Abstract. Methods for the synthesis of various coordination compounds of iron phthalocyanines and their closest structural analogues, *viz.*, iron porphyrazines and naphthalocyanines, their structures, properties and applications are surveyed. The bibliography includes 230 references.

I. Introduction

Haem-containing biological systems play a unique role in living nature. These systems are involved in oxygen binding and transport (haemoglobin and myoglobin) and in catalysis of vital reactions (oxygenases, catalases, peroxidases and cytochromes).^{1,2}

The closest synthetic analogues of porphyrins, *viz.*, phthalocyanines (tetraazatetrabenzoporphins) and related compounds, find wide applications primarily as dyes, pigments and catalysts of oxidative desulfurisation of hydrocarbons.^{3,4} In recent years, these compounds have also been examined and used as components of gas sensors, electrochromic materials, passive laser valves and isolators for amplifying stages of solid-state and chemical lasers. These compounds have also found use as antimicrobial agents and photosensitisers in the photodynamic therapy of cancer.⁵ In the last decades, catalysts exhibiting high oxidase and peroxidase activities have been constructed based on phthalocyanines.³ Iron-containing complexes have particular promise. Increased scientific and practical interest in these complexes stems from the fact that they are characterised by a great diversity of coordination and redox forms.^{6–11} In spite of the fact that different aspects of chemistry and applications of iron phthalocyanines

and their analogues have been considered in a great number of publications and patents, many questions about the structures and the valent and spin states of the major coordination forms of these compounds remain as the subjects of discussion.

The properties and applications of selected coordination forms of complexes of iron phthalocyanines and their analogues have been surveyed in several fundamental reviews.^{3,4,9–11} However, the systematic analysis of a wide range of these compounds is lacking in the literature. In the present review, modern data on the synthesis and coordination chemistry of iron phthalocyanines and their analogues are considered and analysed.

II. Synthesis and properties of iron phthalocyanines and their analogues

In 1928, chemists from the 'Scottish Dyes Ltd.' found a dark-blue compound deposited on the walls of a reactor in the synthesis of phthalimide from phthalic anhydride and ammonia. This compound was extremely stable with respect to acids and alkalis, and it was suggested that it has the structure of PcFe (Pc^RFe , where $\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{R}^4 = \text{H}$) based on the results of a detailed study of its properties and structure.

As a result, a new class of macrocyclic tetrapyrrole compounds, *viz.*, phthalocyanines, has been discovered.^{15–17} The synthesis of PcFe was described in detail for the first time in the classical papers of Linstead.^{16,17} Presently, PcFe and its numerous R -substituted derivatives (Pc^RFe) are prepared by reactions of various derivatives of phthalic acid with iron or its compounds, which are often performed in the presence of catalysts (Scheme 1). In all cases, the reactions are carried out either in a melt of the reagents (the sintering method) or in high-boiling organic sol-

vents.^{3, 4, 10, 11} Thus heating of phthalonitrile with iron(II) hydroxide in trichlorobenzene containing 10% of quinoline afforded PcFe in 73% yield.¹⁸ Boiling of phthalonitrile with iron pentacarbonyl in 1-chloronaphthalene gave PcFe in 50% yield. In the latter case, there was virtually no need for further purification of the product.^{19, 20} The syntheses of PcFe from phthalonitrile and FePy_4Cl_2 (in yields of up to 70%)²¹ or from phthalic anhydride, urea and powdered iron (or its compounds) in the presence of different catalysts (boric acid, ammonium molybdate or titanium chloride) (in yields of up to 65%) were described; however, the purities of the final product were often not reported.^{22–24} Iron phthalocyanine can also be synthesised by metallation of metal-free phthalocyanine (Pc) prepared from the diimino derivative of isoindolinedione or phthalonitrile in the presence of a base (:B). A convenient procedure for the preparation of PcFe and its derivatives by heating the reagents with the use of microwave radiation

was proposed.²⁵ The latter procedure afforded the highly pure (up to 97%) target product in high yields (up to 80%). Iron phthalocyanine was also formed as a result of macrocycle contraction in the reaction of the so-called uranyl superphthalocyanine, which is a pentadentate analogue of phthalocyanine, with iron salts.²⁶ Substituted iron phthalocyanines are synthesised according to procedures virtually identical to those used for the preparation of PcFe. Complexes Pc^RFe containing different numbers of substituents R, where R is the halogen atom or the alkyl, aryl, nitro, alkoxy, aryloxy, alkylthio, arylthio, arylsulfonyl, polyfluoroalkoxy, polyfluorosulfamoyloxy, carboxy, sulfo, *etc.* groups, were described in the literature.^{4, 6–8, 27–36}

Final purification of complexes was carried out by high-temperature sublimation *in vacuo* or by removal of ligands (L) from bisaxially coordinated complexes of the general formula Pc^RFeL_2 on heating *in vacuo* or under a stream of an inert gas.^{6–14}

Polymeric compounds containing the PcFe fragments can be prepared in a way analogous to that for the preparation of substituted iron phthalocyanines.^{37–40} The formation of polymeric PcFe by the reaction of pyromellitic acid, an iron salt and urea in the presence of a catalyst was studied in detail.⁴⁰ The Mössbauer spectra of the resulting polymer contain four doublets belonging to polymeric and monomeric complexes as well as to oxidation products containing the phthalocyanine fragments. After purification of the polymer by gel permeation chromatography and its heating to 300 °C, the Mössbauer spectra exhibit only one doublet with the parameters characteristic of the $[\text{PcFe}^{\text{II}}]_n$ complex.

Like the majority of phthalocyanine complexes with other metals, PcFe can occur in different crystal modifications.^{4, 12, 14} According to the data from X-ray diffraction analysis, the environment about the iron ion in one of these modifications, *viz.*, in the β -modification of PcFe, is a pseudooctahedron formed by four isoindole nitrogen atoms of the virtually planar phthalocyanine ligand and two *meso*-nitrogen atoms of the adjacent PcFe molecules (Table 1).⁴¹ The magnetic moments (μ_{eff}) for different specimens of PcFe at room temperature are in the range of 3.7–4.5 μ_{B} .^{51–53} The Mössbauer spectra of a series of Pc^RFe complexes in which the σ -donor and π -acceptor properties of the peripheral substituents vary over a rather wide range were examined (Table 2). The parameters of the Mössbauer spectra δ and ΔE_{Q} for these complexes, which reflect the character of the Pc–Fe interaction, should correlate with the Hammett constants (σ). However, with the aim of giving an adequate account of the effect of substituents in the phthalocyanine macrocycle on the Mössbauer parameters, the authors^{27, 28} had to introduce two arbitrary additional parameters describing the σ -donor and π -acceptor properties of the substituents (Σ and Π , respectively).

Table 1. Structures of iron phthalocyanine, its biaxially coordinated complexes and their analogues established by X-ray diffraction studies.

^a Relative to metallic iron; ^b relative to sodium nitroprusside.

The Σ value is larger for stronger σ -donors, whereas the Π value is larger for stronger π -donor and weaker π -acceptor. The Mössbauer parameters are related to the Σ and Π constants by the following equations:

$$\delta = -\Sigma + \Pi,$$

$$\Delta E_{\text{Q}} = a\Sigma - b\Pi + c,$$

where a , b and c are constants and $a > b > 0$. The Mössbauer spectra of all the $\text{Pc}^{\text{R}}\text{Fe}$ complexes studied are characterised by high and virtually temperature-independent quadrupole splitting (see Table 2) typical of iron(II) complexes with the intermediate ($S = 1$) spin state.^{27, 28, 41, 51}

Figure 1. Electronic absorption spectra of iron(II) tetrakis(4-*tert*-butyl)phthalocyanine (Pc^{Fe}) in dry degassed benzene (1), $\text{Pc}^{\text{Fe}}\text{Py}_2$ in benzene with an admixture of pyridine (2) and $\text{HPc}^{\text{Fe}}\text{Cl}$ in benzene (3) ($c \approx 10^{-3}$ mol litre $^{-1}$, $l = 0.01$ cm).

The electronic absorption spectra of Pc^{Fe} in the gas phase and in noncoordinating solvents depend on the procedure for the preparation and the purity of the specimen. In our opinion, the most reliable data were obtained for sublimed specimens of Pc^{Fe} dissolved in naphthalene at 110 °C in an atmosphere of helium.⁵⁶ Bands similar in shape and position were observed in the electronic absorption spectra of benzene solutions of $\text{Pc}^{\text{R}}\text{Fe}$ under an inert atmosphere (Table 3, Fig. 1).^{6, 7} The spectra of $\text{Pc}^{\text{R}}\text{Fe}$ both in the gas phase⁶¹ and in noncoordinating solvents^{6, 7, 56} are untypical of the $\text{Pc}^{\text{R}}\text{M}$ complexes (M is metal).^{61, 62} For example, the electronic absorption spectra of iron(II) tetrakis(4-*tert*-butyl)phthalocyanine (Pc^{Fe}) always have several overlapping bands with approximately equal intensities in the long-wavelength region (580–750 nm), whereas this region in the spectrum of its bisaxially coordinated adduct $\text{Pc}^{\text{Fe}}\text{Py}_2$ is typical of the $\text{Pc}^{\text{R}}\text{M}$ complexes (Fig. 1). (It should be noted that axial coordination in the $\text{Pc}^{\text{R}}\text{M}$ complexes of other metals affects rather slightly the electronic absorption spectral patterns.) Originally, this anomaly was attributed to the fact that the $\text{Pc}^{\text{R}}\text{Fe}$ complexes are strongly aggregated in noncoordinating solvents.²⁹ However, more recent studies of $\text{Pc}^{\text{R}}\text{Fe}$ complexes containing bulky substituents at the α position of the phthalocyanine macrocycle did not confirm this suggestion. Thus the spectral patterns of both sterically unhindered complexes and complexes containing bulky substituents, which prevent intermolecular aggregation (for example, the 2,4,6-trimethylphenyl substituents), are approximately identical.⁷ In this connection and taking into account that the planar-square environment is untypical of iron(II) complexes, it was suggested⁷ that $\text{Pc}^{\text{R}}\text{Fe}$ complexes have a tetrahedrally distorted geometry, which leads to a change in the electronic absorption spectra.

The configuration of the ground electronic state of $\text{Pc}^{\text{R}}\text{Fe}$ has been discussed in the literature over a long period. In the late 1960s, based on the results of Mössbauer spectroscopy (including the data obtained in magnetic fields), Dale postulated that the ground electronic state of the iron ion in Pc^{Fe} has the $^3E_g[(d_{xy})^2(d_{xz}, d_{yz})^3(d_{z^2})^1]$ configuration.^{51, 63} Using the data on magnetic susceptibility of Pc^{Fe} , Lever⁵³ postulated another configuration of the iron ion, viz., $^3A_{2g}[(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^2]$. Subsequent quantum-chemical calculations^{64, 65} and studies of the Mössbauer spectra of a wide range of substituted iron phthalocyanines^{27, 28} made it possible to state reliably that the ground electronic state of the iron ion in the compounds under study has the $^3E_g[(d_{xy})^2(d_{xz}, d_{yz})^3(d_{z^2})^1]$ configuration. Apparently, the sole exception is iron tetrakis(4-phenylthio)phthalocyanine, which has anomalous Mössbauer parameters (see Table 2). As a consequence, the configuration of the ground electronic state of

the iron ion in this compound was described as $^3A_{2g}[(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^2]$.²⁷

The reaction of PcFe with potassium *tert*-butylthiolate in the presence of 2,2,2-cryptand ($\text{C}\bar{\text{C}}222$) afforded the one-electron-reduced complex $[\text{C}\bar{\text{C}}222]^+[\text{PcFe}]^-$.⁴² The reaction of PcFe with LiAlH_4 and 18-crown-6 (18-C-6) in a THF solution yielded the two-electron-reduced complex $[\text{Li}_2(\text{THF})(18\text{-C-6})_2]^{2+}[\text{PcFe}]^{2-}$.⁴² In both cases, the central iron atom is coordinated by four nitrogen atoms of the isoindole fragments of the planar phthalocyanine ligand (see Table 1). Based on the results of spectral studies, the following two schemes of the equilibrium of isoelectronic forms of the one- and two-electron-reduced complexes were proposed: $[\text{Fe}^{\text{I}}\text{Pc}^{2-}] \rightleftharpoons [\text{Fe}^{\text{II}}\text{Pc}^{3-}]$ and $[\text{Fe}^{\text{I}}\text{Pc}^{3-}] \rightleftharpoons [\text{Fe}^{\text{II}}\text{Pc}^{4-}]$.

Complexes of iron tetraazaporphin ($\text{TAP}^{\text{R}}\text{Fe}$) have been poorly studied.^{6, 57–60, 66}

Presently, only octaphenyl-^{58, 60} octaethyl-⁵⁷ dibenzobarrelene-^{59, 66} and octakis(4-*tert*-butylphenyl)-containing⁶⁰ complexes (see Table 3 and notes therein) are reliably characterised by electronic absorption spectra, Mössbauer spectra and magnetic susceptibility data. On the basis of the data from magnetic susceptibility (3.8 ⁵⁸ and $3.82 \mu_B$ ⁵⁷ for octaphenyl- and octaethylporphyrzine iron complexes, respectively) and Mössbauer spectroscopy, all $\text{TAP}^{\text{R}}\text{Fe}$ complexes were assigned to iron(II) compounds characterised by the intermediate ($S = 1$) spin state.

Due to the low stability of iron 1,2-naphthalocyanine complexes (1,2-Nc^RFe) and, particularly, iron 2,3-naphthalocyanine complexes (2,3-Nc^RFe), which are prone to oxidation, reliable data on their properties in solutions are lacking. However, these complexes are stable in the solid state, which made it possible to measure their Mössbauer spectra. According to the available results, 2,3-NcFe belongs to iron(II) compounds with the intermediate ($S = 1$) spin.²⁷

Fused aza analogues of PcFe , viz., complexes of tetrakis(2,3-quinoxalino- and -quinolino)porphyrzines, were also synthesised and their thermal stabilities have been examined.⁶⁷

III. Bisaxially coordinated complexes of iron phthalocyanine and its analogues

1. Iron(II) complexes

Coordinatively unsaturated compounds $\text{Pc}^{\text{R}}\text{Fe}$ readily form axially coordinated diamagnetic low-spin ($S = 0$) complexes of

the general formula $\text{Pc}^{\text{R}}\text{FeL}_2$ with nitrogen-,^{15, 17, 46, 68–73} phosphorus-,⁷⁴ sulfur-⁴⁷ and carbon-containing^{75, 76} σ -donor and (or) π -acceptor ligands (L). In addition, mixed complexes with different axial ligands of the general formula $\text{Pc}^{\text{R}}\text{FeL}^1\text{L}^2$ can be formed.^{76–78}

The formation of bisaxially coordinated PcFeL_2 complexes, where L are nitrogen bases, was investigated in detail by kinetic methods.^{77–84} According to concepts developed in these studies, the stepwise successive coordination of two ligand molecules proceeds by a dissociation mechanism

Among complexes of the $\text{Pc}^{\text{R}}\text{FeL}_2$ type, compounds containing nitrogen bases of the heteroaromatic or aliphatic series as axial ligands were studied in most detail.^{46, 68, 69, 71, 72} Complexes with ligands containing the pyridine nitrogen atoms (which act simultaneously as σ -donors and π -acceptors) are more stable compared to complexes containing aliphatic amines (pure σ -donors).^{46, 71, 73} Stynes⁷⁸ studied the kinetics of replacement of the axial ligand in PcFeL_2 , where L is methylimidazole, pyridine or piperidine, by benzyl isocyanide. The direct replacement of one axial ligand was observed only in the dark. When illuminated in the presence of L, the resulting complex $\text{PcFeL}(\text{BnNC})$ reverted to PcFeL_2 .⁷⁸

Pyridine derivatives containing substituents at the β and γ positions enter into the reaction of axial coordination, whereas substituents at the α position inhibit this reaction.⁶⁹ Iron phthalocyanine also readily reacts with primary aliphatic amines, including such sterically hindered compounds as *tert*-butylamine.⁷¹ The range of dialkylamines, which can be axially coordinated to $\text{Pc}^{\text{R}}\text{Fe}$, is narrower. Branching of the carbon skeleton at the α -carbon atom [Pr_2^1NH , $(\text{cyclo-C}_6\text{H}_{11})_2\text{NH}$] prevents the preparation of axially coordinated complexes of the PcFeL_2 type.^{46, 71} In other words, as in the case of pyridine-type ligands, the choice of dialkylamines which can be axially coordinated is limited by steric factors. It is even more difficult to prepare axially coordinated complexes of this type with trialkylamines. Thus an unstable complex with quinuclidine is the only compound of this type, which was isolated and characterised by spectroscopic methods.⁷²

Unlike tertiary amines, trisubstituted phosphines and phosphites readily form complexes with PcFe .^{74, 85, 86} Compounds of the $\text{Pc}^{\text{R}}\text{FeL}_2$ type, where L are aliphatic or aromatic isocyanides,⁷⁵ carbon monoxide^{47, 76–78} or the cyanide ion,^{68, 87, 88} are also well studied. Of complexes containing the Fe—S bond, only those with tetrahydrothiophene and DMSO have been described.^{43, 47} Data on analogous complexes containing the Fe—O bonds are lacking in the literature. Among mixed-ligand complexes of the $\text{Pc}^{\text{R}}\text{FeL}^1\text{L}^2$ type, compounds $\text{PcFe}(\text{CO})\text{L}$ (where L is nitrogen-, sulfur- or oxygen-containing ligands),^{47, 76, 78, 87} $\text{Pc}^{\text{R}}\text{Fe}(\text{CN})\text{L}$ (where L is a nitrogen-containing ligand)⁵⁰ and PcFeL^1L^2 (where L^1 and L^2 are either two different nitrogen-containing ligands⁷⁷ or isocyanide and nitrogen-containing ligands⁷⁸) were studied.

The structures of several complexes of the PcFeL_2 type, viz., $\text{PcFe}(\text{4-MeC}_5\text{H}_4\text{N})_2$, $\text{PcFe}(\text{MeIm})_2$, $\text{PcFe}(\text{DMSO})_2$, $\text{PcFe}(\text{4-MeC}_5\text{H}_{10}\text{N})_2$ and $\text{PcFe}(\text{CO})(\text{DMF})$, were established by X-ray diffraction analysis (see Table 1).^{43–47} It should be noted that the axial ligands in $\text{PcFe}(\text{4-MeC}_5\text{H}_4\text{N})_2$ and $\text{PcFe}(\text{MeIm})_2$ are located in two mutually perpendicular planes, whereas these ligands in $\text{PcFe}(\text{4-MeC}_5\text{H}_{10}\text{N})_2$ are virtually coplanar. This suggests a substantial contribution of back π -bonding in the $\text{PcFe}(\text{4-MeC}_5\text{H}_4\text{N})_2$ and $\text{PcFe}(\text{MeIm})_2$ complexes. For the same reason, the Fe—CO distance in the $\text{PcFe}(\text{CO})(\text{DMF})$ complex is shorter than the corresponding distances in the complexes with other axial ligands and shorter than the Fe—N(Pc) distance (see Table 1). Analogous effects were also observed in complexes with strong π -acceptors, such as isocyanide ligands (see Table 1).^{48, 49}

The electronic absorption spectra of PcFeL_2 containing axial ligands of virtually all known types were measured.^{46, 62, 68–74, 77–84, 87} These spectra consist of a long-wave-

length Q band at 660 nm which has vibrational structure, a charge-transfer band (CTB) at 425 nm and a B band at 330 nm. The σ - and π -acceptor properties of the axially coordinated ligands in these complexes most substantially affect the positions of the charge-transfer bands (Table 4).^{68, 69, 71, 87} The above-mentioned effect has been examined many times (see, for example, Refs 46, 68, 69 and 71). Based on the results of calculations by the extended Hückel method, Goutermann and coworkers⁶⁴ were the first to assign this band to charge transfer from the central iron ion to the unoccupied orbital of the axial ligand (CTB $\text{Fe} \rightarrow \text{L}$). More recently, Dale⁶⁸ studied a series of PcFeL_2 complexes, where L is pyridine, imidazole, butylamine, piperidine, ammonia or the cyanide ion, and assigned this band to $\text{Fe} \rightarrow \text{Pc}$ charge transfer and related its position to the basicity of the axial ligand. Analogous correlations were also observed for a wide range of pyridine⁶⁹ and alkylamine⁷¹ ligands. Ouedraogo and coworkers⁶⁹ followed Goutermann in attributing this band to $\text{Fe} \rightarrow \text{L}$ charge transfer. However, Stillman and coworkers⁸⁷ examined electronic absorption spectra as well as magnetic circular dichroism spectra of a series of PcFeL_2 complexes and demonstrated that the above-mentioned band belongs to a transfer in which one of the states is degenerate. The transition from the $3d_\pi$ orbitals of the central iron atom with symmetry e_g to the unoccupied π^* orbital of the phthalocyanine ligand with the symmetry b_{1u} is the only allowed transition for the low-spin d^6 configuration of the $\text{Fe}(\text{II})$ ion in a complex with D_{4h} symmetry. The axial coordination of the purely σ -donor ligands, for example, of alkylamines, occurs primarily owing to the interaction between the d_{z^2} orbital of the central atom and the n orbital of the ligand. The enhancement of the σ -donor character of the axial ligand leads to an increase in the population of the d_{z^2} orbital of the iron atom and, consequently, to its destabilisation as well as to destabilisation of the d_π orbitals, which, in turn, leads to a bathochromic shift of the charge-transfer band.^{71, 87} The enhancement of the π -acceptor character of the axial ligands results in direct stabilisation of the d_π orbitals of the central atom and, as a consequence, in an increase in the energy of the charge-transfer band. Thus this band is observed at 450, 430, 415 and 400 nm for the PcFeL_2 complexes with the cyanide (σ - and π -donors),^{87, 88} alkylamine (pure σ -donors),^{46, 68, 71} pyridine (σ -donors and π -acceptors)^{68, 69, 87, 90} and isocyanide (weak σ -donors and strong π -acceptors)^{75, 76, 78} ligands, respectively, (see Table 4). To obtain an adequate correlation between the basicity of the axial ligands and the position of the charge-transfer band, the steric properties of these ligands should also be taken into account.⁷¹ A new approach to the estimation of the positions of charge-transfer bands in the spectra of the PcFeL^1L^2 complexes with ligands of all types on the basis of their electronic structures and steric properties using second-order perturbation theory was proposed.^{46, 92} The electronic absorption spectra of the PcFeL_2 complexes with axial pyridine-type ligands containing acceptor substituents have an additional band at 500 nm. This band was assigned to $\text{Fe} \rightarrow \text{L}$ charge transfer.⁶⁹ It should be noted that the nature of the solvent has differing effects on the position of the charge-transfer band in $\text{Pc}^{\text{R}}\text{FeL}_2$ complexes depending on the type of axial ligand. Thus if the axial ligands can form a dative π bond (pyridine-type ligands, isocyanides, etc.), the position of the charge-transfer band depends only slightly on the nature of the solvent. For example, the charge-transfer band for the PcFePy_2 complex was observed at 415, 413.5 and 412 nm in DMSO, pyridine and dichloromethane, respectively.^{68, 69, 79, 87} In the case of alkylamines and, particularly, polyamines, which can form an intramolecular hydrogen bond, the position of this band varies over a wide range depending on the nature of the solvent.^{68, 69, 71, 87} For example, the charge-transfer band for the $\text{PcFe}(\text{NH}_3)_2$ complex is observed at 440 and 426 nm in DMSO⁶⁸ and dichloromethane,⁸⁷ respectively. Probably, this behaviour reflects a decrease in the bond energy on going to the $\text{Pc}^{\text{R}}\text{FeL}_2$ complexes with pure σ -donor ligands. However, there is no direct evidence for this suggestion.

