition.

The addition of aryltellurium trichlorides to alkenes, unlike that of TeCl_4 , occurs nonstereoselectively.

The reactions of allylic derivatives with TeCl_4 take different paths depending on the nature of the substituents at the *sp*³ carbon atom.¹⁰⁷ The reactions of TeCl_4 with allylic alcohols are generally accompanied by resinification of the reaction mixtures and the reaction products cannot be isolated. The reactions of TeCl_4 with allyl ethers occur according to the Markovnikoff rule giving rise to trichlorides **37** in yields above 80%.

The reaction of TeCl_4 with *N*-allylbenzamide,¹⁰⁷ like that with *N*-acetyldiallylamine,¹⁰⁸ afforded zwitterionic dihydrooxazolium salt **38**.

The addition of TeCl_4 to allyl carboxylates proceeded anomalously. In this case, 1,3-addition products, *viz.*, β -acyloxy- γ -chloropropyltellurium trichlorides **39**, rather than 1,2-addition products were obtained.¹⁰⁷

$\text{R} = \text{Me}, \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4, (E)\text{-CH}=\text{CHMe}, (E)\text{-CH}=\text{CHPh}.$

The reaction conditions depend on the nature of the substituent at the carbonyl carbon atom. Thus allyl benzoate and allyl 4-methylbenzoate reacted at room temperature, the reactions with allyl 4-chloro- and 4-nitrobenzoates proceeded only on boiling in chloroform, whereas allyl 2,4-dinitrophenylbenzoate did not react at all even on prolonged heating of the reaction mixture.

The reactions of TeCl_4 and TeBr_4 with allyl cinnamate in a mixture of Et_2O and H_2O at –30 °C occurred as 1,3-addition.¹⁰⁹

According to the data from IR and ¹H NMR spectroscopy,¹⁰⁷ compound **39** ($\text{R} = \text{Me}$) in solution adopts the conformation **A** in which the TeCl_3 group is located in the *gauche* position with respect to the acetoxy group. This conformation is stabilised through the intramolecular O–Te coordinate bond.

Tellurium tetrachloride reacts with α -methylallyl α,α -dimethylallyl and α -ethylallyl benzoates to give also 1,3-addition products.¹⁰⁹

b. Reactions of TeCl_4 with alkynes

The reactions of TeCl_4 with alkynes have been studied to a substantially lesser extent than the reactions with alkenes. The reactions of TeCl_4 with alkynes in CCl_4 proceed regio- and stereospecifically giving rise to 2-chlorovinyltellurium chlorides **40** in yields of 75% and higher.^{54, 110, 111} The *Z* configuration of the compounds **40** was established by halodetelluration yielding (*Z*)-chlorobromo(iodo)alkenes (see Section III).¹¹¹

5. Oxidation of diorganyl ditellurides

A wide range of organytellurium trihalides were prepared by oxidation of diorganyl ditellurides with chlorine,^{22, 26, 91, 112–120} bromine,^{13, 26, 50, 51, 91, 113, 114, 116, 117, 120–131} iodine^{13, 51, 120, 121, 123, 127, 129–132} or fluorine diluted with an inert gas¹³³ at room or reduced temperature. Organytellurium trihalides can be prepared with the use of sulfonyl chloride^{112, 116} or thionyl chloride^{114, 115, 117, 120} instead of chlorine. These reactions are used primarily for the preparation of alkyltellurium trichlorides, aryltellurium tribromides and aryltellurium triiodides.

Poly(ditellurides) are also oxidised with halogens. Thus treatment of poly(methylene ditelluride) with chlorine^{91, 93} or bromine⁹¹ afforded bis(trihalogenotellurio)methanes.

The reaction of bis{2-[N-(p-tolyl)benzylaminomethyl]phenyl} ditelluride (**41**) with SO₂Cl₂ yielded the telluracycle **42**.¹³⁴

R = 4-MeC₆H₄.

The behaviour of dibenzyl ditelluride in the reactions with halogens is anomalous compared to other ditellurides. Treatment of the former with bromine in CCl₄ led to the cleavage of both C–Te bonds giving rise to benzyl bromide and TeBr₄.¹³⁵ The reactions with the use of less than one equivalent of bromine afforded dibenzyltellurium dibromide as the major product.

Ditelluride **43** also behaved anomalously. Thus the reaction with bromine yielded the telluracycle **44**.¹³⁶

Organytellurium trifluorides were synthesised not only with the use of fluorine but also using XeF₂ (see Refs 133, 137 and 138) or ClF.^{138, 139} Ditellurides containing perfluorinated organic groups were converted into organytellurium trifluorides **45** under the action of XeF₂,^{133, 138} whereas diphenyl ditelluride under the same conditions was converted into phenylpentafluorotellurium **46**.¹³⁷

R = C₂F₅ (**a**), C₆F₅ (**b**).

The data on the reaction of bis(pentafluoroethyl) ditelluride with ClF are contradictory. Desjardins *et al.*¹³⁹ believed that the reaction afforded C₂F₅TeF₃ as the major product (*trans*-C₂F₅TeClF₄ and TeClF₅ were isolated as by-products in low yields), whereas Lau *et al.*¹³⁸ reported that a mixture of C₂F₅TeCl_xF_{3–x}, C₂F₅Cl and *trans*-C₂F₅TeClF₄ formed.

Some disulfides act as oxidising agents with respect to diaryl ditellurides. Thus thermochromic aryltellurium tris(dithiocarbamates) **47** were prepared by the reactions of diaryl ditellurides with thiuram disulfides **48** in almost quantitative yields.¹⁴⁰

Ar = Ph, 4-MeOC₆H₄; R¹ = R² = Me, Et; R¹–R² = (CH₂)₅.

Oxidation of diaryl ditellurides with lead tetraacetate afforded the corresponding aryltellurium triacetates.^{141–143} The presence of these compounds in solutions was established by ¹H NMR spectroscopy. However, attempts to isolate these compounds were unsuccessful due to rapid hydrolysis.

6. Exchange reactions of anionoid substituents

σ -Telluranes RTeX_3 containing different anionoid substituents can be synthesised with the use of organytellurium trichlorides in which the chlorine atoms are readily replaced by more nucleophilic anions X^- . Exchange reactions were used for the synthesis of a series of organytellurium tribromides^{61, 73, 74, 82} and organytellurium triiodides.^{13, 61, 73, 74, 82–95} Generally, exchange reactions are performed in aqueous-methanolic (ethanolic) solutions under the action of potassium halides.

X	R	Ref.	X	R	Ref.
Br, I	4-Me ₂ NC ₆ H ₄	61	Br, I	4-ClC ₆ H ₄ COCH ₂	82
Br, I	3-Me-4-HOC ₆ H ₃	73	I	4-HOC ₆ H ₄	13
Br, I	2-Cl-4-HOC ₆ H ₃	74			
Br, I	3-Cl-4-HOC ₆ H ₃	74	I		95
Br, I	2-HOC ₆ H ₄ COCH ₂	82			
Br, I	3-MeOC ₆ H ₄ COCH ₂	82			

The exchange reactions were also used for the synthesis of aryltellurium trifluorides **45c,d**.⁵¹

R = 4-MeOC₆H₄ (**c**), 4-EtOC₆H₄ (**d**).

An analogous reaction was carried out with MeTeI_3 , but attempts to isolate the resulting MeTeF_3 in the pure form failed.¹⁴⁴

The exchange of chlorine atoms in organytellurium trichlorides is used as the major procedure for the synthesis of σ -telluranes RTeX_3 containing such substituents as $\text{SC}(\text{S})\text{NR}_2$ or $\text{SP}(\text{S})(\text{OR})_2$. Thus aryltris(thiocarbamoylthio)tellurium(IV) **47** was prepared by treatment of solutions of RTeCl_3 in CH_2Cl_2 , acetone or methanol with *N*-substituted sodium dithiocarbamates.^{116, 117, 140, 145, 146}

Ar = Ph, 4-MeOC₆H₄, 2-C₆H₄N=NPh, 2-Me₂NCH(Me)C₆H₄, 2-Me₂NCH₂C₆H₄; R = Me, Et, Bn.

The σ -telluranes **47** were also prepared by exchange reactions of aryltellurium trichlorides with $\text{Pb}[\text{SC}(\text{S})\text{NEt}_2]_2$ in dry benzene.¹⁴⁷

Ar = Ph, 4-MeOC₆H₄, 4-EtOC₆H₄, 3-Me-4-MeOC₆H₃.

It should be noted that (according to the data from ¹²⁵Te NMR and Mössbauer spectroscopy¹⁴⁶) 2-(phenylazo)phenyltris(thiocarbamoylthio)tellurium(II) **47** (Ar = 2-C₆H₄N=N-C₆H₄-2) is very unstable and dissociates in solution to form 2-(phenylazo)phenylbis(thiocarbamoylthio)tellurium(II) and $[\text{R}_2\text{NC}(\text{S})\text{S}]_2$.

The evidence for the possible existence of mixed organytellurium trihalides of the RTeX_2Y type is contradictory (see Section II.7). However, compounds of this type were prepared upon treatment of aryltellurium trichlorides with sodium dialkyl-dithiocarbamates. Thus bis(*N,N*-diethylthiocarbamoylthio)-(chloro)phenyltellurium(IV) (**49a**) was synthesised in high yield starting from PhTeCl_3 and $\text{NaSC}(\text{S})\text{NEt}_2$.¹⁴⁸ Treatment of the compound **49a** with potassium *O,O*-diethyl dithiophosphate afforded the mixed σ -tellurane **49b** whose structure was established by X-ray diffraction analysis.¹⁴⁸

Mixed σ -telluranes of this type formed in the reactions of PhTeCl_3 with salts containing the $[\text{SC}(\text{S})\text{NEt}_2]^-$, $[\text{S}(\text{P})\text{S}(\text{OR})_2]^-$ or $[\text{SC}(\text{S})\text{OEt}]^-$ anions were studied in solutions by ¹³C, ³¹P and ¹²⁵Te NMR spectroscopy.¹⁴⁸

Yet another approach to the synthesis of the mixed derivatives **49** is based on oxidative addition of alkyl iodides to bis(*N,N*-diethylthiocarbamoylthio)tellurium(II) (**50**).¹⁴⁸

The mixed derivatives **49c–e** were also synthesised by the reactions of aryltris(*N,N*-dialkylthiocarbamoylthio)tellurium with halogens.^{149–151}

Compound 49	Ar	R	X	Ref.
c	Ph	Et	I	149
d	4-MeOC ₆ H ₄	Me	Br	150
e	4-MeOC ₆ H ₄	Et	I	151

It is noteworthy that the reaction of the compound **49e** with bromine was accompanied by partial replacement of the iodine atoms. The structure of the reaction product **49f** was established by X-ray diffraction analysis.¹⁵¹

The exchange of the chlorine atoms in aryltellurium trichlorides was also used for the synthesis of aryltris(dialkoxythiophosphorylthio)tellurium (compounds **51** and **52**).¹⁵²

Compounds of the type **51** were prepared by the reactions of $\text{PhTe}(\text{OEt})_3$ (which has been prepared *in situ* from PhTeCl_3 and EtONa in EtOH) with *O,O*-dialkyl dithiophosphates, *e.g.*, $\text{HSP}(\text{S})(\text{OPr}^i)_3$.¹⁵²

As in the case of derivatives of dithiocarbamic acid, mixed derivatives can be synthesised.¹⁵³

Ar = Ph, 4-MeOC₆H₄; X = Br, Cl; R = Me, Et, Prⁱ.

Attempts to prepare σ -telluranes RTeX_3 containing $\text{SP}(\text{S})\text{R}_2$ ligands, unlike compounds containing $\text{SC}(\text{S})\text{NR}_2$ or $\text{SP}(\text{S})(\text{OR})_2$ ligands, were unsuccessful. The reaction of PhTeCl_3 with $\text{Na}[\text{SP}(\text{S})\text{R}_2]$ gave rise only to [diorganyl(thiophosphorylthio)]-phenyltellurium(II) **53** due apparently to decomposition of intermediate σ -telluranes of the type **54**.¹⁵⁴

7. Symmetrisation and reverse conversions

Symmetrisation and reverse conversions are well known, have been studied in detail for organic derivatives of Groups II–IV elements and are of preparative importance in the chemistry of organic derivatives of these elements. It was demonstrated¹¹⁵ that the symmetrisation reverse reaction also occurs in the case of diaryltellurium dichlorides.

R = OEt, OMe, H, Br.

Donor substituents favour these reactions. 4-Methoxy- and 4-ethoxyphenyltellurium trichlorides were prepared in 93% and 81% yields, respectively, upon refluxing (5 h) of equimolar mixtures of the reagents. Phenyl- and 4-bromophenyltellurium dichlorides were synthesised under more drastic conditions (a twofold excess of TeCl_4 and prolonged boiling).

8. Miscellaneous procedures

In this section, we consider syntheses of σ -telluranes RTeX_3 , which are exemplified in a few compounds and are of no preparative importance.

Thus 4-hydroxy-3-methoxyphenyltellurium trichloride was prepared along with the corresponding dichloride by condensation of *o*-cresol with TeOCl_2 .¹⁵⁵ It was the only aryltellurium trichloride synthesised according to this procedure.

Organyltellurium trihalides were prepared by the reactions of some organotellurium compounds, viz., organyltellurenyl halides, organyl tellurocyanates, diorganyl tellurides and organyltellurinic acids, with halides (see Section II).

Oxidation of diorganyl ditellurides to form organyltellurium trihalides proceeds through intermediate formation of organyltellurenyl halides RTeX **55**.^{131, 156} Compounds of this type, which do not contain coordinating substituents, are unstable and readily undergo disproportionation to form R_2TeX_2 and Te .¹⁵⁷ Certain groups which can form strong intramolecular coordinate bonds with the Te atom through the N or O atoms stabilise the tellurenyl halides **55**. For example, the NO_2 , CHO, COR, $\text{CH}=\text{N}$, $\text{N}=\text{N}$ and CH_2NR_2 groups located at position 2 of the aryl or alkenyl substituent exert such a stabilising effect.^{158, 159} Compounds **55** can be synthesised not only by oxidation of ditellurides but also according to other procedures.¹⁶⁰ Hence, oxidation of the organyltellurenyl halides **55** was used for the preparation of organyltellurium trihalides.^{161–169}

The oxidative addition is often performed with the use of SO_2Cl_2 instead of chlorine.^{165–167} Some tellurenyl iodides, for example, $\text{PhCOCH}=\text{C}(\text{Ph})\text{TeI}$, were not oxidised with iodine to form the corresponding triiodides.¹⁶⁹

Aryltellurenyl chlorides can be used for the preparation of mixed aryltellurium trihalides ArTeX_2Y **56**.¹⁸

Attempts to synthesise compounds **56** starting from aryl 2-(halogenotellurenyl)vinyl ketones **57** were unsuccessful.¹⁶⁹ Thus the reaction of tellurenyl bromide **57a** with chlorine afforded a mixture of trichloride **58** and tribromide **59** in a ratio of 2:1. Treatment of tellurenyl chloride **57b** with bromine gave rise to a mixture of the same compounds, but the ratio was 1:2.¹⁶⁹

On the contrary, oxidative addition of bromine to tellurenyl iodide **57c** afforded vinyltellurium tribromide **59**.¹⁶⁹

2-(*N,N*-Dimethylthiocarbamoyltellurenyl)azobenzene reacted analogously.¹⁴⁶

The reactions of benzyl tellurocyanates with two equivalents of bromine were accompanied by the cleavage of the $\text{Te}-\text{CN}$ bond yielding the corresponding benzyltellurium tribromides.^{170, 171} Apparently, σ -telluranes **60** were formed in these reactions as intermediates.¹⁷⁰

It is known^{3, 4, 6, 7} that diorganyl tellurides R_2Te react with halogens to form diorganyltellurium dihalides R_2TeX_2 . However, the reactions of some diorganyl tellurides with halogens proceed with the cleavage of one of the $\text{C}-\text{Te}$ bonds giving rise to the corresponding organyltellurium trihalides. Thus butyltellurium tribromide was obtained from butyl-2-thienyl telluride.¹⁷²

Compounds **61** underwent scission under the action of bromine in CCl_4 to form α,ω -bis(tribromotellurio)alkanes **62**.¹⁷³

$n = 6$ (42%), 10 (40%).

Tellurium-substituted alkynes add bromine with simultaneous elimination of organytellurium tribromide.¹⁷⁴

$\text{R}^1 = \text{Ph}, \text{C}_5\text{H}_{11}, 4\text{-BrC}_6\text{H}_4, \text{R}^2 = \text{Bu}; \text{R}^1 = \text{Ph}, \text{R}^2 = 4\text{-MeOC}_6\text{H}_4.$

The C—Te bond was cleaved in the reaction of telluraphthalide **63** with bromine.¹⁷¹ In the presence of alcohols, the reaction afforded 2-alkoxycarbonylbenzyltellurium tribromides **64**.¹⁷¹

$\text{R} = \text{Me}, \text{Et}.$

In the reactions with HI, tellurinic acids are converted into organytellurium triiodides. Thus tellurinic acid as a component of the complexes $\text{Bu}_2\text{TeO} \cdot 3\text{BuTe}(\text{O})\text{OH}$ and $2(\text{Bu}_2\text{TeO}) \cdot \text{BuTe}(\text{O})\text{OH}$, which have been prepared by oxidation of dibutyl telluride, was converted into butyltellurium triiodide under the action of HI.¹⁷⁵

III. Reactions of σ -telluranes RTeX_3

The reactions of σ -telluranes RTeX_3 were studied primarily for organytellurium trichlorides. Some of them proceed with retention of the coordination number of the tellurium atom.[†]

1. Transformations of σ -telluranes RTeX_3 into σ -telluranes R_2TeX_2

Transformations of σ -telluranes RTeX_3 into compounds R_2TeX_2 proceed with retention of the coordination number of the tellurium atom, but are accompanied by the formation of an additional C—Te bond. These reactions are of preparative importance in the synthesis of σ -telluranes $\text{R}^1\text{R}^2\text{TeCl}_2$ (for earlier data, see Refs 3, 4, 6 and 7). Since aryltellurium trichlorides exhibit electrophilic properties, they enter into reactions analogous to those of TeCl_4 . Thus these compounds react with different heteroorganic compounds to form symmetrical and non-symmetrical organytellurium dichlorides $\text{R}^1\text{R}^2\text{TeCl}_2$, are involved in electrophilic substitution with activated arenes to give diaryltellurium dichlorides $\text{Ar}^1\text{Ar}^2\text{TeCl}_2$, react with compounds containing the activated methylene group to form σ -telluranes ($\text{ArTeCl}_2\text{CH}_2\text{COR}$ in the case of ketones) and add to double and triple bonds yielding derivatives of the types $\text{ArTeCl}_2\text{CH}(\text{R}^1)\text{CH}(\text{Cl})\text{R}^2$ and $\text{ArTeCl}_2\text{C}(\text{R}^1)=\text{C}(\text{Cl})\text{R}^2$, respectively. However, aryltellurium trichlorides are weaker electrophilic agents than TeCl_4 , and hence, the above-mentioned reactions proceed under more drastic conditions.

Intramolecular cyclisation of aryl- and arylvinyltellurium trichlorides giving rise to different six- and five-membered tellurium-containing heterocycles is of particular interest.¹⁷⁶ Thus thermal or AlCl_3 -catalysed cyclisation of aryltellurium trichlorides **65** afforded tetracoordinate tellurium derivatives, viz., phenoxatellurine **66a**,⁵⁶ thiophenoxatellurine **66b**,¹³ phenotellurazine **66c**²⁰ and telluroxanthene **66d**.²⁶

$\text{Y} = \text{O} \text{ (a)}, \text{S} \text{ (b)}, \text{NH} \text{ (c)}, \text{CH}_2 \text{ (d)}.$

[†] Exchange reactions of anionoid substituents are considered in Section II.6.

Heating of organytellurium trichlorides **67** and **68** at high temperature gave rise to 1,1,3-trichloro-2-phenylbenzo[*b*]tellurophene (**69**)¹⁷⁷ and 1,1-dichlorodibenzotellurophene (**70**),⁸ respectively.

Aryltellurium trichlorides and vinyltellurium trichlorides can be converted into the corresponding dichlorides by symmetrisation. Thus heating of solutions of 2-chloro-2-phenylvinyltellurium chloride in EtOH or AcOH resulted in elimination of the TeCl_4 molecule.¹¹⁰

Aryltellurium trichlorides do not undergo spontaneous symmetrisation. These compounds were converted into diaryltellurium dichlorides only upon boiling of their solutions in benzene in the presence of a copper powder (the yields were 60%–70%).¹¹⁵

$\text{R} = \text{OMe}, \text{OEt}.$

Aryltellurium trichlorides were converted into diaryltellurium dichlorides also under the action of organylsilicon hydrides.¹⁷⁸ Aryltellurium trichlorides reacted with silicon hydrides (in a ratio of 3:4) with stirring at room temperature for 6–8 h to afford diaryl ditellurides. When refluxed for 6–10 h, the mixture of the reagents taken in a ratio of 1:2 gave rise to diaryltellurium dichlorides in 75%–95% yields.

$\text{Ar} = \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-EtOC}_6\text{H}_4; \text{R}^1, \text{R}^2 = \text{Ph}, \text{C}_6\text{H}_{13}, \text{Me}; n = 1, 2; m = 1, 2.$

Certain reactions of σ -telluranes RTeX_3 are accompanied by a decrease in the coordination number of the Te atom to 2 (reduction) or 3 (hydrolysis).

2. Reduction of aryltellurium trihalides to aryltellurenyl halides[‡]

Reduction of aryltellurium trichlorides affords different products depending on the structure of the organic ligands. Aryltellurium trihalides containing coordinating substituents in the *ortho* position are reduced to aryltellurenyl halides, whereas organytellurium trihalides in which such substituents are absent are reduced only to diorganyl ditellurides.

Aryltellurium trihalides containing $\text{CH}=\text{N}$,^{23,24,120,168} $\text{N}=\text{N}$,¹⁸ NO_2 ,¹⁶¹ CH_2NMe_2 (see Ref. 116) or $\text{CH}(\text{Me})\text{NMe}_2$ (see Ref. 117) groups in the *ortho* position were reduced to aryltellurenyl halides. Hydrazine hydrate^{23,24,116,117,120} NaBH_4 ,¹⁸ NaHSO_3 (see Ref. 161) and $\text{Na}_2\text{S}_2\text{O}_5$ (see Ref. 168) were used as reducing agents.

[‡] Reduction of organytellurium trihalides to ditellurides is not considered in the present review because these reactions have been surveyed in detail in a recent review.¹⁷⁹

R	Reducing agent	Ref.
	N ₂ H ₄ · H ₂ O	23, 24
	N ₂ H ₄ · H ₂ O	24
N = NPh	NaBH ₄	18

CH ₂ NMe ₂	N ₂ H ₄ · H ₂ O	116
CH(Me)NMe ₂	N ₂ H ₄ · H ₂ O	117

In the case of *N*-(2-tribromotelluriobenzylidene)-4-methylaniline (**71a**), both the TeBr₃ and azomethine groups were reduced under the action of sodium borohydride,¹³⁴ whereas the azomethine group in sterically hindered *N*-(2-trichlorotelluriobenzylidene)-2,4,6-trimethylaniline (**71b**) remained unchanged.

3. Hydrolysis of organytellurium trihalides

Alkaline hydrolysis of aryltellurium trihalides followed by acidification of the reaction mixture afforded aryltellurinic acids **72** in 70%–100% yields.

X = Cl, Br.

Ar	Ref.	Ar	Ref.
Ph	180	4-BuOC ₆ H ₄	182
2-MeC ₆ H ₄	113	4-PhOC ₆ H ₄	180, 182
4-HOC ₆ H ₄	46, 180	2-HOCC ₆ H ₄	113

4-MeOC ₆ H ₄	46, 180, 182		

In some cases, acidification gives rise to anhydrides **73** rather than to tellurinic acids **72** due apparently to the existence of the following equilibrium in solution

Presumably, this equilibrium is shifted to the right only in a strongly acidic medium. In the presence of weak acids (for example, AcOH), the anhydrides **73** were formed as the final hydrolysis products of aryltellurium trihalides.^{129, 180–182}

Aryltellurium trichlorides and tribromides undergo partial hydrolysis under the action of cold water to form aryltellurium oxohalides **74**.^{46, 63, 180, 181, 183} Aryltellurium triiodides are inert to cold water. In most cases, hydrolysis at high temperature afforded unidentified compounds. Poor solubility of aryltellurium oxohalides in ordinary organic solvents was attributed¹⁸¹ to the fact that they have a trimeric structure **A**. Attempts to isolate possible intermediate products of partial hydrolysis, viz., compounds (ArTeX₂)₂O, failed.

Aryltellurium oxochlorides **74a,c,d** were also synthesised by treatment of the corresponding aryltellurium trihalides with 2-phenyliodonobenzoate monohydrate.¹⁸⁴

Alkyltellurium oxohalides RTe(O)X (R = Me and X = Cl, Br or I; R = Et and X = I)¹⁸⁵ and anhydrides [RTe(O)]₂O (R = C₈H₁₇, C₁₀H₂₁ or C₁₂H₂₅)¹⁸⁶ were prepared according to a procedure analogous to that used for the synthesis of the aryl analogues **74a–o**. Acidification of an aqueous solution of the salt [Me₃Te]⁺[MeTe(O)O][–] afforded a mixture of methyltellurinic acid and its anhydride.¹⁸⁷

4. Synthesis of salts containing organyltetrahalogenotellurate anions

Reactions yielding salts containing organyltetrahalogenotellurate anions and complexation reactions are accompanied by an increase in the coordination number of the tellurium atom. The reactions of different organytellurium trihalides with onium salts in organic solvents (MeOH or CHCl₃) give rise to salts containing organyltetrahalogenotellurate anions.^{181, 187–192}

Tropylium 4-ethoxyphenyltetra bromotellurate was prepared by the reaction of the corresponding aryltellurium trichloride with tropylium perchlorate followed by anion exchange.¹⁹⁰

The reactions of aryltellurium trihalides with onium salts in aqueous solutions of hydrohalic acids also gave rise to salts **75** in high yields.^{189, 190}

Ar = Ph, 4-EtOC₆H₄; X = Cl, Br; M = cyclo-C₇H₇, Ph₃PMe, Ph₃PCH₂CO₂Et.

5. Complexation

σ-Telluranes RTeX₃ act as Lewis acids in complexation. In contrast to tellurium tetrahalides which typically form 2:1 adducts,¹⁹³ organytellurium trihalides give rise mainly to 1:1 complexes.

Aryltellurium trichlorides ArTeCl₃ (Ar = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-EtOC₆H₄ or 4-PhOC₆H₄)^{125–128} form 1:1 complexes with pyridine, picolines,^{125–128} pyridine *N*-oxide and picoline *N*-oxide.^{194–197} In solution in nitromethane, the complexes with pyridine and picolines act as electrolytes (1:1) and have, apparently, the structure [ArTeCl₂·L]⁺Cl[−].¹⁹⁴ The complexes with *N*-oxides are weak electrolytes of the formula ArTeCl₃·L.¹⁹⁴

In addition to the complexes with the above-mentioned ligands, complexes of aryltellurium trichlorides with a number of other nitrogen-, phosphorus- and oxygen-containing bases, *viz.*, with trimethyl(ethyl)amine,^{195–197} α-naphthylamine,¹⁹⁵ ethylene diamine,¹⁹⁵ benzimidazole,^{195–197} benzothiazole,^{195, 196} 2,2'-bipyridyl,^{195, 197} 1,10-phenanthroline,^{196, 197} triphenylphosphine,¹⁹⁵ triphenylphosphine oxide,^{195–197} triphenylphosphine sulfide,¹⁹⁵ triphenylarsine oxide^{195–197} and dimethyl sulfoxide,^{195–197} were isolated in the individual state as 1:1 complexes. The composition and the enthalpy of formation of the complex of PhTeCl₃ with (C₆H₁₃)₂SO were determined by calorimetric titration.¹⁹⁸ Judging from the enthalpies of formation, the acceptor abilities of tetracoordinate tellurium derivatives decrease in the series TeCl₄ > PhTeCl₃ > Ph₂TeCl₂.¹⁹⁸

It should be noted that Garad¹⁹⁹ assigned the 1:1 and 2:1 compositions to complexes of aryltellurium trichlorides with bidentate ligands (bipyridyl or phenanthroline) and monodentate ligands [pyridine, pyridine *N*-oxide or (C₈H₁₇)₃P=O], respectively, contrary to the above-considered data.^{194–197}

Organytellurium trihalides exhibit acceptor properties also with respect to sulfur-containing donors. It was demonstrated²⁰⁰ that organytellurium trihalides 4-EtOC₆H₄TeX₃ (X = Cl, Br or I), like tellurium tetrahalides, react with tetramethylthiuram disulfide. These reactions are accompanied by extrusion of one sulfur atom to form 2:1 complexes of aryltellurium trihalides with tetramethylthiuram sulfide.

According to IR and ¹H NMR spectral data, the 1:1 complexes of RTeCl₃ and RTeBr₃ (R = Me, Et, 4-MeOC₆H₄ or 4-EtOC₆H₄) with tetramethylthiourea^{130, 195, 201} have a square-pyramidal structure with the organic substituents in apical positions. Three halogen atoms and the *S*-coordinated ligand are located in the base of the pyramid.^{130, 201} The reactions of phenyltellurium trihalides with thiourea in aqueous-methanolic solutions were accompanied by reduction of Te(IV) to form the complexes PhTeX·(NH₂)₂CS.²⁰²

Tetramethyl-¹²⁴ and tetraethyldithiooxamides¹²³ belong to yet another type of sulfur-containing ligands giving the 1:1 complexes ArTeX₃·C(S)(NR₂)C(S)(NR₂) (R = Me or Et) with aryltellurium trihalides 4-RC₆H₄TeX₃ (R = H, Me, MeO, EtO, PhO or PhS; X = Cl, Br or I). The long-wavelength IR spectra and Raman spectra provide evidence in favour of the octahedral

structure of the complexes containing bidentate ligands coordinated through the sulfur atoms of the thiocarbonyl groups.

Measurements of the dipole moments (in benzene) demonstrated that aryltellurium trichlorides form 1:1 complexes with donors of the $\text{Ph}_3\text{P}=\text{X}$ (X is a lone electron pair, O, S or Se) and $\text{PhP}(\text{O})\text{Me}_2$ types.²⁰³ The dipole moments are indicative of the donor-acceptor character of the bond between the components of the complexes. The coordination centres of the complexes adopt a pseudooctahedral configuration in which the donor is located in the *cis* position with respect to the lone electron pair of the tellurium atom and in the *trans* position with respect to the chlorine atom. It is noteworthy that the reactions of 4- $\text{RC}_6\text{H}_4\text{TeCl}_3$ (R = H, OH or OMe) with thiosemicarbazones of benzaldehyde, acetophenone, salicylaldehyde and 2-hydroxyacetophenone afforded ionic tricoordinate Te(II) complexes $[\text{ArTe}(\text{TSK})_2]^+\text{Cl}^-$ (TSK is the corresponding thiosemicarbazone) in which the Te atom is coordinated through the sulfur atom.²⁰⁴

In the reactions with strong Lewis acids, *e.g.*, with SbCl_5 , organytellurium trichlorides RTeCl_3 (R = Me, Et or 4- MeOC_6H_4) act as donors to give 1:1 complexes.¹¹⁹ Ionic structures were assigned to the complexes $[\text{RTeCl}_2]^+\text{SbCl}_6^-$ based on the facts that their IR spectra are similar to those of the ionic complexes $\text{RSeCl}_3 \cdot \text{AlCl}_3$ and have bands characteristic of the SbCl_6^- ion.

The enthalpies of formation of complexes of tetracoordinate tellurium derivatives with AlBr_3 (1:1 composition)¹⁹⁸ are indicative of an increase in the donating ability of the tellurium atom in the series $\text{TeCl}_4 < \text{PhTeCl}_3 < \text{Ph}_2\text{TeCl}_2$.

6. Detelluration

Elimination of tellurium (detelluration) is also characteristic of σ -telluranes RTeX_3 . Some of these reactions are of particular preparative interest. Detelluration is performed by pyrolysis, photolysis or under the action of Raney nickel, Pd(II) salts, oxidants or some nucleophilic reagents.

Heating of 2-chloroethyl-⁹⁷ or 2-chloropropyltellurium trichlorides⁹⁶ afforded Te, HCl, saturated (isopropyl chloride) and unsaturated (vinyl chloride and allyl chloride) halogen-containing derivatives and 1,2-dichloroalkanes. Pyrolysis of 2-chlorocyclohexyltellurium trichloride gave rise to cyclohexyl chloride, hexene and benzene along with Te and HCl.⁹⁶

Photolysis of organytellurium trihalides proceeds in a different way.^{101,205} Irradiation of solutions of these compounds in benzene afforded organic halogen-containing derivatives, the halogen atoms occupying positions to which the tellurium-containing group was initially bound (*ipso* substitution).

R = MeO, Me, H; X = Cl, Br, OAc.

Thus irradiation of a solution of 4-methoxyphenyltellurium trichloride in C_6H_6 using a high-pressure mercury lamp at 20–30 °C for 1 h afforded 4-chloroanisole in 70% yield and 2,4-dichloroanisole as a by-product (20%). Photolysis of 4-methoxyphenyltellurium tribromide gave rise to 4-bromoanisole in 30% yield. Irradiation of a solution of 4-methoxyphenyltellurium triacetate [prepared *in situ* from Ph_2Te_2 and $\text{Pb}(\text{OAc})_4$ in AcOH] afforded 4-acetoxyanisole in 14% yield. In some cases, coupling products of organic radicals of σ -telluranes with benzene were also obtained in trace amounts.^{101,205} The yields of aryl halides decrease as the donor properties of substituents in the aryl groups of σ -telluranes decrease.

The reactions of cycloalkyl- and vinyltellurium trichlorides proceed analogously.^{101,205} In the latter case, the reaction proceeds with retention of the geometric configuration of the initial alkene.

Aryltellurium trichlorides undergo detelluration upon heating with Raney nickel (Ni/Ra) in diglyme to form biaryls.⁷¹ Apparently, this reaction proceeds through initial reduction of tellurium trichlorides to form ditellurides followed by elimination of tellurium.¹⁰⁷ Detelluration of (β -acyloxy- γ -chloroalkyl)tellurium trichlorides of the type **39** under the action of Raney nickel gave rise to chlorohydrin esters in 26%–78% yields.¹⁰⁷

R ¹	R ²	R ³	R ⁴
H	H	H	H
Me	H	H	H
H	Me	H	H
H	H	Me	H
H	H	Me	Me

Biaryls were also formed upon treatment of aryltellurium trichlorides with PdCl_2 and NaOAc in AcOH⁴⁹ or with Li_2PdCl_4 in MeCN.²⁰⁶ The latter reagent is more efficient than the former. The formation of biaryls is favoured by the presence of donor substituents in the aryl groups.

Ar = 4- MeOC_6H_4 (54%), 4- BuOC_6H_4 (26%), 4- PhOC_6H_4 (29%),

The reactions performed under a CO atmosphere afforded biaryls in approximately the same yields, but the reaction rates were substantially higher.²⁰⁶ However, good yields of biaryls were achieved only after treatment of the reaction mixture with a solution of NaOH. In the latter case, carboxylic acids were obtained as by-products. The reactions were accelerated due to the formation of active intermediates **76**–**79** containing Pd–CO bonds.²⁰⁶

Treatment of a mixture of aryltellurium trichlorides, PdCl_2 and NaOAc in AcOH with a tenfold excess of styrene afforded *trans*-stilbenes in rather low yields (7%–38%) along with trace amounts of biaryls.⁴⁹ It should be noted that the yields of stilbenes in the reactions with aryltellurium trichlorides are lower than those obtained in the reactions with diaryltellurium dichlorides containing the same substituents.

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Detelluration of different types of organytellurium trihalides proceeds also under the action of halogens giving rise to the corresponding organyl halides (halodetelluration).^{96, 111, 207} Apparently, halodetelluration was observed for the first time in the treatment of 2-chloropropyltellurium trichloride with bromine.⁹⁶

Iododetelluration of (*Z*)-2-chlorovinyltellurium trichlorides proceeded with retention of the configuration of the initial alkenes giving rise to (*Z*)-chloroiodoalkenes in 40%–94% yields.¹¹¹

$\text{R}^1 = \text{Ph}, \text{R}^2 = \text{H, Me, Et, Ph}; \text{R}^1 = \text{CH}_2\text{OH}, \text{R}^2 = \text{H}$.

Bromodetelluration occurs only upon treatment of vinyltellurium trichlorides with *N*-bromosuccinimide in the presence of AlCl_3 .¹¹¹

Iododetelluration of aryltellurium trichlorides containing donor substituents under the action of iodine proceeded efficiently only in the presence of potassium fluoride, cesium fluoride, ammonium fluoride, mercury(II) chloride or SbCl_5 to form aryl iodides in yields higher than 80%.²⁰⁷ However, the reactions of phenyl- and 4-bromophenyltellurium trichlorides with iodine under identical conditions gave rise to aryl iodides in very low yields. This fact is indicative of the electrophilic character of the reaction.²⁰⁷ Apparently, the catalytic action of fluoride ions is associated with the formation of the intermediates $[\text{ArTeCl}_3\text{F}_2]^-$ due to which the electron density at the tellurium atom and at the C–Te bond increases, which favours the electrophilic attack of the halogen. The function of metal chlorides is to activate iodine by complexation or *in situ* formation of more reactive iodine monochloride.²⁰⁷

$\text{R} = \text{Me, OMe}$.

Bromodetelluration of aryltellurium trichlorides with bromine in MeCN , 1,4-dioxane or CCl_4 gave rise to 2,4-dibromoarenes in rather high yields, while 4-bromoarenes were obtained in trace amounts.²⁰⁷ The selective formation of dibromides was attributed to bromination of the initial 4-bromoarenes catalysed by organic derivatives of tellurium(IV).²⁰⁷

$\text{R} = \text{H, Me, OMe}$.

Chlorodetelluration of aryltellurium trichlorides under the action of different chlorinating agents (Cl_2 , SbCl_5 or Bu^tOCl) proceeded with very low yields even in the case of highly reactive 4-methoxyphenyltellurium trichloride.²⁰⁷ Cyanodetelluration of 4-methoxyphenyltellurium trichloride with CuCN in DMF also occurred in very low yield (5%).²⁰⁷

Halodetelluration of organytellurium trichlorides proceeded rather readily under the action of *tert*-butyl hydroperoxide.^{101, 208} Different types of organytellurium trihalides, *viz.*, with 2-chloro-alkyl-, 2-chlorocyclohexyl-, alkenyl- and aryltellurium trihalides, enter into this reaction. In most of reactions with alkenyl derivatives, the initial configuration is retained.¹⁰¹ The yields of alkenyl halides are lower than those of alkyl and aryl halides. It was thus assumed¹⁰¹ that the reactivities of organytellurium trihalides in oxidative detelluration change in the order: alkyl > aryl > alkenyl.

$\text{R}^1 = \text{C}_8\text{H}_{17}, \text{PhCH}_2; \text{R}^2 = \text{H}; \text{R}^1 - \text{R}^2 = (\text{CH}_2)_4; \text{X} = \text{Cl, I}$.

$\text{R} = \text{H, Ph}$.

$\text{Ar} = 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, \text{1-naphthyl}, \text{2-naphthyl}; \text{X} = \text{Cl, Br}$.

The possible reaction mechanism involving the formation of unstable organic derivatives of tellurium(VI) **80** is shown in the scheme.¹⁰¹

The reactions of aryltellurium trichlorides with $\text{Ni}(\text{CO})_4$ in DMF resulted in detelluration. Subsequent treatment of the reaction mixtures with water afforded carboxylic acids in 35%–51% yields.²⁰⁹ Symmetrical ketones and diaryl tellurides were obtained as by-products (sometimes in yields of up to 15%). The reaction of 4-methoxyphenyltellurium trichloride with $\text{Fe}_2(\text{CO})_9$ yielded bis(4-methoxyphenyl) telluride as the only product.²⁰⁹

$\text{Ar} = 4\text{-MeOC}_6\text{H}_4, \text{1-naphthyl}, \text{2-naphthyl}$.

It is believed²⁰⁹ that carbonylation of aryltellurium trichlorides proceeded according to a scheme involving intermediate aryltelluriocarbonylnickel dichloride **81**.

In some cases, the direction of detelluration of organyltellurium trichlorides under the action of nucleophiles is governed by the presence of intramolecular $O \rightarrow TeCl_3$ coordinate bonds. Thus detelluration of β -trichlorotellurio ketones **25** and **26** proceeded smoothly under the action of basic agents, such as DMSO or amines.⁸⁵

In the reactions with NH_4OH , σ -telluranes **82a,b** containing intramolecular $O \rightarrow Te$ coordinate bonds underwent detelluration with elimination of metallic tellurium to form a mixture of ketones **83a,b** (the yields were 56%–63%) and tellurenyl halides **84a,b** (the yields were 13%–36%).¹⁶⁹

$R^1 = R^2 = Ph$ (a); $R^1 = Ph, R^2 = Me$ (b).

The reactions of the organyltellurium trichlorides **82a,b** with Et_3N in a 1:1 CH_2Cl_2 – $MeOH$ mixture afforded enol methyl ethers **85a,b** (a mixture of stereoisomers, the yields were 56%–80%). The ketones **83a,b** and the tellurenyl halides **84a,b** (in trace amounts) were isolated as by-products.¹⁶⁹

Detelluration of the ketones **82** proceeded under the action of other nucleophiles as well. Thus the reactions of the compounds **82a,c** with sodium benzenethiolate afforded exclusively *Z*-isomers of vinyl ketones **86a,c** in 74%–82% yields, whereas the reaction of the ketone **82a** with hydrazine gave rise to 3,5-diphenylpyrazole and the tellurenyl halide **84a** in 44% and 22% yields, respectively.¹⁶⁹

$R^1 = R^2 = Ph$ (a); $R^1 = 3-FC_6H_4, R^2 = Ph$ (c).

IV. Structures of σ -telluranes $RTeX_3$ in the crystalline state and in solution. Electronic effects of TeX_3 groups

1. Crystal structures of σ -telluranes $RTeX_3$

According to the polarity rule²¹⁰ extended to σ -telluranes,^{211,212} the axial positions in trigonal bipyramids in molecules of these compounds should be occupied by the most electronegative substituents. However, the real structures of a large number of σ -telluranes $RTeX_3$, being determined by the nature of both the electronegative substituents at the tellurium atom and the organic ligands, rarely correspond to trigonal bipyramids predicted theoretically. Three major groups of σ -telluranes $RTeX_3$, which differ in the degree of association in the crystalline state and in the coordinate bonding to the tellurium atom, can be distinguished. Organyltellurium trihalides $RTeHal_3$ whose organic ligands do not contain substituents capable of forming intramolecular coordinate bonds with tellurium atoms belong to the first group. The second group consists of organyltellurium trihalides containing an intramolecular $O(N) \rightarrow Te$ coordinate bond. The third group comprises σ -telluranes $RTeX_3$ containing bidentate (primarily, dithiocarbamate) ligands.

The data on the bond lengths, bond angles and types of associates in organyltellurium trihalides $RTeX_3$ whose organic ligands do not contain substituents capable of forming intramolecular coordinate bonds with tellurium atoms are given in Table 1.

Taking into account secondary interactions, the tellurium trihalides listed in Table 1 contain a pentacoordinate tellurium atom. The major structural unit in these compounds ($CTeX_4$) is characterised by a square-pyramidal configuration of the bonds about the tellurium atom, the organic radical being located in the apical position. The tellurium atom lies virtually in the base of the square pyramid formed by four halogen atoms (the deviation from the plane is insignificant). Two halogen atoms form shorter (terminal) bonds, whereas the two remaining halogen atoms are involved in longer (bridging) bonds through which the tellurium atoms are linked in polymeric or dimeric structures. The dimers are linked to each other through weak secondary bonds, which are substantially longer than the $Te-X_{bridge}$ bonds. σ -Telluranes containing two $TeHal_3$ groups bound to one carbon atom [for example, methylenebis(tellurium trichloride)²¹⁷] or to the vicinal carbon atoms [for example, 1,2-bis(tribromotellurio)cyclohexane²¹⁹] have monomeric structures. The bonds about each tellurium atom in these compounds adopt the square-pyramidal configuration, except that both bridging $Te-X$ bonds are intramolecular.

2-Biphenyltellurium trihalides containing the bulky 2-biphenyl radical also have monomeric structures with a trigonal-bipyramidal arrangement of the ligands about the tellurium atom.^{126,132,220} The axial positions are occupied by the halogen atoms. The angle between the axial bonds in 2-biphenyltellurium tribromide is 178.5°. The corresponding angles in the α and β modifications of the triiodide are 176.5° and 176.0°, respectively. The axial $Te-X$ bonds are substantially longer than the equatorial bonds in accordance with the polarity rule.²¹⁰ Short intramolecular $Te \cdots C$ contacts are observed in 2-biphenyltellurium trihalides [2.945 Å in the tribromide and 3.32 and 3.18 Å in the α and β modifications of the triiodide, respectively; the sum of the van der Waals radii of the tellurium and carbon atoms is 3.90 Å (see Ref. 221)]. Due to these contacts, 2-biphenyltellurium trihalides are readily converted into 5,5-dihalogenodibenzotellurophenes upon heating.⁸ Two modifications of 2-biphenyltellurium triiodide are structurally similar and differ only in intermolecular contacts involving the heavy atoms. In the β modification, the $I \cdots I$ contacts (3.337 Å) occur along with the secondary $Te \cdots I$ contacts,²²⁰ whereas two $I \cdots I$ contacts (3.239 and 3.772 Å) are observed in the α modification.¹³² The difference in the character of these intermolecular interactions is reflected in the colour of the compounds, viz., the crystals of the α and β

Table 1. Average bond lengths (Å) and bond angles (deg) in σ -telluranes $R\text{TeX}_3$.

Compound	Bond length				Bond angle		Type of the associate	Ref.

^a Phenyltellurium trihalide PhTeCl_{1.7}Br_{1.3} prepared by the reaction of equimolar amounts of TeCl₄ and Ph₂BBr also has a polymeric structure;²¹⁵ ^b the Te–X_{eq} bond length; ^c the average Te–X_{ax} bond length; ^d the lengths of the I···I secondary bonds are 3.239 and 3.772 Å; ^e the lengths of the Te···I and I···I secondary bond are 3.703 and 3.337 Å, respectively.

modifications of 2-biphenyltellurium triiodide are black and red, respectively.

The degree of association and, what is more important, the molecular geometry of organytellurium trihalides are changed substantially if the molecules contain substituents with donor

atoms (oxygen, nitrogen or sulfur) capable of being involved in intramolecular coordination with the tellurium atom. The results of X-ray diffraction studies of these compounds are given in Table 2.

Table 2. Average bond lengths (Å) and bond angles (deg) in σ -telluranes $R\text{TeX}_3$ containing intramolecular coordinate bonds.

^a Y = O, S or N; ^b the N → Te coordinate bond length; ^c the O → Te coordinate bond length; ^d the N–Te bond lengths are given; ^e in the complex with CH₂Cl₂.

8-Ethoxycyclooct-4-enyltellurium trichloride (**87**), like other organyltellurium trichlorides, adopts a square-pyramidal configuration. The carbon atom occupies the vertex of the pyramid. The base of the pyramid is formed by three chlorine atoms (the Cl—Te bond lengths have standard values; 2.335–2.505 Å) and the oxygen atom (in other σ -telluranes RTeCl_3 , four chlorine atoms lie in the base of the pyramid, two of these atoms being bridging). The Te $\cdots$ O distance (2.419 Å) is substantially smaller than the sum of the van der Waals radii of the tellurium and oxygen atoms (3.60 Å). In the crystals, there are also very weak secondary Te $\cdots$ Cl bonds (3.558 Å) through which the molecules are linked in dimers. Apparently, 2-ethoxycycloheptyltellurium tribromide (**88**),²²² 2-chloro-3-(allylthio)propyltellurium trichloride (**89**)¹⁰⁶ and 2-(phenylthio)phenyltellurium trichloride (**90**)²²³ have analogous structures.

In organyltellurium trihalides **91–96**, the bonds at the tellurium atoms adopt an octahedral configuration. Two halogen atoms are located in the apical positions. The equatorial positions are occupied by the third halogen atom, the bidentate organic ligand and the lone electron pair of the tellurium atom. Some compounds of this type have monomeric structures. In crystals of other compounds, the molecules are linked in dimers through intermolecular Te $\cdots$ X bonds. However, the lengths of these bonds (3.498 Å in the trichloride **91** and 3.596–3.896 Å in the tribromides **92**, **93** and **96**) are substantially larger than the lengths of the bridging Te—X bonds (see Table 1) and are close to the sums of the van der Waals radii of the corresponding elements. The N $\rightarrow$ TeX₃ coordinate bond lengths are in the range of 2.24–2.42 Å. The hybridisation state of the nitrogen atom affects only slightly the coordinate bond lengths.

The organic ligand in (6-acetyl-2-pyridyl)carbonylmethyltellurium trichloride (**97**) is polydentate, which results in a new structural type.⁸³ The coordination polyhedron about the tellurium atom can be described as a distorted pentagonal bipyramid with two axial Te—Cl bonds (2.492 and 2.500 Å). The equatorial positions are occupied by the Cl atom (Te—Cl_{eq} is 2.431 Å), three atoms of the tridentate organic radical, *viz.*, the carbon (Te—C is 2.129 Å), nitrogen (Te $\cdots$ N is 2.402 Å) and oxygen atoms (Te $\cdots$ O is 2.878 Å), and the lone electron pair of the tellurium atom. The two last-mentioned bond lengths, though larger than the sums of the covalent radii of the corresponding elements (the sum of the Te and N radii is 2.07 Å and the sum of the Te and O radii is 2.03 Å), are substantially smaller than the sums of the van der Waals radii of these elements (the sum of the Te and N 3.70 Å and the sum of the Te and O radii is 3.60 Å²²¹). The presence of the Te $\rightarrow$ N and Te $\rightarrow$ O coordinate bonds was also confirmed by IR spectroscopy.

Selected data for organyltellurium trichlorides containing N $\rightarrow$ TeCl₃ bonds (compounds **98** and **99**) are also given in

Table 2. The N $\rightarrow$ Te bond lengths in these compounds have close values (the differences are only 0.1–0.12 Å). The four-membered PN₂Te ring in the compound **99** is virtually planar. The nitrogen atoms deviate from the plane of the ring by ~ 0.05 Å.²²⁵

σ -Telluranes containing *N,N*-diorganylthiocarbamate ligands (**100a–g**) have analogous structures. Selected structural data for these compounds are listed in Table 3.

Compounds **100a–g** have pentagonal-bipyramidal structures. The equatorial positions of the bipyramid are occupied by five sulfur atoms (compounds **100a,b**) or four sulfur atoms and one halogen atom (compounds **100c–g**). In the tris(dithiocarbamate) derivative **100a**, the axial positions are occupied by the organic group and the sulfur atom of a dithiocarbamate ligand.^{226, 227} In the bis(dithiocarbamate)(dithiophosphate) derivative **100b**, the position of the second axial ligand is occupied by a sulfur atom of the S₂P(OEt)₂ group.¹⁴⁸ In the other compounds, the lone electron pair of the tellurium atom¹⁴⁸ or an atom of the adjacent molecule^{149–151} serves as the second axial ligand. The compounds **100a,b,d** exist as monomers, whereas molecules **100c,e–g**^{149–151} are linked as dimers through weak intermolecular Te $\cdots$ S or Te $\cdots$ Hal bonds.

The reason for the presence of secondary bonds of different nature in the compounds **100c,g** containing virtually identical substituents at the tellurium atom (one bromine atom in the compound **100c** or bromine and iodine atoms in a ratio of 41 : 59 in the compound **100g**) remains unclear. Thus the coordination polyhedron about the tellurium atom in the compound **100c** is completed by the weakly π -coordinated dithiocarbamate ligand of the adjacent molecule,¹⁵⁰ whereas the coordination polyhedron in the compound **100g** is completed by the bromine (iodine) atom.¹⁵¹

The structure of (4-methoxyphenyl)tellurium [(dimethoxythiophosphorylthio)] dibromide, (4-MeOC₆H₄)Te[S₂P(OMe)₂]₂.Br₂, differs from that of bis-(and tris)(dithiocarbamate) derivatives **100a–g** due to the presence of one bidentate ligand in the former compound. The molecule of this compound has a distorted square-pyramidal structure with the bromine atoms (Te—Br bond lengths are 2.616 and 2.677 Å) in *cis* positions relative to each other.¹⁵³ The sulfur atoms of the thiophosphorylthio ligand (the Te—S bond lengths are 2.632 and 2.728 Å) lie in the base of the pyramid. The aryl group (the Te—Br bond length is 2.127 Å) occupies the apical position. In the crystal, weak secondary Te $\cdots$ Br bonds (3.810 Å) are also present.

The structures of σ -telluranes RTeX_3 were also studied by NQR²²⁸ and Mössbauer spectroscopy.^{146, 229–232} The isomer chemical shifts for aryltellurium trichlorides, tribromides and triiodides in the region of 0.9–1.0 mm s^{−1} are substantially larger than those for the corresponding diaryltellurium dihalides and are

Table 3. Average bond lengths (Å) and bond angles (deg) in σ -telluranes containing *N,N*-diorganylthiocarbamate ligands $\text{R}^1\text{Te}(\text{S}_2\text{CNR}^2)_2\text{X}$ (**100a–g**).

^a X is the ligand occupying the second axial position; ^b the range of the five Te—S bonds in the equatorial plane is given; ^c the range of the four Te—S bonds in the equatorial plane is given; ^d solvated with 0.5 equiv. of CH₂Cl₂; ^e the average Te—I bond length for two crystallographically independent molecules is given; ^f the compound was prepared by the reaction of bis(*N,N*-diethylthiocarbamate)(iodo)(4-methoxyphenyl)tellurium(IV) with bromine; ^g the Te—I bond length; ^h the Te—Br bond length.

similar to those for tellurium tetrahalides.²²⁹ The quadrupole splitting (5.9–9.3 mm s⁻¹) decreases in the order: chlorides > bromides > iodides.

2. Structures of organytellurium trihalides in solutions. ¹²⁵Te NMR spectra and dipole moments

The conductivities of solutions of organytellurium trichlorides RTeCl₃ in MeCN, PhNO₂ and Me₂CO^{73, 74, 194, 233} indicate that these compounds do not dissociate into ions. However, organytellurium tribromides and triiodides in these solvents dissociate into ions (RTeX₂⁺ and X⁻),^{73, 74} although Chen and George²³⁴ stated that MeTeBr₃ in nitrobenzene is not an electrolyte. On the contrary, aryltellurium trihalides containing amino(dimethylamino) groups in the aryl fragments are 1:1 electrolytes in the above-mentioned solvents regardless of the nature of the halogen atom.^{61, 62} Apparently, this is due to the higher polarity of the Te–Hal bonds in the latter compounds owing to the presence of strong electron-donor groups.

The results of cryoscopic studies of organytellurium trihalides agree on the whole with the data on conductivity. In solutions, aryltellurium trichlorides [except for amino(dimethylamino) derivatives] exist as monomers and tend to form weak associates as the concentration is increased,^{74, 194, 233} whereas aryltellurium tribromides and triiodides partially dissociate.^{61, 62, 73, 74} In the case of methyltellurium trihalides, the monomer–dimer equilibrium exists in benzene,^{118, 234} the degree of association of methyltellurium tribromide being higher than that of the corresponding trichloride.

The above-considered data agree with the results of spectral studies of organytellurium trihalides. The ¹²⁵Te NMR spectral data for σ-telluranes RTeX₃ are given in Table 4.

The chemical shifts of alkyltellurium and aryltellurium trihalides are in the ranges of 647–1204 and 892–1234 ppm, respectively. In the spectra of organytellurium trichlorides with ligands containing carbonyl groups, the ¹²⁵Te resonance is substantially shifted downfield (1372–1632 ppm) compared to the spectra of alkyltellurium trichlorides. The highest deshielding of the ¹²⁵Te nuclei is observed in β-arylvinylltellurium trichlorides whose chemical shifts are in the range of 2047–2104 ppm. The shielding of the ¹²⁵Te nuclei in PhTe increases on going from phenyltellurium trichloride to phenyltellurium triiodide. It should be noted that the chemical shifts of organytellurium trihalides depend substantially on the nature of the solvent. Thus the chemical shifts for PhTeCl₃ and PhTeBr₃ increase by 312 and 301 ppm, respectively, on going from the PhH–PhMe system to the 2:1 CH₂Cl₂–DMSO system. Apparently, this is associated with the above-mentioned effect of the solvent on the degree of aggregation of organytellurium trihalides in solution.

The dipole moments of aryltellurium trihalides are given in Table 5. The dipole moments of aryltellurium tribromides are smaller than those of the corresponding trichlorides regardless of the substituents in the benzene ring,²¹¹ which is indicative of a weaker electron-withdrawing effect of the TeBr₃ group compared to that of the TeCl₃ group.

3. Electronic effects of the TeX_3 groups

The inductive and mesomeric constants of the TeX_3 groups were determined based on the chemical shifts in the ^{19}F NMR spectra of *m*- and *p*-fluorophenyltellurium trihalides.¹¹⁴

Substituent	$\delta_{\text{meta}}^{\text{F}}/\text{ppm}$	$\delta_{\text{para}}^{\text{F}}/\text{ppm}$	σ_{I}	σ_{C}	σ_{P}
TeCl_3	−3.28	−6.62	0.55	0.11	0.66
TeBr_3	−3.05	−6.43	0.51	0.11	0.62

The σ_{I} and σ_{C} values indicate that interactions between the TeX_3 groups and the π -electron system of the benzene ring are predominantly inductive in character because the σ_{C} constants comprise ~15% of the total electronic effect of the substituent. The σ_{P} constants of the TeX_3 groups, unlike those of the $\text{Te}(\text{R})\text{X}_2$ groups ($\text{X} = \text{F}, \text{Cl}, \text{Br}$ or I), decrease on going from chlorine to bromine.

The orbital populations were calculated and the nature of the highest bonding and lowest unoccupied orbitals of PhTeCl_3 was examined using the extended Hückel method.²¹¹ According to the results of calculations, the π -electron system of the benzene ring is only slightly affected by the substituent and retains six electrons. A large positive charge on the tellurium atom exists due to the fact that its *p* orbitals and the combination of the *p_x* and *p_z* orbitals of the axial chlorine atoms with the appropriate symmetry are combined into the molecular orbital $\text{MO}_{\pi}(\text{E}_{1\text{a}})$.

Calculations demonstrated that the three highest occupied MOs are σ orbitals. The upper orbital is localised primarily at the tellurium atom, whereas the unoccupied orbital, which involves the d_{π} orbital of the tellurium atom, (MO_{34}) is far removed from the highest occupied π -MOs. These quantum-chemical data account for the absence of a noticeable effect of conjugation between the TeCl_3 group and the aryl groups.

V. Conclusion

The data surveyed in the present review suggest that σ -telluranes RTeX_3 are of preparative importance in the chemistry of organotellurium compounds. σ -Telluranes are used as the starting compounds in the synthesis of other classes of organic derivatives of tellurium, *viz.*, of diorganyl ditellurides R_2Te_2 , tellurinic acids $\text{RTe}(\text{O})\text{OH}$, tellurium oxochlorides $\text{RTe}(\text{O})\text{Cl}$, σ -telluranes of the R_2TeX_2 type and pentacoordinate tellurium derivatives $\text{M}^+[\text{RTeX}_4]^-$ (M is the onium group). Intramolecular electrophilic cyclisation of the corresponding organytellurium trichlorides is used for the preparation of different five- and six-membered tellurium-containing heterocycles (benzotelluophenes, dibenzotelluophenes and telluroxanthenes) and six-membered heterocycles involving other heteroatoms along with the tellurium atom (phenoxatellurines, phenothiatellurines and phenotellurazines). These reactions are specific to the synthesis of tellurium-containing heterocycles and have virtually no analogues in the chemistry of the corresponding sulfur and selenium derivatives. Halodetel-

luration of organytellurium trihalides, which in some cases proceeds with rather high yields, can be used for the preparation of biaryls, different types of mono- and dihalogeno derivatives, stilbenes, carboxylic acids and unsaturated ketones.

The development of new procedures for the synthesis of organytellurium trihalides, the synthesis of new tellurium-containing heterocycles starting from these compounds and examination of the possibilities of the use of these compounds in preparative organic chemistry are of obvious interest both in organotellurium chemistry and in organic chemistry as a whole.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 99-03-33132a).

VI. Conclusion	897

Abstract. The structures and properties of monolayers and Langmuir–Blodgett films of conducting oligo- and polythiophenes are analysed. The published data on the influence of the number, size, and composition of substituents in polythiophene molecules and of the pattern of their distribution along the chain on the monolayer stability and Langmuir–Blodgett film quality are generalised. Considerable attention is given to the description of the behaviour of mixed monolayers and Langmuir–Blodgett films composed of polythiophenes and various amphiphilic compounds. The effective conjugation lengths of polymer chains and conductivities of polythiophenes in Langmuir–Blodgett films and cast films are compared. Examples of the use of Langmuir–Blodgett films for scientific and technological purposes are given. The bibliography includes 100 references.

I. Introduction

The Langmuir–Blodgett method is a versatile technique for assembling multilayer planar ensembles. The scope of problems that can be solved with the use of this method has expanded considerably over recent years. Polymer monolayers and Langmuir–Blodgett (LB) films play an important role in fundamental and applied molecular architecture studies. In the author's review,¹ the two-dimensional polymerisation of, mostly, traditional monomers and their analogues with hydrocarbon substituents incorporated in order to increase their amphiphilic properties was discussed. In the majority of cases, polymerisation in monolayers and LB films has been carried out by photo-irradiation of unsaturated compounds such as acrylate and methacrylate lipids, alkyl fumarates and maleates, unsaturated fatty acids, *etc.* Within the latter group of systems, diacetylenes and polydiacetylenic amphiphilic compounds belonging to conducting polymers were considered.

In another paper,² the structure and properties of polymer monolayers and LB films have been analysed. This paper dealt with the characteristic features of the packing of macromolecule

on the surfaces of liquids and solids, the compatibility of high- and low-molecular compounds in monolayers, the influence of the degree of polymerisation, size and orientation of side groups on the phase states of monolayers, the correspondence between the architectures of Langmuir and LB monolayers, and many other issues. However, this paper did not touch upon the so-called special polymers which include conducting macromolecules with conjugated bonds, polymers synthesised for nonlinear optics, and highly stable multifunctional network polymers. The abundance of recent data on the properties of monolayers and LB films of only conducting polymers does not allow a detailed analysis of these systems to be made in the framework of one publication. Therefore, the author intends to present separate discussions on the most promising conducting polymers in the form of LB films that are studied most extensively.

Polythiophenes occupy a particular place among these polymers (polydiacetylenes, polyaniline, polypyrrole, polyphenylenes, *etc.*), primarily because they are soluble in ordinary solvents, form rather stable monolayers on the surface of water in air and have relatively high stability and conductivity in a doped state.

Extensive studies of polymers with internal conductivity started back in the 1970s when polydiacetylene was synthesised.^{3,4} Conducting organic polymers have a quasi one-dimensional structure which, to some extent, is similar to that of charge-transfer complexes (CTC). In the conducting state, both types of materials exist as charged molecules. The conductivity of CTC is much higher along the axial direction of stacked molecules due to overlapping of the π -orbitals of the adjacent complexes. In the case of conducting polymers, charge transfer occurs along the chain due to overlapping of the π -orbitals of the adjacent monomeric units. Due to the chain-like structures of the conducting polymers, strong interactions of the electronic states with the excited conformation states (solitons, polarons, bipolarons) exist, which is typical of one-dimensional systems. The relatively weak interchain interactions provide the diffusion of dopant molecules to the polymeric chain. A decrease in the intensity of interchain interactions in polythiophenes containing substituents at positions 3 and 4 favours the solubility of the polymers in ordinary solvents. This is the most important feature of polythiophenes when deciding whether the Langmuir–Blodgett technique should be used for their organisation. For example, it was noted⁴ that the conductivity of non-substituted polythiophenes ranges from 50 to 100 S cm⁻¹, while it is as high as 500 S cm⁻¹ in the case of poly(3-methylthiophene) and is close to 1000 S cm⁻¹ for some substituted polythiophenes.

Polythiophenes are synthesised by chemical or electrochemical methods. The former method gives non-conducting polymers which can be transformed to the conducting state by chemical or electrochemical doping. In the latter case, doped (oxidised) polymers formed can be reduced chemically (de-doped) to the insulating state. The doping efficiency is determined from the position and intensity of the characteristic $\pi-\pi^*$ transition absorption band and from the change in the polymer colour. In addition, optical absorption spectra enable determination of the effective conjugation length of the polymeric chains. The longer the conjugation length the higher the polymer conductivity. The conjugation length can be increased by chemical synthesis of polythiophenes with a regular structure. As a result, the electric conductivity can be increased by a factor of 100 (Ref. 3).

The features of polythiophenes noted above are used for obtaining monolayers and LB films that are promising as metal and gas sensors, photoelectric and electrochromic devices, optical switches, solar batteries, *etc.*

The Langmuir–Blodgett method is used for the formation of planar ensembles of conjugated polymers in order to obtain ordered, similarly organised molecular chains, *i.e.*, to reach the longest possible conjugation length so as to increase the intramolecular conductivity and provide the transfer of charge carriers between the adjacent molecules. However, the potential of this method can only be realised if true monolayer films with concerted molecular orientation are formed on the surface of a liquid and if these monolayers can be transferred onto solid supports with the formation of multilayered ensembles. The success of these operations is usually judged from the structural or optical spectroscopy studies. The latter method makes it possible to estimate the zone structure features and evaluate the conjugation length of the system formed. Measurement of the conductivity of the LB films obtained is the final step. Depending on the ultimate goal of the studies, other properties of the systems, such as nonlinear optical, photo- and electrophysical properties, can also be determined. The majority of studies on the subject of this review have been carried out according to this scheme, hence it is reasonable to follow it when discussing their results.

It might seem that one glance at the polythiophene chain (**1**)[†] would suffice to make sure that these polymers cannot form stable monolayers on the surface of water and, even more so, on solid supports.

However, as shown below, not all researchers agree with this viewpoint.

The problem of increasing the stability of monolayers of compound **1** can be solved at least by two methods: *viz.*, by incorporation of groups that can enhance the surface activity of the molecule and by creation of mixed monolayers with amphiphilic compounds that form stable monolayers. The merits and drawbacks of these two methods for obtaining stable monolayers from molecules that are not 'strictly amphiphilic' are considered elsewhere.² It should be emphasised here that for polymers with distinct functions which depend, first, on the presence of certain reactive groups or conjugated bonds, and second, on realisation of a given conformation or structure of side chains determining the operating capabilities of molecules and their ensembles, incorporation of a second component is undesirable because it decreases the density of the key elements (functional groups, molecules, domains) in the layer and, as a consequence, decreases the efficiency of devices based on these elements. Therefore, the efforts of researchers are primarily aimed at synthesising such derivatives of polythiophenes whose spreading does not require

dilution with other components, *i.e.* at designing mixed monolayers with the matrix components possessing high surface activities. Let us note the main directions of these studies.

1. Grafting of a polar group to an end of the oligothiophene chain which in this case plays the role of the hydrophobic component of the amphiphilic molecule.

2. Incorporation of a side alkyl chain in each thiophene unit. This method works successfully in the case of linear polymers.²

3. Incorporation of one or two hydroxyalkyl groups, which increase the polarity of the thiophene components, in each thiophene unit.

4. Copolymerisation (including block copolymerisation) of thiophene with other monomers that ensure distribution of the thiophene fragments over the subphase surface. In this case it is important that the second component also had conjugated bonds.

5. Synthesis of regioregular poly(3-R-thiophenes), where R is an alkyl, alkoxy or some other group.

However, these methods do not guarantee the desired result; therefore, mixed systems are studied, in which the functional capabilities of the key elements are preserved, provided that the component ratio remains at the optimum level.

II. Oligothiophene monolayers and Langmuir–Blodgett films

The effect of a polar group on the compression isotherms of a monolayer is shown in Fig. 1 for three-membered oligothiophenes **2–7** on the surface of water at 10 °C. One can see that compounds **2** and **3** do not form stable monolayers.² The esters **4–6** form condensed monolayers, in which the limiting area per molecule (A_0) is 27–29 Å². It is believed that this area corresponds to the vertical arrangement of terthiophene units that are directed towards the air phase, since they are more hydrophobic than the polar components of the oligomer molecules. Taking the parameters of the characteristic points in the compression isotherms of compounds **4–6** into account, Nakahara *et al.*⁵ concluded that the monolayers of these oligomers are stable up to surface pressures (π) of 20 (**4** and **5**) and 30 mN m⁻¹ (**6**).

2–7

X = CHO (**2**), CH₂OH (**3**), CH₂OCOMe (**4**), CH₂OCOCH=CMc₂ (**5**), CH₂OCO(CH₂)₇Me (**6**), CH₂OCO(CH₂)₁₆Me (**7**).

For the long-chain derivative **7**, the surface pressure for destruction is as small as several units, while the value of area per molecule extrapolated to zero surface pressure is no higher than 23 Å². In this case, a condensed monolayer is formed in

Figure 1. Compression isotherms of terthiophene derivatives at 10 °C:⁵ (**1**) **2**, (**2**) **3**, (**3**) **4**, (**4**) **5**, (**5**) **6**, (**6**) **7**.

[†] Henceforth, poly(2,5-diylthiophene) is considered in this review.

which dense packing of hydrocarbon chains probably exists, whereas the less hydrophobic terthiophene group can be immersed in the aqueous phase. The U-shaped configuration of molecules in the monolayer can be ruled out because the areas of the molecules are very small. Presumably, the capability of these compounds to give stable monolayers is overestimated: the isotherms of compound **4** are shifted to smaller areas with increase in temperature. Moreover, the possibility of ‘immersion into water’ of the thiophene groups is determined by interactions of their hydrocarbon substituents with water molecules rather than by the lengths of these substituents. Unfortunately, the data on the changes in the surface pressure following stopping of the mobile barrier of surface balances were not reported.

Monolayers of oligothiophenes with a larger number of units could be obtained only by mixing them with eicosanoic (arachidic) acid.⁵

Monolayers and LB films were obtained from the six-membered oligothiophene **1** ($n = 4$, S_6) using a strategy for the formation of one-dimensional conducting systems.⁶ The monolayers were transferred onto a solid support with the surface pressure of 15 mN m^{-1} and surface area per molecule (A) of $25 \text{ \AA}^2$. The chain orientation found from the dichroic ratio was vertical relative to the support (Fig. 2). The eighteen-layered LB films were thermally polymerised (270°C , 2.5 h). Comparison of the electronic spectra of LB films of the original oligomer S_6 and its thermal polymerisation product showed that the conjugation length in the latter was larger. It was also noted that the S_6 oligomer is completely soluble in nitrobenzene and trichlorobenzene, while the polymer synthesised in LB films is insoluble in these solvents.

Figure 2. Organisation of six-membered thiophenes **1** (S_6) in LB films before and after thermal polymerisation.⁶

The solubility of oligothiophenes in various solvents and the possibility of coordination of their sulfur atoms with metals⁷ are the properties that attract the most attention in relation to the studies in the field of self-assembled monolayers,^{8–10} *i.e.*, systems very similar to LB films. A study of this kind was carried out for systems containing (oligo)thiophene unit(s) with 2-chlorotetramethyldisilanyl and phenylethynyl (compound **8**) or oct-1-ynyl substituents.^{11, 12}

$n = 1, 2, 4$

The adsorption of the oligothiophene **8** from its solution in toluene was carried out onto a SiO_2 surface ($3000 \text{ \AA}$)/Si. The authors succeeded in obtaining self-assembled monolayers the density of which depended on the number of thiophene rings in the molecule and increased with the increase in the length of the oligomeric chain. Obviously, lateral conductivity requires a high density of the surface layer and at least six or seven thiophene units in the oligomer molecule are required for obtaining high transverse conductivity.^{13–17}

III. Polythiophene monolayers and Langmuir–Blodgett films

One attempt at obtaining monolayers and LB films from individual polythiophene derivatives has been undertaken by Logsdon *et al.*¹⁸ Poly(3-dodecylthiophene) was synthesised by electrochemical and chemical polymerisation. Electrochemical polymerisation of 3-dodecylthiophene was carried out under galvanostatic conditions at an anodic current density of 2 mA cm^{-2} at 5°C in an argon atmosphere using nitrobenzene as the solvent.¹⁹ The average molecular mass of the chloroform-soluble fraction of the polymer **9** is 10^5 Da . The chemical synthesis included three steps, *viz.*, synthesis of 3-dodecylthiophene,²⁰ its conversion to diiodo-3-dodecylthiophene²¹ and polymerisation.²² The molecular mass of the final product (**10**) determined by gel-permeation chromatography was $2.3 \times 10^3 \text{ Da}$.

The limiting areas per monomeric unit were 14.4 and $11.2 \text{ \AA}^2$, respectively, for monolayers of poly(3-dodecylthiophenes) synthesised chemically and electrochemically. The authors believe that, since the first value correlates with that of $14.7 \text{ \AA}^2$ calculated using the structural model for thiophene rings arranged at a right angle to the substrate surface, this particular orientation exists in the polythiophene monolayers synthesised chemically. If this is the case, the role of the hydrocarbon chain, the cross-section of which is $\sim 18.5 \text{ \AA}^2$, remains unclear. We shall return to this problem in the analysis of the structure of monolayers of other thiophene derivatives. It should be noted here that both specimens of poly(3-dodecylthiophene) spread poorly and do not form stable true monolayers on the surface of water.² The limiting area of the polythiophene monolayer synthesised chemically was larger than that of the thiophene monolayer obtained electrochemically, but the former monolayers were less stable and could not be transferred onto solid supports. The Langmuir–Blodgett vertical method ‘did not work’ in the case of the electrochemically polymerised poly(3-dodecylthiophene), either. However, the horizontal method at a surface pressure of 12 mN m^{-1} made it possible to transfer the monolayers and to obtain X-type films several tens layers thick on a solid support hydrophobised with trichlorooctadecylsilane. Unfortunately, diffraction methods were not used for structural studies of the resulting films, therefore the structure quality of these films cannot be judged.

Obviously, the films considered above may be, with caution, classified as LB films with distinct molecular orientation in the layers and alternation of the layers. This should be taken into account when considering the results of analysis of poly(3-do-

Figure 3. Dependence of optical absorption (1) and change in resonance frequency (f) of a quartz crystal (2) on the number of monolayers (N) of polythiophene **9**.¹⁸

decylthiophene) LB films presented below. Figure 3 shows the dependences of the optical absorption and the change in the quartz resonator frequency on the number of layers of the chemically polymerised poly(3-dodecylthiophene). The small inflexion on the plot of absorption *versus* the number of layers at $N = 10$ can be explained either by incomplete transfer of thick films onto the support due to the non-uniformity of the morphology of the surface formed or by a decrease in the structural correlation due to disordering of the polymeric segments. The monolayer thickness in LB film calculated from optical absorption data was found to be 35 Å. This value is closer to the result of ellipsometric thickness measurement (30 Å) than to the monolayer thickness determined using the structural model (19–24 Å). The linear dependence of the quartz resonator frequency on N indicates that the mass of the monolayer transferred onto the solid support is constant (the mass of one layer per 1 cm² is 350 ng) and that changes in the slope of the optical absorption on N are due to the orientation effects rather than to changes in the mass of the monolayers transferred. The specific electric conductivity of the non-doped film does not depend on the number of layers for $N \leq 40$ and equals 9×10^{-10} S cm⁻¹. Doping with iodine increases the conductivity by 8 orders of magnitude, and its minimum value depends on the number of layers: the conductivity for $N = 1, 20$ and 40 equals 0.014, 0.20 and 0.51 S cm⁻¹, respectively. The curves of changes in $\sigma_{||}$ (lateral conductivity) and absorption at 760 nm during the doping in iodine vapour are presented in Fig. 4. During the first 460 s, $\sigma_{||}$ increases by 6 orders and then reaches saturation in 4300 s. Flushing the cell with argon, which removes iodine from the system, restores the initial value of conductivity. The cubic susceptibility [$\chi^{(3)}$] of the non-doped film is as high as 1×10^{-9} electrostatic units. After doping, $\chi^{(3)}$ becomes 10% less and acquires its original value upon removal of iodine from the system.²³

Figure 4. Dependences of the specific electric conductivity (1) and optical absorption (2) of a 40-layer LB film of polythiophene **9** on the time of exposure in iodine vapour and changes in these parameters after removal of iodine with a flow of argon.¹⁸

Figure 5. Compression isotherms of monolayers of polythiophene **12** (1) and its monomer **13** on the surface of water (2) and a 10^{-3} M CdCl₂ solution (2').²⁵

It should be emphasised that complex studies of poly(3-dodecylthiophene) LB films did not reveal any specific features of multilayer structures which would be untypical of this conjugated polymer in the bulk.

A decrease²⁴ or increase²⁵ in the length of the alkyl chain at position 3 of the thiophene ring in the polymer (from C₁₂ to C₈ or to C₁₇) virtually does not affect the ability of the polymer to form stable monolayers. The limiting area per unit for poly(3-octylthiophene) (**11**) monolayer does not exceed 10 Å², while that for poly(3-heptadecylthiophene) (**12**) does not exceed 12 Å² (Fig. 5). The small value of the limiting monolayer area obtained in the latter case is explained²⁵ by detachment of some fraction of molecules or their units from the surface of the aqueous subphase (incomplete spreading). According to ellipsometry, the layer thickness is 50% larger than that calculated for the monolayer, hence the small value of A_0 can also be due to the formation of a tilted bilayer structure.²⁵ Figure 5 also shows the compression isotherms for the 3-heptadecylthiophene monomer (**13**). One can see that transition to the monomer, which decreases the intrachain cohesion due to cleavage of the polymer covalent bonds, improves insignificantly the spreading of thiophene and results in a liquid monolayer with low decomposition pressure.

Thus, incorporation of an alkyl chain in the thiophene unit enhances insignificantly the spreading ability of the polymer due to weakening of the cohesion interactions between the thiophene rings. However, the hydrophilicity of the thiophene units remains rather low and does not ensure the formation of a stable monolayer on the surface of water. Incorporation of substituents at positions 3 and 4 of the thiophene ring, for example, of an alkoxy group to give poly(3-octyloxy-4-methylthiophene) (**14**), does not allow a true monolayer to be obtained on the surface of water.^{26, 27}

The idea of hydrophilisation of each thiophene ring in polythiophene was implemented by Callender *et al.*,²⁸ who have synthesised and studied the properties of monolayers of poly(3,4-dibutoxythiophene) (**15**). Polythiophene **15** was synthesised from 3,4-dibromothiophene and sodium butoxide in the presence of copper oxide and platinum iodide with subsequent chemical oxidation of the monomer with iron trichloride.

The compression isotherms of compound **15** at two temperatures are presented in Fig. 6. The monolayer destruction at 11 °C occurs above a surface pressure of 20 mN m⁻¹, which is believed to be due to folding of the monolayer and formation of a bilayer film. Destruction at higher temperatures is observed at lower π . The Langmuir–Blodgett films of polythiophene **15** were obtained at 11 °C and a surface pressure of 12 mN m⁻¹. Under these conditions, changes in π and A were negligibly small within 2 h and the limiting area per residue was 20 Å². It was found²⁹ that the surface of the thiophene chains, whose long axes are arranged at a right angle to the subphase surface and have a dihedral angle of 90°, is 28 Å². However, it was shown¹⁸ that a poly(thiophene) molecule, whose chains are parallel to the surface of water and the rings are oriented perpendicularly to this surface, requires a surface of 14.7 Å² per residue. In this case, the area per residue equal to 20 Å² found for polythiophene **15** should correspond to a polymer with an axis directed parallel to the surface of water and a dihedral angle between repeating units ranging from 0° to 90°. The resulting twisted conformation is formed due to steric interactions between the bulky alkoxy substituents at positions 3 and 4. The absorption spectrum of the 28-layer LB film of polythiophene **15** does not differ from the spectrum of this polymer in the solid state; the absorption intensity in the maximum (the band at 462 nm) increases linearly with an increase in the number of layers ($N \leq 30$). Optical spectroscopy was used to analyse the stability of polythiophene **15** LB films stored under various conditions:²⁸ in the dark, under daylight and under artificial light with a wavelength of > 500 nm. After ageing for 30 days, absorption at 462 nm did not change for the first sample, but it decreased by 35% and 24% for the second and third samples, respectively. The absorption maximum of polythiophene **15** LB films is shifted towards shorter wavelengths relative to the absorption maxima of solid poly(3-alkylthiophenes) (~ 500 nm)³⁰ and poly(3-butoxy-4-methylthiophene) (545 nm).²⁶ These data suggest that steric interactions between the two bulky side chains and the polymer chain favour the formation of such a polymer conformation where the thiophene units are turned relative to each other. This decreases the effective conjugation length. X-Ray diffraction data²⁸ indicate that the bulk polymer **15** is semicrystalline and has a helical conformation, which is apparently preserved in solution (chloroform). Since the polymer chain conformation and the LB film structure determine the electric²⁷ and nonlinear-optical properties to a considerable extent, structural studies of these systems have to be carried out.

Figure 6. Compression isotherms of monolayers of polythiophene **15** on the surface of water at 11 (1) and 26 °C (2).²⁸

After their failure to obtain stable monolayers and LB films of poly(3-alkylthiophenes), Bolognesi *et al.*³¹ synthesised polythiophenes **16–18** containing ether groups at position 3.

Figure 7 shows the compression isotherms of monolayers of polythiophenes **16–18**. One can see that the curves differ noticeably; the regions of area per residue exceeding 14.7 Å² (the minimum area occupied by the thiophene monomer) are the most interesting. The limiting areas per residue are 20, 15.5 and 15.3 Å² for the polymers **16–18**, respectively. Presumably, in all three cases the oxygen atoms in the monolayers are in contact with the aqueous support, whereas the differences in the areas are explained by different slopes of the hydrocarbon spacers in the side chains. The angle between the adjacent monomeric units should also be taken into account; the area per residue can vary from 28 to 14.7 Å² as a function of this angle. The pressures for monolayer collapse differ considerably as well: these are 20.0, 41.0 and 21.5 mN m⁻¹ for compounds **16**, **17** and **18**, respectively. The big difference between the collapse surface pressures (π_c) for polythiophenes **16** and **17**, whose side chains differ only in one CH₂ group, is unexpected. This fact was explained³¹ by the higher polarity of OMe-substituted polythiophene. However, this would imply that the more polar polymer **18** would form a more stable monolayer. In reality, the opposite phenomenon is observed (see Fig. 7). The viewpoint of Bolognesi *et al.*^{31,32} regarding the orientation of polythiophene **17** molecules in the monolayer is also unclear. They consider that the main chain is parallel to the surface of water, the side chain is almost perpendicular to this surface, while the oxygen atom (at the free end of this chain) contacts water. Obviously, the latter two orientations cannot exist simultaneously.

In the case of the polymer **17**, both Y-transfer to a hydrophobic support and Z-transfer to a hydrophilic surface were carried out. In the former case, the transfer ratios were 0.9↑ and 0.8↓ (the arrow indicates the direction of support movement: ↑ means upwards from the subphase, while ↓ means downwards to the subphase) for the first 8–10 cycles, while in the latter case they were 1↑ and 0.2–0.5↓ for the first 12–14 cycles. The transfer ratio decreased as the number of cycles increased. A ten-layer LB film of polythiophene **17** was analysed by optical spectroscopy in combination with a cast film. The difference in positions of the absorption maxima for the LB film ($\lambda_{\text{max}} = 472$ nm) and for the film obtained from solution ($\lambda_{\text{max}} = 460$ nm) is explained by a

Figure 7. Compression isotherms of monolayers of polythiophenes **16** (1), **17** (2) and **18** (3).³¹

larger conjugation length in the case of the LB film. IR spectroscopy was used to demonstrate the higher planarity of the main polythiophene chain in the LB film. Similar data were also obtained for the polymer **16**.³³ These data differed from those of Callender *et al.*²⁸ who had also used optical spectroscopy but did not find differences between the spectra of LB films and those of a solution of polythiophene **15**. The discrepancy between the data obtained by both research groups were explained³¹ by the absence of a spacer in the side group of the polymer **15** between the thiophene ring and the oxygen atom. The ordered structure of polythiophene **17** in LB films was confirmed by polarisation optical spectroscopy and by electron microscopy.³² In addition, alternating LB films containing monolayers of **17** and cadmium alkadiynoate were obtained. Polymerisation of the diacetylene was carried out after transferring the monomer onto a solid support.³² It was shown that polymerisation does not result in destruction of polythiophene, and the spectrum of the Langmuir–Blodgett hetero-film does not show a shift of the exciton band of polydiacetylene, indicating the absence of interactions between the polydiacetylene exciton and the polythiophene macromolecules.

Thus, incorporation of ether groups in the side chain of polythiophene enhances the stability of monolayers in comparison with that of poly(3-alkylthiophenes). However, the problem of orientation of monomeric units both in monolayers and in LB films requires a more thorough analysis.

An increase in the polarity of monomeric units of polythiophene by incorporation of an ester group at position 3 enhances polymer spreading in comparison with that of polyalkylthiophene and polythiophene containing ether groups in the side chains.²⁴ Figure 8 presents the plots of surface pressure *vs.* the monomeric unit area for poly[3-(2-propanoyloxyethyl)thiophene] (**19**), poly[3-(2-decanoyloxyethyl)thiophene] (**20**) and, for comparison, poly(3-octylthiophene) (**11**). The short polar side chain in compound **19** 'stacks' the thiophene ring parallel to the surface of water: the limiting area per residue in this region is $\sim 28 \text{ \AA}^2$. Further, the rings are detached from the surface and the increase in pressure is observed in the region of closest packing of vertically arranged thiophene rings. The more complex isotherm shape in the case of polythiophene **20** monolayer is explained by the contribution of the comparatively long hydrocarbon chain arranged so that the polar group in each monomeric unit faces the water surface. The first inflexion on the isotherm results from detachment of these chains from the subphase surface. Although the monolayers of compounds **19** and **20** are stable, Kim *et al.*²⁴ were unable to transfer them onto solid substrates and to obtain LB films. This problem was solved for mixed monolayers of these polythiophenes with octadecylamine (see below).

Figure 8. Compression isotherms of monolayers of polythiophenes **11** (1), **20** (2) and **19** (3).²⁴

The possibility of an increase in the polarity (hydrophilicity) of the side chains of polyalkylthiophenes for enhancement of the stability of monolayers has already been considered. However, the same result can be achieved by means of a considerable increase in the hydrophobicity of the side chain, as was demonstrated by Robitaille *et al.*³⁴ for poly[3-(4,4,5,5,6,6,7,7,8,8,9,9,9-tridecafluorononyl)thiophene] (**21**). Monolayers on the surface of water were from a solution of the polymer **21** in octafluorotoluene. The compression isotherm of polythiophene **21** at 9°C presented in Fig. 9 was obtained after several preliminary 'compression–expansion' cycles in the surface pressure range from 0 to 25 mN m^{-1} . Extrapolation of the curve to $\pi = 0$ gives the limiting area per residue of $34 \text{ \AA}^2$, which agrees with the area occupied by a fluorinated fatty acid molecule in the monolayer. The thermochromic properties of polythiophene **21** were studied using its LB films obtained at $\pi = 10, 14$ and 18 mN m^{-1} . Unfortunately, good LB films were not formed under these conditions: the transfer ratio onto silanised glass was ~ 0.6 . Transfer did not occur at all when the support moved to the subphase. Figure 10 shows the temperature dependences of optical absorption in the UV and visible spectral regions for the monolayer and a film obtained from solution on a rotating support. Robitaille *et al.*³⁴ believe with good reason that comparison of spectra of the two samples makes it possible to understand the nature of the thermochromism of compound **21**. Heating of the samples shifts the absorption maximum at 488 nm to 396 nm . It is believed^{35,36} that this optical effect results from conformational transition of the main polymer chain. It should be noted that the spectra for the two- (monolayer) and three-dimensional (film from solution) states of polythiophene **21** virtually coincide: in both cases, a coplanar structure existing at low temperature is transformed to a non-planar one at high temperature. Since the effects for the two- and three-dimensional systems are identical (Fig. 10a and b), it is concluded that this thermally induced conformational transition is determined by the polythiophene chain itself and does not depend on interchain interactions. However, it should be taken into account that this conformational transition is possible only if it is not prohibited by steric hindrance from the substituents at position 3. In the case of polythiophene incorporating rather

Figure 9. Compression isotherm of fluorinated polythiophene **21** at 9°C .³⁴

Figure 10. Absorption spectra of a monolayer (a) and a coating obtained from solution (b) of fluorinated polythiophene **21** at various temperatures.³⁴

The numbers at the curves indicate the temperatures (°C).

bulky side chains, such a transition is possible only if regioregular regions exist in the polymer ('head-to-tail' diads); however, the existence of such regions was not reported.³⁴

The problem of the regioregularity of poly(3-R-thiophenes), including the formation of stable molecular ensembles on liquid and solid supports, has made progress only in recent years after poly(3-R-thiophenes) with regioregularity of up to 100% had been synthesised and their study had begun.^{37–44} Two conformations of poly(3-alkylthiophene) are shown below: coplanar ('head-to-tail') (**22a**) and twisted ('head-to-head') (**22b**).

As shown by McCullough *et al.*,^{41–43} an increase in the regioregularity of poly(3-alkylthiophene) increases considerably the electric conductivity of the films and results in greater changes in the physical parameters of the polymers than for the samples synthesised with the use of the standard chemical or electrochemical polymer oxidation procedures. Similar conclusions were drawn^{39,40} in studies of the photoluminescence of poly(3-hexylthiophene) films with different regioregularity obtained from solutions. Obviously, the use of such an efficient organisation method as the Langmuir–Blodgett technique for obtaining ultra-thin films of structurally uniform poly(3-R-thiophenes) will make it possible to increase their uniformity and improve the parameters of various devices constructed from these films.

Ochiai *et al.*⁴⁵ compared the properties of monolayers of regioregular poly(3-{2-[(S)-2-methylbutoxy]ethyl}thiophene) (**23**) containing more than 93% of 'head-to-tail' conformers

(**23a**, $M_w = 2.5 \times 10^4$) and polythiophene containing as little as 46% of 'head-to-head' conformers (**23b**, $M_w = 2.05 \times 10^4$).

A monolayer of compound **23a** forms a condensed phase with a collapse surface pressure of $\sim 18 \text{ mN m}^{-1}$ (Fig. 11). The limiting area per residue is $17 \text{ \AA}^2$, which corresponds to an almost perpendicular arrangement of thiophene rings with respect to the surface; the head groups of these rings are oriented towards the subphase. A monolayer of compound **23b** has a larger limiting area per residue ($19 \text{ \AA}^2$), but the low collapse pressure of this monolayer ($\sim 10 \text{ mN m}^{-1}$) indicates its low stability and random orientation of the molecules. Due to these characteristics of monolayers of **23b**, they do not form LB films. Analysis of the polarised optical spectra in the region of 400–650 nm for LB films of the polymer **23a** showed that its molecules are oriented parallel to the surface of the substrate and the chain orientation correlates with the direction of movement of the support when the monolayers are transferred. Comparison of these spectra with those for films deposited from solution showed that in the case of LB films the molecules have a higher degree of orientation and larger conjugation lengths. This increases the lateral conductivity of polythiophene **23a** LB films doped with NOPF₆ or FeCl₃ to $1\text{--}5 \text{ S cm}^{-1}$, which is 4 to 5 orders higher than the conductivity of polythiophene **23b** films obtained from solution. In addition, LB films of the polymer **23a** have anisotropy of lateral conductivity and high cubic susceptibility.⁴⁵

Unfortunately, there are as yet few studies of this kind within the Langmuir–Blodgett method, and for individual polythiophenes only the studies cited above are available. Solutions, films obtained from solution, and solid polythiophenes are being studied thoroughly. These systems are not covered in the present review dealing with monolayers and LB films; however, we have to dwell on some general issues of the relationship between the structure, composition and properties of polythiophenes in solutions and in the bulk.

It is known⁴⁶ that electrochemical synthesis of poly(3-alkylthiophenes) gives units with substituents at positions 2 and 4, whereas chemical synthesis results in residues with substituents at positions 2 and 5. Both methods give irregular polymers. Naturally, these 'defects' affect the planarity of the main polymer chain

Figure 11. Compression isotherms of monolayers of polythiophenes **23a** (1) and **23b** (2) at 10°C .⁴⁵

and hinder both the intrachain and the interchain transport of charge carriers. As a result, poly(3,4-dialkylthiophenes) and poly(3,3'-dihexyl-2,2'-dithiophenes) mostly containing 'head-to-head' conformers have a small conjugation length and low conductivity.^{47,48} There are prerequisites for increasing the polymer regularity by polymerisation of long-chain 3-alkylthiophenes.^{49,50} However, in this case the polymer contains structural defects as well⁴⁸ [C(2)–C(4') bonds and branchings]. It is believed^{51,52} that regular polymers with high conductivities can be obtained from 3,4-disubstituted thiophenes if steric hindrance is removed. This assumption was checked⁵⁰ by the synthesis of poly(3-alkoxythiophenes), poly(3-alkoxy-4-methylthiophenes) and poly(3,4-dialkoxythiophenes) by chemical oxidation of monomers with anhydrous FeCl₃ (see Refs 48, 53). The effects of the position, size and nature of substituents on the molecular mass, positions of characteristic absorption bands and conductivities of the resulting polymers were determined. It was shown that the absorption band of 3,4-disubstituted polyalkylthiophenes is strongly (by ~200 nm) shifted towards the blue region in comparison with the bands of the other polythiophenes synthesised. This implies a non-planar conformation of chains due to strong steric interactions between the substituents and the main chain. As a result, gaps remain between the conjugated chains of the adjacent molecules; these gaps decrease the probability of charge carrier transfer according to the hopping mechanism.⁵² Replacement of alkyls by alkoxy groups in poly(3,4-dialkylthiophenes) increases considerably the conjugation length and conductivity of the polymer, which is explained by the smaller van der Waals radius of the oxygen atom (1.4 Å) in comparison with the methylene group radius (2.0 Å). This conclusion can be very important in the synthesis of Langmuir monolayers, since incorporation of a polar group enhances the ability of polythiophenes to spread over an aqueous subphase surface.

Studies on the synthesis of regular polythiophenes with various quantitative and qualitative compositions of substituents and their use for obtaining monolayers and LB films are already under way. For example, works have been published on the synthesis and properties of polythiophenes, polybithiophenes and polyterthiophenes containing such substituents as 3-cyclohexyl, 3-methyl-4-cyclohexyl, 3-alkylphenyl, *etc.*^{54–57}

IV. Mixed monolayers and Langmuir–Blodgett films of oligo- and polythiophenes

Analysis of the behaviour of monolayers and LB films of simple oligo- and polythiophenes showed that the formation of stable films on the surface of water requires adjustment of the hydrophilic-lipophilic balance of thiophenes towards enhancement of the hydrophilicity of the head group. In addition, a side group, most commonly an alkoxy group, is to be introduced into each thiophene ring of the main chain (in most cases, at position 3) in order to weaken the interchain interactions responsible for aggregation of macromolecules on the surface of water and incomplete spreading of the compound to form a monolayer. An easier method to obtain stable monolayers containing polythiophenes involves formation of mixed monolayers with an amphiphilic compound which forms stable monolayers with high collapse pressure. The problem of the role of intra- and interchain charge transfer is solved using mixed monolayers of conjugated polymers with compounds which are inert with respect to electric conductivity (fatty acids, alcohols, polymers). Obviously, incorporation of an inert component should not hinder the interchain charge transfer in the case of mixed films.

A five-membered oligomer of thiophene **1** ($n = 3$, S₅) was mixed with stearic acid²⁹ or eicosanoic acid⁵⁸ and placed on the surface of aqueous solutions containing CdCl₂. Compression isotherms obtained for monolayers of mixtures with different component ratios were used to determine the limiting area per molecule of oligothiophene S₅, which was 26 Å² for mixtures of S₅ with stearic acid²⁹ and 19 Å² for mixtures of S₅ with eicosanoic

acid.⁵⁸ Such a large difference was explained by the higher pH used in the former study²⁹ and better correspondence between the lengths of the molecules of S₅ and cadmium stearate (25.8 Å) than of S₅ and cadmium eicosanoate (28 Å). According to calculations,²⁹ the area of an S₅ molecule arranged at a right angle to the film surface and having a dihedral angle of 90° is 28 Å². Therefore, the area per S₅ molecule equal to 26 Å² should correspond to vertical orientation of oligothiophene with the dihedral angle ranging between 20° and 50°.

Figure 12 shows the dependence of the specific electric conductivity of iodine-doped LB films obtained from a mixture of S₅ and stearic acid (the content of S₅ was 30 mol.%) on the number of layers (N) in a Y type film.²⁹ One can see that for $N \leq 7$, the conductivity increases rapidly and reaches a steady-state value of

Figure 12. Dependence of the lateral conductivity on the number of layers in an LB film obtained from a mixture of oligothiophene **1** (S₅) (30 mol.%) and stearic acid.²⁹

0.1 S cm⁻¹ at $N > 15$. The dependences of the lateral conductivity on the mole fraction of S₅ in the mixture for 1-, 3- and 11-layer, iodine-doped LB films are presented in Fig. 13. Two regions are observed in the curves. For the 11-layer LB film, the conductivity reaches a plateau at a mole fraction [S₅] ≥ 0.35. The limiting conductivity (0.2 S cm⁻¹) corresponds to σ_{||} for iodine-doped bulk polythiophene (0.01–0.1 S cm⁻¹)⁵⁹ and exceeds the σ_{||} for the spray-deposited, iodine-doped S₅ film. The lateral conductivity of non-doped LB films does not exceed 10⁻⁹ S cm⁻¹, while the transverse conductivity σ_⊥ is lower than 10⁻¹² S cm⁻¹. The maximum conductivity can be reached by doping for a period of two days. The doping process is partially reversible: for the 21-layer LB film obtained from a mixture of S₅ with stearic acid (1 : 1), σ_{||} and σ_⊥ were 3.0 × 10⁻³ and 1.5 × 10⁻⁷ S cm⁻¹, respectively, after removal of iodine.

Since neither the oligothiophene chain length nor the film ordering affect noticeably the electric conductivity of oligomers

Figure 13. Dependence of the lateral conductivity of LB films consisting of monolayers of oligothiophene **1** (S₅) and stearic acid on the mole fraction of S₅ for an LB film containing 1 (*1*), 3 (*2*) and 11 layers (*3*).²⁹

doped with iodine,²⁹ it was concluded that the electric conductivity of polymers and oligomer ensembles is determined by the intermolecular transfer of charge carriers.

There are many more studies of mixed monolayers and LB films containing polythiophenes than of those dealing with monolayers of oligothiophenes and films of individual compounds. It is believed⁶⁰ that pure poly(3-alkylthiophenes) are unsuitable for obtaining organised ensembles for at least two reasons. First, they do not form true monolayers; when they spread over the surface of water, they form islets visible by naked eye. The same situation is observed for poly(3-alkylthiophenes) containing up to 18 carbon atoms in the side chain. Second, monolayers can be transferred onto solid supports only by the horizontal method. The films obtained in this manner have low degree of organisation. As in the case of oligothiophenes, these drawbacks can usually be overcome by using fatty acids such as stearic and eicosanoic acids.^{61–65}

Figure 14 shows the π - A plots for mixed monolayers with various compositions obtained from mixtures of poly(3-hexylthiophene) and stearic acid.⁶⁰ It is evident that the mixture containing up to 80 mol.% of the polymer (with respect to the repeating thiophene unit) forms a stable condensed monolayer. The phase transition in this monolayer is observed at high surface pressures (25 mN m⁻¹). For all component ratios, π increases with a decrease in the area until the transition region is reached where the surface pressure remains constant. A new abrupt increase in π starts at monolayer areas close to A for a monolayer of pure stearic acid. Obviously, the plateau corresponds to displacement of the polymer molecules from the liquid surface and formation of a bilayer film. This picture is observed for all alkyl-substituted polythiophenes except for poly(3-octadecylthiophene) in which strong interactions of the alkyl chains with the chains of similar length of stearic acid prevent polymer displacement from the interface.

Let us consider the properties of LB films obtained from these mixtures. The LB film thicknesses after one passage of the support through a mixed polythiophene–acid (2 : 1) monolayer at transfer pressures below (20 mN m⁻¹) and above (28 mN m⁻¹) the phase transition (plateau) were 32 and 44 Å, respectively (see Fig. 14). According to the optical spectroscopy data, the bilayer structure formed on the surface of water at high π is transferred onto the solid support. However, more precise X-ray diffraction data showed that the bilayer thickness in LB films correlates with the size of two stearic acid molecules and does not depend on the transfer pressure. The formation of high-quality LB films from a mixture of poly(3-hexylthiophene) with stearic acid was evidenced by linear dependences of the absorption intensity at the maximum of the characteristic absorption band of polythiophene on the

Figure 14. π - A Dependences for mixed monolayers of poly(3-hexylthiophene) and stearic acid for the molar component ratios: 0 : 1 (1); 1 : 2 (2); 1 : 1 (3); 2 : 1 (4) and 5 : 1 (5).⁶⁰

Figure 15. X-Ray diffraction diagrams for LB films consisting of mixed monolayers of poly(3-hexylthiophene) and stearic acid for the molar component ratios: 1 : 2 (1); 1 : 1 (2); 2 : 1 (3) and 5 : 1 (4).⁶⁰

number of layers for various component ratios and surface transfer pressures and by a linear relationship between the inverse capacity of LB films and the number of layers. The layered structure of LB films was confirmed by X-ray diffraction (Fig. 15). The X-ray diffractogram displays distinct Bragg peaks with an interlayer distance of 50 Å, which corresponds to a bilayer of stearic acid. Near-edge X-ray absorption fine structure analysis showed a high degree of organisation of stearic acid hydrocarbon chains in the bilayers and an irregular orientation of poly(3-hexylthiophene) chains. A model of a mixed LB film structure was built on the basis of the experimental data (Fig. 16).

The effect of the content of poly(3-octylthiophene) in a mixture with eicosanoic acid on the properties of monolayers and LB films was studied.⁶⁵ No plateau was found on the compression isotherms of monolayers (the mixture containing 60% of the polymer was an exception). As in other studies, an increase in the polymer fraction in the mixture resulted in an increase in the monolayer limiting area. The high stability of mixed monolayers [unlike the monolayers of pure poly(3-octylthiophene)] and the high surface collapse pressure (> 50 mN m⁻¹) made it possible to form a 45-layer LB film at a

Figure 16. A model of the structure of an LB film obtained from a mixture of poly(3-hexylthiophene) and stearic acid.⁶⁰

transfer ratio close to 1. Despite the instability of pure poly(3-octylthiophene) monolayers, the respective LB films were obtained and their thicknesses were determined by ellipsometry. The thickness of one layer in an LB film was 40 Å, which is 3 Å thicker than that of one monolayer in the LB film obtained from a mixture of eicosanoic acid and poly(3-octylthiophene) measured by the same method. These data were not discussed, but it is easy to understand the origin of the larger thickness of the pure polythiophene LB film if its 'monolayers' were transferred at area per unit parameters insignificantly in excess of 5 Å². It should be noted that the thickness of one LB film layer of pure poly(3-octylthiophene) and its mixtures with eicosanoic acid specified above is considerably larger than the thickness of a densely packed monolayer of eicosanoic acid. In addition, ellipsometry, unlike X-ray diffraction, does not allow determination of the structure spacing parameters and hence does not provide data on the film layered structure. Such data were reported.^{60,66} It was found for mixed LB films of stearic acid with poly(3-hexylthiophene) in the ratios from 2:1 to 1:5 that the structure spacing corresponded to the thickness of a stearic acid bilayer.⁶⁰ It was also found for LB films obtained from binary mixtures (1:10 and 1:3) of poly(3-heptylthiophene), poly(3-decylthiophene) or poly(3-undecylthiophene) with cadmium eicosanoate that the structure spacing of all three systems corresponds to the thickness of a cadmium eicosanoate bilayer (55.2 Å).⁶⁶ Two reflections were observed for rather high contents of poly(3-decylthiophene) in a mixture with cadmium eicosanoate (3:1); these reflections corresponded to interlayer distances of ~70 and ~50 Å. This result and the broadening of the diffraction bands indicated a decrease in the system ordering. Despite the high content of behenic acid in a mixed monolayer with poly(3-hexadecylthiophene) (5:1 w/w) and its high stability ($\pi_c = 60 \text{ mN m}^{-1}$ and $A_0 = 13.7 \text{ Å}^2$ per unit), only a Z-type LB film (20 layers) could be obtained.⁶⁷ It was found in a study of these films by attenuated total internal reflection IR spectroscopy and reflection at grazing light angles that the LB film obtained from a mixture has a less organised structure than the LB film of pure behenic acid.

Mixed monolayers of poly(3-octylthiophene) and unsaturated oleic acid having the same hydrocarbon chain length as stearic acid were studied.⁶⁸ It was shown that an increase in the content of polythiophene in the mixture from 10% to 90% decreased the mean molecular area of the monolayer upon its destruction from 42 to 5 Å². Let us remind that in the case of saturated acids, the monolayer area generally increases with an increase in the polymer fraction.^{60,69} Exposure of the solution used for the formation of mixed monolayers of oleic acid and poly(3-octylthiophene) to daylight shifted the dependence of the monolayer area on the polymer content towards larger areas. The shoulder at 590 nm found⁶⁸ in the absorption spectra of LB films composed of mixed monolayers is explained by the formation of a charge-transfer complex between oleic acid and the thiophene rings.

The study of mixed monolayers of poly(3-butylthiophene) and stearic acid,⁷⁰ like yet another study⁶⁵ of the poly(3-octylthiophene)–eicosanoic acid system, did not show a plateau on the compression isotherms for the polymers with molecular masses differing by an order of magnitude (2.5×10^5 and 1.5×10^4). For these systems, as for the majority of other mixtures of fatty acids with polythiophenes, the area per monomer unit in a monolayer increases with an increase in the polymer content in the mixture.⁶⁵ The main differences in the shape of the compression isotherms for polythiophene samples with different molecular masses were observed in the region of destruction of mixed monolayers, *i.e.* in the transition from a two-dimensional to a three-dimensional state of the material. The surface potential of monolayers is 'insensitive' to these differences and to the obvious differences of the aggregation states of polymer monolayers with significantly different molecular masses. In both cases (as for the majority of monolayers of low- and high-molecular-mass compounds), the surface potential starts to increase at monolayer areas considerably exceeding those where the increase in the surface pressure starts. The transfer

of mixed monolayers onto a glass surface by the vertical method was studied in detail;⁷⁰ it was found that the transfer ratio is close to unity and that the resulting LB films of the Y type have homogeneous structures.

It was noted above that important information on the properties of conjugated systems can be obtained from absorption spectra of LB films and their comparison with the spectra of polymers in solutions. High quality LB films of the Y type with various ratios of stearic acid and poly(3-hexylthiophene) were described.⁶⁰ Differences between the absorption spectra of LB films of individual polythiophenes **16** and **17** and their films obtained from solution were observed;^{31–33} however, no differences were found between similar spectra of LB films obtained from a mixture with stearic acid and that of a film obtained from a solution of pure poly(3-hexylthiophene).^{60,69,70}

The position of the $\pi-\pi^*$ -transition maximum in the absorption spectra of LB films consisting of mixed monolayers of poly(3-alkylthiophenes) and cadmium eicosanoate depends on the length of the polymer alkyl chain.⁶⁶ For example, for LB films of poly(3-decylthiophene) and poly(3-undecylthiophene), the absorption maximum of a 1:3 polymer:salt mixture was observed at 520 and 515 nm, respectively, whereas in the case of a film obtained from solution, the absorption maxima were at 477 and 500 nm. For poly(3-heptylthiophene), no differences between the absorption spectra of mixed LB films and a film formed from solution were found. These data are believed⁶⁶ to be consistent with other data.^{60,71} It was therefore concluded that the conjugation length in poly(3-decylthiophene) and poly(3-undecylthiophene) is larger in LB films than in films formed from solution. This effect was explained by interactions between the hydrocarbon chains of the acid and poly(3-alkylthiophenes). For poly(3-heptylthiophene), no increase in the conjugation length in LB films was observed.

The absorption spectra of LB films containing poly(3-octylthiophene) and eicosanoic acid displayed a red shift of the absorption band maximum by 60 nm in comparison with the position of the absorption band maximum of a solution of the polymer in chloroform.⁶⁵ As in yet another study,³⁶ this effect was explained by conformational reorganisation of the chain in LB films. Ageing of the film shifted this absorption band towards the short-wave region. Doping of LB films was carried out in SbCl₅ or iodine vapour. As a result, the LB film colour changed from red to blue, while the conductivity increased from 2×10^{-9} to $2 \times 10^{-5} \text{ S cm}^{-1}$ for iodine and to $1 \times 10^{-4} \text{ S cm}^{-1}$ for SbCl₅.⁶⁵

The conductivity of a mixed 34-layer LB film doped with nitrosyl hexafluorophosphate depends on the component ratio.⁶⁰ An increase in the poly(3-hexylthiophene) content in a mixture with stearic acid from 1:2 to 5:1 increases the electrical conductivity from 0.02 to 2.0 S cm⁻¹. Similar results were obtained⁷² for LB films consisting of binary mixed monolayers (2:1) of stearic acid with poly(3-butylthiophene), poly(3-octylthiophene) or poly(3-octadecylthiophene); the maximum electric conductivity was 5.0 S cm⁻¹. Doping also results in significant changes in the absorption spectra of mixed LB films. The intensity of the strong absorption band corresponding to $\pi-\pi^*$ -transition of the conjugated main chain ($\lambda_{\text{max}} = 500 \text{ nm}$) decreases considerably and two new bands appear at 800 and 2200 nm, which correspond to transitions between the valence band and the new bipolar charged states that appear due to doping.⁷³

Attempts to incorporate ions in mixed LB films consisting of poly(3-octylthiophene) with stearic acid (1.4:1) were made in order to increase the conductivity of these films.⁶⁹ However, even small contents of *e.g.*, N⁺ (5×10^{14} ions per cm²) violated the LB film layer structure, apparently due to destruction of stearic acid. The conductivity increased to only $10^{-3} \text{ S cm}^{-1}$ with increase in the N⁺ content by 2 orders of magnitude and resulted from formation of a conducting form of carbon. This not only destroyed completely the layer structure of the film but also destroyed the conjugated polymer structure (optical spectroscopy data).