Note. Pip is piperidine, Mor is morpholine and Im is imidazole.

In some cases, the position of the charge-transfer band can be used for analytical purposes, for example, for the determination of CO concentration. Thus when CO was bubbled through a solution of PcFePy₂, the intensity of the charge-transfer band decreased as the amount of the resulting PcFe(CO)Py complex increased.⁷⁸ Analogously, in the reaction of the PcFePy₂ complex with isocyanides, the intensity of the band of the initial complex (at 420 nm) first decreased [the formation of PcFePy(NCR), which gave weak bands at 420 and 394 nm] and then disappeared [the formation of PcFe(NCR)₂, which gave a charge-transfer band at 394 nm].

The Mössbauer spectra of polycrystalline samples or frozen solutions of the PcFeL¹L² complexes were examined (Table 5).^{9, 46, 47, 69, 71, 76, 86, 93–98} The spectra of freshly prepared samples of PcFeL¹L² are manifested as doublets and their parameters are characteristic of low-spin ($S = 0$) iron(II) complexes.^{99, 100} The δ values vary rather slightly, whereas the ΔE_Q value varies over a wider range depending on the nature of the ligand (see Table 5). The isomer shift reflects the s -electron density at the iron nucleus.⁹⁹ Consequently, an increase in the population of the $4s$ orbital of the iron atom leads to a decrease in the δ value. For the complexes under consideration, an increase in the population of the $4s$ orbital of the central atom results directly from an increase in the σ -donor character of the axial ligand and from the fact that the $3d_{z^2}$ and $4s$ orbitals of the central iron atom have the same symmetry and can be mixed.⁹⁹ The ΔE_Q value, which characterises the electric field gradient about the iron nucleus, is more sensitive to the structure of the axial ligand (see Table 5).⁹⁹

$$\Delta E_Q = 1/2eQV_{zz}(1 + 1/3\eta^2)^{1/2}, \quad (1)$$

where $V_{zz} = eq$, $\eta = (|V_{xx} - V_{yy}|)/|V_{zz}|$.

For the PcFeL₂ complexes, $V_{xx} \approx V_{yy}$, and, consequently, $\eta \approx 0$.^{76, 95, 101} The electric field gradient has a positive sign.^{95, 101} For the low-spin iron(II) complexes, the q parameter can be represented as the sum $q = q_{\text{lat}} + q_{\text{val}} + q_{\text{mo}}$.^{99, 102, 103} The first member q_{lat} corresponds to the lattice contribution to the electric field gradient. This value decreases proportionally to the cube of the distance and is negligibly small for bulky complexes. The third member q_{mo} is associated with the difference in the population of different MOs belonging to the same irreducible representation. For the low-spin iron(II) complexes, the ground electronic state has the $(d_{xy})^2(d_{xz}, d_{yz})$ configuration,⁴ and, consequently, this term is equal to zero. The term q_{val} reflects the symmetry of the population of the atomic orbitals of the iron atom and its σ and π interactions with the ligands. This term can be written as follows^{99, 103}

$$q_{\text{val}} = 4/7(1 - R) < r^{-3} >_{3d} [n_{x^2-y^2} + n_{xy} - n_{z^2} - 1/2(n_{xz} + n_{yz})],$$

where R is the Sternheimer factor for antishielding of the iron nucleus, $< r^{-3} >_{3d}$ is the radial component of the $3d$ wave function and n is the population of the corresponding AO.

If the coordination environment about the iron atom is nearly octahedral, the q_{val} term for the low-spin t_{2g} configuration is equal to zero.^{99, 103} In the case of axial distortion, the q_{val} term makes the major contribution to the electric field gradient in complexes of the Pc^RFeL₂ type. Actually, the quadrupole splitting in nearly octahedral complexes with isocyanide ligands is small,^{9, 90} whereas this splitting in complexes with nitrogen-centred axial ligands is significant (see Table 5).^{46, 68, 69, 71, 93, 95–97} An increase in the ΔE_Q value is observed in the following series of axial ligands: isocyanides $\approx$ cyanides $<$ CO $<$ phosphites $<$ (CO)L $\approx$ phosphines $<$ pyridines, alkylamines and other nitrogen-containing ligands. Analysis of Eqn (1) demonstrates that the quadrupole splitting should decrease as both the σ -donor and π -acceptor properties of the axial ligands are strengthened. However, the observed ΔE_Q values for some complexes with ligands exhibiting pronounced π -acceptor properties (CO or isocyanides) are higher than the expected values (see Table 5).^{47, 76} To account for this anomalous behaviour, hypotheses for the *cis* and *trans* effects of the axial ligands on the phthalocyanine macrocycle were invoked.⁷⁶ However, the mechanism that causes a decrease in the quadrupole splitting is still an open question.

Attempts were also made to interpret the available results with the use of empirical and semiempirical approaches. Thus a simple empirical procedure was proposed for the estimation of the ΔE_Q value for the PcFeL₂ complexes using absolute partial quadrupole splittings.¹⁰⁴ A reasonable correlation between the ΔE_Q values and the basicity was obtained.^{46, 92} A correlation between the ΔE_Q values and the steric properties of alkylamines was also found.⁷¹ An approach based on perturbation theory was also proposed for the estimation of the ΔE_Q values for all types of axial ligands.^{46, 92}

The effect of circulating currents of the extended π system on the chemical shifts is clearly manifested in the ¹H NMR spectra of the Pc^RFeL₂ complexes. In all cases, the signals of the coordinated ligands are shifted upfield compared to the signals of the initial amines (Table 6).^{72, 90, 105–109} The high selectivity of axial coordination, high induced shifts of the proton signals and the possibility of the prediction of their positions on the basis of the results of quantum-chemical calculations allow one to solve successfully a number of analytical problems.^{105–108}

Note. Pyz is , HMPT is hexamethylphosphotriamide; ^a relative to sodium nitroprusside; ^b relative to metallic iron.

Studies of the thermal stability of a number of the Pc^RFePy₂ complexes demonstrated that both ligand molecules are eliminated in one stage. Electron-withdrawing substituents in the macrocycle increase thermal stability, whereas electron-donating substituents decrease this stability compared to that of the unsubstituted analogue.⁷⁰

Among axially coordinated PcFe(II) complexes, polymeric compounds of the general formula (Pc^RFeL)_n belong to a special group.^{9, 13, 109–113} These compounds attract great interest because of their semiconducting properties.^{114–119} Since several comprehensive reviews devoted to this subject are available,^{9, 13, 110, 112}

we restrict ourselves to consideration of the major representatives of this group.

Polymeric complexes (Pc^RFeL)_n were synthesised by the reactions of Pc^RFe with different bidentate ligands, such as pyrazine, tetrazine, 4,4'-dipyridyl, 1,4-diisocyanobenzene, 4-phenylenediamine and 9,10-anthracenediisocyanide, which serve as cross-linking agents. These complexes can be divided into two groups according to their semiconducting properties. The first group involves complexes exhibiting good semiconducting properties only upon doping with halogens or other electron acceptors. The second group consists of complexes exhibiting semiconduct-

ing properties without doping (Table 7). Polymeric compounds of the first type are stable up to 100–130 °C and lose their semi-conducting properties in the absence of the doping agent. All complexes except for compounds containing tetrazine as the axial ligand belong to this type. Tetrazine-containing polymers belong to the second type. The latter are thermally more stable and have no need of doping.^{9, 13, 110, 112}

Of the axially coordinated $\text{TAP}^{\text{R}}\text{FeL}_2$ complexes reported in the literature, only complexes of iron octaphenylporphyrazine, where L is a pyridine-type ligand, alkylamine or the cyanide ion, were systematically studied by electronic and Mössbauer spectroscopy (Table 8).^{58, 120–122} All complexes of this type belong to low-spin iron(II) compounds. The δ and ΔE_Q values (relative to sodium nitroprusside) were determined for some octaphenyl-substituted complexes:

Complex	$\delta/\text{mm s}^{-1}$	$\Delta E_Q/\text{mm s}^{-1}$	Ref.
$\text{TAP}^{\text{Ph}}\text{FePy}_2$	0.47	2.26	58
$\text{TAP}^{\text{Ph}}\text{Fe}(4\text{-MeC}_5\text{H}_4\text{N})_2$	0.45	2.30	58
$\text{TAP}^{\text{Ph}}\text{FeIm}_2$	0.18	2.12	58
	0.50	2.10	120, 121

The electronic absorption spectra of the octaphenyl-substituted $\text{TAP}^{\text{Ph}}\text{FeL}_2$ complexes with pyridine-type ligands are analogous in general appearance to those of the PcFeL_2 complexes (Fig. 2).^{6, 57, 58} The band at 550 nm was attributed to the

**Figure 2.** Electronic absorption spectra of the complexes $\text{TAP}^{\text{Ph}}\text{FePy}_2$ (1), PcFePy_2 (2) and $2,3\text{-NcFePy}_2$ (3) in benzene.

Table 7. Selected characteristics of the polymeric complexes of iron phthalocyanines ($\text{Pc}^{\text{R}}\text{FeL}$)_n and iron naphthalocyanines ($\text{Nc}^{\text{R}}\text{FeL}$)_n.^{9, 13, 110–114}

Note. Tz is tetrazine, Me₂Tz is dimethyltetrazine, dabco is 1,4-diazabicyclo[1.2.2]octane, bipy is 2,2'-bipyridyl; ^a relative to metallic iron; ^b ν_{NC} in cm⁻¹, λ_{max} (electronic absorption spectrum) in nm; ^c relative to sodium nitroprusside.

$\text{Fe} \rightarrow \text{TAP} [e_g(d\pi) \rightarrow e_g(\pi^*)]$ charge transfer.⁵⁸ However, this assignment has recently come under strong criticism and this band was attributed^{120, 121} to the $\text{Fe} \rightarrow \text{TAP} [e_g(d\pi) \rightarrow b_{1u}(\pi^*)]$ charge transfer. In the electronic absorption spectra of the $\text{TAP}^{\text{R}}\text{FeL}_2$ complexes containing alkylamines or the cyanide ion as the axial ligands, the intensity of the charge-transfer band at 500 nm is virtually equal to that of the Q band. However, taking into account that the above-mentioned complexes were not characterised by other spectroscopic methods, these data must be considered with caution.^{120–122}

Among complexes of iron naphthalocyanines, compounds containing isocyanide axial ligands have been studied in most detail (Table 9).^{48, 94, 123–126}

Four structural isomers are possible for derivatives of 1,2-Nc^RFeL₂. An individual isomer, which contains the *tert*-butylisocyanide and cyclohexylisocyanide ligands and is characterised by C_{4h} symmetry, was isolated and its structure was established.^{48,49} Due to the strong π-acceptor properties of the axial ligands, the Fe–C_{ax} bond length is smaller than the Fe–N(Pc) distance (see Table 1). On the whole, the spectral characteristics and properties of the 1,2-Nc^RFeL₂ complexes are very similar to those of Pc^RFeL₂ (see Tables 4–7). In the 2,3-Nc^RFeL₂ complexes, linear

annellation of an additional benzene ring (contrary to angular annellation resulting in 1,2-NcFe) leads to a sharp change in the properties of these compounds, which is manifested, for example, in a strong bathochromic shift of the Q band in the electronic absorption spectra and in enhancement of the semiconducting properties (see Tables 7 and 9, Fig. 2).^{9,13,110,112} An extension of the π-system of the macrocycle leads to a decrease in the stability of the complexes containing the 2,3-Nc^RFe fragment.^{123–126}

Complexes of iron tetrakis(2,3-phenanthro)porphyrizine were prepared by photochemical oxidation of *trans*-1,2-dicyano-1,2-diphenylethylene in the presence of iodine followed by template condensation with iron compounds and axial coordination with different isocyanides.¹²⁷ These complexes were characterised by electronic and Mössbauer spectroscopy. In addition, complexes of iron tetrakis(2,3-pyridino)porphyrizine with isocyanides as axial ligands were prepared and characterised (see Table 9).⁹¹

2. Iron(III) complexes

In spite of the fact that azaporphin iron(III) complexes have been considered in the literature over several decades, convincing evidence for the existence of Pc complexes of iron(III) has been reported, and furthermore their properties, have been described only recently. Oxidation of a solution of $\text{Na}_2[\text{PcFe}^{\text{II}}(\text{CN})_2]$ in dichloromethane with bromine afforded the six-coordinate $\text{Na}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ complex.⁵⁵ In the electronic absorption spectra, this process is characterised by distinct isosbestic points (Fig. 3). The $\text{Na}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ complex can also be prepared by oxidation of $\text{Na}_2[\text{PcFe}^{\text{II}}(\text{CN})_2]$ with cumene hydroperoxide¹²⁸ or by the reactions of $\text{Na}[\text{PcFe}^{\text{III}}(\text{OH})_2]$ with cyanides.⁵⁰ The $[\text{PcFe}^{\text{III}}(\text{CN})_2]^-$ complex was characterised in detail by electronic absorption, Mössbauer, IR, Raman, ESR and circular dichroism spectra, magnetic susceptibility data and X-ray diffraction analysis (Table 10).^{50, 55, 129} The magnetic susceptibilities, the parameters of the Mössbauer spectra and the character of the electronic absorption spectra demonstrate that this compound can be described as a low-spin ($S = 1/2$) iron(III) complex with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ electronic configuration. The presence of a hole in the d_π orbital of the central atom results in the appearance of a series of $\text{L}(\text{Pc})-\text{Fe}$ charge-transfer bands in the electronic absorption spectra. The most detailed assignment of the bands in the electronic absorption spectrum of the $\text{Na}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ complex was made by Ough and Stillman.⁵⁵ Based on the analysis of the magnetic circular dichroism and electronic absorption spectra, two $\text{Fe} \rightarrow \text{L}(\text{Pc})$ and four $\text{Fe} \rightarrow \text{Pc}$ charge-transfer bands were identified.⁵⁵ According to the data from X-ray diffraction analysis⁵⁰ (see Table 1), the $\text{Fe}-\text{C}_{\text{ax}}$ bond length in $\text{PNP}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ is larger than the $\text{Fe}-\text{N}(\text{Pc})$ bond length. This complex is more similar in structure to compounds of the $\text{PcFe}^{\text{II}}\text{L}_2$ type with nitrogen-containing axial ligands^{43–46} and differs from analogous complexes with axial ligands exhibiting strong π -acceptor properties.^{48, 49} The reactions of $[\text{PcFe}^{\text{III}}(\text{CN})_2]^-$ with pyridine and imidazole afforded compounds with composition $\text{PcFe}^{\text{III}}(\text{CN})\text{L}$, whereas the reaction with hydrazine was accompanied by reduction of the iron ion to form

Figure 3. Dynamics of oxidation of the $[\text{PcFe}^{\text{II}}(\text{CN})_2]^{2-}$ complex with cumene hydroperoxide to form $[\text{PcFe}^{\text{III}}(\text{CN})_2]^-$.

$[\text{PcFe}^{\text{II}}(\text{CN})(\text{N}_2\text{H}_4)]^-$.⁵⁰ Complexes of the $\text{PcFe}^{\text{III}}(\text{CN})\text{L}$ type can also be prepared by the reactions of the ligand L with the cyanide complex $[\text{PcFe}^{\text{III}}(\text{CN})]^-$.¹³⁰ The reactions of $\text{Na}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ with acids yielded complexes of the $\text{Pc}^+ \text{Fe}^{\text{III}}(\text{CN})\text{X}$ type containing the phthalocyanine radical cation. Finally, $\text{Na}[\text{PcFe}^{\text{III}}(\text{CN})_2]$ can be reduced to the cyanide iron(II) complex under the action of different reducing agents.⁵⁰

Complexes of the general formula $\text{PNP}(\text{PcFe}^{\text{III}}\text{XY})$ ($\text{X} = \text{Y}$) were synthesised^{89, 129} and characterised by electronic absorption, Mössbauer and ESR spectra as well as by magnetic susceptibility data (see Table 10). These compounds exhibit the following characteristic features: (1) the electronic absorption spectra of all complexes have additional $\text{Pc} \rightarrow \text{Fe}$ and $\text{Fe} \rightarrow \text{Pc}$ charge-transfer bands in the region of 400–800 nm, and the Q band is bathochromically shifted compared to that for the PcFeL_2 complexes; (2) in most cases, the electronic absorption spectra are typical of axially coordinated low-spin ($S = 1/2$) iron(III) complexes;^{131, 132} (3) in all the studied complexes, except for the cyanide complex, the quadrupole doublets in the Mössbauer spectra are characterised by substantial asymmetry; a low-intensity broad component of the doublet for the complexes with the $\text{Fe}-\text{O}_{\text{ax}}$ bond is observed at low rates, whereas this component for the complexes with the $\text{Fe}-\text{N}_{\text{ax}}$ bonds is observed at higher rates,¹²⁹ as in the case of the well-studied iron(III) complexes with porphyrin ligands^{100, 133} {for the azide complex anion $[\text{PcFe}^{\text{III}}(\text{N}_3)]^-$, the sign of the electric field gradient was found to be negative¹³⁴}; (4) magnetic moments for all the complexes studied are in the range of 2.0–2.5 μ_{B} at room temperature. Based on the data from mag-

netic circular dichroism and electronic absorption spectroscopy, it was concluded⁵⁵ that the phthalocyanine ligand in the $[\text{PcFe}^{\text{II}}(\text{CN})_2]^{2-}$ complex behaves as a σ -donor and a π -acceptor and the result of oxidation of the iron ion yielding $[\text{PcFe}^{\text{III}}(\text{CN})_2]^-$ is that the phthalocyanine ligand behaves as a σ - and π -donor. Of special note is the $\text{PcFe}^{\text{III}}(\text{NO})\text{Py}$ complex, which was prepared by a ligand exchange reaction. Based on the data from magnetic susceptibility and Mössbauer spectroscopy, this complex should be assigned to low-spin ($S = 1/2$) iron(III) compounds. For this complex, two isomeric forms that differ in the site of localisation of the electron hole are possible:

Polymeric iron(III) complexes linked through bridging ligands, viz., $[\text{PcFe}^{\text{III}}(\text{CN})]_n$, $[2,3\text{-NcFe}^{\text{III}}(\text{CN})]_n$ and $[\text{PcFe}^{\text{III}}(\text{SCN})]_n$, were synthesised^{110,112} analogously to polymeric iron(II) complexes. The resulting polymers are characterised by high thermal stabilities (up to 250 °C) and rather high conductivities at room temperature (10^{-5} – 10^{-3} S cm⁻¹).

The octaphenyl complex $(\text{Bu}_4\text{N})[\text{TAP}^{\text{Ph}}\text{Fe}^{\text{III}}(\text{CN})_2]^{122}$ is the only tetraazaporphin complex of this type characterised by IR and electronic absorption spectroscopy and elemental analysis. Oxidation of the Fe^{2+} ion in this complex to the Fe^{3+} ion, unlike oxidation of the corresponding phthalocyanine complexes, results in a hypsochromic rather than bathochromic shift of the Q band.

3. 'Acidic' complexes of iron phthalocyanine and its analogues

Barrett and coworkers¹⁷ were the first to prepare the so-called 'chlorine-containing' PcFe complex by heating PcFe with concentrated hydrochloric acid. This compound was also synthesised by the reaction of the PcFe μ -oxo dimer,^{6,56,135} $\text{PcFe}(\text{en})_2$ complexes,⁵⁰ where en is ethylenediamine, or the $\text{PNP}[\text{PcFe}^{\text{III}}(\text{OH})_2]$ complex^{89,129} with hydrochloric acid as well as in a direct reaction, for example, upon boiling of a mixture of anhydrous FeCl_3 with phthalonitrile in 1-chloronaphthalene.⁸⁹

Originally, a structure with the chlorine atom at the Fe^{III} atom, viz., $\text{PcFe}^{\text{III}}\text{Cl}$ (**1**), was assigned to the resulting compound.¹⁷ However, Lever⁵³ gave preference to the hydrochloride structure $\text{PcFe}^{\text{II}}\cdot\text{HCl}$ (**2**), because an attempt to sublime the resulting complex *in vacuo* resulted in the formation of PcFe and elimination of hydrogen chloride. Later, Lever, on the basis of magnetic susceptibility data, returned to the initial hypothesis that the complex has the structure of 'chlorine-containing' iron(III) phthalocyanine.⁵² Since then, the above-considered notions of the structures of these compound and analogous five-coordinate complexes with axial acido ligands X co-exist. Thus on the basis of spectral data alone (Table 11), 'acidic' complexes of iron phthalocyanine were assigned to iron(III) derivatives with the mixed-spin ($S = 5/2 - 3/2$) electronic state (structure **1**).^{89,129} Based on the chemical properties and spectral data, these complexes were alternatively considered as iron(II) derivatives with intermediate ($S = 1$) spin (structure **2**),^{6,7,56,136-138} and it was

believed that the proton is most likely localised on the pyrrolenine nitrogen atom.^{6,138}

The electronic absorption spectra of the HPcFeX complexes are characterised by the presence of a charge-transfer band (at ~ 820 – 860 nm) in the near IR region along with an intense Q band in the long-wavelength region (at ~ 660 nm). The position of this charge-transfer band depends on the nature of the ligand X (see Fig. 1, Table 11).^{56,89} The presence of the low-energy charge-transfer band in the near IR region is easily explained in the framework of both structures described above. The position of the Q band in the spectra of HPcFeX virtually coincides with those in the electronic absorption spectra of the $\text{PcFe}^{\text{II}}\text{L}_2$ (see Refs 47 and 68–77) and $\text{PcFe}^{\text{II}}\text{L}(\text{DMSO})$ ⁷⁹⁻⁸⁴ complexes and differs substantially from the position of the Q band in the electronic absorption spectra of the bisaxially coordinated iron(III) complexes $[\text{PcFe}^{\text{III}}\text{X}_2]^-$ (see Table 10).^{89,129} In the Mössbauer spectra (see Table 11) of the 'acidic' complexes, the ΔE_{Q} values are very large, which is untypical of both high- and low-spin iron(III) complexes with macrocyclic ligands.^{86,99,100,103,139} However, these values correlate well with the hypothesis that the iron ions in these complexes exist in an intermediate spin state ($S = 3/2$).^{99,100,103} The only principal fact, which is inconsistent with this suggestion, is that the asymmetry of the doublet, which is characteristic of iron(III) complexes, is absent in the Mössbauer spectra.^{100,133} At the same time, the parameters of the Mössbauer spectra of the 'acidic' complexes are similar to those of the iron(II) complexes containing macrocyclic ligands and the iron ion in the intermediate spin state ($S = 1$).^{99,100,103} The electronic absorption spectra and magnetic susceptibility data of the 'acidic' complexes are available only for unsubstituted phthalocyanines (see Table 11).^{89,129} Unlike the low-spin $[\text{PcFe}^{\text{III}}\text{X}_2]^-$ complexes whose electronic absorption spectra are typical of the d^5 electronic configuration (see Table 10),¹²⁹ most of the 'acidic' complexes either give broad lines or do not give signals at all. The spectra of solid samples differ from each other (see Table 11). Moreover, even the complexes with the same ligand X gave different spectra.¹²⁹ At the same time, the electronic absorption spectra of the analogous high-spin porphyrin complexes¹⁰⁰ and the corresponding porphyrazine complexes containing iron in the intermediate spin state (which are considered below) both in frozen matrices and in the solid state are identical and typical of axial iron(III) complexes. However, if the structure **2** is correct, the electronic absorption spectra should not be observed due to the rapid spin-lattice relaxation typical of paramagnetic iron(II) complexes.¹³² Based on the data from magnetic susceptibility (see Table 11), the 'acidic complexes' were assigned to compounds in which the central iron ions are in the mixed-spin ($S = 3/2 - 5/2$) electronic state^{89,129} because the magnetic susceptibilities differ from the spin-only values ($S = 3/2 \mu_{\text{B}} = 3.87$; $S = 5/2 \mu_{\text{B}} = 5.92$). However, the experimental values are close to those for iron(II) complexes with intermediate spin in the case of strong coupling between ground state spin and orbital angular momenta.⁵¹⁻⁵³ For example, the magnetic susceptibilities of the

^a Temperature at which the Mössbauer spectra were recorded; ^b data from different studies.

PcFe complexes, iron octaethylporphyrine and iron tetraphenylporphyrin at room temperature (3.85,^{51–53} 3.82⁵⁷ and 4.4 μ_B ,¹³⁹ respectively) are close to the μ_{eff} values for the ‘acidic’ complexes (see Table 11). The chemical behaviour of the ‘acidic’ complexes, *viz.*, the elimination of HCl and the formation of PcFe upon sublimation of the ‘chlorine-containing’ PcFe complex,⁵³ the absence of products of radical nature and hydrogen in the reaction of PcFe with HCl,^{6, 56} the formation of ‘acidic’ complexes from the μ -oxo iron(II) dimer (the form 690)^{56, 135} and the absence of redox-conversion products, indicate that the iron ions in these complexes exist, most likely, in the divalent rather than trivalent state. Moreover, the reactions of the μ -oxo PcFe(III) dimer (the form 630) with acids afforded unstable products whose electronic absorption spectra are quite different from those of the ‘acidic’ complexes.⁷

Therefore, taking into account all the above-considered facts, the structure **2** seems to be preferable. However, the unambiguous elucidation of the structures of ‘acidic’ complexes of readily soluble PcFe derivatives calls for further investigations of these compounds both by physical (primarily, electronic absorption spectroscopy and magnetic susceptibility studies) and chemical methods.

In the series of ‘acidic’ porphyrine iron complexes, octaethyl-,^{57, 140} octaphenyl-^{141, 142} and octa(ethylthio)porphyrine¹⁴³ derivatives were studied. These complexes were prepared either by the reactions of the corresponding μ -oxo dimers^{57, 141–143} or anionic dihydro complexes¹⁴³ with acids or by ligand exchange reactions.¹⁴⁰ Based on the data from magnetic susceptibilities and on the parameters of the Mössbauer and electronic absorption spectra in frozen matrices (Table 12), the octaethyl- and octaphenylporphyrine complexes were assigned to iron(III) derivatives with intermediate ($S = 3/2$) spin. This assignment is consistent with the data from X-ray diffraction analysis (see Table 12).^{57, 140} However, the chemical properties and the electronic absorption spectra of ‘acidic’ complexes of *tert*-butyl-substituted analogues⁶ can be better explained on the basis of the structure **2**. Therefore, we believe that final conclusions cannot be made.

An unusual coordination about the central atom was observed in the ‘acidic’ complex of octa(ethylthio)porphyrine.¹⁴³ According to the data from X-ray diffraction analysis, the coordination sphere about the central atom is formed by four nitrogen atoms of the macrocyclic ligand, the chloride ion and the sulfur atom of the peripheral substituent of the adjacent molecule. The different behaviour of this complex in the polycrystalline state and in solution was attributed to the differences in the electronic structure of these two states.¹⁴³ Thus it was suggested that the solid complex exists in the mixed-spin ($S = 5/2 - 1/2$) state, whereas this complex in solution was described as in an intermediate-spin state ($S = 3/2$).¹⁴³

Recently, the spectroscopic parameters of the TAP^{Et}Fe(NO) complex, which has been synthesised by reductive nitrosation of the ‘acidic’ TAP^{Et}Fe complex in the presence of 2,6-dimethylpyridine, were reported (see Table 12).¹⁴⁴ These data made it possible to assign the complex under consideration to five-coordinate iron(II) derivatives with an angular structure of the nitrosyl ligand.

IV. μ -Oxo(-nitrido, -carbido) binuclear complexes of iron phthalocyanine and its analogues

In 1965, the reversible addition of oxygen to iron(II) tetrasulfophthalocyanine (TSPcFe^{II}) in aqueous solution yielding a μ -peroxo dimeric complex was reported.¹⁴⁵

However, the structure TSPcFe^{III}X was assigned to the product of the reaction of TSPcFe^{II} ($\lambda_{\text{max}} = 670$ nm) with oxygen ($\lambda_{\text{max}} = 630$ nm), although attempts to isolate and characterise this product have failed.^{146, 147} In 1971, specimens of PcFe synthesised by different procedures were studied by Mössbauer spectroscopy and it was found that the spectra of the products obtained upon treatment of PcFe with 2-picoline in air and upon heating of PcFe in air ($\delta = 0.29$ and 0.348 mm s⁻¹, $\Delta E_Q = 0.36$ and 1.13 mm s⁻¹, respectively) differ substantially from the spectra of the initially freshly prepared PcFe ($\delta = 0.385$ mm s⁻¹, $\Delta E_Q = 2.58$ mm s⁻¹).⁹⁸ In the following, we will demonstrate

that the first two complexes described as 'other forms of PcFe'⁹⁸ are actually μ -oxo dimeric iron complexes.

More recently, in attempting to isolate Pc^IFe by chromatography, Bundina *et al.*⁵⁶ obtained an oxygen-containing compound as the major product. Its molecular weight was approximately twice as large as that of Pc^IFe and its spectral characteristics differed significantly from those reported for PcFe and its substituted analogues. Based on the spectral data and the chemical properties of chromatographically pure specimens, it was suggested that the compound under consideration had the structure of the μ -oxo dimer with an Fe—O—Fe bridge analogous to the structures of the well-studied μ -oxo dimeric porphyrin iron complexes.^{148–151} In the first study,⁵⁶ the authors considered two alternative structures for the μ -oxo dimeric PcFe complexes, *viz.*, PcFe^{III}OFe^{III}Pc (**3**) and HPcFe^{II}OFe^{II}PcH (**4**), which differ in the oxidation state of the iron atom. Based on the data from elemental analysis and IR, X-ray photoelectron and electronic absorption spectroscopy as well as on the chemical behaviour of this complex, preference was given to the structure **4**. It was suggested that the hydrogen atoms were located at the pyrrolenine nitrogen atoms of the phthalocyanine ligands.^{56, 152}

In 1979, a stable dimeric complex was prepared by the reaction of PcFe with oxygen in DMSO or DMF, and the structure of the μ -peroxo dimer PcFe^{III}OOFc^{III}Pc was assigned to the resulting compound.¹⁵³ However, thereafter this suggestion was rejected^{154, 155} based on spectroscopic data, in particular, on the IR spectra of the complex containing the ¹⁸O isotope in the μ -bridge, and the μ -oxo dimeric structure was proposed. Taking into account the results of volumetric analysis of oxygen absorption by the PcFe complex, the structure **3** with the central iron(III) ions was assigned to the μ -oxo dimer. This point of view has received support from many researchers.^{135, 156–162} At present, this view predominates in spite of the fact that it has recently come under strong criticism.^{7, 128, 163} Although μ -oxo dimeric complexes belong to one of the most stable coordination forms of PcFe, their electronic structures are still questionable. In this connection, let us consider the properties of these complexes in more detail.

The μ -oxo dimeric PcFe complex can be prepared according to the following procedures: (1) by bubbling air or oxygen through a solution of PcFe in sulfuric acid, as well as in DMSO, DMF or

other organic solvents;^{56, 154, 155} (2) by short-term boiling of a suspension of PcFe with sterically hindered aliphatic amines¹⁵⁷ or α -pyridines⁹⁸ in the medium of the amine or in organic solvents; (3) the solid-phase reaction of PcFe with oxygen with heating;⁹⁸ or (4) dimerisation of monomeric bisaxially coordinated PcFe complexes.^{89, 156} The IR spectra of the μ -oxo dimeric PcFe complex have bands at 851 and 822 cm^{−1}, which were assigned to vibrations of the Fe—O—Fe fragment.^{56, 135, 155–157} μ -Oxo dimeric Pc^RFe complexes were prepared by chromatography of the Pc^RFe complexes (using eluents which did not contain potential ligands, such as organic bases or acids)^{56, 135, 152, 163} or according to one of the above-mentioned procedures for the synthesis of the μ -oxo dimer of PcFe.

In the electronic absorption spectra of μ -oxo dimeric PcFe complexes in noncoordinating solvents, the Q and B bands are bathochromically shifted compared to their positions in the spectra of other forms of PcFe (Table 13). This behaviour is untypical of μ -oxo dimeric phthalocyanine complexes of other metals.⁶² The Q band is observed at 700 nm. In all cases, this band is broadened and has a short-wave shoulder.^{6, 7, 56, 135, 152} To explain the bathochromic shift on the basis of the theory of exciton splitting, it was assumed that the phthalocyanine ligands in these complexes are nonparallel or are shifted relative to each other (slipped-stack),¹²⁸ which is untypical of the μ -oxo dimeric iron(III) complexes.^{148, 149}

The unusual geometry of the μ -oxo dimeric PcFe complexes was confirmed by ¹H and ¹³C NMR spectroscopy. As was noted in a number of studies,^{6, 7, 56, 128} the spectra of these compounds are more complicated than those of other PcFe forms containing the μ -oxo fragment (see below) and are similar to those of μ -oxo dimeric silicon phthalocyanines.¹⁶⁴ The spectral patterns indicate that the protons of the peripheral substituents are substantially nonequivalent. This nonequivalence can be explained only on the assumption that the geometry of the μ -oxo dimeric PcFe complexes differs substantially from that typical of other μ -oxo dimeric iron complexes with macrocyclic ligands (the Fe—O—Fe angle is close to 180° and the macrocycles are parallel to each other^{148, 149}).

μ -Oxo dimeric PcFe complexes in the solid state, unlike those in solution, exist as two isomeric forms possessing different

properties.^{135, 156, 157} Dimerisation of the monomer $\text{PNP}[\text{PcFe}^{\text{III}}(\text{OH})_2]$ afforded predominantly the so-called oxo(1) isomer of the μ -oxo dimeric PcFe complex, while bubbling of air through an oxo(1) solution in sulfuric acid or short-term heating of PcFe with sterically hindered aliphatic amines or α -substituted pyridines yielded predominantly the oxo(2) isomer.^{89, 129, 156, 157} According to the data from Mössbauer spectroscopy (see Table 13), chromatographically pure specimens of readily soluble μ -oxo dimeric $\text{Pc}^{\text{R}}\text{Fe}$ complexes occur as mixtures of the oxo(1) and oxo(2) isomers, which have not been isolated in the individual state.^{56, 128, 135, 152} The parameters of the Mössbauer spectra of the μ -oxo dimeric $\text{Pc}^{\text{R}}\text{Fe}$ complexes depend only slightly on the nature of the peripheral substituents; however, the electric field gradients have negative and positive signs for the oxo(1) and oxo(2) isomers, respectively. This fact provides additional evidence for the assumption as to the difference in the geometry of the isomers.¹⁶⁵ In addition, the Mössbauer spectra of the μ -oxo dimeric $\text{Pc}^{\text{t}}\text{Fe}$ complex in frozen matrices (for example, in toluene) at 77 K have only one signal belonging to the oxo(1) isomer.⁶ The proponents of the hypothesis for the trivalent state of the central iron atoms believe that the oxo(1) isomer has an angular geometry, whereas the Fe—O—Fe fragment in the oxo(2) isomer is quasi-linear and both isomers are high-spin iron(III) complexes [in the oxo(1) and oxo(2) isomers, $S = 5/2$ for both Fe atoms].¹⁵⁷ The supporters of the concept of the divalent state suggest that the phthalocyanine ligands in the oxo(1) isomer are, most probably, in the slipped-stack orientation, whereas an angular geometry of the ligands is typical of the oxo(2) isomer. Both iron(II) ions of the latter possess intermediate spin ($S = 1$).^{128, 163} In our opinion, the results obtained in magnetic susceptibility studies and the ESR spectra of the μ -oxo dimeric PcFe oxo(1) and oxo(2) complexes are less reliable.^{135, 155–157} The magnetic susceptibilities of different specimens of the oxo(1) and oxo(2) isomers at room temperature vary from 2.19 to 2.23 μ_{B} and from 1.38 to 1.42 μ_{B} , respectively. The antiferromagnetic interaction constants J calculated from the magnetic susceptibilities are -120 and -195 cm^{-1} , respectively.^{156, 157} On the contrary, the results of measurements of the magnetic susceptibilities for ten chromatographically pure readily soluble specimens of the μ -oxo dimeric $\text{Pc}^{\text{t}}\text{Fe}$ complex, which have been synthesised independently,^{6, 56, 152} suggest the diamagnetism of this compound. The magnetic moments are no higher than 0.48 μ_{B} . Therefore, it should be admitted that specimens of the μ -oxo dimeric PcFe complexes studied in Refs 135 and 155–157 are very likely to contain substantial amounts of monomeric high-spin impurities, which introduce errors into the true values of magnetic susceptibility. This conclusion agrees well with the data from ESR and Mössbauer spectroscopy.^{156, 157, 163} The ESR spectra of powders of μ -oxo dimeric PcFe complexes at the boiling temperatures of nitrogen or helium have signals with a g factor of ~ 6 , which is characteristic of monomeric high-spin iron(III) complexes. Some specimens give additional signals with a g factor of ~ 4.3 , characteristic of monomeric complexes of iron(III) in the intermediate ($S = 3/2$) spin state.^{7, 132} The ESR spectrum of a powder of the μ -oxo dimeric $\text{Pc}^{\text{t}}\text{Fe}$ complex at 77 K has a set of lines with a g factor approximately equal to 2.¹³⁵ Under analogous conditions, very weak signals with a g factor approximating 6 were additionally observed for this compound.¹⁶³ It should be noted that all ESR data were obtained only for powdered samples. However, as has been mentioned many times,^{128, 166} the ESR spectra of the phthalocyanine complexes in the solid state should be considered with caution. Thus signals with g factors close to 2 were observed for many diamagnetic phthalocyanines in the solid phase.¹⁶⁶ Moreover, the lack of reliable data of ESR spectroscopy, in particular, for compounds containing the Fe—O—Fe fragment, was emphasised in a recent review¹⁴⁹ devoted to the synthesis and properties of binuclear iron complexes. Actually, some researchers believed^{163, 167} that solutions of the μ -oxo dimeric $\text{Pc}^{\text{t}}\text{Fe}$ complex are inactive for ESR spectroscopy both at room temperature and at 77 K.

The reaction of μ -oxo dimers of PcFe with nitrogen-containing compounds afforded μ -oxo dimeric complexes in the first stage. According to the hypotheses for the structures of the initial μ -oxo dimers, the structures $\text{LPcFe}^{\text{III}}\text{OFe}^{\text{III}}\text{PcL}$ (**5**),^{168, 169} $\text{H}_2(\text{LPcFe}^{\text{II}}\text{OFe}^{\text{II}}\text{PcL})$ or $(\text{LH})_2[\text{PcFe}^{\text{II}}\text{OFe}^{\text{II}}\text{Pc}]$ (**6**)^{6, 7, 56, 128, 152} were assigned to the above-mentioned complexes. Complete X-ray diffraction analysis of one of the complexes of this type ($\text{L} = \text{MeIm}$) demonstrated that the phthalocyanine ligands in this compound are located parallel to each other.⁴⁵ The Fe—N(MeIm) distance (2.039 Å) virtually coincides with that in the $\text{PcFe}(4\text{-MeC}_5\text{H}_4\text{N})_2$ complex (2.04 Å).⁴⁴ The Fe—O—Fe angle is 178.9° .⁴⁵ The structure of the axially coordinated μ -oxo dimeric PcFe complex exhibits two major distinctions from the structures of the well-characterised μ -oxo dimeric complexes of iron porphyrins without axial ligands:^{148–151} (1) central iron atoms lie virtually in the plane of the phthalocyanine ligand, which is in marked contrast to the structures of the porphyrin analogues in which the high-spin iron(III) ions deviate from the plane of the ligand by 0.3–0.5 Å;^{100, 148, 149} (2) coordination polyhedra about the central atoms are tetragonal bipyramids, whereas the coordination polyhedra in all μ -oxo dimeric iron complexes with macrocyclic ligands are tetragonal pyramids.^{148, 149} In studies^{45, 168} in which the structure **5** was assigned to the axially coordinated μ -dimeric PcFe complex, the first anomaly was attributed to the fact that this complex contains low-spin ($S = 1/2$; $S = 1/2$) rather than high-spin iron(III) ions.¹⁶⁸ The unusual coordination polyhedron was assigned to the 'unique' properties of this class of compounds.⁴⁵ However, it was noted¹²⁸ that the above-mentioned anomalies can be readily explained assuming that the central iron atoms in the μ -oxo dimeric PcFe complexes exist in oxidation state +2 (the structure **6**). Their electronic absorption spectra are typical of μ -oxo dimeric PcFe complexes with the parallel arrangement of the phthalocyanine ligands.⁶² Thus the Q band ($\lambda_{\text{max}} \approx 627 \text{ nm}$) is shifted hypsochromically compared to the Q band of monomeric PcFe complexes and its position depends only slightly on the nature of the axial ligand. The data on magnetic susceptibility and the parameters of the Mössbauer spectra of these compounds are given in Table 14. Note once again that all specimens occur (according to the data from Mössbauer spectroscopy) as mixtures of different coordination forms of PcFe,^{45, 168, 169} and, consequently, magnetic susceptibility data must be considered with caution. However, the parameters of the Mössbauer spectra most probably correspond to low-spin iron(II) complexes (see Tables 2 and 5) rather than to low-spin iron(III) complexes (see Table 10). The electric field gradient of the μ -oxo dimeric PcFe complex, which is axially coordinated by 4-MeC₅H₄N, has a positive sign.¹³⁴ Comparison of the Mössbauer spectra of the form 627 with the spectra of the oxo(1) and oxo(2) isomers suggests that the oxo(2) isomer and the axially coordinated μ -oxo dimeric complex are identical in geometry.