Mixed monolayers and LB films of poly(3-hexylthiophene) or poly(3-dodecylthiophene) with poly(isobutyl methacrylate) were studied.⁷¹ Taking account of the deviation from linearity of the relationship between the monolayer limiting area and composition, it was concluded in this study that polyalkylthiophenes and poly(isobutyl methacrylate) are compatible. Comparison of the optical spectra of mixed LB films with those of films with the same component ratio cast from solution showed that the conjugation efficiency for LB films containing poly(3-dodecylthiophene) is higher than for cast films but it is lower for films containing poly(3-hexylthiophene). The aggregation states of macromolecules are also different for these two film types. The conductivity of mixed LB films doped with sulfuric acid ranged from 0.05 to 0.1 S cm⁻¹; doping changed the LB film colour from red to blue.

Polymerisation of thiophenes can occur in organised planar systems, resulting in the formation of anisotropic macromolecules.⁷⁴ In view of this, the properties of pure thiophene **24** and its mixtures with viologen were studied.⁷⁵

It was shown by X-ray photoelectron spectroscopy with angular resolution^{76–78} that an LB film of compound **24** has a layered structure (bilayers of the Y type) with a distance of 4.6 nm between the thiophene sublayers. In mixed monolayers and in LB films containing thiophene **24**, phase separation does not occur due to interactions between the positive charges of viologen and the deprotonated carboxyls of thiophene resulting in donor-acceptor diads.

In addition to mixed monolayers and LB films of polythiophenes with insulating molecules (mostly, fatty acids), of significant interest are thin planar systems consisting of mixtures of a conducting polythiophene with a conducting compound manifesting a surfactant property in an aqueous medium. Rikukawa *et al.*⁷⁹ used mixed monolayers of poly(3-hexylthiophene) with nickel (**25**) and iron (**26**) tetra-*tert*-butylphthalocyanines.

M = Ni (**25**), Fe (**26**); X = Bu^t.

It is considered^{80, 81} that, along with unique electrical properties, phthalocyanines have an important advantage of higher stability of their monolayers in comparison with the stability of monolayers of fatty acids. The behaviour of pure phthalocyanine monolayers is essentially different: the limiting area of a phthalocyanine **26** monolayer is 75 and that of phthalocyanine **25** monolayer is only 34 Å² per molecule. In the former case, the molecular planes are oriented perpendicularly to the surface of water, and in the latter case the monolayer consists of aggregates whose thickness exceeds the size of one molecule. Incorporation of polythiophene expands slightly the monolayer of compound **25** and increases considerably the area of the monolayer of compound **26**. Thus, in the latter case the compatibility of monolayer components was higher than in the former, and displacement of polythiophene molecules occurred with much greater difficulty.

The structural organisation of mixed monolayers and films on a solid substrate and the character of interactions between the components were determined more accurately by comparison of the optical spectra of two mixed LB films with the spectra of phthalocyanines in solution and with the spectra of mixed LB films of phthalocyanines with stearic acid. It was found that the sulfur atoms of the thiophene rings tend to coordinate with the iron atoms of phthalocyanine. This limits the possibility of formation of phthalocyanine dimers and trimers and increases the extent of molecular mixing. For mixed LB films of compound **25** with polythiophene (as with stearic acid), the interactions between the molecules are not so strong and aggregation of molecules of compound **25** is much stronger than that in mixed LB films containing compound **26**. Interesting results of structural studies of mixed films carried out by small-angle X-ray scattering and by optical spectroscopy were reported. In mixed LB films of phthalocyanine **25** with polythiophene, as in the LB films of pure compounds **25** and **26**, the majority of phthalocyanine molecules form one-dimensional linear structures in which the ring planes are oriented perpendicularly to the substrate surfaces. In mixed films of phthalocyanine **26** and polythiophene, the phthalocyanine molecules exist mainly as monomers and have random organisation because of interaction with the thiophene units. The conjugated polymer chains in both mixed films are oriented parallel to the film surface, while the side chains have no preferential orientation. It should be noted that irreversibility of thermochromic properties was reported only for mixed LB films of poly(3-hexylthiophene) with phthalocyanine **26**:⁷⁹ heating from 25 to 120 °C changed the colour of the film from dark brown to green. The absorption spectrum of the film changed correspondingly. It should be noted that mixed films with the same component ratio cast from solution on a solid substrate did not display thermochromic properties. Doping of mixed LB films was carried out in iodine and SbCl₅ vapours.⁷⁹ As a result, electrical conductivity increased in comparison with the electrical conductivity of the LB films of pure phthalocyanines (10⁻⁵–10⁻⁶ S cm⁻¹) by several orders and reached 10⁻¹–10⁻² S cm⁻¹. Unlike LB films doped with iodine, the films doped with SbCl₅ were stable in vacuo and in an atmosphere of nitrogen. According to optical spectroscopic data, both components of the mixed film underwent doping. Figure 17 shows the dependences of the lateral conductivity of mixed LB films on the content of polythiophene components. It is evident that the maximum conductivity is reached at 80 mol.% of the polymer in the mixture; the conductivity of the system with phthalocyanine **26** is by an order of magnitude higher than that for the systems with phthalocyanine **25**. This effect is explained by coordination between the molecules of polythiophene and iron phthalocyanine.

Of considerable interest are the alternating Langmuir–Blodgett heterofilms consisting of materials with different conductivity band widths. These films are convenient models of quantum wells in organic systems.^{82, 83} In addition, these alternating systems can be used for studies of energy transfer in

Figure 17. Dependence of the lateral conductivity of SbCl₅-doped Langmuir–Blodgett films consisting of mixed monolayers of poly(3-hexylthiophene) and iron (**1**) and nickel (**2**) phthalocyanines on the polymer content (*c*).⁷⁹

Figure 18. Absorption spectra of an alternating Langmuir–Blodgett film obtained from a mixture of polythiophene **17** and alkadiynoic acid at different irradiation times (light with the wavelength of 254 nm).³² Time /min: (1) 0.25; (2) 2; (3) 12; (4) 24; (5) 56.

polymeric materials. For this purpose, Bolognesi *et al.*³² chose alternating mixed LB films consisting of poly(3-methoxydecylthiophene) **17** and cadmium salt of the alkadiynoic acid $\text{H}(\text{CH}_2)_{12}\text{C}\equiv\text{CC}\equiv\text{C}(\text{CH}_2)_8\text{COOH}$. UV irradiation of the LB films formed from a polymer: monomer mixture at a wave length of 254 nm gave a film that contained alternating layers of two conjugated polymers. Figure 18 shows the absorption spectrum of a Langmuir–Blodgett heterofilm for various irradiation times determining the degree of polymerisation of diacetylenic acid. The band at 640 nm corresponds to exciton absorption of the extended polydiacetylenic chain. The band at 540 nm overlapping with the neighbouring bands originates from absorption of short polydiacetylenic chains.⁸⁴ It should be noted that irradiation of the Langmuir–Blodgett heterofilm does not shift the polythiophene absorption band at 505 nm nor decreases its intensity. On the other hand, laser irradiation of the original heterofilm near the polythiophene absorption (488 nm; light with this wavelength does not cause polymerisation of pure diacetylenic acid or its salt) results not only in polymerisation of the amphiphilic diacetylene but also in a shift of the maximum of the polythiophene absorption band to higher energies and in a decrease in its intensity. This result suggests photooxidation of the polythiophene component of the hetero structure and its subsequent sensitising effect on the photopolymerisation of the diacetylene. The identity of the absorption spectra of Langmuir–Blodgett homo- and heterofilms containing polydiacetylene indicates the one-dimensional exciton nature in the structures of both films, *i.e.* the absence of interactions between the polydiacetylene exciton and the polythiophene macromolecules.³²

Mixed monolayers of poly(3-hexylthiophene) and pentacosanoic acid were studied by Tsumura *et al.*⁸⁵ Stable monolayers were obtained for various component ratios; after transferring them onto a solid substrate by the vertical method they were polymerised by exposure to light. It was found that polythiophene does not affect the polymerisation of the diacetylenic acid and the LB film has a layered structure with oriented molecules of both components; the area per molecule in the mixed monolayer and the structure spacing in the LB film indicate the formation of bilayer films.⁸⁵ In this LB film variant, the bilayer consists of identical mixed monolayers rather than of alternating monolayers of different polymers (as in the previous case).

A detailed study of the effect of thickness, temperature and electric field on the conductivity mechanism in LB films consisting of mixed (5:1) monolayers of poly(3-hexylthiophene) and 3-decanolpyrrole was carried out.⁶² The dependence of the lateral conductivity and charge mobility in external electric field for a non-doped LB films, an LB film doped with NOPF₆ and a

Figure 19. Dependences of specific electric conductivity (a) and charge mobility in electric field (b) for LB films consisting of mixed layers (5:1) of poly(3-hexylthiophene) and 3-octadecanoylpyrrole on the number of layers.⁶² Film: (1) non-doped; (2) doped with NOPF₆; (3) dedoped.

dedoped LB film (a sample which was allowed to relax after doping to a certain high conductivity) on the number of layers is presented in Fig. 19. It is evident that doping increases the conductivity by 5 orders of magnitude, while the mobility is increased by 4 orders. In view of this, a conclusion on the primary role of charge mobility in the LB film conductivity was drawn.⁶² The thickness of LB films has but an insignificant effect on these parameters, except for the region between the 3- and 11-layer LB films. The decrease in conductivity upon keeping the samples in air (preparation of the dedoped system) is due to the loss of activity of the PF₆[−] anions because of their reaction with moisture. Obviously, this affects the thinner film most strongly (see Fig. 19). It was shown in the same study that the dependence of conductivity (and charge mobility) on temperature for the non-doped film has the form $\log \sigma \sim T^{-1/4}$. This means that the hopping mechanism is the main mechanism of conductivity.⁸⁶ Based on this conclusion and on the experimental dependences of conductivity on external electric field, the mean hopping length and energy were calculated as 230 Å and 0.41 eV, respectively, using the Mott equation.⁸⁷

In the case of doped and dedoped samples, the temperature dependence of conductivity had the form $\log \sigma \sim T^{-1/4}$ (Fig. 20). Extrapolation of the straight line obtained for the doped LB films to room temperature gave a conductivity of 0.1 S cm^{−1}. After dedoping, the plot slope and hence the activation energy changed, but the dependences still remained linear. Similar relationships are observed in the case of metal and metal-ceramic systems consisting of grains;^{88,89} in view of this, some possible mechanisms describing the conductivity in these systems were considered.⁶² Based on comparative analysis, the conclusion was drawn that the tunnel mechanism with charge transfer operates in poly(3-alkylthiophene) films doped with NOPF₆ (see Ref. 90). It was established on the basis of these concepts that dedoping results in an increase in the size of conducting grains (domains) in LB films from 30 to 50 Å. The conducting domains are formed by the main conjugated polymer chains separated by the side alkyl groups. Interesting data on changes in the conductivity mechanism were obtained for 11-layer LB film samples exposed to external electric fields with field strengths up to 0.5 MV cm^{−1}. Transition to the Fowler–Nordheim tunnelling mechanism was observed in this case.^{91,92}

Analysis of the properties of monolayers and LB films of individual regioregular polythiophenes synthesised in recent years showed the advantages of these structurally homogeneous polymers assembled in organised planar ensembles over the systems

Figure 20. Temperature dependence of specific electric conductivity of a 25-layer LB film consisting of mixed (5 : 1) monolayers of poly(3-hexylthiophene) and 3-octadecanoylpyrrole.

Film: (1) non-doped; (2) moderately doped with NOPF₆; (3) dedoped.

containing poly(3-R-thiophenes) with random orientation of substituents.

The effect of the structural homogeneity of the polymer chain on the properties of monolayers and LB films also manifests itself in the case of mixed monolayers.⁹³ This is evident if one compares the compression isotherms of mixed monolayers of stearic acid with regioregular poly(3-hexylthiophene) containing up to 100% of 'head-to-tail' diads presented in Fig. 21 with the compression isotherms of a mixture of stearic acid with poly(3-hexylthiophene) having a random distribution of the chain substituents (see Fig. 14). Both monolayers consist of two phases, but the larger area and the smoother transitions between the phase states in the range of 20–30 mN m⁻¹ for the former monolayer (see Fig. 21) suggest the better compatibility of stearic acid with the regular polythiophene. A similar trend was observed⁹⁴ in a study of the effect of the chain length of the alkyl substituent in polythiophene on the behaviour of monolayers and LB films obtained from its mixture with stearic acid. Smoothing of compression isotherms in the phase change region observed for the mixture of fatty acid with poly(3-hexylthiophene) is explained by better compatibility in this system than in the system with shorter alkyl substituents in polythiophene.

The mixed monolayers of stearic acid with regioregular poly(3-hexylthiophene) were transferred by the horizontal method at a surface pressure of 20 mN m⁻¹ to give the Y type LB films (20 layers) on a hydrophobised glass plate surface.⁹³ It was shown by X-ray diffraction for LB films containing 2 : 1 polythiophene and stearic acid in monolayers that the film has a distinct layered structure with an interlayer distance of 17 Å. The same structure spacing found previously for poly(3-hexylthiophene) films cast from solution^{42,95} corresponds to the distance between the polymer chains stacked parallel to the substrate

Figure 21. Compression isotherms of monolayers of regioregular poly(3-hexylthiophene) and stearic acid with component molar ratios of 0 : 1 (1); 2 : 1 (2); 5 : 1 (3).⁹³

surface. However, the interlayer distance determined by X-ray diffraction for LB films composed of mixed (1 : 2) monolayers of stearic acid and irregular poly(3-hexylthiophene) corresponded to a bilayer of cadmium stearate, *i.e.*, 50 Å.⁹⁶ Figure 16 illustrates the structure of such an LB film. No similar scheme for LB films consisting of stearic acid and regular poly(3-hexylthiophene) has been reported in the literature; however, it can be expected that the stearic acid molecules in this system either form a tilted phase or are distributed along the polythiophene chains.

Rikukawa *et al.*⁹³ compared the UV and visible absorption spectra for 2 : 1 mixtures of regioregular and irregular poly(3-hexylthiophene) and stearic acid. According to the spectra presented in Fig. 22, the π – π^* -transition energy of the mixture with the regular polymer is lower than that in the system with irregular polythiophene. This implies that the molecules of the former polythiophene in LB films have a more stretched structure and have a larger conjugation length than the molecule of the latter polythiophene. The lateral conductivity of LB films of mixed (5 : 1) monolayers of regioregular poly(3-hexylthiophene) with stearic acid doped with NOPF₆ was 50–100 S cm⁻¹, which is almost 1000 times higher than the lateral conductivity of a similar system containing irregular poly(3-hexylthiophene). It should be noted that the conductivity of LB films obtained from a mixture of regioregular poly(3-hexylthiophene) and stearic acid is several tens times higher than the conductivity of LB films obtained from the pure regioregular compound.⁴⁵

Figure 22. Absorption spectra of a 20-layer LB film consisting of mixed (2 : 1) monolayers of regioregular (1) and irregular (2) poly(3-hexylthiophene) and stearic acid.⁹³

Thus, the regioregularity of polythiophene favours an increase in compatibility of the polymer with stearic acid and results in a sharp increase in electric conductivity of thin films consisting of these components. These features of polythiophene can intensify the development of molecular devices. In addition, comparison of systems containing polythiophenes with different degrees of regularity enables deeper insight into the relationship between the structure and properties of conducting polymers.

V. Prospects for the application of polythiophene Langmuir–Blodgett films in molecular devices

It has been noted in many publications that LB films of polythiophenes and their mixtures with other substances can be used for practical purposes, nevertheless only a few works describing molecular devices based on these compounds are available.

The first study with mixed monolayers of oligothiophene **1** (S₅) with eicosanoic acid in a Langmuir–Blodgett heterofilm (alternating mixed monolayers and pure eicosanoic acid monolayers) was carried out as early as in 1974⁵⁸ (see footnote ‡). A cell was designed for photocurrent measurements, in which the LB film contained a mixed monolayer with oligothiophene S₅ located

‡ This was the first publication of Kuhn and his colleagues who laid the foundation of rapid development of studies in molecular design combined with the Langmuir–Blodgett technique.

close to one of the electrodes (aluminium or mercury) or at a certain distance set by the number of spacer monolayers of pure eicosanoic acid. By measuring the dependences of photocurrent on the applied voltage, temperature, and the arrangement of the conducting and insulating layers, the photophysical parameters of the device and the mechanism of generation of thermo- and photocurrent were determined. The authors suggested the main directions in the design of photoelectric devices. However, to date, scientific literature contains no information on the development of these kinds of devices based on polythiophene LB films. Nevertheless, metal–insulator–semiconductor transistors⁹⁷ and light-emitting devices^{39, 40, 55, 56, 98} suitable for inexpensive flat colour displays and adjustable lasers from oligo- or polythiophene films deposited from solution or spray-deposited on electrodes are being designed.

Ng *et al.*⁹⁹ used LB films of mixed monolayers of poly [3-(6-hydroxyhexyl)thiophene] (**27**) or poly(3-octylthio-2,2'-bithiophene) (**28**) and octadecanol as a sensor for heavy metal ions. A quartz crystal microbalance was used as the recording device. The high quality of the LB films obtained (up to 40 monolayers) was confirmed by the facts that the change in frequency of the quartz resonator depended linearly on the number of LB film layers and that the transfer ratio of monolayers was equal to unity.

Figure 23 shows the dependence of adsorption of metal ions on a 10-layer LB film from mixed (3 : 1) polythiophene **27** : octadecanol monolayers deposited on the quartz resonator on the time of LB film exposure to 20 ppm solutions of ions at neutral pH and 25 °C. Similar results were obtained for mixed (1 : 3) polythiophene **28** : octadecanol LB films. One can see in the figure that the LB films of pure octadecanol does not adsorb metal ions under the same conditions. Complexing of metal ions with the polythiophene sulfur atoms is the driving force of adsorption. The selectivity in the series of ions $\text{Cu}^{2+} > \text{Ni}^{2+} > \text{Co}^{2+} > \text{Zn}^{2+} > \text{Fe}^{2+}$ correlates with the ionisation potentials and ionic sizes in the Irving–Williams series. The higher adsorption of Ag^+ and Hg^{2+} in comparison with the other ions is explained by the high affinity of these ions to the sulfur atom. An important feature of the sensor is its reversibility: complete regeneration of the sensor upon exposure of the resonator with LB films in 1 mM ethylenediaminetetraacetic acid solution occurred in 5 min. An increase in the number of layers in the LB film increased the

Figure 23. Dependence of the adsorption of metal ions on a 10-layer LB film consisting of mixed (3 : 1) polythiophene **27** : octadecanol monolayers on the time of exposure to solutions containing ions: Ag^+ (1); Cu^{2+} (2); Hg^{2+} (3); Ni^{2+} (4); Co^{2+} (5); Zn^{2+} (6); Fe^{2+} (7); Cu^{2+} + octadecanol LB film (8). The concentrations of the ions are 20 ppm (see Ref. 99).

absolute value of the change in the quartz resonator frequency Δf (the mass of the absorbed ions increases). This result indicates that the diffusion of ions in LB films does occur. However, for example, the 40-layer LB film was unstable and delaminated from the substrate after 7–10 measurements, whereas the 20-layer LB film withstood 50 measurements.

The concentration dependences of Δf for Ag^+ and Hg^{2+} ions are shown in Fig. 24. It is evident that a linear dependence is preserved up to the 100 ppm concentration. At higher concentrations, the frequency is unchanged because of saturation of the LB film with ions.

Figure 24. Concentration dependences of changes in the frequency of a quartz resonator with a 20-layer mixed LB film after exposure to a solution containing Hg^{2+} (1) and Ag^+ (2).

Film: (a) polythiophene **27** : octadecanol (3 : 1); (b) polythiophene **28** : octadecanol (1 : 3).⁹⁹

The time dependence (Fig. 25) shows the lower detection limit of Hg^{2+} ions by the 20-layer LB film. Adsorption where Δf exceeds the ‘noise’ (30 Hz) by a factor of three is chosen as the criterion. Each addition of Hg^{2+} ions with a concentration of 0.1 ppm to the solution where the resonator with the LB film is located produces a sharp change in the resonator frequency. The three changes in frequency shown in Fig. 25 corresponded to changes in the Hg^{2+} mass by 45, 38 and 36 ng. It was noted⁹⁹ that the sensor sensitivity can be increased at least twofold. The sensor selectivity was tested for the 5 ppm concentration of the Hg^{2+} ions. It was found that such cations as Na^+ , K^+ , Ca^{2+} , Pb^{2+} , Cr^{2+} , Co^{2+} and Ni^{2+} (but not Ag^+ and Cu^{2+}) interfere with the determination of Hg^{2+} if their concentrations in solution were twice as high as that of mercury. The same concentrations of anions such as CO_3^{2-} , ClO_4^- , SO_4^{2-} , PO_4^{3-} and Cl^- do not affect the

Figure 25. Dependence of the frequency of a quartz resonator with a 20-layer LB film consisting of mixed (3 : 1) polythiophene **27** : octadecanol monolayers on time of exposure in a solution containing Hg^{2+} . The arrows indicate the instants of addition of Hg^{2+} ions with a concentration of 0.1 ppm (see Ref. 99).

determination of Hg^{2+} , but anions such as Br^- , I^- , CrO_4^- and CNS^- form stable complexes with mercury. Thus, although the sensitivity and selectivity for many cations and anions are high, the problem of selectivity remains unsolved for a number of anions.

Mixed (1 : 1) binary monolayers of polythiophenes **11**, **19** and **20** and octadecylamine were studied with the purpose of obtaining a sensor for NO_2 .²⁴ The compression isotherms for the mixtures have the same character as those of the pure compounds but with lower compressibility and a considerably smaller difference in the monolayer areas; the π – A plot for polythiophene **11** is shifted to larger areas: the limiting monolayer area per thiophene unit increased from 9 to 20 Å². Figure 26 shows the dependences of quartz resonator frequency on the exposure time of a 14-layer LB film composed of mixed binary monolayers of polythiophenes **11**, **19** and **20** and octadecylamine in NO_2 (550 ppm). The differences in sensitivity of films containing the three polythiophenes cannot be caused by differences in the initial mass of the deposited substance as the monolayer areas corresponding to the surface pressure used for their transfer (30 mN m^{−1}) differed insignificantly. Taking into account the identity of the head groups of these compounds, one can state that the observed differences in sensitivity are caused by the side chains. Unfortunately, the sensor reversibility was low: treatment of the films in vacuo at 40 °C for one hour changed the frequency by no more than 10% (see Fig. 26).²⁴ NO_2 can be determined using a reported principle¹⁰⁰ for a gas sensor (for NO_2 , H_2S , NH_3 and others) in which a thin film (not LB film) of electropolymerised polythiophene is used as the working element. Changes in electrical resistance of this sensor upon exposure to NO_2 (an electron acceptor) occur due to chemical doping, whereas in the case of electron-donating gases (for example, H_2S), the resistance changes due to a decrease in the number of charge carriers in the polythiophene film.

Figure 26. Dependence of frequency change on the time of exposure of a 14-layer LB film consisting of mixed (1 : 1) polythiophene : octadecylamine monolayers in NO_2 (550 ppm).²⁴ Polythiophene: (1) **20**; (2) **19**; (3) **11**. The vertical lines indicate the times of turning on (I) and off (II) the NO_2 generator.

VI. Conclusion

The above analysis of the properties of conducting polythiophenes in monolayers and LB films shows that these objects are of significant interest for theoretical study and for practical application. The solubility of polythiophenes in ordinary solvents and formation of rather stable monolayers in one-component systems and definitely stable layers in multicomponent systems (in mixtures with inert and reactive amphiphilic compounds) and their resistance against moisture and oxygen in the initial and doped states make these polymers superior to the known conjugated polymers (for example, polydiacetylene, polypyrrole, *etc.*). Incorporation of substituents at positions 3 or 3 and 4 of the thiophene monomer, control of the chain length and polarity of the substituents and the regularity of their arrangement along the

polymer chain make it possible to control the structural, physicochemical and electrophysical characteristics of polythiophenes in organised planar systems. This primarily corresponds to the control of the effective conjugation length of the polythiophene main chain and to the synthesis of uniformly oriented chains separated by distances which provide charge transfer between the adjacent macromolecules. In certain cases, creation of mixed monolayers of polythiophenes with surfactants (fatty acids, alcohols, amines, *etc.*) increases the stability of monolayers, ensures their transfer onto solid substrates and formation of high-quality multilayer LB films. In these cases, the conducting characteristics of polythiophene films are not inferior to those of similar systems containing pure polythiophenes. The use of dopants allows one to reach the electrical conductivity of substituted polythiophenes in the range from 500 to 1000 S cm^{−1}. The practically important properties of polythiophenes also include the photo- and electrochromic properties as well as the ability to form complexes with metals and gases. These properties enable the use of polythiophenes for creating thin-film light-emitting devices, sensors, *etc.* The Langmuir–Blodgett method has good prospects in this respect as it provides organised ultra-thin films with larger conjugation lengths than those of the films formed from solutions, and hence higher functional capabilities of molecular devices.

Based on the analysis carried out above, we can suggest the directions and priorities in the study of these systems. First, it is necessary to synthesise novel polythiophenes with functional substituents which are regularly distributed along the chain but are not included in each thiophene unit. These substituents can be represented, for example, by azo compounds which can undergo photoisomerisation disturbing the macromolecule conformation, which, in turn, should switch the conjugation length and hence change the conductivity and the chromatic characteristics of the systems. Second, more detailed studies of the structure of monolayers on the surface of water with the use of such methods as optical spectroscopy, Brewster angle microscopy and synchrotron X-ray reflectometry should be carried out. Third, the problem of monolayer stability requires a detailed study. In this connection, studies of the relaxation properties of two-dimensional systems would be rather useful. Fourth, it is necessary to study more intensely the structures of LB films comprising both individual and mixed monolayers. In the latter case, it would be desirable to obtain a consistent model of the distribution of film components in the layers. And, fifth, much greater attention should be given to the development of molecular devices based on LB films consisting of polythiophenes.

Abstract. The potentialities of radical cage reactions as a tool for investigating the chemical structures of polymers are considered. The kinetic regularities of triplet carbene reactions in the matrix-isolated state and in clusters are analysed to reveal structural features of the cage surroundings. The possibility of determination of structural characteristics of filled polymers from kinetic data is discussed. The bibliography includes 103 references.

I. Introduction

The first ideas about the relationship between chemical kinetics and molecular organisation of media were formulated by academician N M Emanuel back in the 1960s. In particular, he initiated studies on the influence of the physical structure of polymeric systems on the kinetics and mechanisms of reactions which occur in them. These studies were aimed, on the one hand, at creating a theory of processes of polymer ageing¹ and, on the other hand, at the development of scientifically substantiated methods for their stabilisation and prediction of their lifetime under different operation conditions.² Numerous studies carried out in this direction have shown that kinetic regularities of the reactions occurring in solid polymers are functions of their physical-structural properties. In particular, the kinetics of such reactions is associated with the kinetics of molecular motions of macromolecules. Simple kinetic laws were found to be as a rule inapplicable for the description of chemical processes occurring in solid polymers at temperatures below $\frac{2}{3}$ the glass transition.^{3–5}

The formal kinetic regularities of a chemical process in a condensed medium depend on the rapidity of changes in local medium properties, which influence the reactivity of the species involved, *i.e.*, on the relationship of three temporal parameters, *viz.*, the characteristic time of a chemical transformation (τ_{ch}), the lifetime (τ_1) of the process-controlling active centre and the correlation time (τ_c), which is sufficient for all the reactive species present in a given medium to pass through all possible states where they have different reactivities.⁶ If the condensed medium is represented by solid polymers, the correlation time is much longer

than the reaction time ($\tau_c \gg \tau_{\text{ch}}$), *i.e.*, dispersion of species as regards their reactivities is observed (such species are kinetically non-equivalent).⁶ The observed process rate depends on the distribution pattern of the reacting species and its variation with time. In this context, the kinetics of even an elementary reaction in solid polymers is determined by a set of rate constants which characterise the reactivity of a species in a particular surrounding. The effect of local structural-physical properties of solid polymers on the kinetics of reactions occurring in them is the reason for the structural ‘memory’ of the reacting species on their initial distribution as a function of reactivity. Therefore, the kinetics of chemical reactions in polymers depend on the sample prehistory.⁷

Despite the complexity of the analysis of experimental results, kinetic studies of the reactions occurring in solid polymers are of a tremendous theoretical and applied interest. These offer a unique opportunity for elucidating peculiarities of the microstructures of these subjects, since the reaction kinetics is dependent on the initial polymer state and on changes in the distribution of reacting species over local structural parameters. The present review considers the validity of the approach to the estimation of structural-physical and molecular-dynamic characteristics of solid polymers based on the kinetic analysis of a series of pseudoelementary radical cage reactions, in particular, low-temperature decay of triplet carbenes, thermal dissociation of dimers of stable radicals as well as dissociation of macroradicals induced by nitrogen dioxide and salts of transition metals.

II. The choice of model reactions for the investigation of structural-physical properties of polymers

Certain difficulties are related to the choice of versatile model cage reactions, the kinetics of which may be purposefully used for structural studies of polymers. Apparently, this objective can be hardly achieved using complex free-radical processes, such as thermo- and photooxidation including migration of free valence, decay of macroradicals and reactions of oxidation products. The point is that it is difficult to isolate the stages sensitive to definite structural-physical properties of the matrix in these multistage

[‡]As the temperature increases (above T_g) the intensity of molecular motions is enhanced and the ‘solid-phase’ formal kinetics approaches the conventional liquid-phase kinetics.

processes on the basis of measured kinetic parameters. Even the simpler reaction of thermal decay of radicals cannot always be used as a model. Thus, the death of macroradicals generated by low-temperature photolysis, radiolysis or mechanical impacts on polymers cannot be regarded as the versatile model suitable for the estimation of structural-physical properties, because in this case the mechanism of macroradical decay is rather complicated and may be accompanied by migration of the free valence over considerable distances as the result of diffusion and chemical relay-race. Numerous studies established a characteristic feature of this reaction in solid polymers, *viz.*, its kinetic arrest at constant temperature or its 'stepwise' character.^{6,8} The nature of this phenomenon was rationalised from different stands taking into account the structural-physical heterogeneity of the matrix,^{9,10} differences in the interradsical distances,¹¹ increased concentration of radicals in structural defects,¹² *etc.* However, the kinetic regularities observed in this process can be regarded only as an indirect indication to the dependence of the reactivity-based distribution of radicals on the structural-physical properties of polymers.

Direct analysis of the relationship between kinetic parameters and structural features of the nearest cage environments is confined to those reactions which are not complicated by migration of active centres over considerable distances. These types of processes include, for example, thermal decay of radical pairs (RP) in a cage. In most cases, RP are formed in low-temperature photolysis and γ -radiolysis of frozen solutions or polymers.¹³ The radical pairs arising in radiolysis are sufficiently stable at the temperature of their generation, and processes of their recombination, disproportionation and their exit from the cage can be investigated in the thermal annealing of samples.

Kinetic studies of the RP formation during photodisintegration of a number of low-molecular-weight additives can be used, *e.g.*, for the establishment of the mechanism of radical initiation in the solid phase. The radical pairs offer a unique opportunity for studying structural-physical properties of the medium. The interradsical distances in such pairs can be measured directly by EPR spectroscopy. Thus it was established from the EPR spectra¹⁴ that the mean distance between radicals in the RP generated in the photolysis of a solution of 3,6-di-*tert*-butyl-*o*-benzoquinone and diphenylamine in chlorobenzene changes from 0.62 to 0.64 nm (the accuracy of measurements was 0.005 nm) in the course of RP accumulation, which may be indicative of different geometry of molecular complexes from which these RP were formed.¹⁵ The radical pairs formed under the action of light in monocrystalline matrices in the course of redox reactions involving molecular complexes of quinonediazides with catechols^{16,17} also proved to be kinetically non-equivalent, as followed from the scatter of the rates of their decay during annealing. The solid-phase transfer of hydrogen atoms accompanied by the formation of RP stable at room temperature has been detected in quinone-catechol polycrystalline mixtures under the action of elastic wave pulses.¹⁸⁻²¹ It was shown that in these systems the polymeric matrix decreases the threshold of the elastic wave strength required for the formation of paramagnetic products and enhances the RP stability. It was established²² that the dispersion with respect to the interradsical distances in RP is proportional to the difference between the maximum and minimum activation energies of their decay.

The kinetic non-equivalence of RP may be determined not only by the differences in the interradsical distances, but also by the structural distinctions of the nearest surroundings.^{23,24} Thus the kinetics of thermal dissociation of RP in oriented polyethylene is described by several rate constants, though the mean distance between the radicals ($r_m = 0.53$ nm) remains constant throughout the process. The formation of four types of RP was established in the low-temperature photolysis of single crystals of tetraphenylhydrazine.²⁵ Their formation results from disintegration of molecules differently oriented in a magnetic field. All the four types

are characterised by identical magnetic properties but different rate constants of their decay.

The kinetics of transformation of the RP generated upon γ -irradiation of dimethylglyoxime and dimethylglyoxime- d_2 had been used for the determination of the constants of their decay, the kinetic isotope effect (KIE), the direction of the free valence migration and the distance of the hydrogen atom transfer.²⁶⁻²⁸ Characteristic features of the free valence migration are its stereospecificity, anisotropy of the valence migration directions and sensitivity to weak molecular interactions.

The process of RP recombination does not require relocations of radicals to considerable distances but is rather sensitive to local molecular motions.²⁹ This allows the use of RP reactions for studies of structural transitions and characteristic frequencies of small-scale molecular mobility in a polymeric matrix. Thus in the temperature range from 160 to 260 K, the curves of RP defrosting in polyethylene revealed two structural transitions in the crystalline regions of the matrix. Structural and phase transitions can also be registered from the mean distance between radicals in RP over a wide temperature range.¹³ Kinetic measurements of the exit of radicals from the cage allow determination of the frequency of translational motions.^{23,30}

In principle, the abstraction of a hydrogen atom from the molecules of the medium by active radicals with the formation of a radical matrix can be used as a model of cage reactions.^{25,30} Taking into account that the distance of hydrogen atom transfer is ~ 0.3 nm, one can presume that the kinetic features of this reaction should reflect directly the structural effect of the nearest cage surroundings. However, examples of kinetic studies of the RP reactions and hydrogen abstraction by radicals are mainly confined to the investigations of frozen solutions of low-molecular-weight compounds as well as of mono- and polycrystalline substances (see, *e.g.*, Refs 31-33).

The effect of structural peculiarities of a polymeric matrix at the level of reaction cages on the kinetics of the reactions occurring in the matrix can be studied using the approach proposed by Denisov *et al.*³⁴⁻³⁷ where the reaction of spatially hindered phenoxyl radicals with the hydroperoxide groups of macromolecules has been used for the development of a model of cage reactions

Reaction (1) is the rate-limiting one. This reaction is slow and is not limited by the diffusion of reagents in the case of regular distribution of radicals in the matrix. The phenoxyl radical and the hydroperoxide group enter the reaction cage and react only when they possess sufficient energy E and have a favourable mutual configurations. However, the walls of the cage prevent the achievement of such configuration, and the more 'rigid' the walls the higher the activation energy of the elementary reaction (1). To study the kinetics of this reaction, a stable nitroxyl radical as a spin probe was added along with a phenoxyl radical to the polymer. In this case, the rate constant of the reaction (1) correlated linearly with the frequency of the spin probe rotation (ν_r). Thus the activation energies of the nitroxyl radical rotation in polyethylene, polypropylene and chlorobenzene measured using the EPR spectra at 290-370 K were 28, 32 and 12 kJ mol⁻¹, respectively. The difference in the activation energies of the nitroxyl radical rotation in polymers and chlorobenzene virtually coincided with those for the reaction (1) in the polymer and chlorobenzene.

The results obtained permitted expression of the rate constant of the cage bimolecular reaction (1) in the form

$$k = \frac{6\nu}{n} K_{AB} P_r P \exp\left(-\frac{E_r + E}{RT}\right), \quad (3)$$

where ν and n are the frequency of collisions and the number of 'neighbours' in the cage, K_{AB} is the equilibrium constant of the

A + B pair formation in the cage, $P_r \exp(-E_r/RT)$ is the probability of rotation of the reagents in the cage resulting in the activated complex configuration and P is the steric factor of the reaction in the liquid phase.³⁶ Thus, the rotation frequency of the reagents in the cage and the frequency-related reaction rate constant characterise the cage surrounding of reagents in polymers.

Of special interest for studies of the microstructures of polymeric objects are versatile cage reactions which can be initiated in various matrices over a wide temperature range. In this connection, many possibilities are provided, *e.g.*, by radical processes such as low-temperature decay of triplet carbenes, macroradical dissociation reactions induced by nitrogen dioxide and photoreduction of transition metal salts and thermal dissociation of dimers of stable radicals.

III. Assessment of the structural-physical heterogeneity of polymers from the kinetics of thermal decay of carbenes

Carbenes are most often generated in thermal, thermocatalytic and photochemical degradation of diazo compounds.³⁸ The reactivities of the carbenes formed depend on their spin states.^{39, 40} Insertion into ordinary chemical bonds in a one-step mechanism and also stereospecific addition to double bonds with formation of cyclopropanes are typical reactions of carbenes in a singlet state. The triplet carbenes are also characterised by insertion reactions but these are multistep reactions. Let us consider the reaction of low-temperature decay of triplet carbenes in solid polymeric matrices.

In the first step, the transfer of hydrogen atom[§] from the surrounding macromolecules to a matrix-isolated triplet carbene results in the formation of a short-lived RP in the triplet state which then undergoes triplet–singlet conversion. The RP in the singlet state resulting from this conversion can recombine with formation of the final product of carbene insertion into the C–H bond of the macromolecule. The dynamics of H atom transfer and RP recombination in polymers depends on the polymer structure.

The frequency of the triplet–singlet transition in RP is $\sim 10^8 \text{ s}^{-1}$ (Ref. 41). It is known that the frequency of small-scale molecular motions associated with rotational oscillations of the side groups of macromolecules is of the same order.⁴² Thus, the spin evolution of RP generated in reaction (4) is within the same time scale as the molecular dynamics, which determines dislocations and rotations of the side groups of macromolecules in the cage.

Numerous studies have shown that if the ground state of carbenes is triplet, then the efficiency of carbene transformations by the ‘abstraction–recombination’ mechanism (4) in the transition from the liquid to the solid phase with a decrease in temperature is drastically increased.^{38, 43, 44} The effective constants of the decay rate of triplet carbenes determined experimentally at cryogenic temperatures are very small. For example, they amount to $10^{-3} - 10^{-4} \text{ s}^{-1}$ for different frozen organic matrices (Ref. 45).

One should note the principal distinction of the short-lived RP, appearing as active intermediates in the process of triplet carbene decay from the RP which can be registered owing to the characteristic EPR spectra in frozen solutions of low-molecular-

weight compounds and polymers.¹³ The former type includes the short-lived species whose lifetime in the cage is comparable with the time of their spin conversion ($\sim 10^{-8} \text{ s}^{-1}$). They cannot be recorded by the usual EPR method. However, the existence of such species is confirmed by the influence of the magnetic field on the decay rate of the triplet di-*tert*-butylcyclohexadienone carbene (BCHC) (at 77 K) in hexaethyldisiloxane, ethyl acetate, poly(methyl methacrylate) (PMMA) and cellulose triacetate (CTA).^{46, 47}

The high decay rate of the intermediate RP formed in this process is determined by a small interrational distance ($\sim 0.3 \text{ nm}$) and retardation of rehybridisation of chemical bonds⁴⁸ in the radicals of the ion pair due to difficulties in structural relaxation. As a result of relaxation processes, such pairs can be transformed into RP of the second type ($r > 0.3 \text{ nm}$) which are comparable with free radicals in their thermal stabilities.

1. The effect of spatial orientation factors on the decay kinetics of carbenes in polymers

A characteristic feature of cage reaction (4) of low-temperature decay of carbenes in solid polymers is the kinetic non-equivalence of species.⁴⁹ The time dependence of carbene concentration (N) is described by the following expression:

$$N(t) = N_0 \int_{k_{\min}}^{k_{\max}} \rho(k) \exp(-kt) dk, \quad (5)$$

where $\rho(k)$ is the distribution function of carbenes over decay rate constants. It is natural to presume that the reactivities of carbenes depend on local orientations of the carbene centre and the C–H bonds of the macromolecular matrix in the cage, with a definite decay rate constant corresponding to each orientation. In the system of reaction cages, the distribution $\rho(k)$ changes with the gradual disappearance of carbenes which are best suited for the H atom transfer onto them. Because there is strong restraint of molecular motions in the solid matrix at low temperatures, the favourable orientations of carbenes are not recovered. This structural effect was illustrated by the dependence of the initial decay rate of diphenylcarbenes (DPC) in propanol at 77 K on the duration of their photoregeneration from diphenyldiazomethane (DDM).^{50, 51}

The results reported by Bauschlicher *et al.*⁵² can be used for the theoretical substantiation of the decisive effect of carbene distribution over spatially oriented parameters on their kinetic non-equivalence in the insertion into the C–H bonds of the solid matrix. These authors calculated the ideal geometric configuration of the classical transition state, which corresponds to the minimum height of the potential barrier of the reaction of triplet methylene with a hydrogen molecule and methane. It was shown that hydrogen atom transfer over the trajectory lying in the methylene plane and passing along the bisecting line of the H–C–H angle corresponds to this configuration:

In this case the calculated height of the potential barrier was 103 kJ mol^{-1} . Upon changes in the geometric configuration of the transition state, *i.e.*, the deviation of the trajectory of the migrating hydrogen atom from the ideal one by $20-40^\circ$, the height of the potential barrier increased to 110 kJ mol^{-1} .

The decay kinetics of cyclohexadienone carbenes (CHC) in PMMA at 77–160 K is well described by the equation⁵³

§ The transfer of an H atom requires the approaching of carbene and C–H bond of the macromolecule to a distance of 0.3–0.4 nm and it is these distances that are realised in the cage.

$$N(t) = N_0 \exp(-at^{1/2}), \quad (6)$$

where a is the temperature-dependent parameter. This equation also describes the decay of other carbenes in the glassy and polycrystalline matrices of low-molecular-weight compounds.^{51,54,55} Kinetic equation (6) is derived from Eqn (5) where the distribution function $\rho(k)$ is expressed as:^{56,57}

$$\rho(k) = \frac{a}{k^{3/2}} \exp\left(-\frac{a^2}{4k}\right). \quad (7)$$

The distribution function (7) has a maximum at $k = a^2/6 = k'$. The latter value is the most probable magnitude of the rate constant. Thus, the observed kinetic regularities of the CHC decay in PMMA are explained by the distribution of decay rate constants over the species.

A different kinetic law was established for the decay of BCHC in PMMA.⁵⁸ In this case, the kinetic curves are linearised in the coordinates N/N_0 vs. $\ln t$. It is this kinetic description that is characteristic of the processes with a kinetic arrest, for which the function of distribution over rate constants has usually the form⁵⁹

$$\rho(k) = \frac{1}{k \ln(k_{\max}/k_{\min})}, \quad (8)$$

where $k_{\max}$ and $k_{\min}$ are the boundary values of rate constants. Function (8) corresponds to a rather wide distribution of carbenes with respect to their reactivities, while the kinetic dependence satisfying this distribution is expressed as

$$N(t) = N_0 \left[-\frac{\ln(k_{\min}t)}{\ln(k_{\max}/k_{\min})} \right]. \quad (9)$$

Yakimchenko and Degtyarev⁵⁷ noted that the distribution function (7) is approximated by function (8) for the values of $k > k'$, i.e., where the distribution of species over rate constants is rather narrow: $\ln(k_{\max}/k_{\min}) < 10$. In this case, the k' value correlates with $k_{\min}$, whereas the $k_{\max}$ value may be determined from the initial decay rate of carbenes.

The effect of the spatial orientation factor on the kinetic non-equivalence of carbenes results directly from comparison of the reactivities of CHC and BCHC. Thus at 77 K, the width of distribution regarding the rate constants of CHC decay $\ln(k_{\max}/k_{\min})$ is equal to 5, whereas the same parameter for BCHC is 13. Apparently, introduction of bulky *tert*-butyl substituents into the carbene structure increases the set of the carbene centre orientations relative to the C–H bonds of the surrounding macromolecules and largely expands the distribution of carbenes regarding their reactivities.

The temperature dependences of the rate constants of the H atom transfer to carbenes in polymers (e.g., upon decay of DPC in PMMA) confirm the decisive effect of spatial orientations in the cages on the kinetic non-equivalence of carbene species, which is evidenced by an obvious deviation of these dependences (Fig. 1, lines 1 and 2) from the Arrhenius law (dashed lines in Fig. 1). The effective activation energies decrease with a decrease in temperature from 12–16 kJ mol⁻¹ to an abnormally low value of ~ 5 kJ mol⁻¹ (see Refs 49, 53, 58, 60–62).

The qualitatively similar temperature dependences were also observed for the cage reaction of hydrogen atom abstraction from the solid matrix molecules by free radicals following the tunnelling mechanism.^{31,63} This mechanism takes into account the intermolecular oscillations resulting in changes in the height and width of the potential barrier of the process.^{31,64,65} The temperature dependences of rate constants in both processes can be expressed by the exponential law

$$k(T) = \alpha \exp(\beta T), \quad (10)$$

where α and β are the parameters characterising the properties of the species and the matrix.

Figure 1. Temperature dependences of the rate constants of DPC decay in PMMA $k_{\max}$ (1, 1') and $k_{\min}$ (2, 2');⁶⁰ (1) and (2) dependences of the form $-\ln k \sim T$; (1') and (2') dependences of the form $-\ln k \sim (1/T)$.

It should be noted that the dependence (10) is well described by the tunnelling mechanism of H atom transfer for the entire series of carbenes, as indicated by the similarity of temperature dependences for $k_{\max}$ and $k_{\min}$. The corresponding representations of $k_{\max}$ and $k_{\min}$ in the reaction of DPC decay in PMMA are presented in Fig. 1 (curves 1' and 2'). These results show that the kinetic non-equivalence of carbenes in polymers is due to the same reason, viz., the scatter of parameters (the width and height of the potential barrier) of the tunnelling transfer of the hydrogen atom. The width of carbene distribution with respect to these parameters is in turn determined by geometric heterogeneities of the reaction cages.

According to the tunnelling model of H atom transfer, a bond of the hydrogen-bond type is formed between the C–H bond of the matrix molecule and carbene.

Molecular oscillations in this complex result in changes in the permeability of the potential barrier to H atom transfer. The higher the temperature the larger the amplitude of intermolecular oscillations and the closer the reagents can come to each other and, consequently, the more probable is the tunnelling process. Thus, the effective potential barrier decreases as the temperature increases, and the rate of the process increases accordingly. Vorotnikov *et al.*^{61,66,67} determined the values of parameters for the tunnelling of H atom to CHC and DPC in the same polypiperylene matrix. The height U and the width x of the potential barrier as well as the equilibrium distance (R_0) between carbon atoms of the active centre of carbene and the C–H groups of polypiperylene in the carbene–polypiperylene complex were determined from the kinetic data obtained at 77–133 K. The boundary values of these parameters, which correspond to the maximum and minimum rate constants of carbene decay, are presented in Table 1. These results indicate that the width and height of the potential barrier decrease with the increase in temperature. These values are somewhat higher for DPC than for CHC, which is indicative of the higher CHC activity in the reaction of H atom abstraction in the same polymeric matrix.

Also worthy of note is the proximity of parameters of the hydrogen atom tunnelling from macromolecules to triplet carbenes and the corresponding values of parameters of the H atom tunnelling to macroradicals in their low-temperature decay by the relay-race mechanism.⁶⁵

The frequencies of intermolecular oscillations in a polymer which activate the H atom transfer were estimated from the KIE determined for the low-temperature decay of BCHC and DPC in common and perdeuterated PMMA and polystyrene (PS). The

^a In kJ mol⁻¹.

KIE was shown to be dependent on the reactivities of carbenes. Ensembles of carbenes characterised by higher decay rate constants manifest lower KIE at a given temperature. At $T > 100$ – 115 K, the kinetic isotope effect virtually disappears. The regularities observed are explained in terms of the model of H atom tunnelling across a potential barrier which oscillates due to intermolecular vibrations.

It was shown that for a temperature increase in the range

$$\frac{\hbar\Omega}{4k} < T < \frac{\hbar M\Omega^2}{m\omega_{\text{C}} + \hbar k}$$

[Ω is the characteristic frequency of intermolecular vibrations in the complex, M is the normalised mass of the carbene-CH (or CD) group complex] the KIE should decrease linearly in reactions of hydrogen atom transfer in conformity with the equation

$$\ln \frac{k_{\text{H}}}{k_{\text{D}}} = \left[\frac{\Theta^{1/2} R_0^2 (m_{\text{D}}^{1/2} - m_{\text{H}}^{1/2})}{2\hbar} \right] - \left[\frac{\Theta R_0^2 k T (m_{\text{D}} - m_{\text{H}})}{2\hbar^2 M Q^2} \right], \quad (11)$$

where $\Theta = m_H \omega^2_{C-H} = m_D \omega^2_{C-D}$ is the parameter characterising the rigidity of the C-H and C-D bonds; R_0 is the distance between the potential wells for the H and D atoms. At higher temperatures

$$T > \frac{\hbar M \Omega^2}{m \omega_{\text{C-H}} k}$$

KIE varies in conformity with the T^{-2} law:

$$\ln \frac{k_H}{k_D} \approx \frac{\hbar}{2\Theta^{1/2}} \left(\frac{1}{m_H^{1/2}} - \frac{1}{m_D^{1/2}} \right) \left(\frac{M\Omega^2 R_0}{kT} \right)^2. \quad (12)$$

Analysis of KIE in the reaction of BHC decay in PMMA^{66,67} was performed using relations (11), (12) and the condition $T \approx \hbar m \Omega^2 / m \omega_{C-H} k$, under which the linear temperature dependence is transformed into a T^{-2} dependence. The derived values of characteristic frequencies of intermolecular vibrations ($\Omega \approx 53 \text{ cm}^{-1} \approx 10^{13} \text{ s}^{-1}$) correlate with the Debye frequencies for molecular crystals.⁶⁸ The difference of distances ΔR_0 between potential wells in the reaction of H(D) transfer in different kinetic ensembles of carbenes was also determined from the temperature dependence of KIE.^{48, 66, 69} It turned out that the decrease in the rate constant of BHC decay by one order of magnitude corresponds to $\Delta R_0 \approx 0.006 \text{ nm}$. Such a drastic rate dependence on the distance between reagents is in agreement with the tunnelling mechanism of H atom transfer to triplet carbenes.

Unique information about the nature of the kinetic non-equivalence of carbenes in solid polymers can be obtained from studies of the magnetic field effect (MFE). Numerous literature data (see, *e.g.*, Refs 70–72) demonstrate the possibility of using this effect for the establishment of a detailed mechanism of

Figure 2. Effect of magnetic field on the rate of BCHC decay in PMMA (1) and CTA (2) at 77 K.⁶⁷

processes involving RP. The application of a magnetic field was shown^{46, 67, 69} to influence noticeably the rate of low-temperature decay of BCHC in PMMA and CTA (Fig. 2); however, the character of this influence is different. Based on experimental dependences $W = f(H)$, the effect of magnetic field is explained by the strong exchange interaction J between unpaired electrons and short-lived RP.⁷¹ From the character of MFE, one can draw a conclusion about the existence in polymers of a set of RP differing in energies of exchange interactions. Poly(methyl methacrylate) is more homogeneous than cellulose triacetate, which is reflected in a smaller set of cages with different exchange energies in the radical pairs. The distribution of RP with respect to J corresponding to the scale of the observed effect is determined by the orientational factor associated with different angles of rotation of the axes of the orbitals of unpaired electrons relative to each other in RP.⁷³

The effect of magnetic field on the decay of carbenes in solid polymers is analogous to its influence on their decay in low-molecular-weight organic glasses; however, the scale of the MFE is different. This provides evidence that the extent of differences in the character of MFE is determined not only by the nature of RP, but also by the nature of the matrix. In low-molecular-weight glasses, the reaction cages are more homogeneous with regard to the structural-physical parameter J compared to polymeric matrices.

2. Determination of molecular-dynamic characteristics of polymers from the transformation kinetics of carbenes in clusters

Diazo compounds, like many low-molecular-weight additives, are irregularly distributed in solid polymers due to the existence of defects in the packing of macromolecules.⁷⁴ This leads to a higher concentration of diazo compounds in the regions with a decreased packing density of macromolecules, which can result in the formation of clusters. Thus EPR spectroscopy revealed that photolysis (at 77 K) of DDM in common and perdeuterated PMMA, PS and polycarbonate (PC) resulted in carbenes $\text{Ph}_2\text{C:}$ formed in the matrix-isolated state and also biradicals **1**^{75, 76} generated in the regions with a decreased packing density of macromolecules due to conversion of DPC dimers (**2**) in clusters according to the scheme

The EPR spectrum of biradicals generated in reaction (13) is shown in Fig. 3*a*. It represents an anisotropic signal with the parameters of cleavage in a zero field $D_{\perp} = 11$ mT and $D_{\parallel} = 22$ mT. The mean distance between unpaired electrons is 0.63 nm. The formation of biradicals in reaction (13) is confirmed by the increase in their yields at higher DDM concentrations. At

Figure 3. EPR spectra of biradicals generated in the photolysis of polymers supplemented with DDM at 77 K.⁷⁵ [DDM] (mol kg⁻¹): (a) 0.1; (b) 0.2.

sufficiently high [DDM] (~ 0.2 mol kg⁻¹) a signal of biradicals comprising three or more DPC fragments appears in the central part of the EPR spectrum (Fig. 3 b):

Such species arise in bulkier clusters, their proportion in PC and PMMA does not usually exceed 20% of the total quantity of biradicals.

Reactions of carbenes localised in clusters are interesting in two respects: the yield of biradicals **1** reflects the irregularity of the distribution of carbene precursors as regards their concentrations and this can also be used for the estimation of distribution of other low-molecular-weight additives as regards their concentrations in solid polymers. For example, an analogous distribution of bimolecular, trimolecular and larger clusters should apparently be expected for a number of photostabilisers, antioxidants and photosensitisers (salicylates, bisphenols, benzophenones).

In addition, the kinetics of biradical formation may be used to characterise the intensity of molecular mobility of the cluster surrounding. The kinetics of biradical generation in clusters at 77–120 K is well described by the logarithmic dependence on time. Analysis of experimental kinetic dependences performed by Davydov *et al.*^{66,75} made it possible to establish the distribution pattern of rate constants as regards the Arrhenius parameters. In general case, the reactivities of carbenes in clusters can be determined from the distribution with respect to both effective activation energies of reaction (13) and preexponents.⁷⁷

Figure 4 shows the integral distribution functions $\Theta(E)$ and $\Theta(k_0)$ for the formation of biradicals involving DPC in polycarbonate. As the dependences shown in Fig. 4 are virtually linear, the functions of carbene distribution in clusters with respect to the Arrhenius parameters may be regarded as 'rectangular':

$$\frac{d\Theta(E)}{dE} = \frac{1}{(E_{\max} - E_{\min})}, \quad E_{\min} \leq E \leq E_{\max};$$

$$\frac{d\Theta(k_0)}{d \log k_0} = \log \left(\frac{k_0^{\max}}{k_0^{\min}} \right), \quad \log k_0^{\min} \leq \log k_0 \leq \log k_0^{\max}.$$

The limit values of the Arrhenius parameters in PC are as follows: $E_{\max} = 38$ kJ mol⁻¹, $E_{\min} = 26$ kJ mol⁻¹, $\log k_0^{\max} = 14.4$, $\log k_0^{\min} = 12.8$. The values of the activation energy are typical of the relaxation processes in RP determined by motions of monomer units of macromolecules. These values are in good

Figure 4. Integral functions of DPC distribution with respect to the Arrhenius parameters of biradical generation in PC.⁷⁵

agreement with the activation energies of the spin probe rotation.^{78,79} Thus, it may be concluded that the rate of reaction (13) in PC is controlled by the vibrational mobility of carbenes in clusters. Indeed, the values of $k_0 = 10^{13} - 10^{14}$ s⁻¹ are comparable with the frequencies of motions of low-molecular-weight species in polymers. One should note a relatively narrow dispersion of the Arrhenius parameters in PC: $\Delta E = 12$ kJ mol⁻¹, $\log k_0 = 1.6$.

In PMMA, the limiting values of the Arrhenius parameters are as follows: $E_{\max} = 50$ kJ mol⁻¹, $E_{\min} = 22$ kJ mol⁻¹, $\log k_0^{\max} = 16.0$, $\log k_0^{\min} = 10.5$ kJ mol⁻¹. The mean values of these parameters ($E_{\text{mean}} = 36$ kJ mol⁻¹, $\log k_0^{\text{mean}} = 13.25$) correlate with the activation energy of rotation and the correlation time of the spin probe in PMMA ($E = 38 - 42$ kJ mol⁻¹, $\log \tau = 13.2$).⁷⁸ Of definite interest is a rather broad dispersion of parameters ($\Delta E = 28$ kJ mol⁻¹, $\Delta \log k_0 = 5.5$), which seems to be due to a large set of molecular motions in PMMA at given temperatures. Indeed, the relevant calculations⁸⁰ show that the activation energy of rotational motions in the ester groups of PMMA with concomitant vibrations of the main chain segments near the equilibrium positions is 21.6 kJ mol⁻¹. This value correlates with the minimum activation energy of biradical formation. The activation barrier to rotation of the ester groups increases with the deviation of rotation angles of the main chain segments from their equilibrium values. Relevant calculations give a maximum potential barrier of 68 kJ mol⁻¹ for the torque vibrations about the C–C bonds of the main chain.⁸⁰ Therefore, the increase in the activation energy of reaction (13) to 50 kJ mol⁻¹ is indicative of the existence of ensembles whose reactivities are controlled by the mobilities of segments of the main macromolecular chain.

The results obtained^{75,76} make it possible to consider the reaction of biradical formation in DPC clusters as a specific probe for studying the molecular dynamics of macromolecules at low temperatures. The conventional method based on the use of a paramagnetic probe⁷⁹ is little suited for studies of molecular mobility in polymers at temperatures below the glass transition point. For $T < T_g$, EPR spectroscopy makes it possible to record only a part of the high-frequency spectrum of vibratory motions of the probe. The method based on measurement of the kinetics of DPC transformation in clusters extends considerably the temperature range for studies of the small-scale dynamics of macromolecules. This allows determination of molecular-dynamic characteristics of polymers in the temperature range 90–220 K where the use of other methods is problematic.

IV. Estimation of structural characteristics of filled polymers from the kinetics of cage reactions

Structural-physical modification of polymers at the macroscopic level has a strong effect on the reactivities of radicals in the cage. One of the most popular methods for the modification of the physical structure of polymers is to fill them with inorganic additives. Numerous studies have shown that the effect of polymer filling is associated with the formation of boundary layers^{81–85} with structures noticeably different from the bulk structure of

polymeric medium. The effective width of the boundary layer measured experimentally was found to reflect the behaviour of the filled system in respect of the property under study, *i.e.*, this characteristic can be changed depending on the technique used for its measurement. Information about the boundary layers is as a rule derived from physicochemical parameters which are essentially dependent on the degree of filling, *e.g.*, from the heat capacity (in the range of glass transition temperatures),⁸⁶ density⁸³ and viscosity.⁸⁷ Due to a close relationship between the structural-physical properties of polymers and the kinetics of reactions occurring in them, investigation of kinetic dependences may also be regarded as an informative method for the determination of structural characteristics of filled polymers, in particular of the effective thickness of the boundary layers.

There is a large body of literature data devoted to the analysis of regularities of the thermal decay and thermal oxidation of filled polymers (see Bryk's monograph⁸⁸ and references cited therein). The available information points to a substantial role played by the filler in these processes. However, at high temperatures the kinetics can be influenced, in addition to the structural-physical factor, by the catalytic properties of the filler surface. From this viewpoint, the use of cage radical reactions occurring at low and moderate temperatures offers definite advantages for the estimation of the effect of the structural factor. The kinetics of these reactions should reflect peculiarities of the molecular organisation of boundary layers and the reactions must not be complicated by the interaction of radicals with the filler surface.

1. Effect of the filler on the kinetics of low-temperature decay of matrix-isolated carbenes

Filling of PMMA and TFC with Aerosil decreases the rate of low-temperature decay of BCHC in these polymers.^{66, 89} This effect was observed at 100–140 K. The increase in the filler content decreases the limiting rate constants $k_{\max}$ and $k_{\min}$; however, the width of the distribution as regards the rate constants $\log(k_{\max}/k_{\min})$ remains invariable and amounts to 6.8 in PMMA and 5.5 in CTA at 100 K. As the temperature increases, the constancy of the distribution with respect to the reaction rate constants under isothermal conditions is also confirmed by the approximation of the stepped kinetic curves to the equation

$$\frac{N}{N_0} = (1 + nk_0t)^{-1/n},$$

where n is the parameter characterising the distribution width of carbenes as a function of their reactivities and k_0 is the mean effective rate constant.⁹⁰ Despite different contents of Aerosil, the kinetics of low-temperature BCHC decay in PMMA and CTA is characterised by the parameter n which is constant at a given temperature.^{69, 89}

Figure 5 shows the dependence of k_0 on the distance l between the filler particles. One can see from the graphs presented in Fig. 5 that k_0 varies little at $l > 20$ nm, though it decreases by more than one order of magnitude at $l < 20$ nm. Such a drastic drop of the process rate is related to changes in the physical structure of the polymeric matrix upon transition to the state of boundary layers. The structural rearrangement changes the ratio of the rates of individual stages of BCHC decay as well as the relative population density of the triplet and singlet states of the intermediate RP resulting from changes in their configurations and, consequently, in the exchange energies. All these factors lead to a lower k_0 constant. The kinetic data obtained indicate that the effective thickness of the boundary layers of the filler in PMMA and CTA ranges from 15 to 20 nm.

Figure 5. Dependence of the mean rate constant of BCHC decay on the distance between Aerosil particles in PMMA (a) and CTA (b);⁸⁹ (a) $T = 100$ (1), 113 (2), 125 K (3); (b) $T = 100$ (1), 125 (2), 135 K (3).

2. Effect of the filler on the kinetics of carbene transformation in clusters

In the example of filled PC, the reaction (13) of generation of biradicals in DPC clusters is shown to be noticeably influenced by the presence of a filler.^{75, 76} Figure 6 shows the temperature dependence of the molecular mobility (the 'defrosting' curves), which reflects the reactivity of carbenes and biradicals in DPC clusters, on the Aerosil content in PC. The maximum quantity of biradicals is formed in the Aerosil-free PC at 130–150 K, while the molecular mobility is unfrozen for all ensembles of carbenes. In the filled samples, the maximum is shifted towards lower temperatures ($T \approx 120$ K), because at $T > 120$ K the biradicals

Figure 6. Temperature dependences of the yield of biradicals in the Aerosil-free (1) and Aerosil-filled (2, 3) PC.⁷⁵ The content of the filler (mass %): 50 (2), 65 (3).

are thermally destroyed in these samples. The different time course of the unfreezing curves is determined by a considerable decrease in the thermostability of biradicals with the increase in the degree of polymer filling. The kinetics of biradical decay in PC at different filler contents may be used for the estimation of the effective thickness of boundary layers.⁷⁵ We give below the initial decay rates of biradicals (BR) in the filled PC at 146 K, relative to their initial concentration depending on the proportion (vol.%) of Aerosil V_a .

V_a (%)	0	22	30	40
$(W_0/[BR]_0) \times 10^4 / s^{-1}$	0.25	3	9	15

The non-additive character of the initial rate dependence on V_a and its dramatic increase at $V_a > 20\%$ are determined by the transition of the polymer to the structural state of the boundary layer. The boundary layer thickness was found to be 12 nm. This magnitude is rather close to the value derived from the filler effect on the decay kinetics of the matrix-isolated carbenes.

3. Effect of the filler on the transformation kinetics of macroradicals

Structural modification of polymers upon their filling is reflected in the kinetics of other elementary reactions, in particular of the monomolecular decay of macroradicals. Thus it was found that the kinetics of the radical decay of polyvinylpyrrolidone (PVP) initiated by photoreduction of Fe(III) additives at 77 K^{49,91,92} is dependent on the presence of a filler.

Degradation of the radical cations **3** in the thermal stage results in the formation of macroradicals **4** which are identified from their EPR spectra. The effect of the Aerosil filler on the efficiency of generation of the radicals **4** is reflected by the unfreezing curves shown in Fig. 7. The maximum relative quantity of the radicals **4** is registered at 180–200 K. This characterises the proportion of their precursors, *viz.*, radical cations **3**, which are stabilised in the low-temperature photolysis of samples. It follows from the plots shown in Fig. 7 that in highly filled PVP only 10% of the radical cations **3** are stabilised at 77 K, whereas their content reaches $\sim 70\%$ in non-filled samples. The non-linear character of variation of the radical concentration at a given

Figure 7. Temperature dependences of the yield of macroradicals **4** in the Aerosil-free (**1**) and Aerosil-filled (**2**, **3**) PVP. The filler content (mass %): 15 (**2**), 50 (**3**).⁹²

temperature as a function of the filler content is determined by the structural transition occurring in PVP upon addition of definite amount of Aerosil, *i.e.*, upon transition of the polymeric phase to the boundary layer state. The effect of structural modification on the efficiency of transformation of the radical cations **3** in reaction (14) is particularly strong where the amount of the filler is 50 mass%, which makes the distance between the filler particles equal to ~ 25 nm. This distance may be regarded as the effective thickness of the boundary layer. The observed effect seems to be caused by the formation of a looser molecular packing compared to that in the polymer bulk. The decrease in the molecular packing density favours the lowering of the energetic barrier to rehybridisation of the carbon atom⁴⁸ in macroradicals **4** from the sp^3 to the sp^2 configuration in the reaction (14). As a result, the activation energy of reaction (14) is decreased in the case of filled PVP compared to that in the non-filled polymer and the concentration of the radicals **4** increases accordingly in the photoinitiation at 77 K.

The application of the above reactions to the structural studies is limited to rather low temperatures. The expansion of the temperature range requires further search for radical reactions, the kinetics of which reflect the structural effect under conditions of usual and elevated temperatures and can be measured in a fairly simple manner.

From this standpoint, highly interesting are the reactions in which active radicals may be transformed into stable radicals which can be recognised by their characteristic EPR spectra. Thus dissociation of the radicals **4** leads to the pyrrolidone ring opening, which is accompanied by the formation of radicals **5**.

However, because of their low stabilities, radicals **5** could not be registered by EPR spectroscopy. For this reason, the course of reaction (15) was monitored by following the transformation of the radicals **5** into stable nitroxyl radicals under the action of nitrogen dioxide on the initial and Aerosil-filled (50 mass %) PVP.^{93,94} Under these conditions, free-radical transformations of PVP occur according to the following scheme:⁹⁵

These reactions result in the formation of two stable nitroxyl radicals, *viz.*, **7** and **8**. The EPR spectrum recorded after exposure of PVP in NO_2 represents superimposition of the signals from these radicals (Fig. 8a). The content of the radicals **7** is markedly

Figure 8. The EPR spectra of polyvinylpyrrolidone after its irradiation in the presence of NO_2 .⁹⁴ (a) Aerosil-free PVP; (b) PVP with 50 mass % of Aerosil.

increased in highly filled PVP (Fig. 8b). This fact points to an increase in the efficiency of formation of their precursors, viz., radicals **5**, in reaction (15) owing to a decreased density of molecular packing upon formation of boundary layers. Thus, the proportion of the signal from the radicals **7** in the overall EPR spectrum may be regarded as an indirect characteristic of the depth of the structural-physical modification of the filled polymer.

4. Kinetic features of the dissociation of radical dimers in filled polymers

Structural characteristics of filled polymeric compositions can be estimated at relatively high temperatures using the cage reaction of thermal dissociation of diphthaloylthane (DPE) into two stable radicals.^{96–98}

The reaction (16) is an equilibrium one in liquid state. However, kinetic studies of the DPE-free radicals system in CTA at 320–370 K pointed to a more complex mechanism of this reaction in the solid polymer matrix.^{99, 100}

In the temperature range 320–334 K this process follows the scheme

In the first step, dissociation of DPE yields RP. The rigid cage surrounding it prevents the exit of radicals from the cage. Therefore, some radicals recombine in the cage, while those released into the bulk of the system are transformed into initial DPE as a result of diffusive collisions. At higher temperatures (344–364 K), the reaction scheme is different, which is related to the change in the

mechanism of radical decay. In this case, the linear loss of radicals occurs instead of the quadratic loss.

Taking account of the steady-state concentrations of RP and provided $k_{-1} \gg k_2$, the equations for the steady-state concentrations of radicals are expressed as

$$[\text{R}^{\bullet}]_c = \sqrt{\frac{k_1 k_2 [\text{DPE}]_0}{k_{-1} k_3}}, \quad (17)$$

$$[\text{R}^{\bullet}]_c = \frac{k_1 k_2 [\text{DPE}]}{k_{-1} k'_3}. \quad (18)$$

Structural modification of CTA upon its filling with Aerosil (up to 60%) influences the reactivity of the radicals $\text{R}^{\bullet}$. This effect is demonstrated in Fig. 9, which shows the temperature dependences of the steady-state concentration of radicals in the original and Aerosil-filled CTA. At $T > 340$ K, the concentrations of $\text{R}^{\bullet}$ in the filled samples are higher than those in the Aerosil-free samples. However, the reverse temperature dependence is observed in the high-temperature range. The increase in the steady-state concentration of radicals in the filled CTA at 320–344 K is associated with the decrease in the efficiency of radical decay and lower values of the parameters $k_{-1} k_3$ and $k_{-1} k'_3$ relative to the parameter $k_1 k_2$ in equations (17) and (18). This is also evidenced by the results of measurement of the temperature dependence of the correlation time of the spin probe rotation.^{99, 100} The effective activation energy of the probe rotary mobility increased from 4.6 kJ mol^{−1} in non-filled CTA to 7.6 kJ mol^{−1} in CTA containing 60 mass % of Aerosil, i.e., filling has a substantial effect on the molecular dynamics and hence on the ratio of rate constants in individual stages of the radical process.

Figure 9 shows that the temperature coefficient of the change in $[\text{R}^{\bullet}]$ variation becomes negative for the highly filled CTA at $T > 340$ K. In CTA containing 30 mass % of Aerosil, an intermediate situation is realised in which only a decrease in the efficiency of radical formation was observed as the temperature was increased. These facts indicate that structural modification upon filling influences most effectively the decay of radicals. It is for this reason that the inversion of the dependence shown in Fig. 9 is observed in the region of transition of the quadratic decay of radicals to the linear one. The mean distance between the filler particles in CTA with 60 mass % of Aerosil is estimated as ~ 10 nm. This distance corresponds to the overlapping of bound-

Figure 9. Temperature dependence of the mean radical concentration upon dissociation of DPE in Aerosil-free (1) and Aerosil-filled (2, 3) CTA.¹⁰⁰ Aerosil content (mass %): 30 (2), 60 (3).

dary layers and transition of the entire polymer to a new structural state. Thus, the exit of stable radicals from the cage in the process of thermal dissociation of DPE is rather sensitive to changes in the molecular organisation upon filling of the polymer and can characterise the degree of its structural-physical modification.

V. Conclusion

The kinetics of radical cage reactions demonstrates their clear-cut dependence on the physical structure of solid polymers and filled compositions. A distinctive feature of the processes considered above is their versatile character as regards their possible implementations in diverse polymers and composites over a wide temperature range (77–350 K), viz., from cryogenic to relatively high temperatures. A strong dependence of kinetic parameters on structural factors makes it possible to use such reactions as a sensitive tool for estimating the structural-physical modification of polymers. The results of kinetic studies of radical reactions in polymers can also be of independent significance in designing kinetic models of chemical processes characterised by their spatial-temporal disorder.^{101–103}

Based on the results obtained up to now, it may be concluded that the kinetic regularities of the processes considered reflect physical structures of polymers both on local levels as well as on the scale which is much larger than the sizes of reaction cages. This is evidenced primarily by the results obtained in the studies of the reactions of triplet carbenes. For example, the effect of magnetic field on the kinetics of their low-temperature decay is determined by the distribution of intermediate RP with respect to geometric configurations defined by the nearest cage surrounding. It should be noted that the kinetics of this cage process is rather sensitive to relatively large-scale structural changes which involve the 15–20 nm thick interface layers in filled polymers.

The use of the above 'kinetic' approach in studies of the physical structures of polymers is undoubtedly limited. Today, based on the results obtained, one can speak solely about the possibility of comparative estimation of the extent of structural-physical modification reached in a definite way in a given polymeric material. Thus the dependences of kinetic parameters on the content of a filler may be instrumental in the establishment of polymer transition to a qualitatively different structural state (highly filled polymer) in which the boundary layers begin to overlap. Analogous conclusions about changes in the physical structure may be drawn by measuring yields of definite radicals in the reactions under study. In some cases, kinetic parameters can characterise indirectly the frequencies and energetics of the small-scale molecular mobility.

The difficulties encountered in the attempts to elucidate structural peculiarities based on kinetic data are often due to the fact that the mechanisms underlying the effect of molecular organisation of polymers on the reactivities of the reactants are obscure. Further search for processes which mimic the relationship between the kinetics and the physical structure seems to be in order. The search for the correlation between kinetic parameters and morphological forms of polymers determined by modern physical methods is of great significance for the advance in this direction.

Abstract. Experimental methods and theoretical concepts of colloid chemistry regarding their possible use in nanochemistry and nanotechnology are considered. The main types of disperse systems which can be regarded as nanosystems are distinguished. Some methods for the preparation of colloidal nanosystems are described. Conditions for extrapolation of phenomenological laws of colloid chemistry to nanosize objects are considered. Examples of self-organised colloidal structures are given. The bibliography includes 205 references.

I. Introduction

According to the classification accepted in colloid chemistry, nanosystems are referred to as ultradisperse colloidal systems with the particle sizes ranging from 1 to 100 nm.^{1–3} This range of particle sizes corresponds to the maximum degree of dispersion at which a colloidal system still preserves one of its basic properties, *viz.*, heterogeneity. According to Reh binder,⁴ the minimum size of the disperse phase particles is about 1 nm (3–5 molecular diameters).

In order to establish the relationship between colloid chemistry and nanochemistry, it seems reasonable to recall the main stages in the development of colloid chemistry. After the pioneering studies by M Faraday (1857), who was the first to obtain stable colloidal solutions (sols) of highly dispersed red gold, it was these systems with the particle sizes of 5–100 nm that were the focus of attention of numerous physicists and chemists during the second half of the 19th century and the beginning of the 20th century. Experimental and theoretical studies of different properties of colloidal solutions led to the establishment of the main laws of colloid chemistry, *viz.*, the law of Brownian motion and diffusion of colloidal particles (A Einstein), the heterogeneous nature of colloidal solutions (R Zsigmondy), sedimentation–diffusion equilibria of dispersions in the gravitation field (J Perrin) and in

a centrifuge (T Svedberg), light scattering (J Rayleigh), coagulation of sols with electrolytes (G Schulze and W Hardy). Studies of properties of colloidal solutions of various substances have led to the establishment of the fundamental principle of the universality of the colloidal state (P Weimarn).⁵

During this period, the leading scientists in the field of colloid chemistry understood well the crucial importance of systematic studies of highly dispersed systems; however, experimental methods of that time did not possess sufficiently high resolution, in particular for the establishment of the structures of ultradisperse particles. Probably it was this circumstance that determined a shift of the peak of studies towards disperse systems with larger particles (foams, emulsions, suspensions, aerosols) and structured systems (gels, coagulation and crystallisation structures).

The appearance of high-resolution methods for the structural studies of substances (NMR, electron and atom-force microscopy, special equipment for measurements of very low surface tensions down to 10^{-3} mJ m⁻², computer simulation, photon-correlation spectroscopy and a number of others) in the second half of the 20th century allowed the initiation of systematic studies of the structures and properties of ultradisperse colloidal systems. Over the last 30–35 years, considerable progress has been achieved in this field; in particular, radically novel classes of ultradisperse systems[†] were obtained and studied. A tremendous experience gained in colloid chemistry in the investigations of ultradisperse systems can effectively be used for the solution of a number of basic and applied research problems of nanochemistry, since these systems are nanosystems[‡] in their essence. However, it should be emphasised that one should be very careful in the extrapolation of laws of colloid chemistry and concepts of the structures of disperse particles and thin layers to the nanosize range. The closer the size of a disperse particle (*d*) to the minimum possible one (*i.e.*, to the nanosize), the stronger become the scale effects, *viz.*, the dependence of various properties on the particle size.^{7,8} Nonetheless, the methods and concepts of colloid chemistry can also be successfully used in nanochemistry with due respect for appropriate restrictions. This problem is rather com-

Uspekhi Khimii 69 (11) 995–1008 (2000); translated by V D Gorokhov

[†] A spectacular example of ultradisperse systems may be microemulsions, which are thermodynamically stable systems with the disperse phase composed of droplets several nanometers in diameter.⁶

[‡] To a certain extent, the problem of what to call the particles with the sizes from 1 to 100 nm is terminological rather than that of meaning: the terms ‘nanoparticles’ and ‘nanosystems’ appeared only after the introduction of the SI system of units, *i.e.*, much later than the term ‘ultradispersity’.

prehensive and includes a large set of theoretical and methodological aspects.

The present review pays major attention to the classification of ultradisperse systems, the methods of their preparation, as well as to the theoretical description of processes occurring in these systems.

II. Ultradisperse systems

In the first place, it is useful to discuss what classes (types) of colloidal systems may be regarded as nanosystems. Let us use the classification which is currently accepted in colloid chemistry and relies on certain important characteristics of disperse systems, such as the sizes of the disperse particles d , their dimensionalities (one-, two-, three-dimensional), concentration of particles ν (m^{-3}), the character of interaction between the dispersed phase and the dispersion medium, aggregate states of the dispersed phase and the dispersion medium.^{1–3}

As regards their geometrical parameters, nanosystems and ultradisperse systems are virtually equivalent since in the latter the particle size is in the range 1–100 nm.

Based on their geometrical characteristics (dimensionalities of disperse particles), colloidal nanosystems may be divided into three groups.

1. Three-dimensional (bulk) nanoparticles in which all the three sizes (d_1, d_2, d_3) are in the nanorange. It should be noted that the bulk particles have rather small radii of curvature. This type includes colloidal solutions (sols), microemulsions, nucleation particles formed upon phase transitions of the first type (crystals, drops, gas vesicles), spherical micelles of surfactants in aqueous and non-aqueous media (direct and reverse micelles).

2. Two-dimensional (thin films and layers) nanoparticles in which only one size (thickness) is in the nanorange, while two others (length and width) may be unlimitedly large. These systems include thin liquid films, adsorption mono- and polylayers at the interface (including the Langmuir–Blodgett films),⁹ two-dimensional lamellar micelles of surfactants.¹⁰ Thin liquid films are subdivided into foamy films (between two foam cells), emulsion films (between droplets of direct and reverse emulsions) and wetting films (separating a solid surface and a gas or a liquid). The foamy and emulsion films are referred to as symmetrical films, whereas the wetting films are regarded as non-symmetrical ones. The thickness of symmetrical foamy films stabilised by appropriate surfactants can range from several nanometers (the so-called Newtonian black films)^{11–16} to several tens of nanometers.

3. One-dimensional nanoparticles in which the thickness and width are in the nanorange, while the length may be unlimitedly large. The one-dimensional ultradisperse particles include thin fibres, very thin capillaries and pores, cylindrical micelles of surfactants and nanotubes which much resemble them.^{17,18} This group also includes the wetting line (or the line of three-phase contact), which separates three phases, *viz.*, a solid, a liquid and a gas.^{19,20}

The classification of disperse particles based on their dimensionalities is important not only from the formal viewpoint. In conformity with the Ehrenfest principle, the geometry of particles (the dimensionality of space) has a substantial effect on the character of dependences relating physical parameters.^{21,22} Thus the power index for the distance in the Newtonian gravitation laws and for the electrostatic Coulomb interaction is -2 for three-dimensional space and -1 for two-dimensional space.²²

Yet another remarkable parameter confirming the Ehrenfest principle is the different dependence of the heat capacity of solids at constant volume C_V on temperature T in the range of sufficiently low temperatures. Thus Tarasov^{23–25} showed experimentally that the law of squares ($C_V \sim T^2$) is fulfilled for the lamellar structures (*e.g.*, for graphite and gallium) instead of the Debye law of cubes for isotropic materials whereas the linear dependence ($C_V \sim T$) is observed for the chain structures (of crystals selenium,

HF, BiO_3 and MgSiO_3). The theory of heat capacity of thin films and thin rods (needles) developed by Lifshitz^{26,27} states that at low temperatures the $C_V(T)$ dependences for two- and one-dimensional objects differ substantially from those for three-dimensional crystals.

Yet another example concerns the theory of capillarity. Clerot who put forward in 1743 the hypothesis of the existence of molecular forces suggested that they depend on the distance r in the same way as the gravitation forces ($\sim r^{-2}$). However, this hypothesis contradicted the empirical Juren law (1718) describing the upward movement of wetting liquids in capillary tubes. On the contrary, the Laplace hypothesis (1804)²⁸ of the short-range action of molecular forces ($\sim r^{-1}$) described correctly this phenomenon. It should be noted that the Ehrenfest principle provides the physical substantiation of the Laplace hypothesis. Indeed, the change in the power index from $n = -2$ in the Coulomb law to $n = -1$ in the Laplace hypothesis corresponds, according to Ehrenfest, to the transition from a three-dimensional to a two-dimensional object.

The above-cited regularities reflect changes in a number of physicochemical properties of nanoparticles compared to the corresponding properties of the macrophase. For example, a strong decrease in the melting temperature is observed for nanoparticles of many metals and semiconductors (Ag, Au, Pb, Sn, In, Bi, Ga, CdS).^{29,30} It is also known that the strength of filamentous crystals and fibres can be several times higher than that of macroscopic bodies. Nanosize particles possess an enhanced chemical reactivity manifested in the increase in the rates of chemical reactions involving their particles. This property of nanoparticles is used in the preparation of catalysts. It should also be noted that some phases can appear in nanoparticles which are not revealed in macrosystems. A sufficiently detailed description of special properties of nanoparticles can be found in relevant reviews.^{31–34}

Thus, the Ehrenfest principle has a fundamental significance. However, it has not yet found uses in colloid chemistry, including the theory of surface phenomena, although its potentialities seem to be very large here, especially for the description of nanosystems.

As has been noted, colloidal systems comprise several phases, at least two, therefore, properties of a system depend on the interaction between these phases. Based on the energy of interaction of the disperse phase and the dispersion medium, dispersion systems are divided into two large classes, *viz.*, lyophilic and lyophobic. According to Reh binder,⁴ the formation of stable lyophilic systems results from spontaneous dispersion of a macrophase into particles of colloidal size d . The thermodynamic condition of spontaneous dispersion is described by the expression

$$\sigma d^2 \leq \beta k T, \quad (1)$$

where σ is the surface tension at the disperse phase–dispersion medium interface, β is the coefficient taking into account the particle shape and changes in the entropy of a system due to the involvement of particles in the thermal motion ($\beta = 15–30$), k is the Boltzmann constant and T is temperature. It follows from the condition (1) that the formation of colloidal systems with the particle size of 1–100 nm requires a strong decrease in the surface tension, approximately down to $10^{-2}–10^{-3} \text{ mJ m}^{-2}$. This type of nanocolloids includes microemulsion systems, critical emulsions and micellar systems.^{4,6}

Thus, the range of ultradisperse systems (nanosystems) is very broad and they are very interesting from the scientific viewpoint for reviews, (see, *e.g.*, Refs 35, 36).

III. The formation of ultradisperse systems

Numerous methods have been developed in colloid chemistry for the preparation of ultradisperse systems allowing a rather fine control over the sizes of particles, their shapes and structures. The Nobel Prize winner Th Svedberg³⁷ proposed to divide methods for the preparation of ultradisperse particles into two groups:

dispersion methods (mechanical, thermal, electrical grinding or spraying of a macroscopic phase) and condensation methods (chemical or physical condensation).

It is impossible to consider all these methods in sufficient detail within the frame of this review; therefore, we will discuss only some examples of chemical methods for the preparation of ultradisperse systems. Historically, it was by these methods that the first highly dispersed colloidal solutions were obtained.

1. Preparation of sols

Systematic development of methods for the synthesis and purification of highly dispersed colloidal systems began in the middle of the 19th century when Faraday prepared stable sols of gold (with the particles 2–50 nm in size) by reduction of a dilute solution of a gold salt with yellow phosphorus.³⁸

Later, Zsigmondy³⁹ developed methods (which became classical) for the synthesis of monodisperse gold sols with a predetermined degree of dispersion by the reduction of gold(III) compounds with hydrogen peroxide and formaldehyde.

This process proceeds in two steps. In the first step, nuclei of a new phase are formed and then a slight oversaturation occurs in the sol where no new nuclei are formed and only growth of the existing nuclei takes place. Yellow ($d \sim 20$ nm), red ($d \sim 40$ nm) and blue ($d \sim 100$ nm) sols of gold can be prepared in this way.

The invention of an ultramicroscope (1903) which allowed measurement of ultradisperse particles (down to 3 nm in size) gave a strong impetus to the search for new methods for the preparation of sols and studies of their properties. It is worthwhile to note several basic achievements. Svedberg⁴⁰ synthesised highly dispersed sols of alkali metals in organic solvents on strong cooling. Weimarn⁴¹ was the first to establish the conditions under which any substance can be present in the colloidal state: 'Any substance may be obtained in the form of colloidal solution if one succeeds in bringing about the reaction of its formation in a dispersion medium, which dissolves this substance negligibly, at a sufficiently low concentration of reactants.' He prepared sols of several hundred different substances under laboratory conditions.

In the early 1980s, it was found that the solid-phase nanosize particles have special mechanical, optical, electrical and magnetic properties different from the corresponding properties of macro-systems.^{34, 42, 43} This fact determined the wide uses of nanoparticles in different fields of science and technologies.

Numerous methods of synthesis of nanoparticles have been developed to date. Analysis of methods for the preparation of nanoparticles of different nature is reviewed in Refs 31, 34–46. The present review considers only briefly recent methods for the preparation of sols based on condensation reactions.

Hydrolysis of inorganic salts of metals or metal alkoxides resulting in the formation of sols of oxides and hydroxides of the corresponding metals can serve as an example.^{47–51} Thus iron hydroxide sol can be prepared by the reaction

In this approach to sol preparation, it is important to observe thoroughly the reaction conditions; in particular, it is necessary to control strictly pH and the presence of certain organic compounds in the system. Thus Kandori *et al.*⁵² showed that the size of Fe_2O_3 particles resulting from hydrolysis of FeCl_3 depends on the concentration of triethanolamine, isopropylamine and piperazine.

The presence of a large excess energy in disperse systems related to the highly developed interface favours the processes of aggregation of colloidal particles (see Section V). To prepare sols of required dispersity, it is necessary to arrest growth of particles

in due time. To this end, the surface of particles in the disperse phase is deactivated by formation of a protective layer of surfactants^{53–55} or by complex formation.^{56, 57}

As regards control of the shape and size of nanoparticles, highly promising proved to be the synthesis of nanoparticles in microemulsion systems which will be considered in more detail in Section III.3.

2. The formation of micellar systems

Surfactants, organic substances (synthetic or natural) with limited solubility in water, which can adsorb on the interface thereby reducing the interfacial tension, represent unique aspect of colloid chemistry. These compounds have diphilic structures: a surfactant molecule or ion contains a hydrophobic part and a polar group of some kind. The hydrophobic part is a hydrocarbon radical ($\text{C}_n\text{H}_{2n+1}$, $\text{C}_n\text{H}_{2n-1}$, $\text{C}_n\text{H}_{2n+1}\text{C}_6\text{H}_4$, *etc.*) containing from 8 to 18 carbon atoms. Depending on the nature of the hydrophilic group, the surfactants are divided into cationic (these include primary, secondary and tertiary amines and quaternary ammonium bases), anionic (molecules of these compounds contain carboxy and sulfonic groups and others) and non-ionogenic (these surfactants exist in solution in the form of molecules).⁵⁸

The specificity of the behaviour of surfactants in aqueous solutions is related to peculiarities of the interaction between the water molecules and surfactants. According to numerous studies, at room temperature water is a structured liquid and its structure is similar to that of ice but in contrast to ice, water has only near ordering ($r < 0.8$ nm).^{59, 60} Solubilisation of surfactants induces further structuring of water molecules around non-polar hydrocarbon radicals of surfactants, which leads to a decrease in the entropy of the system. As the system tends to the maximum entropy, at a certain concentration called the critical micelle concentration (CMC), the surfactant molecules or ions begin to form spontaneously associates which are called micelles (as proposed by Mac-Ban who discovered them in 1913). The formation of micelles is accompanied by the release of a portion of structured water which is a thermodynamically advantageous process since it leads to an increase in the entropy of the system.

The formation of micelles is usually revealed from changes in some physical property of the surfactant solution (*e.g.*, surface tension, electric conductivity, density, viscosity, light scattering, *etc.*) depending on the surfactant concentration. The magnitude of CMC depends on a number of factors: the surfactant nature, the length and degree of branching of a hydrocarbon radical, the presence of an electrolyte or other organic compounds and pH of the solution. However, the basic factor is the ratio between hydrophilic and hydrophobic properties of the surfactant. The longer the hydrocarbon radical and the weaker the polar group the smaller the CMC.⁸

At concentrations close to CMC, micelles represent nearly spherical formations in which polar groups contact with water, while hydrophobic radicals are directed inwards to form a non-polar nucleus.^{4, 61} Molecules or ions constituting micelles are in dynamic equilibrium with the bulk of the solution. This is one of the reasons for the 'roughness' of the outer surface of micelles.^{61, 62} The degree of hydration of polar groups, the structure of the hydrate layer, and the structure of the internal nucleus depend on the nature of the surfactant.^{63–66}

At concentrations higher than CMC, the formation of several types of differently shaped micelles is possible (Fig. 1): spherical, cylindrical, hexagonal packed and lamellar ones. Thus, micelles may be regarded as one-, two- and three-dimensional nanoobjects. Depending on the surfactant nature, the aggregation number (n) can change from tens to several hundreds, the sizes of micelles will be changing accordingly.⁶⁷

§ Modern concepts of the thermodynamics of surfactant solutions and micellisation processes are considered in sufficient detail in Rusanov's monograph.⁶¹

Figure 1. Structures arising in solutions of surfactants: (1) monomers; (2) micelle; (3) cylindrical micelle; (4) cylindrical micelles as packed hexagons; (5) lamellar micelle; (6) water droplets packed as hexagons in the reverse micellar system.

Water-insoluble surfactant molecules with a long hydrocarbon radical and a weakly polar group can be dissolved in non-polar liquid phases. In this case, at a definite surfactant concentration the formation of micelles is also observed and is determined by specific interactions between the polar groups of the surfactant.^{68–71} These are called reverse micelles. The shapes of the reverse micelles are not necessarily the same, this depends on the surfactant concentration.

There are two approaches to the description of micelle formation. According to the first approach (the quasi-chemical model), the micellate formation is considered from the standpoint of the mass action law. The second approach interprets the appearance of micelles as the formation of a new phase.

One of the most important properties of the micellar systems is their ability to solubilise, *viz.*, to increase considerably the solubilities of hydrocarbons in aqueous micellar solutions, or, respectively, of polar liquids in the reverse micellar systems.^{72–74} Solubilisation results in the appearance of thermodynamically stable equilibrium isotropic systems, which are called microemulsions (these systems will be considered in more detail in the next section). Due to numerous factors which influence solubilisation (the nature of contacting phases and surfactants, the presence of electrolytes, temperature), the maximum solubilities of substances in surfactant micelles can vary within very broad limits. It should be noted that upon solubilisation the properties of compounds change largely and can also result in changes in the rates of chemical reactions occurring in these systems. This phenomenon known as the micellar catalysis finds wide uses in chemistry, biology, medicine and various technological processes. For example, the increase in the reactivities of compounds is widely used in the processes of emulsional polymerisation^{75–77} and enzymatic catalysis.^{78–80}

3. Formation of microemulsions

Microemulsions are thermodynamically stable isotropic dispersions of two non-miscible liquids. Upon mixing these liquids, the droplets of one of them stabilised by the interfacial film of a surfactant and a co-surfactant (a low-molecular-mass alcohol) are distributed in the other liquid. The term ‘microemulsion’ was proposed by Schulman⁸¹ who was the first to obtain such systems upon addition of surfactants to a macroemulsion. Microemulsions are regarded as lyophilic disperse systems and may be obtained either by spontaneous dispersion of two non-miscible

liquids as a result of a strong decrease in the interface tension or in the process of solubilisation, as noted above. The thermodynamic stabilities of microemulsion systems are determined by low interface tension which, according to the literature data, may be 10^{-5} mJ m⁻² for ionic surfactants and 10^{-4} mJ m⁻² for non-ionogenic surfactants.⁸² Depending on which phase is dispersed and which is continuous, the microemulsions can be direct [oil in water (o/w)] or reverse [water in oil (w/o)].[¶] In both cases the dispersed phase consists of droplets whose size does not exceed 100 nm.

Microemulsions are, as a rule, multicomponent systems comprising different structures (bilayer, cylindrical or spherical micelles).^{83–85} In the process of micelle formation, optically anisotropic micellar phases, for example, lamellar smectic and hexagonal phases consisting of rod-shaped aggregates of infinite lengths, are formed in addition to the liquid isotropic micellar phases, *i.e.*, microemulsions possess internal microstructures which are currently studied by different methods.^{86–88} In the case where the contents of water and oil in the system are comparable, bicontinuous systems can be formed.^{89, 90}

The properties of microemulsions are largely determined by the sizes and shapes of the dispersed phase particles as well as by rheological properties of interface adsorption layers formed by surfactants. Since the microemulsions are highly mobile and possess large interfaces, they can serve as versatile media for numerous chemical syntheses, including the preparation of solid nanoparticles.

4. The formation of solid particles in microemulsions

In a microemulsion system, the dispersed phase particles continuously collide, coalesce and degrade again, which leads to a continuous exchange of their contents. Collision of droplets depends on their diffusion in the oil phase (for the reverse microemulsion system), whereas the process of exchange is determined by the interaction of adsorption layers of surfactants and the flexibility of the interface (the latter circumstance is crucial for carrying out chemical reactions in such systems).^{91, 92}

Reverse microemulsion systems are often used for the preparation of solid nanoparticles. To this end, two identical microemulsion systems (w/o) containing in their aqueous phases

¶ The term ‘oil’ means a non-polar organic liquid.

Figure 2. Scheme of a reaction occurring in the reverse microemulsion system.

compounds A and B which form a poorly soluble product C in the chemical reaction are mixed. The new compound C is formed in droplets as a result of coalescence (Fig. 2). The sizes of the new phase particles will be restricted by the size of droplets of the polar phase.

Metal nanoparticles can also be obtained by adding a reducing agent (*e.g.*, hydrazine) to a microemulsion containing a metal salt or by bubbling a gas (*e.g.*, H_2 or CO) through this emulsion. It was in this way (reduction of a metal salt by hydrazine) that mono-dispersed metal particles of Pt, Pd, Rh and Ir were obtained with a particle sizes of 3–5 nm.⁹³ An analogous method was applied for the synthesis of bimetallic particles of platinum and palladium.⁹⁴

At present, precipitation reactions in microemulsion systems are widely used for the synthesis of metal nanoparticles,^{95–97} semiconductors,^{98–102} barium, calcium and strontium carbonates and sulfates,^{103–107} monodispersed SiO_2 particles^{108–110} and high-temperature ceramics.^{111–113}

Despite the fact that the mechanism of formation of nanoparticles has not yet been ultimately established, it is possible to identify a number of factors which influence this reaction. These are primarily the ratio of the aqueous phase to the surfactant ($W = [H_2O]/[surfactant]$) in the system, the structure and properties of the solubilised aqueous phase, the dynamic behaviour of microemulsions and the mean concentration of reagents in the aqueous phase. The sizes of droplets in the disperse phase are also influenced by the nature of the surfactants which stabilise the microemulsion system. However, in all cases the sizes of nanoparticles formed in the reaction are governed by the sizes of droplets of the initial microemulsion. For instance, Petit and Pileni⁹⁹ showed that the sizes of CdS nanoparticles increase virtually linearly as the ratio W increases. On the other hand, the sizes of particles obtained in the reverse microemulsion system stabilised by sodium di(ethylhexyl) sulfosuccinate (Aerosol OT) proved to be smaller than those in the system stabilised by the non-ionic surfactant Triton X-100 [polyethylene glycol ($n = 10$) *p*-iso-octylphenyl ether].

Microemulsion systems are also used for conducting hydrolysis. Hydrolysis of tetraethoxysilane in the reverse micellar system stabilised by Aerosol OT can serve as an example.¹¹⁴

It should also be noted that microemulsion systems are used for the preparation of organic compounds, which is important for the creation of new medicinal forms.¹¹⁵

Most of studies in this field relate to the synthesis of spherical nanoparticles. On the other hand, the preparation of asymmetrical particles (filaments, discs, ellipsoids) and a rigorous control of their shapes is also of high scientific and practical interest. Syntheses carried out in the microemulsion systems allowed the preparation of $BaCO_3$ nanofibres¹¹⁶ and asymmetrical nanoparticles of various compounds with unusual magnetic properties.^{117–119}

Highly interesting is the synthesis of nanocomposites consisting of particles of one material (the particle size is 50–100 nm) coated with a thin layer of another material.^{120, 121}

5. Preparation of mono- and polymolecular layers

Surfactants can form monomolecular films on various interfaces: water–air, solid–liquid and liquid–liquid. Such films may be regarded as two-dimensional nanosystems. The surfactant monolayers on the water–air interface were studied by Langmuir who developed an experimental method for the studies of these films (the Langmuir balances).¹²² For this work Langmuir was awarded the Nobel Prize in 1932. Monomolecular films on the surface of liquids may be in the gaseous, liquid and solid states. These states are characterised by different energies of interaction of the surfactant molecules.

Under definite conditions (pH, temperature), the water–air interface is the site of spontaneous formation of highly ordered structures, in which the surfactant molecules (or ions) are arranged in such a way that the polar group is in solution, while the hydrocarbon radical is oriented into the air at a small angle to the interface. The processes of self-organisation in a film are determined by the diphilicity of the surfactant molecules and may be analysed from the viewpoint of interaction of the polar group with the water substrate and interaction of the hydrocarbon radicals with each other.^{122–126}

Chemical reactions occurring in monomolecular films are of considerable interest. By varying the surface pressure it is possible to control the orientation of molecules in the surface layer and influence thereby specifically the occurrence of these reactions. Thus the Langmuir–Blodgett films are used for the preparation of solid nanoparticles of different nature directly in the process of chemical reaction or photochemical reduction of metal salts.^{127–130} Similar processes also occur in biological systems.¹³¹

The films deposited onto the solid surface can form both mono- and polylayers. For example, if a glass plate positioned vertically is drawn from water through a monolayer of barium stearate on its surface, this plate becomes coated with a surfactant layer in which the hydrocarbon radicals are oriented outwards. The result is that the surface of this plate becomes hydrophobic. It can then be covered with the next layer. Hydrophilic or hydrophobic surfaces may be obtained by successive deposition of layers.¹³² The films composed of layers of the same orientation are called the X-films, whereas those with the oppositely oriented layers are called the Y-films. In this way, it is possible to obtain polylayer coatings with thicknesses in the range of nanometers.

IV. The structures and forms of ultradisperse particles

The questions concerning the mechanisms of formation and the structures of nanosize particles are regarded as the most important and essential for colloid chemistry. Indeed, ultradisperse particles are some kind of ‘elementary particles’ of colloid chemistry. The transition from a simple qualitative definition of the concept of disperse particles to the determination of their quantitative parameters and relationships requires detailed elucidation of the structures of ultradisperse particles in different colloidal systems, such as sols, micellar solutions, microemulsions, gels, *etc.*

The early concept of the structures of solid ultradisperse particles was based on the suggestion that their structures are analogous to that of the macrophase of the same substance. However, further studies of the process of nucleation and growth of a new phase showed that depending on crystallisation conditions (the degree of oversaturation or overcooling, the presence of admixtures and a number of other factors), both amorphous and crystalline ultradisperse particles can be formed from solutions.^{133, 134} Back in 1910, Weimarn⁵ found that the shapes of $BaSO_4$ particles formed by crystallisation from solution depended on the degree of its oversaturation. Thus he obtained highly dispersed sols, flocculent structures, well faceted microcrystals

and needle-shaped crystals. The temperature of the synthesis of nanoparticles also plays an important role. For example, nanoparticles of titanium dioxide obtained by the sol–gel method are rod-shaped at low temperature and have the form of bipyramidal crystals at high temperature.¹³⁵ Yet another confirmation of the diversity of forms of nanoparticles is the formation of dendrites upon crystallisation from solutions and melts.¹³⁶

The diversity of forms is due to the fact that the processes of new phase formation (the self-organisation processes) occur under essentially non-equilibrium conditions, and the extent of structural perfection depends on how far the crystallisation conditions deviate from the equilibrium conditions. For example, in the synthesis of diamond from a dense gas phase and plasma, a more perfect structure is formed under more non-equilibrium conditions.¹³⁷

Surfactants present in solution can strongly influence the crystallisation process. Depending on the nature and concentration of the surfactants, they can change the rate of nucleation and growth of nuclei of the new phase, the shape of crystals and distribution of nanoparticles with respect to the size.^{138–141} All these effects are related to the selective adsorption of surfactant molecules or ions on different facets of the crystals formed and consequently to the retardation of growth of some facets compared to others.¹⁴² In addition, the nature of the surfactant also influences the polymorphism of the compounds formed. For example, Füredi-Milhofer *et al.*¹⁴³ showed that crystallisation of calcium oxalate in solutions of octaethylene glycol monohexadecyl ether results in the formation of calcium oxalate monohydrate, whereas in solutions of sodium dodecyl sulfate, dihydrate is formed.

An important feature of the crystallisation processes leading to the formation of nanoparticles is that their shapes cannot be described by the methods of usual geometry. These systems are described using the fractal geometry, since in the case of strong deviations from equilibrium and consequently high values of the driving force of the crystallisation process the instability of the interface leads, as a rule, to the formation of fractal structures.¹⁴⁴

Of interest are the studies reported by Melikhov *et al.*^{145, 146} who showed that highly dispersed primary single crystals are formed first in the mutual crystallisation of ammonium halides and cesium iodide from highly oversaturated vapour. Owing to highly developed interface, the disperse system formed possesses a large energy excess and for this reason it is the site of the occurrence of aggregation processes, which are accompanied by the concrescence of the initial single crystalline particles of approximately the same size. This aggregation results in the formation of pseudo-single crystals.

The processes of formation of ultradisperse systems in the case of metal crystallisation are much more complex and diverse. In the essence, investigation of these processes laid the foundation for a new direction known as the chemistry of clusters.^{147–149} Cluster particles occupy the intermediate position between mononuclear compounds and disperse particles. The metal particles with $d < 30$ nm can be obtained by the methods of gas-phase nucleation, cryogenic synthesis and reactions in polymeric matrices and reverse microemulsion systems.^{150–153}

It should be noted in conclusion that until now there is no sufficiently comprehensive quantitative theory of nucleation and growth of colloidal particles.

V. The application of theoretical concepts of colloid chemistry in nanochemistry

The concepts of colloid chemistry may also be used for the description of nanosystems (ultradisperse colloids). However, this involves rather complex methodological problems. These are due to the intermediate position occupied by the ultradisperse particles between molecules (atoms, ions) and macroscopic bodies (phases).

Both chemical and physical approaches are used for the theoretical description of colloidal systems. This is related to the boundary position of colloid chemistry between chemistry and physics, which exerts a strong effect on its methodology.¹⁵⁴ For example, the chemical approach prevails in studies of the highly dispersed state (including surface layers). Chemical methods are applied for the calculation of the electronic structure of nanoparticles (clusters) and its effect on their catalytic properties,¹⁴⁹ surface forces and Hamaker constants,^{155, 156} as well as for the determination of the constants of adsorption equilibrium using the mass action law.⁶¹ Based on the analogy of a bimolecular reaction and an elementary act of coagulation, the theory of rapid coagulation of sols under the action of electrolytes was developed (M Smolukhovsky, 1916). The theory of electrokinetic phenomena (electrophoresis and electroosmosis) is based on the concepts of electrochemistry on the structure of the double electrical layer and electrocapillary effects.

At the same time, the concepts of molecular physics, chemical thermodynamics and mechanics of continuous media are widely used for the description of relatively large particles and colloidal systems formed by them.

Of particular conceptual interest are the colloidal systems where the progress in the studies has been achieved upon the parallel use of chemical and physical theories, models and methods. A spectacular example of this approach is the investigation of the formation of direct and reverse micelles in solutions of surfactants.

The modern theory of micelle formation has been developed based on two complementary models, *viz.*, the quasi-chemical model (the formation of a micelle resulting from the reversible aggregation reaction) and the model of a phase transition of the second type.⁶¹ Such a conceptual dualism is rather characteristic of the methodology of colloid chemistry. Combination of macroscopic and molecular properties in a single object (colloidal particle, surface layer) was duly appreciated long ago by both chemists and physicists. Thus studies of the capillary and surface phenomena have made it possible to derive first quantitative estimates of the sizes of molecules (B Franklin, T Young) and have led to the discovery of forces of molecular attraction (A Clairaut, P Laplace). Studies of the temperature dependence of the capillary rise of organic liquids made it possible to establish their critical temperatures (D Mendeleev). The Boltzmann constant was calculated from the temperature coefficients of surface tension of pure substances.

Yet another example of the combination of physical and chemical approaches to studies of colloidal systems is the discovery of the effect of adsorption-induced decrease in strength (the Rebinder effect).¹⁵⁷ The modern theory of this effect borrows a number of notions and concepts from the physics of solids and mechanics (dislocation, the concept of tensions in the uppermost part of a fissure, the Griffith theory for the calculation of the critical sizes of nuclei of a crack and others). On the other hand, studies of molecular mechanisms of the Rebinder effect involve inevitably chemical processes and factors, since the decrease in the strength and plasticity of metals, ionic crystals and other solids was caused by the adsorption of the corresponding compounds in the predestruction zone.¹⁵⁷

Phenomenological laws of colloid chemistry established on the basis of molecular physics, thermodynamics and mechanics of continuous media have a fundamental character. However, their direct extrapolation to the ultradisperse field is not, as a rule, sufficiently accurate. This is due to the fact that many properties of substances in the ultradisperse field are substantially dependent on the particle size (d), and changes in properties may be caused by different reasons. For instance, in the range of $d < 1$ μm an increase in the strength of crystals is observed as their diameter d decreases. To an order of magnitude, this ‘threshold’ corresponds to the mean distance between dislocations in non-deformed crystals.¹⁵⁸

Colloidal systems are characterised by a very large specific surface Ω of the dispersed phase

$$\Omega \approx \frac{K}{d\rho},$$

where K is a dimensionless coefficient (for the spherical and cubic particles, $K = 6$), ρ is the disperse phase density. Other most important parameters which characterise colloidal systems are the specific free surface energy σ (surface tension), the surface entropy η and the specific adsorption Γ . For the systems with the moderate degree of dispersion, the surface tension σ is determined only by chemical compositions (the nature) of the dispersed phase and dispersion medium. However, for the nanosystems one has to take into account the dependence of the surface tension on the sizes of dispersed particles.

Because of special importance of the surface tension, let us consider this aspect in more detail. Two approaches are widely used for the analysis of the scale (dimensional) dependence of the surface tension. One of them relates the surface tension to the surface curvature and is used, *e.g.*, for the description of surface properties of droplets, gas bubbles and nuclei of the new phase particles. Tolman¹⁵⁹ proposed the following equation for the description of this relationship:

$$\sigma_r \left(1 + 2 \frac{\delta}{r} \right) = \sigma_0, \quad (2)$$

where σ_r is the surface tension corresponding to the curvature radius r , σ_0 is the surface tension for a flat surface, δ is the thickness of the surface layer of a substance characterised (according to Gibbs) by excess thermodynamic functions. According to a number of estimates, $\delta \approx 1$ nm; therefore, for the nanosize particles and gas bubbles a substantial change (increase) in the surface tension is observed. For this reason, the corresponding corrections considering the dependence $\sigma = f(r)$ should be made in all fundamental laws of colloid chemistry, *viz.*, the Laplace law of capillary pressure, the Young law of contact angles of wetting, the Kelvin law of the saturated vapour pressure over a curved surface and others. The dimensional factor plays a rather substantial role in the formation of nucleation particles during phase transitions. Indeed, the classical thermodynamic relations which determine the critical size of the nucleus of a new phase include the surface tension for the surface of small curvature, though it is in the nucleation particle that the surface curvature is the largest.

Let us clarify this statement with the following example. The critical size of the new phase nucleus r_c in the homogeneous formation resulting from the phase transition of the first type is determined in the Gibbs theory by the equation

$$r_c = \frac{2\sigma T_m}{Q_m \Delta T}, \quad (3)$$

where T_m and Q_m are the temperature and heat of phase transition and ΔT is the deviation of temperature from T_m . Thus, rather considerable overcoolings ΔT are required for the crystallisation of very small droplets of liquid metals, starting approximately from 5 nm. For instance, the values of ΔT for mercury, tin, copper and platinum were found to be 77, 118, 236 and 370 °C, respectively.¹⁶⁰ The simplest rationale is the increase in the surface tension as the curvature radius decreases [Eqn (2)], which leads to the corresponding increase in the overcooling ΔT (at a fixed value of the droplet size r_c).