The chemical behaviour of the μ -oxo dimeric PcFe complexes was studied in detail with the aim of determining the valence state of the central iron atoms.^{6, 7, 56, 128, 152} The reactions of the initial μ -oxo dimeric form of both unsubstituted and substituted PcFe (the form 690) with nitrogen-containing heterocyclic com-

pounds^{6, 7, 128, 152, 168, 169} or isocyanides¹³⁵ afforded complexes with composition $\text{PcFe}^{\text{II}}\text{L}_2$ as the final products. On the assumption that the form 690 has the structure **3**, this reaction should be a redox process; however, oxidation products have never been detected. Therefore, the structure **4** is more probable for the form 690. The reactions of the form 690 of the $\text{Pc}^{\text{I}}\text{Fe}$ complex or its axially coordinated analogue (the form 627) with cyanide anions in organic solvents afforded the well-known $\text{Na}_2[\text{Pc}^{\text{I}}\text{Fe}(\text{CN})_2]$ complex.^{128, 167} The electronic absorption spectra for these reactions have distinct isosbestic points.

Data on the oxidation of triphenylphosphine with the μ -oxo dimer of PcFe (the form 690) under an inert atmosphere have been published.¹⁷⁰

The formation of Ph_3PO suggests the trivalent state of the central iron atoms in the initial compound. These results are in contradiction with those obtained in the study of the reaction of the form 690 with diphenylpicrylhydrazine under oxygen-free conditions.⁶ Thus it was found that the oxidation of diphenylpicrylhydrazine under strictly oxygen-free conditions did not occur at all. However, when a controlled amount of oxygen was introduced into a reactor, oxidation catalysed by the metal complex occurred. Moreover, it was demonstrated that the reaction of the form 690 with quinoline (which apparently contained an impurity of isoquinoline) yielded water (in an equimolar amount with respect to the initial form 690).^{6, 152}

This behaviour is consistent with the structure **4** for the form 690. However, it was mentioned^{154, 162} that when μ -oxo dimeric PcFe complexes were prepared by the reactions with O_2 , the oxygen was consumed in a ratio $\text{O}_2 : \text{PcFe} = 1 : 4$, and the only reaction product, *viz.*, the μ -oxo dimer, was formed in quantitative yield. This fact contradicts the structure $[\text{HPc}^{\text{R}}\text{Fe}]_2\text{O}$ (**4**), which can be formed from $\text{Pc}^{\text{R}}\text{Fe}$ and O_2 if a source of hydrogen atoms exists.

With the aim of refining the structure of the form 690, the reaction of $\text{Pc}^{\text{I}}\text{Fe}$ with oxygen in noncoordinating solvents (benzene and cyclohexane) was studied. It was found that: (1) the amount of oxygen consumed per mole of $\text{Pc}^{\text{I}}\text{Fe}$ introduced into the reaction depends on the concentration of the latter, and the $\text{O}_2 : \text{Pc}^{\text{I}}\text{Fe}$ ratio changes from 1 : 5.0 to 1 : 2.7 in the concentration range of $6.3 \times 10^{-3} - 1.1 \times 10^{-1} \text{ mol litre}^{-1}$; (2) the μ -oxo dimer is the major but not the only reaction product; the yield of this dimer varies from 78% to 95%. It was found that the reagents were consumed in side reactions, including oxidative destruction of the macrocycle by oxygen, which is strongly activated due to coordination in the complex with $\text{Pc}^{\text{I}}\text{Fe}$. Therefore, side oxidation reactions of the phthalocyanine macrocycle, substituents in this ring or other substrates can serve as a source of protons for the formation of the form 690.

The formation of the form 690 from the iron(III) derivative, *viz.*, $[\text{PcFe}(\text{OH})_2]^-$,^{128, 156} also calls for explanation. In our opinion, this process is accompanied by reduction of the iron atom with the hydroxide anion, which is one of the strongest reducing agents for PcFe complexes.¹⁷¹

Oxidation of the form 690 was examined for the first time in the study.⁷ The μ -oxo dimeric $\text{Pc}^{\text{I}}\text{Fe}$ complex (hereinafter, the form 630), which was prepared by the reactions of the form 690 with iodosobenzene or peracetic acid, was characterised by electronic absorption spectroscopy ($\lambda_{\text{max}} = 630 \text{ nm}$) and Mössbauer spectroscopy ($\delta = 0.58 \text{ mm s}^{-1}$, $\Delta E_{\text{Q}} = 0.34 \text{ mm s}^{-1}$ at 80 K). Later on, a procedure for the preparation of this compound was improved.¹²⁸ Thus this complex was prepared in virtually quantitative yield by the reaction of the form 690 with cumene hydroperoxide generated *in situ*. These authors were also the first to analyse the NMR spectra of the form 630. The reaction of the form 630 with cyanide anions afforded the known low-spin iron(III) complex, *viz.*, $\text{Na}[\text{Pc}^{\text{I}}\text{Fe}(\text{CN})_2]$,¹²⁸ which can be also

prepared by oxidation of the cyanide complex $\text{Na}_2[\text{Pc}^{\text{I}}\text{Fe}(\text{CN})_2]$ with bromine⁵⁵ or cumene hydroperoxide.¹²⁸ The reaction of the form 630 with hydrogen chloride yielded derivatives of iron(II) and (formally) iron(IV), *viz.*, hydrochloride $\text{Pc}^{\text{I}}\text{Fe} \cdot \text{HCl}$ and the radical cation $\text{Pc}^+ \cdot \text{FeCl}_2$, respectively.⁷ All the aforesaid provides evidence for the trivalent state of the central iron atoms in the form 630. Therefore, on the basis of the spectral data and the chemical properties of the μ -oxo dimeric PcFe complexes, the forms 690 and 627 were characterised as $\text{PcFe}(\text{II})$ derivatives and the form 630 was characterised as the μ -oxo dimer of iron(III) phthalocyanine.^{6, 7, 56, 128, 152, 163}

The reactions of PcFe with azides afforded μ -nitride PcFe complexes of the general formula $\text{PcFe}^{+3.5}\text{NFe}^{+3.5}\text{Pc}$ (Table 15).^{172–174} These compounds can be oxidised electrochemically or chemically to form complexes with composition $(\text{PcFe}^{+4}\text{NFe}^{+4}\text{Pc})^+ \text{X}^-$ (see Table 15).¹⁷² The structure of one of the resulting compounds, *viz.*, $[(\text{PcFe})_2\text{N}]\text{Br}$, was established by X-ray diffraction analysis.¹⁷⁵

Table 15. Parameters of Mössbauer spectra of the μ -nitrido and μ -carbido dimeric $\text{Pc}^{\text{R}}\text{Fe}$ complexes.^{172, 173}

Note. The spectra were recorded at 77 K relative to metallic iron.

The reaction of PcFe with tetraiodomethane in the presence of reducing agents, such as sodium dithionite or sodium borohydride, afforded μ -carbide PcFe complexes of the general formula $\text{PcFe}^{\text{IV}}\text{CFe}^{\text{IV}}\text{Pc}$ (see Table 15).^{176–179} This synthetic procedure has been improved quite recently, *viz.*, the reaction of $[\text{PcFe}^{\text{III}}(\text{OH})_2]^-$ with dichlorocarbene generated *in situ* was used.^{171, 180} Unfortunately, the poor quality of crystals of the $[(\text{MeIm})\text{PcFe}]_2\text{C}$ complex did not allow the researchers to perform a complete structure analysis of this complex.¹⁷⁸ However, the values of selected bond lengths and bond angles were determined. In particular, it was demonstrated that two phthalocyanine ligands in the complex are virtually parallel to each other (the $\text{Fe}-\text{C}-\text{Fe}$ angle is 178°).

Heterobimetallic oxo dimeric complexes of the PCrOFcPc type, where P is the dianion of α -substituted porphyrin, were synthesised and their properties were studied.¹⁸¹ These compounds were prepared by the reactions of $\text{PCr}^{\text{IV}}=\text{O}$ with PcFe . The synthesis, structures and properties of the μ -nitride heterodimer $(\text{TPP})\text{Fe}^{+3.5}\text{NFe}^{+3.5}\text{Pc}$, where TPP is tetraphenylporphin, as well as of its oxidised forms were described.¹⁸²

Among μ -oxo dimeric complexes of iron porphyrines, derivatives of tetra-*tert*-butyl-,⁶ octaphenyl-,¹⁴¹ octaethyl-⁵⁷ and octa(ethylthio)-substituted¹⁴³ porphyrines are presently available. All these compounds were characterised by electronic, IR and NMR spectra. The reaction of the pyridine adduct of iron octaphenylporphyrine with perchloric acid followed by the addition of HN_3 afforded the corresponding μ -nitride dimeric complex, which was characterised by electronic absorption, IR, Mössbauer and ESR spectra.¹⁸³ The pyridine monoadduct of this

complex formed in frozen matrices adds reversibly one oxygen molecule per molecule of the initial complex.

Recently, the synthesis and selected properties of the heterobinuclear complex $\text{TAP}^{\text{Ph}}\text{Mn}=\text{NFeTAP}^{\text{Ph}}$ were reported.¹⁸⁴ However, the data from electronic absorption spectroscopy and mass spectrometry (primarily, the absence of the molecular ion and the $\text{TAP}^{\text{Ph}}\text{FeN}$ fragment) and the lack of Mössbauer spectra require that the suggested structure be considered with particular caution.

V. Some features of coordination chemistry of substituted iron phthalocyanines and their analogues

The interconversions of the coordination forms of iron phthalocyanines are shown in Scheme 2. As expected, the peripheral substituents in the macrocycle often break down these general regularities. Thus when bulky substituents (for example, the 2,4,6-trimethylphenyl substituents) were introduced at the α positions of the macrocycle, the μ -oxo dimeric Fe(II) and Fe(III) complexes were not formed at all due to steric hindrances caused by the substituents.^{7,8} In this case (under conditions of formation of μ -oxo dimeric complexes), the corresponding monomeric hydroxo complexes $\text{HPc}^{\text{R}}\text{Fe}(\text{OH})$ can be isolated. In an alkaline medium, the latter are converted into the corresponding oxoferryl derivatives, which undergo polymerisation upon prolonged storage.^{7,8}

Scheme 2

The effect of the electronic properties of substituents on the behaviour of iron phthalocyanines is generally manifested only in the relative stabilities of particular forms and in the positions of the bands in the electronic absorption spectra. The qualitative characteristic features of this effect can be observed only in special cases. For example, due to the presence of eight electron-withdrawing substituents, iron (3,5)-octakisnitrophthalocyanine^{7,8} reacts with nitrogen bases to give initially the $\text{PcFe}^{\text{II}}\text{L}_2$ complex, which is converted into the isoelectronic form $\text{Pc}^{3-}\text{Fe}^{\text{III}}\text{L}_2$ containing the stable phthalocyanine radical anion. Due to the presence of four SPH substituents in iron tetrakis(phenylthio)phthalocyanine, the iron ion has the $^3A_{2g}[(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^2]$ electronic configuration²⁷ rather than the $^3E_g[(d_{xy})^2(d_{xz},d_{yz})^3(d_{z^2})^1]$ configuration typical of $\text{Pc}^{\text{R}}\text{Fe}$. When eight electron-donating alkoxy groups are introduced into PcFe at positions adjacent to the macrocycle (at positions 1 and 4), the central iron atom is initially subjected to electrochemical oxidation, whereas the phthalocyanine ligands are oxidised in the complexes containing other substituents in the macrocycle.¹⁰⁹

VI. Major fields of application of iron phthalocyanines and their analogues

High catalytic activity of PcFe in decomposition of peroxides and in oxidation of some classes of organic compounds had been discovered by Cook^{185–187} back in the late 1930s. The use of iron phthalocyanines in catalysis has been expanded substantially since these years.^{3,188} Thus these compounds were used as homoge-

neous and heterogeneous catalysts of epoxidation of alkenes,^{188,189} oxidation of hydrocarbons to alcohols, aldehydes, quinones and ketones^{190–194} and oxidation of arylamines,¹⁹⁵ phosphines,^{162,196} thiols^{197–199} and conjugated aromatic systems.²⁰⁰ Electrodes modified with iron phthalocyanines and their analogues were used for electrooxidation of thiols,¹⁹⁷ electroreduction of molecular nitrogen to ammonia^{201,202} and electroreduction of carbon dioxide,²⁰³ sulfur dioxide,²⁰⁴ nitrogen oxides²⁰⁵ and molecular oxygen.^{206–208}

The chemo- and electrochromic properties of iron phthalocyanines and their analogues as well as variations in the conducting properties of these complexes depending on the medium made it possible to use these compounds in sensors for halogens,²⁰⁹ nitrogen oxides,²¹⁰ oxygen²¹¹ and aldehydes.²¹² Photochemical reactions of PcFe are well studied, which allows the use of this compound for the preparation of photosensitive materials (including those operating in the near IR region²¹³), photoconducting devices,²¹⁴ photosensitive inks²¹⁵ and materials for optical data recording and storage^{216,217} as well as for the production of high-contrast photographic materials.²¹⁸

Since axially coordinated complexes of iron phthalocyanines are readily available compounds, highly sensitive and selective membranes for gas separation²¹⁹ and food storage²²⁰ were constructed on the basis of these complexes. The use of cathodes modified with PcFe and its analogues in lithium cells with aggressive electrolytes, such as thionyl chloride and sulfur dioxide, made it possible to improve substantially their discharge characteristics.^{221–225} Intercalation of iron phthalocyanine into the structures of inorganic oxides leads to the appearance of magnetic properties in the resulting materials.²²⁶

In the reactions with reducing agents, such as ascorbic acid, catalysed by iron phthalocyanines, different so-called active oxygen forms (primarily, oxygen-centred radicals) are generated. This made it possible to initiate studies of complexes of iron phthalocyanines and their conjugates with proteins, DNA and RNA as potential drugs in catalytic (dark) therapy of cancer.^{21,227,228} In addition, high antihistamine and antiserotonin activities of PcFe derivatives were observed in a number of studies.^{5,229} The use of these compounds as deodorising agents is based on their high oxidase activity.²³⁰ Semiconducting properties of iron phthalocyanines and their analogues have received little use.^{9,13} Selective axial coordination of iron phthalocyanine to nitrogen-containing compounds allows one to solve a number of analytical problems by NMR spectroscopy.^{105–108}

I. Introduction	347
II. Modelling of macromolecules	350
III. Fractal characteristics of macromolecules	356
IV. Conclusion	364

Abstract. Data on the fractal forms of macromolecules, the existence of which is predetermined by thermodynamic nonequilibrium and by the presence of deterministic order, are considered. The limitations of the concept of polymer fractal (macromolecular coil), of the Vilgis concept, and of the possibility of modelling in terms of the percolation theory and diffusion-limited irreversible aggregation are discussed. It is noted that not only macromolecular coils but also the segments of macromolecules between topological fixing points (cross-links, entanglements) are stochastic fractals; this is confirmed by the model of structure formation in a network polymer. The bibliography includes 141 references.

I. Introduction

The theory of fractals and its application to physical and chemical processes has been vigorously developing in recent years.^{1–8} To facilitate the understanding of the results presented in this review, we shall introduce some notions and definitions and consider briefly the grounds for applying the principles of synergetics and fractal analysis to the description of structures and properties of polymers.

Fractals are self-similar objects invariant with respect to local dilatations, *i.e.* objects that reproduce the same shape during observation at various magnifications. The concept of fractals as self-similar ensembles was introduced by Mandelbrot,¹ who defined a fractal as a set for which the Hausdorff–Besicovitch dimension always exceeds the topological dimension. The fractal dimension D of an object inserted in a d -dimensional Euclidean space varies from 1 to d . Fractal objects are the natural filling of the gap between known Euclidean objects with integer dimensions 0, 1, 2, 3... The majority of naturally existing objects proved to be fractal, which is the main reason for the vigorous development of the methods of fractal analysis.

According to the Family classification,⁹ fractal objects can be divided into two main types, namely, deterministic and statistical objects. Deterministic fractals are self-similar objects which can be precisely constructed on the basis of several fundamental laws.

Typical examples of these fractals are the Cantor set ('dust'), the Koch curve, the Sierpinski gasket, the Vicsek snowflake, *etc.* Two properties of deterministic fractals are most important, namely, the possibility of exact calculation of the fractal dimension and the infinite range of self-similarity ($-\infty$; $+\infty$). Since a line, a plane, or a volume can be divided into an infinite number of fragments in different ways, it is possible to construct an infinite number of deterministic fractals with different fractal dimensions. Therefore, deterministic fractals cannot be classified without introducing other parameters, apart from the fractal dimension.

Statistical fractals are generated by disordered (random) processes. An element of disorder is typical of most real physical phenomena and objects. The fact that disorder, *i.e.* the absence of any spatial correlation, is a sufficient condition for the formation of fractals was first noted by Mandelbrot.¹ A typical example of this type of fractal is the random-walk path. However, real physical systems are often inadequately described by purely statistical models. Among other reasons, this is due to the effect of excluded volume. The essence of this effect lies in the geometric restriction which forbids two different elements of a system to occupy the same volume in space. This restriction is to be taken into account in the corresponding modelling.^{10,11} The best-known examples of this type of models are self-avoiding random walk, 'lattice animals' and statistical percolation.

In a definite range of scales, fractals have different topological structures depending on the maximum number of elements connected with the given element of the system. If each element can be connected to not more than two other elements, the resulting structure has no branching. By analogy with linear polymers, Family⁹ has called these types of fractals linear fractals. If branching does occur, the resulting fractal has a framework structure; these types of fractals are referred to as branched fractals.

The microstructure of polymers can possess a high degree of self-ordering of either natural or artificial origin;¹² this represents one extreme case. The other extreme case is represented by chaos, which is the antithesis of order. Fractal analysis considers intermediate situations, *i.e.* those located between full order and full chaos. As a rule, these systems are obtained under conditions far from thermodynamic equilibrium; they fill the gap between periodic structures and fully disordered systems.¹³ In other words, fractal structures should possess a certain level of intermediate order. Therefore, when studying thermodynamically nonequilibrium solids (the class to which polymers normally belong¹⁴) possessing a local order,¹⁵ it is important to consider the relationship between the level of local order and the degree of fractality.

At present, it is beyond doubt that the approximation of a real polymer by a continuous medium is inadequate.¹⁶ Even during the synthesis of polymers, numerous micro-, meso- and macro-defects arise; during performance, they can be further developed. Moreover, it has been found empirically that even those media that are initially homogeneous acquire upon deformation a hierarchical block structure, the characteristic dimensions of which L_i obey, with rather high accuracy, the relation

$$A_i = \frac{L_{i+1}}{L_i} = \text{const},$$

where A_i is the automodelling coefficient, $i = 0, 1, 2, \dots$ ^{3, 17, 18}

An important characteristic of structural elements of a solid is Euclidean dimension d , which can take on the following values: $d = 0$ implies point defects, $d = 1$ corresponds to linear defects (dislocations), $d = 2$ means planar defects (grain boundaries, twins, etc.), and $d = 3$ describes three-dimensional structures. The Euclidean dimension can characterise highly ordered symmetrical microstructures which do not often arise even in materials produced under quasi-equilibrium conditions. Nonequilibrium systems produced under essentially nonequilibrium conditions, which represent a sort of casts of dynamic dissipative structures, cannot at all be adequately described in terms of classical methods of metallography or radiography.^{17–21} This is even more so for solid (vitreous) polymers, which are, by definition, thermodynamically nonequilibrium systems. Indeed, the atomic structure of nonequilibrium materials can possess a quasicrystalline order, characterised by five-, seven-, thirteen- or higher-fold elements of symmetry²¹ forbidden by the Brouwer theorem, which underlies the classical techniques of X-ray diffraction analysis. Moreover, numerous fractographical^{4, 17, 21} and geophysical¹⁸ studies have revealed fractality of the structures of many materials and essentially non-Euclidean geometry of the deformation and the fracture of solids. Therefore, the traditional methods of the mechanics of continua, which are based on the assumption of homeomorphism of deformations, regarded as imaging of the body being deformed to the Euclidean space, are unable to describe adequately the rheological behaviour and fracture of real materials, in particular, polymers.

A significant breakthrough in tackling this problem is associated with the introduction into physicochemical analysis practice of the ideas and methods of synergetics[†] and fractal analysis.^{3, 5, 6, 8, 20, 21} In particular, it was shown that chaotic systems (amorphous phases, fractured surfaces, etc.) formed under nonequilibrium conditions which are totally disordered at first glance, actually display unusual elements of order.^{2, 20} Whereas crystals possess a certain symmetry and translational invariance, nonequilibrium systems can possess chirality even if they have no quasicrystalline structure³ and, what is the most important, these systems are scale invariant in a definite range of self-similarity.^{2, 3} Self-similarity is characterised quantitatively by the so-called Renyi dimension d_q . Unlike the topological dimension, it can be both an integer and a fraction¹ and is defined by the relations

$$d_q = \begin{cases} \lim_{\varepsilon \rightarrow \infty} \left[\frac{\ln \sum_{i=1}^M P_i^q(\varepsilon)}{(1-q)\ln \varepsilon} \right], & q \neq 1, \\ \lim_{\varepsilon \rightarrow \infty} \left[\frac{\ln \sum_{i=1}^M P_i(\varepsilon) \ln P_i(\varepsilon)}{\ln \varepsilon} \right], & q = 1, \end{cases}$$

where M is the minimum number of d -meric boxes with side ε needed to cover all the elements of a structure, $P_i(\varepsilon)$ is the

probability that a point of the structure belongs to an i th element of the bulk coverage ε^d , and q is the parameter of transformation of the measure ('magnification parameter').

For Euclidean objects (smooth curves or regular lattices in a plane or in a bulk, etc.), the following identity holds:¹⁶

$$d_q \equiv d, \text{ where } -\infty < q < \infty.$$

In the case of regular mathematical fractals such as the Cantor set, the Koch curves and Sierpinski gaskets constructed by recurrent procedures, the Renyi dimension d_q does not depend on q but¹⁶

$$d_q = d_H = \text{const} < d, \text{ } -\infty < q < \infty,$$

where d_H is the Hausdorff–Besicovitch dimension (Hausdorff dimension). According to the mathematical definition,⁴ the Hausdorff dimension d_H is a local characteristic of a set in the range of scales chosen, which can be covered by 'spheres' not necessarily having identical diameters, provided that the diameter of each sphere is smaller than a chosen diameter. The fractal dimension of the structure of a macromolecule d_f can be determined physically in the range of scales in which the structure elements are self-similar, i.e. when they are fractals. Since the ranges of d_f and d_H coincide, the $d_f = d_H$ is referred to as the fractal (Hausdorff) dimension of a macromolecule.

Natural fractals such as clouds, polymers, aerogels, porous media, dendrites, colloidal aggregates, cracks, fractured surfaces of solids, etc., possess only statistical self-similarity, which, furthermore, takes place only in a restricted range of sizes in space.^{1–4, 16} It has been shown experimentally for solid polymers²² that this range is from several angstroms to several tens of angstroms.

The relationship between the level of local order and the degree of fractality of disordered solids can be described using general mathematical terms.³ In particular, as regards the structure of solid polymers, it is noteworthy that the majority of researchers take for granted that segment-size structural associates are formed in polymers, although the particular type of packing in these associates is still debated.^{15, 23} It should be emphasised that the view on the amorphous state as being totally disordered is incorrect. According to the Ramsay theorem,³ any rather great number $i > R(i, j)$ of points or objects (in this particular case, structural elements) contain necessarily a highly ordered subsystem of $N_j \leq R(i, j)$ elements. Thus, no totally disordered systems (structures) exist. It can be shown in a similar way that any structure consisting of N elements, where $N_j > B_N(j)$, is a set comprising a finite number $k \leq j$ of self-similar structures embedded into one another and having, in the general case, different Hausdorff dimensions. This means that, irrespective of its physical nature, any system consisting of a relatively great number of elements is a multifractal (in a special case, monofractal) characterised by a spectrum of Renyi dimensions d_q , $q = -\infty$ to ∞ .³ The tendency of condensed systems to self-organisation into scale invariant multifractal forms is a consequence of fundamental principles of thermodynamics of open systems and d_q values are determined by the competition between short- and long-range interatomic interactions, which stipulate the volume compressibility and the shear rigidity of solids, respectively.²⁴ Since the physicochemical properties of polymers depend appreciably on the topology of the structure, the real polymer structures can be studied using the results of physical and mechanical measurements.^{25, 26}

Yet another important property of fractals which distinguishes them from traditional Euclidean objects is that at least three dimensions have to be determined, namely, d , the dimension of the enveloping Euclidean space, d_f , the fractal (Hausdorff) dimension, and d_s , the spectral (fracton) dimension, which characterises the object connectivity. [For Euclidean spaces, $d = d_f = d_s$; this allows Euclidean objects to be regarded as a specific ('degenerate') case of fractal objects. Below we shall repeatedly encounter this statement.]²⁷ This means that two

[†]Synergetics is an interdisciplinary field of knowledge dealing with identification of the general features of the processes of formation, stability and destruction of ordered time and space patterns in complex nonequilibrium systems of diverse natures.

fractal dimensions, d_f and d_s , are needed to describe the structure of a fractal object (for example, a polymer) even when the d value is fixed. This situation corresponds to the statement of nonequilibrium thermodynamics according to which at least two parameters of order are required to describe thermodynamically nonequilibrium solids (polymers), for which the Prigogine–Defay criterion is not met.^{28, 29}

In conclusion, we consider the relationship between the characteristics of percolation and fractal clusters. First of all, note that a percolation cluster near the percolation threshold is a fractal with a dimension of ~ 2.5 (for $d = 3$).^{7, 30, 31} This value can be easily derived from the known relationship between d and the critical percolation indices β and ν .^{9, 30} The relationships between the critical percolation indices β , ν and t and fractal dimension of a percolation cluster d_f have been reported⁷

$$\beta = \frac{1}{d_f}, \nu = \frac{2}{d_f}, t = \frac{4}{d_f}.$$

The critical indices estimated from these relations fall into the admissible ranges of variation — $\beta = 0.39–0.40$, $\nu = 0.8–0.9$, and $t = 1.6–1.8$, determined in terms of the percolation model for three-dimensional systems. The researchers⁷ noted that not only numerical values but also the meanings of these values coincide. Thus the index β characterises the chain structure of a percolation cluster. The $1/d_f$ value, which serves as the index of the first subset of the fractal percolation cluster in the model considered,⁷ also determines the chain structure of the cluster. The index ν is related to the cellular texture of the percolation cluster. The $2/d_f$ index of the second subset of the fractal percolation cluster is also associated with the cellular structure. By analogy, the index t defines the large-cellular skeleton of the fractal percolation cluster.[‡] Thus, these critical indices are universal and significant for analysis of complex systems, the behaviour of which can be interpreted in terms of the percolation theory.

It has been noted above that the structures and properties of polymers are studied using the principles of synergetics and methods of fractal analysis. This is based on several prerequisites. Firstly, amorphous glassy polymers have thermodynamically nonequilibrium structure.³² Schäfer and Keefer (see Ref. 10, p. 62) showed that fractal structures are formed in nonequilibrium processes. Therefore, there is good reason to believe that there are fractal structures in glassy polymers and that they can be described using the methods of synergetics. These assumptions have been repeatedly confirmed by experiments.^{32–39}

For example, the low-frequency region of the spectra of inelastic light scattering of amorphous polymers is a broad structureless plateau.²² This is due to the fractal structure of polymers on small linear scales.^{22, 35}

Fractal objects are characterised by the following relation between the mass M (or density ρ) and the linear scale of measurement L :³

$$M(L) \propto L^{d_m}, \quad (1)$$

where d_m is the mass scaling index.

Unlike mathematical fractals, real fractals (including polymers) have two natural scale lengths, $L_{\min}$ and $L_{\max}$ (Fig. 1); for lengths outside this range, the object is not a fractal.³ The lower limit $L_{\min}$ is related to the finite size of structural elements, while the upper limit $L_{\max}$ is associated with the tending to the limit of d_f . It has been found experimentally for polymers^{22, 35, 40} that $L_{\min}$ has an order of several angstroms and $L_{\max}$ is about several tens of angstroms. It is noteworthy that the same range of existence of a local order is typical of the cluster model in which the size (length)

Figure 1. Density ρ vs. the length scale L of the real fractal. The range $L_{\min}–L_{\max}$ is the region of existence of the fractal.³

of a statistic segment l_{st} is the lower limit and the distance between the clusters R_{cl} is the upper limit.

It often turns out in studies of polymers that strictly derived relations describe adequately the behaviour of rubbers (*i.e.*, polymers at temperatures above the glass transition temperature T_g) but do not hold for the vitreous state. This is explained, first of all, by the sharp decrease in the mobility of chains below T_g or by ‘freezing’ of the structure.⁴¹ Strictly speaking, there is no fundamental difference between the molecular structure above and below T_g ; in both cases, the structure is formed by long-chain macromolecules. They differ in the fact that the thermodynamically unstable state of the polymer existing below T_g is replaced by a quasi-equilibrium state above T_g . Within the framework of fractal analysis, this means that the polymer structure ceases to be a fractal at $T \geq T_g$ and becomes Euclidean body (or, at least, a fairly close approximation). As noted by Flory,⁴² the ability to withstand severe deformations and restore entirely the initial characteristics when the stress has been relieved is a property exhibited, under appropriate conditions, by almost any polymer consisting of long-chain macromolecules. This feature is also manifested to some degree beyond the temperature range in which the ‘rubber elasticity’ phenomenon is observed. In other words, the macromolecular ‘essence’ of the polymer is more significant than the state in which the polymer occurs. Therefore, the use of the real (fractal) dimension of the object in the relations derived for rubbers⁴² is expected to provide fairly accurate results when applied to vitreous polymers.

Secondly, polymers are known to possess multilevel structures (molecular, topological, supermolecular, and floccular or block levels), the elements of which are interconnected.^{42, 43} In addition, an external action on a polymer can induce the formation of new (secondary) structural elements — cracks, fractured surfaces, plastic flow regions, *etc.* These primary and secondary structural elements as well as the processes forming them are characterised by miscellaneous parameters; therefore, only empirical correlations have been obtained, at best, between these parameters. If each of the above-mentioned elements (processes) is described by a standard parameter, for example, fractal dimension, one can derive analytical equations relating them to one another and containing no adjustable parameters. This is very significant for the computer synthesis of structure and for the prediction of properties and behaviour of polymeric materials during performance. Note that fractal analysis has been employed successfully to describe the phenomena of rubber elasticity^{16, 44, 45} and fluidity.^{25, 46–48}

Thirdly, legitimate application of these methods requires the use of a physically justified number of parameters describing the polymer structure. In this sense, the Euclidean and fractal objects are fundamentally different: the former require only one space dimension (Euclidean), whereas fractal objects (spaces) require not less than three dimensions.

Yet another important aspect is the change in the fractal dimension of polymers when they are simulated on fractal rather than Euclidean lattices. This fact is also important from the

‡ The relationship between the critical percolation indices and the fractal dimension of the percolation cluster for three-dimensional systems and examples of determination of these values for filled polymers are considered in more detail in the book cited.⁷

practical standpoint for multicomponent polymer systems. The introduction of a dispersed filler into a polymer matrix results in structure ‘perturbation’; in terms of fractal analysis, this is expressed as an increase in the fractal dimension of this structure. As shown by Novikov *et al.*,²⁵ the particles of a dispersed filler form in the polymer matrix a skeleton which possesses fractal (in the general case, multifractal) properties and has a fractal dimension. Thus, the formation of the structure of the polymer matrix in a filled polymer takes place in a fractal rather than Euclidean space; this accounts for the structure modifications of the polymer matrix in composites.

Proceeding from general statements, note that the term ‘multifractal’ can be understood in two ways as applied to polymers. It is shown below that the fractal dimension of a chain section between points of chemical cross-linking (or between physical entanglements) D is determined by the molecular mass of this section M_s (M_{en}) or by the cross-linking density v_s (or density of the entanglement network v_{en}). The M_s (M_{en}) value has a definite distribution;²⁷ hence, the dimension D would be characterised by a similar distribution.⁴⁹ Since the parameter D is uniquely related to the fractal dimension d_f of the supermolecular structure, d_f would be also characterised by a certain distribution. In other words, we are dealing with the distribution of fractal dimensions or multifractals. In addition, all the primary and secondary structural elements mentioned above are also multifractals; therefore, a polymer can be represented as a combination of elements having different weights, *i.e.*, again as a multifractal. Below we shall use averaged values of only the fractal dimensions of particular elements, at least as long as this approximation is useful for the understanding of the physical essence of the problem in question but does not decrease substantially the accuracy of estimates. Thus, the purpose of this review is to describe systematically the results obtained within the framework of fractal formalism and concerned with the studies of structure and properties of polymer macromolecules (linear, cross-linked, amorphous, *etc.*).

II. Modelling of macromolecules

1. Fractal dimension

The complexity of the polymer structure is reflected in the large number of dimensions needed to describe it. Alexander and Orbach²⁸ proposed the use of spectral or fracton dimension d_s for the description of the density of states on a fractal. The necessity of introducing d_s is due to the fact that the fractal dimension defined by Eqn (1) does not reflect this parameter. The investigators made use of the fact that anomalous diffusion of particles is expected on a fractal and, hence,

$$\langle r^2(t) \rangle \propto t^{2/(2+\delta)}, \quad (2)$$

where $r(t)$ is the distance covered by a diffusing particle in time t and δ is a scaling index for the diffusion constant. Having omitted the intermediate calculations, we present the final result obtained by Song and Roe¹⁴

$$d_s = \frac{2d_f}{2+\delta}. \quad (3)$$

The spectral dimension d_s is a true property of a fractal and is determined only by its connectivity. It differs from the mass scaling index [see Eqn (1)] or fractal dimension d_f and from the scaling index of the diffusion constant δ by the fact that it does not depend on the way in which a fractal has been inserted into the Euclidean space with dimension d . The dependence of d_s and δ on d_f is described by Eqn (3).

Alexander and Orbach²⁸ found that for a separate linear polymer chain, $d_s = 1$. In the case of a critical percolation cluster, the d_s value does not depend on d and amounts to $\sim 4/3$ (Table 1).

The dimensions of a linear macromolecule in different states have been considered.⁵⁰ The following states are known^{50–53} to be the most typical: 1 — compact globule, 2 — coil at the Θ -point, 3 — impermeable coil in a good solvent, 4 — permeable coil (the

state typical of rigid-chain macromolecules), 5 — completely uncoiled rod-like macromolecule.

The radius of gyration of a macromolecule R_g depends on the molecular mass M and on the geometry of distribution of the molecule in space and is characterised by the scaling index ν (see Refs 32, 50).

$$R_g \propto M^\nu \quad (4)$$

From Eqns (1) and (4), it follows that²⁵

$$d_f = \frac{1}{\nu}. \quad (5)$$

Baranov *et al.*⁵⁰ introduced the dimension d_F , determined from the Flory formula⁵¹ for good solvents

$$d_F = \frac{3 - 2\nu_F}{\nu_F}. \quad (6)$$

The d_F value reflects the dimension of the sublattice in which the macromolecule is arranged, *i.e.*, it is a fractal dimension of the medium in which the molecule is located rather than of the molecule itself; d_F does not always coincide with the Euclidean dimension. The ν , d_f and d_F values of the three-dimensional space and the states of the macromolecule considered above are listed in Table 2.⁵² State 1 is encountered in globular proteins or on precipitation (below the Θ -point) of linear macromolecules from highly dilute solutions.^{53, 54} Conformation 5 is typical of some proteins or linear chains exposed to particular types of external action; conformations 2–4 are more trivial and fairly well studied.⁵¹ Analysis of the data of Table 2 leads to the conclusion that, for example, a macromolecular coil in the most frequently encountered states 2–4 is always a fractal (at $d = 3$).

2. Polymer fractal

Cates⁵⁵ introduced the notion ‘polymer fractal’ by replacing the rigid bonds in a percolation cluster by flexible (phantom) links. This model can be used to describe the gelation process (Fig. 2).⁵⁶ Within the framework of this approach, Cates⁵⁵ described variations of the structure and the dynamics of dilute solutions of polymers. This approach is based on the following main ideas.

The replacement of rigid bonds in a percolation cluster by long phantom chains does not change the connectivity of a fractal (therefore, additional contacts between chains are regarded as

Figure 2. Scheme of the percolation of bonds during gelation:⁵⁶ (a) pre-gel state, (b) gelation point, (c) post-gel state; ξ is the characteristic linear scale.

imaginary) but does influence the dimension and the dynamic properties of the object. To describe the changes, at least three fractal dimensions are required.²⁸ The dimension of the initial fractal (in the percolation lattice) is determined by the fractal dimension d_{f0} using a mass scaling relation similar to (1).⁵⁷ The subscript 0 corresponds to the initial fractal with rigid bonds.⁵⁵ The dynamic properties can be studied using the spectral dimension d_s or (which is equivalent) using random walkers (the dimension d_w) arranged on a fractal. The latter version implies a scaling law for the root-mean-square displacement r [see Eqn (2)] of a random walker on a fractal in a time t ⁵⁶

$$r^{d_{w0}} \propto t, \quad (7)$$

where d_{w0} is the random-walk dimension at $d = 2$.

The case where $d_{w0} = 2$ corresponds to the classical Einstein diffusion. The r value is expressed in Euclidean distances; the process with $d_{w0} > 2$ is usually referred to as slow anomalous diffusion. The density of states is determined by the dimension d_s

$$d_s = \frac{2d_{f0}}{d_{w0}}. \quad (8)$$

It has been noted above that d_s is a true parameter of a fractal determined completely by the object connectivity. The replacement of rigid bonds by flexible links in a percolation cluster does not change d_s , i.e. in the Cates procedure,⁵⁵ d_s is an invariant value. However, the fractal dimension d_f and the walk dimension d_w change upon execution of this procedure. By using the 'Einstein correlation' relating the scaling indices of a fractal (in this case, d_f is used as the index) to the resistivity (a component of viscosity) $\bar{\xi}$, it can be shown^{55, 58} that for polymers with phantom bonds (i.e. for polymers with no excluded volume, for which $\bar{\xi} = 2$) the d_w value can be represented by the sum

$$d_w = d_f + 2. \quad (9)$$

Cates showed⁵⁵ that relation (9) is also valid for structures containing loops. In the case of an ideal polymer fractal with Gaussian chains and the connectivity parameter d_l , the fractal dimension d_f of a percolation cluster with phantom bonds can be expressed as follows:

$$d_f = \frac{2d_l}{2 - d_l}. \quad (9a)$$

For $d_l = 1$ (linear chains), Eqn (9a) provides the correct value, $d_f = 2$, corresponding to a macromolecular coil at the Θ -point (see Table 2). As noted above, $d_s = 4/3$ for a percolation cluster

irrespective of the dimension of the Euclidean space (see Table 1); therefore, from Eqn (9a), we obtain $d_f = 4$, which is consistent with the Flory–Stockmayer theory⁵⁹ for phantom chains. For three-dimensional space, $d_f > 3$ has no physical meaning because the object cannot be packed more densely than an object having Euclidean dimension. It is evident that this discrepancy is due to the phantom nature of the polymer chains postulated by Cates;⁵⁵ it is necessary to take into account self-interactions of chains due to which the dimension of a polymer fractal assumes a value which has a physical meaning.

In Eqn (9a), d_f has the same meaning as the fractal dimension of phantom Gaussian chains; therefore, the standard mean-field theory, taking account of the factor of excluded volume, can be applied to a polymer fractal.⁵⁶

The Flory approach can be used as the first approximation for this purpose.⁵⁹ In this case, the free energy F of an object with self-interactions can be represented by the sum⁵²

$$F = \left(\frac{R}{R_0}\right)^2 + v_u \frac{M^2}{R^d}, \quad (10)$$

where R is the size of a real fractal, R_0 is the size of an ideal phantom fractal without allowance for the interactions of excluded volume, v_u is an excluded volume parameter, M is the total mass of the fractal ($R_0^D \propto M$), and d is the dimension of the Euclidean space in which the fractal has been inserted. The first term in Eqn (10) is the elastic (or entropic) component of the free energy and the second term takes into account the volume interactions in terms of the mean-field theory.^{52, 59}

By minimising the free energy with respect to R , one can find the fractal dimension D of a swollen fractal, which is determined by the equation

$$D = \frac{d_s(d+2)}{d_s+2}. \quad (10a)$$

In the case of percolation clusters, Eqn (10a) gives $D = 2$ for $d_s = 4/3$ and $d = 3$ (see Ref. 56), while for linear polymers, $D = 5/3$ for $d_s = 1$ and $d = 3$ (see Ref. 60), which corresponds to an impermeable coil in a good solvent (see Table 2, state 3). The resulting dimensions are typical of macromolecular coils in monomeric solvents. Using the concept of polymer fractal, one can answer the question of what would happen if the monomeric solvent is replaced by a polymeric one, i.e., whether the polymer clusters and the clusters of a high-molecular-mass 'solvent' would be separated from one another or 'entangled'. This question can be answered by virtue of the equation⁶⁰

$$N = R_g^{D_1+D_2-d}, \quad (10b)$$

where N is the number of intersections of two arbitrary fractals with dimensions D_1 and D_2 .