A different approach to the description of special properties of ultradispersed objects (thin liquid films) is used in the concept of disjoining pressure Π introduced by Deryagin.¹⁹ The disjoining pressure is the difference between the pressure P_H inside the film of thickness H and the pressure in the bulk phase P_0 of the same substance at the same values of temperature and chemical potentials as in the thin film.

$$\Pi = P_H - P_0. \quad (4)$$

The most important feature of thin films is that their thickness H is commensurable with the surface layer thickness δ . The overlapping of the surface layers of two contacting phases (for $H < \delta$) makes an additional contribution to the free energy of the film.

The concept of disjoining pressure has been developed in sufficient detail and is widely used nowadays for the description of many phenomena. Thus the concept of disjoining pressure forms the basis of the theory of stability of colloidal solutions [the Deryagin–Landau–Verwey–Overbeek theory (DLVO)].^{161–163}

Certain problems also arise in the description of wetting of solids with nanosize droplets. In these cases, the equilibrium contact angle of wetting Θ_r depends on the linear tension $\varkappa$. The corresponding equation is

$$\cos \Theta_r = \cos \Theta_0 - \frac{\varkappa}{\sigma r}, \quad (5)$$

where Θ_0 is the equilibrium angle of a droplet at a large curvature radius (≥ 0.1 mm) and r is the radius of the droplet base.

This relation, which is analogous to the Laplace law of capillary pressure $P_r = 2\sigma/r$, was obtained for the first time and confirmed experimentally in measurements of forces on the wetting line in the plane of a bubble base on a solid support.¹⁶⁴ The contact angle Θ_r for a droplet or a bubble with a small radius r is determined from the conditions of mechanical equilibrium on the three-phase contact line (TPL).^{165, 166}

The direct confirmation of the dependence of Θ_r on the linear tension was obtained for microdroplets of organic liquids on asbestos filaments.¹⁶⁷ According to different estimates, the magnitude of linear tension is $\sim 10^{-7}$ mN.¹⁶⁶ Therefore, this can make a noticeable contribution to the magnitude of contact angles (for liquids with the surface tension $\sigma \approx 50$ – 100 mN m⁻¹) only in the case of nanosize droplets ($r \sim 10^{-9}$ m).

The influence of linear tension becomes rather substantial in the heterogeneous formation of the new phase nuclei, *e.g.*, upon vapour condensation on wetted solid substrates. Thermodynamic analysis¹⁶⁶ provides the following equation for the work of a nucleus (droplet) formation as a spherical segment

$$A = \frac{PV}{2} + \frac{\varkappa l}{2}, \quad (6)$$

where P is the capillary pressure, V is the droplet volume, l is the length of the TPL. Relation (6) may be regarded as a generalised equation with the aid of which one can calculate the work of formation of the new phase nucleus in the nanosize range (it is for this purpose that the linear tension $\varkappa$ is introduced). In the case of a spherical droplet $\varkappa = 0$, and relation (6) is transformed into the equation which describes the work of homogeneous formation of the new phase nuclei (A_0).

In order to calculate the work of heterogeneous formation of the new phase nucleus A_h , use is made of the well known Volmer equation¹⁶⁸

$$A_h = A_0(2 - 3 \cos \Theta_0 + \cos^3 \Theta_0). \quad (7)$$

Finally, for $V = 0$ equation (6) describes the work of formation of a two-dimensional nucleus ($A = \varkappa l/2$).

The above-cited examples of extrapolation of some laws of colloid chemistry to nanodispersed objects should be regarded only as a first approximation. The basic reason for the limited action of these laws, even with the consideration of the mentioned corrections, consists in peculiarities of the structure of nanosystems (see Section III). The complexity and non-triviality of the problems arising in this extrapolation will be explained by the example of two nanoobjects which are widely distributed in technological and natural processes: the surface layer of a liquid and LTC.

At the interface of a pure liquid and a gas phase the surface layer (SL) has a very small thickness (δ) which is of the order of several molecular layers (far from the critical temperature), *i.e.*, it represents formally a two-dimensional nanoparticle with two

macroscopic sizes (length and width) and one nanosize (thickness). Such a definition follows from the classical Young–Laplace theory; it is also confirmed by calculations based on macroscopic theories. The Gibbs theory considers the SL of a substance as an independent phase, the thermodynamic parameters of which differ from analogous parameters of the bulk phase of the same substance. Evidently, it is for this reason that the structure of SL of a liquid will differ from the structure in the bulk.

Until recently, the SL structure could not be studied in detail because of the absence of adequate experimental methods. Only in the last 5–7 years has the improved method of small-angle scattering made it possible to obtain reliable information about the SL structure of different liquids (mercury, gallium, alkanes starting from $C_{16}H_{34}$ and some others). It was found for all the compounds studied that their SL represents a two-dimensional quasi-crystalline structure at temperatures several degrees higher than the melting temperature T_m . The thickness of SL is estimated to be 1–2 molecular (atomic) diameters. It was established that the parameters of a two-dimensional crystal differ from the parameters of the lattice of a ‘bulk’ crystal of the same substance.^{169, 170}

These experimental data confirm the recent network model of the surface layer of a liquid,^{171–173} according to which it contains nanoparticles of the solid phase. They form a structure (‘network’) which determines the appearance of the surface tension of a liquid. The model predicts rather simple correlations between the surface tension and the heat of melting, which are in good agreement with experimental data for liquid metals and liquefied inert gases.

These results seem to be of principal significance. It follows from them that the surface nanolayer of a pure liquid has in fact an aggregation state different from the state in the bulk. This confirms one of the initial postulates about the thermodynamics of the surface Gibbs phenomena which states that the SL is an independent phase.^{171, 174}

On this basis, the process of SL formation may be regarded as the phase transition liquid–two-dimensional solid.¹⁶² In the framework of this model, the surface tension σ_m is proportional to the heat of melting Q_m near the melting temperature T_m . It thus follows that

$$\sigma_m = Q_m \rho_s \delta = Q_{sf}, \quad (8)$$

where ρ_s is the solid phase density and Q_{sf} is the heat of SL melting per surface unit. In the first approximation, the thickness of the SL (δ) is equal to a (a is a parameter of the crystal lattice of a given compound). Figure 3 shows that the dependence $\sigma_m = f(Q_m)$ is very well respected for many liquid metals and liquefied inert gases. The thickness of the SL for liquid alkali metals, other melts and liquefied gases corresponds to four, two and one monolayers, respectively.

The model of the solid SL makes it also possible to calculate the temperature coefficient of surface tension $-d\sigma/dT$ from the

Figure 3. Correlation of the surface tension σ_m near the melting point with heat of melting Q_{sf} : (a) liquefied inert gases, (b) alkali metals.

entropy of melting $\Delta S = Q_m/T_m$. Calculations of the coefficients of surface tension for many liquid metals give a rather close correspondence to experimental data.^{171, 172}

Let us consider yet another example of the insufficiency of introduction of additional thermodynamic parameters (the disjoining pressure Π , the linear tension κ) for the development of a comprehensive theory of colloidal nanosystems. In three-phase systems, the most important nanoobject is the three-phase contact line. This appears upon wetting, capillary flow, adhesion of liquids, spreading of drops over the surface of solids, condensation of vapours on supports and other phenomena. In these processes, the TPL is the front boundary of the liquid meniscus. Besides the term ‘three-phase contact line’ (TPL), the term ‘wetting line’ is used in a number of cases. As noted above, the linear tension describes special properties of TPL. Various theoretical models which consider the influence of the linear tension κ on the contact angles Θ [see Eqn (5)] include in the implicit form the suggestion that the wetting line is a regular circumference, *i.e.*, it has the same curvature $1/r$ along the entire length. An analogous assumption is also used, *e.g.*, in the theoretical description of spontaneous spreading of a drop of wetting liquid over a solid or liquid surface,^{7, 175, 176} flows in capillaries and porous media,^{177, 178} *etc.*

However, precision studies of the contour of drops of various liquids on solid supports (electron microscopy, laser interferometry) led to the conclusion about a totally different form of the wetting line. In the nanoscale, it represents an irregular alternation of protrusions and depressions, which are respectively ahead of or behind the mean position of the ‘round’ wetting line, *i.e.*, it is composed of small sites of positive and negative curvature.

This result is rather important for the development of a microscopic theory of wetting. In the first place, it shows that the movement of the wetting line upon the drop spreading should not be regarded as a smooth expansion of the wetted area within the limits of the entire contour (this assumption is used in the hydrodynamic theory of spreading).^{15, 176} A different mechanism of motion appears to be more probable, *viz.*, the fluctuational formation of leading menisci in the radial direction and subsequent tangential flow of a liquid under the action of the capillary pressure created. This mechanism of the wetting line dislocation requires a much lower activation energy than that based on the simultaneous spreading of a drop over the entire perimeter. Such a movement of TPL has much in common with the sliding of edge dislocations in crystals;¹³⁷ therefore, one can effectively use the corresponding models (formation of kinks, their expansion, *etc.*) for its description. At the same time, good prospects are open for the use of methods of fractal geometry for the description of these objects.

VI. Self-organised colloidal structures

A fundamental property of dispersed systems is their capacity for a gradual evolution. This evolution is associated with the nature of the colloidal (dispersed) state and primarily with the thermodynamic non-equilibrium of most colloidal systems. The excess of free energy, which is determined by the presence of a highly developed interface separating the dispersed phase and dispersion medium, stimulates different processes (physical, physicochemical) leading to a decrease in the Helmholtz free energy F .

Without consideration of the chemical component, the variation of the Helmholtz free energy dF at a constant temperature is

$$dF = -TdS + d(\sigma\Omega), \quad (9)$$

where Ω is the interface magnitude.

The thermodynamic condition of evolution $dF < 0$ may be created in energy- and entropy-based ways. The former is characterised by changes in the second member of Eqn (9). This may be attained by decreasing the interface separating the dispersed phase and dispersion medium ($\sigma d\Omega < 0$) and by decreasing the inter-

facial free surface energy (the surface tension) ($\Omega d\sigma < 0$). Upon the decrease in the interface, an increase in the mean sizes of particles d takes place, *i.e.*, the distribution of particles over their sizes, which is fixed directly at the moment of their formation, is shifted with time towards the larger particles. The mechanisms of this process may be completely different: coalescence of droplets in emulsions and of gas bubbles in foams upon their direct contact, isothermal distillation of the disperse phase particles in conformity with the Kelvin law, the Ostwald ripening of solid particles. As a result of these processes, the solid particles can become so large that they lose their sedimentational stability. Ultimately, these processes can lead to the partition of a dispersed system into two macrophases.¹⁷⁹

The decrease in the specific free surface energy $d\sigma < 0$ also occurs upon the interaction of the dispersed particles through the dispersion medium film, as well as upon the loss of aggregation stability by the system in the process of coalescence. The theory of sol stability (the DLVO theory)¹⁶³ considers in the first approximation the interaction of colloidal particles as the sum of dispersion (attraction) and electrostatic (repulsion) interactions which take place upon overlapping of the ionic atmospheres due to the approach of sol particles to each other. In the case where the radius of the dispersed particles is much larger than the thickness of ionic atmosphere, the energy of interaction of colloidal particles $U(h)$ may be expressed as

$$U(h) = \frac{Bc_0kT\gamma^2}{\kappa} \exp(-\kappa H) - \frac{A^*}{12\pi H^2}, \quad (10)$$

where B is a numerical coefficient, c_0 is the electrolyte concentration in the system, $\gamma = \tanh(ze\phi_0/4kT)$ (z is the valence of the counterion and ϕ_0 is the thermodynamic potential of the solid surface), κ is the magnitude of the reciprocal thickness of ionic atmosphere in the Debye–Hückel theory, $\kappa = (\epsilon\epsilon_0kT/2z^2e^2c_0)^{-1/2}$ (ϵ is the dielectric constant of the medium, ϵ_0 is the dielectric constant equal to 8.85×10^{-12} F m⁻¹), H is the thickness of the dispersion medium film between particles, A^* is the Hamaker complex constant characterising the interaction of contacting phases.

It follows from the DLVO theory that if the energy barrier related to the electrostatic repulsion of particles (E_{el}) is substantially higher than the energy of thermal motion (*i.e.*, $E_{el} \gg kT$), then the system is stable to aggregation, and no enlargement of particles occurs.

If $E_{el} \ll kT$, then each collision will lead to the formation of an aggregate, and the rate of formation of aggregates will be limited by the rate of their diffusion in the dispersion medium. This process is called rapid coagulation (M Smolukhovsky, 1916). The parameter which characterises the process of rapid coagulation is the coagulation period (τ), *viz.*, the time during which the concentration of particles v_0 decreases by a factor of two. According to the Smolukhovsky theory,

$$\tau = \frac{3\eta}{8kTv_0}, \quad (11)$$

where η is the viscosity of the dispersion medium. For the rapid coagulation, the value of τ does not usually exceed a few seconds.

Upon a decrease in the electrolyte concentration, the efficiency of collisions decreases and only a portion of them leads to the formation of aggregates. This is the case of the so-called slow coagulation (N Fuchs, 1934). In conformity with the Fuchs theory, the decrease in the rate of aggregate formation is associated with the presence of a barrier in the dependence of potential energy on the distance between the centres of particles.¹⁸⁰ The theoretically predicted dependences of the coagulation rate on concentration, as well as the ratio of rates as a function of the coagulating ion charge are in a satisfactory correlation with experimental results.

The coagulation of sols yields aggregates, the fractal dimensionality of which depends on the coagulation type. For the aggregates formed under the conditions of slow coagulation, the

fractal dimensionality proves to be higher^{181–183} than for the aggregates formed under the conditions of rapid coagulation, which points to a higher degree of their organisation.

Analysis of Eqn (10) showed that at sufficiently large values of H a minimum can be observed on the curve of the dependence of interaction energy of particles on the distance. The interaction of particles at large distances, the so-called far interaction, leads to the formation of ensembles possessing the phase stability. Such ordered formations are called periodic colloidal structures.¹⁸⁴

A spectacular example of the periodic structures are the Schiller layers, *viz.*, the structures formed in sols of iron hydroxides, vanadium oxides and some others whose particles have the anisometric forms. At low sol concentration, the particles form horizontal layers upon sedimentation separated from each other by several hundred nanometers.¹⁸⁵ The increase in the sol concentration leads to the spindle-like aggregates which are called tactoids. In this case, the dispersed particles are arranged nearly in parallel to the spindle axis, while the distance between them is decreased to tens of nanometers. The dispersed particles can also be oriented near a solid support.^{135, 186}

The periodic colloidal structures include also the Liesegang layers and rings,¹⁸⁷ which were apparently the first examples of the self-organised structures studied. Let us consider these objects in more detail.

The Liesegang rings (1896) can be prepared in the following way. A drop of 15% solution of AgNO₃ is placed on a film of the gelatine gel which has been pre-impregnated with 0.4% potassium dichromate solution. The silver salt diffuses gradually into the gel. This results in the precipitation of silver dichromate. The precipitate does not form a continuous zone around the drop but is in the form of concentric rings separated by transparent clear areas.

Usually, the Liesegang rings appear when a concentrated salt solution diffuses through a gel which contains another electrolyte at a lower concentration. The chemical reaction results in the formation of a salt of a poorly soluble compound which is precipitated in some periodic way.^{187–190} The precipitate can form not only the concentrated rings but also segments and radial formations.^{191, 192} It should be noted that despite the long time which has passed since the discovery of Liesegang rings, a sufficiently complete theory of their formation has not been developed until now. It should be mentioned that this phenomenon is of a considerable interest not only for colloid chemistry but also for other sciences, *e.g.*, biophysics. Indeed, the Liesegang rings are similar to ring structures which result from the autowave processes occurring in unidimensional systems (thin layers).¹⁹³ In such ‘distributed’ systems, the periodic wave structures appear due to diffusion undisturbed by convective fluxes, *i.e.*, owing to the distribution of concentration waves. The same conditions are necessary for the formation of Liesegang rings. In the case of the reaction under discussion, one of the possible reasons for the appearance of Liesegang rings may be formation of colloidal particles of silver dichromate which coagulate because of the excess of one of the reagents.

The processes of self-organisation are observed in the disperse systems under external impacts as well. Thus it was shown in a number of studies^{194–198} that the aggregation of initial particles with the formation of ordered structures is possible in the shear flow of suspensions.

The above-cited examples refer to the ordered colloidal nano-systems with relatively large sizes of particles.

Let us consider now another extreme case, *viz.*, the self-organised nanosystems in which the size of dispersed particles is only slightly larger than the molecular size. These systems include, *e.g.*, aqueous solutions of surfactants. The possible cases of self-organisation of the surfactant molecules are shown in Fig. 4; they include adsorption layers of surfactants at the interface, as well as direct and reverse micelles.

Indeed, the close-to-saturation layers of surfactants at the interfaces water–air, water–oil and polar solid surface–surfactant solution can have a rather high degree of ordering at which all

Figure 4. A scheme of the formation of organised structures in solutions of surfactants: (1) surfactant solution; (2) direct micelle in aqueous solution; (3) solubilisation of a non-polar liquid by the direct micelle; (4) reverse micelle in a non-polar liquid; (5) solubilisation of the polar phase by the reverse micelle; (6) adsorption layer of the surfactant at the aqueous solution – air interface.

the surfactant molecules (ions) are oriented perpendicular to the interface in a way ensuring the contact of the polar groups of the surfactant with the polar phase. It should be specially noted that the formation of self-organised biologically active structures on the water surface plays an extremely important role in biological evolution. Numerous data and calculations show that the surfaces of oceans (seas) are the most favourable regions for the appearance of Protozoa.¹⁹³

Another class of self-organised colloidal nanostructures of minimum size includes the direct and reverse spherical micelles of surfactants. The ordering of micelles is characterised by the same orientation of the surfactant molecules (ions) in the radial direction from the centre of the micelle to its outer surface, on which the functional groups similar in their nature to the dispersion medium (water or an organic liquid) are positioned. The self-organised nanostructures of this type also include lamellar and cylindrical micelles, bilayers of surfactants and vesicles.

The factors favouring the formation of self-organised structures of surfactants depend to a considerable extent on the nature of the liquid phase or the nature of the solid substrate (when considering the processes of adsorption of surfactants from solutions on solid surfaces). In aqueous solutions of surfactants, the processes of self-organisation are determined by the general increase in the entropy of the system $dS > 0$ which is the sum of changes in the entropy of the dispersed phase dS_d and in the entropy of the dispersion medium dS_m . In this case, the local decrease in the entropy of the surfactant molecules in the processes of adsorption on the interface aqueous solution – air and micelle formation is compensated by the increase in the entropy of the water molecules so that the total change in the entropy of the system $dS > 0$.^{61, 199–202}

On the contrary, the appearance of micelles in the oil phase, as well as the adsorption of surfactants at the interface water – oil or on a polar solid surface are determined by changes in the enthalpy of the system due to the interaction of the polar groups of surfactants with each other in the nuclei of reverse micelles or because of the interaction of the polar groups of surfactants with a polar solid surface or a polar solvent.^{203, 204}

It should be noted that the processes of self-organisation of surfactant ions can also be observed in gels.²⁰⁵

Thus, the most important feature of the evolutionary processes in colloidal systems consists in that they often lead to the appearance of ordered structures of different scale (nano-, meso-, and micro-macrostructures). These structures may be two-dimensional and three-dimensional, while their size can change from several nanometers to hundreds of nanometers. Such structures are rather widely distributed. They are of a considerable applied and scientific interest, being convenient models of a number of biophysical and biochemical systems.

VII. Conclusion

The nanoparticles considered in colloid chemistry are the ultra-disperse particles. Among the ultradisperse systems a special place is occupied by the systems in which particles have a specific colloidal nature: they include micellar systems, microemulsions, adsorption layers of surfactants at the interface and the Langmuir – Blodgett layers.

The methods for the preparation and studies of ultradispersed systems developed in colloid chemistry may be used rather efficiently in nanochemistry and nanotechnology. In many cases, the methods of colloid chemistry make it possible to regulate rigorously the sizes, shapes, compositions of ultradispersed particles and properties of the structures formed by them. The theoretical concepts of colloid chemistry concerning the surface phenomena, stability and evolution of disperse systems combined with the models used for studies of the thermodynamics of irreversible processes and synergism may also be applied successfully to the nanodisperse systems.

Abstract. Highly sensitive time-resolved magnetic resonance techniques based on the effect of variable radio-frequency and switched constant magnetic fields on the nuclear polarisation of diamagnetic products of radical reactions are considered. The applications of these methods to the investigation of short-lived radical intermediates (radical pairs, biradicals, free radicals and radical ions) formed in photochemical reactions in homogeneous and molecular-organised media are discussed. The bibliography includes 148 references.

I. Introduction

The review is devoted to the use of new time-resolved magnetic resonance techniques based on the detection of nuclear polarisation of diamagnetic products of radical reactions for the study of spin dynamics and chemical kinetics of short-lived radical species (free radicals, radical pairs and radical ion pairs) in photochemical radical reactions. The demand for investigation of fast photochemical reactions in solutions has stimulated the appearance and extensive development of methods for the detection of short-lived radical species, for example, laser flash photolysis, time-resolved EPR, reaction yield detected magnetic resonance methods (RYDMR), *etc.* The progress in the investigations into the mechanisms of photochemical radical reactions is largely associated with the use of magnetic resonance[†] because these methods provide information on the structure of radicals, the rates of chemical reactions, electron exchange interaction, the parameters determining the mobility of radical species in solutions.

Methods based on the application of variable resonance magnetic fields have been greatly developed during the last two decades.^{1–12} A radio-frequency (RF) resonance field induces nuclear polarisation of in-cage (M^1) and escape (M^2 , M^3) diamagnetic products of a photochemical reaction. Polarisation arises either upon RF-induced changes in the singlet–triplet conversion rate in radical pairs (selectively with respect to the

orientation of nuclear spins) or upon electron or nuclear transitions in the free radicals R^1 , R^2 (Scheme 1). The magnitude and the sign of nuclear polarisation induced by an RF field depend on the field frequency and on the type of resonance transition (nuclear or electronic) to which this frequency corresponds.

Scheme 1

There are several methods for detecting magnetic resonance spectra of short-lived radical species.

(i) Stimulation of nuclear transitions in polarised intermediate short-lived radicals with simultaneous recording of the NMR spectra of diamagnetic products.^{13–18} This method was first proposed and implemented in a study by Sagdeev *et al.*¹³ and was developed further by Trifunac *et al.*^{14–18} An obvious advantage of the method is high sensitivity (below 10^8 spins in the sample) and simplicity of line assignment — the lines of the product detected by NMR correspond to a particular nucleus in the radical precursors. The main shortcoming of the method is that its scope is limited to radicals the lifetimes of which are not shorter than several microseconds.

(ii) The method of dynamic nuclear polarisation (DNP). Pumping of electron transitions in the intermediate short-lived radicals gives rise to nuclear polarisation, which is transferred to diamagnetic products after radical recombination.^{12, 19–22} The dependence of the signal intensity in the NMR spectrum of diamagnetic products on the external magnetic field is an EPR spectrum of the intermediate radicals. This method provides information on the mechanism of electron–nucleus interaction in short-lived radicals (contact or dipole–dipole); it opens the way for determining the relaxation times, the signs and the magnitudes of hyperfine coupling (HFC) constants and for investigation of the kinetics of these radicals in solution.

(iii) The method of stimulated nuclear polarisation (SNP). The effect of an RF field with a specified frequency on an ensemble of

[†] The sensitivity of EPR (10^9 spins in a sample) does not always suffice for the investigation of fast radical processes.

radical pairs changes nuclear polarisation in the products formed.^{12, 23–25} By investigating the dependence of nuclear polarisation of the diamagnetic products on the frequency of the saturating field, one can gain information on the EPR spectrum of the intermediate radical pair, exchange interaction, pathways to diamagnetic products, *etc.*

II. Experimental implementation of the methods

For recording the spectra of short-lived radicals, it was necessary to devise instruments which either produce a variable resonance magnetic field at radio frequency or ensure the possibility of switching an external magnetic field directly during a radical reaction with simultaneous recording of the NMR spectra of diamagnetic products. Coupling of a resonator or an oscillator circuit with the probe of a standard NMR spectrometer was a complicated engineering problem. This was done by Sagdeev *et al.*¹³ in the first experiment on recording the NMR spectra of short-lived radicals. In scanning the resonance lines, the frequency sweep of the RF field was accomplished manually; due to the restrictions in the frequency range of the resonance circuit of the NMR spectrometer, only one resonance line was detected. The separate pumping of resonance transitions in radical pairs and recording the NMR spectra of the reaction products proved to be an easier procedure (Fig. 1). A fast-flow system is normally used to transfer the sample into the photolysis cell. A liquid is injected into the cell through a thin Teflon capillary either using a pump^{17, 20, 26} or under a gas pressure.¹² The flow rate of the liquid should be such that the time it takes to transfer the sample from the reaction vessel to the probe of the NMR spectrometer be shorter than the nuclear relaxation time of diamagnetic products, *i.e.* this should require fractions of a second. An original setup for detecting SNP in weak magnetic fields of about 10.0 mT has been developed.²⁷ The transfer of a sample from the magnetic field in which the photochemical reaction took place to the probe of the NMR spectrometer was performed using the pneumatic system of the probe. The frequency of pumping of electron transitions (300 MHz) was equal to the resonance frequency of the NMR spectrometer. The limitations of this method include the use of only one resonance frequency of an RF field.

The magnetic flux chosen (B_0) is largely determined by the goals of the experiment. The resonance frequency employed in existing experimental setups ranges from 50 MHz to 10 GHz.

Figure 1. Block diagram of the setup for the study of SNP: (1) photolysis cell with a sample; (2) RF resonator or oscillating circuit; (3) electro-magnet; (4) laser (308 nm); (5) superconductive magnet and the probe of a Bruker MSL-300 NMR spectrometer (300 MHz); (6) RF generator; (7) control computer of the NMR spectrometer; (8) pulse generator; (9) an oscilloscope; (10) power supply of the magnet and B_0 sweep; (11) fast-flow system consisting of a vessel (I) with the initial substances (argon feed under a pressure of ~ 1.5 atm) and a vessel for the collection of the reaction products (II).

Figure 2. Schematic illustration of the two methods for recording the spectra: continuous (a) and pulse (b).

In pulse methods²⁸ (Fig. 2), the dependence of the intensity of NMR spectra on the time delay (τ) between the laser pulse and the RF pulse is studied. The main difference between the pulse and steady-state methods is as follows. When the continuous variant is used, radical pairs and the intermediate short-lived radicals exist throughout their lifetimes under the influence of an RF field, which induces the singlet – triplet conversion in radical pairs or the DNP. The use of pulse modification provides a new, in principle, opportunity to expose separate sub-ensembles of radical pairs (or radicals) with a particular lifetime to an RF field. The main advantages of the pulse variant over the steady-state method include differentiation of geminate and diffusion pairs by measuring the SNP for different delays τ ; separation of the contributions of SNP and DNP to the RF field-induced nuclear polarisation; the possibility of obtaining information on the pattern of distribution of radical pairs and radicals over lifetimes. In the case of pulse method, time resolution is determined by the rise times of the microwave pulse and the laser pulse and equals 20–30 ns. High time resolution can be achieved by using either cavities with low Q-factors or cavities with high Q-factors but with a higher coupling constant between the resonator and the generator.²⁹ Upon mathematical processing of the data, the time resolution of the method can be improved to 5 ns.²⁷

A substantial drawback of the above methods of recording the spectra is the necessity of using large samples. The use of deuterated solvents markedly increases the cost of the experiment; however, this problem can be solved by taking solvents containing no protons (CCl_4 , C_6F_6 and so on) or by recording the spectra for other nuclei (^{13}C , ^{31}P , ^{19}F and so on.). In the case where the NMR chemical shifts of the solvent and the compound under study differ by several ppm (at least, by 1 ppm), the signal of the solvent should be suppressed.

III. Dynamic nuclear polarisation

The DNP effect means that saturation of the electron levels of free radicals in an external magnetic field gives rise to a non-equilibrium nuclear polarisation.^{30, 31} A radio-frequency resonance magnetic field makes the occupancies of the electron levels equal and thus creates non-equilibrium occupation. Cross-relaxation transitions caused by hyperfine coupling of an electron with the nucleus are directed at restoring the thermal equilibrium between the electron levels. However, since cross-relaxation processes are accompanied by inversion of nuclear spins, polarisation arises on the radical nuclei,

$$p = \xi s f \frac{\gamma_e}{\gamma_n},$$

where, the parameter ξ is determined by the mechanism of the electron – nucleus coupling, $s = (S_0 - \langle S_z \rangle) / S_0$ is the saturation factor of the electron spin system, f is the leakage factor determining the fraction of nuclear relaxation occurring without participation of electron spins, and γ_e and γ_n are gyromagnetic ratios of the electron and nuclear spins. For contact interaction [the change in the total spin of the electron and the nucleus (Δm) is equal to zero], $\xi = 1$, while for dipole interaction ($\Delta m = 2$), $\xi = -1/2$. Figure 3 illustrates qualitatively the mechanism of formation of the DNP upon non-equilibrium electron polarisation of a radical with two equivalent magnetic nuclei ($I_1 = I_2 = 1/2$) and positive

Figure 3. Schematic illustration for the mechanism of the generation of multiplet DPN of the diamagnetic products formed from short-lived radicals. The arrows show the resonance transitions induced by an RF field (1) and cross-relaxation transitions (2).

HFC constants ($A_1 = A_2$).³² Cross-relaxation occurs by a contact mechanism ($\Delta m = 0$).

Study of the dependences of DNP of stable radicals of paramagnetic ions on the temperature, solvent viscosity, and the magnetic field strength makes it possible to solve diverse problems, for example, to study the effect of the medium on the interaction of various molecules with free radicals, to study the roles of the contact and dipole interactions during relaxation, to determine the mechanisms of interaction between radicals and nuclei, etc.[‡]

1. Dynamic nuclear polarisation of neutral intermediate short-lived radicals

Grishin *et al.*¹⁹ was the first to consider the possibility of using the DNP effects for the investigation of intermediate short-lived radicals. Photolysis of benzaldehyde in CCl_4 affords the radical pairs $[\text{Ph}\dot{\text{C}}\text{H}(\text{OH}) \text{Ph}\dot{\text{C}}\text{O}]$.¹⁹ α -Hydroxybenzyl radicals are converted into the starting benzaldehyde upon hydrogen atom transfer. In strong magnetic fields (330 mT), DNP can be detected in the NMR signals of all the diamagnetic reaction products.^{19,33–35} The negative sign of DNP corresponds to a dipole mechanism of cross-relaxation in the intermediate α -hydroxybenzyl radical. In weak and medium magnetic fields (3 and 60 mT) in which the cross-relaxation efficiency is much lower, DNP is negligibly small, the predominant contribution to polarisation being made by SNP. As noted above, an RF field induces nuclear polarisation both by the DNP mechanism, due to cross-relaxation processes in free radicals, and by the SNP mechanism, due to the change in the rate of singlet–triplet transitions in radical pairs. The contributions of these mechanisms to the polarisation of the nuclei of diamagnetic products formed from short-lived radicals can be separated based on the dependence of the width of resonance lines and the SNP and DNP intensities on the RF field amplitude (B_1). For example, photolysis of benzaldehyde in CHCl_3 has been used to study the influence of the RF-field amplitude on the ratio of the SNP and DNP contributions and on the width of individual components of the spectrum.²⁰ This permitted the researchers to estimate the lifetime of the radical pairs (~ 20 ns).

The possibility of separating the contributions of DNP and SNP to the total polarisation by varying the external magnetic field, the RF-field amplitude and the lifetimes of radicals was demonstrated¹² in relation to the photolysis of benzoquinone in solutions. For semiquinoid radicals, the efficiency of cross-relaxation in 50.0 mT fields becomes substantial, and the observed DNP is comparable in magnitude with SNP. For durosemi-

quinoid radicals, cross-relaxation is due to the modulation of HFC caused by rotation of the methyl groups (*i.e.* cross-relaxation follows a contact mechanism); in this case, a positive DNP effect is observed.^{20,21,31–36}

Information on electron relaxation times in short-lived radicals and on the rate of chemical reactions can be gained by using pulsed generation of radicals and by investigating the variation of DNP intensity in the magnetic field corresponding to the maximum of the resonance line *vs.* the time delay between the laser pulse and the leading edge of the RF pulse. These experiments for the neutral radicals generated upon photolysis of benzaldehyde in chloroform were first performed by Yamakage *et al.*³⁷ The experimental results were processed by calculations in terms of the kinetic scheme for the occupancies of the radical levels with allowance for cross-relaxation, electron transitions and the chemical reaction. It was shown that the DNP kinetics actually reflect the radical kinetics and do not depend on the cross-relaxation rate, while the DNP intensity is determined by the ratio of the cross-relaxation, electron relaxation and the chemical reaction rates. The results provided grounds for concluding that the cross-relaxation rate for the α -proton of the α -hydroxybenzyl radical is one or two orders of magnitude lower than that for aromatic protons.

Cross-relaxation processes influence substantially the chemically induced dynamic electron polarisation (CIDEP) of short-lived radicals^{38–40} and, in some cases, account for the change in its sign. Thus McLauchlan *et al.*^{39,40} found the change in the CIDEP sign in the photolysis of aliphatic ketones and suggested that this is due to the cross-relaxation in the intermediate radical. Subsequently, in a theoretical study of the cross-relaxation processes, it was shown⁴¹ that CIDNP and CIDEP are related in time and their kinetics should be considered jointly. Thus, the transfer of electron polarisation to the nuclei should substantially affect the CIDNP kinetics. Experimental research on photolysis of aliphatic ketones by the time-resolved CIDNP method gave ambiguous results. Tsentalovich *et al.*^{42–46} concluded that, when analysing the kinetics of CIDNP detected during the photolysis of acetone in isopropanol and 2,4-dihydroxy-2,4-dimethylpentanone, one should take into account the contribution of the cross-relaxation mechanism. However, Fischer *et al.*⁴⁷ showed that the CIDNP kinetics can be adequately described without allowance for cross-relaxation; only two-photon processes resulting in CIDNP of some reaction products should be taken into account. In addition, CIDEP with a positive sign is observed in the photolysis of 2,4-dihydroxy-2,4-dimethylpentanone, which refutes the conclusions about generation of CIDNP by the cross-relaxation mechanism made by Salzmann.⁴⁵ The main difficulty in comparison of the results obtained by the CIDEP and CIDNP methods is that the fields used in CIDEP experiments are about 330 mT, while the operating fields of NMR spectrometers are usually in the range 3–7 T. The electron and cross-relaxation times are known to depend appreciably on the external magnetic field, while the processes of polarisation transfer are, in turn, determined by these times.

The use of the DNP method clarified the point concerning the nature of inversion of the CIDEP sign.³² A study of the DNP in reactions involving $\text{Me}_2\text{XC}\dot{\text{C}}$ radicals ($\text{X} = \text{Me}, \text{OH}, \text{D}, \text{COMe}$) demonstrated unambiguously the presence of effective scalar ($\Delta m = 0$) electron–nuclear cross-relaxation in the *tert*-butyl and 2-hydroxyprop-2-yl radicals and the absence of cross-relaxation in 2-acetyl and prop-2-yl radicals. Figure 4 shows the DNP and EPR spectra recorded in the X and L ranges for the $\text{Me}_2(\text{OH})\dot{\text{C}}$ radical, resulting from photolysis of 2,4-dihydroxy-2,4-dimethylpentanone in benzene. It can be seen that the signs of polarisation coincide and the intensity ratios of the lines in the spectra are closely similar. Comparison of the obtained results with the results of time-resolved CIDNP studies led to the conclusion that the cross-relaxation is due to the modulation of the isotropic HFC with a characteristic correlation time of $\tau_c \gg 1$ ps.

[‡] The DNP studies of stable radicals are surveyed comprehensively in Ref. 31.

Figure 4. Spectra of 2-hydroxyprop-2-yl radical recorded in the X and L ranges by the time-resolved EPR (a, b) and DNP (c, d) methods. The resonance frequency is 10 (a, c), 1.6 (b) and 1.53 GHz (d).

2. Dynamic nuclear polarisation in radical ions

Radical-ion reactions are accompanied, in the majority of cases, by degenerate electron exchange (DEE) reactions

(D is donor, A is acceptor); therefore, the DNP in radical-ion reactions has several specific features.

In a study of the influence of an RF field on the nuclear polarisation of the products of radical-ion reactions in weak magnetic fields, a pronounced DNP effect was found.⁴⁸ Further studies demonstrated^{22, 49} that this effect is observed in the presence of DEE provided that the magnitude of the external magnetic field is comparable with the HFC constant of the radical ion.

Two different approaches have been proposed for quantitative description of DNP under the conditions of DEE in weak magnetic fields.^{22, 49} One approach is based on numerical solution of the Liouville equation for the spin density matrix of the radical with allowance for the spin dynamics in a weak magnetic field and the DEE process, while the other approach includes solution of the Bloch phenomenological equations with allowance for the relaxation times T_1^e , T_2^e

$$\frac{1}{T_1^e} = 2A^2\tau_e \frac{1}{1 + \omega_0^2\tau_e^2};$$

$$\frac{1}{T_2^e} = A^2\tau_e \left(1 + \frac{1}{1 + \omega_0^2\tau_e^2} \right),$$

where $A^2 = \frac{1}{3} \sum_i I_i(I_i + 1)A_i^2$ is the second moment of the EPR

spectrum of the radical ion for nuclei with spins I_i and HFC constants A_i , τ_e is the DEE time, and ω_0 is the Larmor frequency of electron spins.

The former approach is applicable to any DEE rates, while the latter one is suitable only for high exchange rates ($A^2\tau_e^2 \ll 1$). The main advantages of the latter model include its simplicity and the possibility of using it to study radicals with complex EPR spectra. Comparison of the DNP spectra calculated in terms of these two models showed that at high rates of electron exchange, the spectral patterns are identical; in this case, the use of the phenomenological approach is quite justified. Note that both models take into

account only processes which occur in radical ions, the influence of the RF field on the radical pairs being ignored. Of course, this assumption is rather simplified because the RF field induces singlet–triplet transitions in the radical ion pairs and, thus, it can, in principle, induce CIDEP.⁵⁰ The line shape in the DNP spectrum in the absence of CIDEP was compared to that obtained with the assumption that CIDEP does not depend on the fields B_1 and B_0 . It was shown that the distinctions become significant in the case of DEE and large B_1 values, *i.e.* in those cases where the spectrum width becomes comparable with the field magnitude B_0 .

The DNP effects have also been studied in the photolysis of anthracene with dimethyl- or diethyl-aniline and in the photosensitised *cis*–*trans* isomerisation of fumaronitrile in the presence of naphthalenes.^{22, 24, 49, 51} The researchers studied the influence of the electron exchange rate and the amplitude of the RF field on the pattern of DNP spectra; the results were in good agreement with theoretical predictions. The dependence of the half-width of the spectrum on the reciprocal concentration of diamagnetic molecules participating in the charge exchange was used to determine the rate constants for the electron exchange of the dimethyl- and diethyl-aniline radical cations.

The sign of CIDEP is known to be determined by the multiplicity of the radical pair and by the sign of exchange interaction.⁵² Upon the change in multiplicity, the sign of CIDEP and, hence, the sign of DNP should be reversed. This was observed,^{25, 51} for example, in the photosensitised isomerisation of fumaronitrile in 1,4-dimethoxynaphthalene. The triplet state of the excited 1,4-dimethoxynaphthalene molecule is lower in energy than the radical-ion pair; therefore, by changing the concentration of fumaronitrile, one can change the multiplicity of the radical pair.⁵³

The measurement of the DEE rate constants can be markedly simplified by proceeding from the dependence of the DNP kinetics on the concentration of the diamagnetic product. This method has advantages over investigation of the concentration dependence of the half-width of the DNP spectra because the half-width of the spectra depends appreciably on the amplitude of the RF field B_1 , whereas the DNP kinetics do not. For the first-order reaction of radical decay, an analytical solution was found; for the second-order reaction, a numerical solution was obtained.⁴⁹ It was shown that the DNP kinetics are determined by the time of electron exchange τ_e , the time of electron relaxation T_1^e and the lifetime of radical ions τ_i . For high concentrations of diamagnetic molecules involved in DEE, the kinetics are described by an exponential function with a decay parameter equal to T_1^e . Figure 5 shows the experimental curves for the DNP kinetics of the photolysis of fumaronitrile with perdeuterated naphthalene. Any curve for $\tau_i > 100$ ns can be described by the exponential function $\exp(-k_{\text{obs}}\tau_i)$, where k_{obs} is the observed rate constant for the exponential decay. The initial pattern of the curve presented in Fig. 5b is due to the time for generation of radical ions. At high concentrations of molecules participating in charge exchange, *i.e.* at low times of DEE, the condition $T_1^e \ll \tau_i$ holds, T_1^e and the experimental dependences of k_{obs} on the concentration of fumaronitrile being adequately described by the formula

$$k_{\text{obs}} \simeq \frac{1}{T_1^e} = \frac{2A^2\tau_e}{1 + \omega_0^2\tau_e^2}.$$

The rate constant for DEE k_e is equal to $(4.52 \pm 0.23) \times 10^9$ litre mol^{−1} s^{−1} and is close to the value estimated from the concentration dependence of the spectra.

In a series of studies,^{25, 54, 55} the DNP method together with time-resolved EPR were employed to identify the radical species resulting from photolysis of heteroaromatic azines in the presence of dimethylaniline in polar solvents. In the DNP study of all the compounds, except for phenazine, the recorded spectra of the dimethylaniline radical cation were narrowed down due to the DEE reaction. This provided grounds for conclusion that the radical-ion pathway contributes to the formation of the compounds under consideration.

Figure 5. Time dependences of DNP obtained for the photolysis of naphthalene- d_8 ($c = 5 \times 10^{-4}$ mol litre $^{-1}$) with fumaronitrile in CD_3CN at different DEE rates. Fumaronitrile concentration (mol litre $^{-1}$): (a) 5×10^{-3} (1), 2×10^{-2} (2), 4×10^{-2} (3); (b) 5×10^{-3} ; (c) 4×10^{-2} . The absolute magnitudes of DNP are plotted on a logarithmic scale (a). The continuous lines (b, c) correspond to the decay of radical ions by an exponential law, dashed lines show the second-order decay of radical ions and describe the contributions of the minor geminate (dashed line) and diffusion polarisations (chain line).

3. Electron–nuclei transitions in short-lived radicals in weak magnetic fields

The influence of an RF field on the nuclear polarisation of diamagnetic products of radical reactions in weak magnetic fields, whose magnitudes are comparable with the HFC constants of radicals, possesses several specific features: the intrinsic wave functions of radicals are no longer the products of the electronic and nuclear wave functions, and the resonance transitions are not purely electronic or nuclear transitions. Therefore, all transitions in these fields involve both the nuclear and the electronic spins. Therefore, the use of relatively low RF-field amplitudes results in substantial changes in the occupancy of the electron–nuclear levels. This effect was called NMR detected electron–nuclear transitions in short-lived radicals (NMR ENR).^{56, 57}

The diagram of the electron–nuclear spin levels of a radical with one magnetic nucleus with the spin 1/2 is shown in Fig. 6. In a weak magnetic field, the probabilities (P) of transitions $n_1 \rightleftharpoons n_2$ and $n_3 \rightleftharpoons n_4$ on exposure to a resonance field are proportional to the expression

$$P_{n_i \rightleftharpoons n_j} \sim |\langle \Psi_{n_i} | \hat{B}_{1x} (\hat{S}_x + \hat{I}_x) | \Psi_{n_j} \rangle|^2 = B_1^2 [\gamma_e \beta_e^2 + c_2^2 (\gamma_n \beta_n)^2],$$

where n_i, n_j correspond in pairs to n_1, n_2 and n_3, n_4 ; Ψ_{n_i} are the wave functions of the $n_{i,j}$ states; the coefficients c_1 and c_2 are determined by the relationship between the HFC constant and the B_0 value. When the magnetic field changes, the coefficients c_1^2 and c_2^2 change from 1 and 0, respectively, in strong magnetic fields (where $n_1 \rightleftharpoons n_2$ and $n_3 \rightleftharpoons n_4$ are purely nuclear transitions) to 0.5 and 0.5, respectively, in the zero magnetic field in which these transitions involve changes in the projections of both electron and nuclear spins. In a strong magnetic field ($c_1 = 1, c_2 = 0$), sub-

Figure 6. Scheme of the energy levels of a radical with one magnetic nucleus and the spin 1/2 in a magnetic field. The arrows show all the transitions allowed in a weak field.

stantial amplitudes of the radio-frequency field are required to saturate these transitions in short-lived radicals

$$B_1 \approx \frac{1}{\gamma_n \tau^*},$$

where

$$\frac{1}{\tau^*} = \frac{1}{T_1^n} + \frac{1}{\tau_1} + \frac{1}{T_{cr}},$$

T_1^n is the time of nuclear relaxation of the radical, τ_1 is the lifetime of the radicals and T_{cr} is the time of electron–nuclear cross-relaxation. With the real values $T_1^n \approx 10^{-4}$ s, $\tau_1 \approx 10^{-5} - 10^{-6}$ s, $T_{cr} \approx 10^{-5}$ s, we have $B_1 \approx 1 - 10$ mT. In weak magnetic fields ($c_1^2 \approx c_2^2$), the probability of transitions is high even for much smaller amplitudes of the radio-frequency field

$$B_1 \sim \frac{1}{c_1 \gamma_e \tau^*},$$

where

$$\frac{1}{\tau^*} = \frac{1}{T_1^e} + \frac{1}{\tau_1} + \frac{1}{T_{cr}},$$

T_1^e is the time of electron relaxation of the radical. Thus, in weak magnetic fields, the probability of transitions is high when radio-frequency fields of about 10^{-2} mT are used.

In radical reactions, the occupancies of electron–nuclear sublevels of radicals are usually non-equilibrated due to CIDNP. It is evident that saturation of transitions would result in equalisation of the occupancies and in a substantial change in the nuclear polarisation of the diamagnetic products. In weak magnetic fields, a radio-frequency field acting parallel to an external magnetic field induces the $n_1 \rightleftharpoons n_3$ transition (see Fig. 6), forbidden in strong magnetic fields. The probability of this transition is proportional to the value $(c_1 c_2 \gamma_e B_1)^2$.

Theoretical description of the NMR ENR effect was made using the numerical solution of the Liouville equation for the spin density matrix of the radical with allowance for electron and nuclear relaxation. Theoretical analysis of the main features of this effect showed that its magnitude is determined by several factors, namely, by the amplitude of the applied radio-frequency field, the coefficients c_1 and c_2 , the lifetime of radicals in solution and by the occupancy of the corresponding electron–nuclear levels (Fig. 7). It can be seen that at relatively small amplitudes of the radio-frequency field, the magnitude of this effect does not depend on the type of the transition excited, while at large amplitudes, it does depend on the type of transition. Thus, by comparing the polarisation intensities corresponding to different transitions in the same magnetic field, one can calculate the occupancies of all the electron–nuclear spin levels of free radicals; analysis of the line shape provides information concerning the

Figure 7. Theoretical NMR ENR spectra. Initial occupancies of the levels $n_1 = 0$, $n_2 = 1/2$, $n_3 = 0$, $n_4 = 1/2$. The multiplet CIDNP arises in a 42 mT magnetic field, $\tau_1 \ll T_{1,2}$, $A = 70$ mT, the amplitude of the applied radio-frequency field B_1 (mT): (a) 3, (b) 0.001.

relaxation times of radicals in a weak magnetic field and on their lifetimes.

Ananchenko *et al.*^{56–58} were the first to carry out experiments on the study of the electron–nuclear transitions in phosphonyl radicals resulting from photolysis of (2,4,6-trimethylbenzoyl)diphenylphosphine oxide and dimethyl 2,4,6-trimethylbenzoylphosphonic acid. Figures 8 and 9 present the NMR ENR spectra recorded upon photolysis of 2,4,6-(trimethylbenzoyl)diphenylphosphine oxide (B_1 is parallel to B_0 , Fig. 8) and dimethyl

Figure 8. NMR ENR spectra of the diphenylphosphinyl radical $\text{Ph}_2(\text{O})\text{P}^\bullet$. RF-field frequency ν (MHz): (a) 431, (b) 750, (c) 1530; RF-field amplitude B_1 (mT): (a, c) 1.1, (b) 1.2. Continuous lines are the simulated spectra constructed as the sum of the SNP contributions (chain line) and the theoretical NMR ENR spectra (dashed line).

Figure 9. NMR ENR spectra of the dimethylphosphonyl radical $(\text{MeO})_2(\text{O})\text{P}^\bullet$. RF-field frequency ν (MHz): (a) 315, (b) 1530, (c) 694; RF-field amplitude B_1 (mT): (a) 1.2, (b) 0.7, (c) 0.9. For the designation of lines, see Fig. 8.

2,4,6-trimethylbenzoylphosphonate in dioxane (B_1 is perpendicular to B_0 , Fig. 9). Polarisation was measured in percent of CIDNP for $B_0 = 42$ mT. It can be seen that the intensity of the $n_1 \rightleftharpoons n_2$ and $n_1 \rightleftharpoons n_3$ transitions exceeds the intensity of the $n_4 \rightleftharpoons n_3$ transitions by a large factor. Based on analysis of the intensities and the signs of resonance lines in the spectrum, it was shown that the initial occupancy of the level n_1 is negligibly small compared to that of the levels n_2 , n_3 or n_4 . Thus, it can be concluded that in weak magnetic fields, the magnitudes of which are lower than the HFC constants of radicals, intense electron polarisation should be observed. It is noteworthy that the results are in good agreement with the conclusions based on analysis of the field dependences of CIDNP for radical pairs with large HFC constants.^{59, 60}

IV. Stimulated nuclear polarisation

Stimulated nuclear polarisation is a phenomenon tightly related to other magnetic and spin effects in radical reactions, in particular, to the chemically induced dynamic nuclear polarisation. The CIDNP method does not bear direct quantitative information about the magnetic-resonance parameters of radical pairs; therefore, it should be combined with other methods such as EPR, optical spectroscopy, *etc.* For example, the use of time-resolved CIDNP, first proposed and implemented by Closs *et al.*,⁶¹ provides quantitative information on the kinetics of the intermediate radical species, the lifetimes of triplet molecules, *etc.*^{62–64}

The SNP method is a combination of CIDNP with the RYDMR principles,^{1–10, 65, 66} based on the selective influence of a variable field on the probability of recombination of separate sub-ensembles of radical pairs. The influence of an RF field on the yield of the reaction products is detected from the change of parameters of the system under study (for example, the resonance photoconductivity of organic semiconductors, the intensity of the recombination fluorescence, the optical absorption of the products, the EPR spectra of stable radicals,⁶⁷ *etc.*).

We shall consider the mechanism of SNP in relation to a radical pair with one magnetic nucleus in strong magnetic fields. Let us assume that the pair has formed in the triplet state and

recombination from the triplet state is forbidden. In the case of strong magnetic fields, the S and T_0 states are degenerate and, therefore, transitions from the non-reactive T_0 state to the reactive S state occur efficiently due to hyperfine coupling. However, transitions from the T_- and T_+ states to the S state are suppressed due to the great energy gap between these states. The CIDNP effect is known to be based on the fact that the probabilities of the S–T transitions are different for radical pairs with different orientations of the nuclear spin. Let the g -factors of the radicals be equal. In this case, the CIDNP effect for a radical pair with one magnetic nucleus is equal to zero. The resonance RF field mixes the T_0 state of the radical pair with the T_- and T_+ states, which accelerates the S–T conversion at small amplitudes of the RF field ($\omega_1 < |\Delta\omega|$) and decelerates it at great amplitudes ($\omega_1 > |\Delta\omega|$). [Here, ω_1 is the amplitude of the RF field, $\Delta\omega = \omega_\alpha - \omega_0 = \omega_0 - \omega_\beta$ is the difference between the resonance frequencies of the radicals R^1 and R^2 (partners of the $R^{1*}R^2$ radical pairs), R^1 contains the magnetic nucleus ($\omega_\alpha, \omega_\beta$) and R^2 contains no nuclei with a non-zero HFC constant (ω_0).] We assume that $\omega_1 < |\Delta\omega|$. If the resonance-field frequency is equal to the resonance frequency ω_α of electron transitions in the radical R^1 with α -orientation of the nuclear spins, the acceleration of S–T transitions would involve only the sub-ensemble of radical pairs with this spin orientation and the products of recombination of radical pairs would mainly contain nuclei with the α -projection of spins. This would result in enhanced absorption in the NMR line of in-cage products. The nuclei of the escape products of the recombination of the radical pair would be mainly characterised by the β -projection of spins and the corresponding line in the NMR spectrum would be an emission line (Fig. 10). If the frequency of the RF field is equal to the ω_β frequency of the electron transitions in the R^1 radical with the β -orientation of nuclear spins, emission would be observed in the NMR lines of the in-cage products and absorption would be observed in the spectra of escape products. The effect of the RF field on the resonance frequency of the R^2 radical (ω_0) will induce acceleration of the S–T conversion with the same efficiency for both sub-ensembles of radical pairs and, hence, will not change the nuclear polar-

Figure 10. Scheme for the generation of SNP for a radical pair with one magnetic nucleus (a) and its EPR (b) and SNP (c) spectra.

isation of the products. Thus, the positions of the resonance lines in the SNP spectrum correspond to the resonance frequencies in the EPR spectrum of the radical pair, and the signs of the resonance lines are determined by the signs of the HFC constants and by the pathways to diamagnetic products the NMR spectrum of which is used to detect the SNP.

In the case where $\omega_1 > |\Delta\omega|$, i.e. under spin-locking conditions, the RF field retards the S–T conversion and, hence, the signs of SNP would be opposite to those observed in the case described above. On the basis of these considerations, Mikhailov *et al.*⁶⁸ formulated the rule for determining the sign of polarisation of the products for the case of net SNP

$$\Gamma = \mu\epsilon\psi\eta A_k,$$

where $\Gamma > 0$ corresponds to the positive (absorption) and $\Gamma < 0$, to the negative SNP effect (emission), $\mu = 1$ or -1 for a triplet or a singlet radical pair; $\epsilon = 1$ or -1 for the in-cage or escape product; $\psi = 1$ or -1 for low- or high-field component of the HFC spectrum of the chosen nucleus; $\eta = 1$ for $\omega_1 < |\Delta\omega|$ and $\eta = -1$ for $\omega_1 > |\Delta\omega|$, A_k is the isotropic HFC constant at the k -th nucleus polarisation of which is considered.

For radical pairs with any number of magnetic nuclei, the SNP spectrum is a superposition of the spectra of separate sub-ensembles of radical pairs with fixed configurations of nuclear spins. In a real situation when the spin dynamics of radical pairs are overlapped by the molecular motion of radicals, the spectral lines have a finite width and, in the general case, for several nuclei with different HFC constants, the SNP spectral pattern is markedly complicated. Therefore, to analyse the experimental SNP spectra, one should compare them with the theoretical spectra.

Exchange interaction markedly influences the pattern of the SNP spectra. We shall consider this influence qualitatively in relation to a biradical with one magnetic nucleus (Fig. 11 a,b). The relative positions of the energy levels are determined by the ratio of the HFC constants A , the effective exchange interaction J_0 and the external magnetic field B_0 . The effects of nuclear polarisation, both chemically induced and stimulated, depend substantially on the ratio of the intersystem crossing rates (K_{S-T_0} , K_{S-T_-}). In the case where the average exchange interaction $\gamma_e B_0 < 2|J_0|$ (Fig. 11 a), the rate of intersystem crossing via the S– T_- channel is higher than that via other channels ($K_{S-T_-} > K_{S-T_0}$, K_{S-T_+}); therefore, the occupancy of the T_-^z state is lower than those of the T_+^z or T_0^z states. Radio frequency pumps the T_-^z level and thus increases the number of radical pairs recombining upon $T_-^z \rightarrow S^0$ transitions. As a consequence, the products of recombination become enriched in the nuclei with the β -projection of nuclear spins. The SNP spectrum of radical pairs is an emission line. Otherwise, $\gamma_e B_0 > 2|J_0|$ ($K_{S-T_0} > K_{S-T_-}$, K_{S-T_+}) (Fig. 11 b) and the occupancy of the T_0^z state is lower than that of the T_-^z or T_+^z states. In this case, the number of radical pairs recombining via the S– T_0 channel of intersystem crossing increases under the action of the RF field. The SNP spectral pattern is normal — the signs of polarisation of the spectral lines depend on the signs of the projection of the nuclear spins, the exchange interaction being manifested as a change in the line splitting in the spectrum. Thus,

Figure 11. Diagram of the electron levels of a biradical with one magnetic nucleus for strong (a) and weak (b) exchange interaction.

the magnitude of exchange interaction can be judged both from the pattern of the S–T₀ or S–T_– type spectrum and from the splitting in the S–T₀ type SNP spectrum. Apart from the exchange interaction, splitting in the SNP spectra is influenced by spin-selective decay of radical pairs, which can diminish splitting even in the absence of exchange interaction.⁶⁹ It was shown^{69,70} that exchange interaction, electron relaxation and fast decay of the singlet state are factors influencing the splitting of lines in the SNP spectra because they all result in dephasing of the singlet–triplet transitions.

Theoretical description of the SNP effects has been the object of a number of studies^{69–81} in which various approaches were employed. Thus Mikhailov *et al.*⁶⁸ developed a theory of SNP for reactions of neutral radicals with isotropic reactivity in strong magnetic fields based on the mathematical apparatus used traditionally to study the geminate recombination of radicals with allowance for the S–T₀ transitions in radical pairs. The SNP effects were calculated in this study by summing the contributions to recombination of all the radical re-encounters.⁸² This method is based on the assumption that the spin dynamics in radical pairs and relative molecular motion of radicals in solution are completely separate and implies the use of numerical calculations. However, numerical analysis of the SNP effects in systems with many magnetic nuclei is highly time-consuming. Analytical expressions have been obtained^{72,83} for the calculation of the probability of recombination of radical pairs with a specified configuration of nuclear spins and of the SNP effects on the assumption of low efficiency of singlet–triplet transitions in radical pairs.

The effects of various parameters on the line intensity and the pattern of the SNP spectrum have been studied theoretically.⁶⁸ It was shown that the intensity and the sign of SNP as well as the spectral pattern depend substantially on many molecular-kinetic and magnetic-resonance parameters of the radical pair, solvent viscosity, reactivity of radicals, the occurrence of reactions of the radicals with acceptors, the amplitude and the frequency of a microwave field, the HFC constants and *g*-factors of radicals. Therefore, detailed interpretation of experimental data can only be performed resorting to calculations of the SNP effects.

Osintsev *et al.*⁸⁴ used the kinematic approach to derive the analytical expressions for calculating the SNP effects of radical pairs with one HFC constant in arbitrary magnetic fields. In another study,⁷³ these researchers analysed the line profile in the SNP spectra in weak magnetic fields, comparable with the HFC constant, for different RF-field amplitudes. It was shown that in weak fields, additional lines which are missing in strong fields appear in the spectrum.

The effect of a powerful RF field during recording of the SNP spectra in weak magnetic fields gives rise to new resonance characteristics in the spin dynamics of radical pairs, which are multi-quantum resonances from the standpoint of quantum theory.⁷⁴ Experimentally, this shows itself as the appearance of signals in the SNP spectra in the Zeeman fields *B*₀ approximately divisible by the field of the main resonance.²⁵ The kinematic approximation has also been used successfully⁷³ to design the theory of multi-quantum resonances under the conditions of SNP.

Characteristic features of the SNP spectra for spin-correlated radical pairs in strong magnetic fields have been considered taking a two-position model as an example.⁸¹ It was found that narrow lines the nature of which is due to the degeneracy of two electron transition frequencies appear in the SNP spectra under definite conditions. From the width of these lines, the lifetime of spin-correlated radical pairs can be determined. Note that similar features are characteristic of the spectra of radical pairs measured using the optically detected electron paramagnetic resonance (OD EPR) technique.⁸⁵

The SNP effects in systems with non-zero exchange interaction depending on the distance between the radical sites (short-lived biradicals,⁶⁹ radical pairs in micelles^{75–78}) can be described

using an approach based on the numerical solution of the stochastic Liouville equation.

1. Stimulated nuclear polarisation of radical pairs in homogeneous solutions

The SNP effects were first observed experimentally for recombination of the biradicals formed upon photolysis of cyclododecane.⁸⁶ Subsequently, it has been shown in relation to the photolysis of benzoyl peroxide in various solvents⁸⁷ that recombination of radicals in the liquid phase proceeding *via* the formation of radical pairs consisting of the phenyl and phenacyl radicals [Ph[•]OC(O)Ph] is accompanied by substantial polarisation. Bagryanskaya *et al.*⁸⁷ carried out experiments in weak magnetic fields (*B*₀ = ~ 3.0 mT, *ν* = 94.5 MHz), the magnitudes of which are comparable with the HFC constants in the phenyl radical. The pattern of the SNP spectrum was complex, which substantially hampered interpretation of the data obtained, especially for *B*₁ ≈ *A*. Subsequently, the main regularities of SNP have been investigated in the photolysis of *p*-benzoquinone and duroquinone in CD₃CN, CDCl₃ and CD₃OD in weak and strong magnetic fields.^{12,20,21,34,88} Photolysis of benzoquinone in CD₃CN has been used as an example to study⁸⁶ the effect of spin locking, which was then employed to estimate the amplitude of the RF field when working in a high-frequency resonator. By comparing the dependences of SNP on the amplitude of the radio-frequency field in weak magnetic fields in the case of low pumping frequency (100 MHz, when measurements of the *B*₁ value are rather simple) and in strong magnetic fields in the case of high pumping frequency (1.6 GHz), one can determine the amplitude *B*₁ in the resonator for the high-frequency case. Multi-quantum resonances were detected experimentally in the high-field region of the SNP spectra measured at great RF field amplitudes (*B*₁ ≫ *A*).²⁵

As noted above, the method of SNP permits identification of intermediate short-lived species (radical and radical-ion pairs) and also provides information on the pathways of formation of the reaction products. For example, SNP has been used⁸⁹ to study elementary steps in the photolysis of anthraquinone (AQ) with triethylamine in solvents with different polarities. For the reaction carried out in polar solvents (CD₃CN, CD₃OD), the spectrum of triethylamine radical cation was measured using the NMR line of the triethylamine CH₂ group. Based on the sign of the spectrum, it was concluded that triethylamine is an in-cage product of recombination of the radical-ion pair {[AQ]^{–•}··⁺[Et₃N]}[•]. For the photolysis of triethylamine and anthraquinone in CD₃OD, the SNP spectrum was measured based on the NMR signal of the proton of the hydroxy group in CD₃OH. This spectrum differed from the SNP spectrum recorded using the signal of the triethylamine CH₂ group only by the sign; hence, it corresponds to an escape product of transformation of the triethylamine radical cation. This fact indicates that the hydroxyl proton of the alcohol has come from the CH₂ group of the triethylamine escape radical cation. Thus, the authors concluded that the reaction takes place between hydroxyalkyl and aminoalkyl radicals. In non-polar solvents, in particular, in benzene, the SNP spectrum corresponds to the EPR spectrum of the aminoalkyl radical MeCH₂NEt. In medium-polarity solvents (cyclohexane and isopropanol), both pathways are effective (the radical-ion and radical pathways).

It should be borne in mind that signals in the SNP spectra can differ substantially for continuous and pulse photolysis modes.^{28,90} For example, the intensity of signals recorded during pulse laser photolysis of benzoquinone and benzaldehyde decreases by a factor of dozens when a mercury light is used as a continuous source of light. The signal intensity in the SNP spectra does not change if the radicals decay in a first-order reaction, for example, in the photolysis of benzoyl peroxide, cyclic ketones, *etc.* In the steady-state photolysis, the lifetime of radicals normally exceeds the time of nuclear relaxation of the intermediate radicals (10^{–4} s), the observed polarisation being due to the contribution of the polarisation of the in-cage recombination products. In the

case of pulse generation of radicals, the opposite situation is observed, *i.e.* the lifetime of radicals is usually shorter than the nuclear relaxation time. Hence, the total polarisation of diamagnetic products formed both in the cage and as a result of radical recombination in the bulk markedly decreases or disappears.

In a study of laser photolysis of *p*-benzoquinone in methanol by SNP, it has been found^{25,91} that cyclohexadienyl type radicals with methoxy- or hydroxymethyl groups participate in the reaction. The SNP spectra based on the signals present in the NMR spectra of benzoquinone, hydroquinone and the alcohol (the hydroxyl-proton signal) differ appreciably from the SNP spectra of radical pairs of semiquinoid radicals measured for continuous photolysis under the same conditions. The distance between the terminal lines in the spectrum (4.5 mT) indicates that the reaction involves radicals with the high HFC constants of the ring protons. Comparison of experimental SNP spectra with those calculated for several assumed radical species with allowance for HFC constants (calculated by the MNDO method) made it possible to establish the structure of the intermediate radical.

Figure 12 *a, b* shows the NMR and SNP spectra recorded for the photolysis of 2-chloro-2-methylbutan-3-one in C₆D₁₂.³²

Stimulated nuclear polarisation is observed for all diamagnetic products 1–4. The experimental spectra of in-cage products are in good agreement with the spectra calculated for the [Me₂(CO-Me)C[•]·C₆D₁₁] radical pair. To attain agreement between the theoretical and experimental SNP spectra of escape products,

Figure 12. NMR spectra recorded for the photolysis of 2-methyl-2-chlorobutan-3-one in C₆D₁₂ (*a*) [(1) spectrum in the dark, (2) CIDNP spectrum] and experimental and simulated SNP spectra for reaction products (*b*); (1) product 1, (2) product 2, (3) product 4, (4) product 3. The continuous lines are simulated spectra. (1, 2) with allowance for the contributions to SNP of the escape products of the geminate radical pair [Me₂(COMe)C[•]·C₆D₁₁] and in-cage products of the diffusion radical pair [Me₂(COMe)C[•]·C(COMe)Me₂]; (3, 4) calculations of the SNP of the in-cage products from the geminate radical pair [Me₂(COMe)C[•]·C₆D₁₁].

contributions of both radical pairs, [Me₂(COMe)C[•]·C₆D₁₁] and [Me₂(COMe)C[•]·C(COMe)Me₂], should be taken into account.

The influence of the DEE rate on the pattern of SNP spectra has been studied.⁴⁸ It was shown that, since DEE results in frequency exchange between the components of the spectrum with opposite polarisation signs, the narrowing of lines is accompanied by a decrease in their intensities; in the limit, the lines disappear.

The influence of DEE on the SNP effect has been studied in detail both experimentally and theoretically.⁹² The researchers used two approaches to the theoretical description of the SNP spectra with allowance for DEE. In the former case, the spectra were calculated using the theory of uncorrelated frequency migration for a radical pair with two magnetic nuclei. In the latter case, for a weak RF field ($B_1 \ll A$), a two-position model was proposed. In the case of low DEE rates ($A\tau_e \gg 1$, where τ_e is the time of DEE, $\tau_e = 1/k_e[A]$ (or $[D]$), $[A]$ or $[D]$ is the concentration of the acceptor or the donor participating in the DEE reaction), this model provides an analytical expression describing the variation of the SNP amplitude *vs.* the exchange time τ_e . Photo-induced isomerisation of fumaronitrile in the presence of deuterated naphthalene in acetonitrile was chosen as the model reaction for experimental investigations. Figure 13 shows the SNP spectra of radical pairs resulting from photolysis of fumaronitrile with naphthalene over broad ranges of DEE rates and RF-field amplitudes. At low fumaronitrile concentrations when the influence of DEE is negligibly small, the SNP spectra resemble the spectra based on calculations for neutral radical pairs without

Figure 13. SNP spectra recorded for the photolysis of naphthalene-d₈ (2×10^{-3} mol litre⁻¹) with fumaronitrile and detected from the NMR signal of the fumaronitrile protons. Fumaronitrile concentration (mol litre⁻¹): (1) 10^{-3} , (2) 10^{-2} , (3) 5×10^{-2} . RF-field amplitudes (mT): (*a*) 0.25, (*b*) 0.67, (*c*) 1.2. The dashed lines correspond to the spectra calculated with allowance for all the HFC constants using the theory of SNP for neutral radical pairs without DEE. The continuous lines are the spectra calculated using the theory of uncorrelated frequency migration for a radical pair with two magnetic nuclei.

allowance for charge exchange. The calculation was carried out taking into account all the HFC constants in radical pairs in terms of the theory of SNP in strong magnetic fields. It can be seen from Fig. 13 that the pattern of the SNP spectra is extremely sensitive to the RF-field amplitude. As the concentration of fumaronitrile increases, SNP sharply decreases; line splitting in the spectra also decreases. To measure the rate constant for DEE in radical-ion reactions by comparison of the theoretical and experimental SNP spectral patterns, the dependence of the SNP intensity on the exchange time τ_e at low RF-field amplitudes in the absence of fast trapping of radical ions was used.

The SNP method was utilised to study the photoinduced electron transfer from quadricyclanes to tetrafluorobenzoquinone. It was shown⁹³ that the radical-ion pair in this reaction incorporates the quadricyclane radical cation. Isomerisation of quadricyclane into norbornadiene takes place in the free radical ion rather than in the step of formation of the radical-ion pair.

The majority of researchers studied reactions in homogeneous solutions by ^1H NMR spectroscopy. However, detection of SNP using other nuclei (^{13}C , ^{31}P , ^{19}F , etc.) appears quite promising. Figure 14 presents the ^{31}P SNP spectrum of the radical pair formed in the photolysis of (2,4,6-trimethylbenzoyl)diphenylphosphine oxide. Splitting in the spectrum corresponds to the HFC constant at the phosphorus nucleus. A specific feature of SNP at the ^{31}P nuclei is large HFC constants comparable with the magnitude of the external magnetic field. Therefore, calculations cannot be carried out using the strong magnetic field approximation. In addition, for radical pairs with large HFC constants, contributions of S–T₋ transitions occurring in the area of intersection of terms should be taken into account.^{59, 60}

The potential and advantages of the time-resolved SNP method were verified experimentally²⁸ taking photolysis of benzoyl peroxide (in CD_3OD or CD_3CN) as an example. It was shown that the delay (τ) between the laser pulse and the RF pulse inverts the observed SNP spectrum. A study of the dependence of SNP on τ in different magnetic fields for different resonance lines demonstrated that the inversion of the spectrum takes place at $\tau > 50$ ns, and subsequently the spectral pattern changes only slightly. Apparently, the spectrum corresponds to the $[\text{Ph}^\bullet\text{Ph}]$ and $[\text{Ph}^\bullet\text{CD}_2\text{OD}]$ pairs.

Osintsev *et al.*⁸⁴ have considered theoretically the problem of the line shape in the SNP spectra recorded in time-resolved experiments and the dependence of SNP on the character of motion of the partners of radical pairs. From the theoretical standpoint, consideration of these processes is reduced to the

calculation of the probability of recombination of geminate radical pairs. (The theory of recombination of radical pairs with a Hamiltonian changing abruptly with time has been formulated.^{94, 95}) It was shown⁸⁴ that the width of the SNP line at small amplitudes of the RF field is determined by the amplitude of the RF field, while the intensity of the SNP spectral line depends on this amplitude according to a law describing diffusion motion. The use of a delay between the laser and RF pulses should not result in a substantial narrowing of SNP lines. This is due to the fact that the re-encounter of partners in radical pairs which takes place after a prolonged diffusion walk contributes significantly to the SNP. As long as the delay τ differs from zero, this contribution remains crucial. The variation of the intensity of the SNP line in the magnetic field corresponding to the resonance line maximum vs. the delay τ appears the most informative. For great delays, the dependence typical of diffusion motion should be observed. The SNP kinetics calculated using the two-position model is described by an exponential curve with a characteristic exponent parameter equal to the constant for the irreversible decay of radical pair τ_c . The expected line widths in the SNP spectrum should not depend on the amplitude of the RF field and are determined by the reciprocal time $1/\tau_c$.

Time-resolved SNP experiments for geminate radical pairs in homogeneous solutions are currently impossible because the characteristic lifetime of radical pairs is about several nanoseconds and, to obtain real kinetics, it would be necessary to initiate the reaction by lasers with nanosecond pulse duration. In addition, it would be necessary to create a rise time of about 1 ns for the RF pulse, which is a difficult engineering problem. However, the lifetimes of short-lived biradicals and micellised radical pairs lie in the range from tens to hundreds of nanoseconds; the kinetics of these systems can be studied experimentally.

2. Stimulated nuclear polarisation of short-lived biradicals

Biradicals are formed as intermediates in many photochemical processes; therefore, it is important to investigate them in order to elucidate reaction mechanisms. As a rule, the lifetimes of flexible biradicals are about 0.1–1 μs . They are determined by the rates of intersystem crossing from the non-reactive triplet state to the singlet state, recombination from the singlet state and the conformational motion of radical centres. Photolysis of aliphatic cyclic ketones with rupture of the α -bond is a perfect method for the investigation of short-lived biradicals. The α -bond rupture occurs from the excited triplet state almost in all cases. The introduction of methyl or phenyl groups in the α -position decreases the activation energy and increases the rate of α -rupture to 10^9 s⁻¹ or more. The acylalkyl biradical thus formed can be decarbonylated giving rise to alkyl biradicals. The rate of decarbonylation increases substantially upon α -substitution. For biradicals formed in the photolysis of aliphatic cyclic ketones, the rate of molecular motion in non-viscous solutions at room temperature is much higher than the rate of spin dynamics. In the absence of steric hindrance, recombination from the singlet state is not the rate-determining step either; thus, the lifetime of biradicals is determined by the rate of the triplet–singlet conversion, which depends on the hyperfine electron-exchange and spin-orbital interactions and on the electron spin relaxation.

The main features of the generation of SNP in biradicals have been studied experimentally in relation to the photolysis of several aliphatic cyclic ketones $\text{O}=\text{C}(\text{CH}_2)_n$ ($n = 10\text{--}13$).^{86, 96–99} As noted above, the major pathway of the photolysis of cycloalkanonones is α -rupture in the triplet-excited ketone, resulting in the formation of an acylalkyl biradical. Variation of the length of the polymethylene chain of the ketone, the HFC constants (by using ketones in which the protons in the α -position have been replaced by D or CH_3) and the external magnetic field, as well as detection of SNP from ^1H and ^{13}C NMR spectra make it possible to vary the ratio of A , J and B_0 over a broad range.

Figure 14. ^{31}P SNP spectra of radical pairs formed in the photolysis of (2,4,6-trimethylbenzoyl)diphenylphosphine oxide. The spectra were detected using the NMR signal of diphenylphosphine oxide. Polarisation was measured in percent of the CIDNP for $B_0 = 43$ mT. B_1 (mT): (1) 1, (2) 0.6, (3) 0.4. The continuous lines are the spectra simulated using the analytical formula for weak magnetic fields.⁷³

For biradicals with $n = 10-13$ in weak magnetic fields (3–12 mT), the S–T₋ channel of intersystem crossing predominates. Both emission CIDNP and emission SNP can be observed in the NMR signals of all groups of protons of ketones and aldehydes. Polarisation on the ketone γ -protons, for which the HFC constant in the biradical is close to zero, arises due to the transfer of the nuclear polarisation from the α -CH₂ groups of the ketone, induced by the transfer of the sample from a weak to a strong magnetic field. For ketones with $n = 11-13$ in a ~ 50 mT field, the main intersystem crossing channel is S–T₀; no signals for the ketone protons are observed in the SNP spectra in this field because the HFC constants of α - and β -protons in biradicals have different signs, and the lines for opposite signs overlap. When the chain length decreases, the effective value of exchange interaction increases; an emission SNP spectrum is obtained in a 50 mT field for biradicals formed in the photolysis of cyclodecanone ($n = 10$). Koptug *et al.*⁹⁶ reported calculations of SNP of short-lived biradicals performed for a realistic model, which had been used previously¹⁰⁰ to describe the field dependences of CIDNP. Presumably, exchange interaction occurs through the spatial overlap of the orbitals of unpaired electrons and is attenuated according to an exponential law as the distance r between the electrons increases

$$J(r) = J_0 \exp(-\alpha r),$$

the interaction anisotropy being averaged due to the fast rotations of the terminal groups of the polymethylene chain. Two mechanisms of electron spin relaxation were taken into account, one due to fluctuation of local magnetic fields and one, due to dipole–dipole interaction of the spins of the unpaired electrons. The pattern of the calculated SNP spectra is highly sensitive to the exchange interaction constant J_0 . Using experimental and theoretical spectra obtained for different radio frequencies, the optimal values for J_0 and α were found. Koptug *et al.*⁹⁶ studied theoretically the influence of several parameters, namely, the diffusion coefficient, the rate of trapping of biradicals, the rate of decay of the triplet biradical due to the spin-orbital interaction, and the electron spin relaxation, on the pattern of the SNP spectra. It is significant that all parameters, except the diffusion coefficient, have little influence on the shape of spectral lines but can only cause a decrease in the signal intensity. As noted above, the dependence of the signal intensity in the SNP spectrum on the delay τ bears information on the lifetimes of radical pairs. For instance, this dependence has been used⁹⁶ to estimate the lifetimes of short-lived biradicals formed upon photolysis of cyclodecanone. The characteristic times of SNP decay were ~ 80 ns. Due to the lack of a theory of time-resolved SNP for biradicals, the researchers could not use the experimental data to perform a profound analysis or to gain new information.

The kinetics of SNP of short-lived acylalkyl biradicals in homogeneous solutions in weak magnetic fields (~ 10 mT) have been studied.^{27, 101} Two types of radio-frequency pulses were used, a long pulse (~ 2 μ s) and a short pulse with a duration at half-height of 15 ns. It was shown that the kinetic dependences of SNP pass through a maximum when the delay between the laser pulse and the RF pulse is 40 ns and then decay by an exponential law. The appearance of the maximum is due to the competition between spin-dependent and spin-independent channels of the triplet–singlet conversion. The kinetics of SNP were described using a simple kinetic model. From comparison of the experimental data with the calculated data, the researchers estimated the rate of spin-orbital interaction, the electron relaxation rate and the lifetimes of the excited triplet molecules of ketones. Upon the addition of a quencher for triplet states (*cis*-piperylene), the time for attenuation of the SNP signal diminishes to reach a limiting value equal to the lifetime of the biradical. Proceeding from these results, the lifetimes of biradicals (80 ns for cyclododecanone and 50 ns for cycloundecanone) and of triplet molecules (250 ns for cycloundecanone and 150 ns for cyclododecanone) were estimated.

The ¹³C SNP spectra of acylalkyl biradicals with $n = 11$, in which the ¹³C isotope occurs in the carbonyl position or in the α -position, differ significantly. This is due to the difference between the HFC constants and, correspondingly, different ratios of the external magnetic field to the HFC constants, resulting in dissimilar efficiencies of the competing intersystem crossing channels.¹⁰² As shown by calculations performed in terms of the two-position model in weak and zero magnetic fields, the pattern of the SNP spectra of short-lived biradicals is exceptionally sensitive to the rate of spin-non-selective intersystem crossing; this can be used to measure their rates.

The main regularities of the origination of SNP in the consecutively formed biradicals were studied experimentally and theoretically¹⁰³ in relation to the acylalkyl and bisalkyl biradicals formed in the photolysis of tetramethyl-substituted cycloalkanes with $n = 11-15$. A specific feature of the consecutive biradicals, as well as of the consecutive radical pairs, is the ‘memory effect’, which implies that nuclear polarisation of the diamagnetic products of the secondary radical pairs or biradicals reflects the spin dynamics processes in both the primary and the secondary pair (biradical). Due to the high spectral selectivity, typical of the NMR method, when recording the NMR spectra of various recombination products, the authors were able to obtain simultaneously the SNP spectra of primary and secondary biradicals arising during photolysis. A model for the calculation of SNP for the consecutive biradicals was developed; the generation of SNP was studied both experimentally and theoretically. The main characteristics influencing the line intensity and the pattern of the SNP spectra of secondary biradicals are the rate constant for the electron relaxation of both biradicals, the time required for relaxation processes, the rate constant for the spin-orbital interaction, parameters of the exchange interaction of both primary and secondary biradicals, the rate constant for decarbonylation, the type of the main intersystem crossing channel in the biradicals, and the ratio of the polarisation intensities for the first and the second biradicals. Note that for the symmetrical biradicals, in which the HFC constants for various radical centres are equal, the SNP spectral pattern differs appreciably from the case considered above. This is due to the fact that, in symmetrical biradicals or radical pairs in strong magnetic fields, the SNP effect is equal to zero. This fact can be easily understood from a qualitative consideration. Saturation of the electron transitions in radical pairs with identical orientations of nuclear spins does not accelerate the intersystem crossing. In the radical pairs with the opposite orientation of nuclear spins, the S–T conversion is accelerated for both sub-ensembles of radical pairs. Thus, the overall polarisation induced by a microwave field would be equal to zero. When calculating the SNP in symmetrical biradicals in weak magnetic fields, it is necessary to take into account both HFC constants in the secular approximation. If one HFC constant is taken into account in the secular approximation, while the second, is in a non-secular approximation, a non-symmetrical radical pair is actually considered and an S–T₀ type spectrum appears in the calculated SNP spectra. Unlike biradicals with different HFC constants, for which the spectral pattern is determined by the major channel of the singlet–triplet conversion, for symmetrical biradicals, the SNP spectra would always correspond to the S–T₋ type even in those cases where S–T₀ is the major channel of intersystem crossing.

Study of the SNP of acylalkyl and bisalkyl biradicals in different magnetic fields (Fig. 15) allowed the authors to determine the J_0 value, which describes adequately all the experimental data. In the photolysis of ketones with $n = 11$, on the basis of the NMR signals of the products resulting from the bisalkyl biradicals, the S–T₋ type spectra represented by one emission line ($B_0 = 54.6$ mT) were observed (Fig. 15c). For $n = 12$, inverted S–T₀ type spectra were recorded (Fig. 15d). The lower limit of the J_0 range was established by comparing the calculated and experimental SNP spectra of biradicals with $n = 11$ (S–T₋ type), while

Figure 15. Experimental (dots) and calculated (continuous lines) SNP of acylalkyl $[\text{OC}^*\text{CMe}_2(\text{CH}_2)_{n-2}\text{C}^*\text{Me}_2]$, $n = 11$ (a), 12 (b) and bisalkyl $[\text{MeC}^*(\text{CH}_2)_{n-2}\text{C}^*\text{Me}_2]$, $n = 11$ (c), 12 (d) biradicals formed in the photolysis of tetramethyl-substituted cycloalkanones.

the upper limit was found by comparing the spectra of biradicals with $n = 12$ (S– T_0 type) in a 27 mT field.

In the literature, the short lifetime of the acylalkyl biradicals is attributed most often to the presence of spin-orbital interaction between the radical centres of the biradical (see, for example, Ref. 104). This statement is true for biradicals with relatively short chains ($n = 5, 6$). Evidently, the influence of spin-orbital interaction on the lifetime of the biradical depends on the residence time of radical centres in the reaction volume. For biradicals with long chains, the residence time of the radical centres in the reaction area is short; therefore, the role of relaxation occurring due to spin-orbital interaction should markedly decrease. On the basis of analysis of the SNP experimental kinetics for biradicals with $n = 12$ –15, 17, it was concluded that in addition to the spin-orbital interaction, spin-rotational relaxation also plays an important role.¹⁰³

The influence of temperature and viscosity on the spin and molecular dynamics of short-lived alkylacyl and bisalkyl biradicals formed successively has been studied both experimentally and theoretically.¹⁰⁵ The ^1H and ^{13}C CIDNP and SNP effects were studied in the temperature range from 200 to 360 K for magnetic fields varying from 0 to 0.1 T. The investigators found a unified set of parameters that describe adequately the nuclear polarisation effects for both protons and ^{13}C atoms with different HFC constants in the biradical. The introduction of a temperature dependence of the biradical reactivity proved especially important for attaining quantitative agreement between the calculated and experimental data in the low-temperature range. Comparison of the experimental data with the results of model calculations showed that broadening of the field dependence of CIDNP and slowing down of the decay of SNP signals at temperatures below 240 K is due both to the retardation of the molecular mobility of the polymethylene chain and to the decrease in the reactivity of the acylalkyl biradicals. For the bisalkyl biradicals, spin-orbital interaction is less important for the spin dynamics than in the acylalkyl radicals. The effect of molecular dynamics on the field dependences of the CIDNP of the products formed from bisalkyl biradicals with the change in temperature is more pronounced. Since the lifetime of bisalkyl biradicals is much longer than the lifetime of acylalkyl biradicals, the intensity of nuclear polarisation of the products formed from bisalkyl biradicals is much higher.

3. Stimulated nuclear polarisation of micellised radical pairs

Micellar solutions as a specific microstructured medium have been drawing attention of photochemists during the last decades. Numerous publications^{106–115} are devoted to the detection and investigation of extremal magnetic effects and magnetic isotope effects, nuclear and electron polarisation and other effects in radical pairs located in micelles. In micelles, radical pairs are isolated; this enables detailed investigation of the geminate recombination of radicals and spin and molecular dynamics of radical pairs. Since in radical pairs occurring in micelles, the partners are located at short distances from each other throughout their whole lifetime, the electron exchange interaction has a considerable influence on the intersystem crossing in these radical pairs. The field dependences of ^{13}C CIDNP of radical pairs formed upon photolysis of dibenzyl ketone in sulfate micelles of different sizes have been studied.¹⁰⁸ The polarisation of the ^{13}C nuclei in both strong and weak fields (irrespective of the sign of the HFC constant) was found to be emission polarisation. The ‘maximum’ of the field dependence of CIDNP shifts upfield as the size of micelles decreases. On the basis of experimental data, it was concluded that CIDNP is mainly due to S– T_0 transitions. The effective exchange interaction estimated from the field dependence of CIDNP was ~ 30 mT. However, the results obtained by CIDEP for a number of systems are at variance with the conclusion concerning large values for average exchange interactions. In the EPR spectra of micellised radical pairs, each hyperfine-structure line is split into two. This splitting can be described by including a constant exchange interaction $|J| \approx 5$ –10 MHz into the Hamiltonian in model calculations.¹¹⁵ Similar estimates were obtained in RYDMR experiments in micelles.¹¹⁴ Later, it was shown that modulation of the exchange interaction due to the mutual motion of radicals should be taken into account in the description of the spectral patterns and the CIDEP kinetics of spin-correlated pairs in micelles.¹¹⁶ The use of the SNP method for the investigation of the effect of exchange interaction on the intersystem crossing in radical pairs confined in micelles proved quite effective.^{75–78, 117–123} Stimulated polarisation is detected from the NMR signals of the diamagnetic products of recombination of radical pairs; therefore, it reflects the influence of the exchange interaction on the intersystem crossing in radical pairs localised in micelles to a greater extent than CIDEP, in which the predominant contribution to the spectral signal is made by free radicals.

The ^{13}C and ^{31}P SNP techniques were used to study the radical pairs resulting from photolysis of α -methyldeoxybenzoin,^{77, 119, 122, 123} dibenzyl ketone,^{76, 78, 117, 118, 122} benzoin,⁷⁸ deoxybenzoin,¹²⁴ benzophenone in the presence of *tert*-butylphenol¹²¹ and (2,4,6-trimethylbenzoyl)diphenylphosphine oxide¹²⁰ in the sulfate micelles $\text{Na}^+\text{SO}_3^-\text{O}(\text{CH}_2)_n\text{Me}$ of various sizes ($n = 6$ –11). The significant differences in the ratios of the HFC constants and the lifetimes of these radical pairs permitted the researchers to examine the influence of the exchange interaction on the pattern of the SNP spectra. It was discovered that line splitting and line width in the spectra depend on the size of micelles. From comparison of the spectra recorded in strong and weak magnetic fields and the field dependences of CIDNP with the spectra calculated theoretically, parameters of the molecular and spin dynamics of micellised radical pairs were found.

The dynamics of radical pairs in micelles were described using a microreactor model — one radical was fixed in the centre of a spherical micelle, whereas the other was moving inside the micelle core.^{75–78} In addition, a diffusional character of the motion was assumed. The electron spin relaxation due to the dipole–dipole interaction and due to modulation of the anisotropic part of HFC was taken into account.⁷⁷ The allowance for the dipole–dipole relaxation was made by two methods. One approach is similar to that described previously⁶⁹ for the calculation of the field dependences of CIDNP and SNP in short-lived biradicals. The other approach is more consistent; it was used (in combination with the Monte Carlo method)¹²⁵ to calculate the correlation function of

the dipole–dipole interactions in radical pairs for micelles of different sizes. Subsequently, an analytical expression describing the dipole–dipole relaxation was obtained.¹²⁶ The main parameters determining the molecular dynamics of radicals are the coefficient of mutual diffusion D , the micelle radius L , the reaction radius and the rate constant for the radical exit to the bulk k_{ex} . Splitting in the SNP spectra depends on the ratio of the following values: the HFC constants, the characteristic time between the collisions of radicals inside the micelle

$$\tau_2 = \frac{L^3 - R^3}{3RD} \sim \frac{L^3}{3RD},$$

the exchange interaction and the rate of the spin-selective decay. Upon a decrease in the micelle size, the time the radical pair spends in the reactive state increases relative to the time spent in the non-reactive state. Thus, the time-average exchange interaction and the time-average recombination rate increase.

The experimental implementation of the SNP method for the investigation of radical pairs in micelles has several specific features. On the one hand, due to the higher viscosity of micellar media compared to homogeneous solutions, the nuclear relaxation time of diamagnetic products decreases, resulting in a less intense signal in the SNP spectra. On the other hand, the lifetime of radical pairs in micelles (~ 0.1 – 1 μs) is commensurable with the characteristic time of RF transitions (~ 10 – 100 ns), which is calculated from the expression

$$\omega_1 = \gamma_e B_1$$

(the B_1 value lies in the range 0.1 – 1 mT). This results in a pronounced increase in the intensity of spectral lines and provides the possibility of measuring ^{13}C SNP spectra for samples with natural abundance of ^{13}C . An advantage of the ^{13}C SNP method is that the spectra of radical pairs containing ^{13}C magnetic nuclei are recorded on the basis of the corresponding lines in the ^{13}C NMR spectrum; therefore, the splitting in the SNP spectrum is equal to the HFC constant for this nucleus in the radical.

In small micelles ($n = 7$ – 9) for $A = 2$ – 10 mT, the decrease in the spectral splitting is due to both the exchange interaction J and the rate of spin-selective decay of the radical pair. In larger micelles ($n = 11, 12$) for $A > 2.0$ mT, splitting in the spectrum is equal to the HFC constant, exchange interaction influencing only the widths of individual lines.

The ^{13}C SNP effects involved in the photolysis of α -methyldeoxybenzoin enriched to 96% in the ^{13}C isotope at the carbonyl position have been studied in micelles of different sizes.^{51,77} The splitting in the SNP spectrum for sodium dodecyl sulfate micelles amounts to 12.4 mT; it is equal to the HFC constant for the carbonyl carbon atom in the benzoyl radical (Fig. 16*a*). A decrease in the length of the polymethylene chain of the detergent molecule results in a shorter spacing between the lines in the SNP spectrum and in a changed width of individual lines. From calculations of the SNP spectra and field dependences of CIDNP, the optimal parameters of the electron exchange interaction and spin-selective decay were found ($k_s\tau$): $J_0 = 50$ mT (the parameter for the decay of exchange interaction α is 2 Å) and $k_s\tau = 8$. It is noteworthy that the high sensitivity of the SNP spectra to the change in the rate of re-encounters of radicals in the micelles and, hence, to the change in the intra-micellar viscosity and micelle size can be used to investigate the dependence of the properties of micelles on the temperature and on salt additives (see Fig. 16).¹²³

Parnachev *et al.*¹²¹ studied experimentally the SNP of radical pairs formed in the photolysis of benzophenone- d_{10} in sodium dodecyl sulfate micelles in the presence of 2,4,6-tri-*tert*-butylphenol with the natural abundance of the ^{13}C isotope. On exposure to a 0.03 mT radio-frequency field, the NMR spectrum exhibits signals from six radical pairs differing in the position of ^{13}C (denoted by the Roman numerals I–VI) (Fig. 17*a*).

Figure 16. Temperature dependence of the SNP spectra of the radical pairs formed in the photolysis of α -methyldeoxybenzoin in sodium dodecyl sulfate (*a*) and sodium octyl sulfate (*b*) micelles. The spectra were detected using the NMR signal of the carbonyl carbon atom of α -methyldeoxybenzoin. The continuous lines are the calculated SNP spectra. T ($^{\circ}\text{C}$): (1) 12, (2) 29, (3) 45 (*a*) and (1) 10, (2) 17, (3) 45 (*b*).

The SNP spectra were obtained for all the six radical pairs with different positions of ^{13}C . Figure 17*b* shows the SNP spectra for pairs with the ^{13}C isotope in positions I and II. The opposite phases of these spectra are due to the different signs of the HFC constants for the corresponding ^{13}C nuclei. Measurement of the SNP kinetics makes it possible to determine the lifetimes of radical pairs and to draw conclusions about the mechanisms of their relaxation. The value of the contact electron exchange interaction estimated from comparison of the experimental and theoretically calculated spectra is $|J_0| > 40$ mT. The HFC constants in radical pairs with different positions of the ^{13}C isotope were calculated from analysis of the SNP spectra.

In the limiting case, where the characteristic time of intersystem crossing markedly exceeds the characteristic time period between the re-encounters in the micelle ($A\tau_2 \gg 1$), splitting of lines in the SNP spectra does not depend on the micelle size, and the effect of the exchange interaction reduces to line broadening.¹²⁰ For example, this is the case in the radical pairs formed in the photolysis of (2,4,6-trimethylbenzoyl)diphenylphosphine oxide. In accordance with theoretical predictions, the experimental SNP spectra of radical pairs in sodium octyl sulfate micelles and in sodium dodecyl sulfate micelles show the same splitting; however, agreement between experimental and theoretical spectra is attained only when sodium dodecyl sulfate micelles with a radius of 17–21 Å or sodium octyl sulfate micelles with a radius of 13–15 Å are used. Thus, it was concluded that the effective radius of micelles varies depending on the compounds involved in the reaction.

As noted above, in measuring the EPR spectra, the observed polarisation contains contributions of both radical pairs in micelles and free radicals, whereas SNP arises only in the presence of radical pairs. For example, using SNP and time-resolved EPR, the spectra of the radical pairs formed in the photolysis of α -methyldeoxybenzoin and benzoin in micelles of various size

Figure 17. NMR spectrum of radical pairs formed in the photolysis of benzophenone- d_{10} with 2,4,6-tri-*tert*-butylphenol in the micelles on exposure to a 0.03 mT RF field (a); SNP spectra of radical pairs labelled at position I (1) and II (2) (b) and the kinetic curves of SNP of the radical pairs labelled at positions I–III (1–3, respectively) (c) in different magnetic fields. B_0 (mT): (1) 53.5; (2), (3) 54.1. The calculated relaxation constants k_{rel} 1.2×10^6 (dashed line) and 3.0×10^5 s $^{-1}$ (continuous line).

were recorded. The SNP spectra measured for micelles with different sizes are closely similar because the HFC constants, electron relaxation parameters, radical size, and the reactivity of radical pairs are very close. Meanwhile, the EPR spectra recorded for the photolysis of α -methyldeoxybenzoin and benzoin are different in principle. Whereas the RP formed in α -methyldeoxybenzoin is responsible for an antiphase structure of the spectrum depending on the micelle size, in the case of benzoin, no line splitting due to exchange interaction is observed.¹¹⁶ The radical pairs consisting of hydroxybenzyl radicals formed in benzoin photolysis leave the micelles at a markedly higher rate than the radical pairs consisting of benzyl and benzoyl radicals. As shown by Tarasov *et al.*,¹¹⁶ within 200 ns after the photolysis of α -methyldeoxybenzoin, 70% of the radicals are located in micelles, while in the case of benzoin, this value is only 5%.

The kinetics of micellised radical pairs have been studied by time-resolved SNP. It is obvious that the coherent transitions between singlet and triplet sublevels in radical pairs cannot be described within the framework of a kinetic scheme.¹²⁴ However, since for most radical pairs, the rate of recombination markedly exceeds the relaxation rate, the experimental kinetic dependences of SNP are well described by an exponential curve and are consistent with the calculation based on the simple kinetic scheme.

Yet another approach to the theoretical description of the dynamics of radical pairs is numerical solution of the Liouville equation for the density matrix.⁷⁸ The kinetic curves for time-resolved SNP measured for the photolysis of α -methyldeoxybenzoin and dibenzyl ketone in sodium dodecyl sulfate micelles are described adequately by an exponential function in accordance with the kinetic scheme.

Figure 17c shows the kinetic curves of SNP obtained for the photolysis of benzophenone- d_{10} with 2,4,6-tri-*tert*-butylphenol in sodium dodecyl sulfate micelles. The SNP kinetic curves for radical pairs labelled in positions I–V bear information on the relaxation in various radical pairs. The decay of SNP for the pairs labelled in positions II–V is due to the exit of radicals from the micelle and dipole–dipole relaxation. For a pair labelled in position I, relaxation caused by the modulation of the anisotropic part of HFC plays an important role.

In the photolysis of (2,4,6-trimethylbenzoyl)diphenylphosphine oxide, the rate of the decay of SNP kinetics for sodium dodecyl sulfate micelles is 2.5 times higher than that for sodium octyl sulfate; meanwhile, in the case of photolysis of ketones, this difference was not more than 20%–30%. Analysis of the resulting time dependences in terms of the kinetic model made it possible to estimate the relaxation and recombination rates for the radical pair in this reaction. For sodium octyl sulfate micelles, the relaxation rate is only 1.8 times lower than that for sodium dodecyl sulfate micelles. Thus, the SNP kinetics observed in sodium octyl sulfate micelles is determined by both recombination and relaxation. Note that the parameters determining the kinetics of radical pairs and those determined from theoretical and experimental SNP spectra are in good agreement with the data from the time-resolved EPR spectra.^{127, 128}

The use of the SNP methods in investigating micellised radical pairs provides unique information on their spin dynamics and kinetics. This possibility is due to the high sensitivity of the SNP method and to its selectivity with respect to radical pairs. The information obtained in SNP studies of micellised radical pairs was used in experiments on the measurement of the magnetic isotope effect (MIE) induced by a resonance RF field. The reaction investigated in these experiments was photolysis of dibenzyl ketone.¹²⁹ Saturation of the electron transitions in radical pairs can give rise to enhanced MIE in two different regimes: at small amplitudes of the RF field ($B_1 \ll A$), the S–T conversion in one sub-ensemble of radical pairs containing a magnetic isotope is accelerated, while at large amplitudes of the RF field ($B_1 \gg A$), closing of the S–T conversion for radicals devoid of a magnetic isotope takes place. Tarasov *et al.*¹²⁹ used the former regime but the latter appears to be more promising as regards enhancement of MIE.^{130, 131} The SNP method can provide exact information on the RF-field amplitude that ensures the maximum MIE value.

V. Chemically induced dynamic nuclear polarisation in switched external magnetic fields

The method of time-resolved CIDNP permits one to obtain quantitative information about the kinetics of radical reactions, lifetimes of triplet molecules and electron–nuclear cross-relaxation processes.^{132–135} The procedure involved in the time-resolved CIDNP method is the measurement of the dependence of CIDNP intensity on the variable delay τ between the laser pulse and the detecting radio-frequency pulse (90-degree pulse of an NMR spectrometer) (Fig. 18a). CIDNP arises in the strong magnetic field of the NMR spectrometer; as a rule, this is not the optimal field for observing this effect when many photochemical reactions take place. The time resolution of the method is determined by the duration of the radio-frequency pulse and is equal to 40 ns at best (normally, it is of the order of microseconds). It is often necessary to study CIDNP in weak and medium magnetic fields⁵² because this method can provide information about the exchange interaction, exchange reactions and so on. When measuring CIDNP in

Figure 18. Schematic illustration of time-resolved CIDNP (a) and switched external magnetic field CIDNP (b, c); (1) laser, (2) region of CIDNP generation, (3) detecting radio-frequency pulse. Field switching can occur both with (b) and without (c) change in its direction.

weak and medium magnetic fields, photolysis is normally carried out in the field of a separate magnet and then the sample is transferred into the probe of an NMR spectrometer to record the spectrum. Photolysis can be performed directly in the probe of an NMR spectrometer with detection in weak magnetic fields;¹³⁶ however, in this case, spectral resolution and the sensitivity are very low, which restricts the scope of this method to systems with abnormally high CIDNP intensity. It is evident that time resolution by a traditional time scheme cannot be used in the experiments with transfer of the sample from the field of an individual magnet to the probe of an NMR spectrometer. This opportunity appears in the case of fast switching of the magnetic field within a variable period after the laser pulse initiating the radical reaction (Fig. 18 b, c). The idea of switching the external magnetic field (SEMF) during a photochemical reaction was first proposed and implemented by Lavrik *et al.*¹³⁷ The authors studied the effect of magnetic field switching on the intensity of fluorescence of excimers in radical-ion reactions. On the basis of the results obtained, estimates were made of the lifetimes of radical pairs.

The potential of the methods based on the SEMF during the lifetime of radical pairs was studied theoretically.⁸³ The researchers considered the influence of SEMF on both the probability of recombination of radical pairs and the nuclear polarisation of diamagnetic products in strong magnetic fields (*i.e.* with allowance for only $S-T_0$ transitions). Three different modes of radical recombination were chosen. In the first mode, the singlet-triplet transitions occur in the period between two contacts. This is accompanied by quantum oscillations. In the second mode, the $S-T_0$ transitions do not have time to take place in the interval between two contacts but do occur effectively over the lifetime of the pair in the cage. In this case, no quantum oscillations are displayed; however, the recombination kinetics depend on the frequency of $S-T_0$ transitions. Finally, in the third mode, the singlet-triplet transitions are relatively ineffective. This mode of recombination is of interest because it permits one to determine the lifetime of the pair in the cage. It should be noted that in experiments, the recombination mode is largely 'controllable'. It can be changed, for example, by changing the solution viscosity.

Bagryanskaya *et al.*¹³⁸⁻¹⁴⁰ carried out experiments based on switching of the external magnetic field within a variable period after a laser pulse followed by recording of the CIDNP effect (the SEMF CIDNP method). It was found that the change of nuclear

polarisation of the products of radical reactions upon switching the external magnetic field can be induced both by the change in the conditions of spin dynamics of radical pairs and intermediate short-lived free radicals and by the change in the electron and nuclear polarisation at the instant of switching. On the one hand, this treatment substantially complicates interpretation of the experimental results but, on the other hand, it opens the following ways for the investigation of the chemical kinetics and spin dynamics of radical species.

(i) Study of the dependence of polarisation on the delay τ between the laser pulse and the instant of magnetic field switching allows one to explore the kinetics of CIDNP of geminate radical pairs. The time it takes to switch a magnetic field by 10^{-3} T equals 1–3 ns. The time resolution is determined by the accuracy of synchronisation of the laser pulse and the instant of magnetic field switching (20–30 ns). Unlike the traditional time-resolved CIDNP, this method allows investigation of the CIDNP kinetics in weak and medium magnetic fields. This time resolution in NMR spectrometers is, in principle, impossible in weak fields because it is determined by the duration of the radio-frequency pulse, which lies in the millisecond time interval for weak and medium fields.

(ii) Variation of the delay τ permits one to change selectively the conditions of spin dynamics for geminate and diffusion radical pairs and thus to study the chemical kinetics of radical species.

(iii) Switching of the magnetic field changes the electron and nuclear polarisation of free radicals; this makes it possible to study the mechanisms of electron relaxation and the electron-nuclear cross-relaxation and CIDEP in weak magnetic fields.

Since the change in the magnetic field by $\sim 10^{-2}$ T causes only a minor change in the CIDNP in strong magnetic fields, realisation of the SEMF CIDNP technique in strong magnetic fields requires that a pulsed magnetic field of a substantial magnitude be created. This is a complex engineering problem. In weak magnetic fields, CIDNP changes quite substantially as the magnetic field changes by $\sim 10^{-3}$ T. The SEMF CIDNP method in weak and medium magnetic fields was implemented using a setup in which photolysis was carried out in the field of a separate magnet and, subsequently, after polarisation appeared, the polarised diamagnetic product was rapidly (over a period shorter than the characteristic time of nuclear relaxation) delivered *via* a fast-flow system to the probe of an NMR spectrometer in which CIDNP was recorded. The magnetic field is switched by use of Helmholtz coils, which create an additional field in the magnet with a switching amplitude of ± 7 mT. This markedly restricts the range of fields in which the SEMF CIDNP kinetics can be measured and is due to a requirement of the method according to which the absolute magnitudes of CIDNP in the initial and the final fields should be substantially different. Therefore, the highest sensitivity of the method is attained in those fields, in which the curve for the field dependence of CIDNP has 'steep slopes'.

1. Chemically induced nuclear polarisation under conditions of non-adiabatic switching of the magnetic field

The time of electron relaxation of free radicals does not actually depend on the switching of the external magnetic field. However, the situation changes if the chemical processes, for example DEE, influence the electron relaxation. For radical-ion reactions with DEE, the relaxation times in weak fields can be markedly dependent on the external magnetic field. As has been shown above, CIDNP in radical-ion reactions is influenced substantially by DEE reactions. The dependence of CIDNP kinetics on the concentration of the donor or acceptor molecules can be used to measure the DEE rate and to study the electron polarisation in weak magnetic fields.

The utility of the SEMF CIDNP method for measurement of DEE rates has been demonstrated in relation to the photoisomerisation of fumaronitrile with naphthalene in polar solvents.¹³⁹ Figure 19 presents the kinetic curves for the SEMF CIDNP of fumaronitrile and maleonitrile recorded for magnetic fields

Figure 19. Kinetic curves of the SEMF CIDNP for the photoisomerisation of the fumaronitrile with naphthalene constructed using the NMR signals of maleonitrile ($B_0 = 1$ mT, $B' = -1$ mT) (a) and fumaronitrile ($B_0 = 3$ mT, $B' = 5$ mT) (b). Fumaronitrile concentration (mol litre $^{-1}$): (1) 5×10^{-3} , (2) 2×10^{-2} , (3) 4×10^{-2} .

switched either with or without inversion of their direction. The kinetics of CIDNP detected based on an in-cage reaction product, maleonitrile, are determined by the time required for the formation of radical pairs. For the escape reaction product, fumaronitrile, the kinetics are stipulated by the time of electron relaxation of the intermediate radical anion. The characteristic time of the decay of the CIDNP signal (of maleonitrile) is determined by the time of formation of geminate radical pairs; at high fumaronitrile concentrations $[(2-4) \times 10^{-2}$ mol litre $^{-1}]$ it amounts to 15–20 ns, while at low concentrations (5×10^{-3} mol litre $^{-1}$), it is 30–40 ns. On the basis of analysis of the kinetic curves of CIDNP constructed using the signals of maleonitrile in the NMR spectra, it was concluded that the time it takes for CIDNP in geminate radical pairs to appear is either shorter than or comparable with the duration of a laser pulse. Meanwhile, the kinetic curves of CIDNP detected from the NMR signal of fumaronitrile depend substantially on the rate of DEE. In the case of fast exchange, the obtained values coincide with the times of electron relaxation due to DEE, while for slow exchange, the CIDNP kinetics are determined by both the rate of DEE and the lifetime of free radicals.

It is worth noting that the typical lifetimes of radical pairs in homogeneous solutions are in the nanosecond range. Lasers with a pulse duration of 10–20 ns are used to initiate photochemical reactions; this stipulates the characteristic time of formation of the radical pair. Thus, experimental kinetic curves for CIDNP constructed for geminate radical pairs in homogeneous solutions are expected to reflect the kinetics of formation rather than the lifetime of the pair. The main advantage of the method discussed here is separation of the contributions of geminate and diffusion radical pairs to CIDNP.

The high time resolution and the possibility of investigating the kinetics of CIDNP in weak magnetic fields makes this method attractive for the investigation of spin dynamics of micellised radical pairs and short-lived biradicals. However, an attempt to carry out SEMF CIDNP experiments in micellised radical pairs demonstrated that, to obtain a satisfactory signal-to-noise ratio, the experiments should be carried out in fields whose magnitudes are close to the CIDNP maximum intensity. The field dependence of CIDNP for micellised radical pairs has almost in all cases the characteristic emission appearance, indicating the predominant

contribution of the $S-T_0$ transitions to CIDNP. Thus, the kinetics of SEMF CIDNP should also be calculated with allowance for $S-T_0$ transitions. This brought about the necessity of modifying the theory of CIDNP under conditions of SEMF for the case of radical pairs with limited mobility. This problem was successfully solved^{140, 141} on the basis of a kinematic approach. The time of switching of the magnetic field was assumed to be shorter than the time of intersystem crossing, electron relaxation and the exit of radicals from the micelles. To describe the motion of a micellised radical pair, the model for motion in the confined space was utilised. The calculation of the CIDNP effect as a function of the instant t_0 when the magnetic field is switched using typical parameters of a micellised radical pair showed that no quantum oscillations occur and the effect decays monotonically. The value by which the field changes has no influence on the pattern of time dependence, which is determined by the viscosity of the solution inside the micelle, but influences only the scale of the CIDNP effect. An interesting result is drawn if singlet–triplet transitions in one sub-ensemble of radical pairs stop after the magnetic field switching. In this case, quantum oscillations are observed on the time dependence of the effect. An expression was derived describing averaging of the $S-T_0$ transitions in the absence of relaxation and at low reactivity of the radical pair. In this case, conclusions about the character of movement of radicals in the radical pair can be drawn from the shape of the kinetic curve of SEMF CIDNP.

The purpose of the work by Fedin *et al.*¹⁴⁰ was to test the SEMF CIDNP method on a series of model reactions involving micellised radical pairs, to study the correspondence between the theoretical and experimental data, and to study the possibility of using this method for determination of the parameters of molecular and spin dynamics of micellised pairs. The researchers chose three photochemical reactions corresponding to different limiting cases of the ratio of the rates of radical exit from the micelles (k_{ex}), electron relaxation (k_{rel}) and $S-T_0$ conversion (k_{lc}) and conforming to the approximation at which only one magnetic nucleus is taken into account. In relation to these reactions, it was demonstrated that approximation of the kinetics by numerical calculations can provide information on the exit rate of the radicals from the micelle, the rate of decarbonylation, the rate of dipole–dipole electron relaxation, the rate of electron relaxation caused by anisotropy of HFC, and the rate of $S-T_0$ transitions occurring in the area of energy level crossing. Estimation of the rates of $S-T_0$ transitions for the systems studied suggested strong anisotropy of the exchange interaction.