The final relations for the dimensions of systems involving mixtures of polymer fractals (fractals in low- and high-molecular-mass solvents, melts of identical and arbitrary fractals) are given in Table 3.⁶⁰

The problems of penetration of polymers with arbitrary connectivity into confined spaces (for examples, pores or slits) have been discussed.⁶¹ It has been noted that the Flory theory, the blob model⁶¹ and the scaling concept provide identical results for linear chains; however, in the case of branched polymers, the Flory theory and scaling can lead to contradictory results when applied without invoking additional information.

For branched (and, hence, for cross-linked) polymers, the equation for the index ν in relation (4) has the form⁶¹

$$\nu = \frac{d_s+2}{d+2}, \quad (11)$$

and the fractal dimension D is determined by the ratio

$$D = \frac{d_s}{\nu}. \quad (12)$$

Table 3. Final relations for the dimensions of systems comprising mixtures of polymer fractals.⁶⁰

Parameter	Mono- meric- solvent $\delta_s = \delta_f = 0$	Poly- meric solvent $\delta_s = 1,$ $d_f = 2$	Melt of identical fractals $\delta_s = d_s,$ $\delta_f = d_f$	Melt of arbitrary fractals

Note. The δ_s and δ_f values are the spectral and fractal dimensions of the interglobular space in a solvent.

^a Transition from fractal to non-fractal behaviour.

Equation (5) is a special case of Eqn (12) for linear chains ($d_s = 1$).

In order to avoid the use of values such as the connectivity parameter (or chemical dimension) d_l or spectral dimension d_s , Lhuillier⁶² proposed a d -independent universal index r in the dependence

$$R_{g \max} \propto N_m^r, \quad (13)$$

where $R_{g \max}$ is the maximum radius of gyration of a macromolecular coil and N_m is the number of base units (monomers) in the chain.

The r value is supposed to vary in the range $1/d \leq r \leq 1$. It is believed that the r -fractals thus introduced provide a simple description for real polymers: $r = 1$ for linear chains and $r = 3/4$ for branched chains. However, Vilgis⁶³ have found that, in essence, the following relation holds:

$$r^{-1} = d_s; \quad (14)$$

this, in turn, implies that r -fractals can be reduced to polymer fractals, postulated by Cates.⁵⁵

A study by Stepleton *et al.*⁶⁴ was among the first which confirmed experimentally the fractal nature of a polymer chain taking a protein as an example. In a study of a frozen aqueous solution of a hemoprotein by electron spin relaxation, its fractal dimension was estimated to be 1.65 ± 0.004 . In the opinion of the researchers, this value is in good agreement with the fractal dimension of a self-avoiding random walk, which is equal to $5/3$.⁵⁷ This conclusion was drawn using the equation for the phonon density of states $\rho(\omega)$

$$\rho(\omega) \propto \omega^{d_s-1},$$

where ω is frequency.

It has been suggested^{64,65} that the exponent in the equation for $\rho(\omega)$ is determined by the fractal dimension. However, Alexander and Orbach²⁸ showed that in this case, the spectral dimension d_s is involved, which is not equal to d_f [see Eqn (8) and Table 1]. Note that the publication by Stepleton *et al.*⁶⁴ appeared earlier than the study by Alexander and Orbach.²⁸ In the case of self-avoiding random walk, $d_s = 1$; substitution of this value into the equation for $\rho(\omega)$ gives a result which, as shown by Young (see Ref. 10, p. 168), is at variance with experimental results.

Attempts to resolve this contradiction have been undertaken.^{66,67} Maritan and Stella (see Ref. 10, p. 151) calculated the fractal dimensions for 50 proteins using two methods. In one method, fractal dimension is a scaling index for the contour length of a macromolecule with respect to the distance between its ends

(it is equal to 1.19–1.82), while in the other method, the fractal dimension is a scaling index for the total mass with respect to the length, which is equal to 1.62–2.24. The calculations were performed using X-ray diffraction crystallographic parameters of proteins.

In our opinion, the results obtained for proteins^{64,65} do not appear contradictory. Undoubtedly, the fractal dimension presented in the study⁶⁴ is the spectral dimension d_s . Its value ($d_s = 1.65$) does not seem too great either, if one takes into account that the values $d_s = 1.65$ –1.80 were obtained for block poly(methyl methacrylate).³⁵ These large values of spectral dimension can be due to several reasons, first of all, to the high connectivity of the polymer chain.²⁸

In addition, the polymer chain cannot be modelled by self-avoiding random walk, as has been done by Young. Finally, Cappelli *et al.* (see Ref. 10, p. 156) demonstrated that the effective d_s value can be influenced by the non-homogeneity of block specimens, for example, porosity or inter-grain boundaries.

The difference between the d_l and d_f values found by Colvin and Stepleton⁶⁵ can also be easily explained. Indeed, d_l is a chemical dimension, as follows from the way of its determination,²⁷ d_f is the Hausdorff dimension. These values do not necessarily coincide. By using Eqn (10a) for a fractal swollen in a monomeric solvent, we obtain $D \approx 2.26$ for $d_s = 1.65$ and $d = 3$, which is in good agreement with both experimental data and the limiting D value for branched polymers.⁹

The following relation has been proposed:⁶²

$$d_l = \frac{d_f}{z}, \quad (15)$$

where

$$z = \frac{4+3D}{8}, \text{ for } 4/3 < D < 4. \quad (16)$$

When $D \approx 2.26$, the parameters z and d_l are 1.348 and 1.68, respectively, which is consistent with the estimate made by Colvin and Stepleton.⁶⁵ Calculation by an equation similar to (8) gives $d_w \approx 2.74$, *i.e.* slow anomalous diffusion on the fractal takes place.^{28,56}

The following expression relating d_w to d_l has been proposed:³¹

$$d_w = d_f \left(1 + \frac{1}{d_l} \right). \quad (17)$$

Assuming that $d_w = 3.37$ ('lattice animals'³¹), we obtain $d_l = 0.93$ –1.98. This interval agrees with the range of d_l found experimentally.⁶⁵

Thus, there are no contradictions suggested by Young between the estimates made in the two studies cited above^{64,65} but the large number of fractal dimensions used to describe the polymer structure creates certain difficulties. This is not a matter of principle because the dimensions considered above are interrelated.^{28,55,56,60–63,68–71}

3. Statistical fractal

Family⁹ considered the conformations of statistical branched fractals (which simulate branched polymers) formed in equilibrium processes in terms of the Flory theory. Using this approach, he found only three different states of statistical fractals, which were called uncoiled, compensated, and collapsed states. In particular, it was found that in thermally induced phase transitions, clusters occur in the compensated state and have nearly equal fractal dimensions (~ 2.5). Recall that the value $d_f = 2.5$ in polymers corresponds to the gelation point; this allows gelation to be classified as a critical phenomenon.

The fractal dimension of purely statistical models, *i.e.* models without the effect of excluded volume, can be determined accurately [see Eqn (9a)]. For linear polymers, this model corresponds to phantom random walk. In the case of branched statistical fractals, the corresponding model is a statistical branched cluster,

whose branching obeys the random-walk statistics. Since the root-mean-square distance between the random-walk ends is proportional to the number of walk steps N , then $D = 2$ irrespective of the space dimension. These types of structures have been studied.^{60, 72–74} The value $D = 4$ irrespective of d was obtained for a branched fractal. Unlike ‘ideal’ statistical models, models with excluded volume, *i.e.* those involving correlations, cannot be accurately solved in the general case. The D_f values for these systems are usually found either using numerical methods such as the Monte Carlo method or taking into account the spatial position of a re-normalisation group.

What are the physical conditions under which a statistical fractal has the most branched structure? It is clear that, when a large number of clusters are present in the system, they all occupy the available volume. The presence of other clusters restricts the degree of branching of each cluster; a cluster is more branched in the isolated state than in a concentrated solution. For polymer coils, this is expressed as an increase in D from its value in a dilute solution in a good solvent to the value at the Θ -point in concentrated solutions.⁷⁰

Yet another factor which also influences the shape of the cluster is whether or not attractive interactions are present. As the temperature increases, the attractive interactions diminish. For example, no interactions of this sort are found in isolated macromolecular coils in good solvents at high temperatures.⁷⁴ Family⁹ defined this state of a statistical fractal as an uncoiled state because in this case, it is characterised by the smallest fractal dimension.

Then Family used the version of the Flory theory proposed by Isaacson and Lubensky⁷⁵ for determination of the fractal dimension of an isolated statistical cluster. The method is based on the determination of the most probable cluster conformation using the free energy of repulsion. Under the influence of elastic free energy, the radius of the real cluster ‘tends’ to the radius of the ideal cluster which involves no repulsive interaction. After minimisation of the total free energy, the D_f value for an uncoiled cluster can be found from the expression

$$D = \frac{2(d+2)}{5}, \quad (18)$$

which was first obtained by Isaacson and Lubensky⁷⁵ for branched polymers in dilute solutions.

Equation (18) has two peculiar features: firstly, D depends appreciably on d and, secondly, there exists a critical dimension of Euclidean space $d_c = 8$ for which $D = 4$ in accordance with the ideal statistical model, *i.e.* the model without correlations. At $d_c > 8$, the correlations caused by the effect of excluded volume are no longer significant and D_f does not change. The value $d_c = 8$ was found in studies of branched polymers and ‘lattice animals’.⁷⁶ Calculations by formula (18) are in good agreement with the known results for ‘lattice animals.’

To elucidate the effects which increase D , Family considered conformations of one big cluster comprising N particles in the presence of other clusters with a size distribution. The large cluster does not ‘feel’ the presence of other clusters as long as their average diameter is small compared to its diameter. On the scale of lengths much greater than the radius of an average cluster, the big cluster interacts only with clusters similar to itself. It was found for polymers that, as the sizes of other clusters increase, they start to screen the effect of excluded volume, which is effective in the big cluster. The screening can change the fractal dimension of this cluster.

The best examples of processes with a cluster distribution are percolation and thermal critical phenomena, which are reflected, for example, by the Ising, Potts, and other models. Under equilibrium conditions in a system consisting of clusters with a size distribution, the average cluster size deviates in the vicinity of the critical point.

The state of a statistical fractal in which the excluded volume effect is compensated by the screening effect is referred to as the compensated state. For this state, Family has found that

$$D = \frac{d+2}{2}. \quad (19)$$

This expression is expected to be valid for any statistical critical cluster in the presence of clusters having a size distribution. The upper critical dimension for critical clusters can be determined assuming that in Eqn (19), $D = 4$. The result thus obtained, $d_c = 6$, is in good agreement with the data for percolation.⁷⁵

The above results confirm that the presence of numerous clusters and the deviation of the mean cluster size near the critical point results in the screening of the critical volume effect and in an increase in D . Another way of decreasing the repulsive interactions is to enhance the attractive interactions between the elements of an isolated cluster. In the general form, the free repulsive energy can be represented as a power series with respect to density with virial coefficients $w_2, w_3, \dots$, which describe the effects of interaction between pairs, triplets, *etc.*⁷⁷ The first term (with w_2) in this power series predominates. However, in the presence of attractive interactions, the second virial coefficient w_2 tends to zero and the term with w_3 should be taken into account. When $w_2 \rightarrow 0$, the polymer occurs in the vicinity of the Θ -point.⁷⁴ In this case, with minimisation of the total free energy with respect to R

$$D = \frac{4(d+1)}{7}. \quad (20)$$

This relation was first obtained by Bantle⁷⁸ for the conformation of an isolated branched polymer at the Θ -point. Calculation in terms of Eqn (20) for $D = 4$ gives $d_c = 6$, as for the compensated state.

Thus, the fractal dimension D increases near the compensation point; this is due either to the geometric screening of the excluded volume effect or to the enhancement of the attractive interaction. Big clusters near the critical point in thermally induced phase transitions and polymers at the Θ -point are examples of statistical fractals in the compensated state.⁹

Study of the conformation of a statistical fractal in a system occurring below the critical point and in the isolated state at $w_2 < 0$ showed that the fractal is very compact and has a globular conformation in both cases. This state of a fractal was called collapsed, by analogy with the collapsed state of polymers.

The conformation of clusters under these conditions was determined using the approach proposed⁷⁷ for studying the conformation of a branched polymer in a monodisperse melt, *i.e.* in a solution of coils with identical sizes. In the case of minimisation of the free energy with respect to R ,

$$D = d \quad (21)$$

For a purely statistical fractal for which $D = 4$, we obtain $d_{st} = 4$. This means that this type of statistical cluster is compact up to $d = 4$. Therefore, Family⁹ called this state of statistical fractals the collapsed state.

In the case of an isolated fractal, attractive interactions predominate below the compensation point; the second virial coefficient w_2 is negative and cannot be neglected in the power series mentioned above. The conformation of a fractal is determined by the balance between the first two terms in this series. The results are identical to Eqn (21) for $d_{st} = 4$. Thus, the conformation of an isolated statistical fractal below the compensation point is the same as the conformation of a big cluster below the critical point.

4. Experimental determination of fractal dimensions

Let us consider several experimental estimates of various fractal dimensions for polymers with allowance for the above theoretical statements. The index ν in Eqn (4) has been determined by small-angle neutron scattering for epoxy polymers;⁷⁸ it was found that

$\nu = 0.6$. It has been suggested⁷⁹ that so great a ν value is due to the enhanced chain rigidity of epoxy polymers. However, the use of Eqn (11) with $d_s = 4/3$ and $d = 3$ gives $\nu = 0.666$, which is close to the experimental ν value (see Table 2, the permeable coil model). Calculation using Eqn (12) for $d_s = 4/3$ and $\nu = 0.6$ gives $D \approx 2.22$, which is close to the fractal dimension for the compensated state of branched polymers in accordance with Eqn (20).

Silicate gels and epoxy polymers have been studied by Raman light scattering.^{34, 79} The spectral dimension d_s of silicate gels falls within the range from 1.11 to 1.43, depending on the method of calculation, which is consistent with the conclusion drawn by Alexander and Orbach.²⁸ The results of estimates of d_s from the data of Raman scattering and small-angle neutron scattering for two epoxy polymers with cross-linking densities differing by a factor of two and for the monomer used to prepare these epoxy polymers are presented in Table 4. Attention is drawn to the fact that the d_s values for all the three specimens are virtually equal [if the inaccuracy of determination of d_s is taken to be ± 0.05 (see Ref. 35)], the slight difference being due rather to the determination method used.

Table 4. Value of d_s for the DGEBA monomer^a and for epoxy polymers based on it determined by Raman light scattering (I) and small-angle neutron scattering (II) methods.⁷⁹

Example	I	II

^a Diglycidyl ester of bisphenol A. ^b Ethylenediamine.

The results of investigation of the transfer of energy between molecules acting as electron density donors and acceptors have been reported.^{80, 81} The Raman scattering method gives actually the fractal dimension of the surface on which the energy transfer takes place.⁸¹ The fractal dimensions found for silicates are in the range of 2.23–2.82;⁸¹ that for a polystyrene film is 2.2.⁸⁰

Cappelli *et al.* (see Ref. 10, p. 156) have studied the annihilation of the triplet excitons in naphthalene aggregates located in the pores of various materials including polymers. A common feature of these systems is non-classical annihilation kinetics, which resemble the annihilation kinetics of fractals. The coefficient of the annihilation rate k_a varies with time t

$$k_a \propto t^{-h}, \quad (22)$$

where h is the non-homogeneity index ($0 < h < 1$), which is equal to zero only for homogeneous specimens. The effective spectral dimension of the medium d'_s is given by the relation⁷⁰

$$d'_s = 2(1 - h). \quad (23)$$

The d'_s values for several polymers are listed in Table 5.

Cappelli *et al.*¹⁰ also measured h as a function of temperature. At low temperatures, all the studied polymers exhibit properties similar to the properties of fractals. As the temperature increases, h decreases, i.e. the d'_s value increases. In some specimens, $h \rightarrow 0$

Table 5. Effective spectral dimensions d'_s for some polymers.¹⁰

Acetate A3	1.2	4	0.44	0.9–1.1
Nylon B214	0.2	4	0.21	1.2–1.6
Poly(methyl methacrylate)	—	77	0.1	1.8

as the temperature is raised. This implies that all the effects described by fractional dimensions are associated with disorder.⁸² A number of specimens behave as fractals also at room temperature. It is noteworthy that the d'_s values for the polymers studied vary over wide limits, from 0.8 to 1.8. In the case of poly(methyl methacrylate), d'_s exactly corresponds to the spectral dimension determined by Raman scattering measurements;^{22, 34} it is ~ 1.8 in both cases.

The theoretical concepts outlined above are confirmed rather accurately by experimental data. Nevertheless, it is worth noting that the concept of polymeric (macromolecular) fractal⁵⁵ has been developed for polymer solutions, while the Vilgis theory^{60, 61} is applicable only to rubbers and polymer melts, although it has been developed for condensed media. Therefore, it can be expected that extension of these concepts to the vitreous state of polymers would require some corrections taking into account the specific features of this state.

Some possible approximations have been considered by Cates,⁵⁵ who concentrated attention on macromolecular entanglements, which play an important role in the description of the behaviour of block polymers.^{83–86} Cates believes that the fact that the concept of polymer fractal neglects the effects of macromolecular entanglements is the main drawback of this theory. Nevertheless, Cates⁵⁵ introduced several simplifications which make it possible to ignore these effects for dilute solutions and relatively low molecular masses. However, in the opinion of Cates, even in the case of predominant influence of entanglements, theoretical interpretation of this phenomenon is impossible without preliminary investigation of the properties of the system in terms of Rouse–Zimm dynamics, which can serve as the basis for a more complex theory. It was assumed⁵⁵ that the effects of entanglement can be due to the substantially enhanced local friction of macromolecules.

5. Levels of fractality

Polymers exhibit the fractality inherent in them at different structural levels; both primary and secondary structural elements can be fractals. For example, macromolecular coils in Θ or in good solvents with $d_f \approx 1.66$ (with the Euclidean dimension $d = 3$) are fractals.^{1, 29} The fractality of a polymer at the molecular level can be demonstrated as follows. Lebedev⁸⁷ reported data on the change in the radius of gyration R_g of the macromolecules of block polystyrene, poly(methyl methacrylate) and polyethylene with the molecular mass M_w . The R_g value is related to the length of a macromolecule L_w in the following way:⁸⁸

$$L_w \propto R_g^{d_f}. \quad (24)$$

The length of a macromolecule can be determined from the known M_w , the molecular mass of one unit m_0 , and the projection of the bond length l_0 on the macromolecular axis using the simple dependence

$$L_w = \frac{M_w l_0}{m_0}. \quad (25)$$

The m_0 and l_0 values for the polymers mentioned above were taken from Ref. 89 and Ref. 90, respectively.

Figure 3a shows the variation of L_w vs. R_g . Taking account of this dependence, it was found that $d_f \approx 1.60$, which is close to the corresponding value for a macromolecular coil in a Θ -solvent ($d_f \approx 1.66$, see Table 2). The elements of Koch figures (Fig. 3b) resemble most closely the freely jointed chain model, which is normally used to simulate macromolecules.⁹¹ For this version, $d_f = 1.61$. Thus, the fractality of a block polymer at a molecular level can be regarded as proven.

The cluster model of the structure of amorphous polymers (Fig. 4) provides a quantitative description of supermolecular (supersegmental) structures in this type of polymer. The cluster with chains protruding from it ('interpenetrating' molecules) assumed in this model resembles the well-known cluster used in

Figure 3. Chain length L_w vs. the radius of gyration R_g for a macromolecular coil of polystyrene (1), poly(methyl methacrylate) (2) and polyethylene (3) (a) and a variant of elements of the Koch curves having $d_f = 1.61$ (b).⁸⁸

Figure 4. Cluster model of the structure of an amorphous polymer.

the Witten–Sander (WS) model.^{77,78} Such a cluster distinguished in a polymer bulk restricted by the radius R_w would possess at least two features typical of fractal clusters. One feature is self-similarity, caused by the presence of unstable clusters consisting of fewer segments than thermodynamically stable clusters (Fig. 4 shows them consisting of two segments). The other feature is that the density of particles (statistical segments) comprising the cluster would decrease on moving away from the cluster centre and thus stipulate the $\rho(L)$ dependence typical of fractals (see Fig. 1). In conformity with this dependence, it is assumed that the structure of an amorphous polymer contains sorts of ‘thickened’ and ‘rarefied’ sections. This ‘thickening’ of the material can be explained by assuming the existence of a local order (as opposed to the model of interpenetrating macromolecular coils, *i.e.*, the ‘felt’ model, proposed by Flory).^{92,93} Thus, the fractality of the structure of amorphous polymers in the ~ 0.3 – 5.0 nm range, shown experimentally in a number of studies,^{22,35} is confirmed indirectly by the presence of local order.

The size of a fractal cluster R_w and the number of particles in it N_r are related to each other by the following expression:⁸⁸

$$N_r \propto R_w^{d_f}. \quad (26)$$

Let us consider the procedure for estimation of the N_r and R_w values in terms of the cluster model.^{15,86} A cluster is regarded as a multifunctional unit in a fluctuation network of macromolecular entanglements; therefore, according to Flory,⁴² the reduced molecular mass M per cluster is estimated from Eqn (4). By dividing M into the molecular mass of a statistical segment, we obtain the number of particles (statistical segments) N_{st} per cluster.