The capacity of the SEMF CIDNP method for the investigation into short-lived biradicals has been evaluated¹⁴² taking photolysis of acylalkyl cyclic ketones as an example. The use of substituted ketones allowed the researchers to compare the CIDNP kinetics for biradicals differing only in HFC constants and to estimate the lifetime of the triplet molecule. The measurement of the lifetimes of short-lived biradicals formed upon photolysis of α,α -diphenylcyclododecanone showed that the kinetic curves of CIDNP for this reaction in weak magnetic fields are described with rather high accuracy by an exponential curve and the characteristic time of the curve decay coincides with the data obtained from the optical absorption of biradicals.

2. Chemically induced nuclear polarisation under conditions of adiabatic switching of the external magnetic field

Switching of magnetic field can be accompanied by the transfer of electron polarisation to the nuclei and *vice versa*. The time and conditions of magnetic field switching are important factors determining the type of polarisation transfer (adiabatic or non-adiabatic). It has been shown¹⁴³ that adiabatic switching of the magnetic field with the change in its direction results in the transfer of the integral electron polarisation to the nuclei. The effect of the adiabatic change of the external magnetic field on the transfer of integral CIDEP on the radical nuclei and the subsequent transfer to the diamagnetic products of radical chemical

Figure 20. Schematic illustration of the effect of adiabatic switching of the external magnetic field on the nuclear polarisation of radicals; (a) the initial integral electron polarisation completely disappears after adiabatic switching of the magnetic field, (b) the initial multiplet electron polarisation does not change after the magnetic field switching.

reactions was studied. The limits of the adiabatic character of magnetic field switching were found from the Landau–Zener formula¹⁴⁴ to be 45–1100 nm. The lower limit is determined by the elucidation of time evolution of the spin system under adiabatic conditions, while the upper limit results from the requirement that radicals should react to give a diamagnetic product over a period of time shorter than the time of nuclear relaxation. The switching of the field was supposed to take place after the appearance of CIDEP. The adiabatic field switching is selective with respect to the mechanism of the appearance of CIDEP; the triplet and radical-pair mechanisms were considered as examples (Fig. 20). Passage through the zero magnetic field is accompanied by the transfer of the occupancy of levels: $\beta_e\alpha_n \rightleftharpoons \alpha_e\beta_n$ and $\alpha_e\beta_n \rightleftharpoons \beta_e\alpha_n$. It was found that the integral CIDEP is completely transferred to the radical nuclei and, after radical recombination, it can be detected in diamagnetic products. In the case of multiplet CIDEP, switching of the field does not influence the polarisation of the diamagnetic products. The optimal conditions for the transfer of electron polarisation were analysed numerically in the study cited as functions of the instant the field switching starts, of the duration of its front and of the velocity of passage through the zero-field region.

Evidently, non-zero nuclear polarisation is also transferred on electrons upon switching the magnetic field. This may result in the decay of escape nuclear polarisation. Since most radical reactions in weak magnetic fields are usually accompanied by substantial CIDNP, adiabatic change of the magnetic field can be used to separate the contributions of in-cage and escape polarisations. It has been shown¹³⁹ that transfer of electron polarisation to the nuclei takes place in weak magnetic fields even in the case of non-adiabatic switching of the magnetic field.

The potential of the SEMF ^1H CIDNP method as applied to short-lived radical species in a homogeneous solution has been analysed.¹⁴⁵ For this purpose, several photochemical reactions with participation of alkyl radicals PhCH_2 , Me_3C and PhC(O)CH_2 in magnetic fields of 0.5–2.5 mT were studied. From analysis of experimental data, it was concluded that the kinetics of polarisation is determined by the electron–nuclear relaxation in the intermediate radicals. The measured relaxation times of the PhCH_2 , Me_3C and PhC(O)CH_2 radicals in benzene were 2.2 ± 0.3 , 7.1 ± 0.3 and 1.2 ± 0.2 μs . Figure 21 shows the kinetic curves of CIDNP for the photolysis of dibenzyl ketone constructed using the NMR signals of dibenzyl ketone. The CIDNP kinetics for dibenzyl ketone is determined by the rate of decarbonylation of the phenacyl radical, whereas for dibenzyl, the decay of the kinetic curve does not depend on the initial concen-

Figure 21. Experimental kinetic curves of SEMF CIDNP for the photolysis of dibenzyl ketone detected using the NMR signals of dibenzyl ketone (1) and dibenzyl: (2) I_1 , (3) $I_2 = 3I_1$.

tration of radicals and is equal to the electron relaxation time of the benzyl radical. The decays of the kinetic curves found for the photolyses of other compounds involving the benzyl radical do not depend on the initial concentration of the radicals either (Fig. 22).

Figure 22. Kinetic curves of SEMF CIDNP for the photolysis of dibenzyl ketone (1) and deoxybenzoin (2).

The SEMF ^{31}P CIDNP method was used to determine the spin relaxation times for a series of phosphonyl radicals $\text{O}=\text{P(O)XY}$ (X, Y are various substituents) in a 5 mT field in acetonitrile and in dioxane. If the anisotropy of HFC is modulated only by the rotation of the radical as a whole with characteristic times of the order of several picoseconds, the relaxation time in acetonitrile should be shorter than that in dioxane. However, an opposite relationship was found in the experiment, which was explained by the occurrence of deformation vibrations with characteristic periods of several nanoseconds. It was found that, if the relaxation time of the radical is shorter than its lifetime, the kinetics of SEMF CIDNP are determined by relaxation.

3. Polarisation under conditions of double switching of the external magnetic field

Recently, further updating of the SEMF CIDNP method was proposed, which implies the use of two non-adiabatic magnetic field switchings separated in time during the reaction.¹⁴⁶ The researchers considered the variation of the polarisation of free short-lived radicals induced by double switching of the magnetic field and determined the dependence of CIDNP of the diamagnetic products on the delay between the switchings. The time diagram of the experiment is shown in Fig. 23a. In the first stage when $0 < t < t_1$, the radicals are formed under the action of a laser pulse in the external magnetic field H_1^0 . It is assumed that by the time instant t_1 , the primary polarisation of the radicals has arisen and they have moved out of the cage to the bulk. In the second stage when $t_1 < t < t_2$, the magnetic field undergoes a

Figure 23. Time diagram (a) and vector model (b) in CIDNP experiments with double switching of the external magnetic field; (1) laser pulse, (2) preparation, (3) evolution; (4) recording.

non-adiabatic change to reach the value H_2^0 . The radical polarisation starts to oscillate, the characteristic frequencies of oscillation being dependent on the structure of the spin levels of the radicals in the field H_2^0 and on the level occupancies. Finally, in the third stage when $t_2 < t$, the field undergoes a non-adiabatic change to reach the value $H_{\text{fin}} \gg H_2^0$. The nuclear polarisation of the radicals ceases to change and, upon recombination, passes to the diamagnetic products. Thus, the polarisation of oscillations in the intermediate radicals can be recorded using the dependence of the CIDNP intensity of the recombination products on the delay $\tau = t_2 - t_1$.

The appearance of beats of the CIDNP of radicals and their diamagnetic products can be illustrated using a vector model (Fig. 23 b). For the case of radical with one magnetic nucleus with the spin $I = 1/2$, the two-level approximation $|\alpha\beta N\rangle, |\beta\alpha N\rangle$ and the vector model are applicable. According to Adrian's approach,¹⁴⁷ we consider the operators of the projections $\hat{F}_z, \hat{F}_x$ of the effective spin, which act on the basis functions $|\alpha\beta N\rangle, |\beta\alpha N\rangle$ as the corresponding Pauli matrices

$$\hat{F}_z|\alpha\beta N\rangle = \frac{1}{2}|\alpha\beta N\rangle;$$

$$\hat{F}_z|\beta\alpha N\rangle = -\frac{1}{2}|\beta\alpha N\rangle;$$

$$\hat{F}_x|\alpha\beta N\rangle = \frac{1}{2}|\beta\alpha N\rangle;$$

$$\hat{F}_x|\beta\alpha N\rangle = \frac{1}{2}|\alpha\beta N\rangle.$$

Then the Hamiltonian

$$\hat{H} = \omega_0 \hat{S}_z + A(\hat{S} \hat{I})$$

for the radical in question in a weak field determined in the subspace Ω with the basis set $|\alpha\beta N\rangle, |\beta\alpha N\rangle$ assumes the form

$$\hat{H} = A \hat{F}_x + \omega_0 \hat{F}_z = (\vec{H}_{\text{eff}}, \vec{F}),$$

where $\vec{H}_{\text{eff}} = (A, 0, \omega_0)$.

Thus, evolution of the state $|\Psi\rangle$ from the subspace Ω can be represented as precession of the effective spin $\vec{\sigma}$ in an effective magnetic field with the z component ω_0 , the x component A and

the frequency $\sqrt{\omega_0^2 + A^2}$ (see Fig. 23 b). The projection of the

vector $\vec{\sigma}$ on the z axis is equal to the difference between the occupancies of the levels $|\alpha\beta N\rangle, |\beta\alpha N\rangle$. The nuclear polarisation corresponding to the state $|\Psi\rangle$ is proportional to this value. The permanent generation of effective spins at the preparation stage results in the vectors $\vec{\sigma}_0$ covering uniformly the

surface of the cone, so that the average vector $\vec{\sigma}_S$ is directed along the cone axis, i.e. along the vector $\vec{H}_{\text{eff}}$. After non-adiabatic switching of the magnetic field to reach, for example, a zero magnitude, the vector $\vec{H}_{\text{eff}}$ is directed along the x axis and has the length A . At the initial instant, the vector $\vec{\sigma}_S$ remains constant then it starts to precess along the x axis with a frequency equal in magnitude to the HFC constant. The projection of the vector $\vec{\sigma}_S$ on the z axis varies periodically with the same frequency. If the magnetic field switches from the zero value to the value $H_{\text{fin}} \gg A$ after a time τ , the nuclear polarisation of radicals stops changing and passes to the diamagnetic reaction products after recombination. The vector $\vec{\sigma}_S$ would precess about the z axis and its projection on this axis would remain constant. Thus, by applying a second switching of the magnetic field after different delays τ , one can record the dependence of the oscillation of the CIDNP of diamagnetic products on τ . The paramagnetic relaxation in the radicals would result in a decrease in the length of the vector $\vec{\sigma}_S$ with an increase in the time t_1 and in a decrease in the amplitude of beats with an increase in the delay τ . When $t_1 \gg T_1$ (T_1 is the spin-lattice relaxation time), all the spin levels of the radical are almost equally occupied, which corresponds to the decrease in the length of the vector $\vec{\sigma}_S$ to zero. Evidently, in this case, the CIDNP of the diamagnetic products of the reaction does not oscillate. Thus, for high-quality recording of the oscillation, it is required that T_1 be much longer than t_1 .

Data on the oscillation of the CIDNP of the diamagnetic products bear information on the short-lived intermediates from which these products are formed. The amplitude, the frequency and the phase of oscillations depend on the structure and occupancy of the spin levels in the short-lived intermediate species. The method described above was first implemented by Makarov *et al.*¹⁴⁸ in relation to the photolysis of *p*-benzoquinone with 2-propanol- d_8 and to sensitised photoisomerisation of fumaronitrile. The oscillations of the CIDNP of the reaction products were

Figure 24. Oscillation of the CIDNP of the products of photolysis of *p*-benzoquinone with isopropanol- d_8 in acetonitrile in experiments with double switching of the external magnetic field (a) and Fourier spectrum of the resulting kinetic curve (b). The experimental positions of the resonance frequencies in the spectrum are given (the calculated positions are 0.76 and 1.04).

recorded as functions of the delay τ between the magnetic field switchings (Fig. 24). It was found that the amplitude, phase and the frequency of CIDNP beats are determined by the hyperfine structure and by the occupancies of the spin levels in the intermediate radicals. It was concluded from comparison of the experimental and theoretical data that the electron polarisation of semiquinoid radicals and fumaronitrile radical ions in weak magnetic fields is negative. It appears promising to use this method for investigating electron polarisation and the times of electron–nuclear relaxation of short-lived radicals in weak magnetic fields to which conventional time-resolved EPR is inapplicable.

VI. Conclusion

A vast body of experimental information has been accumulated on the use of high-sensitivity magnetic-resonance techniques based on the influence of variable resonance magnetic fields and switched constant magnetic fields on the nuclear polarisation of the products of radical reactions. The examples given in this review demonstrate the applicability of these methods to the study of the mechanism of radical reactions, identification of latent radical stages and measurement of DEE rates. The main regularities of polarisation of radical species with a broad range of lifetimes and in homogeneous and molecular-organised media have been elucidated. By now, the theory of the influence of RF fields on the nuclear polarisation in radical reactions has been thoroughly developed and employed to gain information on short-lived radical species — their spin dynamics and chemical kinetics.

The time-resolved SNP method can be used to separate the contributions to the polarisation of geminate and diffusion radical pairs and to obtain quantitative data on their kinetics. The SEMF CIDNP technique provides the possibility of measuring the rates of DEE, the kinetics of radicals, the lifetimes of short-lived biradicals and micellised radical pairs. This can prove useful in those cases where the use of flash photolysis is difficult due to the overlap of optical absorption bands. An additional advantage of the SEMF CIDNP method is the spectral resolution of NMR, which allows one to follow the transformation of biradicals into diamagnetic products. The DNP method provides the possibility of measuring the electron relaxation times for short-lived radicals and the signs and magnitudes of their HFC constants. Detection of DNP of the final reaction products can be used to investigate the mechanisms of radical processes. Unlike the CIDNP method, in the case of DNP, the formation of radical pairs in solution is not necessary. The doubly switched external magnetic field CIDNP method is supposed to be suitable for measuring the kinetics and the spin relaxation times of radicals, for investigating the CIDEP in weak magnetic fields, and for gaining information on the occupancy of the spin levels in the radicals.

Thus, nowadays, there exists a basis for the use of highly sensitive magnetic-resonance methods in the studies of complex photochemical reactions. The highest efficiency in the application of these methods can be attained by combining them with the techniques of laser flash photolysis and time-resolved EPR.

Reagents for the preparation and cleavage of 1,3-dithiolanes

A K Banerjee, M S Laya

Contents

I. Introduction	947
II. Reagents for the synthesis of 1,3-dithiolanes based on 1,2-ethanedithiol	947
III. Reagents for the cleavage of 1,3-dithiolanes	951
IV. Conclusion	954

Abstract. Data on procedures for protection of the carbonyl group by its conversion into the 1,3-dithiolane moiety and on cleavage of the latter under the action of different reagents are surveyed. The preparation of 1,3-dithiolanes from carbonyl compounds followed by deprotection can be used in syntheses of various organic compounds. The bibliography includes 54 references.

I. Introduction

Syntheses of organic compounds, including natural products, often generate a need to use protective groups. Thus if it is necessary that the reaction proceed selectively at one of several reaction centres of a polyfunctional compound, all other centres should be temporarily blocked. A good protective group must be removed selectively and quantitatively under the action of readily accessible reagents which do not react with functional groups to be regenerated. Various protective groups have already been developed and these investigations are being continued. Analysis of the published data demonstrated that the introduction and removal of a protective group is often a complex multistep process.

In the synthesis of particular carbonyl-containing products, it is sometimes necessary to prevent the reaction of the carbonyl group with reducing agents of acidic or alkaline nature, catalytic reducing agents and hydrides, some oxidising agents, strong and moderate nucleophiles, organometallic compounds, *etc.* In the reactions of polyfunctional organic compounds, it is very convenient to protect the carbonyl group by converting it into the 1,3-dithiolane moiety because sulfur-containing functional groups are inert with respect to many reagents. Various reagents, which are stable under conventional reaction conditions, have been developed for the synthesis of 1,3-dithiolanes.^{1,2} Generally, 1,3-dithiolanes are prepared by condensation of carbonyl compounds with 1,2-dithiols catalysed by protic or Lewis acids.^{3,4}

In the present review, the data on the reagents for the synthesis and cleavage of 1,3-dithiolanes developed in the last decade are surveyed. The mechanisms of formation and cleavage of 1,3-dithiolanes are beyond the scope of this review.

II. Reagents for the synthesis of 1,3-dithiolanes based on 1,2-ethanedithiol

1. Catalysis by Amberlyst-15

Amberlyst-15 is an efficient catalyst of the synthesis of 1,3-dithiolanes from some aldehydes,⁵ for example, from **1** or **2**, under the action of 1,2-ethanedithiol (CH_2SH)₂.

The reactions proceed at room temperature to form derivatives **3** or **4** in high yields. If the reaction mixtures contain ketones along with aldehydes, the former do not react with $(\text{CH}_2\text{SH})_2$ under these conditions. However, this procedure can also be used for protection of ketones (even sterically hindered ketones), if the reaction is carried out with boiling. Under these conditions, 1,3-dithiane **6** is formed from pinacolone **5**.

In this case, the workup procedure is substantially simpler than those used in the synthesis of 1,3-dithiolanes catalysed by other reagents, in particular, by thionyl chloride and impregnated silica gel,⁶ or in the synthesis of 1,3-dithianes from 2,2-dimethyl-1,3,2-dithiasilane in the presence of boron trifluoride etherate as a catalyst.⁷ Ketones of the type **5** react with $(\text{CH}_2\text{SH})_2$ in the presence of Amberlyst-15 to form dithiolane **6**. An important characteristic feature of this system is the fact that the reactions with ketones proceed at a slow rate because of which this procedure can be used for separation of aldehydes and ketones.

2. Catalysis by tetrachlorosilane

It is known⁸ that tetrachlorosilane (Lewis acid) is a soft and efficient catalyst of the synthesis of 1,3-dithiolanes. This compound catalyses the formation of dithiolanes from aromatic aldehydes containing both electron-donating and electron-with-

A K Banerjee, M S Laya Centre of Chemistry, Venezuelan Scientific Research Institute, Apartado 21827, Caracas 1020-A, Venezuela.

E-mail: abanerje@quimica.ivic.v

drawing substituents. Thus the reactions of aldehydes **7–9** with $(\text{CH}_2\text{SH})_2$ in the presence of SiCl_4 afforded dithiolanes **10–12**, respectively.

The SiCl_4 -catalysed reactions of aromatic aldehydes (for example, **7** and **13**) with $(\text{CH}_2\text{SH})_2$ in the presence of acetophenone (**14**) proceed absolutely chemoselectively to form the 1,3-dithiolanes **10** and **15**, respectively. Methyl-substituted dithiolane **16** is not formed in this reaction. Good selectivity is observed also in the case of aliphatic aldehydes.

Ku and Oh⁸ believed that the bulkiness and branching of the carbonyl compound are the major factors governing the chemoselectivity of formation of 1,3-dithiolanes.

3. Catalysis by bentonite

Miranda *et al.*⁹ developed an excellent procedure for the synthesis of 1,3-dithiolanes. This procedure involves condensation of ketones with $(\text{CH}_2\text{SH})_2$ in the presence of bentonite, which has also been used for the oxirane ring-opening¹⁰ and conversion of oximes into ketones.^{11, 12} Dithiolanes **21–24** were prepared in high yields from ketones **17–20**, respectively. The reactions were performed in anhydrous toluene in the presence of bentonite as a catalyst.

This procedure is very simple and bentonite is inexpensive. It should be noted that the amount of the catalyst required in this case is seven times smaller than the amount of montmorillonite KSF in analogous reactions and the crude reaction mixture gives only one spot on a thin-layer chromatogram.

4. Catalysis by anhydrous LaCl_3

Anhydrous LaCl_3 proved to be a convenient and efficient catalyst¹³ of conversions of the carbonyl compounds **7**, **9**, **13** and **17** under the action of $(\text{CH}_2\text{SH})_2$ into the dithiolanes **10**, **12**, **15** and **21**, respectively. The reactions proceeded smoothly giving the products in very high yields. Owing to mild conditions and the simplicity, this procedure is suitable for multistep syntheses of complex organic compounds. Hydrated rare-earth metal chlorides were ineffective for the preparation of 1,3-dithiolanes from some carbonyl compounds. Apparently, anhydrous salts adsorb water much more actively than the hydrates, which facilitates substitution in the intermediate hemithioacetal with elimination of a water molecule and coordination of the lanthanum ion at the oxygen atom of the carbonyl group resulting in an increase in the electrophilicity of the carbon atom.

5. Catalysis by H-Y zeolite

The reactions of crotonaldehyde (**25**) and aromatic and sterically hindered ketones **26**, **14** and **27** with $(\text{CH}_2\text{SH})_2$ in the presence of H-Y zeolite ($\text{Si} : \text{Al} = 2.43$) afforded 1,3-dithiolanes **28**, **29**, **16** and **30**, respectively.¹⁴

The use of H-ZSM-5 zeolite ($\text{Si} : \text{Al} = 45$) and H-mordenite has met with only limited success. The advantages of H-Y zeolite are the simplicity of separation, high yields of the products and the possibility of regeneration of the catalyst.

6. Catalysis by montmorillonite KSF

Montmorillonite KSF was used¹⁵ for conversions of some aldehydes, for example, of **7**, **9** and **31–33**, in the absence of solvents at room temperature to form 1,3-dithiolanes **10**, **12** and **34–36**, respectively.

7. Catalysis by $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$

8. Catalysis by bis(trimethylsilyl) sulfate adsorbed on silica gel

9. Catalysis by MgI_2 in diethyl ether

10. Catalysis by Dowex-50W-X8

Reaction 1: 4-methylbenzaldehyde (**43**) reacts with $(\text{CH}_2\text{SH})_2$ on Dowex-50W-X8 to form 4-methyl-2,5-dithiolane (**47**).

 Reaction 2: 2,3-benzodioxymethanal (**44**) reacts with $(\text{CH}_2\text{SH})_2$ on Dowex-50W-X8 to form 2,3-benzodioxo-2,5-dithiolane (**48**).

 Reaction 3: 1,2,3,4-tetrahydronaphthalen-1-one (**45**) reacts with $(\text{CH}_2\text{SH})_2$ on Dowex-50W-X8 to form 1,2,3,4-tetrahydro-1,4-dithianaphthalene (**49**).

 Reaction 4: 1,2,3,4,5,6-hexahydro-1H-cyclohepta[1,2-b]pyridine-1-one (**46**) reacts with $(\text{CH}_2\text{SH})_2$ on Dowex-50W-X8 to form 1,2,3,4,5,6-hexahydro-1,4-dithianocyclohepta[1,2-b]pyridine (**50**).

Apparently, resin Dowex-50W-X8 treated with HCl acts as an acidic catalyst and increases the electrophilicity of the carbon atom of the carbonyl group. In the presence of this catalyst, the sterically hindered aromatic ketones **14** and **26** are smoothly converted into the dithiolanes **16** and **29**, respectively. This

method can also be used in the case of compounds containing acid-sensitive groups. The reactions are completed in a short time.

11. Catalysis by CuSO₄

The reactions of some carbonyl compounds, for example, of α -tetralone (27), 5 α -cholestan-3-one (37), dihydrocarvone (51), 4-phenylbutan-2-one (52), acetophenone (14) and benzophenone (26), with 1,2-ethanedithiol in dry THF in the presence of anhydrous copper sulfate, which is a gentle and inexpensive catalyst, afforded the thiolanes 30, 40, 53, 54, 16 and 29, respectively.²⁰

The reactions catalysed by $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ afford dithiolanes in very low yields. The advantage of this method is the fact that it can be applied in the case of various aliphatic, aromatic and steroid ketones.

12. Catalysis by bismuth halides and sulfate

Bismuth halides BiX_3 ($\text{X} = \text{Cl}, \text{Br}$ or I) and bismuth sulfate $\text{Bi}_2(\text{SO}_4)_3$ in acetone are powerful catalysts²¹ of conversions of carbonyl compounds, for example, of 8, 14, 55 and 56, under the action of $(\text{CH}_2\text{SH})_2$ at room temperature giving rise to the dithiolanes 11, 16, 57 and 58, respectively.

These bismuth salts offer the following advantages over various Lewis and Brønsted acids: (1) minimum amounts of these salts are required; (2) the salts exhibit catalytic activities under mild conditions; (3) the synthetic procedure is simple; (4) the products are prepared in high yields; (5) the reactions are chemoselective; (6) the catalyst is inexpensive and nontoxic; (7) it is possible to recognise the type of the carbonyl functional group. The high activity of this catalyst is retained in the presence of a small amount of water. An acid-sensitive substrate, such as furfural (13), is readily converted into dithiolane without self-condensation and ring opening.

13. Catalysis by lithium perchlorate in diethyl ether

The reactions of aldehydes 59–61 with $(\text{CH}_2\text{SH})_2$ yielding dithiolanes 62–64, respectively, are catalysed by lithium perchlorate in diethyl ether.²² Analogously, acetals 65 and 66 are converted into the dithiolanes 10 and 35, respectively.

These reactions proceed at room temperature to form 1,3-dithiolanes in high yields.[†] It appeared that ketones and their acetals react much more slowly than aldehydes and their acetals.

Yet another advantage of the above-mentioned system is its ability to perform chemoselective thioacetalisation of oxoaldehydes 31 and 67–69 in the synthesis of dithiolanes 34 and 70–72, respectively.

In this case, the aldehyde carbonyl group is selectively protected, while the keto group remains intact. The selectivity is absent in the reactions performed with the use of such Lewis acids as BF_3 or AlCl_3 .

14. Catalysis by ammonium cerium nitrate

Some aldehydes, for example, 7, 25, 59 and 61, were converted into dithiolanes 10, 28, 62 and 64, respectively, under the action of $(\text{CH}_2\text{SH})_2$ catalysed by $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$.²⁴ These dithiolanes were prepared in high yields at room temperature. In the presence of ketones, only aldehydes enter into the reactions. The reaction conditions and the synthetic procedure are very simple and convenient. This procedure can be extended to ketones. For example, cyclohexanone (17) gave the dithiolane 21 upon refluxing in chloroform for 10 h. It should be noted that aromatic ketones, γ -lactones and acyclic ketones do not react under the above-mentioned conditions, and hence, this catalyst is convenient for chemoselective thioacetalisation. Ammonium cerium nitrate is comparable in efficiency with the above-described solution of lithium perchlorate in diethyl ether.²²

[†] It should be noted that the reaction of dimethyl acetal 65 with 1,2-ethanedithiol in the presence of TeCl_4 in dichloromethane affords the dithiolane 10 in 99% yield.²³

15. Catalysis by zirconium(IV) chloride adsorbed on silica gel

The dithiolanes **10**, **16**, **21**, **22**, **29** and **57** are formed in high yields by the reactions of the carbonyl compounds **7**, **14**, **17**, **18**, **26** and **55**, respectively, with 1,2-ethanedithiol in the presence of ZrCl_4 adsorbed on silica gel.²⁵ This method has the following advantages: (1) the procedure is simple and convenient; (2) the reactions proceed smoothly; (3) the reactions are rapid and the system can be used in the case of low-reactivity ketones, such as **26** and **14**. Thioacetalisation of α,β -unsaturated aldehydes, for example, of cinnamaldehyde (**55**), can be performed with excellent yield, but attempts to prepare dithiolanes from α,β -unsaturated ketones in good yields were unsuccessful.

16. Catalysis by natural kaolin

Recently, it has been demonstrated²⁶ that kaolin efficiently catalyses conversions of the carbonyl group into the dithiolane moiety, for example, in the reactions of the compounds **7**, **13**, **26** and **55** with $(\text{CH}_2\text{SH})_2$ giving rise to the 1,3-dithiolanes **10**, **15**, **29** and **57**, respectively. It was also noted that the reaction of a mixture of benzaldehyde (**7**) and acetophenone (**14**) with 1,2-ethanedithiol in the presence of 10% of kaolin afforded only the dithiolane **10**, while acetophenone remained unconsumed.

Owing to high chemoselectivity, the reactions catalysed by kaolin may be advantageous in the selective protection of aldehydes in the presence of other carbonyl compounds.

17. Catalysis by LiBr

Aldehydes, for example, **7** and **55**, are converted into the dithiolanes **10** and **57**, respectively, in high yields under the action of $(\text{CH}_2\text{SH})_2$ without a solvent in the presence of catalytic amounts of lithium bromide.²⁷ Under similar conditions, the aromatic and aliphatic ketones **14** and **61** do not react even over several hours. This procedure is unsuitable for the preparation of dithiolanes in such solvents as THF and dichloromethane. In the latter solvents, aldehydes remain unconsumed. Due to the neutrality of the reaction medium, the procedure under consideration is very useful in the case of substrates highly sensitive to acids. The excellent selectivity and simplicity allow one to use this method successfully for selective conversions of aromatic and α,β -unsaturated aldehydes containing other carbonyl groups into 1,3-dithiolanes under very mild conditions.

18. Catalysis by copper(II) trifluoromethanesulfonate adsorbed on silica gel

A large number of aldehydes and ketones, for example, **7**, **8**, **14**, **26**, **32** and **43**, were converted into 1,3-dithiolanes by reactions with $(\text{CH}_2\text{SH})_2$ in the absence of a solvent and in the presence of catalytic amounts of copper(II) trifluoromethanesulfonate $\text{Cu}(\text{OTf})_2$ adsorbed on silica gel.²⁸ Analogous conversions are catalysed by $\text{Cu}(\text{OTf})_2$ in dichloromethane. Aldehydes react more rapidly than ketones. The reactions with aldehydes and ketones proceed chemoselectively, *viz.*, primarily aldehydes are involved in the reactions. In most cases, the reactions proceed smoothly. Such a sterically hindered and low-reactivity ketone as benzophenone (**26**) is inert with respect to the system under consideration without a solvent at room temperature, but the reaction proceeds in toluene on heating to 80 °C. Conversions of some aldehydes and ketones into 1,3-dithiolanes without a solvent were also observed in the presence of catalytic amounts of copper chloride adsorbed on silica gel, but the reactions proceeded slowly with low yields. The procedure for thioacetalisation of carbonyl compounds without a solvent may find wide use in organic synthesis in the future.

19. Catalysis by dibutyl(ethylenedithio)stannane in the presence of $\text{Bu}_2\text{Sn}(\text{OTf})_2$

Sato *et al.*²⁹ reported the conversions of the ketones **17** and **73–75** into the dithiolanes **21** and **76–78**, respectively, upon treatment

with dibutyl(ethylenedithio)stannane $\text{Bu}_2\text{Sn}(\text{SCH}_2)_2$ in the presence of $\text{Bu}_2\text{Sn}(\text{OTf})_2$ in dichloromethane.

This procedure for the synthesis of dithiolanes is to some extent comparable with that proposed by Evans *et al.*³⁰ The latter procedure involves thiosilanes and has been used only for carbonyl compounds. An important advantage of the procedure under consideration is the simplicity of the synthesis of thiostannane from various organotin compounds. In addition, thiostannane is air- and moisture-stable and can be stored in air. The procedure with the use of thiostannane and organotin triflate may be useful in preparing dithiolanes not only from ketones but also from their ketals.

Organotin triflates can be used for separation of ketones (or their ketals). If the reaction mixtures contain cyclopentanone (**73**), heptan-2-one (**79**) or 2-methylcyclohexanone (**80**) along with cyclohexanone (**17**), the reactions proceed primarily with cyclohexanone. The yield of the dithiolane **21** is very high compared to the yields of the compounds **76**, **81** and **82**.

This high selectivity cannot be achieved by conventional methods, for example, with the use of $(\text{CH}_2\text{SH})_2$ and $\text{BF}_3 \cdot \text{OEt}_2$. This possibility of separation is of great importance in the chemistry of steroids.

III. Reagents for the cleavage of 1,3-dithiolanes

A large number of procedures were developed for conversions of dithiolanes into the initial carbonyl compounds.^{1,31} Some of them require drastic conditions or the use of toxic compounds, for example, mercury salts. In some cases, dithiolanes are decomposed under mild conditions in several steps. In this connection, a demand arose for the development of new procedures for deprotection of dithiolanes and construction of new reagents which do not affect other functional groups.

1. The phenyl phosphorodichloridate–sodium iodide system in DMF

Liu and Wiszniewski³² used phenyl phosphorodichloridate in combination with sodium iodide in DMF for conversions of dithiolanes, for example, of **57** and **83–85**, into the corresponding carbonyl compounds **55** and **86–88**.

Ketones are formed in high yields. The reactions can be performed at room temperature. In the reactions with the use of acetonitrile instead of DMF, dithiolanes are recovered. The reactions carried out with boiling afford mixtures of products.

This procedure³² is applicable to aliphatic, aromatic and allylic dithiolanes. In all cases, the reactions proceed smoothly yielding the only desired product, which was confirmed by TLC data.

2. Phosphorus tetraiodide in acetic anhydride

Shigemasa *et al.*³³ developed a procedure for decomposition of 1,3-dithiolanes, for example, of **89–92**, under the action of P₂I₄ in acetic anhydride, chloroform or CCl₄ giving rise to ketones **93–96**, respectively, in high yields.

Dithiolane	Ketone	R ¹	R ²
89	93	MeO	Ph
90	94	Me	Ph
91	95	Cl	Ph
92	96	MeO	Bu ⁿ

The reactions of these 1,3-dithiolanes with P₂I₄ in dichloromethane result primarily in reductive desulfurisation and partial deprotection. In all cases, the amount of the reduced product is substantially higher than the amount of the ketone formed.

3. Amberlyst-15–paraformaldehyde in wet acetone

The dithiolanes **10**, **22**, **35**, **97** and **98** were converted into the ketones **7**, **18**, **33**, **99** and **100**, respectively, under the action of Amberlyst-15 and paraformaldehyde.³⁴

The dithiolanes were dissolved in aqueous acetone. Then paraformaldehyde and Amberlyst-15 were added and the reaction mixture was heated at 80 °C for 15–20 h. In these reactions, acid-sensitive ethers and esters remain intact.

4. Trimethylsilyl trifluoromethanesulfonate–4-nitrobenzaldehyde in CH₂Cl₂

A new procedure for the cleavage of dithiolanes³⁵ involves the addition of CF₃SO₃SiMe₃ to a mixture of dithiolane and 4-nitrobenzaldehyde in dichloromethane at room temperature. This procedure was used for conversions of the dithiolanes **16**, **30**, **35** and **57** into the ketones and aldehydes **14**, **27**, **32** and **55**, respectively. The reactions can be performed with the use of CF₃SO₃SiBu^tMe₂ instead of CF₃SO₃SiMe₃. Of the four aldehydes tested in the study,³⁵ 4-nitrobenzaldehyde was chosen because this reagent made it possible to accelerate the reaction and to improve the efficiency of migration of the sulfur. This method can also be used for selective deprotection of dithiolanes prepared from ketones in the presence of dithiolanes obtained from aldehydes. Thus 1,3-dithiolane **81** was hydrolysed to give ketone **79** in the presence of compound **101**. This is the first example of catalytic transthioacetalisation with simultaneous migration of oxygen and alkanethiol proceeding irreversibly in an anhydrous medium.

5. Dimethyl sulfoxide, 140–160 °C

In the absence of other reagents, DMSO catalyses³⁶ cleavage of some dithiolanes, for example, of **30**, **57**, **102** and **103**, at high temperature giving rise to the corresponding carbonyl compounds **27**, **55**, **104** and **105** in high yields.

It is known that DMSO can decompose dithiolanes in the presence of iodine³⁷ or *tert*-butyl chloride.³⁸

6. Dowex-50W – paraformaldehyde in acetone

Giri and Sankar³⁹ used a mixture of the acidic catalyst Dowex-50W and paraformaldehyde in acetone for the cleavage of dithiolanes of nitrogen-containing heterocyclic compounds **106–108** to yield ketones **109–111**, respectively.

Although the cleavage of such dithiolanes is generally performed with the use of mercury salts, the latter sometimes form insoluble complexes. This difficulty was overcome⁴⁰ by protection of the nitrogen atom before hydrolysis of dithiolanes with triethyloxonium tetrafluoroborate. Taking into account the simplicity of the procedure and the good yield of the product, we believe that this procedure³⁹ is superior in efficiency to all other available procedures for dethioacetalisation of nitrogen-containing heterocycles.

7. *N*-Fluoro-2,4,6-trimethylpyridinium triflate in a 1 : 1 CH_2Cl_2 – THF mixture and H_2O

Dithiolanes **12**, **112** and **113** were decomposed to aldehydes **9**, **114** and **115**, respectively, with the use of *N*-fluoro-2,4,6-trimethylpyridinium triflate $[\text{C}_8\text{H}_{11}\text{NF}]^+[\text{CF}_3\text{SO}_3]^-$ in a 1 : 1 CH_2Cl_2 – THF mixture and 5 equiv. of H_2O .⁴¹ High yields of compounds **9**, **114** and **115** were achieved by performing the reactions under an inert atmosphere (Ar or N_2). The reactions performed in the presence of oxygen or nitrobenzene give rise to a number of unidentified by-products. The reactions in pure dichloromethane, ether, hexane or acetonitrile as the solvent afford aldehydes in low yields. In DMF, dithiolanes do not decompose.

In the reactions of the title reagent with dithiolanes **116a–c**, the latter decompose to form mono- and diketones. The ratio between the monoketones **117a–c** and the diketones **118a–c**

prepared from the thioacetals **116a–c** decreases as the length of the carbon chain separating two dithiolane groups increases.

Compound	<i>n</i>	Yield (%)	
116–118		117	118
a	0	74	5
b	1	57	15
c	2	52	21

The cleavage of dithiolanes of aromatic derivatives **119** and **120** with *N*-fluoro-2,4,6-trimethylpyridinium triflate in the presence of water also afforded predominantly monoketones. The higher selectivity of the formation of *para*-substituted **121** ketone compared to the *meta*-isomer **122** is indicative of the important role of electronic effects and agrees with the cationic nature of intermediates.

Finally, it should be noted that hydrolysis of dithiolanes with a mixture of *N*-fluoro-2,4,6-trimethylpyridinium triflate and water was not accompanied by migration of the electrophilic fluorine atom. This fact is in contradiction with the mechanism of fluorination of organic substrates with *N*-fluoropyridinium cations proposed previously.⁴²

8. Copper(II) chloride – silica gel in CH_2Cl_2

The dithiolanes **16**, **40**, **53** and **54** were decomposed under the action of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ adsorbed on silica gel under mild conditions to form the corresponding carbonyl compounds **14**, **37**, **51** and **52**.²² The yields of the products obtained with the use of dichloromethane are substantially higher than those obtained with the use of THF. The reagent under consideration can be successfully used for the cleavage of dithiolanes of various aliphatic, aromatic and sterically hindered steroid compounds. The reaction conditions are very simple and convenient.

9. Selenium dioxide in acetic acid

A solution of SeO_2 in acetic acid proved to be an efficient reagent for the deprotection of 1,3-dithiolanes **123–126** to yield the aldehydes and ketones **127–130**, respectively.⁴³

The reactions proceed readily at room temperature giving rise to carbonyl compounds in very high yields. Widespread functional groups, such as ethers and esters, do not react with selenium dioxide. This procedure is very useful in the case of dithiolane derivatives of C(7)- and C(13)-steroid ketones whose cleavage generally requires drastic conditions. The presence of acetic acid is of importance because the reactions in aprotic solvents, for example, in THF, dichloromethane or toluene, proceed with very low yields. Hydrolysis in aqueous acetonitrile or acetone proceeds slowly (20–30 h) and affords cleavage products in low yields. Heating of the mixture accelerates the reaction, but the yield becomes even lower because a number of undesirable products are formed. The best results of the cleavage of dithiolanes and the highest yields of ketones regenerated are achieved with the 1,3-dithiolane to SeO_2 ratio of 1 : 5. On the whole, the procedure proposed for hydrolysis of 1,3-dithiolanes is rapid and convenient, characterised by high yields and is applicable to various compounds.

10. Oxone – wet Al_2O_3

Dithiolanes **30**, **131** and **132** were converted into ketones **27**, **133** and **134**, respectively, in high yields under mild conditions with the use of Oxone (potassium hydrogen persulfate, $2\text{KHSO}_5 \cdot \text{KHSO}_4 \cdot \text{K}_2\text{SO}_4$) and wet alumina.⁴⁴

The carbonyl compounds were obtained in high yields by refluxing 1,3-dithiolanes in chloroform in the presence of Oxone on Al_2O_3 , the functional groups, such as ethers and esters, and double bonds remaining intact. The procedure is simple and convenient, which is an additional advantage of this reagent for dethioacetalisation. This procedure is comparable in efficiency

with the above-described procedures for hydrolysis of dithiolanes or even superior to these methods.

11. Iron(III) nitrate – montmorillonite K10 – hexane

Hirano *et al.*⁴⁵ developed an efficient and simple procedure for oxidative cleavage of 1,3-dithiolanes with the use of iron(III) nitrate and montmorillonite K10 in hexane at 50 °C. This procedure was used for conversions of the 1,3-dithiolanes **12**, **57** and **89–92** into the carbonyl compounds **9**, **55** and **93–96**, respectively, in very high yields. In the absence of the clay, the reactions proceed slowly and afford ketones in lower yields. The advantages of this system over other supported reagents, such as iron(III) or copper(II) nitrates on montmorillonite K10 in the absence of hexane⁴⁶ or copper(II) nitrate on silica gel,⁴⁷ are the high reaction rate and the fact that there is no need for pretreatment of the reagent. Therefore, this procedure is an improved modification of the above-described methods. Hexane is a better solvent from economic and environmental standpoints compared to chlorinated hydrocarbons (CH_2Cl_2 , CHCl_3 and CCl_4), which are often used in standard heterogeneous systems. On the whole, this procedure for the cleavage of 1,3-dithiolanes and regeneration of carbonyl compounds is simple and convenient and satisfies economic requirements.

12. Zirconium sulfophenylphosphonate

Mixed zirconium(IV) methylphosphonate sulfophenylphosphonate, $\text{Zr}(\text{O}_3\text{PCH}_3)_{1.2}(\text{O}_3\text{PC}_6\text{H}_4\text{SO}_3\text{H})_{0.8}$, proved to be a very useful catalyst⁴⁸ for mild hydrolysis of 1,3-dithiolanes to form the corresponding carbonyl compounds. Dithiolanes are heated with a catalyst in the presence of glyoxylic acid monohydrate as an exchange reagent. This procedure was used for the preparation of the carbonyl compounds **7**, **14**, **37** and **133** from the dithiolanes **10**, **16**, **40** and **131**, respectively, in very high yields. Zirconium sulfophenylphosphonate is also a very efficient catalyst of the cleavage of cyclic dithioacetal, which is resistant to a number of other reagents.⁴⁹ It is noteworthy that zirconium sulfophenylphosphonate is comparable in activity with the above-described reagents or even superior to them. The essential advantages of this procedure are the absence of the solvent, mild conditions and the simplicity.

13. Miscellaneous procedures

The major reagents and catalysts used for the deprotection of 1,3-dithiolanes were considered in the previous sections. In addition, some dithiolanes were decomposed with the use of systems based on silver nitrate,⁵⁰ bis(trifluoroacetoxy)iodobenzene,⁵¹ nitrogen oxides,⁵² visible light⁵³ and tantalum chloride.⁵⁴ Since these procedures were rarely used, we do not consider them in detail in the present review.

IV. Conclusion

The problem of protection of the carbonyl groups in aldehydes and ketones, in particular, the protection giving rise to 1,3-dithiolanes, is of great importance in organic synthesis due to which an array of procedures for the introduction of this group were developed. The most frequently used methods were considered above. It should be noted that a large number of reagents for subsequent cleavage of 1,3-dithiolanes and regeneration of carbonyl-containing compounds have been proposed in recent years. Apparently, new reagents for introduction and removal of the dithiolane group will be developed in the future. In our opinion, the dithiolane moiety should be more extensively used as a protective group. We hope the present review will help to attract the attention of chemists engaged in organic chemistry to this problem.

Abstract. Characteristic features of the coordination chemistry of Cu(I) and mechanisms of catalytic conversions of alkynes in the $\text{CuCl}-\text{MCl}-\text{H}_2\text{O}-\text{HC}\equiv\text{CR}$ system (MCl is alkali metal or ammonium chloride or amine hydrochloride; $\text{R} = \text{H}, \text{CH}_2\text{OH}, \text{CH}=\text{CH}_2$, etc.) are analysed based on studies of the compositions and structures of copper(I) chloride (bromide) complexes, alkyne π -complexes and ethynyl organometallic polynuclear compounds formed in this system in solutions and in the crystalline state. The role of polynuclear complexes in various reactions of alkynes is discussed. The bibliography includes 149 references.

I. Introduction

Copper(I) complexes occupy a significant place in the chemistry of coordination compounds and in the development and evolution of homogeneous metal-complex catalysis. Copper(I) salts in quinoline were the first catalysts used in homogeneous hydrogenation.^{1,2} Copper(I) chloride was among the first commercial homogeneous metal-complex catalysts (dimerisation of acetylene).^{3,4} Acetylenic complexes of copper(I) were prepared for the first time by Chavastelon as early as 1898 in studies of the reactions of CuCl with C_2H_2 in aqueous solutions of KCl.^{5,6} The compositions $2\text{KCl}\cdot 8\text{CuCl}\cdot \text{C}_2\text{H}_2$, $\text{KCl}\cdot 4\text{CuCl}\cdot \text{C}_2\text{H}_2$, $\text{KCl}\cdot 2\text{CuCl}\cdot \text{C}_2\text{H}_2$ and $2\text{CuCl}\cdot \text{C}_2\text{H}_2$ were assigned to the crystalline adducts isolated.^{5–7} However, interest in the reactions of acetylene with CuCl and in catalysis by copper(I) complexes has particularly increased^{3,4,8,9} after brilliant studies on catalysis of dimerisation and hydrochlorination of acetylene by copper(I) chloride complexes performed by Nieuwland^{3,10} and the development of the commercial synthesis of chloroprene and synthetic rubber neoprene by Carothers (Du Pont de Nemours; see the monograph³). Thus, Nieuwland and coworkers¹⁰ (in 1929–1931) were the first to perform the catalytic synthesis of linear oligomers of C_2H_2 by the reaction of a concentrated solution of NH_4Cl and

CuCl in water (the molar ratio $\text{NH}_4\text{Cl}:\text{CuCl}:\text{H}_2\text{O} = 2:3:7$) with acetylene.

Conversions of acetylene in these systems are accompanied by a sharp decrease in pH of the medium (from ~ 4 to 1.1 at 80°C). Alkali metal chlorides¹¹ or amine hydrochlorides (hereinafter, MCl)¹² can be used instead of NH_4Cl as a component of the catalytic Nieuwland system. Concentrated solutions of MCl and CuCl proved to be also very efficient catalysts of other catalytic reactions of acetylene (for example, the addition of H_2O , HCl, HCN, RSH and C_5H_6 ; see Refs 1 and 13), dienes and dichlorobutenes.¹⁴

The major proposals for the mechanisms of various reactions of alkynes catalysed by copper(I) chloride complexes, including oxidation processes with the participation of the Cu(I)–Cu(II) system, were developed in 1960–1990.^{13,14} Certain specific features of copper(I) halide complexes are of most interest in their coordination chemistry and catalysis, among which are the pronounced tendency to form polynuclear complexes and, consequently, the possibility of the occurrence of multielectron processes, the formation of polynuclear π -complexes and σ -organometallic compounds with μ_2 - and μ_3 -bridging groups, the formation of heterovalent polynuclear complexes¹⁵ and the ability to activate alkynes, alkenes and dienes in various addition, substitution and oxidation reactions.

The distinguishing feature of concentrated solutions of MCl and CuCl in water is the formation of a large number of polynuclear $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes, which can participate to a variable extent in the same catalytic process and react with acetylene and its derivatives giving rise to intermediate π - and σ -complexes with different compositions and structures and of different nature. The understanding of the mechanism of catalytic reactions depends substantially on the available information on the structures of possible intermediates. Until recently, investigations of these intermediates were restricted to isolation of adducts and determination of their chemical compositions. During the last 15 years, a series of studies has been aimed at synthesising copper-containing complexes both of chloride (inorganic) and π - and σ -organocopper compounds and establishing their crystal structures.^{16–19}

Received 3 July 2000

Uspekhi Khimii 69 (11) 1042–1070 (2000); translated by T N Safonova

In this review, the data on the coordination chemistry, synthesis and structures of complex compounds of CuCl (CuBr) with acetylene and its derivatives and on catalysis with the participation of copper(I) chloride (bromide) complexes and alkynes are generalised and systematised and the possible mechanisms of oligomerisation of acetylene and other processes catalysed by copper complexes are discussed. In this connection, particular attention will be given to catalytic reactions of acetylene and its derivatives proceeding in highly concentrated aqueous solutions of MCl and CuCl because it is in these homogeneous systems that copper(I) chloride complexes exhibit the highest catalytic activity.¹³

Researchers from the former Soviet Union and the Community of Independent States (primarily, from Russia and Ukraine) have made a significant contribution to these investigations. In the present review, these studies are considered in detail.

II. Complexes of copper(I) halides in solutions and in the crystalline state

Systems of copper(I) chloride with aqueous solutions of alkali metal chlorides, ammonium chloride or amine hydrochlorides are of such great interest that studies of the state of copper in these solutions and mechanisms of their catalytic reactions, which were started late in the 19th century, are being continued. Investigations of the solubility⁸ and other physicochemical properties of concentrated solutions of MCl and CuCl in water and isolation of the products obtained in the reaction of acetylene with CuCl, which incorporate one, two, three or even six CuCl molecules per C₂H₂ molecule,^{4, 7, 11, 20} provided evidence that these solutions contained polynuclear complexes with composition (Cu_mCl_n)^{(n-m)-}.

1. Physicochemical properties of concentrated MCl–CuCl–H₂O solutions

The abundant data on the solubility of CuCl in aqueous solutions of MCl have been reported in a monograph.⁴ The NH₄Cl–CuCl–H₂O system has been studied extensively.^{21, 22} The solubility of CuCl increases sharply as the concentration of NH₄Cl increases and the mole fraction of water decreases (Figs 1 and 2). The [CuCl]:[NH₄Cl] ratio is noticeably larger than unity at 80 and 100 °C, which is indicative of the formation of polynuclear copper(I) chloride complexes. This is also evident from calculations of the Bjerrum formation function $\tilde{n}$ (or the Sillén function *Z*) based on the results of the potentiometric determination of the equilibrium concentration of the ligand ([Cl]⁻):

$$\tilde{n} = \frac{[\text{Cl}^-]_{\Sigma} - [\text{Cl}^-]}{[\text{CuCl}]_{\Sigma}}$$

Figure 1. Dependence of the [CuCl]/[NH₄Cl] molar ratio on the molal concentration of NH₄Cl at different temperatures.²¹ *T* (°C): (1) 25; (2) 50; (3) 80; (4) 100.

Figure 2. Triangular phase diagram of the solubility of CuCl (mole fractions).²¹ *T* (°C): (1) 25; (2) 80; (3) 100.

At the overall concentration of NH₄Cl and NH₄NO₃ of 10 $\tilde{m}$ ($\tilde{m}$ is the molal concentration), the $\tilde{n}$ value changes from 2.80 to 1.73 as the concentration of CuCl changes from 0.5 to 10 $\tilde{m}$ and the concentration of NH₄Cl changes from 1.5 to 10 $\tilde{m}$ (80 °C). The dependence of $\tilde{n}$ on [CuCl] also indicates the existence of polynuclear complexes.²²

Dissolution of CuCl in solutions of NH₄Cl is a slightly endothermic process (ΔH^0 changes from 16.7 to 4.18 kJ mol⁻¹ as the concentration of NH₄Cl changes from 1.5 to 15 $\tilde{m}$) and is accompanied by an increase in the entropy (ΔS_{298}^0 changes from 36 to 45 J mol⁻¹ K⁻¹).^{21, 23} Dissolution of CuCl is accompanied by dehydration of chloride ions resulting in an increase in *p*_{H₂O} and the activity of water (*a*_{H₂O}).²³ In the range of CuCl concentrations from 0 to 10 $\tilde{m}$ ([NH₄Cl] = 8.84 $\tilde{m}$), the *a*_{H₂O} value increases from ~ 0.74 to 0.83 (55 °C) and 0.88 (85 °C).

Studies of concentrated solutions of copper(I) chloride in NH₄Cl by electronic spectroscopy²⁴ (λ_{max} were 200, 235 and 273–400 nm) demonstrated that these solutions contain two groups of complexes because the optical density of the solution increases in the region of 250–290 nm and decreases in the region of 340–370 nm as the concentration of NH₄Cl increases. The absorption band in the region of 340–370 nm is the sum of absorption bands of different polynuclear complexes.

A comparison of the absorption spectra of chloride and bromide complexes in solutions in KX (5 $\tilde{m}$, X = Cl or Br) in the regions of 273 and 300–330 nm at the CuX concentrations of 0.01 and 0.4 $\tilde{m}$ demonstrated²² that the shifts of the absorption maxima to the long-wavelength region are no larger than 5–8 nm on going from Cl⁻ to Br⁻. It was assumed^{24, 25} that the longer-wavelength bands ($\lambda \simeq 320$ nm, $\epsilon_{\text{Br}^-} \simeq 150$) belong to the forbidden transitions $3d^{10} \rightarrow 3d^9 4s^1$ and the bands at 200 and 273 nm belong to the transitions $3d^{10} \rightarrow 3d^9 4p^1$.

2. Complexation equilibria in the MCl–CuCl–H₂O and NH₄Cl–CuCl–H₂O catalytic systems

The equilibria of the formation of copper(I) chloride complexes in rather dilute solutions have been studied in detail.²⁶ The concentration stability constants ($\beta_{m,n}$) for the complexes (Cu_mCl_n)^{(n-m)-} in the NaClO₄–NaCl–HCl–CuCl system with an ionic strength of the solution *I* = 5 mol litre⁻¹ and [HCl] = 0.1 mol litre⁻¹ (25 °C) were determined by two methods. The potentiometric method was used for [NaCl] = 0.2–0.88 mol litre⁻¹ and [CuCl] ≤ 0.012 mol litre⁻¹ and for [NaCl] = 0.2–4.268 mol litre⁻¹ and [CuCl] ≤ 0.047 mol litre⁻¹. The solubility method was used for [NaCl] ≤ 5.0 mol litre⁻¹ and [CuCl] ≤ 1.16 mol litre⁻¹. In the latter case, polynuclear complexes were revealed and the $\beta_{2,4}$ value for Cu₂Cl₄²⁻ was evaluated (Table 1). The constant *pK_s* = 6.73 was also determined by Andrews and Keefer.³²

Table 1. Stability constants ($\bar{\beta}_{m,n}$) for selected $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes.

Temperature / °C	Ionic strength of the solution / mol litre ⁻¹	$\log \bar{\beta}_{1,2}$	$\log \bar{\beta}_{1,3}$	$\log \bar{\beta}_{1,4}$	$\log \bar{\beta}_{2,4}$	pK _s	Ref.

Note: K_s is the solubility product for CuCl_{solid}. ^a The equilibrium constant $\beta_{m,n} = \beta_{m,n}^* / \gamma_{m,n}$; the constant sum of the concentrations ($\tilde{m}$) of $\text{NH}_4\text{Cl} + \text{NH}_4\text{NO}_3$.

With the aim of establishing the compositions of copper(I) chloride complexes in solutions concentrated with respect to CuCl and NH_4Cl , which were used in catalytic reactions of alkynes,^{3,4,8} the equilibria in the $\text{NH}_4\text{Cl} - \text{CuCl} - \text{H}_2\text{O}$ system were examined at 25, 50 and 80 °C at the concentrations of CuCl varying from 0.03 to 10 $\tilde{m}$ (at 80 °C) and at different constant concentrations of the supporting electrolyte, viz., $\text{NH}_4\text{Cl} + \text{NH}_4\text{NO}_3$ (6.5, 10 and 14 $\tilde{m}$).^{30,31,33} The activities of the Cu^+ (a_{Cu^+}) and Cl^- (a_{Cl^-}) ions used in the cited studies were calculated based on the potentials of copper and silver-chloride electrodes measured in chains with transference (with respect to a standard hydrogen electrode). For the standard conditions ($p_{\text{H}_2} = 1$ atm, $a_{\text{H}^+} = 1$, $a_{\text{Cu}^0} = 1$, $a_{\text{AgCl(solid)}} = 1$, $a_{\text{Ag}^0} = 1$), these activities are directly proportional to the thermodynamic activities of individual Cu^+ and Cl^- ions and are taken as equal to these values at $E_D = 0$ (E_D is the diffusion potential). Under the conditions of $E_D = \text{const}$,^{30,31,33} the proportionality coefficient (which is close to unity) remains constant throughout the concentration ranges of CuCl and NH_4Cl , which made it possible to obtain reliable data on the compositions of the complexes. The activity coefficient of Cl^- (γ_{Cl^-}) was found to remain constant at the constant concentration of NH_4^+ ions throughout the concentration ranges of CuCl and NH_4Cl . It was assumed that $\gamma_{(\text{Cu}_m\text{Cl}_n)^{(n-m)-}}$ also remains constant under these conditions. The compositions of polynuclear complexes were determined and the stability constants were estimated using the Sillén–Hedström method.^{34,35} When using the a_{Cu^+} and a_{Cl^-} values, the stability constants $\beta_{m,n}$ differ from the thermodynamic constants $\beta_{m,n}^*$ by the activity coefficient $\gamma_{m,n}$.

$$\beta_{m,n} = \frac{\beta_{m,n}^*}{\gamma_{m,n}}.$$

The $\beta_{m,n}$ values for 19 $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes are given in Table 2. It should be taken into account that the $\beta_{m,n}$ constants for complexes with large m (4 or 5) and n (7, 8 or 9) values calculated by this method can exhibit an error of up to one order of magnitude. Hence, it can only be said with assurance that single-, double- and triple-charged anions containing from one to four copper atoms exist in solution. The discrepancy between the experimental and calculated concentrations of CuCl at all temperatures is no higher than 10%.²² It can be seen from Table 2 that the multiply-charged complexes ($n - m = 4$) and complexes with $m = 5$ disappear as the temperature increases, the compositions of the complexes being virtually independent of the increase in $[\text{NH}_4^+]$. The possibility of the determination of a large number of complexes and their compositions by the Sillén–Hedström method follows primarily from the independent determination of the a_{Cu^+} and a_{Cl^-} values. Calculations of the activity (and concentration) of Cl^- ions by the Hedström equation with the use of the a_{Cu^+} , $[\text{CuCl}]_\Sigma$ and $[\text{Cl}^-]_\Sigma$ values demonstrated that the calculated and experimental a_{Cl^-} values coincide only up to the CuCl concentrations of 0.5 $\tilde{m}$. At higher concentrations, the

discrepancy increases due to the low accuracy of the graphical method of solution of the Hedström equation.³⁵

Analysis of the distribution of the complexes (Fig. 3) demonstrated that polynuclear complexes appear in noticeable amounts starting with a CuCl concentration of 3–4 $\tilde{m}$. The total concentration of the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes with $m = 2, 3$ and 4 reaches ~30% of the sum of the concentrations of all complexes. Based on the $\beta_{m,n}$ values (Table 2) determined at $I = 6.5$ and with the a_{Cu^+} and a_{Cl^-} values, which were measured²⁶ for the maximum concentrations of NaCl and CuCl, it can be demonstrated that the mole fraction of complexes with $m \geq 2$ is smaller than

**Figure 3.** Distribution of the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes in the $\text{CuCl} - \text{NH}_4\text{Cl} - \text{H}_2\text{O}$ system depending on the concentration of CuCl (80 °C, $[\text{NH}_4^+] = 10 \tilde{m}$).

Note. $[\text{NH}_4^+] = 10 \text{ } \tilde{m}$.

5%. Because of this, these complexes were not determined experimentally.²⁶ Interestingly, the different approaches gave close values of the stability constants $\beta_{m,n}$ and $\beta_{m,n}$ for CuCl_2^- and CuCl_3^{2-} (see Table 1).

Since the activity coefficients of different chlorides (KCl, NaCl and NH_4Cl) in aqueous solutions are virtually independent of the temperature, it was assumed that $d\gamma_{m,n}/dT \approx 0$. This assumption was used for the estimation of the ΔH values of the reactions³³ (Table 3)

The $\beta_{m,n}$ values change in parallel with the temperature (the dependence of $\log\beta_{m,n}$ on $1/T$ is linear).³³ The $\beta_{m,n}$ values at 25°C and at $[\text{NH}_4^+] = 10 \text{ } \tilde{m}$ were determined by the linear interpolation of the values given in Table 2. The addition of each successive CuCl molecule to the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complex causes a decrease in the ΔH value, on the average, by $30\text{--}42 \text{ kJ mol}^{-1}$. According to the estimates obtained, the formation of polynuclear complexes from smaller complexes is also accompanied by a decrease in the enthalpy (Table 4). However, the equilibria are noticeably shifted to the right at rather low temperatures (below $50\text{--}60^\circ\text{C}$) due to a large decrease in the entropy. An increase in the $\beta_{m,n}$ values as the concentration of the cations increases may be associated both with the decrease in $\gamma_{m,n}$ and with the formation of outer-sphere complexes with the NH_4^+ ion. The effect of the anionic complexes with $n-m \geq 2$ on the ionic strength of the solution was assessed¹³ with the use of the Moiseev–Flid equation,^{36,37} which describes the dependence of the acidity function of HCl ($-H_0$) on the ionic strength of the solution (I).

$$-H_0 = \log c_{\text{H}_3\text{O}^+} + LI - \log a_{\text{H}_2\text{O}},$$

where L is a constant dependent on the nature of the salt and the solvent ($L = 0.051 \text{ } \tilde{m}^{-1} \equiv 0.063 \text{ mol}^{-1} \text{ litre}$ at $40\text{--}80^\circ\text{C}$ and $[\text{HCl}] = 0.18\text{--}0.8 \text{ } \tilde{m}$).

The measurements demonstrated³⁸ that the H_0 value remained unchanged over a wide range of CuCl concentrations at $[\text{HCl}] = 0.16 \text{ } \tilde{m}$ (80°C) (Fig. 4).¹³ Taking into account the change in the $a_{\text{H}_2\text{O}}$ value, the ionic strength increases by no more than 0.5 for $[\text{NH}_4\text{Cl}] = 12 \text{ } \tilde{m}$ on going from the $\text{NH}_4\text{Cl}\text{--HCl}\text{--H}_2\text{O}$ system to the $\text{NH}_4\text{Cl}\text{--CuCl}\text{--HCl}\text{--H}_2\text{O}$ system. Hence it follows that multiply-charged anions have virtually no effect on the ionic strength due to their low concentrations (calculated from the data in Table 2) as well as due to

Table 4. Thermodynamic parameters for the association reactions.

Reactions	ΔH_{298}° /kJ mol ⁻¹	ΔS_{298}° /J mol ⁻¹ K ⁻¹

**Figure 4.** Effect of the concentration of CuCl on the acidity function H_0 at 80°C and at different concentrations of NH_4Cl ($[\text{HCl}] = 0.16 \text{ } \tilde{m}$).¹³ $[\text{NH}_4\text{Cl}]$: (1) $5 \text{ } \tilde{m}$; (2) $9 \text{ } \tilde{m}$; (3) $12 \text{ } \tilde{m}$.

their interactions with NH_4^+ ions. Therefore, the $\beta_{m,n}$ value (taking into account the coordination of water) should be represented by the following equation:³¹

$$\beta_{m,n} = \sum_p \sum_q \frac{\beta_{m,n}^*}{\gamma_{m,n,p,q}} a_{\text{NH}_4^+}^p a_{\text{H}_2\text{O}}^q.$$

The presence of various polynuclear complexes and their participation in catalytic reactions were confirmed in subsequent studies of ethynyl complexes of copper in solution, research on the synthesis and isolation of crystalline complexes and investigations on the kinetics of the reactions catalysed by copper(I) complexes.

3. Crystal chemistry of $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anionic complexes

Analysis of the available information on the compositions and crystal structures of complexes isolated from copper halide systems is necessary for an understanding of the mechanisms of catalytic processes and reasons for high catalytic activities of concentrated solutions containing polynuclear copper complexes. In this section, we analyse the structures of the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions and consider the effect of the outer-sphere M^+ cation on the structures of the complexes.

All types of $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions found in the structures of copper(I) halide complexes can be divided into four groups, viz., island, chain (including ribbon), layered and framework structures. The structural classification of the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions is given in Table 5.

Crystal-chemical analysis of the complexes demonstrated that the copper atoms in the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anionic fragments ($\text{X} = \text{Cl}$ or Br) are most often located in a tetrahedral environment (the coordination number is 4) formed by the Cl or Br atoms. The vertices of the tetrahedra are generally located at different distances from the central atom. The $\text{X}\text{--Cu}$ bond lengths depend on the coordination number of the X atom, i.e., on the degree of association of the Cu(I) coordination polyhedra. On the whole, the X atoms characterised by larger coordination numbers are located at larger distances from the central atom (see Table 5).

Planar-trigonal coordination (the coordination number is 3) about the Cu atoms was also found in copper(I) halide complexes. The angular or linear environments (the coordination number is 2) occur more rarely. Among the structurally characterised copper(I) halide complexes, no isolated tetrahedral CuX_4^{3-} anions were found. Apparently, discrete CuX_3^{2-} anions containing the metal atom in a planar-trigonal environment also do not exist.

In the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions containing two or more Cu atoms, the coordination polyhedra can be linked to each other in different fashions, viz., through vertices, edges or faces. The coordination polyhedra are more often linked in a combined mode simultaneously through vertices and edges, which in some cases gives rise to $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions with zeolite-like structures. The numerous cavities of the latter structures can be occupied by small molecules ($\text{HC}\equiv\text{CH}$, H_2O , $\text{CuC}\equiv\text{CH}$, etc.) and even complexes [for example, the Cu(II) complexes in com-

Table 5. Structural characteristics of the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions in copper(I) halide complexes.

Notes. For the Cu—Cl bonds, the first and second figures correspond to the minimum and maximum values, respectively; for the Cu—Cu bonds, the shortest distances are given. The complexes **2a** and **2b**, the complexes **3a**–**c** and **4**, the complexes **9a**–**d** and the complexes **15a,b** and **16** are isostructural. ^a The distances from the Cu atom to the nonbridging Cl atom; ^b the Cu—Br bond lengths are given; ^c ImH is the imidazolium cation; ^d acetylene is adsorbed and does not occupy particular crystallographic positions.

pounds **15a,b** and **16**; see Table 5] to form 'guest–host' systems. The fact that the coordination polyhedra about the Cu atoms are linked *via* edges (faces) results in short Cu...Cu contacts typical of cluster compounds (see Table 5).

Let us consider the types of the $(\text{Cu}_m\text{X}_n)^{(n-m)-}$ anions found in the structures of copper(I) halide complexes in detail. Two types of mononuclear anions, *viz.*, CuX_2^- and CuX_3^{2-} , are known. The CuX_2^- anion serves as an independent unit of the $(\text{CuX}_2)_n$ polymeric anions, which exist as chains or layers in complexes **1** and **2a,b**, respectively (see Table 5). In both case, the coordination polyhedra about the Cu atoms are linked to each other both through vertices and edges.

In isostructural compounds **3a** (or **3b,c**) and **4**, the $(\text{CuX}_3^{2-})_n$ chain fragments of identical structure are formed based on the CuX_3^{2-} anion. In these compounds, the coordination tetrahedra about the Cu(I) atoms are linked only through vertices.

The binuclear Cu_2X_3^- anion can produce two types of $(\text{Cu}_2\text{Cl}_3)_n$ chain fragments. Fragments of the first type are observed in complex **6** and are formed by the Cu(I) coordination tetrahedra and triangles linked to each other simultaneously through vertices and edges. The second type (complex **5**) is formed by the Cu(I) coordination tetrahedra linked to each other exclusively through edges.

For yet another binuclear $\text{Cu}_2\text{X}_5^{3-}$ anion, both the island and chain modes of arrangement of the anionic fragments are observed. Complex **8** contains the $\text{Cu}_2\text{Br}_5^{3-}$ anion of the island type. In this complex, two coordination triangles about the Cu(I) atoms are linked *via* a shared vertex. In complex **7**, the $(\text{Cu}_2\text{Cl}_5^{3-})_n$ chain anion consists only of the Cu(I) coordination tetrahedra, which are linked to each other both through vertices and edges.

The trinuclear $\text{Cu}_3\text{X}_5^{3-}$ anion was found in isotopic compounds **9a–c** with the zeolite-like framework structures formed by the Cu(I) coordination polyhedra linked to each other both through vertices and edges. The $(\text{Cu}_3\text{Cl}_5^{3-})_n$ framework anion was also found in complex **9d** whose composition can be represented as $\text{Rb}_2\text{Cu}_{3-x}\text{Cl}_{5-x} \cdot (2/9\text{H}_3\text{O}^+ + \text{Cl}^-)$ ($x = 0.1$) by analogy with the compounds **9a–c**. Crystals of these four compounds were isolated from the catalytic $\text{MCl–CuCl–H}_2\text{O}$ system ($\text{M} = \text{NH}_4^+$ or Rb^+) in the presence of which oligomerisation of C_2H_2 was performed. The compounds **9a–d** can be considered as stable stoichiometric points in the region of a phase with the variable composition $\text{M}_2\text{Cu}_3\text{Cl}_5 \cdot x \cdot (y\text{C}_2\text{H}_2)$, where $x = 3/9\text{H}_2\text{O} \cdot 1/15\text{CuCl}$ and $(2/9\text{H}_3\text{O}^+ + \text{Cl}^-)$ at $y = 0$ for $\text{M} = \text{NH}_4^+$ and Rb^+ , respectively, and $x = 4/9\text{H}_2\text{O}$ at $y = 1/9$ or $4/9$ for $\text{M} = \text{NH}_4^+$.

The tetranuclear Cu_4X_5^- anion forms an unusual [from the viewpoint of the mode in which the coordination polyhedra about the Cu(I) atoms are linked] $(\text{Cu}_4\text{X}_5)_n$ chain fragment. In complex **10**, these fragments exist as the Cu(I) coordination tetrahedra linked to each other *via* edges and faces.

The tetranuclear $\text{Cu}_4\text{X}_7^{2-}$ anion is observed in complex **11**. These anions form $(\text{Cu}_4\text{Cl}_7^{2-})_n$ chains in which the coordination tetrahedra and triangles about Cu(I) are linked to each other through vertices and edges.

In the structurally characterised copper(I) halide complexes, two types of pentanuclear anions, *viz.*, $\text{Cu}_5\text{X}_7^{2-}$ and $\text{Cu}_5\text{X}_9^{4-}$, were found. In complex **12**, the $(\text{Cu}_5\text{Cl}_7^{2-})_n$ anions are built of the coordination tetrahedra and triangles about the Cu(I) atoms, which are successively linked to each other through vertices and edges to form a zeolite-like framework structure.

The $\text{Cu}_5\text{X}_9^{4-}$ anions in complex **13** are linked in a ribbon-like $(\text{Cu}_5\text{X}_9^{4-})_n$ fragment in which the Cu(I) coordination polyhedra are linked to each other both through vertices and edges.

The island $\text{Cu}_6\text{Br}_9^{3-}$ fragment is an example of a hexanuclear anion. In complex **14**, this anion consists of four Cu(I) coordination tetrahedra linked to each other exclusively through edges. Two opposite vertices of this fragment are additionally coordinated by two Cu atoms with the coordination number 2.

Finally, the polynuclear $\text{Cu}_{15}\text{X}_{24}^{9-}$ anion was found in the zeolite-like structure **16**. The anions form a $[\text{Cu}_{15}\text{Cl}_{24}(\text{Cu}^{\text{II}}\text{Cl}_6)]_n$ layer in which the coordination polyhedra about Cu(I) are linked

Figure 5. Relationship between the degree of association of the coordination polyhedra about the metal atoms and the number of nuclei (m) for the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ anion; (1) terminal Cl; (2), (3) and (4) μ_2 -, μ_3 - and μ_4 -Cl, respectively.

to each other through vertices and edges. The 'guest–host'-type structures of **15a,b** contain the structurally similar $[\text{Cu}_{15}\text{Cl}_{16}\text{Br}_6(\text{Cu}^{\text{II}}\text{Cl}_6)]_n$ anionic layers in which some crystallographic positions are partially occupied by Cl atoms.

For a range of the above-described structural fragments in copper(I) chloride complexes, a marked trend is observed toward their complication as the number of nuclei in the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ anions increases. The relationship between the number of nuclei in the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ fragment (m) and the character of the bridging Cl atom (μ_n , where $n = 2, 3$ or 4) can be represented by a diagram (Fig. 5). It can be readily seen from Fig. 5 that an increase in m is accompanied by an increase in the ability of the chlorine atoms to act as bridging ligands. Thus, the very low degree of association of the Cu(I) coordination polyhedra is characteristic of the anionic fragments at $m = 1$, whereas complex structural forms of anions appear at $m = 2, 3$ or 4 . For $m \geq 4$, though the ability of the bridging chlorine atoms to undergo association is somewhat lower, the structural fragments are, on the whole, complex.

This regularity agrees well with the results of studies of the equilibria in the CuCl–MCl system.^{13, 30, 31, 33} Thus among the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes ($m = 1–5$ and $n = 2–7$), which are present in concentrated solutions of NH_4Cl and CuCl , the complexes with $m = 2, 3$ and 4 prevail. Therefore, the ability of the Cu(I) coordination polyhedra to form complex $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ associates at $m \geq 2, 3$ or 4 is, apparently, one of the major reasons for the high catalytic activity of concentrated solutions of MCl and CuCl .

Complex associates in solution are formed from coordination polyhedra of layered, chain, island or framework types upon cleavage of the bridging $\mu_n\text{-Cl}$ bonds by water molecules or Cl^- anions, which occupy the coordination vacancies in $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes in solutions.

Let us consider the effect of the nature of the outer-sphere M^+ cation involved in the $\text{MCl–CuCl–H}_2\text{O}$ system on the crystal structures of the anionic copper(I) halide complexes.

As mentioned above, dissolution of CuCl and formation of anionic complexes in aqueous solutions of MCl proceed according to the reaction

It is known that copper chloride is a salt, which contains covalent polar Cu–Cl bonds and is characterised by a framework sphalerite-like structure.⁵⁶ Dissolution of CuCl in aqueous solutions of ionic salts MCl involves destruction of the crystal lattice of CuCl under the action of adsorbed Cl[−] anions with the simultaneous cleavage of some Cu–Cl bonds and the appearance of individual (Cu_mCl_n)^{(n−m)−} fragments resulting in the establishment of the equilibria between these fragments. Both processes are accompanied by dehydration of Cl[−] ions present in the solution. Apparently, the structures of the anions (as well as the stoichiometry of the equilibria) are determined to a large extent by the nature of the M⁺ cations. The crystal structures of the complexes isolated from solutions also depend on the type (the size, symmetry, configuration, charge density and other characteristics) of the outer-sphere cation involved in complexation.

Analysis of the structural data demonstrated that NH₄⁺ cations can form crystalline complexes with extremely complex zeolite-like structures, such as the complexes **9a–c**, due to the tetrahedral form of the ammonium cations. The latter interact with Cl[−] ions through N(H)⋯Cl hydrogen bonds⁵⁷ imparting the directed character to the M⁺⋯Cl[−] ionic bonding, which is responsible for the ‘code’ of the structure construction of the complex as a whole. The skeleton structures **1**, **6**, **11** and **12** containing planar PyH⁺, ImH⁺ (Im is imidazole) and C₆H₅NH₃⁺ cations are also formed through (N)H⋯Cl hydrogen bonds. The replacement of NH₄Cl by KCl gives rise to the complexes **2a**, **3a** and **3b** in which K⁺ cations cannot form directed bonds with Cl[−] ions, and, consequently, no complex combinations of the Cu(I) coordination polyhedra are observed.

Apparently, the ability of NH₄⁺ cations and protonated amines to generate complex structural forms of (Cu_mCl_n)^{(n−m)−} anions through spatially oriented M⁺⋯Cl[−] interactions giving rise to outer-sphere complexes in solution is one of the reasons for the fact that catalytic activities in systems containing NH₄⁺ and amine hydrochlorides are higher than those in the KCl–CuCl–H₂O systems.

III. Organocopper compounds

In the previous section, we considered M_(n−m)Cu_mX_n complexes, which were formed in concentrated aqueous solutions of MCl and CuCl and isolated from solutions in the crystalline state. The compositions and structures of these complexes give an idea of the state of the initial catalytic system. In the course of the reaction of the MCl–CuCl–H₂O system with acetylene (for example, under conditions of the oligomerisation according to Nieuwland), acetylene molecules and then products of their conversions (mono- and disubstituted derivatives) form π- and σ-organocopper compounds with (Cu_mCl_n)^{(n−m)−} anions.^{4,13}

In the first stage, π-complexes form. Then these complexes are converted into compounds of the mono- and diacetylenide types depending on pH of the medium.⁵⁸ In the initially weakly acidic medium, organometallic compounds exist predominantly as acetylenide (ethynyl) derivatives, which can be reversibly converted into π-complexes as pH decreases. The latter complexes are the major products of the reactions of alkynes with Cu(I) in acidic solutions. In this section, we will consider π- and σ-organocopper complexes, which are formed in the course of the reactions of acetylenic compounds with concentrated aqueous solutions of MCl and CuCl. Analysis of the structural features of polynuclear ethynyl complexes of copper(I) is required for an understanding of their role in catalytic processes (provided that the structures of the major fragments of the crystalline compounds are retained in solution). Selected structural characteristics of the compounds under consideration are given in Tables 6–9. For simplicity, the types (modes) of coordination of the C≡C group (η¹ or η²) are denoted by σ or π, respectively (or σ,π-mode if both modes of coordination occur).

Examination of the data given in Tables 6–9 allows one to judge the efficiency of π-interactions in copper(I) π-complexes, to estimate the degree of activation of the triple bond and the alkyne molecule by the metal ion, to follow the possible pathways of conversions of π-complexes into acetylenide (ethynyl) complexes

Table 6. Mode of coordination of the C≡C group and the geometric characteristics of the π-coordinated Cu(I) units in the structures of π-complexes of copper(I) halides with acetylene and its monosubstituted derivatives.

and to analyse the characteristic structural features of polynuclear ethynyl compounds.

1. Complexes of CuX with acetylene and its derivatives

The triple bond consists (in addition to the σ-bond) of two mutually orthogonal π-bonds, which are potentially able to interact with Cu(I). In the structures of copper(I) chloride complexes, acetylene always acts as a bridging π-ligand and is

coordinated simultaneously by two metal atoms (Fig. 6). In this respect, the acetylene ligand is isolobal to the bridging μ²-Cl ligand. Some monosubstituted acetylene derivatives in π-complexes with CuCl behave analogously (for example, **28–30**; see Tables 6 and 7). However, the C≡C bond in π-complexes of a series of alkynes and alkenynes, for example, of disubstituted acetylene derivatives (like the alkene bond), is coordinated exclusively by one copper atom [compounds **24–27**, **38–42** and **31–37**

^a The coordination number of Cu is 2; ^b the η²-mode of coordination of the C≡C group to three Cu(I) atoms; ^c the first stage of X-ray diffraction analysis.

(Fig. 7)]. Moreover, the C≡C bond of the alkenyne ligand (*i.e.*, the more sterically hindered bond) successfully competes with the peripheral vinyl groups even in conjugated systems (complex **35**). In the case of the CuCl complex with allylpropargyl alcohol (**31**), the C=C bond of the allyl group, unlike the C≡C bond, is not coordinated to the copper atom. Therefore, the ability of the

C≡C bond to be involved in the π-interaction with copper(I) is higher than that of the C=C bond.

According to the Dewar–Chatt–Duncanson concept,^{13, 80, 81} the formation of acetylene complexes with Cu(I) compounds (3d¹⁰4s⁰4p⁰) is accompanied by interactions between the frontier molecular orbitals (MO) of acetylene and the metal complex [for

Figure 6. Projection of the structure of $\text{Cu}_2\text{Cl}_2(\text{HC}\equiv\text{CH})$ (**17**) onto the xy plane.

Figure 7. Projection of the structure of $\text{CuC}_2(\text{HOCH}_2\text{C}\equiv\text{CH}_2\text{OH})$ (**39a**) onto the xy plane.

example, $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ giving rise to two three-centre MOs. One of them is formed by the overlap of the unoccupied sp^3 -hybridised orbital of Cu(I) with the bonding π -MO of acetylene (the donor-acceptor component of the $\text{M} \leftarrow \text{L}$ bond, where M is metal and L is alkyne), whereas the second MO is formed due to overlapping of one of the symmetry-suitable occupied d orbitals of the metal atom and the antibonding π^* -MO of acetylene (the dative component of the $\text{M} \rightarrow \text{L}$ bond). Both three-centre bonds contribute to the increase in the strength of the $\text{Cu}-\pi$ -ligand bond; however, they have different effects on the properties of the π -ligand. For example, the occupation of the antibonding π^* -MO of acetylene with the electrons of the metal atom (the dative component) in Cu(I) π -complexes leads to a change in the $\text{C}\equiv\text{C}-\text{R}$ angle (*cis* distortion) and elongation of the $\text{C}\equiv\text{C}$ bond. In turn, donation of electrons from π -MO of acetylene to one of the sp^3 -hybridised orbitals of Cu(I) (the donor-acceptor component) results in a decrease in the electron density on the $\text{C}\equiv\text{C}$ bond due to which the carbon atoms acquire positive charges (δ^+) and this π -coordinated acetylene group acts as a soft electrophile. The transfer of the electron density from the ligand to Cu(I) leads also to a decrease in the distance from the Cu(I) atom to the midpoint of the $\text{C}\equiv\text{C}$ bond.

In essence, the above-considered model of the bond in the metal (M) π -complex with alkyne is synergistic because an increase in the $\text{M} \leftarrow \text{L}$ component leads to an increase in the back $\text{M} \rightarrow \text{L}$ transfer.⁸² However, these components make differ-

ent contributions to π -interactions. Calculations of the energies of the Cu(I)–acetylene bond [or the Cu(I)–ethylene bond] demonstrated⁸³ that the contribution of the donor-acceptor electron transfer to the bond energy is approximately three times larger than that of the dative interaction. Hence, the specificity of activation of the acetylene bond on the metal centre in Cu(I)– π -complexes is primarily determined by interactions of the $\text{M} \leftarrow \text{L}$ type. High-level quantum-chemical calculations^{84,85} of the $\text{Cu}(\text{C}_2\text{H}_2)^+$ complex (taking into account the low-lying excited states) demonstrated that the $\text{Cu}^+ - \text{C}_2\text{H}_2$ bond is predominantly ionic in character and the Coulomb Cu(I) ion– π -ligand interaction makes the major contribution (the $\text{C}\equiv\text{C}$ bond length is 1.242 Å, the $\text{C}\equiv\text{CH}$ angle is 168.7°). This is consistent with the conclusion⁸³ that the electron transfer to the metal atom prevails. The ionic character of the bonds was also revealed in bisalkyne complexes $\text{Cl}_2\text{X}(\text{C}\equiv\text{CH})_2 \cdot \text{CuMe}$ (X = C, Si or Ti).⁸⁶ In these complexes, CuMe even donates electrons to the π -ligand.

The Cu(I)–($\text{C}\equiv\text{C}$) [or Cu(I)–($\text{C}=\text{C}$)] bonding in copper(I) chloride π -complexes leads to deformation of the tetrahedral environment about the metal atom characteristic of Cu(I) σ -compounds toward the trigonal pyramid and even toward the planar triangle.^{87,88} Deformation of coordination polyhedra is associated with the appearance of a deficiency of electron density in the $d_{x^2-y^2}$ orbital[†] due to its interaction with antibonding MOs of the multiple carbon–carbon bond. In contrast, the d_{z^2} orbital, which is directed toward the axial ligand (for example, Cl_{ax}), possesses residual electron density. Hence, the interaction of Cu(I) with the multiple carbon–carbon bond is accompanied both by shortening of the bonds between the copper atom and the ligands located in the base of the pyramid and by elongation of the $\text{Cu}-\text{L}_{\text{ax}}$ bond, *i.e.*, the Cu(I) atom moves toward the base of the polyhedron. The more efficient the dative component of the π -bond, the more substantial the deformation, the distance from the Cu atom to the midpoint of the multiple carbon–carbon bond ($\text{Cu}-\text{C}^*$) being also shorter due to the synergism of the $\text{Cu(I)} \leftarrow \text{L}$ and $\text{Cu(I)} \rightarrow \text{L}$ components. Knowing the parameters of the coordination unit, such as the $\text{Cu}-\text{C}^*$ distance, the $\text{Cu}-\text{X}_{\text{ax}}$ bond length (X_{ax} is the axial Cl or Br atom), the sum of the LCuL angles ($\sum \text{LCuL}$) in the base of the polyhedron, which characterises the deviation of the metal atom from the equatorial plane,[‡] and

[†] The $d_{x^2-y^2}$ and d_{z^2} orbitals in the initial tetrahedral ligand field after the removal of degeneracy are characterised by lower energies than the remaining three orbitals of d_e symmetry.⁸⁹

[‡] The sums of the LCuL angles equal to 329.5° and 360° correspond to two limiting cases, *viz.*, to the ideal tetrahedron and planar triangle.

Figure 8. Modes of coordination in the π -complexes of CuCl and CuBr; (a) the trigonal pyramid typical of the Cu(I) atom π -coordinated by the C=C bond; (b) the planar-trigonal environment of Cu(I) in π -complexes with disubstituted acetylene derivatives; (c) the bridging π -coordination of the C≡C bond to the Cu atoms in π -complexes of C₂H₂ and its monosubstituted derivatives.

the length of the π -coordinated multiple carbon–carbon bond, one can assess the state of the C≡C (or C=C) group π -activated on the metal centre and the efficiency of the Cu(I)–(C≡C) [Cu(I)–(C=C)] interaction. The above-mentioned parameters for a series of molecular and anionic copper(I) chloride π -complexes are given in Tables 6–8.

To reveal the differences in the behaviour of the C≡C and C=C bonds with respect to Cu(I), let us consider the data on the alkenyne π -complexes of CuCl and CuBr (Table 7). In the structures of alkenyne complexes **30–37**, the coordination environment about the Cu(I) atom, which is π -coordinated to the C=C bond, is most often a tetrahedron slightly deformed toward the trigonal pyramid (Fig. 8a). The complexes **34** and **35** contain conjugated alkenyne ligands. However, the Cu(I) coordination polyhedron in the complex **34** is more similar to the tetrahedron than that in the complex **35**. In the structure of **35**, the C=C groups interact more efficiently with Cu(I) due to the involvement of the C≡C bond in π -coordination of the metal atom. The distances from the copper atom to the midpoint of the C=C (Cu–C*) bond in the complexes **30–37** are in the range of 1.951(7)–2.00(4) Å, which indicates that the efficiency of the π -bonding is smaller than that of Cu–(C≡C). In particular, the Cu–C*(C=C) distances in the complex **35** are 1.951(7) and 1.962(7) Å, whereas the Cu–C*(C≡C) contact is substantially shorter [1.910(6) Å]. More substantial differences are observed in the structure of **36** in which the multiple bonds of the ligand are isolated [the Cu–C*(C=C) and Cu–C*(C≡C) bonds are 1.97(1) and 1.86(1) Å, respectively]. In this complex, the metal atom coordinated by the C≡C bond is in a planar-trigonal environment (Fig. 8b), whereas the Cu atoms coordinated by the C=C bond are in a trigonal-pyramidal environment. In the copper(I) bromide complexes **33** and **37a,b**, the corresponding geometric parameters of the coordination π -units differ only slightly from each other due to steric hindrances caused by the bulkier bromine atoms. In the complex **32**, the geometric characteristics of the Cu(I) polyhedra formed with the participation of the C≡C or C=C groups are also only slightly different, which suggests that the π -interactions of these bonds with the metal atom are virtually identical in efficiency. To put it differently, the efficiency of π -coordination of the C≡C bond decreases due to

the presence of the phenyl substituent giving rise to steric hindrances. On the whole, the Cu(I) atoms in alkenyne π -complexes tend to interact predominantly with the C≡C bond.

The affinity of alkyne ligands for Cu(I) is particularly pronounced both in molecular and anionic copper(I) halide π -complexes (**24–27** and **38–42**; Tables 6 and 8). If the C≡C group of the alkyne is coordinated only to one Cu atom, the environment of the latter is exclusively planar-trigonal (Fig. 8b). In this case, very short Cu–C*(C≡C) distances [1.886(4)–1.92(1) Å] are observed, which is indicative of efficient interactions (compounds **25**, **26** and **38–42**). In the compounds **24** and **27**, the Cu–C*(C≡C) distances are 1.941(4) and 1.946(6) Å, respectively. Efficient π -interactions in the complexes **24** and **27** are hindered by the phenyl group at the C≡C bond and the bridging character of the octadiyne molecule, respectively.

The propargyl alcohol molecules in the molecular (**28**) and anionic (**29**) π -complexes and the vinylacetylene molecule in the compound **30** whose terminal C≡C group acts as a bridging π -ligand simultaneously coordinated to two metal atoms (Fig. 8c), exhibit peculiar behaviour with respect to Cu(I). One of two copper atoms of the Cu(I)–(C≡C)–Cu(I) unit is always located somewhat closer to the midpoint of the triple bond. If the coordination polyhedra of Cu(I) in the complexes **28–30** are arranged in order of increasing Cu–L_{ax} distances, it can be readily seen that the deformation of the Cu coordination polyhedra from the virtually regular tetrahedron [Cu–L_{ax}, 2.416(2) Å] to the trigonal pyramid [Cu–L_{ax}, 2.605(5)–3.058(7) Å] and then to planar-trigonal coordination [Cu–L_{ax}, 3.738(6) Å] is accompanied by a corresponding shortening of the Cu–C*(C≡C) distance, which indicates an increase in the efficiency of π -bonding in the series under consideration.

The triple bond in the π -complexes of acetylene (**17–23**; Table 6), as in the above-considered complexes **28–30**, is coordinated simultaneously to two metal atoms (Fig. 8c). This coordination is retained both in molecular and anionic compounds. In the structures of the compounds **17–23**, the Cu–C* distances are noticeably longer than those in alkyne and alkenyne π -complexes and are similar to the Cu(I)–(C=C) distances. The average Cu–C* distance in the molecular π -complexes of acetylene **17** (see Fig. 6) and **18** [1.97(2)–2.29(9) Å] is noticeably larger than those in the anionic compounds **20–23** [1.89(2)–1.957(5) Å]. The latter compounds are characterised by virtually planar-trigonal environments about the metal atom.

Therefore, the C≡C group is more prone to interaction with Cu(I) than the C=C group even if the former occupies a position inside the ligand, which is less favourable for coordination to the metal atom. To account for this fact, let us use the data on the electron-donating and electron-withdrawing properties of the ethylene and acetylene molecules and the C₂H₂ molecule π -coordinated to Cu(I).

It is known that acetylene in the ground state exhibits the weaker electron-donating properties (two HOMOs have lower energies) and the weaker electron-withdrawing properties (two LUMOs have higher energies) compared to ethylene.^{13,90} However, in the case of *cis*-distortion of the alkyne molecule in the coordination sphere about the metal atom, the degeneracy of the MOs is removed. As a result, the energies and geometric parameters of the frontier MOs of the alkyne change and it becomes both a better electron-acceptor and electron-donor than alkene. Therefore, the more efficient Cu(I)–(C≡C) π -interaction results from the presence of two π -MOs in the alkyne molecule, which are split into MOs with different energies ($\pi_{||}$ and $\pi_{\perp}$), as well as from the stronger *cis*-distortion of the molecule compared to that of alkenes.

Due to the presence of two MOs in the alkyne, it can interact with Cu(I) and other metals as a bridging ligand and can coordinate two Cu(I) atoms. In this case, as mentioned above, the Cu–C* distances in the Cu(I)–(C≡C) π -units are noticeably shorter than those in the Cu(I)–(C≡C)–Cu(I) π -units, which indicates that the efficiency of the π -interaction in the first case is

higher. This fact is in agreement with the general regularities of coordination chemistry according to which the bond between a bridging μ -L ligand and the metal atom is always weaker than that with the participation of the terminal ligand. This also takes place in the cases of μ -Cl, μ -Me, μ -CO and μ -C₂H₂. In particular, this fact can be explained as follows: if each π -MO of alkyne acts independently (as alkene), two π -MOs, which are weaker π -donors than the highest $\pi_{||}$ -MO of acetylene in the nonbridging π -complex, are involved in bonding. It is also possible that $\pi_{||}$ -MO as well as $\pi_{\perp}^+$ -MO and $\pi_{\perp}^*$ -MO are involved in the formation of the coordination bond in the Cu(I)–(C $\equiv$ C) units.⁹¹ However, this question calls for special investigation.

The efficiency of the interaction between Cu(I) and the multiple carbon–carbon bond affects not only the distance from Cu(I) to the midpoint of the Cu–C* bond, which is determined by the contribution of the donor-acceptor component, but also the length of the coordinated bond determined predominantly by the dative component. The data in Tables 6–8 demonstrate that the smaller the difference in the Cu–C distances (δ), the longer the C $\equiv$ C or C=C bond. Thus, two crystallographically independent C₂H₂ ligands in the crystal of the compound **21a** (Fig. 9) differ in the C $\equiv$ C bond length [1.25(1) and 1.32(2) Å]. This is indicative of the higher and lower efficiency of the corresponding dative components of the Cu(I)–(C $\equiv$ C) π -interactions. In the second case [the coordination unit with the participation of the C(1) $\equiv$ C(1') bond], the asymmetry of the Cu–C bonds is absent, whereas the less elongated C(2) $\equiv$ C(2') bond is located somewhat asymmetrically with respect to the Cu atom [$\delta = 0.03(1)$ Å], which decreases the efficiency of the dative Cu(I)–C(2) $\equiv$ C(2') interaction. This tendency was revealed for a rather large number of examples. However, the C $\equiv$ C bond in the Cu(I)–(C $\equiv$ C) π -unit of the compound **36** is not elongated [1.18(2) Å] in spite of the total symmetry of the Cu–C distances ($\delta = 0$ Å), although the

Figure 9. Projection of the structure of NH₄Cu₃Cl₄(HC $\equiv$ CH) (**21a**) onto the *xy* plane.

Cu–C* distance [1.86(1) Å] is indicative of a substantial charge transfer $M \leftarrow L$ increasing the degree of ionicity of the bond.

In most of the structurally studied Cu(I) π -complexes, the terminal carbon atom of the terminal C=C bond is generally located somewhat closer to the Cu atom, whereas the coordinated inner C $\equiv$ C bond in alkyne and alkenyne ligands is most often symmetrical with respect to the Cu atom. Apparently, the inner C $\equiv$ C bond is more stable to the shift with respect to the Cu–C* axis than the C=C bond due to the presence of two π -MOs in the former case. However, the C $\equiv$ C group in CuCl π -complexes with terminal alkynes is characterised by a high tendency to form the asymmetrical Cu(I)–(C $\equiv$ C) π -unit primarily due to the formation of $\equiv$ C–H $\cdots$ Cl hydrogen bonds with the participation of the terminal H atom.

Acetylene and its monosubstituted derivatives are characterised by high CH-acidity.⁹⁰ The dipole moment (μ) of the C–H bond in acetylene is 1.0 D. The positive charge of the dipole is localised on the H atom (the same direction of the dipole of the =C–H bond is observed in alkenes; however, μ for alkenes is approximately 0.6 D). The acidity of the C–H bond in alkynes increases upon the formation of π -complexes with Cu(I) and some other metals. Due to polarisation of the C δ^- –H δ^+ bond, π -complexes become strong acids, which can dissociate to form acetylide compounds depending on pH of the solution. The tendency for dissociation is associated not only with polarisation of the C–H bond, but also with the high stability of coordination products of the resulting RC $\equiv$ C $^-$ anions with Cu(I).^{4,13} At the same time, polarisation of the C–H bond in π -complexes is favourable for hydrogen bonding with the chloride ion or the coordinated chloride ligand. Thus, acetylene or its monosubstituted derivatives in strongly acidic media form π -complexes with CuCl. In these complexes, $\equiv$ C–H $\cdots$ Cl hydrogen bonds exert a stabilising effect on the structures of the compounds.^{92,93} The energies of the hydrogen bonds of this type are comparable with that of the π -interaction [$E_{C-H\cdots Cl} \sim 20$ kJ mol $^{-1}$; $E_{Cu(I)-(C\equiv C)} \sim 50$ kJ mol $^{-1}$]. In structures of π -complexes with acetylene, the $\equiv$ C–H $\cdots$ Cl contacts cause additional polarisation of the Cu–Cl bonds, thus being favourable for strengthening of the π -bonding in the Cu(I)–(C $\equiv$ C)–Cu(I) unit,¹⁷ which is, in turn, reflected in the geometry of the π -coordinated C $\equiv$ C bond. Moreover, there is a particular relationship between elongation of the coordinated C $\equiv$ C bond and the length of the $\equiv$ C–H $\cdots$ Cl hydrogen bond. Thus elongation of the triple bond is accompanied by weakening of the corresponding C(H) $\cdots$ Cl contact. An increase in the C $\equiv$ C bond length due to weakening of the donor-acceptor interaction and strengthening of the dative interaction leads to a decrease in polarisation of the C–H bond and weakening of the hydrogen bond. On the contrary, a smaller elongation of the triple bond due to the stronger donor-acceptor interaction and an increase in polarisation of the C–H bond results in a stronger hydrogen bond and shortening of the H $\cdots$ Cl distance. The electron-withdrawing chlorine atoms, in turn, can substantially affect polarisation of the C–H bonds of the π -coordinated acetylene molecule due to the C(H) $\cdots$ Cl interaction. Thus the stronger the C(H) $\cdots$ Cl hydrogen bond, the higher the degree of polarisation of the $\equiv$ C δ^- –H δ^+ bond. In other words, the formation of the C–H $\cdots$ Cl hydrogen bond enhances the donor-acceptor interaction, which, in turn, strengthens the hydrogen bond. The scheme of action of the $\equiv$ C–H $\cdots$ Cl hydrogen bonds in the structures of copper(I) chloride π -complexes of C₂H₂ is shown in Fig. 10.

The characteristics of the $\equiv$ C–H $\cdots$ Cl hydrogen bonds in the structures of CuCl π -complexes with acetylene and its monosubstituted derivatives are graphically represented in Fig. 11. According to the criteria reported in a study,⁹⁴ the C–Cl distances indicate the existence of a hydrogen bond. It can be seen from the plot that there is a linear correlation between the elongation of the π -coordinated C $\equiv$ C bond and the H $\cdots$ Cl distance. However, this is true only for π -complexes (anionic and molecular) in the structures of which the C $\equiv$ C bond of the ligand molecule acts a

Figure 10. Scheme of $\equiv\text{C}-\text{H}\cdots\text{Cl}$ hydrogen bonds in the structures of copper(I) chloride π -complexes of acetylene.

Figure 11. Correlation between the $(\text{C})\text{H}\cdots\text{Cl}$ distance and the $\text{C}\equiv\text{C}$ bond lengths in CuCl π -complexes with acetylene and its monosubstituted derivatives (the linear correlation coefficient $r = 0.85$).

bridge to form the $\text{Cu(I)}-(\text{C}\equiv\text{C})-\text{Cu(I)}$ π -unit. The complexes **24–26** are exceptional (see Fig. 11) due to the formation of the $\text{Cu(I)}-(\text{C}\equiv\text{C})$ π -unit in which the π -interaction characteristic of nonbridging π -complexes prevails. Against its background, the polarising effect of the $\equiv\text{C}-\text{H}\cdots\text{Cl}$ contact is less significant.

Hydrogen bonds play an important role in the structures of the anionic π -complexes **20** and **21a**. In the complex **20**, the lengths of the hydrogen bonds between the hydrogen atoms of two crystallographically independent C_2H_2 molecules and the chlorine atoms are virtually equal [2.85(8) and 2.80(9) Å]. In the structure of **21a**, these bonds are substantially different [2.98(12) and 2.55(12) Å] due to which the π -coordinated triple bond of one C_2H_2 molecule is substantially elongated [1.32(2) Å] compared to the second bond [1.25(1) Å]. In the structure of **20**, the parameters of the π -coordinated triple bond are virtually identical [1.28(1) Å] and correspond to the average value for the two limiting $\text{C}\equiv\text{C}$ bond lengths in the structure of **21a**. In these isostoichiometric complexes, the differences are observed not only in the geometric parameters of the crystallographically independent π -coordinated units, but also in the symmetry of their unit cells due to the different effect of the $\equiv\text{C}-\text{H}\cdots\text{Cl}$ hydrogen bonds. The structures of the complexes **20** and **21a** contain structurally similar (but not identical) $(\text{Cu}_4\text{Cl}_4)_n$ chain fragments (Fig. 12). Thus, all units of the chain in the structure of **20** have the symmetry 2 (Fig. 12b), whereas the Cu_4Cl_4 units in the chains of the structure of **21a** are characterised by the symmetry 2 and m (Fig. 12a). Apparently, this effect caused by the replacement of the K^+ ions by the NH_4^+ ions results from the $\text{NH}_4^+\cdots\text{Cl}^-$ interaction. Thus the ammonium cation's adopting the tetrahedral configuration forms $(\text{N})\text{H}\cdots\text{Cl}$ hydrogen bonds [2.20–2.87(9) Å], which is favourable for the formation of the crystal structure of the complex **21a**, which differs from the crystal structure of the complex **20**. Therefore, the competition of two interactions, viz., $\text{M}^+\cdots\text{Cl}^-$ and $\equiv\text{C}-\text{H}\cdots\text{Cl}$, rather than the $\equiv\text{C}-\text{H}\cdots\text{Cl}$ hydrogen bond affects the geometry of the π -coordinated $\text{C}\equiv\text{C}$ bond in the C_2H_2 molecule in the anionic complexes. In the anionic CuCl π -complexes with acetylene and its monosubstituted derivatives, the efficiency of the $\text{Cu(I)}-(\text{C}\equiv\text{C})$ π -interaction depends on the

Figure 12. Chain fragments $(\text{Cu}_4\text{Cl}_4)_n$ in the structures of the complexes $\text{NH}_4\text{Cu}_3\text{Cl}_4(\text{HC}\equiv\text{CH})$ **21a** (a) and $\text{KCu}_3\text{Cl}_4(\text{HC}\equiv\text{CH})$ **20** (b).

efficiency of $\equiv\text{C}-\text{H}\cdots\text{Cl}$ hydrogen bonding whose strength is determined by the type of the outer-sphere M^+ cation (cations of alkali metals, ammonium or protonated amines). In the case of soluble anionic π -complexes, hydrogen bonding can also occur if the bridging or terminal chlorine atoms forming the coordination polyhedra occupy convenient positions. Weak hydrogen bonds between the NH_4^+ ion and the terminal Cl atoms can also exist. The possibility of hydrogen bonding with the participation of water molecules is also beyond question

In this connection, the role of the M^+ cations as a component of the Nieuwland catalyst ($\text{MCl}-\text{CuCl}-\text{H}_2\text{O}$) becomes apparent.

2. Acetylenide (ethynyl) complexes of copper(I)

As mentioned above, the formation of ethynyl compounds (compounds possessing at least one $\text{M}-\text{C}\equiv$ bond) in protophilic media (or in the presence of bases) is a characteristic feature of the reactions of acetylene and monosubstituted alkynes with Cu(I) complexes. The polarisation of the $\equiv\text{C}-\text{H}$ bond in Cu(I) π -complexes is substantial and the strength of the resulting $\text{Cu}-\text{C}\equiv$ bond is so high that the Cu^+ ion reacts with C_2H_2 to form $\text{CuC}\equiv\text{CH}$ even in strongly acidic media in the $\text{Cu}_2\text{SO}_4-\text{H}_2\text{SO}_4$ system (up to $[\text{H}_2\text{SO}_4] = 20\% - 25\%$). This reaction is accompanied by the formation of vinylacetylene in small amounts.⁹⁵

Studies of the formation of the so-called 'yellow' complexes in the reactions of C_2H_2 with solutions of $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ polynuclear anions by spectrophotometric and potentiometric methods demonstrated that the following equilibria occur in solutions at 25–80 °C depending on the acidity of the medium⁵⁸

By increasing the acidity of the medium, one can go from symmetrical acetylenide $(\text{Cu}_m)_p(\text{C}_2^{2-})$ to unsymmetrical $(\text{Cu}_m)(\text{C}_2\text{H}^-)$ and again to the $(\text{Cu}_m)(\text{C}_2\text{H}_2)$ π -complex.

The formation of solid acetylenide complexes containing Cu_2C_2 has been thoroughly studied by Vestin.⁹⁶ In particular, the equilibrium constant of the formation of the 'violet' complex **56** ($K = a_{\text{HCl}}^2/p_{\text{C}_2\text{H}_2} = 4$ at 25 °C) was measured

and the composition of the 'yellow' solid complex **57** was established

It was concluded⁹⁶ that the solution of the $\text{CuCl}-\text{KCl}-\text{H}_2\text{O}$ system contains the $[\text{C}_2(\text{CuCl})_m]^{2-}$ anion. Unsymmetrical ethynyl complexes in solutions⁵⁸ $\{[\text{HCl}] = 0.05-0.6 \text{ } \tilde{m}, \text{ the acidity of the medium } (h_0) \text{ is } 0.2-5, \text{ pH} = 1.1-0.0\}$ have predominantly the compositions $[\text{Cu}_4\text{Cl}_4(\text{C}\equiv\text{CH})]^-$ and $[\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CH})]^{2-}$.

Recently, ethynyl complexes and acetylenide complexes of copper(I) chloride have been synthesised and their structures have been studied (see Table 9 and references therein). These studies provided convincing evidence that unsymmetrical polynuclear ethynyl complexes $[\text{Cu}_m\text{Cl}_n(\text{C}\equiv\text{CR})]^{(n-m+1)-}$ do exist. New structures, which have not been described previously for non-halide complexes, were revealed.⁹⁷⁻¹¹⁶

In the case of acetylene, the $(\text{ImH})_4\text{Cu}_9\text{Cl}_{11}(\text{C}\equiv\text{CH})_2$ (**43**)⁴⁵ and $(\text{PyH})_4\text{Cu}_9\text{Cl}_{12}(\text{C}\equiv\text{CH})$ (**44**)³⁹ compounds were obtained as insoluble (crystalline) acetylenide complexes. In these complexes, the $\text{C}\equiv\text{CH}$ group is bridging and is coordinated to the copper atoms only through one α -carbon atom (the μ - η^1 -, η^1 - $\text{C}\equiv\text{CH}$ - or σ , σ -modes of coordination) (Fig. 13). The $\text{C}\equiv\text{C}$ bond lengths in these complexes are 1.21(2) and 1.19(7) Å, respectively, and the $\text{Cu}-\text{C}$ bond lengths are 1.97(1) and 1.92(3) Å, respectively. This type of the ligand is rather often observed in ethynyl complexes of the $\text{Cu}_2(\text{C}\equiv\text{CR})_2\text{L}_4$ ($\text{L} = \text{PR}_3$) type.⁹⁷ For simplicity, these

ethynyl compounds will be called σ -complexes. The complex **43** contains the $\text{Cu}_4\text{Cl}_5(\text{C}_2\text{H})^{2-}$ anion. In the acetylenide complex $(\text{NH}_4)_8\text{Cu}_{29}\text{Cl}_{29}(\text{C}\equiv\text{C})_4 \cdot 7\text{H}_2\text{O}$ (**45**), the C_2^{2-} anion, unlike the C_2H^- anion, is coordinated both in the η^1 - and η^2 -modes (σ , π -mode) and serves as a bridge between eight copper atoms (Fig. 14). In the structure of **45**, two crystallographically independent C_2^{2-} species are present. Each of these species acts as a

Figure 14. Fragment of the structure of the $(\text{NH}_4)_8\text{Cu}_{29}\text{Cl}_{29}(\text{C}\equiv\text{C})_4 \cdot 7\text{H}_2\text{O}$ complex (**45**). The distances from the $\text{Cu}(3)$ and $\text{Cu}(5)$ atoms to the midpoint of the $\text{C}(1)-\text{C}(2)$ bond are 2.18(3) and 2.01(2) Å, respectively.

Figure 15. π,σ -Coordination units in the structure of the $(\text{NH}_4)_8\text{Cu}_{29}\text{Cl}_{29}(\text{C}\equiv\text{C})_4\cdot 7\text{H}_2\text{O}$ complex (**45**).

bridging σ,π,σ -ligand, which coordinates simultaneously eight metal atoms. Noteworthy are the modes of coordination of the Cu(I) atoms by two independent C_2^{2-} species. Each of two carbon atoms of the $\text{C}(3)\equiv\text{C}(4)$ group forms σ -bonds with three copper atoms (Fig. 15 *a*). Therefore, the $\text{C}(3)\equiv\text{C}(4)$ group is coordinated in the $\mu_3\text{-}\eta^1,\eta^1,\eta^1,\mu_2\text{-}\eta^2,\eta^2,\mu_3\text{-}\eta^1,\eta^1$ -mode, *i.e.*, this group acts as the σ,π,σ -ligand. The effect of six copper(I) atoms η^1 -coordinated to the C_2^{2-} ion and two copper atoms η^2 -coordinated to the same ion on the $\text{C}\equiv\text{C}$ bond is so high that the geometry of the η^2 -unit changes and the $\text{Cu}-\text{C}^*-\text{Cu}$ angle reaches 106° . In this case, the $\text{C}(1)\equiv\text{C}(2)$ bond can additionally coordinate the third copper atom (Fig. 15 *b*). Apparently, the unusual mode of coordination to the copper(I) atoms is the characteristic feature of the C_2^{2-} anion. Thus the perfectly planar coordination σ,π,π,σ -unit

was found in the structure of the complex $[\text{Cu}_4(\text{Ph}_2\text{PCH}_2\text{PPh}_2)_4(\text{C}\equiv\text{C})](\text{BF}_4)_2\cdot 4\text{Me}_2\text{CO}$.¹¹⁷ In this unit, the $\text{Cu}-\text{C}^*-\text{Cu}$ angle is 180° . Apparently, the structure of the 'yellow' complex studied by Vestin⁹⁶ also contains the fragments (*a*) and (*b*) (see Fig. 15). The σ,π -coordination of several copper atoms by the C_2^{2-} group gives rise to clusters in which the shortest $\text{Cu}\cdots\text{Cu}$ distance is $2.452(6)$ Å. Coordination of the ethynyl ligand to three copper(I) atoms ($\mu_3\text{-}\eta^1,\eta^1,\eta^1\text{-C}\equiv\text{C}$) to form the trinuclear cluster is also very typical of ethynyl complexes.⁹⁷ The question about the nature of the η^2 -bonds between the $\text{C}\equiv\text{C}$ group and three metal atoms deserves special analysis.

Structural motifs found in ethynyl complexes containing $\text{RC}\equiv\text{C}$ groups are widely diversified. The efficiency of η^2 -coordination of the Cu(I) atom by the $\text{RC}\equiv\text{C}$ group depends on the η^1 -mode of coordination. The geometric parameters of the π -coordination units in the structures of the CuCl σ,π -complexes with acetylene and its terminal derivatives [which, according to the criteria used in the previous section of this chapter, characterise the efficiency of the $\text{Cu(I)}-(\eta^2\text{-C}\equiv\text{CR})$ bonding] are given in Tables 9 and 10. It can be readily seen that two metal atoms in the coordination π -unit ($\mu\text{-}\eta^2,\eta^2\text{-C}\equiv\text{CR}$) in cluster ethynyl complexes of copper(I) are located at somewhat different distances from the midpoint of the $\text{C}\equiv\text{C}$ bond, as in the CuCl π -complexes with $\text{HC}\equiv\text{CCH}_2\text{OH}$ and $\text{HC}\equiv\text{CCH}=\text{CH}_2$ [compounds **28** and **29** (see Table 6) and **30** (see Table 7)]. However, shortening of the $\text{Cu}-\text{C}^*$ distance in σ,π -complexes, which is determined primarily by the donor-acceptor component of the π -interaction, unlike that in CuCl π -complexes with $\text{HC}\equiv\text{CCH}_2\text{OH}$ and $\text{HC}\equiv\text{CCH}=\text{CH}_2$, is not accompanied by an increase in the dative transfer, *i.e.*, it does not cause additional deformation of the trigonal-pyramidal environment about the Cu(I) atom. Moreover, the σ,π -complexes are characterised by the following effect: the smaller elongation of the $\text{Cu}-\text{X}_{\text{ax}}$ distance in the coordination π -unit ($\mu\text{-}\eta^2,\eta^2\text{-C}\equiv\text{CR}$) corresponds to the shorter $\text{Cu}-\text{C}^*$ distance due, apparently, to the synergism of the $\text{Cu(I)}-(\eta^1\text{-C}\equiv\text{CR})$ and $\text{Cu(I)}-(\eta^2\text{-C}\equiv\text{CR})$ interactions. Such mutual

Table 10. The CuC^*Cu angles in the π -coordinated Cu(I) units in the structures of π,σ -complexes of CuCl with acetylene and its terminal derivatives.

strengthening of the η^1 - and η^2 -bonds is manifested to a greater or lesser extent depending on the number of the σ -coordinated Cu atoms and their arrangement with respect to the $\text{C}\equiv\text{C}$ group.

In this connection, it is worthwhile to consider the stereochemistry of the $[\text{Cu}_4(\text{C}\equiv\text{CR})]$ and $[\text{Cu}_5(\text{C}\equiv\text{CR})]$ clusters found in the structures of copper(I) chloride σ,π -complexes with terminal derivatives of acetylene. Four major types of cluster were distinguished (see Table 10). The differences in their structures are determined by the difference in the orientation of two mutually perpendicular π -MOs of the ethynyl group of the σ,π -coordinated $\text{C}\equiv\text{CR}$ ligand with respect to the plane *P* passing through the $\text{C}\equiv\text{C}$ bond (Fig. 16). In the structures of the complexes containing clusters of type I, the plane of one of the π -MOs of the $\text{C}\equiv\text{C}$ group (for example, $\pi_{||}$) coincides with the plane *P*, *i.e.*, the π -coordinated C(2) atom and the $\text{C}\equiv\text{C}$ bond together with two σ -bonded Cu(3) and Cu(4) atoms are in a single plane, whereas the normal *mn* to this plane coincides with the axis of another $\pi_{\perp}$ -MO [the $\text{Cu(1)}-\text{C}^*$ axis] (Fig. 16 *a*). Both π -MOs of the $\text{C}\equiv\text{C}$ group ($\pi_{||}$ and $\pi_{\perp}$) in clusters of the types II–IV, unlike those in clusters of type I, are located at an angle of 45° to the normal *mn* (as well as to the plane *P*). [In the case of clusters of the types III and IV (Fig. 16 *c,d*), the plane *P* passes perpendicularly to the normal *mn* to retain the spatial orientation of the π -coordinated copper(I) atoms analogous to that in clusters II (Fig. 16 *b*).] The clusters II, III and IV differ primarily in the orientation of the σ -coordinated Cu atoms. Thus, the σ -coordinated Cu(3) and Cu(4) atoms in clusters of the type II lie in the plane *P* (Fig. 16 *b*). The rotation of these σ -coordinated Cu(3) and Cu(4) atoms about the $\text{C}\equiv\text{C}$ axis by 90° in such a way that they form a new plane (*Q*) with the normal *mn* leads to clusters of the type III (Fig. 16 *c*). The replacement of one σ -coordinated Cu(4) atom by two atoms [Cu(4) and Cu(5)] in such a way that these atoms are no longer located in the plane *Q* [the Cu(4) and Cu(5) atoms are located behind and in front of the plane *Q*, respectively; the Cu(4)C(1)Cu(5) angle $\approx 80^\circ$] gives rise to a cluster of the type IV (Fig. 16 *d*). In addition to the above-considered four cluster types, combined types of clusters are also observed in the structures of Cu(I) σ,π -complexes. An example is the $[\text{Cu}_8]$ cluster in the structure of **52**, which consists of clusters of the types I and IV linked to one another through the bridging Cu atom (Fig. 17). The $[\text{Cu}_9]$ cluster in the structure of **54** is composed of two clusters of the type IV (Fig. 18). Clusters of the types I–IV were found for the first time in ethynyl complexes of copper(I) chloride.

In the structures of σ,π -complexes containing clusters of the type I, the coplanar arrangement of the π - and σ -coordinated metal atoms [for example, the π -coordinated Cu(3) atom and the σ -coordinated Cu(1) and Cu(2) atoms in the structure of **50** (Fig. 19)] and the $\text{C}\equiv\text{C}$ bond leads to the mutual strengthening

Figure 16. Types of clusters observed in the structures of ethynyl copper chloride complexes: (a) type I {the $[\text{Cu}_4(\text{C}\equiv\text{CCH}_2\text{OH})]$ cluster}; (b) type II {the $[\text{Cu}_4(\text{C}\equiv\text{CCH}_2\text{OH})]$ cluster}; (c) type III {the $[\text{Cu}_4(\text{C}\equiv\text{CR})]$ cluster, where $\text{R} = \text{CH}=\text{CH}_2$ or CH_2OH }; (d) type IV {the $[\text{Cu}_5(\text{C}\equiv\text{CCH}_2\text{OH})]$ cluster}; mn is the normal to the plane P .

of two individual types of interactions, *viz.*, the acetylenide and π -interactions. This process becomes so efficient that the coordination polyhedra about the σ - and π -coordinated copper(I) atoms become planar-trigonal (see Tables 9 and 10). Apparently, this synergism occurs due to the angular overlapping simultaneously of three orbitals, *viz.*, the occupied $d_{x^2-y^2}$ orbitals of the σ -[Cu(1)] and π -coordinated [Cu(3)] metal atoms, and the antibonding unoccupied MO (for example, $\pi_{\parallel}^*$) of the acetylene bond. It should be noted that there are spatial prerequisites for this 'three-centre' overlapping in the structure of **50** [the $\text{Cu}(2)\text{C}(1)\text{Cu}(1)$, $\text{Cu}(1)\text{C}(1)\text{Cu}(3)$ and $\text{Cu}(2)\text{C}(1)\text{Cu}(4)$ angles are $81.3(9)^\circ$, $84.2(9)^\circ$ and $89.9(9)^\circ$, respectively]. However, mutual strengthening of the $\text{Cu(I)}-(\eta^1\text{-C}\equiv\text{CR})$ and $\text{Cu(I)}-(\eta^2\text{-C}\equiv\text{CR})$ interac-

Figure 20. Anion $[\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CCH}_2\text{OH})_2]^{2-}$ in the structure of the $(\text{NH}_4)_2\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CCH}_2\text{OH})\cdot\text{H}_2\text{O}$ complex (**48**).

tions does not cause the expected substantial elongation of the $\text{C}\equiv\text{C}$ bond in the complex **50** [1.22(3) Å] because the above-described angular dative process causes polarisation of the $\text{C}(1)^{\delta-}\equiv\text{C}(2)^{\delta+}$ bond. Quite a different situation is observed in the case of formation of the cluster of the type II (see Fig. 16*b*). In this cluster, strengthening of two types of interactions (σ and π) is less efficient for geometric reasons because two π -MOs of the alkyne are located at an angle of 45° to the normal mn . As a result, the coordination polyhedra about the σ -coordinated Cu(I) atoms in the structures of **46**, **48** (Fig. 20) and **49** remain tetrahedral, whereas the π -coordinated Cu(I) atoms are characterised by the trigonal-pyramidal environment. In this case, the $\text{C}\equiv\text{C}$ bond is substantially elongated [1.29(1) Å] due to lower polarisation. The considerable synergism of the σ and π interactions is also observed in the complexes **54** (Fig. 21), **53** and **55** (Fig. 22), which contain clusters of the types III and IV (see Figs 16*c,d*). Their π - and σ -coordinated Cu(I) atoms are characterised predominantly by the planar-trigonal environment and the $\text{C}\equiv\text{C}$ bond is virtually not elongated (see Tables 9 and 10).

Figure 21. Cluster fragment $[\text{Cu}_5(\text{C}\equiv\text{CCH}_2\text{OH})]$ in the structure of $\text{Rb}_3\text{Cu}_7\text{Cl}_9(\text{C}\equiv\text{CCH}_2\text{OH})\cdot\text{H}_2\text{O}$ (**51**).

Figure 22. Cluster fragment $[\text{Cu}_4(\text{C}\equiv\text{CCH}=\text{CH}_2)]$ in the structure of $\text{Cu}_{25}\text{Cl}_{17}(\text{C}\equiv\text{CCH}=\text{CH}_2)_8\cdot 14\text{H}_2\text{O}$ (**55**).

3. Structural aspects of formation of some π -complexes and σ -ethynyl derivatives

Structures of π -complexes and products of their reversible conversions (σ -complexes) are determined both by the structures of the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ anions in solution and the stability of the products, *i.e.*, by the favourable formation of a particular struc-

ture. However, the structures of compounds isolated from solution may not be directly associated with the mechanism of their formation because conversions of the initial intermediates of any type lead to the formation of more stable structures, but the least soluble compounds are isolated from solution. Thus, the ethynyl compound with composition $\text{Cu}_m(\text{C}_2\text{H})$ can be formed by the reaction of $\text{Cu}_p(\text{C}_2\text{H})$ with Cu_q ($p+q=m$) in solution. At the same time, it is of interest to analyse possible 'genetic' relations between the structures of the initial copper chloride anions and the products formed in the reactions of the latter with $\text{RC}\equiv\text{CH}$.

Let us consider the group of crystalline compounds formed in the $(\text{C}_6\text{H}_5\text{NH}_3)\text{Cl}-\text{CuCl}-\text{H}_2\text{O}-\text{HC}\equiv\text{CCH}_2\text{OH}$ system. Colourless crystals of $(\text{C}_6\text{H}_5\text{NH}_3)_3\text{Cu}_4\text{Cl}_7$ (**11**), which precipitated from a concentrated almost neutral solution of CuCl (4 mol) and $(\text{C}_6\text{H}_5\text{NH}_3)\text{Cl}$ (3 mol) in H_2O (20 mol), rapidly dissolved after addition of propargyl alcohol to give yellow crystals of the ethynyl complex **53**.

The reaction was accompanied by a decrease in pH to ~ 1.5 . Under analogous conditions [but when CuCl and $(\text{C}_6\text{H}_5\text{NH}_3)\text{Cl}$ were taken in the molar ratio of 2:1], the complex **49** was obtained.

Unlike the complex **53**, the ethynyl complex **49** was converted into the π -complex **29** upon storage in the mother liquor ($\text{pH} \leq 1$). This fact indicates that the process is non-equilibrium in character.

Let us consider the relationship between the stereochemistry of compounds **11** and **53** and the possible mechanism of formation of the latter in the solid-phase process (Fig. 23). The subunit of the $(\text{Cu}_4\text{Cl}_7^{3-})_n$ anion in the structure of **11**, which consists of the Cu coordination polyhedra linked to each other, is shown in Fig. 23*a*. The molecule of propargyl alcohol can replace the $\mu\text{-Cl}$ atom (which is hatched in Fig. 23*a*) in **11** and can be incorporated into the initial macropolyhedron to form the π -complex ($\eta^2\text{-RC}\equiv\text{CH}$). In this case, the octahedral cavity in the macropolyhedron is transformed into a square-pyramidal cavity. Subsequent deprotonation of the π -ligand with the H_2O molecule affords the expected π -complex with the $\text{C}\equiv\text{CR}$ ligand giving rise to the bridging $\mu\text{-}\eta^2, \mu\text{-}\eta^2\text{-C}\equiv\text{CCH}_2\text{OH}$ ligand (Fig. 23*b*). The formation of the π -complex leads to weakening of some Cu–Cl bonds (indicated by dashed lines in Fig. 23*b*) and to their cleavage accompanied by the formation of two new Cu–C η^1 -bonds (Fig. 23*c*) in the $[\text{Cu}_4(\text{C}\equiv\text{CCH}_2\text{OH})]$ cluster, which is a component of the complex **53**. In the structure of the latter, the $[\text{Cu}_8\text{Cl}_{10}(\text{C}\equiv\text{CCH}_2\text{OH})^{3-}]_n$ anions form layers in which the σ, π -coordinated $\text{C}\equiv\text{CR}$ group of each propargylium anion is clamped between four Cu atoms inside the square-pyramidal cavity. Due to steric hindrance to the penetration of the H_3O^+ ion into the cavity toward the α -carbon atom of the $\text{C}\equiv\text{CCH}_2\text{OH}$ ligand and the high strength of bonding of the σ - and π -coordinated anion [in the structure of **53**, the length of one of the Cu–C bonds of the acetylenide type is 1.89(2) Å and the Cu–C*

Figure 23. Conversion of the $(\text{C}_6\text{H}_5\text{NH}_3)_3\text{Cu}_4\text{Cl}_7$ complex (**11**) into the $(\text{C}_6\text{H}_5\text{NH}_3)_3\text{Cu}_8\text{Cl}_{10}(\text{C}\equiv\text{CCH}_2\text{OH})\cdot 2\text{H}_2\text{O}$ complex (**53**) in the presence of $\text{HC}\equiv\text{CCH}_2\text{OH}$ (the stereochemical aspect).

distance is 1.97(1) Å], the complex **53** is very resistant to decomposition or conversion into the π -complex under the action of HCl .

The formation of the complex **49** differs from the above-considered complex in the structural features. Judging from the stoichiometry of the formation of the complex **29**, the Cu_2Cl_3^- anion is involved in the formation of the complex **49**. This anion was revealed for the first time in the CsCu_2Cl_3 complex (**5**) (Fig. 24) and its structure differs fundamentally from that of the $(\text{Cu}_4\text{Cl}_7^{3-})_n$ anion. The Cu_2Cl_3^- anion is characterised by the fact that the coordination polyhedra about the Cu atoms are linked to each other exclusively through edges to form infinite $(\text{Cu}_2\text{Cl}_3^-)_n$ chain fragments within which all metal atoms are virtually in a single plane. In this case, a peculiar sequence of planar (approximately square) $n[\text{Cu}_4]$ matrices with $\text{Cu}\cdots\text{Cu}$ contacts [2.81(1) Å]

Figure 24. Anion in the structure of the CsCu_2Cl_3 complex (**5**).

appears. In solution, the complex **5** (Fig. 24) produces the Cu_2Cl_3^- anions (**A**), which interact with alkyne to form the π -complex $[\text{Cu}_2\text{Cl}_3(\text{RC}_2\text{H})]^-$ (**B**).

Figure 25. Scheme of formation and conversions of the crystals of the $(\text{C}_6\text{H}_5\text{NH}_3)_2\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CCH}_2\text{OH})$ complex (**49**) into $(\text{C}_6\text{H}_5\text{NH}_3)_2\text{Cu}_2\text{Cl}_3(\text{HC}\equiv\text{CCH}_2\text{OH})$ (**29**): (a) the $[\text{Cu}_4\text{Cl}_5(\text{C}_2\text{R})_2]^{2-}_n$ anion; (b) the $[\text{Cu}_2\text{Cl}_3(\text{RC}_2\text{H})]^-_n$ anion.

R = CH₂OH.

The formation of the complex **49** is a non-equilibrium process and is, most likely, determined by the kinetics of its crystallisation. As a consequence, the π -complex **B** rapidly reacts with the Cu_2Cl_3^- ion in solution to yield the ethynyl complex **C**, which precipitates as the compound **49**. The slow reaction of the complex **49** (through the soluble form **C**) with HCl followed by elimination of Cu_2Cl_3^- to form (through the complex **B**) gives rise to the complex **29**, which is thermodynamically more stable under these conditions.

In the $[\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CCH}_2\text{OH})]^{2-}$ anion of the compound **49** (Fig. 25a), the α -carbon atom of the $-\text{C}\equiv\text{CCH}_2\text{OH}$ fragment is accessible to attack by the proton. In addition, the bonds between the σ -coordinated Cu atoms and the α -carbon atom in the structure **49** are weaker [the Cu–C $\equiv$ bonds are in the range of 1.95(2)–2.00(2) Å] than those in the complex **53**. Hence, the possibility of the conversion of the $[\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CCH}_2\text{OH})]^{2-}$ anion in crystals of the complex **49** accompanied by elimination of the Cu_2Cl_3^- fragments to form the $[\text{Cu}_2\text{Cl}_3(\text{HC}\equiv\text{CCH}_2\text{OH})]^-$ anion of the complex **29** must not be ruled out (Fig. 25b). Crystals of the complex **29** appear in the mother liquor (pH $\leq$ 1) immediately after the disappearance of crystals of the complex **49**.

IV. Catalytic conversions of acetylenic compounds in solutions of copper(I) chloride complexes

Studies of the physicochemical properties of the NH_4Cl – CuCl – H_2O system provided the basis for the development of the procedure for investigation of the kinetics of reactions in concentrated aqueous solutions.^{13,118} The principal results of these investigations are considered below.

1. Kinetics of catalytic reactions of acetylene and its derivatives in concentrated aqueous solutions of MCl–CuCl

In studies of the kinetics of various reactions of acetylene (and its derivatives) in concentrated aqueous solutions of MCl and CuCl, kinetic models are generally constructed¹³ with the use of an empirical dependence of the following type:

$$r = \varphi(p_{\text{C}_2\text{H}_2}, [\text{HCl}]_{\Sigma}, [\text{CuCl}]_{\Sigma}, [\text{NH}_4\text{Cl}]_{\Sigma}),$$

where r is the reaction rate and p is the partial pressure.

If the solution contains polynuclear complexes and does not contain an excess of chloride anions with respect to metal, there is no way to express the concentration of free catalytically active complexes (one or several) in terms of $[\text{CuCl}]_{\Sigma}$ (i.e., to account for the material balance with respect to the catalyst in the kinetic equation). Hence, the only approach to a theoretically justified adequate kinetic model and to the elucidation of the reaction mechanism in these systems consists in measuring the concentrations (or activities) of the free reagents and components of the solution (Cu^+ and Cl^-) under stationary conditions of catalytic reactions and in maintaining constant conditions, the partial pressures and concentrations of the reagents being varied, i.e., in maintaining the $[\text{CuCl}]_{\Sigma}:[\text{Cu}^+]$ and $[\text{Cl}^-]_{\Sigma}:[\text{Cl}^-]$ ratios and, consequently, $[(\text{Cu}_m\text{Cl}_n)^{(n-m)-}]$. In other words, it is necessary to add the initial catalyst (CuCl and, if required, MCl) as the catalyst is trapped by the reagent. The values, which are directly proportional to the activities (and concentrations) of the Cu^+ , Cl^- and H_3O^+ ions (see Section II), can be determined by the potentiometric method (under the conditions of constant cationic content).^{22, 30, 118}

Table 11. Catalytic reactions in the CuCl – NH_4Cl – H_2O system.

	<i>o</i>	7–21	13

Note. In the reactions (1–11) $[\text{NH}_4\text{Cl}] = 12 \tilde{m}$; in the reaction (12) $[\text{NH}_4\text{Cl}] = 21 \tilde{m}$. ^a In addition to NH_4Cl , $\text{Cu}_2\text{S}_{\text{solid}}$ is present; ^b in addition to NH_4Cl , RSH is present.

This procedure was used for studying 12 reactions of acetylenic compounds in 15 catalytic systems (Table 11). The kinetic equations obtained under conditions of the constant content of NH_4^+ and at the constant a_{Cu^+} and a_{Cl^-} values are given in Table 12. It was found that the type of equation is independent of the concentration of CuCl (in the kinetic equations, only the observed k_{ij} values are a function of this concentration, where i is the number of the reaction and j is the catalytic system) (see Table 12). In essence, k_{ij} is the function of the stationary concentrations of the $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ complexes and Cl^- ions or of the stationary activities of Cu^+ and Cl^-

$$k_{ij} = f(a_{\text{Cu}^+}, a_{\text{Cl}^-}).$$

In the simplest case (the compositions of the initial copper(I) complex and the intermediate of the first irreversible stage are identical in the Cl^- component), the equation is as follows:

$$k_{ij} = \sum_m \sum_n k_{\text{eff}(m,n)} [(\text{Cu}_m\text{Cl}_n)^{(m-n)-}]. \quad (1)$$

Table 12. Kinetic equations for the reactions of acetylenic compounds in the CuCl – NH_4Cl – H_2O system.

$r_{1a} = k_{1a} p_{\text{C}_2\text{H}_2} [\text{HCl}]$	119
$r_{2b} = k_{2b} p_{\text{C}_3\text{H}_4} [\text{HCl}] + k p_{\text{C}_3\text{H}_4} a_{\text{Cl}^-}$	120
$r_{3c} = k_{3c} p_{\text{C}_3\text{H}_4} [\text{HCl}]$	120
$r_{4d} = k_{4d} p_{\text{C}_4\text{H}_4} [\text{HCl}] + k p_{\text{C}_4\text{H}_4} [\text{HCl}] (a_{\text{Cl}^-}^2 / a_{\text{H}_2\text{O}})$	121
$r_{5e} = k_{5e} p_{\text{C}_2\text{H}_2} [\text{H}_3\text{O}^+] / (1 + k [\text{H}_3\text{O}^+])$	119
$r_{5f} = k_{5f} p_{\text{C}_2\text{H}_2} [\text{H}_3\text{O}^+] + k p_{\text{C}_2\text{H}_2}$	122
$r_{6g} = k_{6g} p_{\text{C}_3\text{H}_4}$	120
$r_{6h} = k_{6h} p_{\text{C}_3\text{H}_4}$	123
$r_{7i} = k_{7i} p_{\text{C}_3\text{H}_4}$	123
$r_{8j} = k_{8j} p_{\text{C}_2\text{H}_2}^2 / (k p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+])$	95
$r_{9k} = k_{9k} p_{\text{C}_2\text{H}_2} p_{\text{C}_4\text{H}_4} / (k p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+])$	124
$r_{10l} = k_{10l} p_{\text{C}_2\text{H}_2} [\text{H}_3\text{O}^+] / (k p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+])$	125
$r_{11m} = k_{11m} p_{\text{C}_2\text{H}_2} p_{\text{HCN}} / [\text{H}_3\text{O}^+]$	126
$r_{12n(o)} = k_{12n(o)} p_{\text{C}_2\text{H}_2} p_{\text{C}_5\text{H}_6} / [\text{H}_3\text{O}^+]$	13

Note. The subscript in the kinetic equation denotes the number of the reaction and the letter denotes the catalytic system (see Table 11).

The $k_{\text{eff}(m,n)}$ values can be determined only if all complexes present in the system are taken into account, *i.e.*, by solving the system of equations of the same type (1). However, taking into account the presence of a large number of complexes in solution, the large error in the determination of k_{ij} (10%–15%) and the errors in the determination of the total set of complexes, one cannot expect that the coefficients of this system thus obtained reflect the true contributions of individual complexes to the reaction rate. In this connection, the average composition of the complexes, which make the major contribution to k_{ij} both due to the large $k_{\text{eff}(m,n)}$ values and the high concentrations of $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$, was estimated. From Eqn (1) it follows:

$$k_{ij} = \sum_m \sum_n k_{\text{eff}(m,n)} \beta_{m,n} a_{\text{Cu}^+}^m a_{\text{Cl}^-}^n = \sum_m \sum_n k_{m,n} a_{\text{Cu}^+}^m a_{\text{Cl}^-}^n. \quad (2)$$

The a_{Cl^-} value decreases as $[\text{CuCl}]_\Sigma$ increases, because a_{Cu^+} and a_{Cl^-} are interdependent:

$$[\text{CuCl}]_\Sigma = \sum_m \sum_n m \beta_{m,n} a_{\text{Cu}^+}^m a_{\text{Cl}^-}^n, \\ [\text{Cl}^-]_\Sigma = [\text{Cl}^-] + \sum_m \sum_n n \beta_{m,n} a_{\text{Cu}^+}^m a_{\text{Cl}^-}^n,$$

due to which the independent determination of m and n is impossible. It was demonstrated^{126,127} that the a_{Cu^+} and a_{Cl^-} values determined by the potentiometric method are related to each other by the empirical dependence throughout the a_{Cu^+} range met in the systems under consideration ($a_{\text{Cu}^+} = 10^{-8} - 10^{-6}$):

$$a_{\text{Cl}^-} = \frac{a_{\text{Cl}^-}^0}{b a_{\text{Cu}^+}^g}. \quad (3)$$

The b and g coefficients were determined experimentally for each case represented in Table 12. From Eqns (2) and (3) it can be shown that

$$k_{ij} = \sum_m \sum_n k_{m,n} a_{\text{Cu}^+}^m a_{\text{Cl}^-}^n = \sum_m \sum_n \frac{k_{m,n} (a_{\text{Cl}^-}^0)^n}{b^n} a_{\text{Cu}^+}^{m-ng} = \\ = \sum_k k_k a_{\text{Cu}^+}^{l_k}. \quad (4)$$

The average observed order ($\hat{l}$) with respect to a_{Cu^+} can be determined by approximating Eqn (4) by Eqn (5)

$$k_{ij} = k_{\text{eff}(i,j)} \hat{a}_{\text{Cu}^+}^{\hat{l}}, \quad (5)$$

where $\hat{l} = \hat{m} - \hat{n}g$ is the weighted-mean value, which accounts for the l_k values for each complex and the fraction of the reaction rate (θ_k) determined by the participation of the k th complex

$$\frac{d \ln k_{ij}}{d \ln a_{\text{Cu}^+}} = \hat{l} = \sum_k l_k \theta_k. \quad (6)$$

From Eqn (6) it follows that the $\hat{n}$ and $\hat{m}$ values are also weighted-mean. In the general case, the $\hat{l}$ value should be variable, because θ_k can change as the $[\text{CuCl}]_\Sigma$ changes. The fact that the $\hat{l}$ value for all processes is constant throughout the range of CuCl concentrations under study indicates that the $m(n)$ values for the complexes, which make the major contribution to k_{ij} , are similar. To estimate the m and n values and the compositions of the initial $(\text{Cu}_m\text{Cl}_y)^{(y-m)-}$ complexes ($y \neq n$ upon elimination or addition of Cl^- ions in the individual stages of the reaction), the following equation was used:

$$\hat{m} = \frac{\hat{l}}{1-g} + \frac{\hat{q}g}{1-g} = \hat{m}_{\min} + \frac{\hat{q}g}{1-g}, \quad (7)$$

where $\hat{q} = \hat{n} - \hat{m}$.

It was assumed that multiply-charged complexes, which are formed in insignificant amounts in concentrated CuCl solutions,^{22,30,31,33} are not involved in the reactions with acetylenic compounds, and hence analysis of the compositions of the $(\text{Cu}_m\text{Cl}_y)^{(y-m)-}$ complexes was restricted to $y-m = 1$ or 2. In addition, it was assumed that acetylene replaces the water molecule upon the formation of a π -complex, thus retaining the charge of the complex. Then the parameter $\hat{q}$ in Eqn (7) can take the values 0, 1, 2 and 3 depending on the presence of stages of elimination of one Cl^- ion ($y = n + 1$, $\hat{q} = 0$ or 1) and stages of conversion of intermediates with the participation of one Cl^- ion ($y = n - 1$, $\hat{q} = 2$ or 3) as well as on the presence of mechanisms in which $y = n$ ($\hat{q} = 1$ or 2). In this case, the $\hat{m}$ values change from $\hat{m}_{\min}$ ($\hat{q} = 0$) to $\hat{m}_{\min} + 3g/(1-g)$. On these assumptions, $\hat{m} \geq 1$ and $\hat{n} \geq \hat{m}$ have a physical meaning.

The dependence of k_{ij} on $[\text{CuCl}]_\Sigma$ is shown in Fig. 26. Although the k_{ij} value increases as $[\text{CuCl}]_\Sigma$ increases in all cases, the character of $k_{ij} = f([\text{CuCl}]_\Sigma)$ is substantially different for different reactions (see Table 11). For dimerisation (8) of acetylene, hydrocyanation (11) of acetylene, hydration of methylacetylene (6*h* and 7*i*) and acetylene (5*f*) and the reactions with cyclopentadiene (12), the k_{ij} value sharply increases only at $[\text{CuCl}]_\Sigma \geq 5 \hat{m}$, *i.e.*, in the concentration range in which polynuclear complexes (Cu_3Cl_4^- , $\text{Cu}_3\text{Cl}_5^{2-}$, Cu_4Cl_5^- , $\text{Cu}_4\text{Cl}_6^{2-}$, *etc.*) appear in noticeable amounts. The observed order with respect to $[\text{CuCl}]_\Sigma$ is smaller than unity only for the reaction with HCl (4*d*). The observed orders with respect to a_{Cu^+} ($\hat{l}$) are given in Table 13.

The $(\text{Cu}_m\text{Cl}_n\text{CN})^{(n-m+1)-}$ and $[\text{Cu}_m\text{Cl}_n(\text{C} \equiv \text{CH})]^{(n-m+1)-}$ complexes are involved in hydrocyanation (11) and diene condensation (12) of acetylene possessing rate-determining stages. These complexes are formed due to the replacement of the Cl^- ion.

Figure 26. Dependence of k_{ij} on the concentration of CuCl : (1) $k_{1a} \times 10^3$; (2) $k_{2b} \times 10^5$; (3) $k_{3c} \times 10^7$; (4) $k_{4d} \times 0.5 \times 10^5$; (5) $k_{5e} \times 10^3$; (6) $k_{5f} \times 10^2$; (7) k_{6g} ; (8) $k_{6h} \times 0.5 \times 10^5$; (9) $k_{7i} \times 0.5 \times 10^5$; (10) $k_{8j} \times 10^4$; (11) $k_{9k} \times 10^7$; (12) k_{11m} ; (13) $k_{12n} \times 10^6$.

Note. At $\hat{q} = 0$, the $(\text{Cu}_m\text{Cl}_y)^{-}$ complexes with $m = 3$ and 4 (catalytic systems m and n) and $m = 5$ (catalytic system o) are involved in the reactions (11) and (12), respectively.

Hence, $y = n + 1$ (at $\hat{q} = 0$ or 1) and $\hat{m}_{\min} = 3.6 - 5.0$ for the reactions (11) and (12). In the reactions (8)–(10), which proceed without rate-determining stages, $\hat{q}$ reflects the composition of the transition state ($y = n$). Polynuclear complexes with $m = 3 - 7$ are involved in the reactions (8), (9) and (12) (see Table 3).

The participation of polynuclear Cu(I) complexes in the dimerisation of acetylene (8) was confirmed by spectrophotometric studies of the dependence of the dimerisation rate on the concentration of the ‘yellow’ complexes $[\text{Cu}_4\text{Cl}_4(\text{C}\equiv\text{CH})^-]$ and $[\text{Cu}_4\text{Cl}_5(\text{C}\equiv\text{CH})^{2-}]$ and on their compositions as a function of a_{Cu^+} , a_{Cl^-} , $p_{\text{C}_2\text{H}_2}$ and $[\text{H}_3\text{O}^+]$ ⁵⁸ (see Section III) and was additionally supported by isolation of crystalline copper chloride and ethynyl complexes formed in the catalytic Nieuwland system (the structures of these complexes are considered in Sections II and III).

2. Kinetics and crystal-chemical aspects of the mechanism of Nieuwland oligomerisation of acetylene

Comprehensive investigations of the kinetics of dimerisation^{58, 95, 125, 128–131} and trimerisation^{124, 125} of acetylene made it possible to state the major features of the mechanism of these reactions. Let us consider dimerisation of acetylene (8) (see Table 11) giving rise to vinylacetylene (VA) in detail. At constant activities of Cu^+ and Cl^- , i.e., at constant concentrations of catalytically active complexes, the reaction rate r_{VA} is described by the equation

$$r_{\text{VA}} = \frac{k_{\text{H}} p_{\text{C}_2\text{H}_2}^2}{k p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+]}. \quad (8)$$

A two-stage mechanism without a rate-determining stage corresponds to this equation, where the copper chloride complex is denoted by $[\text{Cu}]$

The stages 1 and 2, which follow unambiguously from the kinetics, are supplemented by the stage 3, which is required to obtain the final stoichiometric equation for the catalytic reaction (8). It was also found that the k constant in the denominator is independent of $[\text{CuCl}]_{\Sigma}$ (and a_{Cu^+}), but depends on a_{Cl^-} ($k = k'/a_{\text{Cl}^-}$). This fact leads to the equation

$$r_{\text{VA}} = \frac{k'_{\text{H}} p_{\text{C}_2\text{H}_2}}{k' p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+][\text{Cl}^-]}, \quad (9)$$

according to which Cl^- and H_3O^+ are eliminated in the same stage (the stage 1 or the following quasi-equilibrium stage).

Data on the composition of the intermediate X_1 (and to some extent on its nature) were obtained in studies of the kinetics of the preparation of vinylacetylene and 2-chlorovinylacetylene (CVA) in systems containing additionally small concentrations ($\sim 10^{-3}$ mol litre⁻¹) of CuCl_2 .^{132, 133} In the presence of CuCl_2 , the conversion of the intermediate X_1 takes two competitive paths, viz., the stages 3 and 4

Under these conditions, the sum of the rates r_{VA}^* and r_{CVA} is equal to the rate of formation of X_1 (i.e., r_{VA}). The rate ratio is described by the equation

$$\frac{r_{\text{VA}}^*}{r_{\text{CVA}}} = \bar{K} \frac{[\text{H}_3\text{O}^+]}{[\text{CuCl}_2]}, \quad (10)$$

where $\bar{K} = k_3/k_4$.

As a result, the equation for the rate of formation of vinylacetylene includes the concentration of the H_3O^+ ion, which is involved in the stage 3 after the irreversible stage 2

$$r_{\text{VA}}^* = \frac{k_{\text{H}} p_{\text{C}_2\text{H}_2}^2}{k p_{\text{C}_2\text{H}_2} + [\text{H}_3\text{O}^+]} \cdot \frac{\bar{K}[\text{H}_3\text{O}^+]}{\bar{K}[\text{H}_3\text{O}^+] + [\text{CuCl}_2]}. \quad (11)$$

As a consequence, the rate of formation of vinylacetylene (r_{VA}^*) passes through a maximum as $[\text{H}_3\text{O}^+]$ changes. It was

suggested that the intermediate **X₁** with composition [Cu]₄H₃ was formed due to the insertion of acetylene at the Cu–C≡CH bond, *i.e.*, this intermediate is the β-ethynylvinyl derivative of copper (CuCH=CHC≡CH). The reaction of **X₁** (successively with two CuCl₂ molecules) afforded only chlorovinylacetylene. An analogous process took place in the reaction of CuCH=CHCl with two CuCl₂ molecules to form CH₂=CCl₂ (acidolysis yielding CH₂=CHCl was the competitive process).^{134, 135} The formation of chlorovinylacetylene from the intermediate **X₁** (it is the intermediate common to vinyl- and chlorovinylacetylenes) is also confirmed by the fact that none of such compounds as vinylacetylene, diacetylene, vinylidene chloride or vinyl chloride in these systems is converted into chlorovinylacetylene under the above-mentioned conditions.^{132, 133} Investigation of the effect of the addition of HgCl₂ on the synthesis of vinylacetylene demonstrated¹³¹ that an increase in the acidity of the CuCl–NH₄Cl–H₂O systems upon the addition of HgCl₂ is associated with an exchange reaction giving rise to the organomercury derivative ClHgCH=CHC≡CH, which is stable to HCl. Vinylacetylene can be isolated from this derivative only under the action of concentrated HCl.

Let us consider the stages 1–3 in more detail. Activation of acetylene resulting in its deprotonation (stage 1) occurs, most likely, in the course of several reactions the first of which involves the formation of π-complexes **B**

**A****B**

Kinetic studies demonstrated that replacement of Cl[–] in this stage is contradictory to Eqn (9). The formation of the π-complex can occur either in the course of the replacement of the coordinated water molecule or as a result of the cleavage of the μ–Cl bond without the replacement of Cl[–]. The replacement of the bridging chlorine atom accompanied by its migration to other coordination vacancies can also occur. Based on the assumption that the short-range order of complexes dissolved in concentrated solutions (which is similar to that in a melt), for example, of Cu₃Cl₅^{2–} (see Refs 48 and 49), corresponds to the structure of the complex **9a** in the crystalline state (*T*_{m.p.} ≈ 80 °C), the process of replacement of the water molecules can be represented by the scheme shown in Fig. 27. In this process, the formation of the intermediate **B** is accompanied by the migration of the bridging chlorine atom in the complex **A** to the coordination site, which was previously occu-

ried by the water molecule of crystallisation (this molecule is hatched in Fig. 27). The intermediate **B** (more precisely, the coordination π-unit) is structurally similar to one of the π-complexes (**20**, **21a,b**, **22** or **23**).

The reaction of the π-complex (**B**) with a water molecule affords the acetylenide (ethynyl) intermediate **C**. In this case, the Cl[–] ion can be eliminated simultaneously with H₃O⁺, but it can also be eliminated in the following quasi-equilibrium stage, the type of the kinetic equation being the same

Among a wide diversity of the structures of ethynyl compounds (see Section III), the complexes **43** and **44** (see Fig. 13) correspond to the intermediate **C** whose existence was suggested in the study⁹⁶ without convincing reasons.

As mentioned above, variations in the partial pressure of acetylene (*p*_{C₂H₂}) and [H₃O⁺] with the maintenance of constant *a*_{Cu+} and *a*_{Cl–}, *i.e.*, the concentrations of the active copper chloride complex, allows one to solve the question as to what particular σ-organometallic compound, which is present in the solution, serves as an intermediate in the catalytic reaction. In the synthesis of vinylacetylene, an unsymmetrical ethynyl complex serves as such an intermediate. In solution, other ‘yellow’ complexes, for example, the symmetrical acetylenide complex [(Cu₂C₂)(Cu_pCl_q)]^{(q–p)–} existing in equilibrium with the [(Cu_mCl_{n–1})(C₂H)]^{(n–m)–} ion, are present in solution depending on pH. The above-mentioned inactive complex enters into the material balance with respect to [CuCl]_Σ. Hence, the reaction rate of the formation of vinylacetylene passes through a maximum as the concentration of HCl changes if the concentration of (Cu_mCl_n)^{(n–m)–} is not maintained constant.¹²⁸ The maximum rate is observed in the range pH = 1.5–0.9 ([HCl] = 0.05–0.15 *m*). In this case, an increase in the acidity of the solution (pH < 1.5) leads to destruction of symmetrical acetylenide and to an increase in the concentration of unsymmetrical [Cu]C₂H acetylenide. A further increase in the acidity leads to the disappearance of this intermediate and to a decrease in the rate to zero. The formation of a complex containing the Cu₂C₂ fragment of the type **45** at pH = 4 and low temperature is in complete agreement with the above reasoning and observations.

Figure 27. Structural changes in the course of catalytic oligomerisation of acetylene.

Evidently, the subsequent stage of the Nieuwland process (stage 2) giving rise to the intermediate **X₁** involves the insertion of acetylene at the Cu–C₂H bond to form the CuCH=CHC≡CH fragment whose acidolysis affords C₄H₄. Below are represented the stages of the conversion of the intermediate **C** into the intermediate **X₁** (see Fig. 27).

The stage of acidolysis of the intermediate **X₁** (the electrophilic replacement of the Cu atom by the H⁺ ion in the Cu–CH= fragment) is beyond question. This stage was confirmed by the kinetic data [Eqn (11)]. The reaction proceeds very readily even with water.^{136, 137} Stages of this type were also observed in hydration, hydrochlorination and hydrocyanation of acetylene.¹³

The intermediate **E** decomposes to form vinylacetylene (it can be replaced by acetylene) or is involved in trimerisation of acetylene to give hexa-1,5-dien-3-yne [divinylacetylene (DVA)].

The insertion of acetylene giving rise to the intermediate **X₁** is the most important and intricate stage of the process. The fact of insertion is beyond a doubt because the reactions of cuprates R₂Cu·MgX and RCu·MgX₂ with alkynes are well known^{136, 137} and proceed stereoselectively (100% *syn*-addition) under mild conditions. However, the question about the mechanism of the process of insertion remains open. In the mononuclear case, the stage of insertion

is not an elementary concerted process because it is symmetry-forbidden due to the *d*¹⁰ configuration and *sp*³ hybridisation of the atomic orbitals of Cu(I).¹³⁸ Three alternative paths are formally possible.

1. The formation of the metallocarbenium ion (**F**) followed by the rapid migration of the ethynyl group giving rise to the intermediate **X₁** in the first irreversible stage.

2. Dissociation of the [Cu](μ-η¹-C≡C) bond to form the contact ionic pair followed by the addition of the carbanion to the η²-coordinated acetylene.

3. Dissociation of the bridging [Cu](μ-η¹-C≡C) bond accompanied by the conversion of the ethynyl group into the η²-state

followed by the addition of the η²-HC≡C[−] carbanion to η²-alkyne.

Path 1 was considered¹³ for the reactions of cationic Pt(II) complexes with alkynes. This path was assumed¹³ for reactions with the participation of Hg²⁺, but it is less probable for Cu(I) halides. Path 3 is more interesting because a softer nucleophile and a weak base (η²-HC≡C[−]) are involved in the reaction. In addition, paths 2 and 3 provide a more adequate explanation for the high stereoselectivity of the insertion of alkynes. To discuss these alternatives, let us use the data on the structures of the complexes (PyH)₄Cu₉Cl₁₂(C≡CH) (**44**) and NH₄Cu₈.Cl₉(HC≡CH)₄·2/5{[Cu(H₂O)₂]·[CuCl₂]·H₂O} (**23**). Crystal-chemical analysis demonstrated that these compounds are genetically related (Fig. 28). The subunit Cu₈Cl₉ (Fig. 28 *b*) is common to both complexes. This subunit contains four pairs of [Cu₂] ‘matrices’ with the Cu···Cu distance of ~2.8 Å. The η²,η²-coordination of one C₂H₂ molecule at the [Cu₂] matrix each affords the structural fragment shown in Fig. 28 *c*. The coordination of the η¹,η¹-C≡CH ligand at the [Cu₂] matrix gives rise to the fragment shown in Fig. 28 *a*. The relation between the fragments (*a*) and (*c*) suggests the possible stereochemistry of the second and third paths of conversions of the intermediate **D** into **X₁**. Probably, the intermediate **D** is formed by the replacement of the σ-coordinated μ₄-Cl ligand in the complex with acetylene (μ-η²,η²-C₂H₂). The resulting complex **D** (see Fig. 27) contains simultaneously several ligands coordinated at the [Cu₂] matrix, *viz.*, η¹,η¹-C≡CH and η²,η²-C₂H₂. The intermediate **D** can be converted into **X₁** *via* two paths. From the viewpoint of the stereochemistry, the path 2 is the most favourable and involves the cleavage of the Cu–C η¹-bond to form the contact ionic pair **D*** (see Fig. 27). The [−]C₂H ion rapidly attacks one of the C^{δ+} atoms of the π-bonded C₂H₂ molecule. In the case of the path 3, the η¹,η¹-C≡CH ligand should be converted into the η¹,η²-C≡CH ligand. Then the Cu–C η¹-bond can be cleaved followed by the attack of the η²-coordinated anion on the η²-acetylene. Protolysis of the intermediate **X₁** affords π-coordinated vinylacetylene (Fig. 27, the intermediate **E**).

Figure 28. Structural fragment of the (PyH)₄Cu₉Cl₁₂(C≡CH) complex (**44**) (*a*), the Cu₈Cl₉ subunit (*b*) and the structural fragment of the NH₄Cu₈Cl₉(HC≡CH)₄·2/5{[Cu(H₂O)₂]·[CuCl₂]·H₂O} complex (**23**) (*c*).

The $[\text{Cu}_m\text{Cl}_n(\text{C}_4\text{H}_4)]^{(n-m)-}$ complex (**E**) can be deprotonated to form the intermediate **G** (of the type **55**, see Fig. 22). Judging from the kinetic data, the latter is converted into divinylacetylene.

Protolysis of the intermediate X_3 (an analogue of X_1) yields the intermediate **I** (complex **34**).

The intermediate X_1 can interact with yet another acetylene molecule (through the π -complex), which can be inserted at the $\text{Cu}-\text{CH}=\text{CH}_2$ bond, because the insertion of alkynes at the $\text{Cu}(\text{I})$ -alkenyl bond occurs rather readily.¹³⁷ As a result, hexa-1,3-dien-5-yne (the isomer of divinylacetylene) is formed. On certain assumptions, the scheme of its formation agrees with the kinetic data.¹³

3. Addition of cyclopentadiene and HCN to acetylene

The Diels–Alder reaction (12) of acetylene with cyclopentadiene to form norbornadiene **J** proceeds efficiently in highly concentrated solutions of CuCl .

The polynuclear complexes Cu_5 , Cu_6 and Cu_7 also participate in this reaction. The process involves the rate-determining stage because the reaction

proceeds more slowly than the reaction of the ethynyl intermediate with C_2H_2 . Two possible mechanisms of formation and conversion of X_4 should be considered.

1. The classical diene synthesis, *viz.*, [4 + 2]-cycloaddition, with the participation of an active (polarised) dienophile.

2. The insertion of diene at the $\text{Cu}-\text{C}$ bond to form the η^3 -allylic intermediate followed by the repeated intramolecular insertion of $\text{C}\equiv\text{CH}$ at the $\text{Cu}-\text{C}$ bond.

Hydrocyanation of acetylene (11, see Table 12) to form acrylonitrile proceeded in more acidic solutions of CuCl (the HCl content was up to 3 mass %). The process involves the rate-determining stage. At constant a_{Cu^+} and a_{Cl^-} , the process is described by the equation

$$r_{11m} = \frac{k_{11m} p_{\text{C}_2\text{H}_2} p_{\text{HCN}}}{[\text{H}_3\text{O}^+]}. \quad (12)$$

If the concentrations of the active components are not maintained constant, the reaction rate passes through a maximum both

as p_{HCN} and the concentration of H_3O^+ change.¹²⁶ Although the conclusion about the participation of the free CN^- ion or a complex containing the $\sim\text{CuCN}$ fragment cannot be made because of the presence of the rate-determining stage, the experimental data give grounds to suggest that the mechanism is analogous to that of dimerisation of acetylene. The concentration of free cyanide ions in acidic solutions of CuCl cannot be higher than $10^{-9} - 10^{-10} \text{ mol litre}^{-1}$ due to which the attack of the free cyanide ion present in solution on the π -coordinated acetylene ligand is improbable, as in the case of the $\text{HC}\equiv\text{C}^-$ anion in the dimerisation of acetylene.

Catalysis of hydrocyanation of acetylene in concentrated solutions makes it possible to achieve high concentrations of the copper cyanide complex $\sim\text{CuC}\equiv\text{N}$. Thus the concentration of dissolved CuCN in the $\text{CuCl}-\text{NH}_4\text{Cl}-\text{H}_2\text{O}$ system can reach 15 mass %. If HCN is passed through these systems, different mono- and polycyanide complexes of copper, *viz.*, $[\text{Cu}_m\text{Cl}_{n-1}(\text{CN})]^{(n-m)-}$ and $[\text{Cu}_m\text{Cl}_{n-x}(\text{CN})_x]^{(n-m)-}$, can be formed depending on the concentration of HCl . High reactivities of polynuclear cyanide complexes are also associated with their bridging structures analogous to those of the complex $\text{NH}_4\text{Cu}_2(\text{CN})_3 \cdot \text{H}_2\text{O}$ ¹³⁹ (Fig. 29 *a*) or $\text{KCu}_2(\text{CN})_3 \cdot \text{H}_2\text{O}$.¹⁴⁰ In addition, due to the bridging structure, CN^- can be held as an anion in the coordination sphere of the $(\text{Cu}^+\text{C}^-\equiv\text{NCu})$ complex in the course of insertion of acetylene at the $\text{Cu}-\text{CN}$ bond. Acrylonitrile formed after acidolysis of the intermediate $\text{CuCH}=\text{CHC}\equiv\text{NCu}$ can be coordinated to form the π -complex of the type $2\text{CuCl} \cdot \text{CH}_2=\text{CHCN}$.¹⁴¹ In the latter, the acrylonitrile molecule serves as the bridging η^2 - (at the $\text{C}=\text{C}$ bond) and η^1 - (at the N atom) ligand. Interestingly, the CN^- ion can be replaced in the structure of the cyanide complex $\text{KCu}_2(\text{CN})_3 \cdot \text{H}_2\text{O}$ by the C_2^{2-}

Figure 29. The $[\text{Cu}_2(\text{CN})_3]_n^-$ anions in the structure of the $\text{NH}_4\text{Cu}_2(\text{CN})_3 \cdot \text{H}_2\text{O}$ complex¹³⁹ (*a*) and the $[\text{Cu}_2(\text{CN})_2(\text{C}\equiv\text{C})_2]_n^-$ anions in the structure of the $[\text{K}(\text{H}_3\text{O})^+][\text{Cu}_2(\text{CN})_2(\text{C}\equiv\text{C})_2]$ complex¹⁸ (*b*).

dianion (Fig. 29b) to form the complex $[K(H_3O^+) \cdot [Cu_2(CN)_2(C \equiv C)]]^{18}$

4. Participation of ethynyl copper complexes in homogeneous oxidative conversions of alkynes in the CuCl–MCl–CuCl₂ systems

Many oxidative conversions of acetylene and alkynes proceed in concentrated solutions of CuCl in the presence of CuCl₂.^{13, 142} As mentioned above, 2-chlorobut-1-en-3-yne,^{132, 133} *trans*-1,2-dichloroethylene and 1,1-dichloroethylene^{134, 135} formed from acetylene in these systems. Soluble σ -ethynyl derivatives are also involved in oxidative dehydrocondensation of alkynes yielding substituted diacetylenes **K**^{13, 143} and in substituting oxidative chlorination giving rise to chloroalkynes **L**.^{144–147}

The CuCl–CuCl₂ catalytic systems (CuCl₂ is a catalyst in the presence of O₂ or in an electrochemical system) are characterised by the formation of heterovalent polynuclear complexes very typical of copper.¹⁴⁸ The structure of the simplest representative of these complexes, *viz.*, $[(C_2H_5)_4N]Cu_2Cl_4$, has been described.¹⁵ The Cu(I) and Cu(II) centres in the polynuclear chain $(Cu_2Cl_4)_n^{n-}$ differ in symmetry.

Concentrated solutions, which enable one to achieve high concentrations of intermediates ($\sim CuC \equiv CR$, $\sim CuCN$ or $\sim CuCH=CHX$), play an important role in the catalysis of addition at the $C \equiv C$ bonds of the $HC \equiv CH$, HCl , HOH , HCN and C_5H_6 molecules. In oxidative conversions of alkynes, electron transfer from CuR to $CuCl_2$ in mixed complexes occurs so rapidly ($k = 0.5 \times 10^8 \text{ mol}^{-1} \text{ litre s}^{-1}$)¹⁴⁹ that the reaction rates are high even in solutions dilute with respect to CuCl (for example, at the concentrations of LiCl, CuCl and CuCl₂ equal to 5, 0.2 and 0.5 mol litre⁻¹, respectively). The kinetic equations for some reactions proceeding in these systems under conditions of constant high concentration of the cations (Li^+) {when $[CuCl]_{\Sigma} \propto [(CuCl_n)^{(n-1)-}]$ and $[CuCl_2]_{\Sigma} \propto [(CuCl_n)^{(n-2)-}]$ } were obtained. Thus, the rate of oxidative dimerisation of methylacetylene (MA) is described by the equation¹⁴²

$$r_{DDA} = \frac{k_{DDA} p_{MA} [CuCl_2] [CuCl]^2}{[H_3O^+]}, \quad (13)$$

where DDA is dimethyldiacetylene.

The process occurs through the intermediate $CuC \equiv CMe$ and involves the rate-determining stage whose transition state includes Cu(I) and Cu(II) ions $[2Cu(I) \cdot Cu(II)(-C \equiv CR)]^\ddagger$. It should be noted that two CuCl molecules enter into the reaction even in rather dilute solutions. Apparently, these molecules are required for stabilisation of the assumed intermediate, *viz.*, the ethynyl complex of copper(II) ($ClCuC \equiv CMe$). The kinetic data¹⁴² demonstrate that two molecules of the intermediate decompose to form dialkyne

It may be suggested that the ethynyl group in the **M** complex acts as the μ_3 - η^1, η^2, η^2 -ligand. It is also conceivable that two CuCl molecules act as catalysts in the formation of $ClCu^I C \equiv CMe$

The reaction of $\sim Cu^I C \equiv CMe$ with two CuCl₂ molecules affords 1-chloroprop-1-yne (CP). The latter is formed in two stages the first of which is rate-determining.

The reaction rate is described by the equation

$$r_{CP} = \frac{k_{CP} p_{MA} [CuCl_2]^2 [CuCl]}{[H_3O^+]}. \quad (14)$$

It should be noted that heterovalent copper complexes with organic ligands (of the σ - and π -types) are as yet unknown although the complex **15** may be assigned to heterovalent organo-metallic complexes because its structure contains Cu^{2+} ions occupying octahedral cavities and $CuC \equiv CH$ species as 'guests' along with the 'host' complexes.

V. Conclusion

Analysis of the experimental data obtained in studies of the compositions and structures of the complexes $M_{(n-m)}Cu_mCl_n$ in solutions and in the solid phase, copper(I) π -complexes with acetylene and its derivatives and σ -ethynyl compounds, and information gained from investigations of the kinetics of the catalytic conversions of alkynes in the $MCl-CuCl-H_2O$ and $MCl-CuCl-CuCl_2-H_2O$ systems reveals the specific features of the coordination chemistry of copper(I) halide complexes and the peculiarities of the behaviour of copper(I) as a catalyst of conversions of acetylenic compounds.

The formation of coordination polyhedra through bridging chloride (bromide) ligands in which Cl^- acts as the μ_2 -, μ_3 - or μ_4 -ligand gives rise to low-charged polynuclear associates $(Cu_mCl_n)^{(n-m)-}$, which can efficiently interact with acetylene and alkynes to form various π - and σ -organometallic compounds.

The geometric characteristics of the π -coordination polyhedra about the Cu(I) atoms and of the triple $C \equiv C$ bond π -activated at the metal centre in the CuCl π -complexes with acetylene and its derivatives and the higher efficiency of the Cu(I)–($C \equiv C$) π -interaction compared to that of Cu(I)–($C=C$) are consistent with the statement that two degenerate π -MOs are split into two MOs with different energies ($\pi_{||}$ and $\pi_{\perp}$) in the course of π -bonding with Cu(I) due to which the reactivities of alkynes increase. Using the copper(I) halide π -complexes of organic compounds containing the $C \equiv C$ bond as an example, two qualitatively different modes of π -coordination of the $C \equiv C$ groups to the Cu(I) atoms were revealed. These modes differ in the efficiency of the π -interaction. Thus, the first mode of coordination occurs in the case of the probable simultaneous participation of $\pi_{||}$ -, $\pi_{||}^*$ and $\pi_{\perp}^*$ -MOs to form the Cu(I)–($C \equiv C$) π -unit. The second mode of coordination occurs if two individual π -MOs of the $C \equiv C$ bond interact with the Cu(I) atom independently of one another giving rise to the bridging Cu(I)–($C \equiv C$)–Cu(I) π -unit (η^2, η^2 - $HC \equiv CR$). In the latter case, each π -MO of the acetylene group behaves analogously to that of the ethylene group and is independently coordinated to one metal atom. The participation of the higher $\pi_{||}$ -MO and two π^* -MOs is favourable for an increase in the contribution both of the donor-acceptor and dative components of the bond due to which Cu(I)–alkyne bonding in the first case is more efficient.

In the crystalline anionic π -complexes of CuCl with acetylene and its monosubstituted derivatives, the efficiency of the Cu(I)–($C \equiv C$) π -interaction, which is manifested in the elongation of the π -coordinated $C \equiv C$ bond, is substantially affected by $\equiv C-H \cdots Cl$ hydrogen bonds (the length of the π -coordinated $C \equiv C$ bond depends linearly on the $H \cdots Cl$ distance). The reason is that the Cl atoms whose electron-withdrawing properties depend substantially on the strength of the $M^+ \cdots Cl^-$ ionic interaction can affect the polarisation of the $\equiv C-H$ bond of the π -coordinated molecule of terminal alkyne through the $C(H) \cdots Cl$ contact due to which the electron density on the carbon atoms can increase or decrease resulting in the corresponding decrease or increase of the contribution of the dative transfer

$\text{Cu(I)} \rightarrow (\text{HC} \equiv \text{CR})$. In this case, the $\text{C} \equiv \text{C}$ bond is subjected to an insignificant or substantial elongation, respectively.

The high efficiency of π -interactions in copper(I) complexes of the ethynyl type (σ, π -complexes) whose formation in the $\text{MCl}-\text{CuCl}-\text{H}_2\text{O}$ systems (according to the kinetic data) plays a decisive role in many conversions of C_2H_2 and alkynes is associated with the mutual strengthening of individual types of interactions, viz., of $\text{Cu(I)}-(\eta^1\text{-C} \equiv \text{CR})$ and $\text{Cu(I)}-(\eta^2\text{-C} \equiv \text{CR})$. This effect of mutual strengthening (synergism) of acetylenide and π -types of interactions, which was revealed in cluster acetylenides and ethynyl complexes of Cu(I) , is often accompanied by unusual structural manifestations and by the appearance of qualitatively new properties of the $\text{C} \equiv \text{C}$ group π -activated at the metal centre [the $\text{C} \equiv \text{C}^-$ dianion in the compound **45** can be π -coordinated simultaneously to three Cu(I) atoms].

In addition to the modes of coordination of ethynyl groups ($\text{C} \equiv \text{CR}$) to the copper(I) atom (**A**, **B**, **C** and **D**) known in organometallic chemistry,^{96–117} new types of clusters (**E** and **F**) were found in the case of copper chloride complexes.

The polydentate character of coordination of acetylene in π -complexes and of ethynyl ligands in σ -organometallic compounds (as well as of cyanide groups) is the governing factor responsible for the catalytic activity of polynuclear Cu(I) complexes, which is characterised by the following features.

1. The high rate of cleavage of the bridging $\text{Cu}-\text{Cl}$ ($\mu, \mu_3, \mu_4\text{-Cl}$)-bonds to form the initial π -complexes (in some cases, the $\mu\text{-Cl}$ atom is isolobally replaced by alkyne).

2. The high solubility of such molecules as $\text{Cu} \equiv \text{CH}$, $\text{CuC} \equiv \text{CR}$ and CuCN due to reactions with polynuclear $(\text{Cu}_m\text{Cl}_n)^{(n-m)-}$ anions and, consequently, the high concentration of intermediates in solutions (the concentration of 'yellow' acetylenide complexes in the Nieuwland reaction reaches $0.1 \text{ mol litre}^{-1}$).

3. The bridging nature of the coordinated ethynyl and cyanide groups provides various stereochemical possibilities for the appearance of carbanionic ($\text{RC} \equiv \text{C}^-$) and cyanide ($\text{N} \equiv \text{C}^-$) nucleophiles in the complex.

4. The tendency for cluster-formation in polynuclear σ, π -ethynyl complexes has a particular effect on the course of catalytic processes.

5. All stages of the process, including coordination of the products, can occur on the 'matrix' of one complex formed from the $[\text{Cu}_n]$ cluster.

6. The formation of polynuclear heterovalent complexes in oxidation reactions is favourable for the electron transfer in multiple-electron processes.

7. Hydration and hydrochlorination of alkynes in which the σ -organometallic intermediate is formed in the course of the attack of the nucleophile (Cl^- or H_2O), which is present in the solution of the copper(I) π -complex, can also occur without the participation of polynuclear complexes and, correspondingly, need not be catalysed by concentrated solutions.

I. Introduction	985
II. Reactions of polymers with nitrogen dioxide	986
III. The effect of nitric oxide on polymers	994
IV. Conclusion	997

Abstract. The mechanisms of the reactions of nitrogen oxides and different classes of solid polymers are considered. Particular emphasis is given to the analysis of the mechanisms of the formation of stable nitroxyl radicals. Double bonds and amide groups of macromolecules, as well as hydroperoxides and peroxide macroradicals are shown to be involved in the reactions with nitrogen oxides. The application of nitrogen oxides for the preparation of spin-labelled polymers and the use of the ESR imaging technique (ESR tomography) for the investigation of the structure of the reaction front during nitration of solid polymers are considered. The bibliography includes 111 references.

I. Introduction

Investigations aimed at finding relations between the processes of thermal, thermal-oxidative, photolytic, photo-oxidative and mechanochemical ageing of different classes of polymers and destruction effects, as well as studies on stabilisation of polymers to withstand these effects have been carried out for a long time. The main goal of these investigations is to retain the operating characteristics of polymeric materials.

Among numerous publications devoted to generalisation of the results obtained in this area of scientific exploration (see, *e.g.*, Refs 1–20), monographs by Emanuel and Buchachenko^{2,4} can be highlighted. In these studies, the kinetics of the ageing of polymers under the action of different factors have been analysed taking account of specific features of elementary acts of the corresponding solid-phase chemical transformations.

In the mid-twentieth century, it was recognised that the increasing amount of industrial waste discharged to the atmosphere pollutes it with such aggressive compounds as sulfurous anhydride, different nitrogen oxides and ozone. These give rise to acid rains and smogs,²¹ which cause deterioration of structural materials (concrete, marble, bricks, polymeric materials, lacquers and paints).

Reactions of polymers with nitrogen oxides constitute an important factor responsible for deterioration of the functions of polymers. Studies on nitration of organic compounds both in the

liquid and gas phases began in the mid-nineteenth century. Both nitric acid and nitrogen oxides were used as nitrating agents. The nitration of aromatic compounds is, as a rule, an ionic process,^{22–24} whereas that of the paraffin hydrocarbons is a free-radical process initiated by nitrogen dioxide, NO₂.^{25–27} In this case, nitric acid served as a source of nitrogen oxides. The addition of small amounts of nitrogen dioxide initiates degenerate branched chain oxidation of hydrocarbons in the liquid phase and, on the other hand, results in chain termination of oxidation reactions.²⁸

Systematic studies of the effect of nitrogen oxides on the stability of polymeric materials began in the late 1950s.^{29–32} The major contribution to the solution of this problem was made by Jellinek who studied degradation of different classes of polymers in an atmosphere of nitrogen dioxide and its dimer at ambient temperatures and under the combined action of nitrogen dioxide, oxygen and near-UV light and visible light.³²

Eight oxides of nitrogen are known; however, only three of them, *viz.*, NO, NO₂ and N₂O₄, are thought to be air pollutants.³³ The atmospheric concentrations of other nitrogen oxides are too low to have a pronounced effect on the ageing of polymers under natural conditions.

The concentrations of nitrogen oxides in the atmosphere are subject to diurnal and seasonal variations over a rather wide range and depend on the position and weather conditions. The maximum permissible concentrations of nitric oxide in urban atmospheres are 2×10^{-8} mol litre⁻¹ (the peak concentration) and 2×10^{-9} mol litre⁻¹ (the daily average concentration). The maximum permissible concentration of nitrogen dioxide is 1.85×10^{-9} mol litre⁻¹ in both cases. In the production areas, the permissible concentration of NO₂ is about 1.1×10^{-7} mol litre⁻¹ (Refs 34, 35).

Nitrogen dioxide always exists in equilibrium with its colourless linear dimer, N₂O₄. The heat of formation of N₂O₄ is -61.4 kJ mol⁻¹ at 298 K.

The equilibrium constant decreases with the increase in the total pressure of NO₂ + N₂O₄ (*P*) and is 0.1415 atm at $P = 4.3 \times 10^{-2}$ atm and $T = 298$ K.³⁶

Based on experimental and calculated data,^{37–40} it was assumed that nitrosation of alkenes in non-polar solvents is the result of the reaction of carbon–carbon double bonds with nitroso nitrate, ON–ONO₂, a less stable isomer of linear N₂O₄.

Some additional remarks are to be made before analysing the results of investigations on the reactions of polymers with nitrogen oxides and establishing the possibility of extrapolating them in order to assess the ageing of polymers in a polluted atmosphere. Since the atmospheric concentrations of nitrogen oxides are low, the rates of their reactions are also low. Therefore, the ageing processes due to other factors (*e.g.*, thermal oxidation, photo-initiated oxidation, ozone ageing, biodegradation of polymers *etc.*) can compete with or be more efficient than the reactions involving nitrogen oxides. Therefore, the results of tests under natural conditions can hardly be used for evaluation of the contribution of the processes initiated by nitrogen oxides. These reactions are usually studied at the concentrations of air pollutant gases which are several orders of magnitude higher than their atmospheric concentrations. The results obtained under these conditions are, as a rule, linearly extrapolated to the atmospheric concentrations. Such *a priori* extrapolation is not obvious, since the contributions of particular stages to the overall ageing process under the conditions of accelerated tests can vary depending on the experimental conditions.

Ageing of polymers exposed to nitrogen oxides is due to the reactions of gases diffusing into the polymer with reactive groups of macromolecules. These processes are characterised by non-uniform propagation of the reaction through the bulk of the sample and require complicated description of their kinetics.

'Kinetic inequivalence' of reactants is typical of the chemical reactions in solid polymers.^{2,4} This means that the species with the same chemical structure have different nearest environments and therefore react with different rate constants. As a consequence, the most reactive species are consumed rapidly so that the overall rate constants decrease with time. However, relaxation processes occurring in polymers favour the recovery of the initial distribution of reactivities of the species. Therefore, the reaction kinetics appears to be dependent on the ratio of the rates of chemical reactions and relaxation processes.⁴¹ This also requires a critical view on simple transfer of the results of accelerated tests to the ageing of polymers in atmospheres polluted with nitrogen oxides.

Finally, it should be noted that most of the studies of the effect of nitrogen oxides on polymeric materials involve the determination of changes in the average degree of polymerisation. However, this parameter characterises only one reaction, *viz.*, degradation of macromolecules, though this is of prime importance. A detailed study of degradation in reactions of various polymers with nitrogen dioxide was carried out by Jellinek.³² He has divided all polymers into three main groups differing in stability toward NO₂. In the present review, the results will also be analysed using this classification. Changes in the mechanical properties can be considered as important operating characteristics of a polymer as a structural material; however, this parameter provides no direct information on the chemical transformations and structure of macromolecules. This information can be obtained using IR spectroscopy, but changes in the absorption spectra can usually be detected only at rather high degrees of conversion. Therefore, the use of other physicochemical methods for the analysis of the transformations occurring in the polymers exposed to nitrogen oxides, as well as the analysis of the distribution of the reaction over the bulk of the sample are of crucial importance for the elucidation of complicated mechanisms of these reactions. Sometimes, ageing products can be more reactive towards nitrogen oxides than the initial polymer.

In the present review, we considered the results obtained in studies on the ageing of different classes of polymers by traditional methods of physicochemical analysis and in the investigations of these processes by ESR spectroscopy, which allow one to draw conclusions on free-radical stages of the ageing of polymers involving nitrogen oxides from the structure of stable nitrogen-containing macroradicals produced in the reactions.

II. Reactions of polymers with nitrogen dioxide

Nitrogen dioxide plays the role of a moderately reactive free radical (the strength of the ONO—H bond is 322 to 326 kJ mol⁻¹),⁴² which can initiate several types of reactions, *e.g.*, hydrogen abstraction from molecules of organic compounds and reversible addition to carbon—carbon double bonds. Additionally, NO₂ and its dimer can enter into specific reactions with functional groups of macromolecules.

1. Carbon-chain polymers containing no carbon—carbon double bonds

Carbon-chain polymers containing no carbon—carbon double bonds in both the main chain and side groups [*e.g.*, polyethylene (PE), polypropylene (PP), polystyrene (PS), poly(methyl methacrylate) (PMMA), polyacrylonitrile (PAN), poly(vinyl chloride) (PVC) and poly(vinyl fluoride) (PVF)] are characterised by insignificant changes in their properties under the conditions of accelerated tests (Jellinek *et al.*^{43,44} carried out their experiments at a NO₂ concentration of 7.8×10^{-3} mol litre⁻¹ and $T = 308$ K; the exposure time was ~ 30 h). Linear extrapolation of the results obtained to the NO₂ concentration typical of polluted atmospheres predicts a long-term stability of the polymers.⁴⁵

Let us consider the results of investigations of the effect of NO₂ on particular representatives of these polymers in more detail.

Pioneering studies of the reaction of nitrogen dioxide with PE and PP have been carried out by Ogihara *et al.*^{30,31} Using IR spectroscopy, they have found that nitrogen dioxide cannot abstract secondary and tertiary hydrogen atoms from the PE and PP molecules at 298 K. It can only add to the vinyl, vinylene and vinylidene units that are formed in the synthesis of, *e.g.*, PE. These reactions resulted in dinitro compounds and nitro nitrites.

At $T \geq 373$ K, nitro, nitrite, nitrate, carbonyl and hydroxy pendent groups are formed in these polymers.

The following reaction mechanism was proposed:

Subsequent reactions involving the RO^{*} radicals result in macromolecular nitrates, alcohols and carbonyl compounds. This scheme allows rationalisation of the accumulation of the nitro groups, which proceeds at a constant rate, and autoaccelerated formation of nitrates, alcohols and carbonyl compounds; however, it provides no explanation for the S-shaped dependence of the accumulation of nitrites.

The activation energy (E_a) for the NO₂ addition to the double bonds of PE obtained by different methods is 8 to 16 kJ mol⁻¹. The activation energy for hydrogen abstraction lies between 56 and 68 kJ mol⁻¹ for PE and is 60 kJ mol⁻¹ for PP.

At room temperature and NO₂ concentrations lying between 5.4×10^{-4} and 5.4×10^{-3} mol litre⁻¹, the characteristics of PE, PP, PAN and PMMA change only slightly even if they are simultaneously exposed to a combination of NO₂, O₂ and UV radiation.⁴³ The reactions of NO₂ with PVC and PVF resulted in a

slight decrease in the content of chlorine and fluorine atoms, respectively.^{32, 43}

At temperatures between 298 and 328 K, nitrogen dioxide (7.8×10^{-3} – 3.4×10^{-2} mol litre⁻¹) can abstract tertiary hydrogen atoms from PS molecules to form pendent nitro and nitrite groups.³² These reactions proceed at low rates and are accompanied by chain scissions of the macromolecules.^{32, 45, 46} According to Jellinek, the dependence of the decrease in the average degree of polymerisation of PS exposed to NO₂ on the exposure time has three (initial, middle and final) linear regions. A decrease in the apparent degradation rate was observed during the second stage of the reaction (the middle region of the dependence). Presumably, this was related to the association of the macromolecules in solution, which is due to the effect of polar groups and can affect the results of viscosimetric measurements. Subsequent increase in the apparent degradation rate was attributed to the consumption of these nitrogen-containing groups and to a decrease in the degree of association of the macromolecules.

Polystyrene films were also simultaneously exposed to NO₂ (1.1×10^{-4} mol litre⁻¹) and light ($\lambda > 280$ nm).⁴⁶ No polymer degradation was observed in the initial stage (at exposure times of no longer than 10 h). Then chain scissions occurred at a constant rate. After 40 h, degradation ceased. The mechanism of degradation under these conditions was not discussed.

An attempt to carry out a quantitative study of the ageing of PS and poly(*tert*-butyl methacrylate) (PTBMA) under the conditions simulating the ageing of these polymers in an atmosphere polluted with NO₂ has been undertaken by Huber.⁴⁷ Glass supports coated with the samples were exposed to a stream of air containing NO₂ (2.5×10^{-6} to 3.7×10^{-5} mol litre⁻¹) at 300 K and simultaneously irradiated with light ($\lambda > 290$ nm). The number of chain scissions per 10 000 monomer units (α) was determined from the data of viscosimetric measurements. The dependence of α on the exposure time can be described by an empirical equation

$$\alpha = \frac{P}{Q} (\exp Qt - 1),$$

where P and Q are constants and t is time. This equation describes an autocatalytic process. At $Q \rightarrow 0$, degradation occurs at a constant rate. As the thickness of the sample increases, both constants, P and Q , decrease, the former decreasing faster than the latter. Autocatalytic process is more pronounced for thin films. Degradation of thin PS films under the same conditions occurs slower than that of the PTBMA films and its autocatalytic nature is more pronounced. Possible reasons for the dependence of the kinetic parameters of degradation on thickness of the samples have not been considered.

The autocatalytic type of degradation of PTBMA was associated⁴⁷ with the photo-induced formation of isobutylene, which reacts with NO₂, thus initiating free-radical degradation processes of macromolecules.

The IR spectrum of PS exposed to NO₂ and light under conditions mentioned above exhibits two bands at 1686 and 3400 cm⁻¹ corresponding to the carbonyl and hydroxy groups, respectively. The formation of nitrogen-containing products has not been observed in both PTBMA and PS. The following reactions have been assumed⁴⁷ to proceed in PS:

It is believed that the decomposition of hydroperoxides exposed to NO and light [reactions (4) and (5)] leads to autocatalytic degradation of PS.

The results of investigations on the mechanisms and kinetics of the reactions of macromolecular hydroperoxides with nitric oxide are considered in more detail in the forthcoming sections.

2. Reactions of nitrogen dioxide with carbon-chain polymers containing carbon–carbon double bonds

Among the reactions of NO₂ with carbon-chain polymers containing carbon–carbon double bonds, its reactions with rubbers have been studied in most detail. Rubbers are much more susceptible to NO₂ than the polymers containing no double bonds in both the main chain and side groups of the macromolecules. First, this is due to the ability of NO₂ to add reversibly to carbon–carbon double bonds to give nitroalkyl radicals [reaction (1)], thus initiating free-radical transformations of elastomers. Second, it was found⁴⁸ that the rate of the formation of products (Prod) of the liquid-phase reactions of NO₂ with alkenes is described by the equation

$$\frac{d[\text{Prod}]}{dt} = k'[\text{alkene}][\text{NO}_2] + k''[\text{alkene}][\text{NO}_2]^2,$$

where k' is the effective rate constant for the formation of products in the reactions of allyl radicals with NO₂ and k'' is the effective rate constant for the formation of products in reactions (1)–(3).

The second term of this equation dominates at high NO₂ concentrations; this corresponds to the formation of products in the recombination reactions of nitroalkyl radicals with nitrogen dioxide [reactions (1)–(3)]. The first term of this equation dominates at low NO₂ concentrations; this is associated with the ability of nitrogen dioxide to abstract hydrogen atoms in β -position to the double bond to give allyl radicals, which then combine with an NO₂ molecule. Depending on the structure of the alkene, the reaction resulting in the formation of the allyl radical can be either weakly exothermic or weakly endothermic. For instance, the strengths of the weakest C–H bonds in the structural fragment $-\text{C}(1)\text{H}_2-[\text{C}(2)\text{H}_3]\text{C}=\text{CH}-\text{C}(3)\text{H}_2-$ of synthetic isoprene rubber are 334, 351 and 316 kJ mol⁻¹ for the C(1)–H, C(2)–H and C(3)–H bonds, respectively.⁴⁹

In preliminary studies it was shown⁴³ that exposure of polyisoprene and polybutadiene to nitrogen dioxide leads to both degradation and cross-linking of the macromolecules, whereas butyl rubber (a copolymer of isobutylene with 1.75% of isoprene) only undergoes degradation. Jellinek *et al.*^{32, 50, 51} carried out a detailed study of the ageing of butyl rubber exposed to (i) NO₂ (5.2×10^{-7} to 5.2×10^{-5} mol litre⁻¹) alone, (ii) an NO₂–O₂ mixture and (iii) an NO₂–O₂ mixture plus UV light ($\lambda > 280$ nm). It was found that in the first case the polymer degradation is described by the formula

$$\alpha = k_{\text{ef}}t,$$

where k_{ef} depends on the NO₂ pressure. This equation is valid except for the initial portion of the curve where the reaction rate decreases with time. A kinetic scheme of the main-chain scission was proposed.

Exposure to a mixture of O₂ (6.8×10^{-4} to 7.8×10^{-3} mol litre⁻¹) and NO₂ (5.2×10^{-7} to 5.2×10^{-5} mol litre⁻¹) leads to an increase in the degradation rate of the

rubber with the increase in the concentrations of both gases. According to Jellinek, there are three factors governing the main-chain scissioning in the polymers exposed to O_2 – NO_2 mixtures. These are (i) degradation induced by NO_2 alone, (ii) oxidative degradation of macromolecules and (iii) scissions of macromolecules owing to the synergistic effect of NO_2 and O_2 , which in turn is due to the NO_2 -induced decomposition of hydroperoxides formed in the reaction.

According to Jellinek, the degradation kinetics of butyl rubber exposed to NO_2 – O_2 mixture and UV irradiation is described by the following equation:

$$\alpha = k'_{ef}t^2 + k''_{ef}[NO_2][1 - \exp(-k'''t)],$$

where k' and k'' are the effective rate constants for different groups of reactions and k''' is the rate constant for degradation of the elastomer exposed to NO_2 alone. At low NO_2 pressures, the degradation rate increases with time. At high NO_2 pressures, the reaction slows down.

3. ESR studies of the reactions of nitrogen dioxide with double bonds in solid polymers

As was mentioned above, nitration of aromatic compounds usually follows an ionic mechanism, whereas nitration of aliphatic compounds (in particular, the reaction of NO_2 or its dimer with carbon–carbon double bonds in non-polar media) proceeds by free-radical mechanism.^{37, 48, 52, 53} Liquid-phase reactions of low-molecular-mass alkenes with NO_2 – N_2O_4 mixture produce paramagnetic centres.⁵⁴ It was found that the ESR spectra arising are temperature-dependent and that their parameters differed from those of the spectra of nitroalkyl radicals. These spectra were associated with the π -complexes formed in the reactions of nitrogen dioxide with the double bonds of alkenes. Nitroalkyl radicals produced in the styrene– NO_2 (or α -methylstyrene– NO_2) systems were identified by Kommandeur *et al.*⁵⁵ in the ESR spectra of the spin adducts of these radicals with nitrosobenzene. Paramagnetic centres observed⁵⁴ were assigned to the nitroxyl radicals generated in the reactions

It is believed that reaction (6) is due to the trace amounts of NO in nitrogen dioxide. Analysis of this scheme shows that the formation of nitroxyl radicals (7) must be autoaccelerated. This was confirmed in further studies.⁵⁶

a. Reactions of UV-irradiated poly(methyl methacrylate) with nitrogen dioxide

Nitrogen dioxide virtually does not react with PMMA. On the other hand, it is known that irradiation of this polymer with UV light causes elimination of the ester groups leading mainly to methyl formate, $HCOOCH_3$, and macromolecular structures containing double bonds in the main chain.⁵⁷ The reaction of nitrogen dioxide with the double bonds formed must initiate free-radical ageing reactions in the polymer.

The formation of paramagnetic species in PMMA containing 0.3 – 0.4 mol kg^{-1} of the $\sim(CH_3)C(COOCH_3)-CH=C(CH_3)-CH_2\sim$ units (produced upon photolysis) under the action of NO_2 has been studied by ESR spectroscopy.⁵⁸ The experimental ESR spectrum of the solid polymer is a superposition of two anisotropic triplets typical of dialkylnitroxyl and acylalkylnitroxyl radicals in the solid phase with low frequencies of rotational motions.^{59, 60} Dialkylnitroxyl macroradicals $R-N(O^{\bullet})-R$ give an anisotropic triplet with $A_{||}^N = 3.2 \pm 0.1$ mT and $g_{||} = 2.0026 \pm 0.0005$, while the triplet corresponding to acylalkylni-

troxyl radicals $RC(=O)-N(O^{\bullet})-R$ is characterised by the parameters $A_{||}^N = 2.1 \pm 0.1$ mT and $g_{||} = 2.0027 \pm 0.0005$. In a benzene solution of PMMA, these radicals exhibit triplet ESR spectra with the parameters $a^N = 1.5 \pm 0.1$ mT, $g = 2.0064 \pm 0.0005$ and $a^N = 0.8 \pm 0.1$ mT and $g = 2.0065 \pm 0.0005$, respectively. The absence of an additional hyperfine splitting in the spectra of these radicals indicates that the carbon atoms neighbouring to the $NO^{\bullet}$ group are tertiary.

The accumulation of dialkylnitroxyl macroradicals occurs without an induction period and its initial rate is proportional to the concentration of nitrogen dioxide in the gas phase.

The kinetics observed shows that the scheme of the formation of dialkylnitroxyl radicals [reactions (1), (6) and (7)] in the liquid phase (see above) is inapplicable to the solid polymer due to the low probability of the encounter of a macroradical with the macromolecular nitroso compound. It was assumed that these radicals are produced as a result of a series of 'pseudocage' reactions such as those shown below:

According to this scheme, the NO_2 group and the free valence are localised on the neighbouring carbon atoms of the primary nitroalkyl radical and can react with each other to produce unstable, four-membered alkoxyalkylnitroxyl radicals, which decompose to give the alkoxy radical and nitroso group at the adjacent carbon atom. Subsequent decomposition of the alkoxy radical macroradical results in an alkyl radical and nitroso compound located in the immediate vicinity of each other. The reaction between them, resulting in the formation of a dialkylnitroxyl macroradical, can be initiated by small-amplitude translational and rotational motions. Acylalkylnitroxyl radicals appear in the reactions of the low-molecular-mass methoxycarbonyl radicals with tertiary nitroso compounds. This reaction scheme ignores concurrent transformations of reactive free radicals, which proceed without formation of nitroxyl radicals. These processes seem to be responsible for the low yield of $R-N(O^{\bullet})-R$ radicals

(about one hundredth of the total number of consumed NO_2 molecules).

The ability of nitro compounds to undergo reduction to nitroso compounds through the stages of formation and decomposition of alkoxyalkylnitroxyl radicals in the liquid phase has been pointed out.^{61–63}

It was also concluded that the reaction between the double bonds of PMMA and NO_2 is accompanied by chain scissions in the macromolecules and elimination of the ester side groups.⁵⁸ In addition, the structure of the nitroxyl macroradicals produced suggests that NO_2 is added not only to the less sterically shielded carbon atom of the double bond, but also to the neighbouring atom. This was also observed in the liquid-phase reaction of methyl methacrylate with nitrogen dioxide.⁶⁴

b. Nitroxyl radicals produced in reactions of nitrogen dioxide with rubbers

As was mentioned in the preceding Section, macromolecular nitroxyl radicals produced in the reactions of NO_2 with the double bonds of polymers are spin labels which carry information on macromolecular dynamics. Knowledge of the formation rules and structure of nitroxyl radicals allows elucidation of the mechanisms of macromolecular transformations in the polymers.

This approach was used⁶⁵ to obtain spin-labelled macromolecules of 1,4-*cis*-polyisoprene (synthetic isoprene rubber, or SKI[®]) and a copolymer of ethylene, propylene and dicyclopentadiene (SKEPT-40[®]). These spin labels were used to study the macromolecular dynamics in solid SKI[®] and the structure of the reaction front during nitration of the polymer.⁶⁶

Nitroxyl macroradicals formed in these polymers at 293 K exhibit nearly identical ESR spectra. The ESR spectrum of nitroxyl radicals in SKI[®] recorded at 298 K is shown in Fig. 1*a*. It is an anisotropic triplet with $A_{\parallel}^N = 3.10$ mT and $g_{\parallel} = 2.0028 \pm 0.0005$. This indicates that the correlation time, τ_c , of rotational motions at this temperature is longer than 10^{-9} s. As the temperature increases, the spectra become triplets with $a^N = 1.53 \pm 0.03$ mT and $g = 2.0057 \pm 0.0005$ (Fig. 1*b*), which indicates a substantial shortening of the correlation time. The change in τ_c in the temperature interval from 293 to 373 K (Fig. 2) is described by the equation

$$\tau_c = \tau_0 \exp\left(\frac{E}{RT}\right),$$

where $\log \tau_0 = -14.2$ and E is the activation energy for rotational diffusion (34.7 kJ mol⁻¹).

These values are close to the corresponding values determined for SKI[®] using a bulky spin probe.⁶⁷

Studies on the kinetics of the formation of nitroxyl radicals in solid elastomers showed that free-radical transformations of double bonds in the presence of nitrogen dioxide differ fundamentally from analogous liquid-phase reactions.⁵⁶

Figure 1. ESR spectra of nitroxyl macroradicals produced in the reaction of nitrogen dioxide with SKI[®]-3M at 293 (*a*) and 373 K (*b*).

Figure 2. Temperature dependence of the correlation time τ_c of rotational diffusion of SKI[®] macromolecules measured using spin labels obtained in the reaction of polyisoprene with nitrogen dioxide.

The changes in the concentration of nitroxyl radicals as functions of the nitration time of SKI[®] at different concentrations of nitrogen dioxide in the gas phase are shown in Fig. 3*a*. As in the case of PMMA, these radicals are formed in an NO_2 - N_2O_4 atmosphere without an induction period and the initial rate of formation is proportional to the concentration of nitrogen dioxide. Initially, the concentration of radicals increases and reaches a maximum value at $[\text{NO}_2] = (7-8) \times 10^{-4}$ mol litre⁻¹ and then decreases. It was assumed that this shape of the kinetic curves is due to the loss of nitroxyl radicals in the trapping reactions and in the redox reactions involving the nitrogen dioxide dimer.

A long induction period is observed in the presence of O_2 in the gas mixture (Fig. 3*b*, curve 2). The apparent accumulation rate of radicals to the end of this period is 50 to 60 times lower than that in the absence of oxygen at the same NO_2 concentration; however, the amount of radicals accumulated is three times as large as that

Figure 3. Kinetic curves of accumulation of nitroxyl macroradicals in SKI[®] exposed to NO_2 (*a*) and an NO_2 - O_2 mixture (*b*); (*a*): $[\text{NO}_2]$ /mol litre⁻¹: 2.2×10^{-3} (1), 7×10^{-4} (2) and 10^{-5} (3); (*b*): kinetic curve (1) and the initial portion of curve 1 (2); $[\text{NO}_2] = 7 \times 10^{-4}$ mol litre⁻¹ and $[\text{O}_2] = 1.2 \times 10^{-2}$ mol litre⁻¹.

accumulated in the former case. It was concluded that in the absence of O_2 nitroxyl macroradicals are formed in two ways. The first mechanism is the same as the liquid-phase one, while the second is a 'pseudocage' mechanism, which predominates if the reaction is carried out in the absence of oxygen. In the presence of O_2 , 'pseudocage' reactions are inhibited due to the conversion of initially formed nitroalkyl macroradicals into nitroperoxide radicals. From these data it also follows that the recombination of nitroxyl macroradicals with nitroalkyl and allylic macroradicals in the absence of O_2 must lead to gradual cross-linking of the SKI[®] macromolecules.

Similar kinetics of accumulation of nitroxyl macroradicals was also observed for SKEPT-40[®], which differs from SKI[®] by a substantially lower proportion of double bonds.

The mechanism of formation of nitroxyl radicals in these polymers by the 'pseudocage reactions' is in essence the same as that in the case of PMMA containing double bonds. Alkoxyl macroradicals produced in the 'pseudocage reactions' cause degradation of polymers, while recombination of nitroxyl radicals with nitroalkyl radicals leads to cross-linking of the elastomer.

Reactions of NO_2 with solid polymers can be considered as the interaction between the molecules diffusing from the gas phase and reacting in the bulk of the polymer. In this case, a non-uniform distribution of the reaction front in the bulk of the polymer must be present. The method of ESR tomography (or the ESR imaging technique),^{68–70} which has been rapidly developed recently, allows determination of the spatial distribution of paramagnetic species. In the case of reaction of NO_2 with the double bonds of elastomers, the spatial distribution of nitroxyl macroradicals characterises the structure of the reaction front during nitration of the polymers.

The results of investigations of the reactions of SKI[®] with NO_2 and NO_2 – O_2 mixtures by ESR tomography have been reported.⁶⁶ The spatial distributions of nitroxyl macroradicals in the initial and deep stages of the nitration of SKI[®] by a NO_2 – N_2O_4 mixture are shown in Fig. 4a and Fig. 4b, respec-

tively. As can be seen, after the initial 2.5 h the reaction front penetrates the surface of the polymer to a depth of ~ 1 mm. The interior of the sample is inaccessible to nitrogen dioxide. As the reaction time is extended to 740 h, the depth of the reaction zone increases only by 20% to 30%. The extent of the reaction is maximal in the near-surface layer and decreases as the reaction front moves deeper into the sample. The results obtained show that the initial structure of the reaction front is due to the penetration of NO_2 into the bulk of the sample along pores, cracks, sites with low local density and that further propagation of the reaction front is very slow. Studies of the rates of diffusion of the low-molecular-mass radical (2,2,6,6-tetramethyl-4-oxopiperidinoxyl) from the gas phase into the bulk of an SKI[®] sample nitrated for different periods of time showed that nitration was accompanied by the efficient formation of a three-dimensional network structure, which precludes the diffusion of low-molecular-mass compounds into the sample.

When an SKI[®] sample is exposed to an NO_2 – N_2O_4 – O_2 mixture, the limitations on diffusion due to the changes in the structure of the polymer must diminish since the concentration of cross-links decreases in the presence of oxygen. Therefore, one could expect a greater depth of the reaction zone and a more uniform distribution of nitroxyl macroradicals in the bulk of the polymer. In fact, the distribution of nitroxyl macroradicals in the bulk of the sample and its change during nitration of the samples with an NO_2 – O_2 mixture (Fig. 4c,d) are similar to those for the sample exposed to an NO_2 – N_2O_4 mixture, but the reaction zone penetrates the sample to a smaller depth. This can likely be rationalised by the fact that the structure of the reaction front is due to the membrane-like type of the process.⁷¹ Under these conditions, the propagation velocity of the reaction front is determined by the consumption rate of nitroalkyl macroradicals: the higher the consumption rate, the smaller the depth to which the reaction front penetrates. Introduction of O_2 into the system causes an increase in the consumption rate of nitroalkyl radicals, thus decreasing the depth of the reaction front. Thus, the results obtained by ESR tomography showed that if rubbers are exposed to high NO_2 concentrations, the degradation and cross-linking of macromolecules occur in the narrow (of the order of 1 mm thick) surface layer and that no modification occurs in the bulk of the polymer sample for long.

4. Reactions of nitrogen dioxide with polyamides, polyurethanes and polyamidoimides

a. Effect of nitrogen dioxide on aliphatic polyamides

Polymers containing amide and urethane groups form a particular class of materials sensitive to NO_2 . Jellinek *et al.*^{72,73} showed that exposure of nylon-66 films of different morphology to NO_2 (2.6×10^{-5} to 10.4×10^{-5} mol litre⁻¹) causes main-chain scission in the polymers. The degradation of nylon is a diffusion-controlled reaction. Its rate and depth depend essentially on the degree of crystallinity of specimens and on the size of crystallites. The reaction can be inhibited by small amounts of benzaldehyde or benzoic acid. The degradation is accelerated in the presence of air and UV light in addition to NO_2 . It is believed that benzoic acid blocks the amide groups and that only a few of them, not involved in hydrogen bonding, enter into the reaction. The following mechanism for the polymer degradation under the action of NO_2 was proposed.

Figure 4. Bulk distribution of nitroxyl macroradicals produced upon nitration of SKI[®] by NO_2 with a concentration of 3.8×10^{-4} mol litre⁻¹ (a, b) and a mixture of NO_2 (5.5×10^{-4} mol litre⁻¹) with O_2 (1.5×10^{-3} mol litre⁻¹) (c, d). Nitration time/h: 2.5 (a), 720 (b), 168 (c) and 505 (d). It should be remembered that NO_2 always is in equilibrium with N_2O_4 .

The effect of nitrogen dioxide on nylon fibres has been studied.⁷⁴ It was found that long-term storage of samples in an atmosphere with low NO₂ concentration at room temperature did not lead to their darkening or to a decrease in the tensile strength. These characteristics deteriorated at elevated temperatures. Degradation of nylon fibres irradiated with UV light in air was more pronounced in the presence of nitrogen oxides.

The results of the UV, IR and ESR studies on the ageing of polycapramide (PCA) in a nitrogen dioxide atmosphere have been reported.⁷⁵ The absorption bands in the region of 390–435 nm typical of *N*-nitroso amides were observed in the UV spectra of PCA films stored in an NO₂ atmosphere.⁷⁶ IR studies showed that the intensity of the band at 3293 cm⁻¹ assigned to the stretching vibrations of hydrogen-bonded N–H groups decreases on storage of thin PCA films in an NO₂ (4 × 10⁻⁵ to 4 × 10⁻⁴ mol litre⁻¹) atmosphere. The intensities of the bands at 1642 and 1563 cm⁻¹ also decrease. A band at 1730 cm⁻¹ characteristic of the stretching vibrations of the C=O groups not involved in hydrogen bonding appears instead of these bands, as well as two bands, at 1504 and 1387 cm⁻¹, corresponding to the antisymmetrical and symmetrical stretching vibrations of the –N=O groups of nitroso amides. It was found that under these conditions the initial rate of the nitrosation of PCA is proportional to [NO₂]^{*n*}, where *n* ≈ 2. The formation of the nitroso amide groups can be depicted as follows:

Nitrosation of PCA leads to disappearance of the system of hydrogen bonds, which determines its mechanical properties. After exposure to NO₂, the PCA films degraded at minimum mechanical actions.

White^{77,78} carried out detailed studies of the liquid-phase reactions of low-molecular-mass amides with nitrogen dioxide. He suggested that the action of N₂O₄ used as the nitrosating agent is due to the equilibrium

and that the reaction proceeds by an ionic mechanism. Jellinek *et al.*^{72,73} proposed a free-radical mechanism of the interaction of polyamides with NO₂, which implies the formation of an *N*-nitro amide with a characteristic IR absorption band at 1580 cm⁻¹ as the main product. However, no formation of this product was detected, probably, due to the low proportion of the free-radical reactions in the overall process. The formation of amidyl radicals was confirmed by the accumulation of acylalkylnitroxyl macroradicals (which occurs without induction period, however).⁷⁵ These macroradicals are generated in the reactions

Thus, there are two concurrent mechanisms for the transformation of polyamides in the presence of nitrogen dioxide, namely, the free-radical mechanism with the rate proportional to the concentration of NO₂ and the ionic mechanism, the rate of which is proportional to the square of the NO₂ concentration. The ratio of these processes depends on the concentration of nitrogen dioxide in the gas phase. Therefore, linear extrapolation of the results obtained under the conditions of accelerated tests cannot be used for predicting the stability of polyamides.

b. The effect of nitrogen dioxide on polyvinylpyrrolidone

Polyvinylpyrrolidone (PVP) is a carbon-chain polymer containing a tertiary amide group in the pendent ring.

The interaction of PVP with NO₂ has been described.⁷⁵ Two absorption bands, at λ_{max} = 413 and 435 nm, were observed in the UV spectra of products of the reaction of NO₂ with PVP. As in the case of PCA, these peaks can be assigned to the absorption of the nitroso amide groups N(NO)–C(=O)–(CH₂)₃ formed in PVP due to the elimination of the side cyclic fragments.

X is a free radical.

ESR studies of the reaction of NO₂ (10⁻⁴ to 10⁻³ mol litre⁻¹) with PVP revealed two additional mechanisms for the transformation of the polymer.

The ESR spectrum of paramagnetic species formed in this polymer (Fig. 5) is a superposition of the signals of iminoxyl and acylalkylnitroxyl radicals with the parameters *A*_{||}^N = 4.33 mT, *A*_⊥^N = 2.44 mT, *g*_{||} = 2.0029 and *g*_⊥ = 2.0053 and *A*_{||}^N = 1.94 mT and *g*_{||} = 2.003, respectively.

The iminoxyl radicals are produced as follows. Nitric oxide recombines with (R¹)[•] to give nitroso compounds which undergo

Figure 5. The ESR spectrum of paramagnetic species formed in the reaction of PVP with nitrogen dioxide. The low-field component of the hyperfine structure of acylalkylnitroxyl macroradicals is shown by an arrow.

isomerisation into oximes to produce iminoxyl radicals in the reaction with NO_2

Nitrous acid is the source of nitric oxide in the system

The formation of acylalkylnitroxyl radicals can be represented as follows.

It was found that the kinetics of the accumulation of iminoxyl and acylalkylnitroxyl radicals are different. The concentration of iminoxyl radicals increases initially (the rate of accumulation decreases with time), reaches a maximum value and then decreases. The accumulation of acylalkylnitroxyl radicals occurs initially in an autoaccelerated manner and then the rate of the process decreases and the concentration of the radicals reaches a constant value. This indicates that nitrogen-containing radicals are produced from different precursors following reactions with different rate-limiting stages. It was found that the structure and properties of the matrix affect the relative rates of the formation of nitrogen-containing radicals in PVP samples filled with aerosil.⁷⁹

Thus, one can conclude that the presence of tertiary amide groups in the monomer units of PVP leads to weakening of the C–H bonds in the >CH- and $-\text{CH}_2-$ groups neighbouring to the nitrogen atom. Nitrogen dioxide can abstract hydrogen atoms from these groups with ease to produce macroradicals which decompose with the cleavage of the C–C bonds in the β -position to the free valence. Alkyl macroradicals also recombine with nitrogen oxides to give nitrites, nitrates and nitroso compounds and then nitroxyl macroradicals. Trapping of the alkyl macroradicals $(\text{R}^1)^{\bullet}$ and $(\text{R}^2)^{\bullet}$ by the nitroso compounds and nitroxyl radicals must be accompanied by cross-linking of the macromolecules.

c. Reactions of NO_2 with polyurethanes

Jellinek *et al.*^{80,81} studied the effect of NO_2 on films of linear polyurethane (PU) synthesised from tetramethylene glycol and hexamethylene diisocyanate. It was found that the degradation of PU is accompanied by cross-linking of macromolecules and that the degree of degradation and the yield (the weight percentage) of the gel fraction are complex functions of the exposure time. For instance, the yield of the gel fraction initially increases up to 20% and then decreases down to nearly zero at 333 K and a NO_2 concentration of 10^{-3} mol litre⁻¹. The number of chain scissions in the sol fraction (*i.e.*, the degree of degradation) increases initially, then decreases and eventually increases again; however, the final degradation rate is lower than the initial one. Exposure of

the PU films to NO_2 is accompanied by evolution of CO_2 , which is a monotonic function of the exposure time. The IR spectra of the films allow assessment of the consumption of the NH bonds ($\nu = 3300$ cm⁻¹).

The reaction mechanism proposed by Jellinek *et al.*^{80,81} involves the abstraction of hydrogen atoms from two types of structures, namely, a carbamate structure (A) and a tertiary amido structure (B)

where Z is a side alkyl group, as the initial step. The mechanism involves the following main stages:

According to Jellinek, recombination of the $(\text{R}^1)^{\bullet}$ and $(\text{R}^2)^{\bullet}$ radicals leads to cross-linking of the polymer chains, while decomposition of the $(\text{R}^1)^{\bullet}$ radicals results in the degradation of macromolecules and evolution of CO_2 . Energetically, the decomposition of the $(\text{R}^1)^{\bullet}$ radicals seems to be hardly probable since this reaction results in the terminal macroradical $(\text{R}^3)^{\bullet}$ and a nitrene, which is a very reactive species. On the other hand, more probable decomposition reactions of $(\text{R}^1)^{\bullet}$ involving cleavage of the C–C or C–O bonds produce no alkoxy carbonyl macroradicals $(\text{R}^3)^{\bullet}$, which can undergo decarboxylation (see Ref. 82). Taking into account the mechanisms of the reaction of nitrogen dioxide with aliphatic polyamides and PVP, the ageing of PU in an NO_2 atmosphere can be represented as follows:

$i = 1-4$.

This scheme allows a rationalisation of the degradation accompanied by cross-linking of macromolecules, the consump-

tion of NH groups of the polymer as well as the evolution of carbon dioxide upon degradation.

d. The reaction of NO₂ with a polyamidoimide

The effect of NO₂ on the mechanical properties of a polyamidoimide (PAI) obtained by the polycondensation of chloroformylphthalic anhydride with 4,4'-diaminodiphenyl ether has been studied.⁸³ The experiments were carried out at 323 K and an NO₂ concentration of 5×10^{-3} mol litre⁻¹ and involved the measurements of the temperature dependence of the storage modulus E' and the loss modulus E'' for different exposure times of the PAI samples to NO₂. At 473 K, the parameter E' revealed a non-monotonic decrease and the strongest temperature dependence. An increase in E' at the glass transition temperature (~ 563 K) was observed for the films exposed to NO₂ over a period of eight days. When studying the temperature dependences of the loss moduli E'' of the films exposed to NO₂ for different times, an absorption peak was found to appear at 473 K, which indicates degradation of polymers. All these facts were associated with degradation accompanied by cross-linking of macromolecules.

A decrease in the band intensities of the stretching vibrations of the N–H bonds and the appearance of the peaks associated with the addition of NO₂ groups to macromolecules was observed in the IR spectra of the PAI films. No reaction mechanisms were discussed.

To elucidate possible reaction mechanisms, we carried out ESR studies of the effect of NO₂ (10^{-3} mol litre⁻¹, at 293 K) on PAI of the same structure as that of the polymer studied by Kambe and Yokota.⁸³ Under these conditions, iminoxyl radicals with the ESR spectral parameters $A_{\parallel}^N = 4.1$ mT, $A_{\perp}^N = 2.1$ mT and $g_{\parallel} = 2.0028$, $g_{\perp} = 2.0058$ are mainly produced in PAI. The proportion of the acylalkylnitroxyl macroradicals which have nearly the same ESR spectral parameters as those of polyamide and are likely produced by the same mechanism [reactions (8) and (9)] is less than 35%. Formation of iminoxyl radicals in this system is quite unexpected. A conventional mechanism of their formation [reactions of the types (10) and (13) in PVP] involves (i) hydrogen abstraction from the CH₂ group of a molecule, (ii) NO addition to the radical produced and (iii) isomerisation of the newly formed nitroso compound into an oxime. Abstraction of labile hydrogen atoms from the oxime molecules by NO₂ results in iminoxyl radicals. Since the PAI molecules contain no CH₂ groups, this mechanism is impossible. It was assumed that the spin density in the amidyl radicals produced is partially delocalised over the phenyl ring, which facilitates cleavage of the polymer ether bond. The following mechanism of the reaction of NO₂ with PAI was proposed.

Decomposition of the radicals (R¹)^{*} leads to the scission of the main chain of PAI, while their reactions with NO₂, as in the case of PCA, result in acylalkylnitroxyl radicals. The reaction of the radicals (R²)^{*} with the phenyl rings of neighbouring macromolecules causes cross-linking of the polymer and the reaction with NO₂ results in the appearance of NO₂ groups in the sample.⁸³

Kinetic curves of the accumulation of the iminoxyl radicals correspond to the following overall reactions

Their transformation in the coordinates of the following equation

$$\ln \frac{[(\text{R}^4)^{\cdot}]_s}{[(\text{R}^4)^{\cdot}]_s - [(\text{R}^4)^{\cdot}]} = \frac{W_0 t}{[(\text{R}^4)^{\cdot}]_s},$$

where $[(\text{R}^4)^{\cdot}]$ and $[(\text{R}^4)^{\cdot}]_s$ are the current and steady-state concentrations of the radicals, respectively, and W_0 is the rate of formation of the iminoxyl radicals, allows the minimum degradation rate of the polymer, W_d , to be determined from the accumulation of the iminoxyl radicals; W_d was found to be 10^{-8} mol kg⁻¹ s⁻¹. The mechanism proposed allows a rationalisation of the degradation accompanied by cross-linking of the PAI macromolecules as well as the introduction of the NO₂ groups.⁸³

5. On the possibility of polymer degradation resulting from the reaction of nitrogen dioxide with peroxy macroradicals

As was mentioned above, at room temperature nitrogen dioxide can (i) abstract labile hydrogen atoms from macromolecules to produce alkyl or allyl macroradicals and (ii) add to the double bonds, thus producing the nitroalkyl macroradicals. If the reaction is carried out in air, carbon-centred macroradicals are oxidized to give peroxy radicals. Presumably, the reactions of the latter with NO₂ must result in relatively unstable peroxy nitrates, ROONO₂, similarly to the low-molecular-mass radicals $\text{RO}_2^{\cdot}$.^{84–86}

Decomposition of peroxyacetyl nitrate, $\text{CH}_3\text{C}(=\text{O})\text{OONO}_2$, was studied in detail and two mechanisms were considered.^{87,88}

Using the spin trap technique, it was shown that peroxyacetyl nitrate decomposes mainly following reaction (16), which is reverse to the formation reaction of $\text{CH}_3\text{C}(=\text{O})\text{OONO}_2$.⁸⁹ An analogous conclusion was also drawn based on the results of quantum-chemical calculations.⁹⁰ Stabilities and transformation mechanisms of other low-molecular-mass peroxy nitrates have been much less studied.

The thermal stability of products of the reactions of NO_2 with internal $\sim\text{CF}_2\text{CF}(\text{OO}^\bullet)\text{CF}_2\sim (\text{R}_{\text{in}}\text{O}_2^\bullet)$ and terminal $\sim\text{CF}_2-\text{CF}_2-\text{OO}^\bullet (\text{R}_{\text{t}}\text{O}_2^\bullet)$ peroxy macroradicals of poly(tetrafluoroethylene) (PTFE) produced under the action of penetrating radiation or UV light in an O_2 atmosphere was studied by ESR spectroscopy.⁹¹ These macroradicals are stable at $T \leq 333$ K but can enter into reactions with nitrogen dioxide.

If the reaction of the type (16) is the only way of the transformation of peroxy nitrates into PTFE, complete regeneration of the initial peroxy macroradicals must be observed *in vacuo*. The alkoxy macroradicals produced by the reaction (17) can undergo effective decomposition accompanied by scission of the main chain of the polymer.⁹² For instance,

The reaction of terminal alkyl macroradicals with NO_3 or NO_2 results in the formation of stable products and in a decrease in the degree of regeneration of $\text{RO}_2^\bullet$.

It was found⁹¹ that $\text{R}_{\text{in}}\text{OONO}_2$ do decompose with partial regeneration of $\text{R}_{\text{in}}\text{O}_2^\bullet$ at room and elevated temperatures. At 298 K, the peroxy nitrate molecules which undergo dissociation are kinetically inequivalent. At 313 K, they undergo a unimolecular decomposition with a rate constant of the reaction of the type (16), $4.0 \times 10^{-4} \leq k_{16} \leq 4.8 \times 10^{-4} \text{ s}^{-1}$ (Fig. 6a), which is

independent of either $[\text{R}_{\text{in}}\text{O}_2^\bullet]_0$ or the exposure time (t^*) of the samples to nitrogen dioxide. The effective constant k_{16} obtained is about three orders of magnitude smaller than the rate constant for decomposition of $\text{CClF}_2\text{O}_2\text{NO}_2$.⁹³ This seems to be due to the low probability of the escape of NO_2 molecules from the 'cage' in the solid phase. However, the t^* value determines the limiting concentration of regenerated peroxy macroradicals, $[\text{R}_{\text{in}}\text{O}_2^\bullet]_\infty$ (Fig. 6b)

$$[\text{R}_{\text{in}}\text{O}_2^\bullet]_\infty = \frac{k_{16}}{k_{16} + k_{17}} [\text{R}_{\text{in}}\text{O}_2^\bullet]_0 \exp(-k_{\text{ef}} t^*),$$

where k_{ef} is the effective rate constant for various conversions of peroxy nitrate exposed to NO_2 including those involving alkoxy macroradicals. It was found that $k_{17} < k_{\text{ef}} < 7.6 \times 10^{-5} \text{ s}^{-1}$, i.e., the rate constant of a reaction of the type (17), which can result in degradation of the PTFE macromolecules, does not exceed $\sim 20\%$ of k_{16} .

Unexpected results were obtained in studies of the thermal stability of the reactions products of $\text{R}_{\text{t}}\text{O}_2^\bullet$ with nitrogen dioxide. Heating of samples *in vacuo* at temperatures up to 413 K did not lead to production of free radicals. This can be due to either the fact that no peroxy nitrates are formed in this case or to the fact that the reaction proceeds through a six-membered cyclic transition state and results in the fast formation of stable products.

Thus, if a polymer containing rather stable peroxy radicals (e.g., PTFE) is exposed to high concentrations of nitrogen dioxide for long, the second decomposition route of peroxy nitrate [reaction of the type (17)] can lead to a high degree of degradation of the polymer due to the irreversibility of reaction (18) despite the fact that the corresponding rate constant is five or more times smaller than that typical of the first decomposition route [reaction of the type (16)].