The distance between the clusters R_{cl} should be taken as R_w

$$R_{cl} = 18 \left(\frac{2V_{cl}}{F} \right)^{-1/3}, \quad (26a)$$

Figure 5. Number of statistical segments N_{st} in a cluster vs. its radius R_w for amorphous (1) and amorphous-crystalline (2) polymers under the assumption that the sizes of fractal and percolation clusters are equal.

where V_{cl} is the density of the cluster network and F is the cluster functionality.

Figure 5 presents the dependence of N_{st} on R_w for five amorphous vitreous and five amorphous-crystalline polymers.⁸ It can be seen that this correlation is fully consistent with relation (26). The d_f value of the cluster structure determined from the slope of the straight line is ~ 2.75 . The fractal dimension of the cluster in the WS model lies in the range of 2.25 – 2.75 ,⁸⁸ which is in agreement with the above estimate.

The fractal dimension for the structure of the amorphous polymer can be found from the relation⁹⁴

$$d_f = (d - 1)(1 + \mu), \quad (27)$$

where μ is the Poisson coefficient.

For a cluster structure with $d_f \approx 2.75$, the μ value is equal to ~ 0.375 , which is consistent with the known μ values for amorphous vitreous polymers.^{95,96}

As an example of fractality displayed in polymers at a macroscopic level (a secondary structural element), we shall consider the growth of a crack in a film of amorphous vitreous polyarylate-sulfone.⁹⁷ The surfaces of cracks have irregularities of at least two scales: ~ 20 μm (Fig. 6a) and ~ 20 mm (Fig. 6b). This provides grounds for describing them in terms of fractal models.^{98–100} The triangular profile throughout the whole period of growth of the crack allows the use of the relationship proposed by Mosolov⁹⁸

$$d_{sk} \propto r_{sk}^{D_{sk}/2}, \quad (28)$$

where d_{sk} is the crack opening, r_{sk} is the distance from the crack top and D_{sk} is the fractal dimension of the crack.

Figure 6. Crack coast-line (a), general view of a stable crack (b) and opening of the crack δ_{sk} vs. the distance to its top r_{sk} (c) for polycarbonate (1) and polyarylate (2).⁸

Figure 6c shows the plots for the variation of δ_{sk} vs. r_{sk} for two amorphous polymers; the plots correspond to relation (28). In other words, a stable crack in polymer film samples is a stochastic fractal with the dimension $D_{sk} \approx 1.48$. The linearity of plots shown in Fig. 6c reflects the self-similarity of the crack at different stages of its growth. Thus, polymers also exhibit fractal properties at the macroscopic level.

The examples considered above do not reflect the whole diversity of manifestation of fractality in polymers. Nevertheless, they help to understand the meaning of the term ‘multifractality’ as applied to polymers.

III. Fractal characteristics of macromolecules

Condensed systems start to behave as polymers after a certain molecular mass has been attained and a network of macromolecular entanglements or chemical nodes has been formed.⁵⁶ In consideration of condensed polymers, it is especially important to describe the sections of the macromolecule between the points of chemical cross-linking or entanglements.⁵⁵ The deformability and mobility of these sections largely determine the macroscopic properties of polymers.^{56, 101} The general physical grounds which account for the fractality of these chain sections are considered below in relation to epoxy polymers.

To determine the fractality of an object, three aspects are usually considered.¹² First, as noted above, a real physical object possesses fractal properties only in a definite scale range (see Fig. 1). The boundary sizes for a macromolecular section can be determined using the data of several publications.^{22, 35, 102} The lower boundary is related to the finite size of a structural element; in terms of the cluster model, this is the length of the statistical segment l_{st}

$$l_{st} = l_0 C_\infty, \quad (29)$$

where l_0 is the length of a chemical bond and C_∞ is the characteristic ratio.

For most polymers, $l_0 = 0.125$ nm (see Ref. 90), the minimum $C_\infty = 2$ (see Ref. 91); therefore, the minimum possible l_{st} is 0.25 nm. This value is in good agreement with the experimental estimate of the lower limit of fractality in polymers (~ 0.3 nm²²) and should be accepted as the L_{min} for the chain section between chemical cross-links. The length of this section L_s can be taken as the upper limit. For most of the epoxy polymers considered, this value is in the range from ~ 1.6 to 7.4 nm, which is also consistent with the data of Refs 22 and 35.

The second aspect is associated with the self-similarity of the object considered. A section of the macromolecule between chemical cross-linking points represented by a freely jointed Kuhn chain or by a chain with free or hindered rotation about the bond⁹¹ is simulated by a broken line having the topological dimension $d_t = 1$.³ In the case of simulation by the freely jointed Kuhn chain, the broken line consists of N_s statistical segments of length A , each of them being simulated by a straight-line segment. These straight-line segments are standard self-similar objects but the chain sections consisting of them are self-similar only when their lengths L_s and the A values vary proportionally. For the epoxy polymers in question, this condition is fulfilled;¹⁰³ therefore, these sections are self-similar objects.¹⁰⁴

Finally, the third aspect concerns determination of the fractal dimension D of an object.¹² For fractals, the condition

$$D > d_t.$$

should hold.¹⁶ In the case where a macromolecular section between chemical cross-linking points is represented by the freely jointed Kuhn chain, the following equality should hold:¹⁰¹

$$R_s^2 = L_s A, \quad (30)$$

where R_s is the smallest (straight-line) distance between chemical cross-links.

A fractal broken line can be described by the relation⁸⁸

$$\frac{L}{a} = \left(\frac{R}{a}\right)^D, \quad (31)$$

where L is the length of the line, R is the straight-line distance between its ends, a is the scale of measurements in the macromolecule.

By dividing both parts of Eqn (30) by A^2 , we find that

$$\frac{L_s}{A} = \left(\frac{R_s}{a}\right)^2, \quad (32)$$

i.e., a freely jointed Kuhn chain is a broken line with dimension 2 provided that condition (30) is fulfilled. Note that in this case, the chain is a fractal because $D > d_t$. Since the random-walk dimension d_w for this model of a macromolecule is also equal to 2,⁶⁶ the spectral dimension d_s of the chain can be estimated [see Eqn (8)]. For a freely jointed Kuhn chain, it is also equal to 2.

Let us consider conditions under which $d_s = 2$. For a real polymer, with allowance for the effect of excluded volume, one can write that⁵⁶

$$D = \frac{2d_s}{\alpha - d_s}, \quad (33)$$

where

$$\alpha = d_s + \frac{2(d_s + 2)}{d + 2}. \quad (34)$$

When $D = d_s = 2$, Eqns (32) and (34) are correct only when $d = 2$. This means that the ranges of variation of the fractal dimension of a macromolecule section between cross-linking points are $d_t < D \leq d$ or $1 < D \leq 2$.

However, the freely jointed Kuhn chain is the most idealised model for a real macromolecule; therefore, there exist several corrections taking into account specific features of the polymer structure. Thus, for chains in which $L_s/A < 10$, condition (30) no longer holds. The modified condition is written as follows⁹¹

$$R_s^2 = L_s A - \frac{A(1 - e^{-2L_s A})}{2}. \quad (35)$$

Equation (35) points to a decrease in L_s at a constant R_s and, hence, to a decrease in D , in conformity with Eqn (31). Note that the condition $L_s/A < 10$ holds for nine of the ten specimens of epoxy polymers; this automatically means that $D < 2$.⁸

The hindrance of rotation of the macro-chain around bonds, which necessarily occurs in a vitreous polymer, accounts for the decrease in the real A value to A_{rot} according to the relation⁹¹

$$\sigma^2 = \frac{A}{A_{rot}}, \quad (36)$$

The hindrance parameter σ can be determined from the empirical equation¹⁰⁵

$$T_g = C(\sigma - 1), \quad (37)$$

where T_g is the experimental glass transition temperature and C is a constant (for carbon-chain polymers, $C = 270$ K).

Now we can calculate non-fractal values R_s and L_s as functions of the cross-linking density v_s using Eqn (29) and the relation¹⁰⁴

$$L_s = \frac{F_{ch}}{2Sv_s}, \quad (38)$$

where F_{ch} is the functionality of a chemical cross-linking point (hereinafter, we assume that $F_{ch} = 4$) and S is the cross-section area of the macromolecule.

The results of calculation of D as a function of v_s for the epoxy polymers considered here using Eqn (31) with $a = A_{rot}$, $L = L_s$ and $R = R_s$ are shown in Fig. 7, curve 1. It can be seen that the allowance for the hindered character of rotation has resulted in a monotonic decrease in D following an increase in v_s . As has been shown,¹⁰¹ this implies a decrease in the mobility (deformability) of

Figure 7. Fractal dimension D of a macromolecule section between chemical cross-linking points vs. cross-linking density v_s for epoxy polymers based on epoxy oligomers and amino-containing curing agents. The D values were found from Eqn (31) for $a = A_{\text{rot}}$ (1), A (2) and 0.25 nm (3).

the macromolecule section between the points of chemical cross-linking.

The calculation of D from Eqn (31) but for $a = A$ gives $D \approx 2$ irrespective of v_s (Fig. 7, curve 2). Finally, when persistence of the chain section is taken into account, *i.e.* the chain parameters vary according to Eqn (35), a somewhat higher D value is obtained, although the difference does not exceed $\sim 3\%$. The change in the scale of measurements also changes the fractal dimension of the chain. Curve 3 in Fig. 7 reflects the dependence of D on v_s for $a = 0.25 \text{ nm}$ (*i.e.*, for the minimum size). This curve runs parallel to curve 1 but is characterised by somewhat lower D (by $\sim 3\% - 13\%$). Our choice of the scale of measurement of A_{rot} (or l_{st}) is due to the fact that it reflects the real state of the chain under particular conditions ('natural' scale of measurements).

Let us discuss in more detail the physical meaning of the fractal dimension D of a chain section between chemical cross-linking points (or between entanglement points). Substitution $L = L_s$, $R = R_s$ and $a = l_{\text{st}}$ in Eqn (31) gives the relation^{101, 106}

$$\frac{L_s}{l_{\text{st}}} = \left(\frac{R_s}{l_{\text{st}}} \right)^D, \quad (39)$$

which implies that when $D = 1$, $L_s = R_s$, *i.e.* the chain between the cross-links is completely stretched and loses the capacity for deformation (mobility). This is consistent with the data of a publication,⁵¹ according to which $D = 1$ corresponds to a completely uncoiled chain (see Table 2). Recall that the condition $D = 1$ means that the given section of the macromolecule has completely lost fractal properties. When $D = 2$, we obtain the maximum possible length of the chain section L_s for a fixed R_s and the greatest l_{st} , *i.e.* the chain deformability (mobility) is the most pronounced in this case. Note that the highest stretching ratio λ_{max} for a given chain section is equal to L_s/R_s .^{107, 108} It is clear that $D = 2$ is attained for rubbers, and intermediate values, $1 < D < 2$, describe different degrees of mobility of a macromolecule section between chemical cross-links (entanglements). This quantitative measure of mobility is convenient because the fractional part of D provides actually a relative measure of mobility, irrespective of the structure of the macromolecule or other features of the polymers.⁸²

Let us consider the physical reasons for the fractality of the macromolecule, *i.e.* for the dependence of the chain length L_s on the scale of measurement A_{rot} or l_{st} . The first reason is that L_s can change upon conformational changes in the macromolecule due to variation of C_∞ , *i.e.* the bond angle θ_v can change according to the equation⁹¹

$$\sigma^2 = C_\infty \frac{1 - \cos \theta_v}{\cos \theta_v}. \quad (40)$$

Figure 8. Schemes of two adjacent bonds of a macromolecule (a) and the enveloping tube (b).

Figure 8a shows schematically two consecutive bonds with the length l_0 . The total length of such a section l projected onto the axis of one of the bonds is equal to

$$l = l_0 + l_0 \cos \theta_v. \quad (41)$$

It is clear that the smaller θ_v , the greater the second term in Eqn (41) and the greater L_s . The maximum L_s value is attained for tetrahedral angles ($\theta_v = 70.5^\circ$).⁹¹ The distance between the cross-links determined in this way (we shall call it conformational length L_{conf}) is obviously equal to

$$L_{\text{conf}} = \frac{L_s l}{2l_0}. \quad (42)$$

Another physical representation of the effect in question is the use of the reptation model,⁴¹ in which a macromolecule is assumed to be encapsulated in a 'tube' of a finite thickness (Fig. 8b). In this case, the topological skeleton of the chain consists of N_{pr} units of length l_{pr} , which form a primitive path with the length

$$L_{\text{pr}} = N_{\text{pr}} l_{\text{pr}}.$$

It is also assumed that the ends of fragments of the primitive path with the length l_{pr} are fixed in a definite manner; therefore, the N_{pr} and L_{pr} values can be found fairly easily using l_{pr} . The L_{pr} value can be expressed as follows:⁴¹

$$L_{\text{pr}} = L_s \frac{A_{\text{rot}}}{l_{\text{pr}}}, \quad (43)$$

where l_{pr} is assumed to be equal to the distance between clusters R_{cl} , which can be calculated from Eqn (26a).

The length of the fractal broken line L_f is expressed in the following way:³

$$L_f = L' a^{1-D}, \quad (44)$$

where $L' > 1$ is the length of the non-fractal line.

Since the L_s value determined using Eqn (38) is calculated, in the first approximation, as the length of a cylinder with the cross-section area S , *i.e.* of a non-fractal object, it can be assumed that $L' \approx L_s$. If the two above examples point to the presence of fractal properties of a section between chemical cross-links (entanglements), the following relation should be obeyed:

$$L_f \approx L_{\text{conf}} \approx L_{\text{pr}}. \quad (45)$$

Relation (45) actually holds (with a deviation of $\pm 20\%$) for epoxy polymers based on bisphenol A and cured by diamine (EP-1) or anhydride (EP-2) (Fig. 9).⁴⁷ This indicates that the fractality of the macromolecule section between chemical cross-linking points (entanglements) in a vitreous polymer is due to known mechanisms of the change in the statistical rigidity.

It follows from Eqn (39) that the loss of fractality by a chain section, irrespective of the scale of measurements, takes place in the case of full stretching of this section between cross-linking

Figure 9. Relationships between the conformational length L_{conf} (1, 3) and primitive path L_{pr} (2, 4) of the chain section between chemical cross-linking points and its fractal length L_f for EP-1 (1, 2) and EP-2 (3, 4).

Figure 10. Fractal dimension of the macromolecule section between chemical cross-linking point (D) vs. scale of measurement a for EP-1. $v_s \times 10^{-27} / \text{m}^{-3}$: (1) 0.2, (2) 0.6, (3) 1.7.

points (entanglements), *i.e.* when $L_s = R_s$. In addition, for $a \rightarrow 0$, the $L(a)$ value would tend to a final limit equal to the length of the straight line. Figure 10 shows the $D(a)$ plots for EP-1. It can be seen that, when $a \rightarrow 0$, the fractality of the chain section between cross-linking points is retained. Therefore, the behaviour of this section of a macromolecule is more intricate than that of a mere fractal broken line; this can be due to a more complex structure of the macromolecule. Indeed, transition to a non-fractal behaviour requires not only that condition $L_s = R_s$ be fulfilled, as for an ordinary broken line, for example, for a coast-line, but also that a conformation condition — Eqn (30) — be fulfilled. In this case, it is necessary that the bond angle θ_v reach a value which complies with the equality (for $l_{\text{st}} = A$)

$$C_\infty = \frac{A}{l_0} \cos \frac{\theta_v}{2}. \quad (46)$$

A chain for which $D \neq 1$ can be referred to as ‘true fractal’.

Examination of Eqns (26a) and (38) leads to yet another, at least formal, reason for the fractal properties of the section of a macromolecule between the cross-links. For a given cross-linking density, the L_s value (unlike R_s) depends on the cross-sectional area S of the macromolecule, which should also result in the variation of D . Figure 11 shows the dependences of D on S for two arbitrary v_s values, namely, 1×10^{27} and $2 \times 10^{27} \text{ m}^{-3}$. It can be seen that D rapidly decreases as S increases; when $S \approx 0.80$ and 0.55 nm^2 , respectively, D reaches the lower limit ($D = 1$). This implies full ‘freezing’ of the molecular mobility of the chain,¹⁰¹ which should result in a high fragility of the polymer. This assumption is confirmed in practice. It is known that polystyrene and poly(methyl methacrylate) are fragile polymers ($S = 0.698$ and 0.638 nm^2 , respectively) and poly(n-dodecyl methacrylate) and poly(n-octyl methacrylate) are highly fragile polymers ($S = 1.766$ and 1.351 nm^2 , respectively).¹⁰⁹

Thus, the section of the macromolecule between chemical cross-links and physical entanglements possesses fractal properties. This is due to the fact that the length of this section is shorter than the size of the macromolecule. This factor is due to various

Figure 11. Fractal dimension of a section of macromolecule between chemical cross-linking points (D) vs. cross-sectional area of the macromolecule S . $v_s \times 10^{-27} / \text{m}^{-3}$: (1) 1, (2) 2.

steric restrictions, which induce deviations from the behavior predicted by Eqn (30). In the general case, Eqn (30) is valid for a non-perturbed (quasi-equilibrium) coil;³² therefore, the fractality of the chain section considered can be interpreted as being due to the deviation from the quasi-equilibrium state.¹² The deviation changes the degree of the ‘sinuosity’ of the macromolecular section (*i.e.* the length of the statistical segment); therefore, the l_{st} (or A , or A_{rot}) value can be considered to be a ‘natural’ scale of measurement. Since the structure of a macromolecule is more complex than the geometric image represented by a broken line, its behaviour would also be more complicated; this is confirmed by the change in D when $a \rightarrow 0$. In other words, the section of a macromolecule between cross-links has configurational fractal properties, stipulated by the mutual arrangement of the rigidity sections of the macromolecule, and conformational fractal properties, caused by the state of the bonds within this rigidity section (statistical segment).

1. The dimension of the sections of a macromolecule between topological fixing points

A cross-linked polymer is formally one giant macromolecule (fractal cluster); therefore, the models considered above provide the dimension d_f of exactly this cluster. The Vilgis concept^{60,61} assumes the existence of several clusters of this type and linear macromolecules between them. In practice, parameters used more widely are the density of the network of nodes (chemical cross-links) v_s or the molecular mass of the macromolecular section between the cross-links M_s , which are related to each other in the following way:

$$v_s = \frac{\rho N_A}{M_s}, \quad (46a)$$

where N_A is the Avogadro number and ρ is the polymer density.

In a study by Sandakov *et al.*,⁴⁹ the term ‘molecule’ for cross-linked polymers was used to denote only a section of the macromolecule with the molecular mass M_s , because it is known⁴³ that it is the parameters v_s and M_s that determine the properties of network polymers. In addition, the difference between the scales of fractality of a big macromolecular cluster and the polymer structure in the vitreous state should be taken into account, *i.e.* one should have in view lengths of the order of ~ 0.3 – 5.0 nm where a macromolecule is a fractal.²²

Below we consider practical aspects of the estimation of the fractal dimension D of a macromolecule section between chemical cross-linking points with allowance for these statements as well as for those considered in the preceding Sections. This approach differs fundamentally from that of the Cates⁵⁵ and Vilgis models.^{60,61} All the foregoing is valid not only for a network of chemical bonds but also for a network of macromolecular entanglements in linear polymers.

Several methods for the estimation of the D value exist. One method makes use of the relation¹¹⁰

$$D = \frac{\ln n_{st}}{\ln l_{st}}, \quad (47)$$

where n_{st} is the number of statistical segments of length l_{st} in a chain fragment between entanglements (chemical cross-links).

Yet another variant of calculation of D is given by Eqn (39). The following relation has been obtained:¹¹¹

$$\frac{2}{\varphi_{cl}} = C_{\infty}^D, \quad (48)$$

where φ_{cl} is the relative part of local order (clusters) in the polymer.

The relationship between D and d_f [see Eqn (27)] is reflected by the expression:^{112, 113}

$$D = \frac{\ln n_{st}}{\ln(4 - d_f) - \ln(3 - d_f)}. \quad (49)$$

The D values estimated using Eqns (39) and (47)–(49) vary from 1 to 2.

The use of fractal analysis makes it possible to relate molecular parameters to characteristics of supermolecular structure of polymers. Figure 12 illustrates the linear correlation between D and d_f [d_f was estimated from Eqn (27)] for epoxy polymers. When the molecular mobility is suppressed ($D = 1$), the structure of the polymer has the fractal dimension $d_f = 2.5$, which corresponds to $\mu = 0.25$. The given value of the Poisson coefficient corresponds to the boundary of ideally brittle structure; at $\mu < 0.25$, the polymer is collapsed without viscoelastic or plastic dissipation of energy.³ This is fully consistent with the Kausch conclusion¹¹⁴ stating that any increase in the molecular mobility enhances dissipation of the mechanical energy supplied from the outside and, as a consequence, increases plasticity of the polymer. When $D = 2$ the d_f value is equal to 3, which corresponds to $\mu = 0.5$, typical of the rubbery state.