III. The effect of nitric oxide on polymers

Nitric oxide is less reactive than nitrogen dioxide. Currently, it is known with certainty that at room temperature nitric oxide cannot abstract tertiary or allylic hydrogen atoms from organic molecules, since the $\text{H}-\text{NO}$ bond with a strength of $208.6 \pm 2.1 \text{ kJ mol}^{-1}$ is weaker than the $\text{C}-\text{H}$ bonds in organic compounds. Nitric oxide cannot also add to isolated double bonds.⁹⁴⁻⁹⁶ Opinions differ widely as to the ability of NO to react with low-molecular-mass dienes and polyenes. It is known that NO can add to substituted *o*-quinodimethane, phorone and β -carotene to produce free radicals.⁹⁷⁻⁹⁹ It is also believed that the reactions of NO with dienes are actually initiated by admixtures of NO_2 .⁹⁶ In any case, it is of interest to study the regularities of the reaction of nitric oxide with the ageing products of polymers, e.g., hydroperoxides.^{100,101} In addition, NO readily reacts with free radicals to give nitroso compounds, which are efficient spin traps for the free radicals. Analysis of the kinetic curves of the formation and the structures of nitrogen-containing radicals which are stabilised in this case makes it possible to draw conclusions on the mechanisms of free-radical processes in the polymers.

1. Photolysis and radiolysis of poly(methyl methacrylate) and cellulose triacetate in the presence of nitric oxide

Photolysis of PMMA exposed to NO leads to the formation of stable nitrogen-containing radicals. The structures of the radicals formed depend on the temperature and the wavelength of the photolysing light.¹⁰² For instance, acylalkylnitroxyl radicals, $\text{R}^1\text{N}(\text{O}^\bullet)\text{C}(=\text{O})\text{OR}^2$, are produced upon photolysis of PMMA by unfiltered light of a mercury lamp at 298 K. In solid PMMA, they exhibit an anisotropic triplet ESR spectrum with $A_{\parallel}^{\text{N}} = 2.1 \pm 0.1 \text{ mT}$ and $g_{\parallel} = 2.0027$ (Fig. 7a). In a solution of the polymer, the parameters of the ESR spectrum of these radicals are $a^{\text{N}} = 0.8 \pm 0.1 \text{ mT}$ and $g_{\parallel} = 2.0065$. Not only acylalkyl, but also dialkylnitroxyl radicals, $\text{RN}(\text{O}^\bullet)\text{R}$, are produced in the samples photolysed at 383 K. The latter exhibit the ESR spectra

Figure 6. Kinetic curve of regeneration of $\text{R}_{\text{in}}\text{O}_2^\bullet$ radicals after exposure of PTFE to NO_2 ($2.8 \times 10^{-3} \text{ mol litre}^{-1}$) for 1.5 h (a) and the limiting degree of regeneration of $(\text{R}_{\text{in}}\text{O}_2^\bullet)_\infty$ radicals as a function of the time of preliminary exposure of sample t^* to NO_2 ($7 \times 10^{-3} \text{ mol litre}^{-1}$) (b). Kinetic curve (1) and semilogarithmic transformation of curve 1 (2).

the case of γ -radiolysis of PTFE in oxygen-containing atmosphere, a certain fraction of internal alkyl macroradicals has no time to be oxidised and undergoes decomposition accompanied by scission of the main chain of the polymer.

The terminal alkyl groups are oxidised into terminal peroxide groups so that the neighbouring terminal peroxy macroradicals and terminal double bonds are stabilised in the polymer. After exposure of such samples to NO, the peroxy radicals can be converted as follows:

Terminal alkyl macroradicals recombine with NO to produce terminal nitroso groups neighbouring to the terminal double bonds, which interact with terminal nitrosyl fragments to generate nitroxyl macroradicals

It was found¹⁰⁷ that low-molecular-mass perfluoroalkenes of different structures as well as hydrogen- or fluorine-containing nitroso compounds can enter in these reactions. Similar radicals were also produced in the copolymer of tetrafluoroethylene with hexafluoropropylene.¹⁰⁶ This copolymer was used to generate yet another type of radicals, namely, $\sim\text{CF}_2\text{N}(\text{O}')\text{CF}_3$, with an ESR spectrum consisting of eight HFS components split by 0.88 ± 0.02 mT and $g = 2.0067$. These parameters nearly coincide with the corresponding values for low-molecular-mass perfluoro-nitroxyl radicals of a similar structure in the liquid phase.¹⁰⁷ The pattern of the ESR spectrum of the internal nitroxyl macroradical is due to partial averaging of the anisotropy of HFS and g -factor owing to fast rotation of the nitroxyl fragment about the long axis of the macromolecule. The mobility of the radical fragment in terminal nitroxyl radical is much higher, which in fact is responsible for a complete averaging of the anisotropy of the hyperfine interaction and g -tensors in its ESR spectrum.

Thus, thermally stable spin-labelled macromolecules are generated in the bulk of the samples as a result of post-radiation, free-radical transformations in fluorinated polymers exposed to NO. Their concentration is sufficiently high to allow the ESR studies on molecular dynamics in polymers. The advantage of this method for the introduction of a spin label is that the free-radical (nitroxyl) group can be introduced into various chain fragments, which allows one to obtain optimum information on the macromolecular dynamics.

3. Interaction of polypropylene hydroperoxides with nitric oxide

Polymeric hydroperoxides are reactive intermediates in the oxidative degradation of polymers. Investigations of the reactions of nitrogen oxides with these species furnishes insights into the mechanisms of the effect of air pollutant gases on the stabilities of polymeric materials. For instance, autoaccelerated degradation of PS macromolecules subject to the combined action of NO₂, air and UV radiation was associated with the NO-induced decomposition of hydroperoxides.⁴⁷ It is believed (see, *e.g.*, Refs 100 and 108) that the process begins with the reaction

Figure 9. Kinetic curves of consumption of PP hydroperoxides at NO concentrations (in the gas phase) of 1.6×10^{-3} (1), 3.2×10^{-3} (2) and 4.1×10^{-2} mol litre⁻¹ (3).

It was also assumed (see Ref. 101) that the reaction proceeds to give the peroxy radicals.

At high concentrations of hydroperoxides, NO-induced decomposition of their dimers was postulated for the liquid phase.¹⁰⁸

The decomposition kinetics of PP-derived hydroperoxides at 298 K and different NO pressures has been studied in detail.¹⁰⁹ The kinetic curves for decomposition of hydroperoxides are shown in Fig. 9. As can be seen, the rate of hydroperoxide consumption is initially low and then increases substantially. Reactions (19)–(21) cannot provide an explanation for this type of reaction kinetics. Using ESR spectroscopy, it was found that the decomposition of hydroperoxides is accompanied by accumulation of dialkylnitroxyl macroradicals and that the induction period is long. The duration of the induction periods for the decomposition of hydroperoxides and the formation of nitroxyl macroradicals increases as the concentration of nitric oxide in the gas phase decreases and is dependent on the presence of trace amounts of impurities (in particular, NO₂) at a given NO concentration. It was concluded that the primary step in the decomposition of hydroperoxide is initiated by N₂O₃ rather than NO.

This reaction results in a thermally unstable peroxy nitrite, which can either undergo a fast 'intracage' conversion into nitrate

or decompose into alkoxy macroradical and nitrogen dioxide, which then pass in the bulk of the sample. In turn, the alkoxy radicals can either decompose or enter into substitution reaction, thus producing internal (R'_{in}) and terminal (R'_{t}) alkyl macroradicals and low-molecular-mass alkyl radicals r' (see Ref. 100). These radicals react with NO to give nitroso compounds.

Acceleration of peroxide decomposition can be associated with the reactions which involve nitroso compounds¹¹⁰

Alkyl radicals formed in the system can initiate decomposition of hydroperoxides.

Yet another process which can be responsible for the increase in the hydroperoxide decomposition rate is disproportionation of NO into N₂ and NO₃ in the reactions with the nitroso compounds.⁹⁴

The ONO₂ radical is a highly reactive species (the O₂NO—H binding energy is 423 kJ mol⁻¹, see Ref. 111), which can abstract hydrogen atoms from the PP macromolecules, thus increasing the concentration of free radicals in the polymer

and also reacts with NO

which results in an increase in the concentration of nitrogen dioxide.

Thus, taking PP as an example, it was found that decomposition of hydroperoxides in an atmosphere of NO is initiated by higher nitrogen oxides and proceeds by an autocatalytic mechanism.

In an atmosphere polluted with nitrogen oxides, the primary step of the decomposition of hydroperoxides can be their nitrosation by the dimeric form of nitrogen dioxide, the concentration of which is much higher than that of nitrous anhydride N₂O₃. On account of the great excess of oxygen compared to nitrogen oxides, the probability of the formation of nitroso compounds, which play the key role in the development of autoaccelerated reaction under the conditions used by Gaponova and Pariiskii,¹⁰⁹ must be rather low in a polluted atmosphere due to the oxidation of alkyl radicals into peroxy radicals. Investigation of the ROOH—NO system showed¹⁰⁹ that the results obtained under conditions of accelerated tests must be used with great caution when assessing the stability of polymers in atmosphere polluted with nitrogen oxides.

IV. Conclusion

The results summarised in this review show that nitrogen dioxide, which is an inorganic free radical of moderate reactivity, can perform some functions in the ageing of polymers in polluted atmosphere. On the one hand, at ambient temperatures it can abstract labile hydrogen atoms (tertiary hydrogen atoms in PS and polyvinylpyrrolidone and allylic hydrogen atoms in the polymers containing carbon—carbon double bonds in the main chain) and add to the double bonds of macromolecules, thus generating free radicals and, hence, initiating free-radical ageing processes in the system. At elevated temperatures ($T \geq 373$ K), NO₂ also reacts with stronger C—H bonds, e.g., in the CH₂ groups of polymers. On the other hand, it can react with alkyl, alkoxyl and peroxy macroradicals generated in the reactions, thus inhibiting free-radical transformations of polymers and resulting in valence-saturated products of different thermal stabilities.

The dimer of nitrogen dioxide, N₂O₄, is an efficient nitrosating agent and its reactions are responsible for the ageing of the polymers containing amide groups (polyamides, polyurethanes and polyamidoimides). Free-radical reactions initiated by NO₂ are accompanied by production of stable nitrogen-containing radicals. Analysis of their structures and kinetics of formation provides additional information on the free-radical stages of complex processes of nitration of polymers under various conditions.

Nitric oxide, NO, is also a paramagnetic molecule, which is much less reactive than nitrogen dioxide. At ambient temperatures, it cannot abstract even the most mobile (labile) hydrogen atoms from the molecules of organic compounds or add to isolated double bonds to produce free radicals. In addition, it is an efficient acceptor of free radicals which can inhibit free-radical chain reactions. Nitroso compounds formed in the reactions with alkyl radicals are efficient spin traps and can in turn inhibit free-radical processes in polymers. However, at high NO pressures their reactions with nitroso compounds lead to disproportionation of NO into N₂ and ONO₂, which is a reactive radical capable of initiating free-radical processes in polymers. This reaction seems to be the stage responsible for autoaccelerated decomposition of hydroperoxides in an atmosphere of nitric oxide.

Free radicals in solid polymers can be generated by photolysis, γ -radiolysis, thermal decomposition of initiators etc. Free-radical processes in solid polymers carried out in an atmosphere of NO are accompanied by production of nitrogen-containing macroradicals of different structures. Analysis of their structures and kinetics of formation allows one to obtain additional information on the mechanisms of the above-mentioned processes. Performing free-radical reactions in chemically inert, insoluble polymers [e.g., poly(perfluoroalkenes)] in an atmosphere of nitric oxide makes it possible to prepare spin-labelled macromolecules with either internal or terminal NO[•] groups. These spin labels perturb the polymer chain dynamics to the smallest extent and are therefore the most appropriate for using in the ESR studies.

Abstract. Data on tandem transformations initiated by the Michael reaction published over the last five years are analysed, systematised and generalised. The bibliography includes 86 references.

I. Introduction

Syntheses of polyfunctional organic compounds with complex structures from simpler compounds by tandem one-pot transformations were described in a series of reviews (see, for example, Refs 1–6). Tandem transformations are multistep transformations in which each subsequent step is strictly determined by the preceding one and occurs under the same reaction conditions. The advantage of these transformations is the formation of several bonds and complication of the structure of the compound in one step, which is generally accompanied by the high stereoselectivity of the reaction. Minimisation of waste products, a decrease in the amount of required solvents, reagents and adsorbents, reduction in the energy and a decrease in the number of laboratory operations provide the economic and ecological feasibility of this type of processes.

According to the mechanism of the first step, tandem conversions are divided into cationic, anionic, radical, pericyclic, photochemical and transition-metal-induced processes. The terms 'tandem', 'cascade' and 'domino' reactions are used as synonyms.

Most tandem transformations proceed through the formation of an anionic intermediate. This first step governs the subsequent transformations. Most often, deprotonation of the CH group of

the substrate occurs giving rise to a carbanion followed by its reaction with an electrophile to form a new anionic intermediate. This anion can attack another electrophilic centre, *etc.* The sequence is completed with trapping of an electrophile (for example, H^+) or elimination of the leaving group X^- .

In many cases, anionic transformations are either initiated or governed by the Michael reaction. In the present review, most attention is given to this type of transformation studied in recent years.[†]

II. A tandem Michael reaction

One of the approaches which is most popular for the formation of C–C bonds is based on the Michael reaction involving compounds containing an activated methylene group and α,β -unsaturated esters or ketones. A combination of two consecutive Michael addition reactions has considerable promise for the efficient construction of cyclic and polycyclic compounds because the second addition reaction often results in ring closure. This type of transformation is named the Michael Ring Closure (MIRC) or the Michael-Michael Ring Closure (MIMIRC).² Of all tandem transformations, a combination of two Michael reactions has been described in most detail. The examples considered below clearly demonstrate the importance of this approach in synthetic organic chemistry.

In studies of intramolecular double Michael addition reactions, a series of polycyclic structures were prepared⁷ which served as the basis for the total synthesis of some natural compounds. The total synthesis of a sesquiterpenoid fungicide ($\pm$)-culmorin (**1**) was developed.⁸ The tricyclo[6.3.0.0^{3,9}]undecan-10-one skeleton of **1** was constructed in one step by intramolecular cyclisation of 4-substituted cyclopent-2-enone **2** according to a scheme of double conjugate addition.

LHMDS is lithium hexamethyldisilazide.

The same strategy was used for the preparation of sesquiterpenoids ($\pm$)-8,14-cedranediol (**3**) and ($\pm$)-8,14-cedrane oxide (**4**) based on 5-substituted cyclopent-2-enone **5**.^{9, 10}

TMSCl is trimethylsilyl chloride.

The total synthesis of alkaloid cylindricine A (**6**) of animal origin, which was first isolated from ascidia in 1993, was performed.¹¹ The Michael addition of ammonia to the conjugated diene system of the ketone **7** afforded the key synthon, *viz.*, perhydroquinolinone **8**. Its subsequent reaction with *N*-chlorosuccinimide and radical cyclisation gave rise to a 55 : 45 mixture of cylindricine A (**6**) and its epimer, which could be readily separated.

The total synthesis of alkaloid cylindricine C (**9**) related to compound **6** was performed in two steps¹² starting from the azide **10**. Selective reduction of the azide in the presence of the diene system was carried out with the use of CrCl_2 . The resulting amine entered into the highly convergent and efficient double Michael addition reaction.

TBS is the *tert*-butyldimethylsilyl group, TBAF is tetrabutylammonium fluoride.

The synthetic potential of enamines in a two-step process involving the Michael addition followed by cyclisation has been examined.¹³ Readily accessible 1-aza-1,3-butadienes (enamines) **11** and **12** reacted with methyl acetoacetate and acetylacetone in the presence of catalytic amounts of LiI to form unsymmetrically substituted 1,4-dihydropyridines **13** or cyclohexenone derivatives **14**.

The reaction pathway depends on the structure of the enamine used. The reaction of methyl acetoacetate with *N*-benzylenamines of type **11** gives rise to 1,4-dihydropyridine derivative **13**. If the benzyl group in the acceptor is replaced by the *tert*-butyl group (compound **12**), the reaction follows another pathway to form the cyclohexenone derivative **14**. In these reactions, either two (path *a*) or three (path *b*) carbon atoms of the 1,3-dicarbonyl compound are involved in the formation of the six-membered ring.

$\text{R}^1 = \text{Alk}$, Ar ; $\text{R}^2, \text{R}^3 = \text{H}$, Alk .

This divergence was not observed in the reactions of enamines **11** and **12** with dimethyl 3-oxoglutarate. Both enamines formed derivatives of bicyclo[3.3.1]nonan-3-one **15**.

$\text{E} = \text{CO}_2\text{Me}$; $\text{R}^1, \text{R}^2 = \text{H}$, Alk , Ar ; $\text{R}^3 = \text{CH}_2\text{Ph}$ (**11**), Bu^t (**12**).

This result indicates that two molecules of the oxo diester are involved in the reaction. When the diester and enamine were taken in a ratio of 2 : 1, the product **15** was obtained in higher yield. The possible mechanism of transformation involves the formation of the intermediate **A**, which enters into the second Michael reaction followed by cyclisation.

The double Michael addition makes it possible to construct the bicyclo[2.2.2]octane skeleton of many natural compounds based on oxophorone (**16**) and its derivatives.¹⁴ The reactions of oxophorone enolates with α,β -unsaturated carbonyl compounds **17** gave rise to the intermediate **A**, which underwent 6-*endo-trig* cyclisation following the path *a* to form the only product **18**. The isomer **19**, which could be formed in the case of the path *b*, was not detected.

The double conjugate addition of enones **20** to fulvene (**21**) offers a convenient approach to tricyclo[5.3.0.*n*^{2,5}]alkane systems.¹⁵ The dienolate anion generated from enone enters into the Michael reaction with fulvene to give an anionic intermediate. The latter undergoes cyclisation as a result of the intramolecular Michael reaction giving rise to tricyclic ketone **22** or **23** with high stereoselectivity. The reaction is particularly efficient with the use of cyclopentenone as the Michael acceptor. In the latter case, tricycloalkanes are obtained in 75%–96% yields.

R¹, **R**² = H, Alk; *n* = 1–3; LDA is lithium diisopropylamide.

The new method for the construction of polyfunctional cyclic compounds containing several substituents developed by Grossman *et al.*^{16–19} is based on the use of the double Michael reaction of carboxylates **24** with but-3-yn-2-one.

Y, **Z** = CN, CO₂Et; *n* = 0, 1.

Cyclic products **25** are convenient starting compounds for the synthesis of biologically active polycyclic compounds. In particular, the Dieckmann reaction and intramolecular reductive ami-

nation of these compounds afforded *trans*-decalin **26** and *trans*-perhydroisoquinoline **27**, respectively. Three new C–C or C–N bonds, the ring system of bicyclo[4.4.0]decane and up to four new stereocentres can be constructed starting from two readily accessible acyclic compounds.

Tandem reactions giving rise to angular polyquinanes were reported.²⁰ The derivative of squaric acids, *viz.*, *cis*-13-methyltricyclo[10.3.0.0^{4,9}]pentadeca-4(5),12(13)-diene-3,14-dione (**28**), was involved in intramolecular cyclisation initiated by PhS[–]. Enolate **29** formed in the first intermolecular Michael reaction underwent intramolecular transannular cyclisation in the second step to give the angular polyquinane **30**.

The Michael reactions of methyl (chloro)cyclopropylideneacetate (**31**) with cyclic dienolates formed from enones **32** and **33** were studied.²¹ These reactions gave rise to tricyclic adducts **34** and **35**, respectively. It was proposed that the compound **35** can be used as an intermediate in the synthesis of sea diterpenoids, *viz.*, mediterraneols A and B (**36**).

n = 5 (**a**), 6 (**b**), 7 (**c**).

Compound 34	Yield (%)
a	40
b	34
c	78

The methodology of tandem 1,4-inter- and intramolecular addition reactions has been used for the preparation of pyrazolo[1,5-*a*]quinoline ring systems **38** and **39** inhibiting DNA synthesis in bacteria starting from the quinolone **37**.²² The key tricyclic synthons **40a,b** were synthesised by the reactions of the quinolone **37** with different acrylates.

R = Me (a), Bu^t (b).

The double Michael reactions of 1-nitrocyclohexene (**41**) with ynols **42a,b** afforded nitrooctahydrobenzofurans (**43a**) and -pyrans (**43b**), respectively.²³ The possible reaction mechanism involves the addition of the alcohols **42a,b** at the double bond of the cycloalkene **41** and intramolecular cyclisation of the resulting anion **A** via the transition state **B** to give the anionic intermediate **C** containing *cis*-fused rings. Subsequent protonation of the anion **C** affords a mixture of the *E*- and *Z*-isomers **43a,b**.

n = 0 (a), 1 (b); R¹, R² = H, Alk; R³ = OAlk, NMe₂.

The use of terminal alkynes enables one to change the order in which the reagents enter into the reaction. In this case also, the reaction results in a five-membered heterocyclic compound.²⁴ Thus the reaction of acyclic nitroalkene **44** with the ynol **45**

R¹ = Alk; R² = Alk, Ar; R³, R⁴ = H, Alk.

afforded tetrahydrofuran derivative **46**. The aza-Michael addition of *N*-methylprop-2-ynylamine (**47**) to nitroalkenes **44** proceeded regio- and stereoselectively to form 3-methylenepyrrolidines **48**.

A new procedure for the stereoselective preparation of tricyclo[5.3.1.0^{2,6}]undecane-4,11-diones (**49a**) and tricyclo[5.4.1.0^{2,6}]dodecane-4,12-diones (**49b**) is based on the inter- and intramolecular Michael reactions of 1-pyrrolidinocyclohexene (**50a**) and -cycloheptene (**50b**), respectively, with the mesylate **51**.²⁵

R = Alk, Ar; *n* = 1 (a), 2 (b); Ms is mesyl.

Organolithium compounds initiate Michael cyclisation of α,β,ψ,ω-unsaturated bisphosphonates **52**.²⁶ Thus the addition of PhLi to a solution of tetraester **52** afforded cyclic bisphosphonate **53**, which is a product of the tandem Michael reaction.

The reaction of cyclohexane-1,3-dione (**54**) with ethyl acrylate proceeded as an intermolecular double Michael addition.²⁷

In the presence of catalytic amounts of a base, the reaction gave rise to a mixture of two products, *viz.*, **55** and **56**, in a ratio of 3 : 1. The reaction in the presence of an equimolar amount of a base afforded only the monoaddition product **55**. The observed difference can be explained as follows. An appropriate amount of the enolate anion **54'** is generated under the action of catalytic amounts of a base. The Michael reaction of this anion with ethyl acrylate yields the anion **55'** whose intramolecular isomerisation gives rise to the anion **55''**. The latter either undergoes protonation to form the product **55** or enters into the second Michael reaction. The enolate anion **56'** abstracts the labile proton from the diketone **54** yielding the anion **54'** and the diester **56**. As a result, a mixture of the products **55** and **56** is obtained. In the presence of one equivalent of a base, the enolate anion **54'** is formed in quantitative yield. The Michael reaction affords the anion **55'**, which undergoes intramolecular deprotonation–protonation to give the anion **55''** and then exclusively the monoaddition product **55**.

Esters of $\alpha,\beta,\alpha',\beta'$ -dienedioic acids can serve as potential substrates for anionotropic tandem transformations. The intermediate enolate which is generated in the first step of intermolecular conjugate addition of the nucleophile attacks the second α,β -unsaturated ester group according to an intramolecular mechanism. The use of a chiral nucleophile in these tandem conversions allows the preparation of optically active adducts. Thus the reaction of homochiral lithium [(1*R*)-methylbenzyl]benzylamide with dimethyl octa-2,6-dienedioate (**57**) gave rise to chiral cyclopentane derivative **58**, the configurations of the C(1) and C(2) atoms being completely controlled and the configuration of the C(5) atom being controlled to a large degree [the content of the C(5)-epimer **59** was < 5%].²⁸

The reaction of 4,4-dimethoxycyclohexa-2,5-dienone (**60**) with ethyl acetoacetate and acetylacetone proceeded as a tandem

Michael reaction.²⁹ Compounds **61a,b** were formed as a result of successive Michael C- and O-addition.

X = OEt (**a**), Me (**b**).

The bifunctional reagent, *viz.*, 2-bromomethyl-3-phenylsulfonylprop-1-ene (**62**), reacts with different electrophilic alkenes to give [3 + 2]-cycloadducts.³⁰ The use of acyclic (*E*)-enoates in these reactions allows the preparation of stereohomogeneous *trans*, *trans*-trisubstituted methylenecyclopentanones **63** in high yields (90%). The tandem reactions of bromosulfone **62** with α,β -unsaturated esters containing the O atom at the γ position, in particular, with (4*S*)-enoate **64**, also proceeded with good facial selectivity. Subsequent ozonolysis of the alkene **65a** gave rise to enantiomerically pure cyclopentanone **66**.

Abundant data on tandem reactions of 1,6-anhydro-3,4-dideoxy- β -D-glycero-hexopyranos-3-en-2-one, the so-called levoglucosenone (**67**), are now available in the literature (see, for example, Refs 31–33). Interesting conversions take place upon treatment of levoglucosenone with pyrazole under conditions of electrolysis. The first stage involves the cathode-initiated addition of pyrazole followed by the selective addition of yet another molecule **67** to the adduct to form the dimer **68** in quantitative yield.³⁴ Previously, the dimer **68** was obtained in low yield (8%)

along with trimers³³ by heating levoglucosenone in aqueous Et₃N.

The introduction of the halogen atom at position 3 of levoglucosenone extends the possibilities of its tandem transformations. The effects of the temperature and the reagent ratio on the structure of the product were examined using the reaction of sodium ethyl acetoacetate with 3-iodolevoglucosenone (**69**) as an example.³⁵

The reactions with an excess of the ketone **69** (2 equiv.) at room temperature afforded two products, viz., stable oxetene derivative **70** and polycyclic compound **71** containing the cyclobutane fragment. The reaction of equimolar amounts of the reagents at -60°C gave rise to 1:1 adducts **72** and **73**. It should be noted that the reaction of the compound **72** with 3-iodolevoglucosenone in the presence of NaH yielded the adduct **70**.³⁶ The assumed mechanism of conversions is shown in Scheme 1.

The reaction of yet another representative of CH-acids, viz., acetylacetone, with 3-iodolevoglucosenone (**69**) proceeded analogously.

III. Tandem 'Michael reaction – nucleophilic substitution' sequence

As mentioned above, the addition of a nucleophile to an acceptor gives rise to an anionic intermediate, which can act as a new nucleophile. If the molecule of the latter contains a good leaving group X, the subsequent intramolecular nucleophilic substitution can occur.

The procedure 'tandem oxa-Michael addition – intramolecular S_N2'-substitution' was used³⁷ for the efficient and stereo-controlled synthesis of poorly studied allenetetrahydrofurans. Nitrocycloalkenes **74a–c** react smoothly with 4-chlorobut-2-yn-1-ol to give bicyclic adducts **75a–c**. The reaction mechanism is analogous to that of the well-studied reactions of nitroalkenes with O-nucleophiles. Initially, the oxa-Michael addition affords the nitronate **A**, which undergoes cyclisation of the S_N2' type to form the allene derivative **75**.

R = H, $n = 1$ (a); R = H, $n = 2$ (b); R–R = OCH₂O, $n = 2$ (c).

A procedure for cyclopropanation of cyclic and acyclic enones is based on the 'intermolecular Michael reaction – intramolecular alkylation' sequence.³⁸ Thus the reactions of readily accessible

α -haloenones **76** and **77** with mild C-nucleophiles **78** gave rise to cyclopropane derivatives **79** and **80**, respectively.

$n = 1, 2$; $Y = \text{CO}_2\text{Alk}, \text{CN}, \text{H}$; $Z = \text{CO}_2\text{Alk}, \text{NO}_2$; THAB is tetrahexylammonium bromide.

$X = \text{Cl}, \text{Br}$; $R^1, R^2 = \text{Alk}, \text{Ar}$.

Cyclopropane derivative **81** was synthesised by the reaction of the malonate anion with 3-iodolevoglucosenone (**69**) as an electrophilic component.³⁹

Apparently, a 1,3-shift of electron density occurs in the intermediate carbanion **A** resulting in generation of the more stable carbanion **B**, which eliminates the iodide ion to give the product **81** containing the cyclopropane ring.

Analogously, 3-iodolevoglucosenone (**69**) reacted with sodium ethyl cyanoacetate at -60°C to give the corresponding cyclopropane **82**.³⁵ However, the reaction of the ketone **69** with ethyl cyanoacetate at 20°C afforded imide **83**, which is the product of the cascade reaction of the cyclopropane **82** with a

second cyanoacetate anion. This fact was confirmed by the reaction of the individual cyclopropane **82** with sodium ethyl cyanoacetate or the malonate anion at 20°C giving rise to tetracyclic compounds **83** and **84**, respectively.

The classical tandem reaction of polyfunctional substrates, *viz.*, of electrophile **85** and nucleophile **86**, (Scheme 2) has been described.⁴⁰ It appeared that the result of transformations is governed by the order in which the reagents are added. The addition of dimethyl 3-oxoglutarate (**86**) to a suspension of the dibromide **85** (*i.e.*, in the presence of an excess of **85**) and Na_2CO_3 in dry THF afforded substituted benzo[*g*]isochromene **87**. On the contrary, the addition of the dibromide **85** to a suspension of the diester **86** (*i.e.*, in the presence of an excess of **86**) and Na_2CO_3 in THF gave rise to a derivative of cyclopenta[1,3]cyclopropa[1,2-*b*]naphthalene **88**. The observed selectivity can be explained as follows. Alkylation of the β -oxo ester **86** with the highly reactive benzyl-type bromide **85** leads to the intermediate **A**. The latter can react in two different ways. In the presence of an excess of the bromide **85**, the intermediate **A** is subjected to O-alkylation to form the intermediate **B**, which undergoes the intramolecular Michael cyclisation with elimination of HBr to give benzoisochromene **C**. Isomerisation of the double bond in the latter affords the final product **87**. If the reagents are added in the reverse order, the intramolecular Michael reaction takes place and the intermediate **A** is converted into the spiro compound **D**. The latter undergoes smooth cyclisation to form cyclopropane **E** and subsequent alkylation at the activated CH group with the second molecule of the dibromide **85** affords the product **88**.

A new strategy for the synthesis of carbocyclic β -amino acids was reported.⁴¹ The conjugate addition of the chiral analogue of ammonia, *viz.*, (*S*)-(-)-1-(trimethylsilylamino)-2-(methoxymethyl)pyrrolidine (TMS-SAMP), to ω -halogen-substituted enoates **89** gave rise to intermediate ester **A**,

which underwent intramolecular cyclisation to give compound **90** with high stereoselectivity. Subsequent removal of the protective trimethylsilyl group, reduction of the N–N bond and hydrolysis of the ester group afforded carbocyclic β -amino acid **91**.

$n = 0-4$; HMPA is hexamethylphosphoramide;

A procedure for the synthesis of chiral bicyclo[3.3.1]nonanes from homologues of carvone (**92**) has been developed.⁴² The reactions of allylic bromides **93** with different CH-acids occur as

Scheme 2

the tandem ‘intermolecular alkylation–intramolecular Michael reaction’ sequence giving rise to bicyclic compounds **94**.

R = H, Me; X, Y = CO_2Alk ; NBS is *N*-bromosuccinimide.

The reaction of 2-(2-chloro-4-nitrophenylsulfonyl)acetylthiophene (**95**) with ethyl acrylate proceeds in a ‘Michael reaction–nucleophilic substitution’ sequence.⁴³ The possible mechanism involves generation of the anions **A** and **B** under basic conditions. The oxygen atom of the anion **B** bearing a negative charge can readily attack the C(2) atom of the benzene ring resulting in intramolecular nucleophilic substitution to form cyclic product **96** (Scheme 3).

Scheme 3

DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.

IV. Tandem 'Michael reaction – aldol reaction' sequence

The basic medium required for the Michael reaction favours a subsequent aldol reaction. This type of transformation has been described in the literature in detail.

The short stereospecific synthesis of bicyclo[3.3.1]nonane derivatives (**97**) from acyclic diester **86** and enal **98** was performed by Michael addition followed by intramolecular aldolisation with the use of the reagent ratio **86**:**98** = 2:1.⁴⁴

$R^1, R^2, R^3 = \text{H, Alk, Ar.}$

An efficient procedure was developed for the construction of five–seven-membered carbocycles by the tandem 'Michael reaction – aldol cyclisation' sequence based on ω -oxo- α,β -unsaturated esters **99**.⁴⁵ Treatment of the latter with lithium α -toluenethiolates afforded cyclisation products **100** with a good stereoselectivity and in high yields.

Compounds 99 and 100	R	n	Yield of 100 (%)
a	Et	0	96
b	Me	1	95
c	Et	2	33

An efficient one-pot procedure was proposed for the construction of trisubstituted phenols **101** starting from prop-2-ynals **102** and the diester **86**.⁴⁶ This tandem process involves the Michael addition followed by aldol cyclisation of the intermediate enolate

anion. The phenols **101** were obtained in high yields. Only the reaction with the use of propynal ($R = \text{H}$) as an acceptor gave the product in low yield (11%), which is attributable to side anionic polymerisation of propynal.

$R = \text{H, Alk.}$

The tandem 'conjugate addition – aldol condensation' sequence has been used in the synthesis of the β -lactam fragment of thienamycin (**103**).⁴⁷ The highly stereoselective conjugate addition of lithium (*R*)-(α -methylbenzyl)allylamide (**104**) to an unsaturated ester, viz., to (*E*)-*tert*-butylpenta-2,4-dienoate (**105**), followed by aldol condensation with acetaldehyde (**106**) led to assembly of all three stereocentres of azetidinone **103** with the required absolute stereochemistry.

The tandem 'Michael addition – aldol reaction' and 'Michael addition – aldol reaction – Michael reaction' sequences have been described.⁴⁸ Dimethyl fumarate **107** reacted with heterocyclic ketone **108** in the presence of Et_3N to give the expected Michael adduct **109** (the yield was 38%) along with pyrrolo[1,2-*a*]indoles **110** (16%) and **111** (3%) (Scheme 4). Heating of the individual compound **109** with Et_3N afforded the product **110** the formation of which is attributable to spontaneous intramolecular cyclisation of the diester **109** followed by elimination of MeOH . The Michael addition of the pyrrole **110** to the dimethyl fumarate **107** afforded the tetraester **111**.

The 'Michael reaction – intramolecular aldol cyclisation' sequence was used for the synthesis of cycloalkenols **112** from oxo aldehydes **113** under the action of piperidine.⁴⁹ The resulting

Scheme 4

Scheme 5

cyclic intermediate **A** (for $R = \text{Ph}$, this intermediate is stable for several days) eliminated piperidine (slowly for $R = \text{Ph}$) to give the enol **112**.

$R = \text{Alk, Ph}; n = 1, 2$.

The reaction of enamine **114** with methyl vinyl ketone at room temperature afforded only the product **115** in 95% yield (Scheme 5).⁵⁰ Refluxing of the reactants gave rise to the tetracycle **116** (the yield was 72%) along with the compound **115** (10%). Apparently, this is attributable to the initial addition of one molecule of methyl vinyl ketone at the α -carbon atom of the enamine followed by isomerisation of the double bond of the adduct and addition of the second molecule of methyl vinyl ketone. The process is completed with intramolecular aldol condensation (path *a*) giving rise to the tricycle **115**. Upon heating, aldol condensation (path *b*) occurs faster than the reaction following the path *a* and product **116** is formed.

The reactions of heterocyclic enamines **114** and **117** with dimethyl acetylenedicarboxylate (DMAD) afforded a mixture of the corresponding Michael addition (**118** and **119**) and cyclisation products (**120** and **121**). The individual compounds **118** and **119** were quantitatively converted upon heating into the cyclic ketones **120** and **121**, respectively.

The adduct **122** was obtained in good yield and high *syn*-selectivity by the reaction of a mixture of lithium thiophenoxide, an α,β -unsaturated ester and an aldehyde.⁵¹ The reaction began with the nucleophilic attack of the thiolate at the β -carbon atom of the acceptor giving rise to intermediate enolate which entered into the aldol reaction with the aldehyde to form the polyfunctionalised adduct **122** as a mixture of the *syn*- and *anti*-isomers. An analogous mixture of isomers was obtained in the reaction with the use of lithium selenolate generated *in situ* under the action of methyl lithium on diphenyl selenide.

$\text{R}^1, \text{R}^2 = \text{H, Alk.}$

syn : *anti* = 9 : 1

$\text{R} = \text{H, Alk.}$

Previously, it had been demonstrated that the reaction of levoglucosenone (**67**) with an excess of nitromethane afforded the addition product **123** (the yield was 89%). The reaction in the presence of an excess of levoglucosenone gave rise to the adduct **124** (95%).³¹ The reaction with the use of an equimolar mixture of the reagents gave both products **123** and **124** in 18% and 61% yields, respectively.³² The electrochemical method proved to be more selective.³⁴ Electrolysis of an equimolar mixture of nitromethane and levoglucosenone afforded exclusively the ketone **124** (the yield was 92%).

MsCl is mesyl chloride; DMAP is dimethylaminopyridine.

The assumed mechanism of formation of the adduct **124** involves the Michael addition of the anion **A**, which is generated by the addition of the nitromethane molecule to the ketone **67**, to the second levoglucosenone molecules followed by intramolecular aldol condensation of the intermediate diketone **B**.

The 'Michael reaction–aldol reaction' sequence was used as the key stage in the synthesis of the prostaglandin 11-deoxy-PGF_{1α} (**125**).⁵² The reaction of cyclopent-2-en-1-one with dibenzyl methylmalonate (**126**) and the aldehyde **127** in the presence of aluminium lithium bis[(*S*)-1,1'-bi-2-naphthoxide] (ALB) as a catalyst produced the expected three-component coupling product **128** as a mixture of two diastereomers in a ratio varying from 6:1 to 17:1. The use of this catalyst not only initiates tandem conversions, but also provides high stereoselectivity of addition. Mesylation of the adduct **128** followed by elimination of MsOH afforded optically pure compound **129**, which can be converted into the target product **125** (Scheme 6).

V. Tandem Mannich and Michael reactions

It is known that Mannich bases are very convenient intermediates in a number of syntheses. These bases can readily be converted into vinyl ketones and used in the Michael reaction as electrophiles. Due to their proneness to polymerisation, acceptors are generated from Mannich bases *in situ*. Since decomposition of Mannich bases produces secondary amines, which can catalyse the Michael reaction, an additional amount of base need not be added.

The Mannich and Michael reactions of imines with the Danishefsky diene proceed in tandem.⁵³ Electron-excessive 1-methoxy-3-trimethylsilyloxybutadiene (**130**) reacted with the imine **131** in the presence of a Lewis acid to give the addition product **A**. Acid treatment of the latter led to rapid intramolecular

Michael addition and elimination of MeOH to form cyclic enaminone **132**.

The tandem Mannich and Michael reactions were used for the enantioselective synthesis of chiral piperidine derivatives.⁵⁴ Aldimines derived from tetra-*O*-pivaloyl-β-D-galactopyranosylamine (**133a,b**) and the diene **130** gave 2-substituted dehydropiperidine derivatives **134a,b**, respectively. The latter were transformed into alkaloids coniine (**135**) and anabasine (**136**).

Piv = C(O)CMe₃.

Compounds 133 and 134	R	Yield of 134 (%)
a	Pr ⁿ	96
b	3-Pyridyl	90

An efficient and short procedure was developed for the synthesis of tetra- and hexahydrobenzoquinolizinones, which are precursors of psychoactive alkaloids of the berberine series.⁵⁵ The Mannich and Michael reactions of 2-bromohomoveratrylamine (**137**) and silyoxydiene **130** gave rise to *N*-substituted enaminone **138**, which underwent Heck cyclisation to form the heterocycle **139**.

R = H, Alk or Ar; dba is dibenzylideneacetone.

VI. Tandem Michael reaction and heterocyclisation

The Michael addition of cyclohexanimines (which react as enamines) to β -substituted nitroalkenes is accompanied by cyclisation and elimination of the nitro group to form substituted tetrahydroindoles.⁵⁶ The imine **140** reacted with *trans*- β -nitro alkenes **141a,b** to give the expected tetrahydroindoles **142a,b**, respectively.

Compounds **141** and **142** R Yield of **142** (%)

a	Ph	70
b	Et	76

Allene-1,3-dicarboxylate (**143**) acts as an extremely reactive acceptor in the Michael reaction. This compound reacts with secondary amines to give the ion **A** as a result of conjugate addition. The ion **A** can also exist as the dianion **B**. The latter contains a good leaving group and undergoes smooth cyclisation. The final product, *viz.*, azabicyclic **144**, represents a skeleton of pyrrolizidine alkaloids.⁵⁷

The procedure for the synthesis of various different functionalised 3-methylidenetetrahydrofurans **145**⁵⁸ is based on the conjugate addition of anions of propargylic alcohols **146** to alkylidene- or arylmethylidenemalonate initiated by catalytic amounts of a base and subsequent *in situ* Pd-catalysed *exo-dig* cyclisation.

R¹, R² = H, Alk, Ar; R³ = Alk, Ar; Z¹, Z² = CO₂Et, CN.

This approach was used in the synthesis of 3-methylidenepyrrolidines **148**.⁵⁹ *N*-Substituted propargylamine **147** is used as the nucleophilic substrate, which reacts with different acceptors to give pyrrolidines **148** in good yields.

R¹, R² = Alk, Ar; Z¹, Z² = CO₂Et, CN.

The tandem 'Michael addition – intramolecular condensation' sequence was used in the synthesis of functionalised pyrroloisindoles.⁶⁰ Treatment of methyl ester of *N*-phthaloylalanine (**149**) with lithium hexamethyldisilazide afforded carbanion **A**, which reacted with α,β -unsaturated compounds to give intermediates **B** and **C** and then pyrrolo[2,1-*a*]isindol-5-ones (**150**) according to a standard scheme.

R = H, CO₂Et; Z = CO₂Et, CN.

The reactions of levoglucosenone (**67**) with binucleophiles proceed with the participation of the C=C and C=O bonds and can be used for the synthesis of fused heterocyclic systems containing the carbohydrate fragment. Thus the addition of nitroacetamide (**151a**) to levoglucosenone was accompanied by cyclisation to yield exclusively the stereoisomer **152a**.³⁴ The reactions of *N*-hexylnitroacetamide (**151b**) and α -nitropropion-

amide (**151c**) with levoglucosenone produced compounds **152b,c**, respectively.⁶¹

Compounds 151 and 152	R ¹	R ²	Yield of 152 (%)
a	H	H	62
b	H	(CH ₂) ₅ Me	49
c	Me	H	69

The reactions of levoglucosenone with urea (**153a**), thiourea (**153b**), *N*-cyanoguanidine (**153c**) and *N*-nitroguanidine (**153d**) in the presence of bases were accompanied by pyrimidine-ring closure to form compounds **154a-d**, respectively.⁶² In spite of drastic reaction conditions, water was not eliminated from the molecule **154**, as in the above-considered reaction, which is in agreement with the Bredt rule.

Compounds 153 and 154	X	Yield of 154 (%)
a	O	58
b	S	53
c	NCN	31
d	NNO ₂	48

The reactions of levoglucosenone with α -aminoazoles **155a-d** gave rise to azolo[1,5-*a*]pyrimidine systems **156a-d**, respectively.⁶³ In the reaction with the triazole **155b**, the Michael adduct **157** was also formed.

Compounds 155 and 156	X	Yield of 156 (%)
a	N	75
b	CH	39
c	CNO ₂	76
d	CCF ₃	62

Apparently, deprotonation of the NH group of the heterocycle under the action of the base results in the anion, which attacks the double bond of levoglucosenone. If the C=C bond is subjected to the attack of the nitrogen atom adjacent to the amino group, the reaction is not terminated at the stage of formation of

the intermediate **A** and the latter undergoes cyclisation to give compound **156**. On the contrary, if the C=C bond is subjected to attack by the nitrogen atom remote from the amino group (the intermediate **B**), cyclisation does not take place because it should lead to the closure of the seven-membered ring, which is much less probable than the closure of the six-membered ring.

The reaction of levoglucosenone with 2-aminopyridine (**158**) was examined.⁶³ If the reagents were taken in an equimolar ratio, the reaction gave rise to a mixture of the addition product **159** and polycyclic compound **160**. The reaction with a twofold molar excess of levoglucosenone afforded virtually exclusively the product **160**. The compound **160** is structurally very similar to the 2:1 adduct of levoglucosenone with nitromethane, and, consequently, the probable mechanism of its formation involves the addition of two levoglucosenone molecules at the nucleophilic centre followed by intramolecular aldol condensation.

The reaction of levoglucosenone with dimedone (**161a**) yielded only the product **162a**. The reaction of levoglucosenone with barbituric acid (**161b**) produced the tetraketone **163** along with the heterocyclisation product **162b**. The formation of pyrans of the type **162** in the reactions of dimedone or barbituric acid with compound **67** may result from the enhanced reactivity of the carbonyl group of levoglucosenone as well as from steric factors favouring cyclisation.

X = CH₂, Y = CMe₂ (**a**); X = NH, Y = CO (**b**).

Six-membered hemiaminals **164a,b** smoothly formed in the reactions of the enamine derived from ethyl acetoacetate with levoglucosenone (**67**)⁶³ and 3-iodolevoglucosenone (**69**), respectively.³⁶

X = H (**67, 164a**), I (**69, 164b**).

VII. Tandem ‘anionotropic rearrangement – Michael reaction’ sequence

Heating of diketones **165** with *N,N*-diethylaniline (DEA) to 200 °C afforded pyranopyrans **166**.⁶⁴ Apparently, the compound **165** undergoes a sigmatropic rearrangement upon heating to give intermediate **A**, which can undergo intramolecular Michael cyclisation giving rise to the final product **166** due to the suitable arrangement of the phenolic OH group.

R = H, Alk, Cl, NO₂.

The tandem ‘Brook rearrangement – intramolecular Michael reaction’ sequence is suitable for the construction of functionalised carbocycles.⁶⁵ Acylsilanes containing the double bond at a suitable position (separated by 2, 3 or 4 carbon atoms) serve as substrates for cyclisation. The addition of phenyllithium to a solution of the acylsilane **167** brings about the Brook rearrangement and the intramolecular Michael reaction, which proceed smoothly to form diastereomeric cycloalkanes **168** and **169** in a total yield of 70%–82%.

n = 1–3.

VIII. Tandem Michael and Dieckmann reactions

The cascade processes involving more than three different reactions remain poorly studied. Of these processes, the ‘Michael reaction – aldol condensation – retro-Dieckmann reaction’ sequences, which are also called MARD cascades, have received the most study.

Previously, it has been demonstrated⁶⁶ that the reactions of α-oxocyclopentanecarboxylates with acroleins under mild conditions were accompanied by two-carbon-atom ring expansion. The five-step domino reactions of simple cyclic β-oxo esters **170** and **171** with 2-substituted acroleins **172** were used for the synthesis of valuable highly substituted cycloheptenones **173** and **174**, respectively, containing two stereocentres, the double bond and two chemically different carbonyl groups.⁶⁷ The transformation cascade involves the Michael addition, intramolecular aldol condensation and retro-Dieckmann reaction followed by dehydration and chemoselective saponification of one ester group. The configurations of the asymmetric centres are determined by the stereo-differentiating stage of the aldol cyclisation.

R = Alk, Ar.

The synthesis of non-symmetrical and symmetrical resorcinols **175** and **176** from aliphatic compounds by the tandem ‘Michael reaction – Dieckmann cyclisation’ sequence was investigated.⁶⁸ The reactions of dimethyl 3-oxoglutarate (**86**) with alkyl alkynoates **177a–c** at 25 °C produced non-symmetrical resorcinols **175a–c**, respectively. The reactions with the use of methyl alkynoates **177d,e** at low temperatures afforded symmetrical resorcinols **176a,b**, respectively. Apparently, conjugate addition of the enolate **86** to methyl alkynoates **177a–e** affords vinyl

Compound 177	R	Product	Yield (%)
a	Me	175a	59
b	Ph	175b	84
c	CH ₂ OBz	175c	67
d	H	176a	18
e	CO ₂ Me	176b	34

carbanion **A**. The latter is rapidly protonated with the most acidic methylene proton to give carbanion **B**, which is a precursor of symmetrical products **176a,b**. Contrary to the expected stability, the anion **B** underwent isomerisation (at 25 °C) to form enolate **C**, which is a precursor of the non-symmetrical products **175a–c**. It is believed that the delocalised anion **B** is more rapidly generated from the vinyl carbanion **A** and is stable only at low temperatures (up to 0 °C). On the contrary, this anion undergoes isomerisation to give the more stable enolate at room temperature. Consequently, the enolate **A** undergoes cyclisation to form symmetrical resorcinols **176a,b** when low temperature is required for prevention of polymerisation.

The tandem ‘Michael addition–intramolecular Dieckmann cyclisation’ sequence was used as the key stage in the total synthesis of mycophenolic acid exhibiting fungicidal, antibacterial, antiviral and immunosuppressive properties.⁶⁹ The reaction of dimethyl 2-geranyl-3-oxoglutarate (**178**) with 4-pivaloyloxybut-2-ynal (**179**) gave rise to the totally substituted resorcinol **180** with the required arrangement of all substituents. The resulting adduct was converted into the target mycophenolic acid (**181**) in six steps.

The use of readily accessible optically pure α,β -unsaturated ketones, such as carvone (**94a**) or methylcarvone (**94b**), in the tandem sequence of three Michael reactions and Dieckmann cyclisation allows the preparation of optically pure tricyclo[5.3.1.0^{3,8}]undecanes **182a,b**,⁷⁰ which are structural cores of seychellane.

Compounds 94 and 182	R	Yield of 182 (%)
a	H	40
b	Me	44

IX. Tandem Mukaiyama and Michael reactions

The tandem ‘Mukaiyama reaction–Michael reaction–aldol cyclisation’ sequence was used as the key stage in the synthesis of biologically active compound **183**.⁷¹ Under conditions of the Mukaiyama reaction, enol silyl ether **184** and spiro compound **185** gave enolate **A** whose conjugate addition to the chalcone **186** afforded enolate **B**. Intramolecular aldol condensation of the latter gave rise to compound **187** from which the target product **183** was obtained (Scheme 7).

The tandem Michael and Mukaiyama reactions were used in the total synthesis of vitamin D₃ (**188**).⁷²

The reaction of ketene hemithioacetal **189** with 2-methylcyclopent-2-enone (**190**) catalysed by a Lewis acid afforded enol silyl ether. The latter entered into the second conjugate addition reaction with methyl vinyl ketone acetal **191** as a reactive intermediate. The key precursor of blocks of the C/D type (**192**) was prepared in one step starting from three components.

The tandem ‘Mukaiyama–Michael reaction–Mukaiyama reaction–aldol reaction’ sequence was used for the introduction of two chains at the α and β positions of cyclic α,β -unsaturated ketones.⁷³ The low temperature at which this reaction was performed (–60 °C) hindered the formation of by-products of the crotonic type and enabled the achievement of high dia-

M is a group stabilising enolate.

stereoselectivity (*cis* : *trans* = 98 : 2) and good yields of the adduct **193**. This reaction is the first example of the lanthanide-catalysed tandem formation of C–C intermolecular bonds.

X. Miscellaneous tandem transformations involving Michael reactions

Recently, a large number of new tandem reactions have been developed. Thus a three-step ring expansion was used for the conversion of methyl dialkylcyclopent-1-en-1-ylacetate **194** into methyl cyclohexylacetate **195**.⁷⁴ The process involved ozonolytic cleavage of the double bond in **194**, the Wittig olefination of the product and the tandem sequence of dealkoxycarbonylation of the oxo ester **196** and the Michael addition. Intramolecular cyclisation gave rise to the ester **195**.

An analogous sequence was used for the preparation of lactones and lactams.⁷⁵ Precursors of lactones **197a–c** were synthesised from the corresponding salicylaldehyde derivatives **198a–c** by introducing the acrylic-acid fragment using the Wittig

olefination and esterification of the 2-OH group for the subsequent ring closure. The precursor of the lactam **197d** was synthesised analogously from 2-aminobenzaldehyde (**198d**).

DMEU is 1,3-dimethyl-2-imidazolidinone.

Compounds 197 and 198	R	X	Yield of 197 (%)
a	H	O	62
b	5-OMe	O	50
c	3,4-benzo	O	52
d	H	NH	76

The reaction of levoglucosenone with malononitrile in the presence of piperidine afforded polycyclic compound **199** (Scheme 8).⁷⁶

The tandem Michael and Wittig reactions involving five-membered phosphonium ylides **200** and α,β -unsaturated esters gave rise to seven-membered vinyl ethers **201**.⁷⁷ The process occurred *via* the structurally rigid phosphorus-containing bicyclic intermediate **A**

which provided high stereoselectivity of the formation of vinyl ethers. Analogous reactions were observed in the case of α,β -unsaturated thioesters⁷⁸ yielding cycloheptene derivatives **202**.

Scheme 8

R = Alk, Ar.

A new procedure was developed for the solid-phase synthesis of imidazolidin-2-ones with the use of the tandem ‘aminoacylation–Michael addition’ sequence.⁷⁹ The reaction of the allylic amine **203** bound to an ion-exchange resin with phenyl isocyanate proceeded regioselectively to form imidazolidin-2-one **204**.

The tandem Michael and Corey–Chaykovsky reactions of five-membered oxosulfonium ylides **205** with β -acetoxy- α -methylidene ketones **206** produced cycloheptene oxide derivatives **207**.⁸⁰ Initially, the Michael addition of the ylide **205** to the enone **206** occurred. Then the acetoxy group was eliminated to form the cation **A** followed by generation of the ylide and the intramolecular Corey–Chaykovsky reaction, which proceeded *via* the stable intermediate **B**. The latter was converted into epoxide **207**.

The tandem ‘Michael addition–Meerwein–Ponndorf–Verley reduction’ sequence was used for the asymmetric reduction of α,β -unsaturated ketones giving rise to secondary alcohols.⁸¹ The reaction of the enone **208** with (–)-10-mercaptoisoborneol (**209**) in the presence of Me_2AlCl afforded the expected product **210**. In this tandem process, the chiral mercaptoalcohol reacted with enone to give an adduct, which was converted into the alcohol **210** as a result of intramolecular proton transfer. Reductive desulfurisation of the latter produced the optically active alcohol **211**.

R¹, R², R³ = H, Alk, Ar.

The three-step ‘reductive amination–intramolecular Michael reaction–lactonisation’ sequence was used for the construction of the ring skeleton of homoaza-sugars in the synthesis of higher homologues of 1-deoxy-L-ido-nojirimycin (**212**) exhibiting a broad spectrum of biological activities.⁸² Apparently, reductive amination of the anomeric centre was succeeded by intramolecu-

lar ring closure at the activated double bond and lactonisation. Reduction of the ester group and deprotection gave rise to the target product **112**.

The tandem Michael addition and elimination were used as the key stages in the total synthesis of the S-containing yellow pigment of Australian sponges, *viz.*, benzylthiocrellidone (**213**),⁸³ which was prepared by the reaction of ketene dithioacetal **214** with dimedone.

The transformation of *cis*-1-bromo-2-(1-naphthyl)ethylene containing the dimethylamino group at the *peri* position (**215**) into *N*-methylbenzo[*de*]quinoline **216** was studied.⁸⁴ The tandem addition–elimination reactions can follow two alternative pathways, *viz.*, 6-*endo-trig* addition–elimination (path *a*) or tandem 5-*exo-trig* Michael addition followed by the carbene rearrangement (path *b*) (Scheme 9).

A new approach to the synthesis of 9–15-membered cyclic compound was devised.⁸⁵ Very dilute solutions of substrates **217–219** were treated with cesium fluoride, which induced a sequence of ring opening and ring closure reactions to yield cyclopentadecanone, cyclotetradecanone and cyclononanone derivatives (**220**, **221** and **222**), respectively (Scheme 10).

The efficiency of the intramolecular Michael addition, which is the crucial step and consists in the transformation of the carbanion **A** into the final product, depends essentially on the ‘bridging’ X group.

X = (CH₂)₂, CH = CH.

The tandem Peterson and Michael reactions have been described.⁸⁶ The reactions of α -silyl- α -formyl carbanions with carbonyl compounds containing a nucleophilic group gave rise to

Scheme 10

cyclic compounds with a functionalised side chain. Tandem reactions of α -trimethylsilylalkylphosphine oxide (**223**) or α -trimethylsilylalkylphosphine sulfide (**224**) with *n*-butyllithium and then with lithium tetrahydropyran-2-olate gave rise to products **225** and **226**, respectively, in high yields.

X = O (**223**, **225**), S (**224**, **226**); R¹, R², R³ = H, Ar.

* * *

To summarise, tandem transformations, which represent an advantageous combination of the thermodynamic and kinetic parameters of a single process, play an important role in procedures for the preparation of complex organic compounds. There is no doubt that the development of one-pot tandem reactions based on compounds containing various functional groups resulting in substantial complication of the starting structures is an important problem of modern organic synthesis.

Abstract. The published data on the synthesis of β -enamino ketones, δ -amino dienones and conjugated ω -amino polyenones of diverse structures are generalised. The bibliography includes 129 references.

I. Introduction

Conjugated ω -amino ketones represent an ample class of organic compounds which attract the attention of a broad circle of organic chemists, biochemists, physicochemists, *etc.* Owing to their high reactivities, these compounds find application in the synthesis of various biologically active heterocyclic systems, natural compounds, dyes and photosensitive materials.

The presence in ω -amino ketones of an electron-donating and an electron-withdrawing group separated by conjugated double bonds imparts to them specific properties and makes them perfect models for the study of fundamental problems, such as the nature of chemical bonds, electron transfer along the conjugation chain, chromaticity, sensitivity to the action of different kinds of energy, tautomerism, *cis-trans*-isomerism, *etc.*

The methods employed in the synthesis of β -aminovinyl ketones (AVK) have been generalised in reviews^{1,2} and the monograph by Freimanis.³ Several novel versions of conventional reactions which make it possible to increase the yields of the target products and to simplify the synthetic procedures have been proposed recently. The approaches to regio- and stereospecific synthesis of enamino ketones containing additional functional groups are being developed intensively. The most practicable methods for the synthesis of AVK and those based on unusual chemical conversions are considered in this review. Special attention is given to conjugated ω -amino polyenones prepared with the help of procedures developed in recent years. These compounds include α,α' -bis(ω -aminopolyenyl)alkanones, which contain two polymethine chains linked through a carbonyl group and manifest unusual spectral and luminescent properties.

II. Methods of synthesis of β -aminovinyl ketones, δ -amino dienones and α,α' -bis(3-aminopropenylidene)alkanones

1. Reactions of β -diketones with amines

Condensation of readily accessible β -diketones with ammonia and amines is a traditional approach to the synthesis of β -aminovinyl ketones.^{1–8} The starting diketone reacts in both diketo- and keto-enol forms. This reaction is usually carried out by boiling β -diketone–amine mixtures in solvents (*e.g.*, benzene, toluene) which allow removal of the water formed.^{4–7} In the reaction of non-symmetrical β -diketones **1** ($R^1 \neq R^3$), one or both regioisomeric AVK **2**, β -aminovinylimine **3** or their mixture can be formed due to the non-equivalence of the electrophilic centres C(1) and C(2).^{1,3,6–8}

The difference in the reactivities of the electrophilic centres C(1) and C(3) is especially pronounced in the case of non-symmetrical polyfluorinated β -diketones **4** due to the difference in the inductive effects of the substituents R_F and R^1 (Refs 6–8). Polyfluorinated β -diketones **4** react with ammonia and amines at only one of the electrophilic centres to give fluorine-containing AVK **5**.^{6–8}

$R_F = CF_3, H(CF_2)_2, H(CF_2)_4$; $R^1 = Me, Bu^a, Bu^t, Ph, C_6H_4Cl, C_6H_4Br, C_6H_4NO_2, C_3H_4Me, C_6H_4OMe$; $R^2R^3N = NH_2, NHPh$,

It is of note that the condensation of arylfluoroalkyl diketones **4** with NH_3 , NH_2Me and NH_2Ph affords a mixture of regioisomeric AVK **5** and **6**; the proportion of the isomer **6** with a geminal amino group and the fluoroalkyl residue depends on the length of the fluoroalkyl substituent and the nature of substituents in the amine.^{7,8} This reaction is carried out with azeotropic distillation of the water eliminated. In the case of low-boiling amines, this reaction is difficult to perform, since this requires repeated

Yu V Smirnova, Zh A Krasnaya N D Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky prosp. 47, 119992 Moscow, Russian Federation. Fax (7-095) 135 53 28. Tel. (7-095) 135 89 61. E-mail: yusmir@cacr.ioc.ac.ru (Yu V Smirnova), kra@cacr.ioc.ac.ru (Zh A Krasnaya)

Received 26 September 2000

Uspekhi Khimii 69 (12) 1111–1127 (2000); translated by R L Birnova

bubbling of the amine into the reaction mixture for the reaction to complete.^{4,6,7,9} This reaction is also accompanied by scission of the β -diketones at the C(1)–C(2) bond and by secondary condensations.^{1,8} Therefore, modifications of the process^{10–14} which exclude the formation of by-products, increase the selectivity and simplify the procedure are of special interest.

Thus, a method for the synthesis of AVK **2** was proposed which includes boiling 1,3-diketones with ammonium acetate or acetates of low-boiling amines in benzene in the presence of AcOH; the water formed is removed by azeotropic distillation.¹⁰

$\text{R}^1 = \text{Me, Ph; R}^2 = \text{Me; R}^3 = \text{H, CH}_2\text{CH}=\text{CH}_2$;
 $\text{R}^2-\text{R}^3 = (\text{CH}_2)_3, \text{CH}_2\text{CH}(\text{Me})\text{CH}_2$; $\text{R}^4 = \text{H, Et}$.

Satisfactory results were obtained in the condensation of methyl diketones with primary amines on inorganic supports.^{11,12} Under heterogenous conditions, the reactions proceed with higher selectivities and under milder conditions than the corresponding homogenous reactions.

$\text{R}^1 = \text{Me, Ph; R}^2 = \text{H, Me, Et, Bu}^t, \text{Pr}^i, \text{Ph, Bn, CH}_2\text{CN}$;
 (a) Al_2O_3 ; (b) montmorillonite K10.

Neutral alumina or montmorillonite K10 can be used as solid supports. The reagents must be completely adsorbed on the support. This procedure is extremely simple as regards its implementation. To isolate enamino ketones **2**, the reaction mixture is diluted with CH_2Cl_2 , the solid phase is filtered off, the solvent is removed *in vacuo* and the residue is subjected to distillation. In reactions with acetyl acetone (**1**, $\text{R}^1 = \text{Me}$), primary amines can be used as aqueous solutions, which is especially important in the case of low-boiling amines.¹²

If heterogenous reactions are carried out in a microwave (MW) oven,^{13,14} the reaction time decreases from 24 h to 1–20 min. Both primary and secondary amines can be introduced into the reaction.¹³

$\text{R}^1 = \text{R}^2 = \text{Ph, R}^3-\text{R}^4 = (\text{CH}_2)_4, (\text{CH}_2)_5$; $\text{R}^1 = \text{Me, R}^2 = \text{Ph, OMe}$;
 $\text{R}^3-\text{R}^4 = (\text{CH}_2)_4$; (a) SiO_2 , MW, 1–20 min; (b) montmorillonite K10, MW, 1–20 min.

It was shown¹³ that primary amines yield acyclic AVK **2** with *Z*-configuration of the α,β -double bond. The use of symmetrical disubstituted ureas **7**¹⁴ instead of amines also results in AVK **2** having a *Z*-configuration of the double bond and stabilised by an intramolecular hydrogen bond.

$\text{R}^1 = \text{R}^2 = \text{Me, Ph; R}^3 = \text{H, Me, Et, Ph}$; (a) SiO_2 , MW, 1–20 min;
 (b) montmorillonite K10, MW, 1–20 min.

2. Reactions of unsaturated alkoxy ketones with amines

The alkoxy group in readily accessible β -alkoxyvinyl ketones **8**^{15–18} is exchanged for an amino group upon reactions with ammonia and primary and secondary amines.^{3,18–22} This reaction is widely employed in the synthesis of halogen-containing AVK **9**.^{18–22} As a rule, the reaction of amines with β -alkoxyvinyl ketones proceeds at room temperature or with gentle heating and results in high yields of AVK **9** even in the case of sterically hindered amines.^{15,19–22}

The reactions of alkoxy-substituted *2H*- and *4H*-pyrones with amines also belong to this type of transformations.^{3,23–25} Thus prolonged boiling of 6-methyl-4-methoxy-2-pyrone **10** with amines in the absence of solvents resulted in the formation of AVK **2**.²⁴ The details of these experiments have not been reported.

$\text{R}^1 = \text{H; R}^2 = \text{C}_7\text{H}_{15}$; $\text{R}^1-\text{R}^2 = (\text{CH}_2)_4$.

It is believed²⁴ that AVK **2** are formed as a result of an attack by the amine at position 6 of the pyrone ring with subsequent decarboxylation and hydrolysis of the diacetoacetic acid derivative.

Treatment of dihydropyrones **11** with aqueous or methanolic ammonia gives amino dienones **12**.²⁵

$\text{R} = \text{CF}_3, \text{CCl}_3$.

δ -Alkoxy hexadienone **13** obtained by the acylation of 1-ethoxybuta-1,3-diene (**14**) with trifluoroacetic anhydride reacts with amines much like β -alkoxyvinyl ketones.²⁶ The alkoxy group in the dienone **13** is readily exchanged for an amino group to give δ -amino dienones **15**.

$\text{R}^1 = \text{R}^2 = \text{H, Et; R}^1 = \text{Me, R}^2 = \text{Ph}$.

δ -Amino dienones **15** were also prepared²⁷ from 3,4-dihydro-*2H*-pyran derivative **16**. Compound **16** reacts with various aliphatic and aromatic amines to give substituted diketones **17**. Presumably,²⁷ the putative mechanism of this reaction involves

ethoxy-substituted dienedione **18** as an intermediate. Acid hydrolysis of diketones **17** with aliphatic substituents at the nitrogen atom results in δ -amino dienones **15**. Diketones **17** with aromatic substituents at the nitrogen atom do not undergo deacetylation under conditions of acid hydrolysis.

$\text{R}^1 = \text{R}^2 = \text{Me, Et, Bn}$; $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Ph}$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4, (\text{CH}_2)_5$.

Non-fluorinated derivatives of 3,4-dihydro-2H-pyran do not react with amines. An attempt to apply this approach to the synthesis of 6-dimethylaminohexa-3,5-dien-2-one (**19**) was unsuccessful.²⁷

3. Reductive cleavage of isoxazoles

Reductive cleavage of the isoxazole ring under conditions of catalytic hydrogenation is one of the most well-studied and widely employed procedures for the preparation of enamino ketones.^{28–31} Diaminodivinyl diketones **20** were obtained by the reduction of the diisoxazolylmethane derivatives **21** in the presence of Raney nickel (Ni/Ra).

$\text{R}^1 = \text{R}^2 = \text{Me, Ph}$; $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$.

Catalytic hydrogenation of isoxazoles affords enamino ketones selectively, other functional groups of the starting compounds are not affected.³¹

$n = 3, 5$; $\text{R} = \text{C}_5\text{H}_{11}, \text{CH}_2\text{OC}_6\text{H}_4\text{F-2}$.

The enamino ketones **2** were obtained in good yields by reductive cleavage of 3,4,5-substituted isoxazolium salts **22** with lithium dialkyl cuprates generated *in situ* from methyl- or butyllithium and copper iodide.³² This reaction proceeds very quickly

and under very mild conditions (-20°C , 15 min) and affords enamino ketones **2** with different (including functional) substituents in the α -position.³²

$\text{R}^1 = \text{R}^3 = \text{R}^4 = \text{Me, Ph}$; $\text{R}^2 = \text{H, Br, Cl, CPh, COMe, CO}_2\text{Et, CN, NO}_2$.

More readily accessible 5-substituted isoxazolium salts **23** do not react with lithium cuprates. In this case, preliminary treatment with triethylamine resulting in oxo ketene imines **24** is required. The reactions of the latter with organocuprates **25** afford AVK **2**, simultaneously a substituent is introduced into the β -position of the AVK formed.³³

$\text{X} = \text{ClO}_4, \text{BF}_4^-$; $\text{R}^1 = \text{Me, Ph}$; $\text{R}^2 = \text{Bu}^t, \text{Et}$; $\text{R}^3 = \text{Me, Bu}^n, \text{Bu}^t, \text{Ph}$.

The reaction of oxo ketene imine **24** ($\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bu}^t$) with lithium diallyl cuprate (**26**) leads to the isomerisation of the allyl group into the propenyl group to yield a mixture of enamino ketones **27** and **28** containing conjugated and isolated double bonds.

4. Condensation of acid nitriles with methyl ketones

Until recently, information concerning the synthesis of AVK by condensation of nitriles with ketones was scarce.^{3, 34} A method for the synthesis of enamino ketones containing a primary amino group from nitriles and methyl ketones has been developed in the last few years where (phenyl)ethylaminomagnesium bromide is used as a condensing reagent. This procedure affords enamino ketones of various structures, which are difficult to prepare by other methods.^{35, 36}

The yields of enamino ketones depend on the nature of substituents in the starting compounds. The best results were obtained in the reaction of trichloroacetonitrile with aryl(hetaryl) methyl ketones and *tert*-alkyl methyl ketones with acid nitriles containing electron-withdrawing aromatic substituents.³⁶

R^1	R^2	Yield (%)	R^1	R^2	Yield (%)
Ph	Bu^t	48	PhOCH_2	Bu^t	48
4-MeOC ₆ H ₄	Bu^t	26	CCl_3	Bu^t	58
4-BrC ₆ H ₄	Bu^t	80	Pr ⁱ	Ph	34
			Ph		73
	Bu^t	60			71
Bn	Bu^t	54			

The presence of a double bond³⁷ or a functional group^{38–46} in the molecule of a methyl ketone does not prevent the reaction with nitriles, the cyano group of which is activated by a polyhalogenoalkyl substituent, which makes it possible to synthesise enamino ketones containing several functional groups.

Thus the reaction of trichloro- and trifluoroacetonitriles with α,β -unsaturated ketones **29a–d** results in β -aminodiviny ketones **30a–d**.³⁷

$\text{R}^1 = \text{CCl}_3, \text{CF}_3$; $\text{R}^2 = \text{R}^3 = \text{Me}$ (**a**); $\text{R}^2 = \text{H}$; $\text{R}^3 = \text{Ph}$ (**b**),

4-MeOC₆H₄ (**c**),  (**d**).

The condensation of β -acylaminoalkyl methyl ketones **31** with halogenoacetonitriles gives AVK **32**.³⁸ This is the first example of the involvement of β -acylaminoalkyl methyl ketones as a methyl-ene component in aldol-type reactions.

$\text{R}^1 = \text{CCl}_3, \text{CF}_3$; $\text{R}^2 = \text{Me}, \text{Ph}$.

The reaction of trichloro- and trifluoroacetonitrile with the so-called diacetone alcohol **33** proceeds as nucleophilic addition to the nitrile group and yields β -aminovinyl β' -hydroxyalkyl ketones **34**; the latter are stable compounds, which occur exclusively in the acyclic form.³⁹

$\text{R} = \text{CCl}_3, \text{CF}_3$.

The condensation of trichloro- or trifluoroacetonitrile with 2-hydroxyacetophenone³⁹ and 2-acetyl-1-naphthol⁴⁰ gives the corresponding hydroxy enamino ketones **35** and **36**, which occur as *Z*-isomers with a coplanar *s-cis*-configuration stabilised by intramolecular hydrogen bonds.

$\text{R} = \text{CCl}_3, \text{CF}_3$.

On going to sterically hindered β -hydroxyalkyl methyl ketones, the structures of the reaction products depend on the nature of the halogen in the halogenoacetonitrile.^{41, 42} Thus the reaction of trichloroacetonitrile with 4-hydroxy-3,3-dimethylbutan-2-one (**37**) is not stopped in the formation of an open form of

the hydroxy enamino ketone **38**; its spontaneous cyclisation yields tetrahydropyranone **39**.⁴¹

The condensation of trichloroacetonitrile with 1-acetyl-1-hydroxymethylcyclohexane⁴¹ and 1-acetyl-2-naphthol⁴⁰ proceeds similarly to give the cyclic products **40** and **41**. Acyclic forms were absent in both cases.

The reactions of polyfluorocarboxylic acid nitriles with sterically hindered β -hydroxyalkyl ketones **42** under the same conditions afford hydroxy enamino ketones **43** as the final products; the latter are stable on storage and do not cyclise spontaneously into tetrahydropyranones.⁴²

$\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^1-\text{R}^2 = (\text{CH}_2)_5$; $\text{R}^F = \text{CF}_3, (\text{CF}_2)_2\text{H}$.

The reaction of trichloro- and trifluoroacetonitrile with acyclic hydroxyalkyl ketones **44** in the presence of (phenyl)ethylmagnesium bromide results in the corresponding hydroxy enamino ketones **45**.^{43, 44}

$\text{R}^1 = \text{Me}, \text{Et}, \text{Bu}^t$; $\text{R}^2 = \text{CCl}_3, \text{CF}_3$.

As in the case of sterically hindered β -hydroxyalkyl methyl ketones, the structures of the products formed in the reactions of nitriles with sterically hindered α -hydroxyalkyl methyl ketones depend on the nature of the halogen which activates the cyano group.^{45, 46} Thus the condensation of 1-acetylcyclohexan-1-ol (**46**) with trichloroacetonitrile does not afford α -hydroxy enamino ketone **47** as might be expected, but rather gives its cyclic isomer **48**.⁴⁵

The condensation of α -hydroxy ketone **46** with trifluoroacetonitrile results in α -hydroxy enamino ketone **49** with a geminal amino group and the trifluoromethyl substituent.⁴⁶

5. Modification of β -aminovinyl ketones based on the use of their lithium salts

Enamino ketones containing other functional groups in addition to the aminoenone group cannot be prepared in the majority of cases using traditional methods.^{2, 3, 19, 21, 31–33} Therefore, procedures based on directed introduction of functional groups into more readily accessible AVK acquire special importance. The use of N,α' - and N,γ -dilithium salts of AVK in reactions with electrophiles is an example of a successful application of synthetic approaches to regio-controlled introduction of functional groups into AVK.

Studies of reactivities of N,α' - and N,γ -dilithium derivatives with respect to various electrophiles have shown that these are convenient starting compounds for the synthesis of heterocyclic compounds and for the introduction of functional groups into the α' - and γ -positions of AVK.^{47–58}

The alkylation of cyclic AVK **50** is the first example of such an approach.⁴⁷ It was shown that depending on conditions of preparation of lithium salts (*viz.*, the reagent ratios, the nature of a base, temperature), the alkylation predominantly occurs either at position 6 or at position 4 to give the AVK derivatives **51** or **52**, respectively.

$R^1 = \text{Me}, \text{C}_6\text{H}_{11}$; $R^2 = \text{Bn}, \text{Me}$; $X = \text{I}, \text{Br}$; LDA is lithium N,N -diisopropylamide; LTMSA is lithium bis(trimethylsilyl)amide.

Treatment of the enamino ketone **50** with lithium N,N -diisopropylamide (LDA) in ether or THF at -78°C results in deprotonation of the α' -position to afford a kinetically more favourable dianion (termed an α' -dianion); its alkylation gives rise to the cyclic AVK **51**. Deprotonation of the γ -position which gives a thermodynamically more favourable dianion (termed a γ -dianion) occurs upon treatment of compound **50** with lithium bis(trimethylsilyl)amide (LTMSA). Subsequent alkylation results in a practically exclusive formation of AVK **52**.⁴⁷ However, this approach could not be used for the alkylation of acyclic AVK, since it gave a mixture of alkylation products irrespective of the base used.⁴⁷

The conditions favouring the preparation of α' - or γ -dilithium derivatives from acyclic β -(N -monoalkylamino)vinyl ketones and the factors influencing the regioselectivity of their formation have been studied in detail.^{48, 49}

Treatment of 4-(N -alkylamino)pent-3-enones **2a–e** with an excess of a strong base (2.5 equiv., THF) gives both α' - (**53**) and γ -dilithium derivatives **54** which exist in a dynamic equilibrium (see Ref. 48).[†]

$R = \text{Me}$ (**a**), Pr^i (**b**), cyclo- C_6H_{11} (**c**), PhCHMe (**d**), Bu^t (**e**).

Depending on the strength of the base and the substituent R in the starting compound (AVK **2**), the equilibrium can be practi-

cally completely shifted towards one of the dianions.^{48–51} The α' -dianion **53** which is predominantly formed upon treatment of AVK **2** with lithium 2,2,6,6-tetramethylpiperidide (LTMP) is kinetically more favourable. Thermodynamic calculations demonstrate that under these conditions the conformation of the α' -dianion **53** prevents its isomerisation into a thermodynamically more stable γ -dianion **54**.⁴⁸ It should be noted that the regioselectivity of formation of the α' -dianion **53** depends on the size of the substituent at the nitrogen atom. The predominant formation of the α' -dianion **53** is observed only in the case of bulky substituents, such as Bu^t and Ph .^{49, 51} In the presence of less bulky substituents ($R = \text{Me}, \text{Pr}^i$) the γ -dianion **54** is formed together with the α' -dianion **53**.⁵¹ The predominant formation of a thermodynamically more favourable γ -dianion **54** takes place under the action of a stronger base, *viz.*, methyllithium, in the presence of N,N,N',N' -tetramethylethylenediamine (TMEDA). Under these conditions, the α' -dianion which is formed first adopts a conformation which allows its rapid isomerisation into a more stable γ -dianion **54**.^{48, 51} The size of a substituent at the nitrogen atom does not influence the regioselectivity of formation of the γ -dianion **54**.⁴⁸ The dianions **53** and **54** can also be prepared from enamino ketones with secondary amino groups.^{48–50, 54, 58}

The reactions of the dianions **53** and **54** with electrophiles proceed at low temperatures (-100 to -20°C) and take as a rule from 5 min to 2 h. The alkylation of dianions of the type **53** and **54** afforded the corresponding α' - and γ -alkyl-substituted AVK in good yields. It is noteworthy that this reaction proceeds as C-alkylation and does not affect the primary amino group.^{48, 52}

$R = \text{Me}, \text{Bn}$; $X = \text{Br}, \text{I}$.

$R^1 = \text{Me}, \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$; $R^2 = \text{Me}, \text{Pr}^i, \text{Bu}^t$;
 $R^3 = \text{Me}, \text{Et}, \text{Pr}^i, \text{Bn}, n\text{-C}_{10}\text{H}_{23}, \text{CH}_2\text{CH}=\text{CH}_2, \text{CH}_2\text{C}\equiv\text{CH}$;
 $X = \text{Cl}, \text{Br}, \text{I}$.

In addition to alkyl halides, allyl and propargyl bromides can be used as alkylating agents.⁵²

α' -Dianions of the type **53** react smoothly with nitriles under mild conditions to give bis(aminovinyl) ketones **55**. During chromatography on SiO_2 , compounds **55** are partly converted into 4-pyridones **56**. This reaction is quantitative when solutions of enamino ketones are kept over SiO_2 for 2 days.⁵⁰

$R^1 = \text{Pr}^i, \text{Ph}$; $R^2 = \text{Et}, \text{Bn}, \text{H}$; $R^3 = \text{Ph}, \text{Bu}^n, 2\text{-ClC}_6\text{H}_4$.

[†] Hereinafter, for convenience sake we shall refer to the dilithium derivatives **53** and **54** as dianions and omit Li cations in the structural formulae.

According to ^1H and ^{13}C NMR and X-ray diffraction data, compounds **55** exist in both solutions and crystalline state as tautomers **A** containing two enamine fragments, but not as oxo- (**B**) or hydroxy imines (**C**).⁵⁰

Hydroxy derivatives of enamino ketones were obtained in the reaction of α' - (**53**) or γ -dianions (**54**) with oxiranes,⁴⁹ aldehydes, ketones^{51, 53} and esters.⁵⁴

The reaction of dianions of the type **53** and **54** with oxiranes **57** is accompanied by the opening of the epoxide ring to give the corresponding γ' - or ε -hydroxy derivatives **58** and **59**. This reaction proceeds as bimolecular $\text{S}_{\text{N}}2$ nucleophilic substitution; non-symmetrical epoxides react at the least substituted carbon atom. The opening of the epoxide ring occurs in a stereo- and regioselective manner resulting in only one of the possible isomers.⁴⁹

$\text{R}^1 = \text{Bu}^t$ (**53e**), Ph (**53f**); $\text{R}^2 = \text{H}$; $\text{R}^3 = \text{H}, \text{Me}, \text{Et}, \text{Bu}, \text{Ph}$;
 $\text{R}^2-\text{R}^3 = (\text{CH}_2)_4$.

$\text{R}^1 = \text{Me}, \text{Bu}$; $\text{R}^2 = \text{H}, \text{Ph}, \text{Me}_3\text{Si}$; $\text{R}^3 = \text{H}, \text{Me}, \text{Et}, \text{CH}_2\text{Cl}$;
 $\text{R}^2-\text{R}^3 = (\text{CH}_2)_4$.

The condensation of the α' -dianion **53f** with aldehydes and ketones was used to obtain β -aminovinyl β' -hydroxy alkyl ketones **60**.⁵¹ Like aminovinyl β' -hydroxyalkyl ketones **34**, these are stable in the acyclic form.

$\text{R}^1 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^2 = \text{Me}, \text{Pr}, \text{Bu}^t, n\text{-C}_6\text{H}_{13}, \text{Ph}, (\text{CH}_2)_2\text{Ph}$.

Compounds **60** are produced in high yields even if sterically hindered aldehydes and ketones (trimethylacetaldehyde or benzophenone) and enolisable ketones (*e.g.*, acetophenone) are introduced into the reaction.

In contrast to the α' -dianion **53f**, the condensation of the γ -dianion **54a** with aldehydes and ketones is non-regiospecific and results in the formation of both δ - (**60**) and β' -hydroxyenamino ketones (**61**).⁵¹

$\text{R}^1 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^2 = \text{Me}, \text{Pr}^n, \text{Bu}^t, n\text{-C}_6\text{H}_{13}, \text{Ph}, (\text{CH}_2)_2\text{Ph}$,
 $\text{CH} = \text{CHPh}$.

Presumably,^{48, 51} the attack of bulky electrophiles, such as carbonyl compounds, at the sterically hindered γ -position of the γ -dianion **54a** which exists in the *syn*-conformation proceeds with great difficulty. However, owing to the presence in the reaction mixture of a small amount of a more reactive α' -dianion **53a** the latter reacts with carbonyl compounds much faster to give a β' -hydroxy derivative, which is accumulated in the mixture due to rapid isomerisation of the anion **54a**. This suggestion is corroborated by the fact that the yield of the undesirable β' -hydroxy ketone **60** increases in the case of sterically more hindered ketones, *e.g.*, benzophenone.⁵¹ Its formation could be completely excluded using an enamino ketone with a phenyl substituent as a starting compound.

$\text{R}^1 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^2 = \text{Me}, \text{Et}, \text{Ph}, \text{cyclo-C}_6\text{H}_{11}$.

Direct aldol condensation of γ -dianions of the type **54** with aldehydes and ketones gave chiral *anti*- β -amino- δ -hydroxyalk-1-enyl ketones **62**.⁵³ The stereoselectivity of this reaction depends critically on steric factors, being increased in the case of sterically more hindered starting enamino ketones and carbonyl compounds.⁵³

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{H}, \text{Me}, \text{Bn}$;
 $\text{R}^1-\text{R}^2 = (\text{CH}_2)_2$; $\text{R}^3 = \text{H}, \text{Me}$;
 $\text{R}^4 = \text{Me}, (\text{CH}_2)_2\text{Ph}, \text{Bu}^t$.

Under conditions of acid hydrolysis, enamino ketones **62** undergo cyclisation into 4-imino-2,3-dihydropyrans **63**. Compounds **63** are stable in acid media, apparently due to the formation of a more stable protonated form **64**. However, in neutral media iminopyrans **63** are unstable and isomerise into enamino ketones **65**.⁵³

$\text{R}^1 = \text{H}, \text{Bn}, \text{Me}$; $\text{R}^2 = \text{Me}, \text{Bu}^t, \text{Ph}$; $\text{R}^3 = \text{H}, \text{Me}$.

The reaction of the dilithium derivative **53f** with esters results in enamino enols **66**.⁵⁴

$\text{R}^1 = \text{Ph}, 4\text{-ClC}_6\text{H}_4, \text{EtCHBr}; \text{R}^2 = \text{Me}, \text{Et}, \text{C}(\text{Me})=\text{CH}_2.$

It was proposed⁵⁴ that the adduct **67** stabilised by bridging bonds, is the intermediate in this reaction. The yields of compounds **66** are very high in the case of aromatic acid esters, but decrease dramatically if aliphatic acid esters are used. Moreover, the reaction of dilithium derivatives with aliphatic acid esters is accompanied by the formation of ester self-condensation products; their proportion increases with time. It is suggested⁵⁴ that a transmetallation reaction between the dilithium derivative **53f** and the ester favours self-condensation of esters. According to ^1H NMR spectroscopic data, compounds **66** exist in solutions as two tautomers, *viz.*, ketoenols **66a** and diketones **66b**, the equilibrium being markedly shifted towards the enol form **66a**.⁵⁴

It should be noted that the reaction of dilithium derivatives of the type **54** with esters yields unsaturated amino alcohols **68** as the main product; these are formed as a result of condensation of two molecules of the enamino ketone with one molecule of the ester. Obviously, the intermediate **69** which is formed first is far less stable than the adduct **67** and is decomposed with elimination of the alcoholate anion to give the monolithium derivative **70**. The carbonyl group of the latter is not coordinated with the lithium ion and behaves as the free carbonyl group. Its reaction with the second molecule of the γ -dilithium derivative **54** affords the polyfunctional compounds **68**.⁵⁴ The expected products of this reaction, *viz.*, enamino diketones **71**, are formed in insignificant amounts.

$\text{R}^1 = \text{Pr}^i, \text{Me}; \text{R}^2 = \text{Me}, \text{Et}, \text{Ph}, \text{Pr}; \text{R}^3 = \text{Me}, \text{Et}, \text{C}(\text{Me})=\text{CH}_2.$

The AVK derivatives **72** with a carboxy group in the α' -position were obtained by the reaction of the α' -dianions **53** with carbon dioxide.⁵⁵ For $\text{R}^1 \neq \text{H}$, the acids **72** are unstable and undergo decarboxylation within several hours to give the starting AVK. For $\text{R}^1 = \text{H}$, the acids **72** retain their stability at lowered temperatures over a period of several months. The dianions of the type **54** do not react with carbon dioxide.⁵⁵

$\text{R}^1 = \text{H}, \text{Me}, \text{Et}, \text{Bn}; \text{R}^2 = \text{Me}, \text{Pr}^i, \text{Ph}, \text{cyclo-C}_7\text{H}_{12};$
 $\text{R}^3 = \text{Me}, \text{Ph}(\text{CH}_2)_2.$

The α' -dianions of the type **53** react with diethyl carbonate to give enamino oxo acids **73**.⁵⁵ The maximum yields of compounds **72** and **73** were obtained for compounds with bulky substituents at the nitrogen atom.⁵⁵

$\text{R}^1 = \text{Me}, \text{Pr}^i, \text{Ph}; \text{R}^2 = \text{Me}, \text{Et}.$

The γ -dianions of the type **54** react with diethyl carbonate to produce α -amino- β -benzoylacrylates **74**.⁵⁵

$\text{R} = \text{Me}, \text{Pr}^i, \text{Ph}.$

It is noteworthy that the condensation of $(\text{EtO})_2\text{CO}$ with the dianions **54** containing an aliphatic substituent instead of a phenyl substituent yields a complex mixture of products.⁵⁵

The dianions **53** and **54** add to the double bond of nitroalkenes to give γ' - (**75**) or ε -nitro- β -enamino ketones (**76**). As a rule, this reaction yields only one of the possible diastereomers.⁵⁶

$\text{R}^1 = \text{Ph} \text{ (53f)}, \text{Pr}^i \text{ (53b)}; \text{R}^2 = \text{H}, \text{Me}; \text{R}^3 = \text{Ph}, \text{Et}, \text{Ph}(\text{CH}_2)_2, 4\text{-MeOC}_6\text{H}_4.$

$\text{R}^1 = \text{Ph}, \text{Me}; \text{R}^2 = \text{Me}, \text{Pr}^i, \text{Ph}; \text{R}^3 = \text{H}, \text{Me}; \text{R}^4 = \text{Et}, \text{Ph}, \text{Ph}(\text{CH}_2)_2, 4\text{-MeOC}_6\text{H}_4.$

The cross-conjugated enamino ketones **77** were obtained by the reaction of aldehydes and ketones with dianions formed upon treatment of α' -(trimethylsilyl)enamino ketones **78** with bases.^{57, 58}

$\text{R}^1 = \text{Pr}^i, \text{Bu}^t; \text{R}^2 = \text{Ph}, \text{PhCH}=\text{CH}, \text{Et}; \text{R}^3 = \text{H}, \text{Me}.$

The structures of the products formed depend on the reaction conditions. In tetrahydrofuran, only silyl-substituted hydroxy enamino ketones **79** or their mixture with compounds **77** are isolated. In the presence of tetramethylethylenediamine which binds lithium cations and thus facilitates the elimination of trimethylsilanol only α',β' -unsaturated amino ketones **77** in a total yield of 53% to 82% are obtained. It is noteworthy that the ratios of the (5E)- to (5Z)-isomers of compounds **77** depend on the reaction time, viz., the (5Z)-isomer is mainly formed upon elimination after 2 h, whereas the (5Z)-isomer is isomerised into the (5E)-isomer with an increase in the reaction time to 20 h.⁵⁸

6. Reactions of amide and lactam acetals and ester amins with compounds containing an activated methylene group

Reactions of amide and lactam acetals and ester amins with compounds containing an activated methyl or methylene group is one of the most popular approaches to the synthesis of enamines including enaminoketones.^{1,59–62} Among amide and lactam acetals and ester amins synthesised to date,^{59,61–66} dialkyl acetals of *N,N*-dialkylformamides **80** and *N,N*-dimethylacetamide **81** as well as diethylacetals of *N*-methylbutyro- (**82a**) and -valerolactams (**82b**) are the most well-studied and popular synthetic reagents.

$\text{R}^1 = \text{R}^2 = \text{Et}, \text{Me}; \text{R}^1-\text{R}^2 = (\text{CH}_2)_5; \text{R}^3 = \text{Me}, \text{Et};$
 $\text{R}^4 = \text{Me}$ (**81a**), Et (**81b**); $n = 1$ (**82a**), 2 (**82b**).

In solutions of amide acetals, an equilibrium exists between acetals **83a**, ambidental cations **83b** and α -alkoxy enamines **83c**.^{66–71}

Reactions of nucleophilic substitution of amide acetals proceed in the absence of catalysts, since the abstraction of a proton from an activated methyl or methylene group occurs by virtue of the basic properties of the acetal amide itself. In some cases, azeotropic distillation may be required to remove the alcohol formed.

The condensation of dimethylformamide acetal and alkylformate amination with various ketones (e.g., aromatic, heterocyclic) and diketones gave enaminoketones **84**,⁷² **85**,⁷³ **86**,⁷⁴ **87**⁷⁵ and **88**.⁷⁶

88 ($\text{R} = \text{H}, \text{Et}$).

Dialkyl acetals of *N,N*-dialkylformamides **80**^{77,78} react with 2-acetylcycloalkane-1,3-diones **89** exclusively at the acetyl group to give enaminotriketones **90**.⁷⁷

$\text{R} = \text{Me}, \text{Et}; \text{X} = \text{CH}_2, (\text{CH}_2)_2, \text{CH}_2\text{CHMe}.$

The dioxo derivatives of tetrahydrobenzopyrans **92** formed upon cyclodeamination of enaminotriketones **93** are the reaction products of 2-propionylcyclohexane-1,3-diones **91** with *N,N*-dialkylformamide acetals **80**.⁷⁸

$\text{R}_2\text{N} = \text{Me}_2\text{N}, \text{Et}_2\text{N}, \text{N} \begin{smallmatrix} \diagup \\ \diagdown \end{smallmatrix} \text{C}_6\text{H}_4 \begin{smallmatrix} \diagdown \\ \diagup \end{smallmatrix} \text{N}; \text{R}^2 = \text{H}, \text{Me}; \text{X} = \text{CH}_2, \text{CMe}_2.$

Diaminodienediones **94** were synthesised by heating cyclic enamino β -diketones **95** with an excess of acetals **80**;⁷⁹ in this case, the reaction occurs at the methyl group which is separated from the carbonyl function by a double bond. Only few examples of this kind of reactions are documented.^{79–81}

$\text{R}^1 = \text{Me}, \text{Et}; \text{R}^2 = \text{H}, \text{Me}.$

The condensation of crotonamide **96** with a large excess of *tert*-butylformate bis(*N,N*-dimethylaminal) **97** at 140 °C yields

enamidines **98** as a result of reactions at both methyl and the primary amino group.⁸¹

An unusual reaction was observed in the study of the reactions of *N,N*-dimethylacetamide diethyl acetal **81b** and acetals of *N*-methylbutyro- (**82b**) and -valerolactams (**82b**) with enamino diketones. ^{1, 62, 69–71, 82} Quite unexpectedly, the reaction of the enamino diketone **99** with the acetal **81b** occurs not at the primary amino group to give enamine **100**,⁸³ but at the double bond and yields a mixture of diaminodiene diketone **101** and its dimethylaminoethylidene derivative **102**.^{1, 62, 69, 82}

It is assumed that the reaction with enamino diketone **99** involves ketene acetal-amine **81c** rather than dimethylacetamide acetal **81b** which is in equilibrium with the former. High electron density in the β -position of ketene acetal-amine **81c**, which is provided by two strong electron-donor substituents, favours its easy addition to the double bond of the enamino diketone **99**. This results in the zwitterion **103** the alkoxy group of which reacts with dimethylamine formed in the course of the reaction to give the diaminodiene **101** or with ammonia and an excess of acetal **81b** to give amidine **102**.⁶⁹ It is clear from the scheme presented why the dimethylformamide acetals **80** for which the equilibrium of the type $\mathbf{81b} \rightleftharpoons \mathbf{81c}$ is impossible do not enter into such reactions.

Obviously, this reaction is ambiguous because of the presence of the primary amino group in the enamino diketone **99**. The introduction of *N*-substituted enamino diketones **104** and **105** into the reaction with acetal **81b** allows selective synthesis of the diamino dienediketone **101**.⁶⁹

R = Ph, Bn.

The reaction of *N,N*-dimethylacetamide acetal (**81b**) with other cyclic and acyclic enamino dicarbonyl compounds also occurs at the double bond and results in diamino dienediketones **106**.^{69, 71}

$R^1 = R^2 = \text{Me, Ph}; R^1 - R^2 = \text{OCH}_2\text{O}, (\text{CH}_2)_3$.

According to ¹H NMR spectroscopic data, δ,δ -diamino dienediones **101** and **106** exist predominantly as *s-trans*-conformers with respect to the C(β)–C(γ) bond ($J = 14.2–14.7$ Hz).

N-Methylbutyro- and -valerolactam acetals (**82a**) and (**82b**)⁷⁰ react with the enamino diketones **99** and **105** in a similar way. Thus the enamine **99** gives cyclic derivatives of dienediamines **107a,b** in high yields.⁷⁰

The structure of the reaction product of the lactam acetal **82a** with the enamino diketone **105** depends on the reagent ratio, *viz.*, the dihydropyrrole diene **108** is formed in the case of an equimolar ratio, whereas triene **109** is formed in the presence of an excess of the lactam acetal.⁷⁰

Dimethylformamide acetal (**80**) can also be used in the synthesis of di(β -aminovinyl) ketones.^{84–87} Thus the synthesis of 1,5-bis(dimethylamino)penta-1,4-dien-3-one (**111**) is based on the reaction of dimethylformamide acetal (**80**) with 3-oxoglutaric acid (**110**).^{84, 85}

Di(aminomethylidene)cycloalkanones **112** are formed in the reaction of dimethylformamide acetal **80** with cyclopentanone or cyclohexanone which proceeds under very drastic conditions; the yields of the target products are usually low.⁸⁶

In the presence of 1,5-diazabicyclo[4.3.0]non-5-ene as a catalyst, the yields of compounds **112** increase up to 36%–50%.⁸⁷

7. Synthesis of δ -aminodienones and α, α' -bis(3-aminopropenylidene)alkanones

Some examples of the synthesis of δ -amino dienones were described earlier.^{88–90} In most cases, the procedures employed for the synthesis of enamino ketones are inapplicable to the synthesis of conjugated δ -amino dienones and, particularly, of polyunsaturated ω -amino ketones where the number of conjugated double bonds between the NMe₂ and CO groups is more than two.

Thus the reaction of the enynone **113** with diethylamine was used for the synthesis of δ -aminodienone **19**. The ketone **113** was synthesised from 4-dimethylaminobut-3-en-2-one (**114**) and ethynylmagnesium bromide.⁸⁸

Polyunsaturated amino ketones can, in principle, be synthesised by reiteration of this procedure. However, it has been shown⁸⁹ that this approach is ineffective even in the case of trienones.

The δ -amino dienones **115** possessing aryl substituents were obtained by the reaction of aryl β -chlorovinyl ketones **116** with enamines **117** in the presence of triethylamine.⁹⁰

$R^1 = \text{H}, R^2 = \text{Me, Et, Ph}; R^1 - R^2 = (\text{CH}_2)_3; R^3 = \text{Ph, 4-MeC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4.$

The condensation of 3-dimethylamino-1,1,3-trimethoxypropane (**118**) (see Ref. 91) with ketones is successfully employed in the synthesis of δ -dimethylamino dienones.^{86, 92–95} Depending on the conditions, the reaction can be directed towards the formation of ketones containing one (**119a–j**) or two (**120a–j**) 3-dimethylaminopropenylidene substituents in the α -position.^{86, 92, 93, 95}

$R^1 = R^2 = \text{H}$ (**a**); $R^1 = \text{H}, R^2 = \text{Me}$ (**b**); $R^1 - R^2 = (\text{CH}_2)_2$ (**c**), $(\text{CH}_2)_3$ (**d**), $(\text{CH}_2)_4$ (**e**), $(\text{CH}_2)_2\text{CHMe}$ (**f**), $\text{CH}_2\text{CH}(\text{Me})\text{CH}_2$ (**g**), $\text{CH}_2\text{CH}(\text{Me})\text{CHMe}$ (**h**), CH_2OCHMe (**i**), CH_2OCMe_2 (**j**).

β -Dimethylaminoacrolein acetal-aminals or aminals **121** can be used for the synthesis of compounds **119** and **120** instead of 3-dimethylaminotrimethoxypropane **118**.⁹⁶ In both cases, the condensation occurs in the presence of a catalyst and virtually does not result in the formation of by-products. An important advantage of this method is the possibility to synthesise compounds **120** containing two aminopolyenoic chromophores.

Owing to the interaction of two chromophores through the carbonyl group, the ketones **120** possess specific properties, such as pronounced solvatochromism⁹⁷ and thermochromism,⁹⁸ fluorescence and the ability to generate laser radiation with high efficiency.⁹⁹ The exceptionally easy alkylation and protonation of these compounds at the carbonyl group is accompanied by drastic changes in their colour.^{100, 101}

The reaction of β -dimethylaminoacrolein acetals or acetal-aminals **121** with cyclic ketones **122a,b** gave the intermediate compounds (diamines **123a,b**) which are quantitatively converted into α -(3-dimethylaminopropenylidene)cycloalkanones **124a,b** in CHCl_3 in the presence of SiO_2 .⁹⁴

$Y = \text{OMe, NMe}_2; n = 9$ (**a**), **12** (**b**).

The reaction of acetals or acetal-aminals **125**¹⁰² substituted in position 2 with ketones often gives only ketones **126a–h** with one 3-dimethylaminopropenylidene substituent.^{103–105}

$Y = \text{OMe, NMe}_2.$

Compo- und 126	R ¹	R ²	R ³	Compo- und 126	R ¹	R ²	R ³
a	H	H	Me	e	(CH ₂) ₂		Me
b	H	H	OEt	f	(CH ₂) ₂		Cl
c	H	H	Cl	g	(CH ₂) ₂		Br
d	H	H	Br	h	(CH ₂) ₂		OEt

According to ¹H NMR spectroscopic data, ketone **126a** has a *trans*-configuration of the α,β -double bond ($J = 15$ Hz).¹⁰⁵ The cyclic ketones **126e–h** represent *E*-isomers with a *trans*-arrangement of the carbonyl group and a substituent in the γ -position ($^3J_{\text{CO-H}\beta} = 5.0\text{--}5.8$ Hz).^{103, 104}

In contrast to dienones **126a–h**, which exist exclusively in the open form, the γ -substituted compounds **126i–k** and **127a,b** containing a six-membered ring exist in some solvents in a dynamic equilibrium between the *Z*-isomer of the δ -amino dienone form and the corresponding 2*H*-pyran. Evidence for the existence of both forms is provided by the detection of two sets of signals in the ¹H and ¹³C NMR spectra as well as by absorption bands from both valence isomers in the UV spectra.^{103–106}

Y = NMe₂, OMe; R = Me (**126i**, **127a**), OEt (**126j**), Cl (**126k**, **127b**).

Bis(ω -dimethylamino) polyenones **128** and **129** containing Me, Ph, Cl and OEt in the γ,γ' -positions were synthesised by the reaction of the corresponding substituted acetals or acetal-aminals **125** with acetone^{107, 108} and cyclopentanone.^{103, 104, 109} Bis(3-dimethylaminopropenyldene)cyclohexanone **130** was obtained using fluorine-substituted acetals **125**.¹¹⁰

R = Me, Ph.

R = Me, OEt, Cl.

Compound **131** which is formed first was isolated in the form of its valence isomer, *viz.*, 2*H*-pyran **132**, in the reaction of α -phenyl- β -dimethylaminoacrolein acetals or acetal-aminals with cyclohexanone.¹⁰⁸

Y = OMe, NMe₂.

δ -Amino dienones **133** containing heterocyclic and heteroorganic substituents were synthesised¹¹¹ using β -dimethylaminoacrolein acetals or acetal-aminals **121**.

R¹ = Ph, PhCH=CH, , , , C₅H₅FeC₅H₄;
R² = H, Me, Ph.

Azaacetal **134** was used for the synthesis of unsaturated amino ketones of various structures. Thus the condensation of cycloalkanones **119c,d** with the azaacetal **134** is accompanied by the cleavage of the C=N bond resulting in non-symmetrical bis(dimethylaminoalkenyldene)alkanones **135**.¹¹²

X = CH₂ (**119c**, **135a**), (CH₂)₂ (**119d**, **135b**).

The cleavage of the C=N bond also takes place in the reaction of the azaacetal **134** with cycloalkanones and acetone at an equimolar ratio of the reagents.¹¹²

R¹ = R² = H; R¹–R² = (CH₂)₂, (CH₂)₃, (CH₂)₄.

The ketones **136** and **137** containing an azamethine group were synthesised at an cycloalkanone :azaacetal **134** ratio of 1 : 2 (PrOH, 80 °C, 5 h).¹¹²

III. Conjugated ω-amino polyenones

1. Condensation of α,β-unsaturated ketones with β-dimethylaminoacrolein acetals and acetal-aminals

β-Dimethylaminoacrolein **121** acetals and acetal-aminals manifest exceptionally high reactivity. They react with cyclic and acyclic unsaturated ketones **138a,d** and their vinilologues **138b,c,e** containing no more than three double bonds at both the α-methyl (or α-methylene) group and the methyl group separated from the carbonyl function by double bonds to give bis(dimethylamino)-polyunsaturated ketones **139–141** (Scheme 1).¹¹³

Y = NMe₂, OMe.

Compounds **138**, **139**

	R ¹	R ²	n	Yield of 139 (%)
a	H	H	0	54
b	H	H	1	40
c	H	H	2	27
d	(CH ₂) ₃		0	75
e	(CH ₂) ₃		1	48

In undeca-3,5,7,9-tetraen-2-one (**142**), the mobility of hydrogen atoms of the methyl group separated from the carbonyl function by four double bonds is insufficient for the condensation with compounds **121**; only the methyl group in the α-position

Y = NMe₂, OMe.

relative to the carbonyl group reacts to yield ketone **143** containing one 3-dimethylaminopropenyldiene group.¹¹³

Y = NMe₂, OMe.

In conjugated ketones **138a,e**, the mobility of hydrogen atoms of the methyl or methylene group vicinal to the carbonyl group is higher than that of the methyl group separated from the carbonyl group by one or several double bonds. This allows one to carry out condensation under milder conditions, *e.g.*, at equimolar ratios of reagents and without heating, which results in selective formation of reaction products involving the α-methylene group.¹¹³

n = 0–2; R¹ = R² = H; R¹–R² = (CH₂)₃.

Unfortunately, this method is confined mainly to the synthesis of non-symmetrical polyunsaturated bis(3-dimethylaminopropenyldiene)alkanones. Moreover, this requires difficultly accessible unsaturated ketones as starting compounds.

2. Condensation of acetals and acetal-aminals of β-dimethylaminoacrolein vinilologues with ketones

The synthesis of symmetrical polyconjugated α,α'-bis(dimethylaminoalkenyldiene)alkanones is based on the use of acetals and acetal-aminals of conjugated ω-dimethylaminopolyenals **144** (n = 2, 3) which react with different ketones at both methyl or methylene groups to give bis(dimethylamino)polyunsaturated ketones **145a–e**.¹¹⁴

Y = OMe, NMe₂.

Compounds **145**

	R ¹	R ²	n	Yield of 145 (%)
a	H	H	2	98
b		(CH ₂) ₂	2	62
c		(CH ₂) ₃	2	60
d	H	H	3	3
e		(CH ₂) ₂	3	12

In the case of compounds **144** (where n = 3), the reaction proceeds under more drastic conditions where the polyunsaturated ketones formed are unstable. The corresponding derivatives **145d,e** could be isolated only in reactions with acetone and cyclopentanone in low yields.¹¹⁴

The condensation of acetals or acetal-aminals of δ-dimethylaminodial **144** (n = 2) with enamino, dienamino and trien-amino ketones was used for the synthesis of non-symmetrical polyunsaturated bis(dimethylamino) ketones **146–148** (Scheme 2).^{114, 115}

It should be noted that compounds **144** (where n = 2) are characterised by sufficiently high reactivities to react with 2-ethylidenecyclohexanone (**149**) at both the α-methylene and the methyl

Scheme 1

Scheme 2

group separated from the carbonyl function by a double bond to yield the derivative **150**.¹¹⁴

With a change in reaction conditions (*viz.*, with equimolar ratio of the reactants, gentle, short-term heating), the reaction of acetals and acetal-aminals of ω -dimethylaminopolyenals **144** with ketones occurs in a regioselective manner and yields the polyunsaturated ketones **151–153** which contain only one dimethylamino group.¹¹⁶

3. Condensation of ketones with polymethine salts

Yet another well-studied approach to the synthesis of ω -amino polyenones, is the condensation of ketones with trimethine or pentamethine salts in the presence of bases, such as NaNH_2 ,¹¹⁷ MeOK , MeONa or Bu^tOK ,^{87, 111, 118–120} NaH or LDA .^{121–124} As a rule, this reaction is carried out in triethylamine or pyridine.

δ -Dimethylaminoalka-1,3-dienyl ketones **154** having substituents in the aminopolyene chain were prepared by the condensation

of aromatic and heteroaromatic methyl ketones with the substituted trimethine salts **155**.^{111, 118, 120}

The reaction of the pentamethine salt **156** with methyl ketones makes it possible to synthesise ω -aminopolyunsaturated ketones **157** with a more extended chromophore.¹¹¹

The condensation of isophorone with the pentamethine salt **156** involves the methyl group (rather than the sterically shielded α -methylene group), which affords the aminopolyunsaturated ketone **158** where NMe_2 and CO groups are separated by four double bonds.¹¹¹

The reaction of tri- and pentamethine salts **159** with ketones in pyridine in the presence of MeONa (2 equiv.) or Bu^tOK was used¹¹⁹ to obtain the symmetrical diamino polyenones **120a,c,d** and **160a,b**. The yields of ξ -dimethylamino trienones **160a,b** do not exceed 35%.

Compounds	R ¹	R ²	n	Yield (%)
120a	H	H	1	55
120c	(CH ₂) ₂		1	83
120d	(CH ₂) ₃		1	65
160a	(CH ₂) ₂		2	26
160b	(CH ₂) ₃		2	35

The non-symmetrical cyclic polyunsaturated ketones **162** were prepared from cyclic enamino ketones **161**.⁸⁷

R¹ = H, Me; R² = Ph, Me.

IV. Conjugated ω-amino ketones containing a heterocyclic fragment

The synthesis of conjugated ω-amino ketones containing a heterocyclic fragment which strongly affects their physicochemical properties has been carried out in the last few years.

Thus the condensation of heterocyclic ketones containing an acetyl or an activated methylene group with acetals and acetal-aminals **121** or **144a,b** was used to obtain δ-amino dienones **163a**,¹¹³ **164**, **165a**, **166a**,¹⁰⁹ **167a**, **168a**¹²⁵ and ξ-amino trienones **163b**, **165b**, **166b**, **167b**, **168b**¹²⁵ and **169**¹¹⁶ containing a heterocyclic fragment.

X = O, S; n = 1 (**a**), 2 (**b**);
X = O; n = 2 (**c**), 3 (**d**).

n = 1 (**a**), 2 (**b**).

n = 1 (**a**), 2 (**b**).

n = 1 (**a**), 2 (**b**).

n = 1 (**a**), 2 (**b**).

High reactivities of compounds **121** enable their reactions with the methyl group separated from the carbonyl group by a double bond or by a heterocyclic fragment to give the ω-amino polyenones **170–172**.^{113, 125, 126}

R¹ = Me, OH; R² = H, OMe.

X = O, S.

R = H, Me, Ph.

* * *

In conclusion, it may be said that the ω-amino polyenones **168**, **169** and **170** containing a coumarin fragment are very valuable, since coumarin derivatives constitute an important group of organic luminophores and laser dyes which effectively generate radiation in the region of 400–560 nm.^{127, 128} In addition, they are widely employed in medicine and biochemistry as fluorescent compounds.¹²⁹ 2,6-Bis(4-dimethylaminoalka-1,3-dienyl)-4H-pyran-4-ones (**172**) appeared to be very interesting reagents from the spectral and synthetic standpoints.¹²⁶

Abstract. Published data on the optical spectra and theoretical investigations of dioxins, polychlorinated derivatives of dibenzo-*p*-dioxin, which are well-known environmental toxins, are generalised. The geometrical and electronic structures of the molecules and their vibrational and electronically excited states are considered. The influence of the number and positions of chlorine atoms in dioxin molecules on the optical spectra (IR and UV absorption, fluorescence and phosphorescence spectra), in particular, on the low-temperature fine-structure phosphorescence spectra of solid solutions and on the photophysical deactivation of triplet electronic states are discussed. The results of the use of optical spectroscopy for identification and quantification of dioxins are presented. The bibliography includes 108 references.

I. Introduction

Compounds of the dibenzo-*p*-dioxin series, also called dioxins, became widely known and fell into disrepute after high toxicity of some polychlorinated dibenzo-*p*-dioxins (PCDD) had been established.^{1–5} Due to their high stability, dioxins formed in industrial processes can be retained in soil and water for long periods, enter living organisms and be accumulated in them. Due to the extreme hazard of dioxin ecotoxins, investigation of their physicochemical properties and development of highly sensitive methods for their detection and quantification have become urgent.

Several reviews devoted to the methods and results of determination of PCDD in environmental objects and biological tissues have been published;^{6–10} however, they mainly discuss the data of GC/MS methods of analysis, while the data of spectroscopic studies used for analytical purposes are scanty. Since the mid-1980s, the physicochemical properties of PCDD have been studied more vigorously, in particular, by spectroscopic methods. These methods possess a great analytical potential; they can be used to identify various PCDD in different media and to perform quantitative analysis. Furthermore, spectroscopic meth-

ods can also be used to solve a fundamental problem, namely, to elucidate the relationship between the structures and physicochemical properties of PCDD molecules. They provide valuable information about the interaction of the molecule with light, its steric and electronic structure, various types of intra- and intermolecular interactions, *etc.* With the progress in elucidation of the structure and physicochemical properties of PCDD, the mechanism of toxic action and the pathways of deactivation of these toxins would gradually become clear.

The present review is, in our opinion, the first attempt to survey the published data obtained by both experimental and theoretical methods of optical spectroscopy on the structure, vibrational and electronic states of dioxin molecules and the physicochemical properties of dioxins. Data from IR, Raman, electronic absorption, fluorescence and phosphorescence spectra are discussed, in particular, fine-structure electronic-vibrational (vibronic) phosphorescence spectra at temperatures of 77 and 4.2 K are presented. The manifestation of vibronic and vibronic-spin-orbit couplings in the fine structure of vibronic spectra, the change of the nuclear configuration of molecules in the triplet excited state, the rate constants of radiative deactivation of singlet and triplet electronic states, and the effect of the number and the positions of chlorine atoms in the PCDD molecule on the phosphorescence spectra and the phosphorescence rate constants are discussed. The last Section contains the results of the use of optical spectra (UV and IR absorption, fluorescence, phosphorescence) for identification of dioxins and determination of their quantity.

II. Molecular and electronic structure of dioxins

1. Molecular structure

Dibenzo-*p*-dioxin (DD) is an aromatic cyclic ether consisting of two benzene rings connected through oxygen bridges.

X-Ray diffraction data for DD^{11–13} and for five of its chloro-derivatives [mono-, di-, tetra-, hexa-, and octachlorodioxins (OCDD)]^{14–19} have been described in the literature. In the crystals, the dioxin molecules are nearly planar, although some atoms including Cl atoms deflect from the plane. Thus in di-¹⁶ and

Uspekhi Khimii 69 (12) 1128–1148 (2000); translated by Z P Bobkova

hexachlorodioxin molecules,¹⁷ the angle between the C—Cl bond and the plane amounts to 3–4°, while in mono-,^{14, 16} octa-^{16, 18} and tetrachlorodioxins,^{15, 16, 19} this angle does not exceed 2°. The C—Cl bond length in mono-, di- and hexachlorodioxin molecules varies from 1.69 to 1.75 Å. The geometric parameters of the central fragment of the molecules differ insignificantly: the C—O bond length is equal to 1.36–1.38 Å and the angle between the C—O bonds (δ_{COC}) is $\sim 116^\circ$. Thus, the size of the COC angle in dioxins is intermediate between those in anisole (110°) and diphenyl oxide (120°).²⁰

According to X-ray diffraction data, the central fragment of dioxin molecules can be considered to be planar. In the 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (β -TCDD),[†] the oxygen atoms deflect slightly from the plane through the four carbon atoms in different directions, thus forming a 'chair' configuration of the central fragment.¹⁶ However, the angle of deflection is only 0.8° . In the DD molecule,¹¹ all six atoms of the central fragment lie in one plane but this plane as a whole is somewhat (by 0.5°) rotated around axis 1. The C—O bond length in dibenzo-*p*-dioxin is 1.383 Å, the internal and external CCO angles are 122° and 118° , and the central COC angle is 116° . Note that the geometric parameters determined from X-ray diffraction data refer to molecules forming the crystal lattice. No experimental data for these parameters in free dioxin molecules have been reported in the literature.

In several studies, the geometric structures of dioxins have been determined theoretically, the geometry being optimised using semiempirical²¹ and *ab initio*^{22, 23} calculations. According to some data,^{21, 22} the DD and β -TCDD molecules are planar and the calculated values of bond lengths and angles are close to those found experimentally.¹⁵ According to another publication,²³ the DD molecule is non-planar: the benzene rings are rotated with respect to the axis which passes through oxygen atoms (axis *z*) to form a dihedral angle equal to 167.93° (subsequently, this molecular configuration is called a 'butterfly'). According to a calculation²³ carried out in the same approximation, the cation derived from the DD molecule is planar in the ground electronic state.

In an earlier publication,²¹ DD has also been suggested to have a 'butterfly' configuration. Thus the dipole moment of a solution of DD in benzene was found to be 0.55 D (rather than zero). The molecule was modelled as the 'butterfly' configuration and the dihedral angle was estimated from the dipole moment. It was found to be 164° . Note that this conclusion cannot be regarded as unambiguous because the molecule could acquire a dipole moment due to interaction with the solvent without losing planarity; for example, it could occur as a configuration with C_{2v} symmetry with retention of the $C_2(z)$ symmetry axis.

The problem of the structure of dioxins attracts attention because the toxicity of PCDD is supposed to be correlated with either planar or non-planar structure of their molecules.²⁴ Grainger *et al.*²⁴ proposed determination of the molecular configuration on the basis of the δ_{COC} angle: if this angle is 109 – 111° , the molecular is non-planar. For some PCDD, the COC angles were found²⁴ using approximate calculation procedures based on a triatomic model and using spectroscopic data on the frequency of the stretching antisymmetrical vibrations of C—O—C groups. It was concluded that the PCDD molecule becomes more planar as the number of α -chlorine atoms decreases. However, this conclusion should be treated critically because the triatomic model is too rough to provide an adequate description of the vibrations of a polyatomic molecule.

The authors of most spectroscopic studies of dioxins give preference to the planar configuration, relying on the experimental data on molecular geometry; however, some researchers decide in favour of the 'butterfly'.

[†] In considering the spectral properties of polyaromatic derivatives, for example, substituted naphthalenes, anthracenes, 9,10-anthraquinones and so on, the positions of substituents are designated by Greek letters.

The highest-symmetry group to which planar dioxin molecules can belong is the D_{2h} group (this group of symmetry corresponds to the planar molecules of DD, β -TCDD, 1,4,6,9-Cl₄DD and OCDD). A molecule with the 'butterfly' configuration has C_{2v} symmetry in which the following symmetry elements are retained: the $C_2(x)$ axis and two symmetry planes σ_1 and σ_2 , perpendicular to the Cartesian coordinates *z* and *y*, respectively. The $C_{2v}(D_{2h})$ groups of symmetry are matched by the following correlation of irreversible representations:

$$A_1(A_g + B_{3u}), B_2(B_{2u} + B_{1g}), B_1(B_{1u} + B_{2g}), A_2(B_{3g} + A_u). \quad (1)$$

To answer the question about the configuration of the dioxin molecules mentioned above, it is expedient to use correlation (1) and employ selection rules when analysing spectroscopic data (see Sections III and IV).

2. Electronic structure of molecules

The ground electronic state (S_0) of the planar DD molecule is characterised by the following charges (ρ_e) on the atoms of the central fragment, oxygen and four carbons: $\rho_e(\text{O}) \approx -0.37$ and $\rho_e(\text{C}) \approx +0.22$ (in the electron charge units) on each of equivalent atoms. The calculation was carried out by the INDO/S semi-empirical approximation. The charges on the C—H group atoms are small in magnitude (~ 0.05 – 0.09 units) and have opposite signs (for carbon $\rho_e < 0$).

The presence of four Cl atoms in the planar β -TCDD molecule does not change the charge distribution in the central fragment with respect to that in DD. Charge redistribution in β -TCDD takes place on the atoms of the C—Cl groups — the negative charge on each chlorine atom [$\rho_e(\text{Cl}) \approx -0.12$] reverses the sign of the charge on the corresponding β -carbon atoms [$\rho_e(\text{C}) \approx +0.11$]. The changes in the charge on the C—H group atoms are reduced to a slight increase in their magnitude ρ_e (to ~ 0.08 – 0.12), their signs being retained. The same pattern of charge distribution is observed for OCDD: $\rho_e(\text{O}) \approx -0.34$, $\rho_e(\text{C}) \approx +0.20$ in the central fragment, while for C—Cl groups with the chlorine atoms in the α - and β -positions $\rho_e(\text{Cl}) \approx -(0.09$ – $0.10)$ and $\rho_e(\text{C}) \approx +(0.07$ – $0.09)$.

Thus, an increase in the number of Cl atoms in dioxin molecules (from zero to eight) barely influences the charge distribution on the atoms of the central six-membered fragment of the molecules in the ground electronic state S_0 . A theoretical study²⁵ of the electron-donating properties of DD, β -TCDD and 1,4,6,9-Cl₄DD molecules has also demonstrated that the π -donor properties of these molecules (as well as their geometric structure) depend only slightly on the positions of Cl atoms.

An important characteristic of the ground electronic state S_0 of a molecule is the ionisation potential (IP). The first IP for several dioxin molecules (DD, 2-ClDD, 2,8-Cl₂DD) cooled in a supersonic jet of argon were determined experimentally by the resonance-enhanced two-colour two-photon ionisation technique.^{23, 26} For nine dioxins containing zero to eight chlorine atoms in the molecule, a semiempirical calculation²³ of the IP values in the Koopmans approximation was performed. It was found that, as the number of chlorine atoms in the molecule increases, the IP value increases monotonically by approximately 0.1 eV for each additional Cl atom. Indeed, the IP for DD, β -TCDD and OCDD are 7.58, 7.99 and 8.42 eV, respectively. It is of interest that the pattern of dependence of the IP on the number of Cl atoms in dioxins differs substantially from that observed in the series of chloro-substituted benzene derivatives in which the number of Cl atoms ranges from zero to six.^{23, 27} In the case of chlorobenzenes, the IP value barely changes upon an increase in the number of Cl atoms (9.25 and 9.19 eV for benzene and hexachlorobenzene, respectively). This difference between the patterns of IP variation for these series of compounds was attributed²³ to the presence of oxygen in dioxin molecules.

According to the Koopmans approximation, the IP values are determined by the energy of the highest occupied molecular orbital (with allowance for an adjusting parameter selected

Figure 1. Classification of four MO of the DD molecule according to irreducible representations of the $D_{2h}(C_{2v})$ groups and their representation as a LCAO. The numerical values for the coefficients²⁸ at the $2p_x$ -AO are given; the dark and light circles correspond to different signs of the coefficients at these AO.²³

empirically for a particular series of molecules, for example, for dioxins²³). Figure 1 shows a π -MO (MO_{48}) of the DD molecule for which the 'butterfly' configuration has been accepted.²³ From representation of the structure of this MO_{48} as a linear combination of atomic orbitals (AO), one can see that the oxygen atoms can actually affect substantially the IP in the DD molecule.

In connection with the results of studies of the dioxin IP, it is of interest to mention the data obtained in the calculations of the electronic states in the planar dioxin molecules^{28,29} concerning the influence of Cl atoms on the structure of the highest occupied π -MO (MO_{48}), which determines the theoretical IP value. It was found that for this MO, the coefficients at the $2p_x$ -AO centered at the O and C atoms in the β -TCDD and OCDD molecules with D_{2h} symmetry differ only slightly (by hundredths of a unit) from the corresponding values for the DD molecule (see MO_{48} in Fig. 1). For OCDD, the coefficients at the $2p_x$ -AO of the chlorine atoms proved to be relatively low: +0.13 for β -Cl and -0.03 for α -Cl. Since the coefficients at the $2p_x$ -AO of oxygen for DD, β -TCDD and OCDD do not depend (with an accuracy of < 3%) on the number of chlorine atoms in the molecule, in our opinion, the difference between the patterns of variation of IP in chlorobenzenes and dioxins can hardly be definitely attributed to the influence of the O atoms, as has been proposed in a publication.²³

Figure 1 also shows characteristics of a lower occupied MO_{47} , the removal of an electron from which²³ transforms the DD molecule into a cation, as well as characteristics of the vacant MO_{49} and MO_{50} . The electronic configurations corresponding to the transition of an electron from MO_{48} to MO_{50} and from MO_{47} to MO_{49} determine the properties mainly of the lower singlet electronically excited state S_1 having $B_2(B_{2u})$ symmetry. This is a resonance state in two-photon two-colour resonance-enhanced ionisation experiments.²³ Analysis of the signs of the coefficients at $2p_x$ -AO (see Fig. 1) centred on the atoms of the C—O—C groups for four MO led the researchers to the conclusion²³ that the DD molecule has different configurations in different electronic states. For instance, on passing from the S_0 state with a 'butterfly' configuration to the cationic form or to the S_1 state, the DD molecule is believed to become flatter, due to the increase in the bond orders in these states. However, the arguments presented in the study in question²³ seem inconclusive. The spectroscopic data concerning the problem of the configuration of the DD molecule

in different electronic states (S_0 and S_1) are presented in Section IV.

III. Vibrational states

1. Experimental data

The molecules of dioxins contain 22 atoms and have 60 normal modes. In planar molecules, 41 modes are in-plane vibrations and 19 modes are out-of-plane vibrations. In the infrared, Raman, fluorescence and phosphorescence spectra, which display the vibrations of molecules in the ground electronic state, only vibrations with particular types of symmetry can be observed, depending on the symmetry of the molecule, in accordance with the selection rules.

In molecules with D_{2h} symmetry, vibrations are classified into eight representations (types of symmetry) of this group:

$$11A_g + 10B_{3g} + 10B_{1u} + 10B_{2u} + 4B_{1g} + 5B_{2g} + 5A_u + 5B_{3u}.$$

The last four types are out-of-plane vibrations (which normally correspond to frequencies of < 1000 cm^{-1}). Vibrations with g type of symmetry are active in the Raman spectra, while u -type vibrations (except for A_u) are IR active. The vibrations active in the phosphorescence spectra are totally symmetric A_g and non-totally symmetric vibrations of either g or u type, depending on the type of symmetry of the electronically excited state. Of the set of non-totally symmetric vibrations, out-of-plane vibrations are usually responsible for the most intense lines in the $\pi\pi^*$ phosphorescence spectra of heteroaromatic compounds³⁰ (it is these spectra that are typical of dioxins).

Thus, in order to gain exhaustive information concerning the vibrations of dioxin molecules with a symmetry higher than C_s , various spectroscopic methods should be used. Meanwhile, IR spectra of dioxins have been studied most extensively due to the necessity of identifying these hazardous compounds.

The molecules of chlorinated dioxins contain heavy Cl atoms; the frequencies of the fundamental vibrations of these molecules vary²² over a broad range, ~ 3300 – 20 cm^{-1} . However, as a rule, the IR spectra of dioxins are measured^{2,24,31–37} in a narrower frequency range, namely, above 800 cm^{-1} . Data on the IR vibration frequencies of PCDD molecules in KBr pellets,^{2,31} in the gas phase,^{24,34} and under conditions of matrix isolation (argon matrix at 12 K)^{33,35–37} have been reported. In particular, the spectra of 22 isomers of tetrachloro-substituted DD in an argon matrix and in the vapour phase were recorded.³³

The attention was focused on the IR spectra of the most toxic β -TCDD.^{2,32–34} The IR spectrum of this compound in a KBr pellet was measured² in a wider frequency range (4000–375 cm^{-1}) than the spectra of other tetrachloro-substituted DD. Figure 2 shows a fragment of this spectrum.³⁷

Figure 2. IR absorption spectrum of β -TCDD in a KBr pellet.² The arrows mark the spectral regions in which analytical lines were identified in a study with matrix isolation.³⁷

The researchers were especially interested in the fact^{22,34} that the IR spectra of tetrachloro-substituted DD recorded under various experimental conditions exhibited doublet splitting of some lines. In the case of β -TCDD, this splitting is observed in the region of 1480, 1315 and 1115 cm^{-1} (see Fig. 2). The results of a theoretical study of the possible causes of this effect in β -TCDD gave rise to the conclusion²² that Fermi resonance is the main reason.

If the molecular configuration of any dioxin has an inversion centre, only about a half of the fundamental modes are displayed in the IR spectra, while the other frequencies are active in the Raman spectra. The most comprehensive IR and Raman data have been reported for DD^{38,39} and OCDD⁴⁰ (Raman spectra of OCDD are shown in Fig. 3). For other PCDD, to the best of our knowledge, no data on the Raman spectra are available.

Figure 3. Raman spectrum of the OCDD powder, $\lambda_{\text{excit}} = 488 \text{ nm}$.⁴⁰ The spectral lines are marked by the letter designations of vibrations used in Tables 1 and 2. The asterisk marks the vibration frequencies for which a different interpretation is possible (see Table 4).

The frequencies of the fundamental modes of the molecules of some dioxins [DD, β -TCDD, 1,3,6,8-tetrachlorodibenzo-*p*-dioxin (α,β -TCDD), OCDD] in the ground electronic state were also determined by analysis of the fine-structure phosphorescence spectra^{39,41–43} (the results of analysis of these spectra are outlined in Section V). For DD, 2,7-Cl₂DD, 2,8-Cl₂DD and 2,3-Cl₂DD molecules cooled in a supersonic jet, the vibrational structure of the first singlet electronically excited (S_1) state was obtained using the resonance two-photon ionisation method.^{23,26,44–46}

On the basis of a study of the IR spectra, an empirical interpretation of a number of absorption bands of dioxins has been proposed.^{2,24,31,37} As an example, we cite the empirical interpretation of seven frequencies corresponding to the analytical lines in the β -TCDD spectrum (see Fig. 2):³⁷ 1575, 1489, 1471 cm^{-1} are skeletal in-plane vibrations of the C=C groups in the aromatic fragments; 1312 cm^{-1} is an antisymmetric stretching vibration of the C–O–C groups; 1176 and 1117 cm^{-1} are in-plane deformation and stretching (breathing) vibrations of the aromatic fragments; and 879 cm^{-1} is an out-of-plane vibration of the C–H groups. Studies of the vibrations of dioxins resorting to the data of theoretical calculations^{22,39–41} have shown that this assignment has to be corrected.

2. Calculation and interpretation of vibrations

The calculations for vibrations in the harmonic approximation were performed with the assumption of a planar configuration of the molecule. For several tetrachloro-substituted DD isomers (β -TCDD, 1,4,6,9-Cl₄DD, 1,3,7,8-Cl₄DD, 1,4,7,8-Cl₄DD)²² and a number of hepta- and hexa-chloro-substituted PCDD isomers,⁴⁷ an *ab initio* quantum-chemical calculation of vibrations was performed using scaling factors. For a number of molecules

having the same D_{2h} symmetry but different numbers of chlorine atoms, DD, β -TCDD and OCDD, the normal modes were calculated^{39–41} by the classical method.⁴⁸ When applying this method to dioxins, the potential field of a molecule with a similar structure (xanthone) was chosen as the base.^{49,50} As the hydrogen atoms were replaced by chlorine atoms, the increments³⁹ corresponding to the force constants of the C–C(Cl)–C groups in chlorinated benzenes were introduced without variations. Scaling factors for some natural vibrational coordinates of related molecules were used in the *ab initio* calculation;^{22,51} for PCDD, they were not varied either.

The results of calculations were used to determine the frequencies of all the normal modes of the dioxins studied;^{22,39–41} an interpretation for each vibration was proposed.

In view of the fact that each vibration of the molecule usually has a complex form (combination of the amplitudes of variation of all bond lengths and bond angles in the molecule), different approaches to the interpretation have been proposed;^{50,51} they were presented, for example, in Refs 22 and 40. One approach⁵¹ makes use of the results of calculations of the distribution of the total energy of vibrations over atomic groups. In this case, each calculated vibration frequency in dioxins²² is usually matched to vibrations of several atomic groups. For instance, the intense band with a maximum at about 1480 cm^{-1} (see Fig. 2) in the IR spectrum of β -TCDD was assigned²² to the skeletal vibrations of the aromatic fragments and the deformation vibrations of the CH groups in the plane of the molecule. In another approach,⁵⁰ for each calculated normal mode of dioxins,⁴⁰ data on the local type of symmetry were taken into account [within the framework of the D_{6h} (D_{2h}) groups of symmetry for the movement of atoms in the separate six-membered fragment of the molecule⁵⁰], in addition to the relative vibration amplitudes of separate groups of atoms (Table 1). In Table 1, the vibration modes were assigned to the vibrations of particular atomic groups – the benzene fragment

Table 1. Letter designations⁴⁰ of the vibrations of dioxins and their assignment.

Designation of vibrations ^a	Atomic group
In-plane vibrations	
$k [e_{2g}(a_g)], l [e_{2g}(b_{3g})], m [e_{1u}(b_{1u})], n [e_{1u}(b_{2u})], o [b_{2u}(b_{2u})], r [a_{1g}(a_g)]$	C=C stretching (BF)
$p [b_{1u}(b_{1u})], s [e_{2g}(b_{3g})], t [e_{2g}(a_g)]$	CCC deformation (BF)
$q (a_g), q (b_{2u}), z (b_{3g}), z (b_{1u})$	CO stretching (CF)
$u (a_g), c (b_{1u}), c (b_{3g})$	COC, OCC deformation (CF)
$a [b_{2u}(b_{2u})], b [e_{1u}(b_{1u})], d [e_{1u}(b_{2u})], e [a_{2g}(b_{3g})]$	CCH deformation ^b
ε	CCl stretching
η	CCCl deformation ^c
Out-of-plane (deformation) vibrations	
$v [b_{2g}(b_{2g})], y [e_{2u}(b_{3u})], \omega [e_{2u}(a_u)]$	CCCC (BF)
$f [e_{2u}(b_{3u})], g [a_{2u}(b_{3u})], i [e_{1g}(b_{2g})], j [b_{2g}(b_{2g})]$	CH ^b
ρ	CCl ^c
$\chi (b_{2g}), \chi (b_{3u})$	CCOC (CF)
$x (b_{1g}), x (b_{3u}), h (a_u)$	BF + CF ^d

Note. BF and CF are the benzene and central fragments.

^a The local types of symmetry [$\Gamma(\Gamma')$] of the D_{6h} (D_{2h}) point group are given in brackets.

^b For terminal atomic groups, the designation [$\Gamma(\Gamma')$] has a meaning if all their four atoms in a fragment are identical.

^c For C–Cl groups, subscripts can be added to the designations η and ρ corresponding to the letter designations for the C–H groups (to provide a more detailed interpretation of vibrations) if the fragment contains four chlorine atoms.

^d Vibrations of the benzene fragments mutual with respect to one another.

(local symmetry D_{6h}) and the central fragment (local symmetry D_{2h}) and to vibrations of the terminal (C–H and C–Cl) atomic groups. A more detailed interpretation of vibrations according to their form⁴⁰ was performed taking into account the definite alternation of the signs of the amplitudes characterising the changes in the bond lengths and angles in the given molecular fragment; this characteristic is reflected in a definite local (for each fragment) type of symmetry of the $D_{6h}(D_{2h})$ point group. This type of analysis of the forms of vibrations makes it possible to distinguish between normal modes assigned roughly to the same atomic groups (for example, to six-membered carbon fragments). This individual form of a normal mode of dioxin was designated by a special letter symbol (in particular, the known Whiffen designations of the vibrations of benzene and monosubstituted benzene derivatives were used).

Tables 2–5 contain the calculated values for all the vibration frequencies^{22,40} in the DD, β -TCDD and OCDD molecules distributed over types of symmetry of the D_{2h} point group, together with the corresponding experimental values found from vibrational spectra (IR and Raman) or fine-structure phosphorescence spectra. In the case of β -TCDD, the calculated vibration frequencies determined by different methods^{22,40} are in fairly good agreement; however, the use of different methods for the

analysis of the forms of vibrations^{50,51} precludes a proper comparison of various approaches to the interpretation.

It is worth noting that the approach⁵⁰ taking into account the local symmetry of vibrations (unlike that described in Refs 22 and 51) allows correlation of the vibrations of molecules which belong

to different point groups of symmetry. For example, this approach was used to perform a correlation of all the vibrations in mono-, di- and tetrachloro-substituted 9,10-anthraquinones.⁵² In addition, in experimental and theoretical studies of the vibrations of the DD and β -TCDD molecules as well as 9,10-anthraquinone and tetra- β -chloro-substituted 9,10-anthraquinone molecules, it has been established that the frequencies and forms of vibrations for these molecules are very close.³⁹ Therefore, interpretation of the vibrations of chlorinated 9,10-anthraquinones, which are more readily available, can be taken as the base for the investigation of the corresponding dioxins.⁵²

The variation of frequencies of all 60 vibrations following an increase in the number of Cl atoms in the series of DD, β -TCDD and OCDD, the molecules of which correspond to the same group of symmetry D_{2h} , was discussed in detail.⁴⁰ We shall briefly note some regularities⁴⁰ of the variation of the frequencies of vibrations with the same form in the DD, β -TCDD and OCDD molecules.

In-plane vibrations. The high-frequency in-plane vibrations of the carbon skeleton (in the range of 1650–1200 cm^{-1}), which can be assigned to the k , l , m , n , o stretching modes (of the benzene fragments) and q , z stretching modes (of the central fragment), change insignificantly, on the average by 5%, as the H atoms are replaced by Cl atoms (see Tables 2, 3). In the case of the two other stretching vibrations (A_g and B_{2u}) of the benzene fragments, designated by r (which should be matched to the only totally symmetric vibration r of the core of benzene molecule in the region of 995 cm^{-1}), the vibration frequencies found for DD and OCDD differ appreciably, by a factor of about two. Note that the vibrations r are characterised by low frequencies also in other molecules with benzene side fragments, even when they contain no heavy atoms.⁵⁰ For example,⁵³ in anthracene $\nu_r = 753$ (A_g) and 808 cm^{-1} (B_{2u}).

The frequencies of all [except for one, s (B_{3g})] low-frequency deformation vibrations of the carbon skeleton of the molecule (p , s , t , c , u) also change substantially, by approximately 200–300 cm^{-1} (by up to 65%), when all the H atoms have been replaced by Cl atoms. The stretching vibrations of the C–Cl (ϵ) groups of the OCDD molecule were matched to frequencies in the region of 1000–750 cm^{-1} .

In many studies, considerable attention is devoted to the identification of the IR bands caused by the presence of the

C–O ether groups in the molecules.²⁰ For example, in the case of diphenyl oxide, which contains a C–O–C group, the frequency $\nu_{C-O}^{as} = 1236$ cm^{-1} was assigned to antisymmetric stretching vibrations of this group. In molecules with D_{2h} symmetry, the q (B_{2u}) and z (B_{3g}) modes can be matched to these vibrations (see Tables 2, 3). In various PCDD, frequencies in the region of 1330–1280 cm^{-1} were attributed to an antisymmetric vibration. It is noteworthy that the vibration frequencies of the C–C groups in the anthracene molecule with the rigid six-membered central fragment are close to the vibration frequencies of the C–O ether groups in DD. The frequencies (in cm^{-1}) of the stretching vibrations of the C–O or C–C groups of the central fragment of DD, 9,10-anthraquinone and anthracene are presented below for comparison.^{50, 53}

	DD	9,10-Anthraquinone	Anthracene
A_g	1226	1148	1260
B_{3g}	1317	1284	1376
B_{1u}	1200	1335	1274
B_{2u}	1395	1173	1398

In the DD molecule, as in other molecules having a similar structure and containing eight H atoms in the benzene fragments, each of the eight in-plane deformation vibrations of the C–C–H groups belongs to a particular frequency region (see Tables 2, 3), namely, 1360–1240 cm^{-1} (e are high-frequency vibrations) and 1150–1000 cm^{-1} (a , b , d is a group of relatively low-frequency vibrations). For similar deformation vibrations of the C–C–Cl (η) groups of the OCDD molecule, two appreciably different frequency regions can also be distinguished. The range of 800–700 cm^{-1} is typical of the analogues of the vibrations e , while 200–150 cm^{-1} is the range where the analogues of the vibrations a , b and d show themselves.

The empirical interpretation of the spectrum does not always coincide with the interpretation based on calculations. Below we present the assignment of vibrations according to their form based on the use of the local types of symmetry for several vibration frequencies of the β -TCDD molecule, which differs from the empirical assignment (presented at the end of Section III.1).³⁷ Thus the frequency of 1312 cm^{-1} (B_{2u}) refers to the vibration o of the benzene fragments (with the local type of symmetry b_{2u}); 1172 (B_{1u}) and 1114 cm^{-1} (B_{2u}) correspond to the stretching vibrations z of the central fragment and ϵ of the C–Cl groups, respectively. A frequency of 450 cm^{-1} was assigned to the ‘breathing vibration’ r of the benzene molecules (the vibration B_{2u} with the local symmetry a_{1g}), while a frequency of 1326 cm^{-1} was attributed to the antisymmetric vibration of the C–O–C groups.

Out-of-plane vibrations. The main distinctive feature of most of the 11 out-of-plane vibrations of the carbon skeleton of the DD, β -TCDD and OCDD molecules is that their frequencies increase rather than decrease upon an increase in the number of Cl atoms in the molecule (see Tables 4, 5). Indeed, in the region above 300 cm^{-1} , the frequencies of only two, the highest-frequency out-of-plane vibrations of OCDD (of the v type, assigned to the benzene fragments) change relatively slightly (by 3%–4%) with respect to the frequencies of the same vibrations in β -TCDD and DD. The other vibration frequencies increase appreciably, by 13%–33%, which implies displacement of the bands in the spectrum by 70–140 cm^{-1} .

A different pattern of variation is observed for the other four lower-frequency vibrations of the molecular skeleton (below 300 cm^{-1}), namely, one vibration ω , which was assigned to the benzene moieties, and three vibrations x and h , assigned to the central moiety. These frequencies, conversely, tend to decrease (by 25% to 75%).

It should be mentioned that the vibrations x and h can be related to the rotations of two benzene fragments with respect to one another (Fig. 4). The molecule thus assumes a ‘butterfly’ (x , B_{3u}), ‘chair’ (x , B_{1g}) or ‘propeller’ (h , A_u) configuration. For comparison, Fig. 4 shows the form of the high-frequency out-of-

Figure 4. Forms of some out-of-plane vibrations of the DD molecule of D_{2h} symmetry (for vibration frequencies, see Tables 4, 5). The signs and the magnitudes of the displacements of atoms with respect to the plane of the molecule are marked by circles of different sizes and colours.

plane vibration $\chi (B_{3u})$. It can be seen that both x and χ vibrations of the B_{3u} type can be attributed to the molecule in the 'butterfly' configuration but x is related to a larger extent to the rotations of the benzene fragments and χ is related to the shifts of oxygen atoms.

The four out-of-plane vibrations of the C–Cl groups (ρ) of the β -TCDD molecule show themselves at low frequencies, about ~ 100 , 215 and 320 cm^{-1} . An increase in the number of chlorine atoms does not result in any significant increase in the frequency range for the eight vibrations ρ of the OCDD molecule; these vibrations remain in approximately the same frequency regions: ~ 90 – 140 , ~ 215 and $\sim 360\text{ cm}^{-1}$.

Note that the eight out-of-plane vibrations of the C–C–H groups in DD, like those in other molecules having a similar structure and containing eight H atoms in the benzene fragments, correspond to a definite frequency region: 980 – 940 cm^{-1} (j, f), $\sim 860\text{ cm}^{-1}$ (i), 750 – 680 cm^{-1} (g). However, it was found that similar vibrations of the C–C–Cl groups (ρ with the corresponding subscripts) of the OCDD molecule cannot be matched successively to higher or lower frequencies (see Tables 4, 5). For example, both ρ_j and ρ_g vibrations in OCDD are characterised by low frequencies.

Molecular configuration. To decide between the planar and non-planar ('butterfly') configurations of the DD and OCDD molecules, we shall consider the structure of their Raman spectra taking into account the selection rules for the D_{2h} and C_{2v} groups of symmetry and the correlation of their irreducible representations (1). If the molecule has the 'butterfly' configuration, *i.e.* belongs to the C_{2v} symmetry group, all the vibrations should be active in the Raman spectra, including the u -type vibrations, which are forbidden in the case of the D_{2h} group [see expression (1)]. In particular, the out-of-plane B_{3u} vibrations of the D_{2h} group become totally symmetric. The results of interpretation of the Raman spectra of two dioxins, DD and OCDD, demonstrate that all lines in the spectra of these compounds can be assigned to g -type vibrations, which implies a planar configuration of the molecule (see Fig. 3, Tables 2, 4).

IV. Singlet electronically excited states

1. Experimental data

Dioxins, like most benzene derivatives, are colourless, *i.e.* they do not absorb light in the visible region. The UV absorption spectra of dioxins [$S_m(\pi\pi^*) \leftarrow S_0$] have been studied in solution^{2, 54–57} and in the vapour phase.⁵⁸ Tables listing the absorption maxima

and the molar extinction coefficients (ϵ_{max}) have been reported;² the absorption curves for DD and its chloro-derivatives (β -TCDD, 1,2,3,7,8-Cl₅DD and OCDD) can be found in several publications.^{55, 56, 58}

The absorption spectra of DD and PCDD occur in the region of 200–350 nm and consist of two bands — a weak broad long-wavelength band (**A**) in the region of 280–320 nm with a maximum at ~ 300 – 304 nm and a short-wavelength narrow intense band (**B**) with a maximum at about ~ 220 – 240 nm . It can be seen from the absorption curves of some dioxins^{56, 58} that the high-frequency absorption band has one more, even shorter-wavelength maximum (**C**); for example, in the spectra of solutions of DD, it is separated from band **B** by $\sim 5.5\text{ nm}$.⁵⁵ As examples, Figs 5 and 6 show the absorption spectra of a solution of DD and of the β -TCDD vapour.

Figure 5. Electronic absorption spectrum of a solution of DD in isopentane at 77 K⁵⁶ and results of a quantum-chemical calculation²⁹ (vertical lines) of the energy and the type of symmetry of electronic $\pi\pi^*$ states and the oscillator strengths of transitions (given in parentheses). Dipole-inactive transitions are marked by arrows. The calculated spectrum as a whole is shifted by $\sim 5000\text{ cm}^{-1}$ to lower frequencies.

The ratio of the molar extinction coefficients of bands **B** and **A**, ϵ_B/ϵ_A , for solutions of DD in isopentane⁵⁶ is equal to ~ 10 , while for β -TCDD and OCDD vapours,⁵⁸ $\epsilon_B/\epsilon_A = 9$ and 35. In particular,⁵⁸ for OCDD, $\epsilon_A = 0.05 \times 10^4$ and $\epsilon_B = 1.73 \times 10^4\text{ litre mol}^{-1}\text{ cm}^{-1}$.

It should be noted that the data on the molar extinction coefficients are presented in few publications and, moreover, the reported ϵ values are not always close in magnitude. For example, for DD in isopentane,⁵⁷ chloroform² and heptane,²¹ $\epsilon_A = 0.37 \times 10^4$, 0.37×10^4 and $0.74 \times 10^4\text{ litre mol}^{-1}\text{ cm}^{-1}$; for β -TCDD in chloroform² and in the vapour phase,⁵⁸ $\epsilon_A = 0.56$ and $0.41 \times 10^4\text{ litre mol}^{-1}\text{ cm}^{-1}$. The ϵ_A values reported for vapour and for chloroform solutions of OCDD^{2, 58} differ by a factor of five. These differences may be due to both the interaction of dioxins with a solvent and the error in the determination of the true concentration of dioxins in the samples studied.

The spectra of chloroform solutions of DD and several PCDD² showed an unusual intensity ratio of the absorption bands, namely, the short-wavelength band **B** was found to be less intense than band **A**. For example, $\epsilon_B/\epsilon_A = 0.28$, 0.53 and 5.5 for DD, β -TCDD and OCDD [for comparison, for DD in isopentane, $\epsilon_B/\epsilon_A \approx 10$ (see Ref. 56)]. In our opinion, this effect is caused by the disturbing influence of the solvent, which also absorbs in the short-wavelength region of the spectrum ($< 240\text{ nm}$).⁵⁹

The absorption properties of DD are similar to those of other aromatic ethers. The spectra of ethers usually contain two absorption bands; the long-wavelength band with $\epsilon \approx (0.16$ – $0.3) \times 10^4\text{ litre mol}^{-1}\text{ cm}^{-1}$ is located at about

Figure 6. Electronic absorption spectrum of β -TCDD vapours⁵⁸ and the results of a quantum-chemical calculation²⁹ of the energy and type of symmetry of electronic $\pi\pi^*$ states and the oscillator strengths of transitions. For designations, see Fig. 5.

250–290 nm and the short-wavelength band with $\epsilon \approx (0.8–1.8) \times 10^4$ litre mol⁻¹ cm⁻¹ occurs in the region of 210–240 nm.²⁰ Both bands are associated with transitions from the electronic states corresponding to the benzene chromophore perturbed by the heteroatom of the ether group.

As the number of chlorine atoms in dioxin molecules increases from zero to eight, the long-wavelength band in the absorption spectra of solutions shifts bathochromically.² Thus in the spectra of chloroform solutions of DD, β -TCDD and OCDD, bands A are responsible for maxima at 293, 310 and 318 nm. However, in the case of vapours, the positions of the maxima of bands A and B virtually do not change — in the series β -TCDD, 1,2,3,7,8-Cl₅DD and OCDD, band A has a maximum at about 303–305 nm, while the maximum of band B is at ~ 223 nm.⁵⁸

In the UV absorption spectra of DD in isopentane recorded at 77 K, the long-wavelength band has several maxima,⁵⁶ which can be attributed to the vibrational structure. The vibrational fine structure of the electronically excited state S_1 for the DD, 2,7-Cl₂DD, 2,8-Cl₂DD and β -TCDD molecules was obtained using the method of resonance-enhanced two-photon ionisation in a supersonic argon jet.^{44–46} The vibrational structure of the S_1 state of the DD molecule²³ is shown in Fig. 7. In this type of spectrum of any dioxin, the first (lowest-frequency) line was assigned to the purely electronic transition $S_1 \leftarrow S_0$. As a result, the following energies of the S_1 state were determined for these dioxins:²³ 33774 (DD), 32805 (2,7-Cl₂DD), 32729 (2,8-Cl₂DD) and 32100 cm⁻¹ (β -TCDD). These frequencies are shifted by ~ 750 cm⁻¹ to shorter wavelengths²³ with respect to those in the spectra of iso-octane solutions.

The fine structure of the spectra of the $S_1 \leftarrow S_0$ electronic transition has not been interpreted yet. It should be noted that the results of full interpretation of the spectra performed for many other molecules are widely used, for example, to determine the symmetry of the first electronically excited state, to study the mechanisms of intramolecular interactions, to decide between the retention and the change of the symmetry of the nuclear configuration of the molecule upon transition from the ground state to the electronically excited state and to gain quantitative data concerning the change in the geometrical parameters of the molecule in the electronically excited state. Some results of the interpretation of the spectra of dioxins for the lower triplet state are presented in Section V.

Figure 7. Vibrational structure of the electronically excited state S_1 ($\pi\pi^*$) of DD molecules cooled in a supersonic jet of argon recorded using resonance-enhanced two-photon ionisation.²³

The spectrum shown in Fig. 7 has prompted several conclusions²³ (which we consider erroneous) concerning the nuclear configurations of this molecule in the ground and in the S_1 electronic states. For example, the most intense line of this spectrum (vibration frequency 22 cm⁻¹) was assigned²³ to a ‘butterfly’ type vibration in the electronically excited state S_1 [the form and the frequency of this vibration, $\chi(B_{3u})$, in the ground electronic state are presented in Fig. 4 and in Tables 4, 5). Since this spectrum contained numerous low-frequency lines and the researchers found it to be similar to the corresponding spectrum of dihydroanthracene,⁶⁰ they²³ arrived at the conclusion that the configurations of the DD molecule in the S_1 and S_0 states are different. It was concluded that the molecule has a ‘butterfly’ configuration in the S_0 state and becomes flatter in the S_1 state. However, this conclusion appears doubtful. Indeed, the ratio of the intensities of the strong and weak lines in the spectrum of DD (see Fig. 7) can be distorted due to the known saturation effect.⁶¹ In addition, the strong line, assigned to a ‘butterfly’ type vibration, does not form an intense progression (unlike that in the spectrum of the dihydroanthracene molecule): the lines corresponding to the frequencies 22×2 , 22×3 , etc., are either weak or missing. Meanwhile, it is intense lines due to vibration overtones in the electronic-vibrational spectra that normally point to a change in the nuclear configuration of the molecule.^{62, 63}

2. Calculation of the electronic states

In order to interpret the observed electronic spectra of several dioxins (DD, β -TCDD, α,β -TCDD and OCDD), semiempirical calculations for electronically excited states have been carried out in the PPP, CNDO/S and INDO/S approximations taking into account singly excited electronic configurations.^{21, 29, 43, 56, 64, 65} The calculated spectra of DD and β -TCDD, in comparison with the experimental spectra, are presented in Figs 5 and 6. It can be seen that, although the absolute magnitudes of energies in the calculated spectra usually prove to be overestimated, the calculations represent satisfactorily the general pattern of the absorption spectrum, *i.e.* the relative arrangement and the relative intensities of the weak and strong bands.

According to calculations,^{29, 43, 65} the spectral region corresponding to the long-wavelength band A contains the frequencies of the first four electronic transitions from S_0 to $\pi\pi^*$ states, namely, B_{3g} , B_{2u} , A_g and B_{1u} but only two of these states are dipole-active. Note that the mutual arrangement of the energy levels corresponding to the first three electronic states changes

depending on the parametrisation accepted in the semiempirical calculations; thus, the S_1 state can belong to the B_{3g} , B_{2u} and A_g types. To the best of our knowledge, no experimental data on the type of symmetry of the S_1 state are available. The S_4 state in dioxins has B_{1u} symmetry.

The short-wavelength absorption bands **B** and **C** are due to the third and fourth dipole-allowed transitions from $\pi\pi^*$ states with the B_{2u} and B_{1u} types of symmetry, respectively (see Figs 5, 6).

The calculations of electronic states showed that the structure of the $\pi\pi^*$ -absorption spectrum indicated above does not change substantially in the sequence DD, β -TCDD, α,β -TCDD and OCDD; the increase in the number of chlorine atoms in the molecule changes somewhat the energies of these states (this is in agreement with the experimental results pointing to the small difference between the positions of the band maxima in the UV spectra of various dioxins). The slight influence of the increase in the number of chlorine atoms on the $\pi\pi^*$ -absorption spectrum is also known for other molecules (for example, for chlorinated 9,10-anthraquinones⁶⁶).

It should be mentioned that the calculation, which describes satisfactorily the relative oscillator strengths for transitions, reproduces poorly, as a rule, their absolute magnitudes. For example, according to experimental data ($\epsilon_A = 0.37 \times 10^4$ litre mol⁻¹ cm⁻¹), band **A** of the DD molecule corresponds to the oscillator strength $f_A = 0.067$.²⁹ Various semiempirical calculations which used different molecular models and different approximations or parametrisations gave the following f_A values for DD corresponding to the sum of the oscillator strengths of the first two dipole-active transitions: $f_A = 0.368$,²¹ 0.032²⁹ and 0.17.^{64, 65} The calculated^{64, 65} relative f_B/f_A values for the DD, β -TCDD and OCDD molecules ($f_B/f_A = 9.8, 6.2$ and 70, respectively) agree in order of magnitude with the ratios of extinction coefficients found experimentally (10, 9 and 35, respectively^{56, 58}). Thus, the calculation of the electronic states for planar models of the molecules confirms the experimental data^{56, 58} concerning the substantial decrease in the absorption cross-section at 305 nm for OCDD molecule relative to the DD or β -TCDD molecules.

The **A**–**C** bands in the singlet–singlet $\pi\pi^*$ -absorption spectrum of DD (or other dioxins) can be matched to the corresponding bands in the benzene spectrum. Scheme 1 shows three transitions from states with different types of symmetry and the corresponding absorption maxima for benzene.⁶⁷

Scheme 1

The $B_{2u} \leftarrow S_0$ and $B_{1u} \leftarrow S_0$ transitions are dipole-inactive in the D_{6h} symmetry group and are allowed only upon vibronic (Herzberg–Teller) coupling.

The B_{1u} and B_{2u} states of benzene should be matched to four states of the DD molecule with D_{2h} symmetry, which contains two benzene fragments, namely, B_{2u} and A_g (analogues of B_{2u} in benzene) and B_{1u} and B_{3g} (analogues of B_{1u} in benzene). In the D_{2h} symmetry group, the B_{2u} and B_{1u} states are dipole-active but (in line with their origin) they are characterised by low oscillator strengths. These four transitions correspond to one weak, the longest-wavelength band **A** in dioxins (see Figs 5, 6).

The band with a maximum at 180 nm in the spectrum of benzene is due to the dipole-active $E_{1u} \leftarrow S_0$ transition. In molecules with D_{2h} symmetry, for example in DD, two (according to the number of benzene fragments) electronic states E_{1u} of benzene are matched by the B_{2u} , B_{1u} , A_g and B_{3g} states. The u -type states (B_{2u} and B_{1u}) in DD and in other dioxins should be identified with intense absorption bands **B** and **C** with maxima at about ~ 250 nm. According to calculations, they are characterised by great oscillator strengths of transitions.

The analogy between the electronic states of benzene and dioxins is confirmed by calculations of the corresponding π -MO of the molecule.²⁸ Indeed, for at least six lower electronic states, the symmetry of the π -MO of benzene is approximately retained in the benzene fragments of DD. This is reflected, for example, in Fig. 1, which shows the distribution of the coefficients at the $2p_x$ -AO centred on the atoms of the six-membered benzene fragments of the molecule for four MO. It can be seen that this distribution is similar to the known distribution of the coefficients in the vacant (E_{1g}) and occupied (E_{2u}) π -MO of benzene.

The oxygen atoms have little influence on the local symmetry of the MO under study, although the lone electron pairs (l -electrons) of oxygen, which occupy the $2p_x$ -AO, also contribute to π -conjugation (when this is allowed by the type of symmetry of the whole MO of the molecule). They bring about the greatest perturbation of occupied rather than of vacant MO of dioxins.^{28, 56} For the highest occupied MO of the DD molecule, this contribution is 26%; in the S_1 state, 0.15 of an electron charge is transferred from the oxygen atoms to the carbon atoms of the benzene fragments.

The effect of l -electrons on the S_1 state normally shows itself as a substantial decrease in the energy of the π/π^* state with respect to the $\pi\pi^*$ state and as an increase in the corresponding dipole moment of the transition. For dioxins, this influence of the l -electrons of oxygen and chlorine on the S_1 state is slight; hence, the π/π^* state can be designated by $\pi\pi^*$.

In dioxins, the lone electron pairs (n electrons), which occupy $2p_z$ - or $2p_y$ -AO, form very deeply located MO and the absorption bands corresponding to the $n\pi^* \leftarrow S_0$ transitions should occur in the vacuum UV region. According to calculations,⁶⁵ the spectral region between absorption bands **A** and **B** of dioxins, as in the case of benzene, contains bands corresponding to the $\pi\sigma^* \leftarrow S_0$ transitions.

The analogy between the electronic transitions in DD and benzene (with allowance for the slight influence of chlorine atoms on the spectrum) accounts for the distribution of band intensity in the UV spectra of dioxins.

The same analogy can be drawn between the $\pi\pi^*$ electronic states of benzene, DD and other molecules, for example, 9,10-anthraquinone and anthracene, which contain, like DD, two benzene side fragments. The DD, 9,10-anthraquinone and anthracene molecule differ in the central fragments. Comparison of the spectral and theoretical data concerning their $\pi\pi^*$ states demonstrates the influence of the electronic structure of the central fragment on the mutual arrangement of the first four energy levels. Recall that the first four electronic transitions in DD are responsible for one band **A**. According to theoretical and experimental data,⁶⁸ in 9,10-anthraquinone, the energy level of the state analogous to the $S_4(B_{1u})$ state of DD proves to be shifted to short-wavelength region with respect to the first states B_{2u} , B_{3g} and A_g to such an extent that a separate band with a maximum at ~ 270 nm is attributed to the corresponding transition. Conversely, in the anthracene molecule, the energy level of the state analogous to $S_4(B_{1u})$ in DD is shifted to longer wavelengths with respect to the other three states; thus, it becomes the $S_1(B_{1u})$ state and the onset of the band corresponds to a wavelength of ~ 280 nm.^{53, 69}

Let us briefly summarise the data on the singlet–singlet transitions in dioxins. The long-wavelength band in the absorption spectrum has a combination structure in the sense that it ‘hides’ transitions from the four electronic states having different types of symmetry: B_{1u} , B_{3g} , A_g and B_{2u} , where B_{1u} corresponds to the S_4 state. Variation of the number of chlorine atoms from zero (DD) to eight (OCDD) does not change generally this structure of the band but results in a nearly parallel shift of the energy levels of the corresponding states towards lower frequencies. The mutual arrangement of the energy levels of the B_{1u} and B_{2u} states changes substantially only in a series of molecules having similar structures but containing different atomic groups in the central fragment, for example, in the series of DD, 9,10-anthraquinone and anthracene, in which the above-mentioned states are of the same nature. Thus,

the structure of the long-wavelength band in the spectra of dioxins is determined by the presence of the ether C—O—C groups in the central fragment.

The energy levels calculated for the B_{2u} , B_{3g} and A_g states in dioxins are close; therefore, additional investigations are required to determine the type of symmetry of the S_1 state of a particular molecule. For example, it would be useful to obtain and study the fine vibrational structure of the fluorescence spectrum.

The low intensity of the long-wavelength band in the spectra of dioxins is due to its origin: the electronic transitions corresponding to this band are analogues of the first two, dipole-inactive transitions in benzene. The change in the number of chlorine atoms generally has little influence on the intensity distribution in the UV spectra of dioxins.

V. Luminescence

Dioxins belong to the class of luminescing compounds. Luminescence is due to the $S_1 \rightarrow S_0$ transition from the lower singlet electronically excited state (fluorescence) and to the $T_1 \rightarrow S_0$ transition from the lower triplet state (phosphorescence). Solutions of dioxins fluoresce in the region of 310–400 nm; when frozen (77 K), they display a bright long-living blue to light-blue phosphorescence. As an example, Fig. 8 presents the emission spectrum of a solution of DD in isopentane recorded at 77 K.⁵⁶ This spectrum demonstrates an important feature characteristic of both DD and PCDD, namely, very low intensity of the fluorescence band 1 with respect to the phosphorescence band 2.

Figure 8. Luminescence spectra of a solution of DD in isopentane at 77 K;⁵⁶ (1) fluorescence, (2) phosphorescence.

1. Photophysical characteristics of luminescence

In this Section, the quantitative data on the deactivation of the first singlet and triplet electronically excited states of dioxins are presented. We discuss experimental values for the quantum yields and the decay times of fluorescence (ϕ_f and τ_f) and phosphorescence (ϕ_{ph} and τ_{ph}), the rate constants for deactivation of the lower singlet and triplet electronically excited states (k_f and k_{ph}), theoretical estimates of the k_{ph} values, and the results of calculations of the influence of the number of chlorine atoms in the molecule on k_{ph} and τ_{ph} .

a. Fluorescence

The fluorescence spectra of solutions of DD and PCDD exhibit a structureless band (see Fig. 8). The use of selective laser excitation of fluorescence, which often gives rise to a fine (vibrational) structure in the spectra of solutions,⁷⁰ still has not allowed recording of structured spectra for the molecules under study (β -TCDD, 1,3,7,8-Cl₄DD and OCDD).⁵⁸

The most complete experimental data, reported in the literature, on the deactivation of the S_1 state for solutions of DD in isopentane^{29, 56} and ethanol⁷¹ are presented below.

ϕ_f	τ_f / ns	k_f / s ⁻¹	Ref.
0.003	3.5	0.9×10^6	56
0.000	< 1	—	71
—	—	1.6×10^7	29

For β -TCDD, an approximate estimate gave $\tau_f \approx 10$ ns (vapour, 473 K)⁵⁸ and $k_f \approx 4.0 \times 10^7$ s⁻¹ (vapour and a solution in CHCl₃, 77 K).²⁹ The difference between the given ϕ_f and τ_f values determined for DD in the publications cited is due to the fact that the measurements were performed near the limit of the capacity of the equipment employed and to the influence of the solvent.

The k_f values for isopentane solutions of DD have been determined by different methods.^{29, 56} For DD (as well as for β -TCDD), the k_f values for the $S_1(B_{2u}) \rightarrow S_0$ transition were estimated²⁹ using the calculated data on the ratio of the oscillator strengths of the $^1B_{2u} \leftarrow S_0$ and $^1B_{1u} \leftarrow S_0$ transitions, which are responsible for the long-wavelength band A in the absorption spectra, and experimental data on the integrated intensity of this band (see Figs 5, 6). The k_f values found in this way are over-estimated because the integrated extinction coefficient of band A can contain contributions of the transitions caused by the Herzberg–Teller vibronic coupling. In another method,⁵⁶ the k_f value was estimated from the expression $k_f = \phi_f / \tau_f$.

It is difficult to explain this great (by an order of magnitude) discrepancy of the k_f values found for DD. The main reason may be as follows. One value²⁹ corresponds to the dipole-allowed $^1B_{2u} \rightarrow S_0$ transition. The other, smaller k_f value⁵⁶ might refer to the emission from a g -type rather than u -type S_1 singlet state, for example, to the $^1A_g \rightarrow S_0$ transition, *i.e.* to a transition allowed only with account of the Herzberg–Teller intramolecular interactions. Some possible errors both in spectral measurements and in quantum-chemical calculations should also be taken into account.

An interesting dependence of the fluorescence and phosphorescence quantum yields on the structural factor for the series DD, dihydroanthracene and xanthene has been found.⁵⁶

	Dihydroanthracene	Xanthene	DD
ϕ_f	0.26	0.26	0.003
ϕ_{ph}	0.14	0.14	0.4

Despite the fact that the dihydroanthracene and xanthene molecules have the same luminescence quantum yields, the ϕ_f value for DD is much smaller. Meanwhile, the ϕ_{ph} value for DD is almost 3 times as great as those for dihydroanthracene or xanthene.

According to calculations,⁵⁶ the S_1 state in the xanthene and DD molecules can be assigned to the π/π^* type of orbital; the change in the π -electron density on the oxygen atoms in this state is nearly the same for these two molecules. Therefore, the sharp (by two orders of magnitude) decrease in the ϕ_f value for DD with respect to xanthene is believed to be due to the higher rate constant for the $S_1 \rightarrow T_j$ intersystem crossing (k_{isc}) in the case of DD.

It is known that the k_{isc} values for the transfer of energy between states of different orbital natures, $\pi\pi^*$ and $n\pi^*$ (or $\sigma\pi^*$), are several orders of magnitude higher than those for states with the same orbital nature ($\pi\pi^*$ and $\pi\pi^*$).⁷² For this reason, the higher k_{isc} value found for DD was interpreted⁵⁶ by assuming that only DD possesses a T_j state of the $n\pi^*$ type the energy of which is very close to the energy of S_1 . This arrangement is believed to be due to the lowering of the energy levels of the $n\pi^*$ states in this molecule (containing two oxygen atoms) with respect to those in the xanthene molecule (with one oxygen atom). However, it follows from the calculations for the $n\pi^*$, $\pi\sigma^*$ and $\sigma\pi^*$ states that the energies of the corresponding triplet levels of the DD

molecule are more than $10\,000\text{ cm}^{-1}$ higher than the energy of the S_1 state.^{29,65} These states cannot ensure high k_{isc} . The difference between the ϕ_{n} values in xanthene and DD might be due to the difference between the symmetries of the xanthene (C_{2v}) and DD (D_{2h}) molecules, in particular, to the fact that the S_1 state in the DD molecule might correspond to the g type: the first line in the spectrum of the $S_1 \leftarrow S_0$ transition shown in Fig. 7 has a relatively low intensity. In our opinion, the question of what is the reason for the low ϕ_{n} value in DD remains open.

b. Phosphorescence

Phosphorescence is manifested as a relatively intense band in the spectrum shown in Fig. 8. Using specific experimental conditions, spectra with clear-cut vibrational structure of this band have been obtained for DD and PCDD (see Section V.2).

For a number of dioxins, the phosphorescence lifetimes τ_{ph} at 77 K have been measured.^{2,43,56,64,65,73} For example, in the case of DD, $\tau_{\text{ph}} = 0.54\text{ s}$ (77 K, a solution in a 1:5:5 mixture of ethanol, isopentane and ether)² and 0.7 s (77 K, a solution in isopentane).⁵⁶ For chloro-substituted derivatives, the phosphorescence lifetimes are shorter than for unsubstituted DD.²

In the case of PCDD, the τ_{ph} values found by different researchers can be substantially different. Thus for a number of dioxins (ranging from mono- to octa-substituted derivatives), τ_{ph} values varying from 0.29 to 0.075 s have been reported.² According to another publication,⁷³ the τ_{ph} values for another series of tetra- and penta-substituted dioxins in *n*-hexane vary over the 1.55–1.03 s range. The τ_{ph} values presented in the two publications^{2,73} for the only compound common to both of them, 1,2,3,4-Cl₄DD, differ by more than an order of magnitude — 0.057 and 1.03 s. Both groups of researchers noted little differences in the τ_{ph} values within the series of dioxins they studied. Shorter τ_{ph} values were found² for those dioxins which contain several (3 or 4) Cl atoms in only one benzene fragment.

The great discrepancies between τ_{ph} found for PCDD in different studies are apparently due to some systematic error of measurements (rather than to the use of different solvents). For OCDD, β -TCDD and α,β -TCDD as solutions in *n*-hexane, the times τ_{ph} have been measured (see below) at 77 K.^{43,64,65} These values were found to be in satisfactory agreement with τ_{ph} measured for solutions in a 1:5:5 mixture of ethanol, isopentane and ether.²

	OCDD	β -TCDD	α,β -TCDD
<i>n</i> -Hexane			
$\tau_{\text{ph}}/\text{s}$	0.30	0.20	0.30
Solvent mixture			
$\tau_{\text{ph}}/\text{s}$	0.25	—	0.25

The radiative $T \rightarrow S_0$ transitions are allowed due to intramolecular spin-orbit (SO) and vibronic-spin-orbit (VSO) couplings.^{74,75} Correspondingly, the rate constant k_{rad} for the radiative deactivation of the triplet state can be represented as $k_{\text{rad}} = k_{\text{SO}} + k_{\text{VSO}}$; in the case of phosphorescence, $T = T_1$ and $k_{\text{rad}} = k_{\text{ph}}$. It has been proposed to use the data on the distribution of the intensity in fine-structure electronic-vibrational phosphorescence spectra for estimating the k_{VSO} to k_{SO} ratio.⁷⁶ These estimates obtained for the T_1 states of DD, β -TCDD and OCDD show⁴² that the magnitudes of the phosphorescence rate constants k_{ph} for these molecules are stipulated by different mechanisms of intramolecular interactions. More precisely, this constant for DD is determined by only vibronic-spin-orbit coupling, while in β -TCDD and OCDD, they are determined by both spin-orbit and vibronic-spin-orbit couplings (see Section V.2).

Let us dwell now on the data on k_{ph} . It follows from the τ_{ph} and ϕ_{ph} values measured for the DD molecule⁵⁶ that $k_{\text{ph}} = 0.57\text{ s}^{-1}$, $k_{\text{SO}} = 0$; hence, $k_{\text{ph}} = k_{\text{VSO}}$. For PCDD, no experimental data on k_{ph} are currently available, although the τ_{ph} values are known; they can be found from the relation

$$\tau_{\text{ph}} = \frac{1}{k_{\text{ph}} + k_{\text{nr}}^T},$$

where k_{ph} is the rate constant for the radiative and k_{nr}^T is the rate constant for the non-radiative deactivation of the T_1 state. For several dioxin molecules, the k_{SO} , k_{VSO} and k_{ph} values have been estimated theoretically.^{43,64,65}

Quantum-chemical calculations were employed to estimate the k_{SO} values for DD, β -TCDD, α,β -TCDD and OCDD; it was found^{43,64,65} that the number and the arrangement of Cl atoms in the molecule influences k_{SO} values for the $^3B_{1u}$ states. First, it was concluded that each heteroatom (O, α -Cl or β -Cl) in these molecules makes an additive contribution to the dipole moment of the P_{0-0} transition (the square of which is related to k_{SO}). Second, a cancellation effect of the α -Cl and β -Cl atoms on the P_{0-0} value was found. As a result, it was found that $k_{\text{SO}}(\beta\text{-TCDD})/k_{\text{SO}}(\text{OCDD}) = 3.6$, *i.e.* the decrease in the number of Cl atoms in the molecules of β -TCDD with respect to that in OCDD (by a factor of two) induces a substantial increase rather than a decrease in the k_{SO} component of the k_{rad} rate constant. It was concluded^{43,65} that the cancellation effect of several heteroatoms (chemically identical but differing in the position in the molecule) on the spin-orbit coupling, found in the study of dioxins, could be useful in elucidating the reasons for the known abnormal influence^{77,78} of an internal heavy atom on the k_{ph} and τ_{ph} values in some organic molecules.

The use of calculated k_{SO} values and experimental data on the $k_{\text{SO}}/k_{\text{VSO}}$ ratio gave the following estimates for the rate constants k_{ph} for β -TCDD and OCDD: 7 and 5 s^{-1} . Modelling of the k_{nr}^T values made it possible to determine theoretically⁶⁴ the ratio of τ_{ph} for these molecules [$\tau_{\text{ph}}(\text{OCDD})/\tau_{\text{ph}}(\beta\text{-TCDD}) = 1.6 \pm 0.2$], which is consistent with the experimental value 1.5 (the experimental data on τ_{ph} were mentioned above). The theoretical absolute magnitudes of τ_{ph} for these molecules also proved to be close to experimental values. For instance, for OCDD, the calculated value was $\tau_{\text{ph}} = 0.10\text{--}0.20\text{ s}$.

2. Fine-structure phosphorescence spectra

In this Section, we consider the results of investigations of fine-structure phosphorescence spectra of dioxins concerning the energies and types of symmetry of lower triplet electronic states, the frequencies and types of symmetry of vibrations (in particular, low-frequency vibrations), and the contributions of intramolecular spin-orbit and vibronic-spin-orbit couplings to the phosphorescence rate constant. The results of theoretical calculations for the change in the electron density and the estimates of the change in the molecular geometry in the lower excited triplet $\pi\pi^*$ state with respect to the ground electronic state are presented.

a. Spectra at 77 K

Below we consider experimental data on the influence of solvents (non-branched alkanes) on the pattern of the low-temperature phosphorescence spectra of dioxins.

The fine structure of broad-band phosphorescence spectra (see, for example, Fig. 8) can be recorded under specific conditions, which include conducting the experiment at low temperatures, selection of the appropriate solvent and, in some cases, selection of a particular wavelength of the exciting light.^{70,79} These experimental conditions should ensure low electron–phonon interactions and slight inhomogeneous or homogeneous spectral broadening.^{70,80} A well-known method for recording the structured luminescence spectra of complex organic compounds is the Shpol'skii method,⁷⁹ based on the use of *n*-alkanes (*n*-hexane, *n*-heptane, *n*-octane, *etc.*), which form a polycrystalline material at low temperatures, as solvents. These solvents ensure slight inhomogeneous broadening of the spectrum. Upon deep cooling of solutions of luminescent molecules in these solvents down to the boiling point of liquid nitrogen (77 K) or liquid helium (4.2 K), the electron–phonon interaction and homogeneous broadening of the spectrum decrease.⁸⁰ As a con-

sequence, the electronic-vibrational (vibronic) emission spectra consist of a large number of quasi-lines (lines). These spectra are referred to as quasi-line or fine-structure spectra.

The vibrational structure of the phosphorescence spectra of DD and PCDD was revealed at 77 K for solutions in a 1:5:5 mixture of ethanol, isopentane and ether² and in normal hydrocarbons.^{81,82} When the Shpol'skii method is used to make the structure of the spectrum as clear as possible at a specified temperature, it is important to select an appropriate solvent. The Bolotnikova rule⁸³ concerning the commensurability of the linear dimensions of the molecules of the solvent and of the compound under study serves as a criterion for choosing the solvent. Since dioxins are highly toxic, the problem of selecting the solvent has been studied in detail only for DD.⁸¹ It was established that the most clear spectrum is observed in n-hexane and n-heptane matrices (Fig. 9). The spectral patterns in these solvents are more structured than in a 1:5:5 mixture of ethanol, isopentane and ether.

The structured phosphorescence spectra of solid solutions exhibit so-called components of the Shpol'skii multiplet, which are due to luminescence of different centres. Each of the luminescence centres is matched by lines for transition to vibrational sublevels of the ground electronic state (this is the vibronic structure of the spectrum) and by a line corresponding to a purely electronic transition (if it is dipole-allowed) with the frequency ν_{0-0} . As a consequence, the spectrum often has a very intricate structure. At 77 K, the lines are normally markedly broadened due to the phonon wing and they are often called quasi-lines.^{62,70}

Table 6 lists the quasi-line maxima (1–9) in the spectra of DD and PCDD;⁸² only for 1,2,3,4,6-Cl₅DD was it impossible to obtain a quasi-line spectrum in solid solutions in hydrocarbons. The spectrum of this compound was a broad structureless band with a maximum at 480 nm. The same spectral pattern with a maximum at 485 nm was obtained for solutions of 1,2,3,4-Cl₄DD in a 1:5:5 mixture of ethanol, isopentane and ether and in n-hexane at 77 K.^{2,73}

Now we consider briefly the possible reason for the absence of structure and the bathochromic shift of the phosphorescence band in the spectra of solutions of 1,2,3,4-Cl₄DD^{2,73} and 1,2,3,4,6-Cl₅DD.⁸² A specific feature of these molecules is that one benzene ring in them is fully chlorinated, while the other contains either no chlorine atoms or only one atom. Molecules with so asymmetric an arrangement of chlorine atoms are polar.

It has been shown that polar molecules of oxygen-containing compounds dimerise in solutions in saturated hydrocarbons.⁸⁴ Thus the broad structureless bands in the phosphorescence spectra of 1,2,3,4-Cl₄DD and 1,2,3,4,6-Cl₅DD may belong to their dimers. However, to elucidate more definitely the reason for the structure-

Note. The numerals 1 to 9 mark the numbers of lines in the spectra. The wavelengths corresponding to the most intense quasi-lines in the phosphorescence spectra are typed in bold.

less spectral pattern and the bathochromic shift of the phosphorescence band in the spectra of these compounds with respect to the spectra of other PCDD, additional investigations are needed.

Data on the positions of the quasi-line maxima in the spectra and on the distribution of the relative intensities of quasi-lines led to the conclusion^{82, 85} that these spectra are highly individual and could be used for identification of various dioxins, in particular, isomers (see Section VI).

b. Spectra at 4.2 K

Study of the phosphorescence spectra of a number of dioxins at 4.2 K (see compounds in Table 6) showed⁸² that, as the temperature decreases from 77 to 4.2 K, the half-width of the quasi-lines decreases by an order of magnitude (to 0.2–0.5 nm), while the peak intensity of lines increases. In addition, whereas the spectra recorded at the boiling point of liquid nitrogen consist, on the average, of 10–15 quasi-lines, the spectra at 4.7 K contain several dozens of quasi-lines.

At low temperatures (for example, 4.2 K), the vibronic structure of the emission spectra is due to the transitions from the zero vibrational sublevel of the electronically excited state to various vibrational sublevels of the ground electronic state S_0 . This spectrum contains vibration frequencies which are detected in the vibrational spectra (IR and Raman). As an example, Figure 10 shows a fine-structure phosphorescence spectrum of a solution of DD, while Table 7 presents the assignment of the structure of this spectrum,⁴¹ namely, determination of the components of the Shpol'skii multiplet, the frequencies of purely electronic transitions ν_{0-0} , the frequencies of the fundamental vibrations and the sum vibration frequencies. A similar analysis of the spectral structure has been carried out for solutions of β -TCDD, α,β -TCDD and OCDD.^{39, 42, 43}

The $T_1 \rightarrow S_0$ transition, which is spin forbidden, becomes allowed as a result of spin-orbit and vibronic-spin-orbit couplings.^{74, 75} As a consequence, the fine-structure electronic spectra do not exhibit all vibrations but only totally symmetric vibrations and some types of non-totally symmetric ones. By taking account of the characteristic matrix elements⁷² for the spin-orbit coupling and of the dipole moments of the ${}^1\sigma\pi^* \rightarrow S_0$ and ${}^1\pi\pi^* \rightarrow S_0$ transitions, which influence the line intensity, it can be concluded³⁰ that the out-of-plane vibrations may be responsible for intense lines in the $\pi\pi^*$ phosphorescence spectra. Vibronic lines of

this type are actually observed in the phosphorescence spectra of dioxins (see Figs 10, 11 and Table 7).

Determination of the symmetry of the T_1 state in dioxins is difficult. According to quantum-chemical calculations,^{29, 65} the two $\pi\pi^*$ triplet states lowest in energy (more precisely, π/π^*) correspond to electronic functions of g and u types, the T state of the u type being analogous in orbital structure to the fourth $\pi\pi^*$ singlet state $S_4(B_{1u})$, the band of which is 'hidden' in the long-wavelength absorption band (see Figs 5, 6). The difference between the energies of the two T states is small ($\sim 1000 \text{ cm}^{-1}$); hence, variation of the positions of chlorine atoms in PCDD molecules can change the mutual arrangement of these triplet states. However, the accuracy of calculations does not suffice for deciding which of the states with the calculated types of symmetry B_{3g} and B_{1u} is the lowest (T_1). Moreover, the $\pi\pi^*$ phosphorescence spectra of dioxins the molecules of which have an inversion centre can exhibit intense lines corresponding to out-of-plane vibrations for both symmetry forbidden (when T_1 belongs to the g type of symmetry) and symmetry allowed (when T_1 belongs to the u type of symmetry) transitions.

The question of the type of symmetry of the T_1 state can be answered by determining the type of symmetry of non-totally symmetric vibrations the frequencies of which $\nu(\text{phos})$ are observed in the phosphorescence spectra. For the $T_1 \rightarrow S_0$ transitions from the states corresponding to g or u symmetry, non-totally symmetric (out-of-plane) vibrations of only a particular type of symmetry, either u or g , respectively, can manifest themselves, in conformity with the selection rules.⁷⁵ This regularity was used^{39, 41–43} to determine the type of symmetry of the T_1 state of dioxins. These states in DD, β -TCDD and OCDD were assigned to different (B_{3g} and B_{1u}) types of symmetry (Fig. 12). The experimental values of the energies (ν_{0-0}) of the T_1 state and the corresponding k_{SO}/k_{VSO} ratios for the components of the phosphorescence rate constants have also been determined for these compounds.⁴²

^a $\Delta\nu = \nu_{0-0} - \nu_N$, where ν_{0-0} is the frequency of the purely electronic transition. ^b The ordinal number *L* of the fundamental mode found in the phosphorescence spectrum is given. The frequencies ν_L , separated from the sum frequencies, with the numbers *L* = 9–14 correspond to totally symmetric fundamental vibrations (their frequencies are given in parentheses); the frequencies ν_L with the numbers *L* = 1–8 were assigned to out-of-plane vibrations of the B_{3u} and A_u types of symmetry (their letter designations are given in parentheses).

Figure 12. Symmetry of the T_1 and T_2 electronic states.⁴²

decrease somewhat in the sequence DD, β -TCDD and OCDD^{39,41–43} (the values presented above are the ν_{0-0} frequencies of one or several components of the Shpol'skii multiplet, which accounts for the most intense vibronic lines in the spectrum).

The out-of-plane vibrations of dioxins are characterised by low frequencies which are unknown from IR or Raman spectra for the vast majority of dioxins. Therefore, in the absence of experimental data, the symmetry types of the vibrations the frequencies of which $\nu(\text{phos})$ can be seen in the phosphorescence spectra can be determined by comparing the calculated vibration frequencies with $\nu(\text{phos})$. Generally, this comparison provides a satisfactory result (see the phosphorescence spectrum of β -TCDD shown in Fig. 11 and the data on the frequencies of the fundamental modes in β -TCDD listed in Tables 2–5).

The most complicated problem is to interpret the phosphorescence spectra corresponding to a forbidden purely electronic transition because in this spectrum, it is difficult to find lines due to the components of the Shpol'skii multiplet and ν_{0-0} (see, for example, Fig. 10 and Table 7, data for DD). The positions of lines corresponding to the ν_{0-0} frequencies are determined from the $\nu(\text{phos})$ values for non-totally symmetric vibrations. Therefore, to interpret these spectra, reliable experimental (from IR or Raman spectra) or theoretical data on the low-frequency vibrations of the molecule are needed.

According to the results of quantum-chemical calculations,^{43,65} the $T_2(B_{1u})$ state of the DD molecule and the $T_1(B_{1u})$ state of the β -TCDD, α,β -TCDD and OCDD molecules are very close in orbital structure and are charge transfer states. For β -TCDD, the changes in the π -electron density on atoms and on valence bonds in the T_1 state with respect to those in the S_0 state (Fig. 13) have been calculated.⁸⁶ It was concluded that in this state, charge transfer takes place from all heteroatoms of the molecule to the carbon atoms; the electron density on the C–O bonds in the central fragment of the molecule increases, which implies that the bonds are shortened.

The data on the ν_{0-0} frequencies corresponding to the singlet S_1 state²³ and the triplet T_1 state (see Fig. 12) of DD and β -TCDD molecules in solutions can be used to estimate the difference between the energies of these states — 7430 and 6940 cm^{-1} . These values are typical of aromatic molecules with an electron-

donating group;⁶⁹ this is consistent with the theoretical data on the pattern of electron density redistribution in the S_1 and T_1 states.

The distribution of the intensity of vibronic lines in the fine-structure phosphorescence spectra depends on the intramolecular interactions.^{62,63,87} The relative intensities of the vibronic lines with maxima at $\nu_{0-0} - \nu_N$ corresponding to the fundamental modes with the frequencies ν_N were measured in the phosphorescence spectra of DD, β -TCDD, α,β -TCDD and OCDD.^{39,41–43}

The intensity distribution of the lines corresponding to totally symmetric vibrations is determined by the Franck–Condon interaction, which results in a changed equilibrium geometry of the molecule in the electronically excited state. The symmetry of the nuclear configuration typical of the S_0 state is retained. The change in the geometry induces a shift of the minimum of the electron potential (Δ_{el}) along the normal vibration coordinates Q .⁶²

The Δ_{el} values were determined experimentally for the $T_1(^3B_{3g})$ electronic state of DD²⁸ and for the $T_1(^3B_{1u})$ electronic state of β -TCDD.⁸⁶ In the case of β -TCDD, the highest Δ_{el} value corresponds to the normal coordinate with the index η , which describes bending of the C–Cl bond in the plane of the molecule (see the letter designations of vibrations in Table 1). In each of these molecules, the highest Δ_{el} value for vibrations involving the benzene fragment corresponds to the normal coordinate Q_k , which is typical of electronic states of the B_{3g} or B_{1u} types (but not A_g or B_{2u}).^{28,30}

Using a simple theoretical model of the Franck–Condon interactions,²⁸ which reflects satisfactorily the experimental Δ_{el} values, the changes in the geometric parameters in the benzene fragments of DD and β -TCDD in the T_1 state have been calculated.^{28,86} It was found that the changes in the lengths of all bonds parallel to the z axis of the molecule [C(2)–C(3) and the three other] are about an order of magnitude greater than the changes in the other bond lengths in the benzene fragments. This is consistent with the results obtained by INDO/S calculations of electronic states (see Fig. 13). The changes in the bond lengths are nearly the same in each molecule and are equal to 0.021 and 0.027 Å for DD and β -TCDD, respectively. In β -TCDD, the C–Cl bonds are rotated in the molecular plane through 0.9°, according to an approximate estimate.³⁹

The intensity of the region in the phosphorescence spectrum associated with the purely electronic transition and with totally symmetric vibrations is determined by the spin-orbit coupling, while the intensity of the other spectral region is governed by the vibronic-spin-orbit coupling.⁷⁵ Determination of the relative intensities of some lines in the spectrum provides⁷⁶ an experimental estimate of the contributions of spin-orbit and vibronic-spin-orbit couplings to the phosphorescence rate constant ($k_{ph} = k_{SO} + k_{VSO}$). The k_{SO}/k_{VSO} values were estimated for the T_1 state of DD, β -TCDD, α,β -TCDD and OCDD molecules.^{39,42,43} The quantitative results obtained^{39,41–43} indicate that an increase in the number of Cl atoms in the molecule (β -TCDD and OCDD) sharply increases the contribution of the vibronic-spin-orbit coupling (with respect to the spin-orbit coupling) to the constant k_{ph} .

The lines corresponding to non-totally symmetric modes do not form progressions if they have originated due to the Herzberg–Teller interactions, *i.e.* if no change in the nuclear configuration of the molecule related to the change of its symmetry typical of the S_0 state is involved. However, apparently, it would be possible to establish correlations between the relative intensities of the vibronic lines caused by Herzberg–Teller interactions and the probable destruction processes of dioxins in photochemical reactions in the electronic state T_1 . For instance, some correlations have been found between the intensity of vibronic lines related to non-totally symmetric vibrations of a particular form and the structural changes in the molecules of carbonyl-containing compounds upon photochemical reactions in the triplet ($\pi\pi^*$) and ($\pi\pi^*$) electronically excited states.⁸⁸

Figure 13. Changes in the electron density on the bonds and atoms of the β -TCDD molecule in the lower triplet excited state $^3B_{1u}(\pi\pi^*)$.⁸⁶ The values for only one of the equivalent atoms are presented.

VI. Spectroscopic analytical investigations

It has been mentioned in the Introduction that dioxins are formed as trace side products in some industrial processes including chemical (production of chlorinated phenols, herbicides and so on) and pulp-and-paper (paper bleaching) processes and during the operation of garbage-incineration plants. This is accompanied by dioxin pollution of the environment. Polychlorinated dibenzo-*p*-dioxins are highly stable compounds. They do not decompose at high temperatures (up to 750 °C); the half-life of PCDD in soil is about 10 years.⁸⁹ Due to their stability, the dioxin toxicants are accumulated in soil, water, plants and animals, which creates hazard for humans and other living organisms, because dioxins are many orders of magnitude more toxic than commonly known poisons (such as potassium cyanide or curare). Realisation of the dioxin menace stimulated the governments of many countries to adopt special programmes on the protection of the environment from these toxic compounds.

One aspect of the environmental protection is the development of highly sensitive methods for determination and quantitative analysis of traces of PCDD. Since dioxins are very hazardous compounds, methods for their analysis should be highly sensitive, at the picogram level. Yet another, equally significant requirement to the methods of dioxin analysis is high selectivity. This requirement originates due to the fact that dioxins having different structures differ markedly in toxic properties.^{4,90,91}

Figure 14 presents the results of an experiment with guinea-pigs. It demonstrates how sharply (by approximately four orders of magnitude) the toxicity of PCDD containing from seven to four chlorine atoms increases as the α -Cl atoms are successively replaced by hydrogen atoms. The effect of PCDD on organisms is appreciably variable; however, generally, the regularity presented in Fig. 14 holds. Thus β -TCDD is considered to be the most toxic.

At present, toxicity equivalent factors (TEF)⁹¹ common to humans and mammals have been established (for β -TCDD, TEF = 1). Apart from β -TCDD, six more PCDD containing four chlorine atoms in the β -positions are considered to be toxic. For example, for 1,2,3,7,8-Cl₅DD and the three isomers of hexachloro-substituted dibenzo-*p*-dioxins, TEF = 1 and 0.1, respectively; for the octasubstituted dibenzo-*p*-dioxin, TEF = 0.0001. Therefore, in monitoring the dioxin contamination, the problem of identification of the most hazardous PCDD is a crucial point. Identification is also important in connection with the need to determine precisely the reason (*i.e.* who is to blame) for the contamination and to control the process of dioxin destruction. From the scientific viewpoint, this is important for determining the mechanisms and the products of destruction of dioxins during incineration, photolysis and chemical or biological deactivation.

Figure 14. Toxicity of dioxins (the lethal dose LD₅₀ for guinea-pigs) vs. the number (*N*) of hydrogen atoms occupying α -positions in the 1,2,3,4,6,7,8-Cl₇DD (1), 1,2,3,6,7,8-Cl₆DD and 1,2,3,7,8,9-Cl₆DD (2), 1,2,3,4,7,8-Cl₅DD (3), 1,2,3,7,8-Cl₅DD (4) and β -TCDD (5) molecules.²⁴

The best developed and most widely used methods for analysis of dioxins not related to optical spectroscopy include various modifications of the chromatographic method,^{92–95} chromatomass spectrometry,^{96–98} a method combining chromatographic separation of isomers with their NMR detection,⁹⁹ *etc.* Description of all the methods used currently is beyond the scope of this review. We shall restrict ourselves to a brief description of the optical methods of analysis employed for this purpose.

Among optical methods, Fourier IR spectroscopy (FTIR) is used most extensively to analyse dioxins. Usually, this technique is combined with chromatographic methods.⁹⁸ Thus even in the first publications^{32,34} dealing with analysis of dioxins by gas chromatography and FTIR (GC-FTIR method), using reflectance and absorption spectra, the researchers were able to identify all the 22 isomers of tetrachloro-substituted dioxin. This method permits detection of dioxins present in concentrations of several hundreds of nanograms.

A higher sensitivity of the method can be attained by using matrix isolation of the analysed compounds (GC-MI-FTIR).¹⁰⁰ In this case, the isomers separated by chromatography were present in an argon matrix at 12 K; this decreases the line half-width and, correspondingly, increases the peak intensity of lines. The IR spectra of all the 22 isomers of tetrachloro-substituted dioxin were recorded by this method,^{33,35,36} including the spectra of β -TCDD and its completely isotope-substituted analogue ([¹³C] β -TCDD), in which all the ¹²C atoms have been replaced by ¹³C. This technique is suitable for the analysis of samples with contents of tetrachloro-substituted DD of the order of hundreds of picograms.^{36,100,101} For example, the use of [¹³C] β -TCDD as the internal standard permitted determination of β -TCDD in a concentration of 15–45 pg per g in an extract from a fish tissue.³⁷

To identify dioxins on the basis of their IR spectra, several characteristic bands in the range of 1600–800 cm⁻¹ are used.^{24,33,35} Figure 15 presents the IR spectrum of the extract from a fish tissue containing β -TCDD and an internal standard admixed. Generally, the positions of bands in the spectrum recorded by the GC-MI-FTIR method coincide with the positions of the corresponding bands in the spectrum of β -TCDD in a KBr pellet (see Fig. 2).

Figure 16 shows an example of identification, based on IR bands, of two tetrachloro-substituted DD isomers which are poorly resolved by gas chromatography^{102,103} but are separated by gas liquid chromatography. In the frequency range of 1600–800 cm⁻¹, the positions of the maxima of bands in the spectra of these isomers differ only slightly; however, the isomers can be identified based on the different relative intensities of bands. It has also been proposed^{24,35} to identify isomers using the

Figure 15. Absorption spectrum of the extract from a fish tissue containing β -TCDD and an admixture of [¹³C] β -TCDD added as the internal standard. The spectrum was recorded by the GC-MI-FTIR technique; the analytical lines of the β -TCDD toxin³⁷ are marked by arrows.

Figure 16. Absorption spectrum recorded by the GC-MI-FTIR method for the isomers 1,2,4,8-Cl₄DD (a) and 1,2,4,7-Cl₄DD (b).³⁵ The numerals 1–5 mark the analytical lines the relative intensities of which at 1420 cm^{−1} (lines 1, 2) and at 980–820 cm^{−1} (lines 3–5) can be used to identify the isomers.

$\nu_{\text{C-O}}^{\text{as}}$ frequencies of the antisymmetric stretching vibrations of the C–O–C groups in the range of 1330–1280 cm^{−1}. However, in our opinion, this spectral region is less reliable for identification because the semiempirical triatomic model considered³⁵ determines the $\nu_{\text{C-O}}^{\text{as}}$ values too crudely; meanwhile, the difference between the experimental values of these frequencies for some pairs of isomers is very little (1–2 cm^{−1}).

The results of identification of PCDD isomers by four independent methods: chromatography, GC-MS, GC-FTIR and ¹H and ¹³C NMR spectroscopy have been compared.¹⁰⁴ For several isomers, the results of identification did not coincide.

It has been proposed^{22,47} to use the frequencies of normal modes of PCDD isomers found theoretically (by *ab initio* calculations) to identify the isomers based on their IR spectra.

Now we shall mention several other spectral methods for determination of dioxins. For example, theoretical estimates of the limits of detection of dioxins by Raman spectroscopy (~2 pg) and by giant Raman scattering (GRS, ~2 × 10^{−4} pg) allow the GRS method to be regarded as a promising analytical technique.¹⁰⁵ A simple photometric method based on the ability of PCDD to be protonated and to form coloured associates with transition metal anions has been proposed.¹⁰⁶ The lower limit of the β-TCDD concentration in a hexane extract determined by this method is 20 pg cm^{−3}.

The detection powers of the setups used in the studies of dioxins by UV absorption and fluorescence methods have been evaluated.^{58,73} Fluorescence of dioxins shows itself as a broad band with a maximum in the region of 330–390 nm. For n-hexane solutions of PCDD containing 5 to 8 Cl atoms, the detection limit of the fluorescence analysis amounts to 0.5–5 ng cm^{−3} at room temperature for excitation with the wavelength $\lambda_{\text{excit}} = 230$ –245 nm.⁷³ This spectrum region contains the maximum of band **B**, the most intense band in the UV absorption of dioxins (see Figs 5, 6). In laser-induced fluorescence analysis of dioxin vapours (β-TCDD, 1,2,3,7,8-Cl₅DD and OCDD) with

$\lambda_{\text{excit}} = 303$ nm and at 170–270 °C, the detection limit was approximately four orders of magnitude lower; it was 0.09–0.13 pg cm^{−3} (see Ref. 58).

The detection power of the setup using the UV absorption method in the short-wavelength region (~224 nm) has been evaluated. The limit of detection of β-TCDD, 1,2,3,7,8-Cl₅DD and OCDD in vapours amounted to 8–90 pg cm^{−3} (see Ref. 58). It is noteworthy that the methods of detection mentioned above are not selective because the UV absorption and fluorescence bands of dioxins are very broad and, moreover, the maxima of these bands shift only slightly upon the change in the number of chlorine atoms in PCDD molecules (see Section IV).

The use of phosphorescence, more precisely, low-temperature quasi-line phosphorescence spectra of solid solutions, for identification of dioxins has also been proposed.^{73,82,85} For example, it is known that the luminescence spectra recorded by this method (Shpol'skii method) have been used successfully to determine the content of polycyclic aromatic hydrocarbons as hazardous contaminants in foodstuffs and in non-edible oils.^{107,108} The phosphorescence spectra of solid solutions of DD and many of PCDD in a 1 : 5 : 5 mixture of ethanol, isopentane and ether⁷³ at 77 K and in n-alkanes at 77 and 4.2 K^{81,82,85} were shown to possess a quasi-line structure, the structures of spectra of different PCDD being substantially dissimilar (see Table 6). The differences are observed both in the positions of lines and in the intensity distribution. Thus, these spectra possess advantages over the structureless UV absorption and fluorescence spectra in the identification of compounds.

Figure 17 presents the phosphorescence spectrum (4.2 K) of a mixture of β-TCDD and α,β-TCDD isomers with concentrations

Figure 17. Phosphorescence spectra of α,β-TCDD (a), β-TCDD (b) and their mixtures (c) in n-hexane at 4.2 K.⁸² In spectrum c, the analytical lines 1 and 2 corresponding to the two isomers (a and b) are marked.

of 4.5×10^{-5} and 3×10^{-5} mol litre $^{-1}$, respectively. The quasi-lines observed in the emission spectrum of a two-component solution can be assigned unambiguously to one of the mixture components, which is a clear illustration of the possibility of selective determination of isomers using these spectra. At 77 K, the phosphorescence spectra of PCDD isomers are less suitable for selective recording due to the greater ($\sim 2-4$ nm) half-width of bands. However, the simplicity of the equipment and the process of recording provides the possibility of developing a screening method for dioxin detection based on them.

The detection capacity of the spectral setups used for the detection of dioxins on the basis of quasi-line phosphorescence spectra has been evaluated.^{73, 81, 82} At 77 K, for n-hexane solutions of dioxins containing 4 to 7 Cl atoms, the detection limit is 1–12 ng cm $^{-3}$ (see Ref. 73). The spectra of β -TCDD were found to be recorded reliably down to a concentration of 16 ng cm $^{-3}$ (see Ref. 82). When analysing microvolumes of β -TCDD with recording of the most intense line in the spectrum ($\lambda = 410$ nm, see Table 6), determination of its amounts not lower than 100 pg is possible. It is expected that the limit of detection of tetrachloro-substituted DD could be markedly decreased by decreasing the temperature to 4.2 K, due to the increase in the peak intensity of vibronic lines.

The differences between the quasi-line phosphorescence spectra even for isomers with close structures and for PCDD with different numbers of Cl atoms gives hope that development of such a method would allow reliable identification of PCDD in complex mixtures.

VII. Conclusion

Since it is the molecular structure that accounts for the different photophysical properties of compounds, it is important to establish the geometrical structure of dioxins. X-Ray diffraction data point to a planar or nearly planar structure of DD and PCDD molecules in the crystals. No direct experimental data on the structures of these molecules in the gas phase or in solutions are available to date. Only indirect methods of determination do exist, relying on the data on the dipole moment of DD in solutions or on the results of theoretical calculations. Depending on the theoretical method of modelling employed, the equilibrium nuclear configuration of the molecule in the ground electronic state S_0 is found to be either planar or non-planar. In the case where the dioxin molecules are found to be non-planar, some researchers concluded that, in particular, DD has a 'butterfly' configuration. Data on the structures of dioxin molecules are contradictory. Some investigators who give credit to X-ray diffraction data believe that the dioxin molecules are planar; other researchers who rely on calculations consider that the molecules are non-planar. Note that the intramolecular vibration mode of the 'butterfly' type shows itself at a low frequency for all dioxins. Dioxin molecules might occur in different configurations depending on the experimental conditions (temperature, intermolecular interactions).

In some studies, attempts are made to relate different toxicities of PCDD to either planar or non-planar geometrical configuration. Spectroscopic methods of investigation are especially promising for the solution of the problem of the structure of dioxins (at least, four of them, DD, β -TCDD, 1,4,6,9-Cl $_4$ DD and OCDD) which belong to the D_{2h} group of symmetry in the case of a planar configuration. Analysis of the IR and Raman spectra from the standpoint of selection rules could promote solution of the problem of the molecular configuration in the ground electronic state S_0 . This type of analysis of the fine vibrational structure of the spectra recorded by electronic-vibrational spectroscopy methods (low-temperature UV absorption, hole burning, fluorescence, phosphorescence, excitation of luminescence) and by the resonance enhanced two-photon ionisation technique could facilitate solution of the problem (which has not yet been solved either) of the symmetry of the dioxin molecules in the S_1 and T_1 states.

However, no comprehensive experimental and theoretical studies of dioxin vibrations that could answer the questions about the molecular configuration have been reported so far.

In view of the foregoing, one of the most important problems in the studies of dioxins is to investigate the intramolecular vibrations (both theoretically and experimentally). At present, almost no data on the Raman spectra are available. Despite the extensive use of IR spectroscopy for analytical purposes, data on low-frequency vibrations can scarcely be found in the literature. The results on the theoretical calculations that provide information on not only the frequencies but also the forms and types of symmetry of vibrations are also few. The data on the vibrations of dioxin molecules are also important for the interpretation of the fine vibrational structure of the electronic-vibrational spectra, in particular, phosphorescence spectra of solid solutions because the structure of these spectra is complicated by the presence of the Shpol'skii multiplet components. Interpretation of the vibrational structure of these spectra provides valuable information on the type of symmetry of the triplet electronic state, on the influence of chlorine atoms on the processes of photophysical deactivation of the electronically excited state and on the changes in the nuclear configuration of the molecule in this state.

Fourier Transform IR spectroscopy with matrix isolation of the molecule (combined with chromatography) is currently the main spectral method used to detect and identify dioxins. We believe that the Shpol'skii method would become yet another technique for the detection and identification of dioxins (at present, it is used for polycyclic aromatic hydrocarbons), provided that the light-gathering power of the equipment would be increased somewhat, for instance, by using FT spectrometers. At present, the results of investigation of the fine-structure phosphorescence spectra of solutions of dioxins in non-branched alkanes at 77 and 4.2 K (using a standard spectrometer with diffraction gratings) confirmed the good prospects for using this technique for analytical purposes as a highly sensitive and selective method.

The knowledge of experimental photophysical characteristics of dioxins and their changes induced by particular factors (medium, temperature, *etc.*) is required not only for theoretical investigations of the mechanisms of deactivation of electronic states but also for the solution of some practical problems. Thus it is known that photochemical decomposition, which is supposed to proceed through a T_1 state, is the most effective process for the destruction of these toxicants. However, the available data on the photophysical studies of dioxins are obviously insufficient to provide optimisation of the methods for their photochemical deactivation. These data are also needed for searching for the ways of increasing the sensitivity of the spectral luminescence methods of analysis.

New data on the structure and properties of dioxins would help to disclose the mechanism of action of these ecotoxins; they would enable further development and perfection of both analytical methods for the detection of dioxins and methods of environmental protection.

Abstract. The main chemical aspects of the preparation of thin copper films from the vapour of monovalent and divalent copper derivatives as precursors in the CVD technique are considered. Data on the methods of synthesis and the properties of various types of these compounds are generalised and described systematically. The possible decomposition mechanisms of copper compounds under CVD conditions are discussed. The prospects of using the CVD technology for the preparation of thin copper films in integrated circuits of microelectronic devices are outlined. The bibliography includes 432 references.

I. Introduction

Micro- and nanoelectronics are the most promising fields for the application of thin copper films. Such films are used as conducting paths in large-scale and very-large-scale integrated circuits (LIC and VLIC, respectively); they make an alternative to aluminium films. It is known that non-doped aluminium films used as electric wiring in LIC and VLIC have a number of drawbacks. First, discontinuity of aluminium films is observed during operation of integrated circuits because of the large atom electromigration coefficient, which was shown by calculations to be due to relaxation of the bulk upon passage of a flow of vacancies.¹ On the other hand, the electromigration coefficients in the layers of copper atoms are a few orders of magnitude smaller than in aluminium atom layers. Second, the specific electric resistance (SER) of copper is 30% smaller than that of aluminium. The addition of copper or silicon (2 at.%–4 at.%) to aluminium films does not eliminate all the drawbacks of aluminium as a material for interconnections in LIC and VLIC.^{2–9}

In addition, thin copper films are used in devices which employ the effect of the gross magnetic resistance in polycrystalline Co/Cu multilayers. The thickness of the cobalt and copper

layers ranges from a few fractions of a nanometre to several nanometres.^{10–14}

Copper films are deposited onto substrates. Silicon and silicon dioxide are the most common substrate materials. The diffusion coefficients of copper into silicon and silicon dioxide are high, they are a few orders of magnitude higher than those of other metals. The use of barrier layers in order to decrease this coefficient was suggested. At first, it was attempted to solve this problem by means of PVD (Physical Vapour Deposition) technology, using such methods as thermal evaporation, plasma spraying, magnetron or laser scattering, as well as by spray deposition of thin layers of other metals (Cr, Co, W, Ti, Ta) on an SiO₂ surface. However, little progress has been made in this direction. Later, metal nitrides used as the barrier layer materials showed better performance than the pure metals.

The common drawback of PVD technology is the necessity of heating a substance to high temperatures (above the vaporisation temperature). Therefore, intense development of CVD (Chemical Vapour Deposition) technology has started in recent years; this technique involves chemical methods of deposition of thin films from the gas phase using metal-containing compounds. Chemical methods have a number of advantages over physical methods. These include relatively mild conditions for film deposition, comparatively low vaporisation temperatures of the starting compounds, conditions favourable for good adhesion of the films to the substrate, wider technological prospects for the development of microelectronic devices with required parameters.

This review considers the chemical methods used in CVD technology for the preparation of copper films from volatile copper(II) and copper(I) derivatives. The main attention is given to work published within the period from 1991 to 1999, although earlier fundamental studies have also been taken into account.

The majority of compounds which we name 'copper-containing compounds' (CCC) correspond to copper complexes with copper–oxygen bonds. As to the specific CCC types, the review mentions virtually all classes of compounds considered as promising starting compounds for CVD technology. Many of these compounds have not yet found application in the synthesis of copper films. Nevertheless, we felt it worthwhile to mention them as well, at least because it is quite possible that other CCC of the same classes may be suitable for CVD processes.

II. Equipment used in CVD processes

A vast literature (see, *e.g.*, Refs 15–28) is devoted to CVD technology. In essence, the CVD process involves evaporation of volatile metal-containing compounds followed by transfer of their vapour to a reaction compartment, where the starting compound is decomposed and the decomposition products are deposited onto a substrate in the form of a film. Most commonly, decomposition is accomplished by means of thermolysis, sometimes along with exposure to plasma or irradiation. Side products are removed from the reaction zone in the form of vapour.

If the process is carried out with the use of an inert gas as the carrier for the vapour of the starting compound, it is usually purified from oxygen and other admixtures by passing it preliminarily through adsorbents or a membrane. Hydrogen is purified by passing it through palladium.²⁹ Liquid compounds are injected using devices based on controlling the mass consumption rate.^{30, 31}

Various designs of reactors have been developed for the CVD processes.[†] As an example, Fig. 1 shows a simple reactor scheme for pyrolytic deposition of films by evaporation of metal-containing compounds followed by transportation of the vapour to the deposition zone.

Figure 1. The simplest CVD reactor scheme;⁴⁰ (1) flow controller, (2) reactor, (3) substrate, (4) heater, (5) thermocouple, (6) CCC source, (7) manometer, (8) pump, (9) liquid nitrogen trap.

Many reactor designs and film deposition processes have been patented.^{35, 41–44} A number of firms manufacture serial reactors, *e.g.*, MR-200 (Cambridge Instruments, Great Britain),⁴⁵ EMCORE (GS/3300 firm, USA) with a rotating disk and uniformity of the substrate temperature to within 1 °C,⁴⁶ EPISON (Thomas Swan Ltd, Great Britain).^{47, 48}

[†]They can arbitrarily be divided in two groups: vertical^{32–35} and horizontal.^{35–39} A review of the equipment used before 1972 for the deposition of films and coatings by CVD can be found in Ref. 15 (see p. 180 *ff*).

High-performance technological equipment for the preparation of thin layers by CVD has been developed at the Samsung company's institute (Republic of Korea). This equipment makes it possible to manufacture more than 10 000 devices (diodes, photo diodes, *etc.*) simultaneously.³⁶

The design of a CVD reactor in which hydrogen plasma is used was reported.⁴⁹ High-quality copper films with a SER of 2.0 $\mu\Omega$ cm are obtained in such reactors.

In recent years, combined instruments (of the so-called cluster type) for the deposition of any type of thin films by physical or chemical methods, including CVD technology, have appeared (see, *e.g.*, Ref. 50). These instruments allow one to deposit multi-layer coatings from different materials.⁵¹ An example of such an instrument is shown in Fig. 2.

Figure 2. Block diagram of a 'cluster' apparatus for the preparation of thin films;⁵²

(1, 2) process modules, (3) observation module, (4) multifunctional module (exposure, polishing, *etc.*), (5) sample preparation module, (6, 8) measuring modules, (7) support inlet.

CVD methods are successfully used if high-quality and uniform films (both with respect to the composition and thickness) of large area are required. For this purpose, the substrates in the reactor are rotated; laminar gas streams in the reactor and uniform heating are provided. In this way, thickness uniformity within 2% and chemical composition uniformity within 1% can be achieved over the entire film surface.^{53–56} Visualisation of convective flows in the growth chamber can be provided by laser illumination of dispersed particles or by creation of a 3D image by interference holography.

The production of integrated circuits requires the preparation of planar deposited copper layers. For this purpose, the technology of chemical and mechanical polishing of copper films has been developed which includes treatment of the film surface with a suspension of fine SiO_2 and Al_2O_3 particles; benzotriazole is added as an oxidant if necessary. In the latter case, the rate of film surface polishing depends on the concentration of benzotriazole.^{57, 58}

The waste gases are utilised using catalytic combustion, physical adsorption with activated carbon with or without oxidation and dry purification in reaction columns.^{59, 60} The CS-GmbH company (Germany) has developed three types of gas absorbents: absorbing cartridges (Cleanvent), washing and purifying systems (Cleantorb) and emergency absorption systems (Clean-Protect). The Cleanvent cartridges are intended for *in situ* removal of hazardous gases from gas distribution systems.⁶¹

III. Barrier layers preventing the diffusion of copper atoms into the substrate

Diffusion of copper atoms into the substrate during the operation of microelectronic devices impairs their characteristics. This can be prevented by means of barrier layers between the copper film and the substrate. These layers consist of certain metals and/or binary compounds and can be obtained using PVD or CVD

technologies. CVD favours the formation of amorphous films, as shown, *e.g.*, for tantalum nitride.⁶²

1. Barrier layers prepared by PVD methods

Originally, diffusion of copper atoms into silicon as the most common substrate was prevented by thin barrier layers of diamond-like carbon and metal films obtained by PVD methods.^{63, 64} Films of various binary compounds, primarily titanium, tungsten and tantalum silicides, borides and nitrides, are also suitable for this purpose.^{65–85}

Tungsten and tantalum are regarded as the best metals for the deposition of barrier layers by PVD, as they have the smallest self-diffusion coefficients in the series $Ti > Cr > Nb > Mo > Ta \sim W$.⁶⁴ After deposition, the layers are exposed to annealing in hydrogen for 1 h at 600 °C.⁶⁴

Metal film barrier layers were gradually replaced by films of titanium and tungsten silicides and nitrides.^{65–74} In this case, the thermal stabilities of the layers increased to 500 °C (WSi_x multilayer)⁶⁸ and 700 °C (WSiN/WSi_x/W multilayer).⁶⁹ The layers of solid solutions of titanium in tungsten, TiW (30 at.% Ti), have somewhat different characteristics. If the barrier layers are 100 nm thick, the Cu/TiW/Si multilayers are stable up to 775 °C, and their stabilities increase to 850 °C upon keeping in air. In the latter case, 0.2 at.% of oxygen was detected in the film.⁷²

The pure tantalum film 10 nm thick is an efficient barrier against the diffusion of copper into the silicon substrate up to 500 °C.⁶⁹ The films of tantalum nitrides, *viz.*, Ta₂N, TaN, and those of the Ta₃₆Si₄₄N₅₀ alloy provide even more reliable protection against penetration of copper atoms into the silicon substrate.^{75–77, 79, 82} The characteristics of barrier layers are listed in Table 1.

2. Barrier layers prepared by the CVD method

The compositions and properties of barrier layers obtained by thermolysis using the CVD technology depend both on the

conditions of the process and on the properties of the starting volatile compounds.

Generally, the CVD method allows one to work with a wide range of starting volatile compounds of metals (for example, 15 starting volatile compounds have been listed⁷⁸ for the preparation of just one compound, TiN); layers with required properties can be obtained by varying the process parameters (vapour phase composition, deposition temperature, pressure).

Table 2 lists the starting compounds and some characteristics of CVD processes for the preparation of thin barrier layers of TiN, TaN, Ta, Ti, Cr, and Co.

It should be noted that PVD methods for the preparation of thin layers from the gas phase (spraying of compounds by bombardment with high-energy electrons and ions, magnetron and radio-frequency spray deposition, *etc.*) require that higher energy was applied to the substance for evaporation. The growth of films generally starts with the formation of separate islets-droplets, which subsequently merge to form a continuous film. Polycrystalline films are mostly formed; this is undesirable in terms of the diffusion of copper atoms, as the grain boundaries have higher diffusion coefficients than the grain bulk.

On the other hand, CVD of compounds from the gas phase generally occurs at lower temperatures. In this case, amorphous films are formed. The diffusion coefficients of copper atoms through the bulk of such films are smaller than through the grain boundaries. This is one of the advantages of chemical methods for film deposition from the gas phase over physical methods.

Yet another advantage of CVD methods is the possibility of selective processes, *i.e.*, preferential deposition, in particular of copper, on one substrate material or surface area with certain mechanical characteristics with respect to another material or surface area. This is a very useful feature for the production of microelectronic devices, as it can replace lithographic template preparation in the creation of an integrated circuit.

Table 1. Parameters of barrier multilayers preventing the diffusion of copper atoms into the silicon substrate.

Multilayers	Deposition method	<i>l</i> /nm	<i>T</i> ₁ /°C	<i>T</i> ₂ /°C	Ref.

IV. The starting copper-containing compounds: copper(II) derivatives

Volatile copper(II)-containing compounds had been synthesised long before the CVD technology appeared. Of these, chelate complexes of copper(II) with β -diketones **1** have been studied most thoroughly.

Copper(II) acetylacetonate, $\text{Cu}(\text{acac})_2$ (**1**, $\text{R} = \text{R}' = \text{Me}$) synthesised in the past century,¹⁰⁶ was the first compound of this series which may be regarded as an appropriate volatile CCC for CVD. By the early 1960s, the number of copper(II) β -diketonates with various starting β -diketones exceeded sixty.^{107–109}

Initially, the application of these compounds was limited to their use as convenient labels for characterisation of the corresponding β -diketones and in gas chromatography for the separation of metals.¹⁰⁹ As a matter of fact, the use of copper β -diketonates in CVD technologies began in 1965 when the first study devoted to the CVD synthesis of thin copper films based on β -diketonates appeared.¹¹⁰ To date, there are several reviews dealing with copper β -diketonates as volatile CCC (see, for example, Refs 26 and 111), but they did not cover the work published in recent years.

Certainly, not all copper(II) β -diketonates and their derivatives are suitable for CVD processes. The synthetic accessibility of the starting β -diketone is of certain importance, but the practical value of a particular copper(II) β -diketonate is determined by the combination of its physicochemical properties.

The relationship between the volatilities of metal β -diketonates (including that of copper) and their structures was analysed by Mazurenko *et al.*^{112, 113} (see also the review by Tsyganova and Dyagileva¹¹⁴). The main criteria of stability of these compounds in the vapour phase have been stated in these reports. It is

believed¹¹³ that the rather high volatilities of these compounds are due to shielding of the coordination unit by the highly developed 'periphery' of the molecules, which decreases the contributions of the electrostatic and intermolecular interactions to the intermolecular potential.

However, volatility is a necessary but insufficient condition for the applicability of compounds in CVD technology. The basic requirements to the starting CCC are as follows:¹¹³ the ability to undergo sublimation in low vacuum at as low temperatures as possible, providing as high a vapour pressure as possible; the ability to undergo sublimation and resublimation without decomposition; the ability to undergo thermolytic decomposition on a substrate surface at as low a substrate temperature as possible with a minimum possible content of admixtures in the resulting copper film.

Analysis of these requirements makes it possible to conclude that the thermolytic stability of the starting compound should have an optimum. In the best case, an insufficiently stable compound will reach the substrate surface as decomposition products, which is unfavourable for reproducibility of the process. If the compound is very stable, high substrate temperature (or additional energy in the form of radiation) is inevitably required for thermolysis, which generally affects adversely the film quality.

The starting volatile copper(II) derivatives with optimum technological properties for the CVD method have been sought among several basic groups of compounds considered below.

1. Copper(II) β -diketonates with alkyl groups

The main advantage of copper(II) β -diketonates with alkyl groups is their synthetic accessibility. However, they were not the first compounds used for the development of the CVD preparation of copper films; their polyfluorinated analogues were the first substances.^{110, 115, 116} This is most probably due to the rather low volatilities of this type of copper(II) β -diketonates.¹¹⁷ The β -diketonates required for the preparation of metal β -diketonates can be synthesised rather easily by the Claisen condensation of the corresponding ketones with esters in the presence of nucleophilic reagents.¹¹⁸

The suitability of copper(II) acetylacetonate $\text{Cu}(\text{acac})_2$ and copper(II) dipivaloylmethanate $\text{Cu}(\text{DPM})_2$ in CVD processes was considered. The latter compound is more volatile than $\text{Cu}(\text{acac})_2$ because the β -diketone has a branched hydrocarbon chain (see **1**, $\text{R} = \text{R}' = \text{Bu}^t$).¹¹⁶

Substituted copper(II) acetoacetates¹¹⁷ (Section IV.4a) provide an alternative to these compounds in the hydrocarbon series.

a. Synthesis and physicochemical properties

The main method for the synthesis of $\text{Cu}(\text{acac})_2$ and other copper(II) β -diketonates with alkyl groups involves the reaction of the corresponding β -diketone or its hydrate with a hot aqueous solution of copper(II) acetate¹¹⁹ or a mixture of a water-soluble copper(II) salt with sodium acetate.¹²⁰ Copper β -diketonate hydrates are usually obtained in this way; anhydrous compounds are obtained by heating or by keeping the hydrates over H_2SO_4 .¹²⁰ It was noted, however, that the formation of a hydrate is untypical of $\text{Cu}(\text{acac})_2$.¹²¹

Direct reaction of copper(II) acetate with an anhydrous β -diketone, which occurs in several minutes in boiling β -diketone, is also possible.¹¹⁹

The structure and spectral properties of the simplest β -diketonate, *viz.*, $\text{Cu}(\text{acac})_2$, have been studied rather thoroughly: all bond lengths and bond angles in the $\text{Cu}(\text{acac})_2$ molecule have been determined;¹²² quantum-chemical calculations of the electronic structure of $\text{Cu}(\text{acac})_2$ have been carried out;^{123,124} the ESR spectra of this compound have been recorded (see, *e.g.*, Refs 125 and 126); a detailed assignment of its IR spectral bands has been performed.¹²⁷

When deciding whether a compound can be used in CVD, its molecular structure and thermogravimetric data are of special importance. It was shown that in $\text{Cu}(\text{acac})_2$ and other copper(II) β -diketonates, the separate molecules form infinite chains through intermolecular copper–chelate ring carbon bonds^{128,129} with a bond length of 0.301–0.312 nm. This interaction complements the coordination of copper atoms to give a strongly stretched tetragonal bipyramid. The relative instabilities of these intermolecular bonds can be a reason for the volatility of this class of compound.¹¹³

The thermodynamic parameters of the $\text{Cu}(\text{acac})_2$ molecule are listed in Ref. 130. The vapour pressures of this compound were measured at various temperatures (for example, it is ~ 0.3 Torr at 150 °C) and the temperature dependence of the vapour pressure was obtained.¹³¹ It was shown by thermogravimetry that $\text{Cu}(\text{acac})_2$ is sublimed completely and does not undergo decomposition in an inert atmosphere.¹³² On the other hand, the results of thermogravimetric analysis of $\text{Cu}(\text{acac})_2$ in air suggest that a single-step thermal decomposition occurs at 305 °C.¹³³ The usual temperature range of $\text{Cu}(\text{acac})_2$ sublimation in a CVD process is 100–170 °C.¹³⁴

Dipivaloylmethane $\text{H}(\text{DPM})$ and $\text{Cu}(\text{DPM})_2$ were first obtained by condensation of ketones with esters in the presence of NaNH_2 .¹²¹ Simpler methods for the synthesis of $\text{Cu}(\text{DPM})_2$, *e.g.*, the reaction of $\text{H}(\text{DPM})$ with an aqueous solution of CuSO_4 in the presence of sodium acetate, were developed later.¹³⁵ The properties of $\text{Cu}(\text{DPM})_2$ have also been studied rather thoroughly: the crystal structure has been determined;¹³⁶ thermogravimetric data have been obtained showing that in a nitrogen atmosphere $\text{Cu}(\text{DPM})_2$ sublimates completely at 240–245 °C;^{131,132} its sublimation enthalpy (74.8 kJ mol⁻¹) and entropy (132.2 J mol⁻¹ K⁻¹) have been determined.¹³⁵ Analysis of thermogravimetric curves for a wide range of copper(II) β -diketonates with alkyl groups^{131,132} showed that

$\text{Cu}(\text{DPM})_2$ is actually the most volatile compound in the series where both ligands are identical (the compounds with different ligands are less accessible synthetically).

b. The mechanisms of decomposition of copper-containing compounds on substrate surfaces

The mechanisms of formation of copper films from copper(II) β -diketonates with alkyl groups in CVD processes have been studied in various respects. A number of studies (see, *e.g.*, Refs 137, 138 and references cited therein) deal mainly with the physical aspects of the growth of copper films and its mathematical simulation.

Turgambayeva *et al.*^{139,140} used mass-spectrometric data to analyse the thermolysis of $\text{Cu}(\text{acac})_2$ molecules in the vapour phase in a vacuum as well as in a stream of oxygen and hydrogen. It was shown that, depending on the temperature, thermolysis can result in various volatile organic products, such as $\text{H}(\text{acac})$, acetone, ethyl methyl ketone, *etc.* The kinetic and activation parameters of the thermal decomposition of $\text{Cu}(\text{acac})_2$ in the vapour phase were reported;^{140,141} this process was described satisfactorily by a first-order kinetic equation. It was concluded on the basis of IR spectra of $\text{Cu}(\text{acac})_2$ that the decomposition starts with destabilisation of the coordination unit at the copper–oxygen bonds of the complex.¹⁴² A similar study of the kinetics and thermal decomposition products in the vapour phase was also carried out for $\text{Cu}(\text{DPM})_2$.¹⁴³

It is very important to have data on the mechanism of thermolytic decomposition of compounds directly on the substrate in order to bring the CVD processes to perfection.

One of the first schemes suggested for the description of $\text{Cu}(\text{acac})_2$ decomposition on heated substrate surfaces involved a radical mechanism:¹⁶

It is considered that subsequent decomposition of the acetylacetone radical will produce contaminants (admixture of carbon and copper oxides) in the film.

A somewhat different scheme of $\text{Cu}(\text{DPM})_2$ decomposition is described in Refs 144–146. A study of the thermolysis mechanism by *in situ* Fourier IR spectroscopy at a substrate temperature of 500 °C and a pressure of 20 Torr showed that the process starts with the cleavage of the C–C bonds of the chelate ring accompanied by simultaneous partial elimination of the *tert*-butyl groups. As a result, isobutene is formed. The thermolysis is abruptly accelerated at 600–700 °C; the films formed at temperatures above 600 °C are considerably contaminated with carbon. The overall decomposition equation is:

The interaction of $\text{Cu}(\text{DPM})_2$ with a substrate surface was studied by IR spectroscopy during the decomposition of the vapour in the presence of H_2O on the (100) planes of SiO_2 crystals (see Refs 147 and 148) and SrTiO_3 crystals (see Ref. 149) with formation of a copper film.

It was shown that the film formation on the SiO_2 surface starts with stoichiometric chemisorption of the copper(II) β -diketonate involving reactive surface OH groups. This reaction occurs even at 50 °C and results in the disappearance of the peak assigned to OH groups in the IR spectrum.¹⁴⁸ It was found that one $\text{Cu}(\text{DPM})_2$ molecule at the surface is coordinated with two or three OH groups.

In the presence of water vapour providing adsorbed water on the substrate or upon direct participation of OH group protons, decomposition of $\text{Cu}(\text{DPM})_2$ with elimination of one $\text{H}(\text{DPM})$ molecule and formation of copper(I) dipivaloylmethanate $\text{Cu}(\text{DPM})$ occur, as confirmed by XPS data.

As shown in more detail for polyfluorinated analogues (see Section IV.2.b), the intermediate copper(I) compound can undergo both reduction and disproportionation to give metallic copper and the original copper(II) compound.

This reaction on the SiO₂ surface also gives copper(I) oxide.¹⁴⁷

Deposition of copper onto the SrTiO₃ substrate was preceded by bombardment with Ar⁺ ions giving Ti³⁺ ions in the near-surface layer, which favoured the adsorption of the H₂O molecules. The mechanism of Cu(DPM)₂ transformations on the SrTiO₃ substrate is similar to that described above for the SiO₂ substrate.¹⁴⁹

Improvement of copper film characteristics in the CVD process based on copper(II) β-diketonates with alkyl groups, in particular a decrease in the SER, is reached under additional UV irradiation. Zama *et al.*¹⁵⁰ believe that in this case, UV irradiation favours the migration of the copper atoms over the growing copper film surface, thus decreasing the grain size and, hence, producing a smoother surface.

c. Preparation and characteristics of copper films

The use of copper(II) acetylacetonate as the starting CCC for the preparation of thin copper films by CVD began in the early 1990s,^{134, 151} though some earlier works on this process (mostly patents) are known (see Ref. 16).

A study of CVD of copper films from Cu(acac)₂ vapour onto a SiO₂/Si substrate at 220–250 °C (with an argon–hydrogen mixture as the carrier gas) showed that the structure and morphology of copper films are primarily determined by two factors, *viz.*, the deposition rate and the partial pressure of hydrogen in the carrier gas.¹⁵¹ In a later study,¹⁵² polycrystalline copper films were obtained from Cu(acac)₂ vapour in pure hydrogen. The preparation of copper films with satisfactory characteristics from the same CCC but at higher substrate temperatures (*T_s*) of 300–450 °C (Table 3) has been patented.¹⁵³

A high temperature is required for CVD with Cu(acac)₂ as the starting compound. It was suggested that it may be decreased (by ~75 °) and the film deposition rate increased by using UV irradiation.¹⁵⁴

Yet another way for the activation of the CVD process involves the plasma-activated decomposition of Cu(acac)₂ vapour in hydrogen (PACVD), which allows generation of reactive hydrogen species at rather low temperatures.¹⁵⁵ For example, smooth thin copper films with a low SER (see Table 3) were obtained from Cu(acac)₂ vapour.¹³⁴ The decomposition was carried out in the presence of hydrogen (carrier gas) up to a substrate temperature of 300 °C; it was found that at higher temperatures decomposition does not depend on the nature of the carrier gas. This is apparently due to the fact that the amount of hydrogen formed upon intense pyrolysis in this temperature range is sufficient for the reduction of copper.¹⁴⁶ However, the presence of even small concentrations of O₂ results in an abrupt increase in the SER of the films.

If Cu(DPM)₂ vapour is used, the copper film growth on a quartz substrate starts at 350 °C.^{133, 156} The polycrystalline films obtained by this method¹³³ were preferentially oriented along the [111] direction and had a thickness > 300 nm and an SER of 10 μΩ cm (see Table 3). According to XPS data, carbon and oxygen were the main admixtures in this case (their total content was up to 10%); their simultaneous presence in the film could result from the reaction of copper with CO formed upon decomposition.¹⁴⁶

The specific electric resistance of copper films obtained¹¹⁶ from Cu(DPM)₂ vapour increased continuously from 8.1 to 41.2 μΩ cm (see Table 3) as their thickness decreased from 60 to 40.9 nm. It was noted that the films were smooth and mirror-like up to 300 °C but became dim as the temperature was increased. If the samples are cooled in a hydrogen atmosphere, carbon and oxygen admixtures in the film are virtually absent. On the other hand, cooling of the films in a nitrogen atmosphere results in a rather high content of the carbon admixture (12%–19%).

The factors determining the growth rate, the adhesion to the substrate and the morphology of the copper films obtained from Cu(DPM)₂ vapour in the CVD process were considered in detail by Dutta *et al.*¹⁵⁷ The effect of additional UV irradiation on such films was discussed:¹⁵⁰ at a constant substrate temperature, additional photostimulation of thermolysis decreased significantly the SER of the films (see Table 3).

The following variant of the CVD process has been suggested:¹⁵⁸ the vapour of the starting Cu(DPM)₂ was carried with a stream of nitrogen containing hydrogen and was then decomposed on a borosilicate glass substrate in the temperature range from 220 to 400 °C. In this case, the deposition of copper films was rather fast for Cu(DPM)₂ (26 nm min^{−1}) at a relatively low SER (1.7–2.7 μΩ cm at thicknesses ≥ 50 nm).

2. Polyfluorinated copper(II) β-diketonates

It is known that incorporation of fluorine atoms into molecules of organic compounds generally increases their volatilities, despite the essential increase in the molecular masses. The nature of this effect is still uncertain. It is assumed that it can be due to weakening of the van der Waals interactions^{111, 159} and (in some cases) due to the disappearance of hydrogen bonds upon replacement of hydrogen atoms in the molecule by fluorine atoms.¹⁰⁹ However, this can hardly be regarded as a comprehensive explanation.

Copper (II) β-diketonates also obey this rule.^{132, 159, 160} For example, replacement of methyl groups in the Cu(acac)₂ molecule by trifluoromethyl groups results in a 10⁴-fold increase in saturated vapour pressure of the chelate at constant temperature.¹⁶⁰ In addition, the thermal decomposition of polyfluorinated copper(II) β-diketonates results in films with a lower content of impurities (in particular, carbon). In most cases, the formation of copper fluorides is not observed even under rather drastic deposition conditions,¹⁶¹ though the formation of CuF as a labile intermediate product is possible. This can be due both to the relative strength of the C–F bond in comparison with the C–O and

C—C bonds and to the high stabilities and volatilities of the polyfluorinated organic products of thermolysis. Owing to these properties, polyfluorinated copper(II) β -diketonates became the first CCC utilised in the CVD technology.¹¹⁰

Copper(II) hexafluoroacetylacetonate $\text{Cu}(\text{HFA})_2$ (**1**, $\text{R} = \text{R}' = \text{CF}_3$) is the polyfluorinated copper(II) β -diketonate studied most thoroughly and used most widely in the CVD process.¹¹¹ Copper(II) trifluoroacetylacetonate $\text{Cu}(\text{TFA})_2$ (**1**, $\text{R} = \text{CH}_3$, $\text{R}' = \text{CF}_3$) was also considered as a starting CCC. The use of copper(II) pivaloyltrifluoroacetylacetonate $\text{Cu}(\text{PTA})_2$ and some other substances of this series was much less common.

a. Synthesis and physicochemical properties

Polyfluorinated copper(II) β -diketonates are synthesised from the corresponding polyfluoro- β -diketones. These starting compounds were difficult to prepare¹⁶² until they became available by the Claisen condensation.^{163, 164}

$\text{R} = \text{CH}_3, \text{CF}_3, \text{etc.}$

This reaction became a reliable source of trifluoro- and hexafluoroacetylacetone and a series of their analogues.

The classical method for the synthesis of copper(II) hexafluoroacetylacetonate $\text{Cu}(\text{HFA})_2$ involves the reaction of copper(II) nitrate with hexafluoroacetylacetone in aqueous solution in the presence of sodium acetate (molar ratio 1:2:2).¹²⁰ This results in the precipitation of green crystals, the composition of which was determined differently by different researchers.^{119, 165, 166} It is believed¹²⁰ that these are the crystal hydrates $\text{Cu}(\text{HFA})_2 \cdot 2\text{H}_2\text{O}$ which do not decompose on sublimation. However, this conclusion was disputed later¹⁶⁷ and it was noted that the amount of water of crystallisation in the $\text{Cu}(\text{HFA})_2$ hydrate is not constant. According to the results of Funck and Ortolano,¹⁶⁷ the green crystals are monohydrates (see also Ref. 168), since the dihydrate isolated by them was a thermally unstable yellowish-green compound. Difficulties in assigning $\text{Cu}(\text{HFA})_2 \cdot n\text{H}_2\text{O}$ obtained by this method to mono- and dihydrates were also encountered later.¹⁶¹

Yet another method for the preparation of $\text{Cu}(\text{HFA})_2$ is the reaction of the ammonia complex of $\text{H}(\text{HFA})$ with CuCl_2 in aqueous solution.¹⁶⁹ The main product in the form of bluish-green crystals was characterised as a dihydrate, its melting point coincided with that reported previously.¹²⁰ Nevertheless, these data disagree with other reported results.¹⁶⁷

Yet another method for the synthesis of high-purity $\text{Cu}(\text{HFA})_2$ with the use of $\text{H}(\text{HFA})$ and copper(I) oxide was patented.¹⁷⁰

A drawback of the monohydrate $\text{Cu}(\text{HFA})_2 \cdot \text{H}_2\text{O}$ as the starting compound in the CVD processes is its ability to undergo decomposition with elimination of water in the reactor at low pressures in a carrier gas stream.¹⁷¹ Therefore, anhydrous $\text{Cu}(\text{HFA})_2$ is extensively used in these processes; under standard conditions, it has the form of purple crystals which are rather hygroscopic in air.¹²⁰

Copper(II) trifluoroacetylacetonate $\text{Cu}(\text{TFA})_2$ was first synthesised by Schultz and Larsen¹⁷² from the corresponding β -diketone (see also later studies^{164, 173}). A procedure for its preparation with the use of ammonium β -diketonate was reported.¹⁶⁹ Many fluorine-containing copper(II) β -diketonates [including $\text{Cu}(\text{TFA})_2$] and the corresponding β -diketones have been obtained by Park *et al.*¹⁷⁴

Generally, $\text{Cu}(\text{TFA})_2$ and $\text{Cu}(\text{HFA})_2$ are much more volatile than their analogues with alkyl groups described in the previous section.^{175–177} Furthermore, they were found to be the most volatile in a large series of fluorine-containing copper(II) β -diketonates, as indicated by thermogravimetric data.¹⁷⁸ The vapour pressure of $\text{Cu}(\text{HFA})_2$ measured by various methods^{179, 180} is 3 Torr at room temperature and atmospheric pressure.¹⁸¹

The initial study of the decomposition of $\text{Cu}(\text{TFA})_2$ and $\text{Cu}(\text{HFA})_2 \cdot \text{H}_2\text{O}$ vapour in the CVD process showed that the sublimation of these CCC occurs at 85 and 65 °C, respectively.¹¹⁰ The standard enthalpy of evaporation of $\text{Cu}(\text{HFA})_2$ is $13.2 \pm 0.8 \text{ kcal mol}^{-1}$ (see Ref. 180).

The β -diketonates of divalent copper containing the *n*-heptafluoropropyl group are rather exotic but quite suitable for the preparation of thin copper films by CVD. These compounds include such chelates as copper 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dionate $\text{Cu}(\text{FOD})_2$ (**1**, $\text{R} = \text{Bu}^t$, $\text{R}' = n\text{-C}_3\text{F}_7$)¹⁸² and copper 1,1,1,2,2,3,3,7,7,8,8,9,9,9-tetradecafluorononane-4,6-dionate $\text{Cu}(\text{FND})_2$ (**1**, $\text{R} = \text{R}' = n\text{-C}_3\text{F}_7$). These β -diketonates can be synthesised from β -diketones by the usual method.¹⁸³

Stabnikov *et al.*¹⁸⁴ studied the possibility of synthesis of mixed-ligand copper(II) β -diketonates where the copper atom is simultaneously bound to diketones with alkyl (*acac*, *DPM*, *etc.*) and fluorinated alkyl groups (*TFA*, *HFA*). The crystal and molecular structures of some of these compounds were studied.^{160, 185–187} It was shown that they have intermediate properties between those of 'homogeneous' bisdiketonates incorporating the corresponding ligands; in the vapour phase, mixed-ligand compounds can undergo disproportionation to give homogeneous bisdiketonates. It was therefore concluded that these compounds have no advantages which would make them promising for practical use in CVD technologies.¹⁸⁴

b. Mechanisms of decomposition on the substrate surface

The thermal decomposition of $\text{Cu}(\text{HFA})_2$ vapour in CVD processes and its products have been studied in detail.^{139, 188, 189} It was shown that $\text{H}(\text{HFA})$ is the main decomposition product of $\text{Cu}(\text{HFA})_2$ in the vapour phase, while thermal decomposition on a SiO_2 surface at 480 °C can give either a CuO film (in air) or a film of metallic copper with small admixtures of Cu_2O and HFA decomposition products (in an argon atmosphere). The main decomposition product in air at 800 °C is Cu_2O in the form of finely dispersed particles.

As shown by Lecohier *et al.*,¹⁹⁰ the growth of a copper film from $\text{Cu}(\text{HFA})_2$ vapour involves several stages. During an induction period, the duration of which depends on the properties of the substrate surface and on the deposition method, film growth is not observed. Subsequently, the formation of isolated copper islets starts. Their merging results in a sharp decrease in the SER.

Van Hemert *et al.*¹¹⁰ suggested a mechanism of copper reduction from its chelate in a hydrogen atmosphere; this mechanism can be expressed by the overall equation

In the case of copper(II) β -diketonate hydrates, the formation of precursors in hydrated form was postulated.

A similar decomposition equation was suggested for the thermolysis of $\text{Cu}(\text{HFA})_2$ at relatively low temperatures (below 340 °C).¹⁸⁰

Thus, it is believed that thermolysis of the compounds in question starts with the cleavage of the copper—oxygen bonds. It was noted that at higher temperatures (500–600 °C) cleavage of the C—C bonds in the ligand also occurs and results in carbon admixtures in the film.

These concepts are basically correct but they do not provide a sufficiently full description of the processes occurring when the molecules of the starting CCC reach a heated substrate surface. A detailed scheme of these processes was developed somewhat later and generalised by Kim *et al.*¹⁹¹

The following assumptions were used in the description of the mechanism of transformations in the CVD processes: the CCC and hydrogen molecules are adsorbed on different sites of the substrate surface; the adsorption of molecules of CCC competes with that of the original β -diketone formed upon reduction; the reduction occurs on the substrate rather than in the gas phase.

A scheme consisting of five basic steps was suggested based on these assumptions:

(1) adsorption of molecules of CCC with their partial dissociation

(2) disproportionation of partially adsorbed copper(I)-containing intermediates

or

(2') progression of dissociation of the intermediate copper(I) derivative

(3) dissociative adsorption of hydrogen

(4) formation of a volatile product, *viz.*, a β -diketone, on the surface

(5) desorption of the β -diketone

Here A^* and B^* indicate the active sites of, initially, the substrate and, later, the growing copper film capable of chemisorption.¹⁹² Step 4 is the limiting step of the entire process.^{192, 193}

A somewhat simplified version of this mechanism was suggested earlier.¹⁹⁴ It was noted that the irreversibility of the entire process begins in the step where metallic copper adsorbed on the substrate appears. The copper atoms form microclusters on the substrate surface, which consist of 8–12 copper atoms and are clearly separated from the organic ligands.¹⁹⁵

Certainly, the temperature of the process and the material of the substrate affect the course of the steps considered. A study of the thermodynamic parameters of the thermal decomposition of Cu(HFA)_2 and the phase compositions of the copper films formed in a rather broad temperature range showed that copper(I) fluoride can be formed in one of the intermediate steps at rather low temperatures. This is not taken into account in the scheme suggested above. As the temperature increases, the amount of CuF decreases until it disappears completely.¹⁹⁶

The effect of the substrate material on the mechanism of thermolysis of Cu(HFA)_2 vapour was analysed in detail.¹⁹⁷ It was noted that decomposition of Cu(HFA)_2 in a stream of H_2 on a TiN surface can result in replacement of fluorine atoms in the trifluoromethyl group by hydrogen atoms. In the case of the SiO_2 substrate, a noticeable amount of CF_3COOH is formed, which is the product of cleavage of the $\text{C}-\text{C}$ bonds in the HFA fragment.

Let us outline the applicability limits of the mechanism considered. Two types of CVD processes are distinguished, depending on the conditions.¹⁹⁸ At rather low temperatures and partial vapour pressures of the starting CCC, the process is primarily characterised by reactions on the substrate surface occurring in accordance with the mechanism described above (the so-called reaction-limited conditions). At high substrate temperatures and pressures in the reactor and at high vapour pressures of the substance, this mechanism does not operate and the film deposition process is characterised by the transport of molecules of CCC to the substrate (transport-limited conditions). These conditions generally result in film heterogeneity.¹⁹⁸

In order to reveal the details of the thermal decomposition mechanism of Cu(HFA)_2 on various substrates, some authors used ultrahigh vacuum conditions ($\leq 10^{-7}$ Torr). Such conditions are unlikely to be suitable for industrial CVD processes, but we feel that the results obtained should be discussed.

If thermal decomposition of Cu(HFA)_2 vapour during CVD is carried out in ultrahigh vacuum, the process mechanism changes

essentially. In this case, disproportionation of the intermediate copper(I) derivative does not occur.¹⁹⁹ For example, the Cu(HFA)_2 molecules are quickly desorbed from the TiN substrate at as low temperature as 75 °C, and further decomposition of the intermediate [reaction (2'), see above] becomes the dominating process. At 200 °C, decomposition of the adsorbed ligand begins to give CO, CO_2 and CF_4 ; as a result, $\sim 30\%$ of Cu from the starting material remains on the substrate.

Disproportionation of copper(I) intermediates is not observed, either, in the deposition of copper films onto polycrystalline tantalum substrates from Cu(HFA)_2 vapour.²⁰⁰ It was noted that adsorption of CCC on a tantalum surface starts at 158 °C; formation of a copper film occurs at temperatures ≤ 117 °C, while diffusion of copper into tantalum is observed at 477 °C.

The adsorption of Cu(HFA)_2 molecules and their subsequent decomposition on the (100) and (111) surfaces of copper single crystals in ultrahigh vacuum (10^{-10} Torr) have been studied.²⁰¹ It was shown that under these conditions, surface migration of ligands of the adsorbed molecules of CCC with formation of isolated HFA groups adsorbed on the substrate parallel to its surface occurs even at low temperatures (~ -73 °C). At 102 °C, their decomposition gives CO, CO_2 (quickly desorbed from the substrate), CF_3 and the ketenylidene fragments $\text{C}=\text{C}=\text{O}$ adsorbed through the terminal carbon atom. At temperatures above 227 °C, the CF_3 species are desorbed, while the $\text{C}=\text{C}=\text{O}$ fragments undergo decarbonylation; the carbon remaining on the surface is the basic source of film contamination.

As shown for the adsorption of Cu(HFA)_2 on a platinum surface under similar conditions,²⁰² the orientation of HFA groups depends on the thickness of the layer of molecules of CCC adsorbed on the substrate. Ligand orientation parallel to the substrate surface is characteristic of very thin films; as their thickness increases, the ligands are 'reoriented' to become perpendicular to the substrate. It was also noted that difluorocarbene CF_2 is the most strongly adsorbed species, which is desorbed in ultrahigh vacuum only at 577 °C.

The nature of interaction of Cu(HFA)_2 and the β -diketone H(HFA) itself with the surface of the SiO_2 substrate was studied in detail.²⁰³ The experiments were carried out in ultrahigh vacuum (5×10^{-8} Torr). In this case, everything is determined by the presence of OH groups, both isolated and connected by hydrogen bonds, and siloxane bonds, $\text{Si}-\text{O}-\text{Si}$, on the surface of the substrate. It was shown that preferential adsorption of Cu(HFA)_2 molecules at 25 °C occurs with involvement of isolated surface OH groups. On heating the substrate (studied in the range up to 400 °C), decomposition of adsorbed Cu(HFA)_2 was observed; in this case, the OH groups involved in the adsorption were not recovered.

Farkas *et al.*²⁰³ reported experiments aimed at decreasing the density of OH groups on a SiO_2 surface as a result of its thermal treatment. It was found that in this case strong adsorption of the Cu(HFA)_2 molecules involves surface siloxane bonds, which are cleaved irreversibly upon subsequent heating and thermolysis of Cu(HFA)_2 . However, desorption of the decomposition products occurs at rather high temperatures, *viz.*, about 400 °C irrespective of pretreatment of the SiO_2 surface. The mechanism suggested by the authors involves direct axial coordination of the copper(II) atom with the non-shared electron pairs of the oxygen atoms of the OH groups or the $\text{Si}-\text{O}-\text{Si}$ bonds, giving a five-coordinate complex. A similar explanation was suggested previously for the interaction of Cu(acac)_2 with a SiO_2 surface.²⁰⁴

The deposition mechanism of copper films from Cu(HFA)_2 vapour in the presence of water vapour was considered in detail.^{205–208} It was assumed that intermediate formation of a Cu(HFA)_2 mono- or dihydrate occurs in the gas phase

In the resulting complex (under gas-phase conditions) an intramolecular transfer of H₂O protons to the ligand occurs, which weakens the copper–oxygen bonds. Adsorption of this complex on the surface results in elimination of the hydrated enol form of the β -diketone

The adsorbed Cu²⁺ ions are reduced under the action of hydrogen.

Since reduction is the limiting step of the process, the side formation of copper(I) oxide is observed at low deposition temperatures.^{209,210} It was found with the use of the ¹⁸O isotope that the formation of an oxide phase involves the oxygen atoms of H₂O rather than those of the H(HFA) ligand.²⁰⁹ However, in general, the addition of water vapour to the carrier gas in an optimum temperature mode does not result in contamination of films with copper oxides. This is believed to be due to the fact that the reduction of copper

is an exothermic process (the equilibrium constant is 0.78×10^8 at 325 °C).²⁰⁵

The presence of water vapour in the carrier gas improves the morphological characteristics of the films. This can be due to the fact that the nucleation rate of copper is determined by the rather low activation energy for decomposition of the adsorbed Cu(HFA)₂ hydrate and hence almost does not depend on the properties of the substrate surface. Owing to the high density of the nucleation centres determined by the amount of the adsorbed hydrate, smooth films with good morphology are formed. On the other hand, the formation of film nuclei in usual systems is limited by a surface reaction between the adsorbed molecules of anhydrous CCC and hydrogen, the rate of which depends on the density of the adsorption centres on the substrate surface. In this case, the film is very sensitive to the quality of the substrate.²⁰⁵

The role of molecules of an alcohol in the deposition of copper films from vapour of solutions of the starting CCC in the alcohol is somewhat similar to the role of water molecules.

Like water, methanol and ethanol in the vapour phase can be coordinated with the copper(II) ion in copper β -diketonate; as a result, molecules of the complex of copper β -diketonate with the corresponding alcohol are deposited on the substrate.²⁰⁸ The proton of the alcohol molecule in the adsorbed complex can then be transferred to the adsorbed HFA ligand obtained due to the CCC decomposition; this favours the desorption of an H(HFA) molecule from the substrate surface. An adsorbed alkoxy group that remains on the surface can be removed by two pathways: either by elimination of the hydrogen atom from the α -carbon atom to give a volatile carbonyl compound, or by the reaction with the adsorbed hydrogen atom from the carrier gas to give the alcohol.^{211,212} In the former case, the alcohol acts as a reducing agent, while in the latter case, as a reduction catalyst. Propan-2-ol is the most efficient compound,²¹³ in spite of the fact that propan-2-olic complexes of copper β -diketonates are the least stable complexes with alcohols.²⁰⁸

The mechanism of photochemical deposition of copper films from the vapour of CCC under laser irradiation of substrates was suggested and considered in detail by Ehrlich and Tsao.²¹⁴ Special attention was given to film growth rate simulation.

A study by Zheng *et al.*²¹⁵ dealt with the mechanism of Cu(HFA)₂ vapour decomposition in a stream of hydrogen under exposure to plasma. It was shown that under these conditions preferential consecutive elimination of CF₃ groups from the ligand is observed, rather than elimination of the entire ligand with cleavage of the Cu–O bonds. Nevertheless, this decomposition pathway also gives only volatile organic products which do not contaminate the film obtained.

The thermodynamics of decomposition of Cu(HFA)₂ and its analogue, Cu(FOD)₂, in the PACVD process has been considered.²¹⁶

The authors of the first studies on the PACVD method for the preparation of copper films assumed that the role of plasma involves the formation of a high concentration of reactive hydrogen species.^{155,216,217} However, the details of the mechanism remained unclear. A model of decomposition of Cu(HFA)₂ with the use of hydrogen plasma was described.¹⁹³ It was noted that in this process the hydrogen plasma is mainly electropositive and consists of cations, *i.e.*, H⁺, H₂⁺ and H₃⁺, electrons and hydrogen atoms. The overall process occurs according to the five-step mechanism discussed above; however, both the hydrogen atoms adsorbed on the substrate and the hydrogen atoms from the gas phase can participate in the limiting fourth step. The film quality and the deposition rate are determined by the pressure in the reactor, the electric field power and the substrate temperature. At small power (up to 25 W), the following kinetic equation is valid:

$$R_d = k[\text{Cu(HFA)}_2]^{1/2}[\text{H}] ,$$

where R_d is the rate of the direct deposition reaction, k is the rate constant of the limiting (fourth) step. At high electric field power, decomposition of HFA fragments starts, the process becomes more complicated and strong contamination of films with carbon and fluorine is observed.¹⁹³

The decomposition mechanisms of other fluorinated copper(II) β -diketonates in CVD processes have almost not been studied. It was shown¹⁸⁹ that H(FOD) is the main product of Cu(FOD)₂ decomposition in the vapour phase. One can also mention a study of the kinetics of thermal decomposition of Cu(PTA)₂ vapour upon heating of the substrate with a CO₂ laser;²¹⁸ the observed phenomena are in full agreement with the concepts of the reaction-limited and transport-limited processes as a function of deposition conditions. Data are available on the products of Cu(FND)₂ thermolysis and its behaviour under CVD conditions in the presence of vapour of water and alcohols.²⁰⁸

c. Preparation and characteristics of copper films

In the first experiments on the preparation of thin copper films by CVD based on decomposition of Cu(TFA)₂ and Cu(HFA)₂ · H₂O vapour in a stream of hydrogen under atmospheric pressure, the optimum temperature of glass substrates on which films are formed was found to be 250 °C. However, the characteristics of films were not reported.¹¹⁰ The decomposition was purely thermal, without additional activation with laser radiation or plasma. A little later, a similar procedure was patented by the same authors.²¹⁹

The process of non-activated thermal deposition of copper films from Cu(HFA)₂ vapour was also studied in a number of works (see, *e.g.*, Refs 40, 115, 180, 191, 194, 219–244).

Typical conditions were used by Kim *et al.*:¹⁹¹ the pressure in the reactor was 10 Torr, the temperature of the TiSi₂/Si substrate was 300–400 °C, an H₂/Ar mixture (3 : 1) was used as the carrier gas (Table 4). It was found that at low pressure and with this substrate material, no growth of the copper film on the substrate occurred at temperatures up to 300 °C. Above this temperature, the growth rate was 10–100 nm min^{−1}. The film thickness depended linearly on the deposition rate, *i.e.*, the deposition rate was practically the same in each experiment. As the hydrogen partial pressure in the carrier gas was decreased, a considerable decrease in the deposition rate was observed. The surface morphology of the films obtained under these conditions was studied in detail.^{220,223}

The deposition of copper films by decomposition of Cu(HFA)₂ vapour on SiO₂/Si substrates in the temperature range from 250 to 650 °C in the absence of hydrogen (with pure argon as the carrier gas) was studied by Temple *et al.*,¹⁸⁰ who did not observe the formation of films at 250 °C, as opposed to the results of other studies.¹¹⁰ Pure copper films appeared in the

Table 4. CVD conditions and properties of copper films obtained from polyfluorinated copper(II) β -diketonates.

^a In plasma. ^b Under laser irradiation followed by cooling to 250 $^\circ\text{C}$. ^c Under laser irradiation.

temperature range of 340–390 $^\circ\text{C}$ (see Table 4). Upon further heating of the substrate to 430 $^\circ\text{C}$, the films containing 65% of carbon (25% of copper) were formed, while the films obtained at 500 $^\circ\text{C}$ consisted of pure carbon.

In other studies, the temperature range for the formation of pure copper films by decomposition of Cu(HFA)₂ vapour in argon was somewhat wider, *viz.*, from 310 to 400 $^\circ\text{C}$.^{221, 222} Films of rather high quality were obtained with a growth rate of 65 nm min^{−1}. It was noted that the substrate (TiN, TiW) surfaces had to be cleaned from oxide contaminants.²²²

Awaya and Arita²²⁴ synthesised copper films from Cu(HFA)₂ vapour on a Si substrate coated with a few buffer layers at once (the top layer consisted of chromium, see Table 4). Such films had low SER values and contained an admixture with chromium.

In addition to hydrogen, water can be used as a reducing agent for Cu(HFA)₂.^{171, 190, 205, 225, 226} In this case, the growth rate of copper films depends directly on the amount of water vapour in the gas phase.²²⁵ The presence of water vapour during the decomposition of Cu(HFA)₂ vapour increases considerably the film growth rate (approximately by two orders of magnitude¹⁷¹) but the selectivity of the process decreases (see Section VI). The specifics of the film growth kinetics in this method and the film morphology were considered in detail.¹⁹⁰ It was reported¹⁷¹ that the SER of the resulting films can be as low as ~ 2.0 – $2.1 \mu\Omega$ cm while the deposition rate remains high.

Another group of researchers who studied a similar process suggested the use of Cu(HFA)₂ dihydrate rather than Cu(HFA)₂ as the starting CCC.²⁰⁵ They reported a high deposition rate and good morphology of the copper film surfaces. However, the results of this study were poorly reproducible, probably due to the instability of the dihydrate; it was reported that this substance readily eliminates water molecules in the vapour phase.²²⁷ The use of anhydrous Cu(HFA)₂ in the presence of water vapour gave films with low SER (deposition rates up to 90 nm min^{−1}).

An interesting modification of the method considered above involves the deposition of copper films from the vapour phase of a CCC solution in an alcohol.²¹¹ It is known that anhydrous Cu(HFA)₂ is freely soluble in alcohols (ethanol, propan-2-ol). In

this method, a stream of the carrier gas (H₂) is passed through an $\sim 0.4 \text{ g ml}^{-1}$ alcoholic solution of Cu(HFA)₂ (higher concentrations result in an increased solution viscosity and, as a consequence, instability of the process). The alcohol vapour present in the gas phase serves as an additional reducing agent.

The advantage of this technique is the significant (approximately fivefold²¹¹) increase in the deposition rate of copper films in comparison with that in the usual process in a stream of hydrogen. However, the films obtained using this technique have higher porosity which inevitably impairs their properties. For example, the SER of copper films synthesised by Borgharkar *et al.*²¹¹ was 2.5–5 $\mu\Omega$ cm (see Table 4) provided that their thickness was no less than 1000 nm. The characteristics of these films can be improved by addition of water vapour to the carrier gas; in this case, the SER of the films was 2.6–2.9 $\mu\Omega$ cm.²¹¹ A technique for CVD of copper films from CCC with participation of a solvent has been patented.²²⁸

Attempts at performing the CVD process with Cu(HFA)₂ with an excess of the starting β -diketone H(HFA), which in turn is a decomposition product of the precursor, were reported. It was noted¹⁹⁴ that the excess of H(HFA) decreased the copper film deposition rate. Nevertheless, if SiO₂ templates deposited on a copper substrate were used for the preparation of thin copper strips from Cu(HFA)₂, pretreatment of the template channels with H(HFA) vapour improved considerably the characteristics of the strips, but the presence of H(HFA) vapour during the deposition process is unacceptable as it caused an abrupt impairment of the strip morphology and a loss of selectivity.²²⁹

It is known that polyfluorinated copper(II) β -diketonates are photo-labile compounds. Their photochemistry in solution²³⁰ and in the gas phase^{231–233} has been studied rather thoroughly. Laser irradiation of the substrate is a popular method for decomposition of the vapour of these compounds for deposition on substrates.^{181, 232, 234–238} In this case, Cu(HFA)₂ itself or its alcoholic solution (an ‘alcoholic’ CVD technique) can be utilised for the preparation of films.

This creates certain difficulties. First, it is difficult to estimate to what degree the observed process is pyrolytic and to what

degree it is photochemical, as the substrate temperature is $\sim 250^\circ\text{C}$,²³⁶ and it is difficult to estimate accurately the temperature of the process in laser experiments.²³⁹ It is known that the quantum yield of decomposition of copper(II) β -diketonate vapour to the metal is rather small; this determines the low film growth rates by the purely photochemical mechanism and the irregularity of their morphology. Second, photochemical decomposition can increase the content of the carbon admixture in the copper film; fluorine and oxygen are removed with the volatile photolysis products.²³⁴ It was shown in experiments on copper film deposition under laser irradiation with a wavelength corresponding to the visible spectrum range that carbon is a photolytic admixture in this case; under these conditions, the carbon contamination of the films was absent.²³⁶

A thorough refinement of the photochemical process modes for the deposition of films was required to overcome the difficulties noted above.^{237, 240} In a study devoted to the effect of laser power on the growth rate of copper films from $\text{Cu}(\text{HFA})_2$ vapour,²⁴¹ the deposition rate was increased from 20 to 120 nm min^{-1} in a stream of an argon–hydrogen mixture and from 4 to 27 nm min^{-1} in a stream of argon, but the SER of the films were not reported. It was noted that in the presence of ethanol under laser activation conditions, as in the usual thermolysis, the growth rate of copper films increased.^{234, 238}

The properties of films obtained with the use of a laser were analysed by Hoyle *et al.*²³⁶ The films were formed on a silicon substrate at $\sim 800^\circ\text{C}$ (the power density of laser radiation was $4 \times 10^5 \text{ W cm}^{-2}$). As the film grew, the substrate temperature decreased gradually to 250°C , *i.e.*, the optimum value for $\text{Cu}(\text{HFA})_2$ vapour decomposition. The films had good adhesion properties but rather high SER values (see Table 4).

The preparation of film microstructures (copper microstrips) from $\text{Cu}(\text{HFA})_2$ vapour is a promising field of application of the CVD process with the use of laser radiation. The optimum conditions of the process for the preparation of strips 2 mm long were chosen and the factors determining their basic characteristics were studied.²⁴⁰

A milder way of photochemical decomposition of $\text{Cu}(\text{HFA})_2$ vapour is the use of UV irradiation.²⁴² In this case, the level of contamination of copper films is much lower.

Yet another method for activation of decomposition of $\text{Cu}(\text{HFA})_2$ vapour is the use of plasma.^{161, 243, 244} It was shown in the very first study on this technique that if the process is carried out in a stream of hydrogen, high-quality thin copper films could be obtained virtually without carbon admixtures by varying the source power and the substrate temperature.¹⁶¹ The SER of the best film samples, 60–80 nm thick, were within 1.7–2.4 $\mu\Omega \text{ cm}$; these values could not be reached with laser radiation. This can be due to the fact that efficient growth of films in the plasma method requires a considerably lower source power; an increase in the power immediately resulted in carbon contamination.

Plasma activation was used to improve considerably the characteristics of the copper films obtained by the 'alcoholic' method. For example, decomposition of the vapour of an ethanolic solution of $\text{Cu}(\text{HFA})_2$ in a stream of hydrogen at a plasma source power of 45 W gave a copper film 63 nm thick with a low SER (see Table 4).²⁴³ An optimum content of hydrogen in the carrier gas is a prerequisite for the preparation of high-quality copper films by this method: at a hydrogen concentration lower than 88%, the SER of copper films increased to 9–10 $\mu\Omega \text{ cm}$. An opposite relationship was observed for the grain size in the copper film: a decrease in the fraction of hydrogen in the carrier gas decreased the grain size from ~ 100 (88% H_2) to ~ 10 nm (0% H_2). The reasons for this phenomenon were not rationalised.

Copper films with good characteristics were obtained²⁴⁴ using a similar technique by decomposition of the vapour of $\text{Cu}(\text{HFA})_2$ solutions in ethanol and propan-2-ol at relatively low substrate temperatures and a power density of the plasma source of 0.13–0.25 W cm^{-2} . A high film growth rate, *viz.*, 25 nm min^{-1} , was reported; the SER of films 440 nm thick was 1.7–1.9 $\mu\Omega \text{ cm}$.

Polycrystalline copper films 500–1000 nm thick were obtained from the vapour of a rather rare starting CCC, *viz.*, $\text{Cu}(\text{FOD})_2$.¹⁸² The resulting copper film (argon as the carrier gas) contained up to 24% admixtures (C, O, F). Replacement of argon with hydrogen resulted in a pure copper film with good characteristics; in this case, a decrease in the substrate temperature (to 250°C and lower) increased the SER of the films considerably (see Table 4).

3. Complexes of copper(II) β -diketonates with additional ligands

The copper atom in copper(II) β -diketonates is coordination-unsaturated, hence it is possible to synthesise adducts of copper(II) β -diketonates with various organic Lewis bases (primarily, nitrogen- and oxygen-containing ones). Some of these adducts are volatile. However, the prospects of their use in the CVD technology as precursors are doubtful.

Unlike copper(I) β -diketonates, copper(II) β -diketonates are convenient starting CCC for the CVD technology. As a rule, it is easier to change their properties by modifying the starting β -diketone than to try to obtain a stable adduct with an additional ligand which can be sublimed.

Nevertheless, the use was suggested of some compounds of this type as volatile CCC, for example, the adduct of $\text{Cu}(\text{DPM})_2$ with *o*-phenanthroline (1 : 1), which is sublimed *in vacuo* at 130°C without decomposition.²⁴⁵ Under the same conditions, $\text{Cu}(\text{DPM})_2$ itself is sublimed at 160°C . It was reported that an attempt at sublimation of a similar $\text{Cu}(\text{acac})_2$ adduct resulted in its decomposition.

The 1 : 1 adducts of $\text{Cu}(\text{HFA})_2$ and $\text{Cu}(\text{PTA})_2$ with *o*-phenanthroline and 2,2'-bipyridyl are also volatile.²⁴⁶ However, the sublimation temperatures for all four adducts exceed 160°C , which is higher than those for the original copper β -diketonates.

More promising in this respect is the synthesis of a series of volatile adducts of $\text{Cu}(\text{HFA})_2$ with ethanolamines.²⁴⁷ As noted above, the addition of ethanol vapour to the carrier gas increased the copper film deposition rate. It was assumed that the ethanol-amine adducts obtained, which contained a 'preformed' ethanol fragment, will maintain this advantage; on the other hand, the presence of the amino group should impart stability to the adduct under sublimation conditions.

Preliminary CVD experiments on this type of copper(II) derivatives showed that the adduct of $\text{Cu}(\text{HFA})_2$ with 1-dimethylaminopropan-2-ol, which forms a copper film at a substrate temperature of 300°C , has quite satisfactory characteristics suitable for CVD processes.²⁴⁷ However, the parameters of the process and the film characteristics were not reported. No films were obtained with the use of a similar adduct with ethanolamine.

4. Other classes of volatile compounds of copper(II)

The range of volatile organic derivatives of copper(II) suitable for CVD processes is not limited to β -diketonates, but the choice is rather narrow.

a. Chelate complexes, analogues of copper(II) β -diketonates

Nitrogen-containing analogues of β -diketones (iminoketones) form volatile derivatives of copper(II) with physicochemical properties satisfactory for CVD processes.²⁴⁸ Nevertheless, we could find only one study devoted to the practical preparation of copper films from this class of compound.²⁴⁹ A new compound synthesised by the authors, *viz.*, bis[4-(2,2,2-trifluoroethyl)imino-1,1,1,5,5,5-hexafluoropentan-2-onato]copper(II) designated as $\text{Cu}(\text{nona-F})_2$, had a decomposition temperature of 270°C . Copper films with satisfactory characteristics were obtained from this compound but no further developments were reported.

Of compounds the structure of which is somewhat similar to that of copper β -diketonates, chelate complexes of copper(II) with analogues of ethyl acetoacetate ($\text{CH}_3\text{COCH}_2\text{COOR}$) can be considered as a real alternative to the former. A series of these compounds ($\text{R} = \text{Me}, \text{Et}, \text{Bu}^t, \text{CH}_2\text{Ph}$ and $\text{CH}_2\text{CH}_2\text{OCH}_3$), their hydrates and adducts with alcohols were synthesised²⁵⁰ using a

technique similar to that used for copper β -diketonates.¹²⁰ The sublimation temperatures of these compounds were from 78 to 113 °C at 0.16 Torr. The crystal structure of $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$ monohydrate was determined.¹³⁶

CVD experiments with compounds of this series at low pressures (0.1–1 Torr) in the presence of hydrogen resulted in high-quality copper films with SER values ranging from 1.8 to 2.5 $\mu\Omega$ cm; in addition, the factors determining their adhesion to the substrate were studied.^{250, 251} A Si substrate with a TiN or TiW barrier layer was used; the deposition rate varied from 0.5 to 20 nm min⁻¹ at substrate temperatures from 160 to 330 °C. Judging by the characteristics of the films obtained, $\text{Cu}(\text{CH}_3\text{COCHCOOCH}_2\text{CH}_2\text{OCH}_3)_2$ was the best starting CCC in this series.²⁵⁰

If copper(II) ester chelates are used, copper films are formed at a relatively low substrate temperature (160 °C). For comparison: the minimum substrate temperature is 310 °C for $\text{Cu}(\text{HFA})_2$.^{220, 223} This is an important advantage of copper(II) ester chelates in comparison with copper(II) β -diketonates. No noticeable thermolysis of the adsorbed free ligands occurs at 160 °C; this ensures that the films are not contaminated.

The surface morphology of copper films synthesised by the CVD method from $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$ vapour was studied in detail.²⁵² Comparison of the deposition processes and microstructures of copper films obtained from $\text{Cu}(\text{DPM})_2$ and $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$ showed that dense, crack-free films are formed from both CCC at substrate temperatures up to 350 °C, but the substrate temperature required for the deposition is about 100 °C lower in the case of $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$.^{253, 254} The growth rate of the copper film from $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$ vapour is several-fold smaller, but the film structure is much better than that of the film obtained from $\text{Cu}(\text{DPM})_2$ vapour. In another study by the same scientific group,¹¹⁷ the SER of copper films synthesised from $\text{Cu}(\text{CH}_3\text{COCHCOOBu}^t)_2$ at 225 °C was reported to be 2.5–4.0 $\mu\Omega$ cm at a film thickness of 50–120 nm.

$\text{Cu}(\text{CH}_3\text{COCHCOOEt})_2$ is also believed by many authors to be a promising starting CCC for the deposition of copper films. For example, dense fine-grain copper films ≥ 95 nm thick were obtained from this compound at 225 °C (on a SiO_2 substrate) in a hydrogen atmosphere;²⁵⁵ the SER of these films was close to that of metallic copper. This compound was also used²⁵⁶ in a CVD process with plasma activation giving a copper film > 250 nm thick with a SER of 2.0 $\mu\Omega$ cm. The same work also reported the preparation of a 256 Mb RAM chip by CVD using decomposition of $\text{Cu}(\text{CH}_3\text{COCHCOOEt})_2$ vapour.

b. Copper(II) carboxylates

Copper(II) carboxylates that are more readily accessible synthetically than copper β -diketonates could become a real alternative to the latter in CVD processes. However, the use of this class of substances, first of all copper(II) formate $\text{Cu}(\text{HCOO})_2$, for the preparation of copper films was originally limited to deposition from liquids and aerosols.^{63, 257, 258}

Nevertheless, it was shown subsequently that $\text{Cu}(\text{HCOO})_2$ hydrate can be directly used in the CVD process.^{259, 260} Preparation of copper films from the vapour of this compound was carried out on Si(100) and TiN substrates at 200–350 °C with and without a carrier gas (H_2 , Ar). The highest-quality crystalline copper films without oxygen admixtures were obtained at a substrate temperature of ~ 300 °C.

Of copper carboxylates intended as potential starting CCC, volatile complexes of copper(II) polyfluorocarboxylates with 1,4-dioxane were also obtained; these compounds can sublime without decomposition at 120–130 °C (0.05 Torr).²⁶¹

c. Copper(II) alkoxides and their derivatives

Volatile alkyl derivatives of copper^{262, 263} cannot be regarded as technologically suitable compounds, both with respect to their

synthetic accessibility and properties. Alkoxide derivatives of divalent copper are much more stable and accessible.

The simplest copper(II) alkoxides of the type $\text{Cu}(\text{OR})_2$, where $\text{R} = \text{Me}$, Et, etc., are unsuitable for CVD processes because they are polymeric non-volatile compounds.²⁶⁴ Compounds obtained by partial replacement of hydrogen atoms in Cu(II) alkoxides by fluorine atoms sublime at 80–90 °C. Their thermal decomposition occurs at 140–200 °C,²⁶⁵ but these compounds have not been studied from the viewpoint of their use in CVD technology. Attempts were made to synthesise monomeric alkoxides as the starting compounds for CVD processes.^{266, 267} In fact, a series of convenient compounds [e.g., $\text{Cu}(\text{OCH}_2\text{CH}_2\text{NR}_2)_2$, where $\text{R} = \text{Me}$, Et] which sublime *in vacuo* at 60–110 °C were obtained, but no experiments on the preparation of copper films using CVD from them as the starting CCC were carried out.

An interesting development of this line of research was a rather simple synthesis of volatile complexes of copper(II) fluoroalkoxides with various nitrogen-containing Lewis bases with general formula $\text{Cu}(\text{OR})_2 \cdot \text{L}$, where R is hexafluoroisopropyl $\text{CH}(\text{CF}_3)_2$ (HFIP) and $\text{C}(\text{CH}_3)(\text{CF}_3)_2$, while $\text{L} = \text{N}, \text{N}', \text{N}'', \text{N}'''$ -tetramethylenediamine (TMED) and 2,2'-bipyridyl.²⁶⁸ These complexes are monomeric and undergo sublimation with partial decomposition. However, it was shown that decomposition of vaporised $(\text{HFIP})_2\text{Cu}(\text{TMED})$ complex on silicon substrates at 300 °C gives a copper film with an admixture of < 1% carbon. However, in the authors' opinion,²⁶⁸ the search for starting compounds which would be more competitive with copper β -diketonates among this class of compounds is necessary.

V. The starting copper-containing compounds: copper(I) derivatives

Disproportionation to copper(II) derivatives and metallic copper is one of the main reactions of copper(I) compounds. It is no wonder that this process attracted the attention of researchers in the field of preparation of thin copper films by the CVD process.

It is known that it is more difficult to synthesise volatile copper(I) derivatives than similar compounds containing copper(II). However, studies in the field of CVD processes with the use of monovalent copper compounds, which have started rather recently, are very intense.^{111, 269} This is due to the fact that thermally induced disproportionation has certain advantages over thermal decomposition.

These advantages include the following: the process occurs with higher deposition rate and at lower temperatures; the ligands bound to the Cu(I) atoms are removed in a more favourable temperature range without decomposition to volatile products. This provides good technological characteristics: the process is safer as generally there is no need to use a carrier gas and hydrogen as the reducing agent; a high-purity film grows because it is not contaminated with carbon, fluorine and oxygen. These advantages expand the prospects and reduce the restrictions related to the design and control of the technological process of selective deposition of copper films.

It should be noted that in the case of CVD processes involving copper(I) derivatives, a certain competition exists between the CCC with organic ligands and the starting inorganic CCC (usually, copper halides).

Attempts were made to use copper(I) halides for the preparation of copper films by the CVD method.^{270, 271} High evaporator temperatures are required in this case; in addition, the problem of film purity arises owing to the low volatility of the starting compounds.¹¹¹ Copper(I) halides are more volatile than copper(II) halides.^{272–274} For example, dense fine-grain copper films with SER of 1.9 $\mu\Omega$ cm devoid of iodine admixture were obtained from CuI (the temperature of the SiO_2 substrate was 697 °C).²⁷⁴ However, too high substrate temperatures are required for CVD process based on monovalent copper halides; this limits essentially the use of these compounds.

1. Copper(I) β -diketonates and their complexes

Among volatile copper(I) compounds, as among copper(II) derivatives, β -diketonates are promising for CVD technology. These compounds are attractive due to their ability to undergo disproportionation at comparatively low temperatures to give the corresponding volatile copper(II) β -diketonates and metallic copper directly in the form of thin films

However, the operation with copper(I) β -diketonates has specific difficulties. First, the contact of these compounds with atmospheric oxygen during synthesis results in their smooth oxidation to the corresponding copper(II) β -diketonates, which necessitates that their synthesis be carried out in an inert atmosphere. Moreover, pure copper(I) β -diketonates are unstable and undergo disproportionation even at relatively low temperatures.²⁷⁵ This can be prevented by additional complexing of the coordination-unsaturated copper atom with various ligands (Lewis bases).

Various organic and inorganic compounds (carbon monoxide, alkynes, dienes, phosphines, amines) forming volatile complexes $(\beta\text{-diket})\text{Cu} \cdot \text{L}_n$ can be used as additional ligands. The additional ligand is eliminated upon disproportionation of the complex to give a volatile neutral compound

Of numerous compounds of this type synthesised to date, only compounds with H(HFA) satisfy the CVD process requirements. Derivatives of other β -diketones are generally insufficiently stable or do not provide reproducible results in the film synthesis. For example, rather stable complexes of Cu(acac) with trimethylsilylalkynes and trimethylsilylalkadiynes were obtained. These complexes were suggested as volatile CCC,²⁷⁶ but CVD processes based on them have not been carried out.

We believe that the problem of stability of complexes with copper(I) β -diketonates, in particular with Cu(HFA), with additional ligands is a key problem for the evaluation of their possible use as the starting CCC in CVD technology. Thermodynamically stable complexes with high activation energies of thermolysis upon film deposition require high substrate temperatures or additional energy sources (plasma, laser radiation); this diminishes the advantages of these CCC over similar copper(II) β -diketonates which are much more readily accessible synthetically. Cu(I) complexes of low stability cannot provide the deposition efficiency and the process reproducibility. Hence, there should be a certain optimum degree of stabilisation of the Cu(HFA) molecule by virtue of the π -donor ability of a Lewis base used as the additional ligand. In fact, of all $\text{Cu}(\text{HFA}) \cdot \text{L}$ complexes synthesised, derivatives considered as potential starting CCC for CVD processes include those which contain moderately strong π -donors (*e.g.*, phosphines rather than amines) or compounds in which the π -donor ability of the multiple bond is somewhat weakened due to the incorporation of π -accepting trimethylsilyl groups [trimethylvinylsilane, bis(trimethylsilyl)acetylene].²⁷⁷

To date, several methods for the preparation of complexes of copper(I) β -diketonates with Lewis bases have been described. These include direct reaction with copper(I) oxide, the exchange reaction with sodium β -diketonates and metallation of β -diketonates with monovalent copper compounds.^{278–282}

Each of these variants involves certain synthetic difficulties. For example, reaction (1) is, technically, the simplest method.²⁸² However, water formed in the reaction favours undesirable disproportionation during the synthesis. In addition, it is difficult

to monitor the stoichiometry of the products in this method.²⁸³ The order of addition of the reagents is very important, since the formation of free Cu(I) β -diketonate, which undergoes disproportionation below 78 °C, should not be allowed. This is avoided by using an excess of the Lewis base.

The additional problem in method (2) involves the presence of sodium cations, which can appear as admixtures in the films obtained from the CCC synthesised using this approach.¹¹¹ The presence of these admixtures is absolutely unacceptable.

The reaction according to the pathway (3) occurs without complications; however, the cyclopentadienyl complex of copper(I) required is the least accessible potential starting compound of all three pathways.

a. Complexes of Cu(I) β -diketonates with alkenes and alkenylsilanes

The stabilising effect of the double bond in alkenes with respect to copper(I) β -diketonates is generally sufficient for the formation of stable complexes that can serve as the starting CCC. This is exemplified in the complex of (HFA)Cu(I) with vinylcyclohexane (VCH) synthesised²⁸⁴ according to the procedure described previously.²⁸² Unfortunately, data on the physicochemical properties of this compound were not reported. The substrate temperature during the film deposition was 100–175 °C, which is lower than the temperatures for other CCC. The copper films obtained had low SER and virtually did not contain admixtures.

Of copper(I) derivatives stabilised by double bonds of the additional ligand, complexes of Cu(HFA) with alkenyltrimethylsilanes are among the most promising compounds for the synthesis of copper films.

It is known that the trimethylsilyl group manifests a significant π -acceptor effect²⁷⁷ which is unfavourable for the coordination of the adjacent C=C bond of the alkene with the monovalent copper ion. In fact, the compound Cu(HFA) with the simplest alkenyltrimethylsilane, *viz.*, vinyltrimethylsilane (VTMS) **2** first described in 1991,²⁸⁵ is readily oxidised in air to give copper(II) derivatives and is quickly decomposed at ~ 150 °C.²⁸⁶

The decomposition of (HFA)Cu(VTMS) was noted even on storage of this compound at room temperature.²⁸⁷ However, these drawbacks are compensated by the fact that this compound is a volatile liquid even at 20 °C. The vapour pressure of (HFA).Cu(VTMS) is 0.14 Torr at 30 °C (see Ref. 288) and 0.3 Torr at 40 °C (see Ref. 289) and is considerably higher than the similar parameter for $\text{Cu}(\text{HFA})_2$ up to 95 °C.²⁸⁵

The thermolysis activation energies of (HFA)Cu(VTMS) for various deposition conditions and substrate materials have been reported.^{290,291} Various aspects of substrate surface pretreatment for maximising the deposition efficiency of copper films from this compound were studied in detail for TiN.^{292–296} The best characteristics of copper films obtained from vapour on this widespread material were achieved on substrate surfaces pretreated with WF_6 vapour.²⁹⁵

On the whole, the CVD process involving (HFA)Cu(VTMS) has been studied rather thoroughly. An inert gas (He, Ar, N_2) or its mixture with H_2 was used as a carrier gas in most cases. It was shown²⁸⁸ that the deposition rate of copper films increases with increase in the partial pressure of CCC vapour, reaching a maximum (36 nm min^{-1}) at a pressure of 5.7 mTorr. The SER of the copper films was $\sim 2.2 \mu\Omega \text{ cm}$ at thicknesses $> 500 \text{ nm}$. Similar values were obtained under the same or similar conditions in other studies.^{297,298}

As mentioned above, the presence of a reducing gas (H_2) in the thermolytic disproportionation of copper(I) derivatives is generally unnecessary. Nevertheless, it was noted²⁹⁶ that the characteristics of copper films can be improved essentially by additional annealing at 450 °C in a stream of Ar/H_2 (9:1). This increases the grain size in the films, and their SER is decreased from 2.35 to 2.12 $\mu\Omega$ cm.

Various aspects of the favourable effect of hydrogen as the carrier gas in the CVD process based on (HFA)Cu(VTMS) were considered by Lin and Chen.²⁹⁹ It was shown that the use of H_2 provides denser copper films with lower SER values and increases the deposition rate. The film deposition rate can be increased additionally by substrate surface pretreatment with nitrogen plasma.

Braeckelmann *et al.*³⁰⁰ studied the effect of the TiN substrate temperature in the range from 165 to 205 °C on the characteristics of copper films obtained from (HFA)Cu(VTMS) vapour. It was shown in particular that an increase in temperature decreased the SER of copper films from 2.15 to 1.8 $\mu\Omega$ cm and increased the deposition rate by a factor of 2.5. This is attributed to an increase in the CCC disproportionation rate. However, it was shown in a study of a similar process on W/Si substrates³⁰¹ that the SER of the copper films obtained in the substrate temperature range from 160 to 190 °C remained virtually unchanged. The temperature of 190 °C was found to be the optimum providing the maximum film growth rate (up to 500 nm min⁻¹).

It was found in a study of the deposition of copper films on a TiN substrate from (HFA)Cu(VTMS) vapour in a wider temperature range (from 160 to 330 °C)²⁹⁰ that below 200 °C the SER of the films is ~ 2.0 $\mu\Omega$ cm. An increase in the temperature sharply impairs the morphology of the films and increases their SER.

In addition to the substrate temperature, the partial pressure of the starting CCC vapour is an important factor determining the deposition rate and the resulting copper film parameters. A study of the deposition of copper films from (HFA)Cu(VTMS) vapour (TiN/Ti/Si substrate at a temperature of 170 °C) at an overall pressure of 0.5 Torr showed^{302,303} that under these conditions, an increase in the partial pressure of CCC vapour to 0.048 Torr increased the deposition rate monotonically up to 25 nm min⁻¹, and the SER of the film decreased monotonically to 2.00 $\mu\Omega$ cm. With an increase in the partial pressure, the copper films became denser and had fewer surface defects. At partial pressures of (HFA)Cu(VTMS) vapour above 0.048 Torr, the deposition rate and the SER of copper films became virtually constant.

A similar dependence was obtained by Awaya and Arita.³⁰⁴ It was shown that at temperatures below 200 °C, the rate of deposition of copper films from (HFA)Cu(VTMS) vapour is proportional to the square root of the CCC vapour partial pressure.

It was noted above that if copper(II) derivatives [for example, $Cu(HFA)_2$] are used in CVD process, the addition of water vapour to the carrier gas increased the growth rate of copper films while their SER remained unchanged, and in some cases (not always) also increased the process selectivity.^{171, 190, 205, 225, 226} Similar effects were reported for (HFA)Cu(VTMS).

Deposition of copper films from (HFA)Cu(VTMS) vapour on SiO_2 and Pt/ SiO_2 substrates at 150–250 °C gave copper films 800 nm thick with low SER in the absence of water vapour.³⁰⁵ The addition of water vapour did not accelerate the process in the case of the SiO_2 substrate. In the case of Pt/ SiO_2 substrates, a small increase in the deposition rate was observed, but much smaller than that with the use of copper(II) derivatives under the same conditions. The copper films obtained in the presence of water vapour had rough surface structure and high SER (> 20 $\mu\Omega$ cm).

More successful experiments on the deposition of copper films from (HFA)Cu(VTMS) vapour in the presence of water were carried out by Gelatos *et al.*²⁸⁹ It was shown that at rather low partial pressure of water vapour (< 0.4 Torr), as in the case of $Cu(HFA)_2$ vapour, a sharp increase in the copper film deposition rate was in fact observed. This effect was particularly well

pronounced at $P_{H_2O} < 0.2$ Torr. The specific electric resistance of the films obtained was 2.3 ± 0.1 $\mu\Omega$ cm. Subsequent annealing decreased the SER to 1.9 ± 0.1 $\mu\Omega$ cm, and the copper films had a considerably higher density than similar films obtained by CVD from (HFA)Cu(VTMS) vapour in the absence of water vapour. It was noted that such a low SER value was reached in the presence of water vapour at a film thickness of 50 nm, while under 'anhydrous' deposition conditions, this required a film thickness of at least 300 nm. An increase in the water vapour partial pressure to 0.75 Torr impairs strongly the characteristics of the films.^{289, 306}

The possibility of optimisation of a CVD process involving (HFA)Cu(VTMS) and water vapour was studied.^{307, 308} An important fact was noted: the preparation of copper films with low SER, good adhesion and high deposition rate requires that the injection of water vapour be carried out quickly in the beginning of the process. Copper films with SER of 1.9 $\mu\Omega$ cm (after annealing), and copper strips 0.4 μ m wide and 1 μ m thick with good characteristics were obtained under these conditions.

The addition of small amounts of H(HFA) vapour in the CVD of copper films from (HFA)Cu(VTMS) vapour can improve substantially the copper film morphology.²²⁹ The presence of the β -diketone favours an accelerated and uniform growth of nucleation centres on the entire film surface, thus protecting it from cracks and roughening. However, the process loses its selectivity completely in this case.

One more variant for the deposition of copper films by the CVD method from (HFA)Cu(VTMS) vapour involves the addition of an excess of liquid VTMS to the starting CCC (40%–60% relative to the volume of the starting CCC) before the evaporation.^{309, 310} This enabled deposition rates of 40–60 nm min⁻¹ to be achieved. It was noted that replacement of the carrier gas by hydrogen did not change essentially the film growth rate.³¹⁰ The mean specific electric resistance of the copper films obtained, with thicknesses from 200 to 1800 nm, was 1.86 $\mu\Omega$ cm; additional annealing of copper films at 600 °C in a high vacuum (10^{-7} Torr) decreased it to 1.76–1.77 $\mu\Omega$ cm.³⁰⁹

Simultaneous use of H(HFA) and VTMS vapour is possible.³¹¹ The H(HFA) vapour increases the copper film deposition rate, and the VTMS vapour accelerates the CCC evaporation.

The rate of copper film deposition increases considerably if a CVD process with the use of (HFA)Cu(VTMS) vapour is carried out with simultaneous application of a shifting voltage of -30 V to the substrate.^{312, 313} This effect is explained by reorientation of the dipole molecules of the starting CCC in the electric field stimulating their adhesion to the substrate.

The decomposition of (HFA)Cu(VTMS) vapour can be additionally promoted [as in the case of copper(II) derivatives as the starting CCC] by radiation. This variant can primarily be used in the preparation of microstructures from this CCC by lithographic methods.

In the study of Ochiani *et al.*,³¹⁴ deposition of copper films from (HFA)Cu(VTMS) vapour was carried out simultaneously with electron lithography. The copper film samples obtained had rather low SER.

The formation of copper films from (HFA)Cu(VTMS) exposed to an electron beam has been studied.³¹⁵ It was found that the energy threshold where decomposition starts is 4 ± 0.5 eV and that decomposition occurs by dissociative electron addition. However, the films obtained by this method are considerably contaminated with carbon, apparently due to decomposition of HFA fragments under these rather drastic conditions.

A study of the preparation of thin copper strips 3 μ m wide by thermal decomposition of (HFA)Cu(VTMS) vapour under argon laser radiation²⁸⁶ showed that in this case, as with $Cu(HFA)_2$ vapour,²²⁵ the addition of water vapour to the vapour of the starting CCC affects favourably the deposition rate and the characteristics of the resulting copper microstructures. The SER values of the best copper strips obtained this way were close to the SER of metallic copper. Similar results were obtained under

analogous conditions;³¹⁶ it was also noted that the morphology of the surface copper strips depends essentially on the laser radiation power. Moilanen *et al.*³¹⁷ achieved rather high film deposition rates of up to 400 nm s⁻¹, but the SER of the strips increased somewhat (up to 3.7 $\mu\Omega$ cm).

Thin copper strips (channels) up to 16 μ m deep were obtained by CVD using decomposition of (HFA)Cu(VTMS) vapour.³¹⁸ The specific electric resistance of the copper channels was 1.95 $\mu\Omega$ cm; annealing gave a value of 1.86 $\mu\Omega$ cm.

Successful optimisation of preparation of copper strips with SER of ≤ 2.0 $\mu\Omega$ cm using CVD from (HFA)Cu(VTMS) vapour was reported.³¹⁹

Popovici *et al.*³²⁰ observed the terrace growth of copper films during the decomposition of (HFA)Cu(VTMS) vapour on Teflon substrates under excimer laser radiation ($\lambda = 248$ nm). It was assumed that growth of this type occurs owing to the interference between the Teflon support and the precipitated copper layers.

In turn, the successful use of (HFA)Cu(VTMS) vapour as a convenient starting CCC for the CVD process has served as an incentive for the search for volatile Cu(HFA) complexes with similar compositions and physicochemical characteristics. As a result, new starting CCC were reported, where allyltrimethylsilane (ATMS) (for example, compound 3)^{321–323} and vinylalkoxysilanes, such as vinyltrimethoxysilane (VTMOS),²⁸⁷ vinyl(dimethoxy)methylsilane (VDMOMS)³²⁴ and vinyltriethoxysilane (VTEOS),^{324,325} served as Lewis bases. These CCC are more stable than (HFA)Cu(VTMS). They are liquid at room temperature, but data on their physicochemical properties were not reported in these studies.

If (HFA)Cu(VTMS) vapour is used, the optimum temperature range for the TiN substrate, where copper films with the best characteristics are formed, is 175–200 °C.²⁸⁷ The lowest SER of the films obtained under these conditions is 2.5 $\mu\Omega$ cm.

Somewhat better results (deposition rate up to 100 nm min⁻¹ and lower SER of the films) were obtained in CVD processes based on (HFA)Cu(VDMOMS) and (HFA)Cu(VTEOS).^{324,325} It was noted that the presence of water vapour during the deposition of films is necessary for the former compound.³²⁴

Very interesting results were obtained in CVD processes using (HFA)Cu(ATMS). It was found that, other conditions being equal, the incorporation of ATMS in the complex decreases considerably the temperatures for copper film deposition in comparison with those for similar compounds without ATMS. (HFA)Cu(ATMS) evaporates well at 40–45 °C and forms copper films with low SER at substrate temperatures of 60–170 °C.³²¹ It was noted that the film parameters remain almost unchanged in this rather wide temperature range. A certain role in these features of CVD processes is apparently associated with the fact that (HFA)Cu(ATMS) is even less stable thermally than (HFA)Cu(VTMS) and (HFA)Cu(VTMS), and hence it is more reactive.^{323,326} At a temperature as low as 60 °C, the IR spectra of (HFA)Cu(ATMS) vapour contain bands corresponding to Cu(HFA)₂. It is interesting that the morphology of the copper film surfaces obtained also depends on the reactivity of the starting compounds: for example, the grain size in the copper films obtained from (HFA)Cu(ATMS) vapour is much larger than that in the copper films obtained from (HFA)Cu(VTMS) vapour.³²³

b. Complexes of copper(I) β -diketonates with isocyanides

Of copper(I) β -diketonate complexes stabilised by interactions of the copper(I) ion with the double bond, those with *tert*-butyl isocyanide (Bu^tNC) are considered as promising starting CCC for the preparation of copper films by CVD technology. It should be noted that the corresponding complexes of copper(I) derivatives with nitriles RCN decompose even at room temperature.³²⁷ It is known that the nitrile group is an efficient π -acceptor [the resonance constant is $\sigma_R^0 = +0.08$ (see Ref. 277)] and hence it cannot form stable complexes with the copper(I) ion. On the other hand, the corresponding effect of the isocyanide group is close to zero,²⁷⁷ and the additional π -donor *tert*-butyl group makes the complex sufficiently stable.

Kruck and Terfloth³²⁸ reported data on the synthesis [by method (2)] and the physicochemical properties of volatile (HFA)Cu · Bu^tNC and (HFA)Cu · (Bu^tNC)₂ complexes (in particular, the sublimation temperatures at 0.1 Torr are 55 and 95 °C, respectively). CVD processes with the use of vapour of these compounds gave copper films with good characteristics.³²⁹

c. Complexes of copper(I) β -diketonates with dienes

Dienes form rather stable 1 : 1 complexes with the copper(I) ion. Copper(I) β -diketonates are usually stabilised by 1,5-cyclooctadiene (1,5-COD).

Like complexes with VTMS, complexes of 1,5-COD with Cu(acac) and Cu(TFA) have low stability,²⁸² on the contrary, (HFA)Cu(1,5-COD) is a very stable compound which sublimes without decomposition at 65–70 °C and remains unchanged in air for a period of one year. The vapour pressure of this compound is ~ 56 mTorr at 62 °C.³³⁰

The spatial structure of the (HFA)Cu(1,5-COD) molecule (Fig. 3) was determined²⁸² and analysed in detail.²⁸⁰ It was noted in the latter study that the actual coordination of the Cu(I) centre is more complex than Fig. 3 shows and fits a 3 + 1 scheme. In other words, the 1,5-COD fragment is coordinated asymmetrically. Decomposition of vapour of this CCC at 200 °C resulted in copper film formation and evolution of volatile decomposition products, *viz.*, Cu(HFA)₂ and 1,5-COD.²⁸²

The preparation of copper films by CVD from (HFA)Cu(1,5-COD) vapour has been described in a number of papers.^{330–335} For example, it was noted³³⁰ that a temperature of 65 °C in the evaporator and a temperature of 70 °C of the reactor cell walls are sufficient for the process. Admixtures of carbon, oxygen and fluorine are virtually absent in the films (< 1%).

The specific electric resistance of films obtained from (HFA)Cu(1,5-COD) vapour depends primarily on the substrate temperature. At the optimum temperature (190–210 °C), the SER of the films was 1.97 ± 0.10 $\mu\Omega$ cm. Higher deposition rates (> 15 nm min⁻¹) and larger film thicknesses (> 250 nm) worsen this parameter.

Figure 3. (HFA)Cu(1,5-COD) molecule.

(HFA)Cu(1,5-COD) is a promising starting compound in an aerosol modification of CVD technology.³³⁵ The films are deposited from an aerosol of a toluene solution of the starting compound. The aerosol is fed to the reactor cell in a stream of an inert gas (nitrogen); intermediate preheating of the vapour to 40–100 °C is provided. Even at a substrate temperature of 120 °C, crystalline copper films were obtained; their SER were within 1.7–3.5 $\mu\Omega$ cm under optimum process conditions (140 °C, deposition rate 80 nm min⁻¹).

Copper films with good characteristics are obtained using (HFA)Cu(1,5-COD) as the starting CCC in the presence of CO.³³⁶ Carbon monoxide displaces the 1,5-COD ligand from the complex at -70 °C to give an intermediate unstable carbonyl compound, (HFA)Cu(CO), which in this case serves as the starting CCC in the CVD process. Isolation of this carbonyl complex in a pure state failed.

1,5-COD is not the only diene that can give volatile complexes with copper(I) β -diketonates applicable in CVD technology. In particular, a hydrocarbon which is rare but quite accessible synthetically, *viz.*, 7-*tert*-butoxynorbornadiene 7-Bu'O-NBD, was suggested for this purpose³³⁷ (for its synthesis, see Ref. 338). Using a procedure which is a modification of the method (2), Chi *et al.*³³⁷ obtained a series of complexes of the type (β -diket)Cu(7-Bu'O-NBD), where β -diket = acac, TFA, HFA, FOD, with sublimation temperatures from 75 to 90 °C at 0.1 Torr. The geometry of the molecules was determined for all of these complexes. However, only one of these compounds, namely, Cu(HFA)(7-Bu'O-NBD), was found to be suitable for the preparation of copper films. The specific electric resistance of the films was satisfactory at sufficiently high substrate temperatures; the SER of films increased abruptly (> 1000 $\mu\Omega$ cm) and their surface morphology is deteriorated upon decrease in the temperature of the substrate to 170 °C.³³⁷

d. Complexes of copper(I) β -diketonates with alkynes

It is known that the triple bond, particularly that in alkyl-substituted acetylenes, has a stronger π -donor effect than the double bond.²⁷⁷ Hence, alkynes should form sufficiently stable complexes with the copper(I) atom in β -diketonate derivatives.

The first synthesis of volatile η^2 -complexes of Cu(HFA) with alkynes, *viz.*, but-2-yne, bis(trimethylsilyl)acetylene and diphenylacetylene, was carried out by the reaction of (HFA)Na with CuCl in the presence of excess alkyne.²⁷⁸ Volatile Cu(HFA) complexes with pent-2-yne³³⁹ and hex-3-yne³⁴⁰ were also obtained. A little later, a simple one-stage procedure was proposed for the synthesis of Cu(HFA) complexes with but-2-yne³⁴¹ and bis(trimethylsilyl)acetylene.³⁴² A series of compounds of this class containing silicon atoms at the triple bond were patented as the starting CCC for CVD technology.³⁴³

According to X-ray diffraction data, the copper(I) atom in the compounds in question has a flat trigonal configuration with coplanar diketonate and alkyne ligands (Fig. 4).²⁷⁸ The nature of bonding and the electron interaction of the fragments in this type of complex was studied in more detail using ¹H and ¹³C NMR spectroscopy.^{281, 342}

The possibility of the existence of equilibrium between mononuclear and binuclear forms of these complexes was also considered,³⁴² as some of them undergo chemical transformations in the bubbler of the CVD reactor at 45–65 °C to give low-volatility products.^{340, 341} In this case, the corresponding binuclear complexes are obviously formed by μ - η^2 bonding of the triple bond with the copper atom [the ratio alkyne: Cu(HFA) = 1 : 2]. Such complexes are also known in the chemistry of other transition metals.^{344, 345} However, in this case the complexes are extremely unstable³⁴² and can only be formed as labile intermediates. On the whole, the nature of this reaction has been studied insufficiently.

The Cu(HFA) complex with but-2-yne is decomposed on the substrate at 150–210 °C under the conditions of the CVD process to give dense mirror-like copper films with low SER.³³⁹ The rate of deposition of such films can be increased by addition of water

Figure 4. (HFA)Cu(CH₃C≡CCH₃) molecule.

vapour.³⁰⁶ The possibility of selective deposition of copper films starting from this compound was considered.³⁴⁶

An unusual modification of this type of the starting CCC was suggested by Schmidt and Behrens.³⁴⁷ They synthesised a volatile 2 : 1 Cu(HFA) complex with bis(*tert*-butylethynyl) sulfide. It was shown that the sulfur atom did not participate in coordination with the copper(I) ion. Similar Cu(I) complexes with other β -diketonates as the ligands were found to be unstable even at room temperature.

e. Complexes of copper(I) β -diketonates with phosphines

Yet another possibility to stabilise Cu(HFA) is the preparation of its complexes with derivatives of VA Group elements. Of these derivatives, trialkylphosphines are used most widely as additional ligands. However, the volatility of biscomplexes of the type (β -diket)Cu(PAlk₃)₂ synthesised first³⁴⁸ was insufficient for their use in CVD technology.

The syntheses of volatile monomeric 1 : 1 complexes of copper(I) β -diketonates with organic phosphines for CVD were first reported by Shin *et al.*^{349–351} Initially, the reaction according to pathway (3) became the main method for their synthesis;³⁵¹ the applicability of pathway (2) was shown later.^{279, 352} The compounds obtained were low-melting crystals capable of sublimation or viscous liquids.

As in the case of similar complexes with 1,5-COD,²⁸⁰ the HFA derivative (Fig. 5) was the most stable of the series of compounds with the general formula (β -diket)Cu(PMe₃), where β -diket = acac, TFA, HFA.

The same is true for complexes with other trialkylphosphines.³⁵² To interpret this phenomenon and to study the nature of the interaction of the copper(I) ion with the phosphine molecule, photoelectron spectroscopic data and quantum-chemical calculations were used.³⁵³

Figure 5. (HFA)Cu(PMe₃) molecule.

The vapour pressure of $\text{Cu}(\text{HFA})(\text{PMe}_3)$ was measured at various temperatures and the $\log P - 1/T$ relationship was plotted.²⁷⁹ The corresponding vapour pressures of $\text{Cu}(\text{HFA})(\text{PMe}_3)$ and $\text{Cu}(\text{HFA})_2$ were found to be similar.¹⁷⁹

The first experiments on CVD of thin films with the use of phosphine complexes of copper(II) β -diketonates as CCC gave promising results. For example, a rather high deposition rate (up to 100 nm min^{-1}) was achieved at 150°C on a Pt/SiO_2 substrate resulting in dense mirror-like copper films with good adhesion.³⁵⁴ It was reported that the process can occur selectively.³⁵⁰ A more detailed study showed that phosphine complexes of $\text{Cu}(\text{HFA})$ have higher selectivity than similar complexes with 1,5-COD or alkynes under comparable conditions.

Thin copper films were also deposited from $\text{Cu}(\text{HFA})(\text{PMe}_3)$ vapour in the presence of water and organic solvents (alcohols, toluene, tetrahydrofuran).²⁰⁶ It was shown that this compound can react with water at room temperature with partial oxidation of copper(I) to copper(II). The use of alcohols results in reversible coordination of the alcohol molecules with copper(I) ions with formation of a more volatile alkoxide and, hence, leads to an increase in the deposition rate of copper films.

2. Volatile compounds of copper(I) devoid of β -diketonate ligands

A series of volatile derivatives of monovalent copper includes CCC which are not inferior to β -diketonates in terms of physicochemical properties required in CVD technology. Such CCC can be considered as alternatives to the classical β -diketonate copper(I) complexes. An obvious direction of the molecular design of such compounds is some structural similarity to copper β -diketonates. In view of this, we included copper β -iminoketonates and β -oxocarboxylates in our consideration.

Yet another direction in the creation of new CCC is the search for fragments capable of replacing completely the β -diketonate group while preserving the properties needed for CVD technology. The promising compounds of this type include alkoxides, amides, cyclopentadiene derivatives and heterocyclic compounds (e.g., pyrazole derivatives).

a. Copper(I) β -iminoketonates and β -oxoacid derivatives

Fluorinated β -iminoketonates required for the synthesis of stable nitrogen-containing analogues of copper(I) β -diketonates are obtained by a two-step procedure from the corresponding β -diketonates.³⁵⁵ This fact itself implies the low competitiveness of copper(I) β -iminoketonates synthesised from sodium β -iminoketonates by reaction (2) in comparison with similar copper(I) β -diketonates.

At room temperature, complexes of this series (with trialkylphosphines as additional ligands) are volatile liquids or solid compounds. A study of whether copper films can be obtained by CVD from vapours of copper(I) β -iminoketonates did not reveal any considerable advantages of these compounds over the more accessible oxygen analogues,^{355, 356} i.e., copper(I) β -diketonates. Only one study was published³⁵⁷ reporting good results in the preparation of copper films by CVD with the use of a complex of copper(I) 3-oxobutanoate with trimethylphosphine which is rather stable and resistant against oxidation in air.

b. Copper(I) alkoxides

The main drawback of copper(I) alkoxides as potential CCC for CVD technology is their rather easy transition into non-volatile polymers. Nevertheless, successful attempts at the preparation of copper films from tetrameric copper(I) *tert*-butoxide $[\text{Cu}(\text{OBu}^t)]_4$ were reported.^{358, 359} The pyrolysis temperature of this compound is rather high ($\sim 400^\circ\text{C}$). As indicated by Lemmen *et al.*,³⁶⁰ this compound is rather sensitive to oxygen and atmospheric moisture (the films obtained contained from 2% to 5% of oxygen), therefore it was not widely used in CVD technology.

Hampden-Smith *et al.*³⁶¹ synthesised a volatile monomeric complex of copper(I) *tert*-butoxide with trimethylphosphine

$(\text{Bu}^t\text{O})\text{Cu}(\text{PMe}_3)$. The CVD method made it possible to obtain pure copper films containing no oxygen and phosphorus admixtures from this compound.³⁶¹

c. Amide derivatives of copper(I)

In the series of volatile amide derivatives of copper(I), there is one unusual compound used as a CCC, *viz.*, the tetrameric cluster $\{\text{Cu}[\text{N}(\text{SiMe}_3)_2]\}_4$.³⁶² This compound sublimes at rather high temperature ($\sim 180^\circ\text{C}$). Nevertheless, it produces copper films with satisfactory characteristics. It is possible that further research on copper(I) amide derivatives will allow one to obtain compounds of this class that would be more volatile and, accordingly, more promising for CVD technology.

d. Cyclopentadienyl derivatives of copper(I)

Cyclopentadienyl derivatives of copper(I) compete satisfactorily with copper β -diketonates as starting compounds in CVD processes. Cyclopentadienyl derivatives of copper(I) are usually stabilised by trialkylphosphines and isocyanides.

Trialkylphosphine complexes of cyclopentadienylcopper(I) are usually synthesised using a procedure similar to the pathway (2) from cyclopentadienylsodium and halophosphine complexes of copper(I).^{363, 364} Their typical sublimation temperatures are $60\text{--}70^\circ\text{C}$, and the thermal decomposition temperatures are $120\text{--}125^\circ\text{C}$.³⁶⁵ The calculated vapour pressure of $(\text{Cp})\text{Cu}(\text{PMe}_3)$ at 80 and 100°C are 14 and 30 Torr, respectively.⁷

For similar platinum compounds, it was found that incorporation of a methyl group in the cyclopentadiene ring increases considerably the volatility of the compound.³⁶⁴ In view of this, copper(I) methylcyclopentadienyl complexes with trialkylphosphines were synthesised,³⁶³ but their sublimation temperatures and vapour pressures were almost the same as those of the non-substituted analogues. A study of the physicochemical properties showed that the methyl-substituted derivatives are less stable and undergo decomposition at temperatures $15\text{--}20^\circ\text{C}$ lower than the non-substituted compounds. This is an advantage of methyl-substituted cyclopentadienyl derivatives of copper(I) for the CVD process. Recently, a number of methyl- and ethyl-substituted cyclopentadienyl complexes of copper(I) with triisopropylphosphine were patented as promising volatile CCC for CVD technology.³⁶⁶

Originally, such complexes were used in CVD for the synthesis of mixed copper-containing semiconductor systems of the CuGaS_2 type.³⁶⁵ The first studies on the CVD of copper films with the use of these complexes gave good results. For example, it was shown³⁶⁷ that decomposition of $(\text{Cp})\text{Cu}(\text{PAlk}_3)$ vapour (Alk = Me, Et, Bu) on substrates made of different materials *in vacuo* gave high-purity copper films with a SER that differed from the SER of bulk metallic copper by $\sim 10\%$. Based on $(\text{Cp})\text{Cu}(\text{PMe}_3)$, copper films with SER of $1.8\text{--}2.2 \mu\Omega \text{ cm}$ were obtained,³⁶¹ but this value was achieved only after annealing. The morphology of the surface of copper films formed from $(\text{Cp})\text{Cu}(\text{PET}_3)$ vapour on SiO_2 was considered in detail.³⁶⁸

The $(\text{Cp})\text{Cu}(\text{PET}_3)$ complex was used as the starting CCC in laser-activated preparation of copper strips and in thermal laser lithography.³⁶⁹ Irradiation of a thin layer of this compound with the light of an argon laser at $\lambda = 514 \text{ nm}$ gave a copper strip containing less than 10% carbon and with SER of $\sim 6.8 \mu\Omega \text{ cm}$. The use of radiation excimer lasers with shorter wavelengths resulted in strips of copper-carbon composites.

The $(\text{Cp})\text{Cu}(\text{PET}_3)$ complex was used for the CVD synthesis of thin copper-aluminium films *in situ*.⁷ In this method, the rather low concentration of copper ($\sim 1.4\%$) decreases greatly the SER of the basic aluminium film. The valuable property of $(\text{Cp})\text{Cu}(\text{PET}_3)$ is that, unlike the majority of the starting volatile CCC, it is chemically inert with respect to the second aluminium-containing starting compound used simultaneously, *viz.*, dimethylalane $(\text{CH}_3)_2\text{AlH}$.

As in the case of $\text{Cu}(\text{HFA})$, *tert*-butyl isocyanide can be used for the stabilisation of copper(I) cyclopentadienyl complexes. The

(Cp)Cu(Bu⁴NC) compound was obtained for the first time using method (1) and was used as a catalyst of some organic reactions.³⁷⁰ Later, this substance was synthesised using method (2) and was suggested as a starting CCC for the preparation of copper films by CVD.³²⁸ Studies of the behaviour of this compound in CVD showed^{329,371} that high-quality films free from carbon admixtures can in fact be obtained on its basis. The optimum substrate temperature range is 200–350 °C,³⁷¹ although noticeable decomposition of (Cp)Cu(Bu⁴NC) starts at 135 °C.³²⁸

e. Complexes of copper(I) with pyrazole derivatives

Many volatile compounds are known in which the copper(I) ion is bound to heterocyclic fragments. However, only one study is devoted to the synthesis of copper(I) pyrazolyl borate complexes with triethylphosphine.³⁷² At a substrate temperature of 150 °C, these compounds give polycrystalline copper films with good characteristics and high selectivity. Apparently, studies in this direction will continue.

3. Mechanisms of decomposition of copper(I) derivatives on the substrate

It is generally believed that copper films are formed from mono-valent copper–HFA complexes due to their disproportionation followed by removal of the volatile product. The formation of Cu(HFA)₂ from (HFA)Cu(VTMS) in the gas phase was proved by spectral methods.^{189,373}

The initial step of (HFA)Cu(VTMS) decomposition should apparently involve cleavage of the weakest bond in the molecule, *i.e.*, the bond between the copper(I) ion and the VTMS molecule. The question is, where does this cleavage occur? There are two answers to this question: first, on the substrate surface; second, in the vapour phase. Evidence in favour of both variants can be found in the literature.

The majority of the authors favour the first variant.^{201,290,374} For example, a comparative study of the Cu(HFA)₂ and (HFA)Cu(VTMS) decomposition by Fourier IR spectroscopy revealed bands unambiguously assigned to the VTMS ligand in the spectra of (HFA)Cu(VTMS) adsorbed on a Si(100) substrate at –148 °C.²⁰¹ However, these bands disappeared at 27 °C, which made it possible to conclude²⁰¹ that at this temperature VTMS was eliminated extremely quickly from the adsorbed compound. The disproportionation of the resulting Cu(HFA) molecules was proved and considered in detail.^{310,374–376}

Thus, taking this into account, one can make the conclusion that the most probable mechanism of decomposition of (HFA)Cu(VTMS) vapour involves four steps:

(1) adsorption of the entire molecule on the substrate

(2) elimination of VTMS followed by fast desorption

(3) bimolecular disproportionation of the intermediate formed

(4) desorption of the volatile product of Cu(HFA)₂ disproportionation

However, studies of the kinetics of (HFA)Cu(VTMS) decomposition³⁷⁷ gave evidence in favour of the second variant, *i.e.*, molecular decomposition in the vapour phase. Hence, it is the intermediate Cu(HFA) that should be considered the actual starting compound in the copper film formation. The second mechanism, alternative to the one mentioned above, is as follows:

(1) vapour-phase thermolysis

(2) adsorption of the intermediate

(3) bimolecular disproportionation of the intermediate formed

(4) desorption of the volatile product of Cu(HFA)₂ disproportionation

The third and fourth steps are similar in both cases.

It is possible that bimolecular disproportionation (third step) is not the only pathway for the transformation of the Cu(HFA) intermediate. A direct relationship between the activation energy of the copper nucleation from (HFA)Cu(VTMS) on the surface and the electric conductivity of the substrate was established; this is believed³⁷⁸ to suggest a certain role of one-electron transfer from the surface to the adsorbed Cu(HFA), which was not taken into account in the mechanism considered above.

One can imagine a situation (for example, at a sufficiently high temperature of the vapour flow) where a portion of molecules of the starting CCC are decomposed in the vapour phase, while the other portion do so on the substrate surface. The relative fractions of each process depend on the particular conditions of the process.

The effect of the substrate temperature on the mechanism of low-vacuum deposition of the copper film from the (HFA)Cu(VTMS) vapour was studied in detail.²⁹⁸ It was shown that in the temperature range of 140–220 °C, deposition obeys the Arrhenius law; at temperatures higher than 220 °C, the process switches to the saturation mode (the ‘transport-limited’ situation). In this mode, the SER of the film and the content of contaminating carbon increase.³⁷⁹ In addition, the film formed becomes less uniform due to a decrease in mobility of copper atoms under the effect of the atoms of the quickly growing surface layers.³⁸⁰

The mechanism of the effect of partial pressure of (HFA)Cu(VTMS) vapour on the characteristics of films considered by Lee *et al.*³⁰² fits completely the deposition scheme described above. At low partial pressure of CCC vapour, the sites for the adsorption of the Cu(HFA) intermediates are preserved on the substrate surface. As the pressure is increased to a certain threshold, the surface becomes ‘adsorption-saturated’ and the copper film deposition rate no longer depends on the partial pressure.

As in a case of Cu(HFA)₂, a special situation arises if CVD is carried out with the use of (HFA)Cu(VTMS) under ultrahigh vacuum (10^{–9}–10^{–10} Torr).¹⁹⁹ Under these conditions, the first stage involves chemisorption of the entire CCC molecule on the substrate (TiN). At 27 °C, the CCC is completely transformed to the adsorbed Cu(HFA) intermediate, which does not disproportionate upon heating but is decomposed to CO, CO₂, CF₄ and metallic copper. About 90% of the copper contained in the precursor remains on the substrate [~30% in the case of Cu(HFA)₂ under the same conditions]. At 280 °C, the diffusion of copper into the substrate starts.

It is believed³⁰⁶ that the favourable effect of water vapour on the deposition rate of copper films upon decomposition of (HFA)Cu(VTMS) vapour is associated with facilitation of the VTMS ligand elimination. The observed impairment of the characteristics of copper films at high partial pressure of water vapour^{289,306} occurs because of the side reaction of water with the adsorbed Cu(HFA) intermediate resulting in a Cu₂O admixture in the films. Experiments with water labelled with the ¹⁸O isotope showed that it is the oxygen atoms from water molecules that are incorporated in the film.³⁰⁶

A mechanism of (HFA)Cu(VTMS) decomposition under ion beam impact to give copper films has been suggested.³⁸¹

The decomposition mechanism of other copper(I) derivatives, such as Cu(HFA)(1,5-COD), and Cu(HFA) complexes with but-

2-yne on a silicon substrate during the CVD process ($\sim 210^\circ\text{C}$) is totally similar to the mechanism considered above^{375, 382} (including that in the presence of water vapour³⁰⁶). However, there are no data on the elimination of additional ligands (Lewis bases) from these compounds directly in the vapour phase.

The mechanisms of transformations in thin copper films during their subsequent annealing^{289, 309} have not been elucidated so far. The available data on the effect of annealing on the characteristics of films are rather contradictory. For example, it was reported that annealing of films decreased their SER considerably,^{289, 383} decreased it slightly³⁰⁹ or did not affect it.³⁸⁴ This could result from processes affecting the SER in opposite ways: annealing increases the film crystallinity and, on the other hand,

favours their oxidation and enhances the diffusion of copper atoms into the substrate material.³⁸⁵

The mechanism of thermal decomposition of the vapour of copper(I) *tert*-butoxide tetramer on the substrate was studied in detail.³⁵⁹ It was shown that a homolytic process results in intermediate *tert*-butyl radicals and copper(I) oxide; the effect of the latter can explain the presence of oxygen in the films obtained. On the other hand, thermal decomposition of a vapourised phosphine complex of copper(I) *tert*-butoxide did not result in either the formation of Cu_2O or an admixture of oxygen in the films. Data on the deposition conditions of copper films from copper(I) derivatives and the corresponding SER values are listed in Table 5.

Table 5. CVD conditions and properties of copper films obtained from copper(I) compounds.

VI. The problem of selective deposition of copper films

The selectivity of deposition of copper films by the CVD method from the vapour of copper(II) and copper(I) derivatives deserves a separate discussion. Let us note the short reviews^{391,392} on the subject.

The selectivity of deposition implies preferential growth of the copper film on the surface of a certain material relative to the surface of some other material. This problem is important because at the present time there are no versatile methods for etching copper films covering the entire surface of a sample, which would allow one to obtain predetermined shapes on the surface required in the production of microelectronic devices.

For example, a method for the dry etching of copper by consecutive treatment of its surface with H_2O_2 (which oxidises copper to Cu_2O) and $\text{H}(\text{HFA})$ (which transforms Cu_2O into a volatile copper β -diketonate) was suggested.³⁸⁸ A similar idea was implemented by Steger and Masel³⁹³ who used $\text{H}(\text{HFA})$ vapour in a stream of O_2 . However, though high etching rates were achieved [$\sim 1000 \text{ nm min}^{-1}$ at 190°C (see Ref. 388) and $\sim 1500 \text{ nm min}^{-1}$ at 350°C (see Ref. 393)], these techniques did not become popular. This is also true for the other known etching methods requiring rather drastic conditions, such as a method with the use of SiCl_4 in a stream of N_2 ($T > 250^\circ\text{C}$)³⁹⁴ and treatment with a mixture of chlorine and PEt_3 vapour in the presence of $\text{H}(\text{HFA})$ at $420\text{--}540^\circ\text{C}$.³⁹⁵

1. Deposition of copper films in 'metal–dielectric' systems

As a rule, SiO_2 is used as a dielectric for the deposition of copper films in 'metal–dielectric' systems.

The growth of a copper film on a dielectric substrate surface primarily depends on the ease of adsorption of molecules of volatile CCC and compounds accompanying the process on the surface. The growth step following adsorption is nucleation, *i.e.*, formation of primary grains of the growing film at the sites where adsorption is the most efficient and where decomposition of molecules of the CCC mostly starts. It was assumed that it is this step that determines the overall process selectivity.³⁸⁷

Hence, the simplest solution for the selectivity problem can involve suppressing the nucleation³⁹⁶ or providing conditions where adsorption of molecules of the CCC on the dielectric surface is suppressed, while that on the metal surface is not suppressed. However, this solution also involves certain difficulties. The main of these results from the fact that, depending on the deposition conditions (temperature, pressure, carrier gas), the adsorption of molecules of CCC can be either physical or chemical.²⁰³ Therefore, a versatile method for the treatment of SiO_2 substrate surfaces in order to minimise adsorption and achieve the maximum selectivity obviously cannot exist: everything depends on the particular CVD technology and the CCC used.

The nature of selectivity in the deposition of copper films from $\text{Cu}(\text{HFA})_2$ vapour on Ag/SiO_2 substrates was considered in detail by Cohen *et al.*³⁷⁶ It was assumed that selectivity is provided due to the existence of several paths of the CVD process: on the surface of silver, fast reduction of copper(II) to copper(I) occurs with desorption of the HFA ligand due to electron transfer from the metal surface, whereas on the surface of the SiO_2 dielectric, the molecules of the starting CCC are adsorbed in the original state.

The consecutive growth of film layers relative to the dielectric substrate can be regarded as a particular case of the above scheme. Deposition of copper films by decomposition of $\text{Cu}(\text{HFA})_2$ vapour in the presence of water vapour decreases greatly the selectivity of film growth in comparison with the 'water-free' technique.^{171,205} On the other hand, the presence of water vapour increases the growth rate. In order to keep this advantage and still preserve the process selectivity, the films are prepared at rather high substrate temperatures in the absence of H_2 (He, Ar as carrier gases).^{171,190,226} If high selectivity of the process is required,

another variant is used in which such a substrate or barrier layer material is selected where water molecules are adsorbed poorly.²⁰⁵

Analysis of the dependence of the properties of the growing copper film, which is formed upon decomposition of $(\text{HFA})\text{Cu}(\text{VTMS})$ vapour, on the thickness of the primary copper layers on SiO_2 showed³⁹⁷ that the highest deposition rate of copper is observed at a copper layer thickness of 4 nm, and the lowest SER of the film is observed at a thickness of 15 nm. The selectivity of the CVD process with the use of this CCC in the Cu/SiO_2 system at temperatures below 200°C depends on the carrier gas and on the CCC vapour partial pressure.³⁰⁴

Awaya *et al.*²²⁹ conducted a comparative study of the effect of the β -diketone excess on the rate and selectivity of CVD of copper strips upon decomposition of $\text{Cu}(\text{HFA})_2$ and $(\text{HFA})\text{Cu}(\text{VTMS})$ vapour. The copper strips were deposited in the presence of water vapour on copper substrates with SiO_2 templates previously sputter-deposited on the surface, at a substrate temperature of 390°C . It was found that the optimum (fast and selective) process for the preparation of copper strips involves two stages. In the first stage, the substrate is treated with $\text{H}(\text{HFA})$ vapour in the presence of H_2 ; after that, $\text{Cu}(\text{HFA})_2$ is fed into the reactor and reduced on the substrate in the presence of H_2 . However, the presence of a free β -diketone in the stage of $\text{Cu}(\text{HFA})_2$ reduction results in the loss of selectivity.

In the case where $(\text{HFA})\text{Cu}(\text{VTMS})$ vapour is used in CVD processes, copper with a sputter-deposited SiO_2 template was also used as the substrate; the substrate temperature was $160\text{--}180^\circ\text{C}$. It was shown that, unlike in the experiment with the $\text{Cu}(\text{HFA})_2$ vapour described above, the presence of $\text{H}(\text{HFA})$ in the stage of strip formation increases the rate of filling the template channel; however, this completely suppresses the process selectivity, as distinct strip edges could not be obtained. It is believed²²⁹ that such a different behaviour of copper(I) and copper(II) compounds in this case is due to the difference between their decomposition mechanisms. Optimisation of the CVD process for film deposition with the use of vapour of copper(I) derivatives and similar templates was considered by Norman *et al.*³⁹⁸

Some increase in selectivity can be achieved by the preparation of copper strips on the same substrates, *viz.*, Cu/SiO_2 (template), from $(\text{HFA})\text{Cu}(\text{VTMS})$ vapour. This is due to the fact that adsorption of the precursor molecules on SiO_2 , which decreases selectivity, depends directly on the presence of reactive hydroxy groups on the substrate surface.^{386,399} Therefore, to exclude a decrease in selectivity, it was suggested³⁹⁹ to pre-treat the SiO_2 surface with dichlorodimethylsilane vapour. This compound eliminates the reactive OH groups from the SiO_2 surface, thus creating unfavourable conditions for adsorption and film growth at these sites. Nevertheless, as the overall process selectivity is controlled by several factors (*e.g.*, the substrate temperature and the dichlorodimethylsilane vapour pressure), it is difficult to obtain reproducible results.

The selective deposition of copper films can also be provided by using thermally grown SiO_2 as the substrate.^{400,401} In this case, the presence of H_2 during the process [which is usually the case for processes based on $\text{Cu}(\text{II})$ derivatives] is an unfavourable factor for the selectivity, as it results in reduction of the SiO_2 surface layer and generation of OH groups.⁴⁰²

A study of nucleation upon decomposition of $(\text{HFA})\text{Cu}(\text{VTMS})$ on a SiO_2 surface 'freed' from the OH groups showed that under these conditions, an increase in the flow rate of the starting CCC virtually does not affect selectivity;⁴⁰³ the pressure in the reactor becomes the main parameter for controlling selectivity.

$\text{Cu}(\text{HFA})(1,5\text{-COD})$ manifests certain selectivity with respect to the substrate material: the formation and growth of copper films on the surfaces of such dielectrics as SiO_2 and Si_3N_4 occurs with much greater difficulty than on metal substrates.³³⁴ However, this effect is not observed at sufficiently high temperatures ($> 200^\circ\text{C}$).³³⁰

A very high selectivity in the deposition of copper films in 'metal-SiO₂' systems is achieved if Cu(HFA)(PMe₃) and Cu(HFA)(PEt₃) complexes are used.³³¹

An unexpectedly high selectivity with respect to SiO₂ was shown by copper(I) pyrazolyl borate complexes as the starting CCC upon deposition on Pt/SiO₂, Au/SiO₂, Al/SiO₂ and W/SiO₂ substrates.³⁷² However, this effect was not observed on the Pd/SiO₂ substrate relative to SiO₂.

2. Use of substrates made of polymeric materials in CVD processes

The use of polymers as substrate materials in CVD processes has certain advantages. For example, it was found that the chemisorption of precursor molecules and the adhesion of copper films to polyimide substrates are much weaker than in the case of SiO₂; this fact enables highly selective deposition.⁴⁰⁴ CVD processes with the use of Teflon for the preparation of copper films have become especially popular.

Teflon is used as a dielectric layer with unique properties, such as high resistivity and small dielectric constant. When combined with the low SER of copper films, this affords a very promising basis for the creation of fast microelectronic devices with short signal delay times.⁴⁰⁵

In this case, selectivity is based on two processes. Laser irradiation of the Teflon surface results in cleavage of the polymer chains with simultaneous formation of cross-links between the chains and perfluorocarbons with short chains in the near-surface layer. Both of these processes result in a strong decrease in the copper adhesion on the irradiated substrate areas.⁴⁰⁶ Alkaline etching of Teflon results in partial defluorination of the surface layer to a depth of ≥ 300 nm and, hence, formation of a rough surface enriched with carbon atoms, which favours the efficient adhesion of copper films.^{405, 407} Hence, a combination of irradiated and etched zones on a Teflon surface can serve as a template owing to purely mechanical properties.

The principles of 'Teflon technologies' were formulated in a series of papers.^{408–410} The process usually includes three stages: alkaline etching, creation of a pattern by KrF laser radiation, and high-selectivity CVD of the film (the copper film remains only on the etched areas). In the best experiments, the deposition rate of up to $1 \mu\text{m min}^{-1}$ was reached and the SER of the films was $\sim 1.8 \mu\Omega \text{ cm}$.⁴¹⁰

VII. Conclusion

Until 1995 accumulation of basic experimental data and the accompanying development of concepts on the mechanisms of CVD of thin copper films with the use of volatile CCC had occurred. Subsequently, the research in this field reached a qualitatively different level.

Over the last two or three years, a certain decrease in the number of original papers was accompanied by an increase in the number of patents obtained both in the fields of the new volatile CCC, the ways for the synthesis of the already known compounds, and the specific details of CVD processes. This is also true for copper(I) and copper(II) derivatives as the starting CCC: the former are attractive due to the low temperatures of evaporation (sublimation) and decomposition on a substrate and the high film deposition rates; the latter, due to the stability during storage and the rather simple synthesis.

For example, copper(II) 6-ethyl-2,2-dimethyloctane-3,5-dionate was patented as a new starting volatile CCC.⁴¹¹ A series of patents were obtained for many compounds as potential starting CCC for CVD processes in the series of complexes of Cu(HFA) with silylalkenes^{412–415} and silylalkynes.⁴¹⁶ Analysis of the composition and properties of the compounds patented shows that by varying the electronic effects of the substituents at the silicon atom and in the diketone fragment, it is possible to reach an optimum ratio between the stability of the compound and its ability to decompose at low temperatures.

Let us note some technological patents with the use of (HFA)Cu(VTMS). A two-stage CVD process based on this CCC with addition of H(HFA) vapour⁴¹⁷ and H₂O vapour⁴¹⁸ has been patented. It should probably be expected that the number of patents in this field will increase.

Yet another trend worthy of note is the fast progress in the technologies for the selective deposition of films. The 'Teflon technologies' are a significant but not the only achievement in this field. The first specialised review devoted to these technologies⁴¹⁹ generalised the results obtained by that time. So far, a number of important studies have been completed (see, *e.g.*, Refs 420 and 421) that allow one to state that new microelectronic devices have been created using these technologies.

In our opinion, one more promising field for the application of CVD technologies based on volatile copper(II) and copper(I) compounds is the preparation of copper films doped with other metals within one technological process. For example, it was found that the doping of copper films with zirconium atoms provides a good protection against electromigration with an insignificant increase in SER.⁴²² The addition of a small amount of Pd(HFA)₂ to (HFA)Cu(VTMS) vapour results in a copper film containing $\sim 0.5\%$ Pd, which is completely stable against oxidation in air up to 300°C (see Refs 423 and 424). Attempts at synthesis of similar films doped with Co (see Refs 425 and 426) and Sn (see Ref. 427) were reported. Further development of studies in this field may well result in new materials with unique properties.

A conceptually similar approach is the development of CVD methods for the integrated deposition (using the same equipment) of a buffer layer onto a silicon substrate and a copper film atop this layer. The first study using this approach made it possible to obtain a copper film with very good characteristics (SER = $1.8 \mu\Omega \text{ cm}$) from (HFA)Cu(VTMS) vapour on silicon substrates with a TiN layer sputter-deposited prior to copper deposition.³⁸⁹

Perhaps, the above study reflects the most fundamental trend in the field, *i.e.*, the transition from separate experimental studies on the CVD preparation of copper films with the use of concrete starting volatile copper compounds to the creation of integrated CVD technologies with full optimisation of all the conditions of the process up to the preparation of the final product.

Spectacular examples of this approach include: the complete optimisation of a CVD process based on the industrially produced CCC of the CupraSelect grade ('Schumacher', Germany),⁴²⁸ the study where the technological approach to super-resolution resists was suggested,³⁹² and the study suggesting the full-scale CVD production of copper films with SER $< 2.0 \mu\Omega \text{ cm}$, deposition rate $> 200 \text{ nm min}^{-1}$, good adhesion and selectivity, and with ensured reproducibility of the properties of the batch films.³⁹⁰ It is obvious that the number of studies in this field will increase.

In addition, the CVD-based preparation of copper films can be a technological component of the production of more complex systems. Recently, a technique for optimal CVD of copper films as an intermediate stage in the production of absorbing layers for solar batteries based on CuInSe₂ was developed.⁴²⁹

Considerable help in the development of CVD technology for the deposition of copper films is provided by the database for quantum-chemical calculations that has appeared recently. For example, the deposition of copper films from (HFA)Cu(VTMS) vapour in a stream of argon was simulated numerically on a computer using the PHOENICS-CVD program and this database.⁴³⁰ The calculations made it possible to optimise both the conditions of the process and the equipment.

In conclusion of the topic of the development and creation of volatile copper(I) and copper(II) derivatives, it is necessary to mention the attempts to go from searches for new specific technologically promising substances to the development of a general methodology for the synthesis of starting volatile CCC, based both on the analysis of the crystal and molecular structures of the already existing CCC and on quantum-chemical calcula-

tions of the thermodynamic parameters of crystal–vapour phase transitions. Developments of suitable algorithms are under way,^{431,432} and it may well be that this approach has great prospects.