Figure 12b shows the variation of D vs. v_s for the epoxy polymers considered here. The dependence is non-linear, the D value decreases with an increase in v_s ; even for small v_s values, a substantial decay in D is observed. It is of interest that the end of this decay and transition to a much slower decrease in D takes place at $v_s \approx 8 \times 10^{26} \text{ m}^{-3}$, which corresponds to ~ 10 monomer units between the cross-links. Actually, this can be interpreted as transition to densely cross-linked epoxy polymers in which an increase in v_s influences the suppression of the molecular mobility to a substantially lower degree than in the region where $v_s = 0.8 \times 10^{27} \text{ m}^{-3}$ (see Ref. 8).

If the conformational and/or physical state of the section between cross-links are assumed to coincide with that of the whole

macromolecule (see Table 2), the plot shown in Fig. 12b allows one to judge the nature and the ranges of variation of these states. The first characteristic dimension $D = 2$ corresponds to the state of a statistical coil in an ideal solvent, the second one $D \approx 1.67$ corresponds to an impermeable coil in a good solvent, the third one $D = 1.50$ is matched by a permeable coil (the state typical of rigid-chain polymers), and the fourth value, $D = 1$, describes a completely uncoiled macromolecule.⁵⁰ It can be assumed that the increase in the cross-linking density between the above D values is accompanied by gradual transition from a state with greater D to a state with smaller D . Thus, depending on v_s , a network polymer can be both a rubber and a rigid-chain polymer.¹¹⁵ Therefore, it is evident that the knowledge of these regularities is important for controlling the properties of network polymers.

Now we attempt to estimate D within the framework of the theoretical views on polymer fractals.^{22, 35, 55, 60–63} It is assumed⁶⁶ that the fractal dimensions d_s , d_w and D are related to one another via an expression similar to Eqn (8). The relationship between the parameters d_s and D has been considered.⁶⁵ It is believed that d_s is a dynamic value which responds to a change in the conditions of the interaction of a macromolecule with its surrounding and D is a static parameter. However, in our opinion, the opposite situation occurs in reality; this is indicated by the following facts, some of which have been noted above. It has been shown experimentally⁶⁹ that a twofold increase in the cross-linking density does not change d_s , while, according to the plot shown in Fig. 12b, v_s has an appreciable influence on D . Moreover, the monomer and the cross-linked epoxy polymer have nearly identical d_s values (see Table 4). Helman *et al.*⁶⁶ proposed a fractal model in which they employ the notion of weightless bridges. In accordance with this model, d_s is equal to D when the concentration of these bridges is relatively high. However, theoretical analysis and computer simulation^{10, 67} show that the inclusion into consideration of bridges of a finite length does not change the spectral dimension of the system. With allowance for this fact, it was assumed that the d_s value would be equal to that determined experimentally for an epoxy polymer in a three-dimensional space, $d_s = 1.44$ (see Ref. 69).

Two hypotheses can be used to estimate d_w — the Alexander – Orbach (AO) and Aharoni – Stauffer (AS) hypotheses.¹⁰ The AO hypothesis is based on the following relation:

$$d_w = \frac{3}{2} d_f,$$

while the AS hypothesis assumes the relation

$$d_w = 1 + d_f.$$

It is considered that d_w is determined by the properties of the supermolecular structure of epoxy polymers, namely, by the degree of local order in them. This assumption arises due to the well-known succession of relationships between the diffusion process and d_w ,²⁸ between the diffusion process and the fluctuation free volume f_{iv} ,¹¹⁶ and between f_{iv} and the cluster structure.¹¹⁷ Therefore, the fractal dimension of the cluster structure of cross-linked polymers,^{102, 107} estimated from Eqn (27), is taken to be d_f . Since the D value is determined for an Euclidean space with $d = 2$, it was also assumed in Eqn (27) that $d = 2$. The d_s value was found for a three-dimensional space; therefore, a graph¹¹⁸ for converting d_s from three- to two-dimensional space was used in subsequent calculations. The D values were further calculated from Eqn (8) in terms of the AO and AS hypotheses. Figure 13 shows the dependences of D on v_s calculated from Eqns (8) and (39). The dependences of D on v_s and the absolute magnitudes of D are in good agreement, especially when the AO hypothesis is used. When v_s is low, the D values calculated from Eqn (39) deviate towards the curve estimated using the AO hypothesis. Nevertheless, the discrepancy between the calculations by two methods does not exceed 10%.

Thus, the fractal dimension of a section of the macromolecule between chemical cross-linking points in network polymers varies

Figure 12. Correlation between fractal dimensions of the structure d_f and the chain section between chemical cross-linking points D (a) and the $D(v_s)$ dependence (b) for EP-1 (1) and EP-2 (2).¹⁰⁶ The straight line was drawn through the points: $D = 1.0$, $d_f = 2.5$ and $D = 2.0$, $d_f = 3.0$.

Figure 13. Fractal dimension of the chain section between chemical cross-linking points D vs. cross-linking density ν_s . Calculation using Eqn (39) for EP-1 (1) and EP-2 (2); calculation using Eqn (8) for EP-1 and EP-2 in terms of the AS (3) and AO (4) hypotheses.

over limits close to those predicted for a fractal broken line, *i.e.* $1 \leq D \leq 2$. The dimension D can serve as a measure of the molecular mobility and is related to the fractal dimension of the cluster structure of epoxy polymers d_f . The dependence of D on d_f can also be derived theoretically. The calculation procedures proposed take into account the influence on D of characteristics of the molecular and topological structural levels of cross-linked polymers.

2. The concept of macromolecular skeletons

a. The model of a network polymer

The model of network polymers considered below describes quantitatively the formation of structure (and, hence, properties) and is based on fundamental principles of physics. The initial parameters used for cross-linked systems are the ν_s value (topological characteristics) and some generally accepted molecular parameters. Since the chemical cross-linking processes are complex, the model makes use of the simplest scheme of structure formation, which does not take into account, for example, the decrease in the rate of structure formation with time when one structure element starts to influence the conditions of formation of an adjacent element. An example of taking account of effects of this type has been reported.¹¹⁸ Although this scheme is simple, it provides a quantitative description of the processes considered and the structures formed.

One point of the model under discussion is estimation of the relationship between ν_s and the level of local order in the structure of epoxy polymers, which is characterised by the density V_{cl} of the cluster network of macromolecular entanglements.^{101–103} A parameter characterising the level of local order more rigorously is the fraction of clusters φ_{cl} in the polymer.

Curing is supposed to be a turbulent process because it requires mobility of structural elements and takes place in a viscous medium. In addition, transition to a turbulent mode implies an increase in the degree of ordering, *i.e.* self-organisation of dissipative structures such as clusters.¹¹⁹ A fundamental property of turbulent flows is fractality of turbulent structures.^{3, 10} It is generally believed that dissipation of energy in three-dimensional turbulent flows is concentrated on a set with a non-integral fractal dimension. However, experimental data on the beginning of fluctuations indicate that the small-scale properties of a turbulent flow cannot be described by virtue of fractals.³ Therefore, turbulent dissipative structures are described using 'non-homogeneous fractals,' the rules of formation of which are chosen at random at each step of scale hierarchy in accordance with some probability distribution.^{120, 121} In this case, the transfer of energy is described by virtue of random fragmentation model with the assumption that no correlations exist between stages of the process. Nevertheless, it is possible to calculate the fractal dimension of turbulent structures (D_f), which is defined by the relation

$$\langle N_n \rangle \sim L_n^{-D_f}, \quad (50)$$

where N_n is the number of active vortices at an n -th fragmentation step, L_n is the scale of the n -th vortex, and D is estimated using the following equation:¹⁰

$$D_f = 3 + \log_2 \beta, \quad (51)$$

in which β is the fraction of the volume occupied by vortices of the scale L_n .

As a first approximation, it can be assumed that $D_f = d_f^t$, where d_f^t is the fractal dimension of the topological structure of the polymer, which can be found from Eqn (27).

It is clear that the chain fragments with the molecular mass M_s are considered in a plane ($d = 2$) and the formation of clusters is discussed in a volume ($d = 3$). The D value calculated from Eqn (39) for a two-dimensional fractal can be used to find the value for a three-dimensional fractal by applying Eqn (27) to the dimension d_f^t . This method is not highly accurate but simple. Equation (51) makes it possible to determine the fraction of volume β occupied by vortices of the L_n scale. Assuming that the β and φ_{cl} values are equal, the V_{cl} value can be calculated from the relation

$$V_{cl} = \frac{\varphi_{cl}}{S l_0 C_\infty}.$$

Comparison of the V_{cl} values found in this way with those obtained experimentally⁴⁷ for systems EP-1 and EP-2 showed that the two methods provide the same order of magnitude. Nevertheless, to attain better agreement between the results, it can be assumed that not all the active turbulent vortices are converted into local order regions; in general, this is obvious due to the fluctuational nature of these regions.⁸⁹ This means that $\varphi_{cl} = C\beta$, where C is a proportionality coefficient. Assuming that for EP-1 and EP-2, $C = 0.6$, we obtain a much better quantitative agreement between experimental and calculated data. It is clear that the coefficient C reflects the influence of variable characteristics of curing such as temperature, time, viscosity of the medium, *etc.* The fact that the dimension of non-homogeneous fractal D_f is always greater than the dimension of the corresponding homogeneous fractal d_f^t might serve as yet another reason for the inconsistency between the φ_{cl} and β values, mentioned above.¹²² The condition $D_f > d_f^t$ implies a decrease in β in the calculations using Eqn (51).

Fractality of the structures of polymers influences their properties. According to modern concepts,^{123–125} the glass transition of amorphous polymers is regarded as the formation of 'frozen' local order (dissipative structures). Generally, for amorphous systems, this is considered to be a complex and hierarchically multistage process. The first stage involves the formation of seeds of microcrystals, which are unable to grow and serve as a sort of substrate for deposition of amorphous clusters. The second stage is characterised by self-organisation of mesoclusters.¹²⁶ As applied to the glass transition of polymers, these processes can be specified in the following way. The first stage starts at the temperature of so-called liquid–liquid transition T_{ll} , in which regions of dynamic short-lived local order are formed.²³ At the glass transition temperature, avalanche-like accumulation of clusters takes place, which characterises the formation of 'frozen' local order (the second stage). For this process,

$$\tau^* \propto (R^*)^{d_f}, \quad (51a)$$

where τ^* is the time before the onset of this process and R^* is the critical cluster size.⁹⁸

Since the temperature–time superposition is correct for polymers, we assume that $R^* \propto l_{st}$ and write relation (51a) in the following form

$$T_g \propto l_{st}^{-\alpha}.$$

The dependence of the experimental T_g values¹¹² on l_{st} for epoxy polymers can be represented by a correlation function. In addition, $\alpha \simeq 0.28$, which complies with the necessary condition

$\alpha = d - d_f$.⁸⁸ Hence, the change in T_g upon the variation of v_s is also an indication of the fractal structure of network polymers.

Note that the behaviour of network polymers is in agreement with several other fundamental physical principles. Let us illustrate this by two examples. An integral stoichiometry implies stability and ordering of the structure of a compound.³ This is confirmed by the data of Beloshenko *et al.*,¹⁰² according to which the maximum degree of local ordering in epoxy polymers is attained when an oligomer and a curing agent are taken in stoichiometric amounts, *i.e.* when $K = 1.0$ (or is close to 1).

Structure parameters and characteristics of properties of epoxy polymers are not random values either. Thus the length of statistical segment l_{st} obeys the automodelling relation

$$\frac{l_{sti}}{l_{st(i+1)}} = \Delta^{1/m}, \quad (52)$$

where $\Delta = 10$ and m varies according to a geometric progression law

$$m = 2, 4, 8, 16, 32, \dots, 2^n, \dots, \infty. \quad (53)$$

Hence, formation of the structure and properties of epoxy polymers during curing is determined by fundamental physical principles. This is accompanied by the change in the characteristic ratio C_∞ (molecular characteristics), although the structure of the macromolecule remains invariant. The use of the above physical principles even in the simplest version provides a correct description of the structure and properties of network polymers.

b. Scaling representation of a macromolecule

A number of methods exist for the modelling of polymers at a molecular level. One of the most widely used methods is scaling presentation,⁵² according to which the diameter ϕ of the 'tube' in which the macromolecule is enclosed (it is equal to the distance between the entanglement points) can be estimated from the ratio⁷²

$$\phi^2 = C_\infty \frac{M_s l_0^2}{m_0}. \quad (54)$$

The main difference between physical entanglements (loops) and chemical cross-links is that the former allow creeping of chains. The density of both types of link are determined using the same rubber elasticity equation, a factor of 0.8 being frequently added to take creeping into account.⁷²

Yet another representation of a macromolecular chain as a fractal is considered below. Olemskoy and Flat¹²⁷ have noted that the concept of fractals rather than description of an observed geometric image is usually applied to condensed media. As regards a macromolecule, modelled by a freely jointed chain consisting of statistical segments, one can hardly find a geometrical image more vivid than a fractal broken line. In addition, it should be noted that representation of a macromolecule by either one-dimensional (as a curve) or three-dimensional (as a cylinder) object appears to be a fairly rough approximation in view of the real structure of a macromolecule, *i.e.* the presence of side chains, flexible bonds, rigid segments, *etc.*

As noted above, a change in the density of chemical cross-linking v_s in epoxy polymers results in an extremal variation of the characteristic ratio C_∞ with the minimum $K \simeq 1.0$.¹¹⁵ If the section of a macromolecule between chemical cross-links is modelled by a freely jointed chain, the use of known L_s and l_{st} values results in a typical fractal dependence¹¹⁹

$$N_{st}(\xi l_{st}) = \xi^{-D} N_{st}(l_{st}), \quad \xi < 1, \quad (55)$$

where N_{st} is the number of statistical segments per fragment of a macromolecule with the molecular mass M_s , and ξ is a similarity parameter.

With the assumption that $L_s = \text{const}$ and $K = 1.0$, $\xi = 0.85$ was obtained; with $L_s = \text{const}$ and $K > 1.0$, the calculations gave $\xi = (0.85)^{1/2} = 0.926$. The calculation of the dimension D from

Table 6. Calculated molecular characteristics of epoxy polymers.⁸

Polymer	K	D	C_∞		
			I	II	III
EP-1	0.50	2.06	5.23	4.83	5.28
	0.75	1.60	4.32	6.97	3.50
	1.00	1.25	3.38	9.94	3.68
	1.25	1.35	3.75	8.89	3.19
	1.50	1.50	4.05	7.68	3.34
EP-2	0.50	1.85	5.27	6.54	5.35
	0.75	1.43	3.98	8.89	4.69
	1.00	1.32	3.40	9.24	3.37
	1.25	1.35	3.70	9.24	3.90
	1.50	1.55	4.10	7.96	4.29

Note. The following designations are used: I — data of Ref. 121, II — calculation by Eqn (54), III — calculation by Eqn (57).

Eqn (55) gave 1.17. Thus, when the condition mentioned above is fulfilled, the section of a macromolecule between chemical cross-linking points can be represented as a fractal. Variation of K changes the cross-linking density v_s and, hence, L_s . As a consequence, the chain ceases to be a self-similar fractal. Nevertheless, it still can be modelled by a non-homogeneous fractal with the same fragmentation step but with a variable D value, determined from relation (39). The D values calculated in this way are listed in Table 6.

The results of calculation of the characteristic ratio C_∞ from Eqn (54) are inconsistent in kind with the data obtained by Jean *et al.*¹²⁸ Indeed, the maximum rather than the minimum C_∞ is attained at $K = 1.0$. Since

$$\phi^2 \propto v_s^{-2/3}, \quad M_s \propto v_s^{-1},$$

then, according to Eqn (54), the C_∞ value should be proportional to $v_s^{1/2}$. In other words, an increase in the density of cross-links should increase the chain flexibility, which is inconsistent with the extremal increase in the glass transition temperature of epoxy polymers.^{115, 129}

Let us consider the reasons for this inconsistency.

Since

$$C_\infty l_0 = l_{st}, \quad \frac{M l_0}{m} = L_0,$$

multiplication and division of Eqn (54) by l_{st}^2 gives the relation⁸

$$\frac{L_0}{l_{st}} = \left(\frac{R_s}{l_{st}} \right)^2, \quad (56)$$

which is similar to Eqn (39). Comparison of Eqns (39) and (56) shows that the scaling relation (54) is a specific case of the fractal formula (39) for $D = 2$. For the epoxy polymers considered, condition $D = 2$ does not hold (see Table 6); this may account for the discrepancy found. Using relations (39) and (56), the scaling equation (54) can be written in a more general form

$$a^D = C_\infty^{D-1} \frac{M_s l_0^D}{m}. \quad (57)$$

The calculation of C_∞ using Eqn (57) give values that are in good agreement with the results obtained by Jean *et al.*¹²⁸

It has been shown⁹⁰ that in the case of linear polymers, the following empirical correlation is obeyed for physical entanglements

$$R_s \simeq 10 C_\infty. \quad (58)$$

Taking into account the data presented above, the same (or similar) correlation should be expected for chemical cross-links in network polymers.

Figure 14. Distance between chemical cross-linking points R_s vs. characteristic ratio C_∞ for EP-1 (1) and EP-2 (2).⁸

The relationship between the C_∞ values found using Eqn (57) and R_s calculated using Eqn (26a) is linear

$$R_s \approx 5C_\infty, \quad (59)$$

which is illustrated by Fig. 14.

Equations (58) and (59) are qualitatively similar and the discrepancy of numerical coefficients can be due to the approximate character of these relations and to the difference between the methods used to calculate R_s .¹³⁰

Recall that the parameter D characterises the degree of deformability (mobility) of a macromolecule fragment between chemical cross-linking points. Indeed, an increase in the chain flexibility brings about an increase in C_∞ , *i.e.* an increase in D . It should be noted that extrapolation of straight line $D(C_\infty)$ to $D = 1$ gives $C_\infty \approx 2.55$; evidently, this is the limiting value for epoxy polymers considered. It is also noteworthy that it is close to C_∞ for a linear polymer with a similar structure, for example, for polycarbonate, which has $C_\infty = 2.4$.⁹⁰

Apparently, the deformability of a macromolecule in vitreous epoxy polymers is determined not only by their molecular characteristics but also by supermolecular (supersegmental) 'frozen' structure, which can be characterised quantitatively in terms of the cluster model. It should be borne in mind that an amorphous polymer contains regions of local order (clusters) and that fixing of one or several statistical chain segments in a cluster should change the D value. The most probable reason for the change in D is that the fixed segment becomes expelled from the freely jointed chain, as it has lost its mobility in the junction points. Evidently, this decreases the L_s value in Eqn (39) by l_{st} and, finally, induces a decrease in D . Thus in the case of epoxy polymer EP-1, elimination of one statistical segment induces a decrease in D from 2.06 to 1.73; when two segments are eliminated, D decreases to 1.65; in the case of three segments, it decreases to 1.56, *etc.* In the absence of 'frozen' local order, *i.e.*, for rubbers ($\varphi_{cl} = 0$), $D = 2$ and the loss of chain mobility (deformability) is attained at $\varphi_{cl} \approx 0.65$. The opposite effect is also possible; an increase in v_s induces a decrease in D , *i.e.* the chain becomes more taut, which should increase the level of local order.¹³¹

In the case of linear polymers, the network of macromolecular entanglements is the analogue of the network of chemical bonds; their density V_{en} is determined at $T > T_g$.

Thus, relation (54) is a specific case of a more general fractal relation (57) and is applicable only to rubbers, for which it has actually been derived.

c. Estimation of structural parameters

The cited examples demonstrate the capacity and the prospects of using fractal concepts for the description of macromolecular characteristics of network and linear polymers. The change in the C_∞ value induced by variation of v_s or V_{en} implies that an absolutely different polymer can be formed although the chemical composition of the macromolecule has remained almost the same. This 'new' polymer would have different molecular characteristics (C_∞ , D), a different supersegmental structure (V_{cl} , φ_{cl}), and other properties (glass transition temperature T_g , elasticity modulus E ,

etc.). Equation (54) gives the maximum C_∞ value possible for the given v_s (see Table 6); the minimum values can be obtained by extrapolating the straight line $D(C_\infty)$ to $D = 1$.

At present, vitreous network polymers are mainly characterised by the v_s value.⁴³ However, one network polymer with constant v_s can possess different properties, for example, different glass transition temperatures.¹³² This is explained by the change in the supermolecular structure of a network polymer during physical ageing, namely, by an increase in the level of local order. This effect has been described quantitatively in terms of the cluster model. In turn, the level of local order determines the fractal dimension d_f of the supermolecular (supersegmental) structure of the polymer.⁸ Thus, it becomes possible to predict structural characteristics (and, hence, properties) of network polymers in the vitreous state based on the degree of chemical cross-linking up to the gelation point.

Analysis of the relationship between v_s and d_f for the epoxy polymers considered showed that an increase in the fractal dimension of the framework to the gelation point induces a decrease in the fractal dimension of the supermolecular (supersegmental) structure of the network polymer in the glassy state.

It has been noted in the Introduction that description of fractal structures requires, at least, two dimensions, d_s and d_f , at a constant d value.²⁷ However, the fractal concept is a mathematical model, which does not provide identification of the specific features of the polymer structure. Therefore, in order to use the parameters d_s and d_f in practice (for instance, in computer simulation), one has to find out which elements of the polymer structure (in particular, of network polymers) they embody. It is known⁵⁵ that d_s characterises the degree of connectivity of the framework and d_f (which might be time-dependent) refers to the structure of this framework. The d_f value can be found from Eqn (27), which indicates that d_f is a function only of the Poisson coefficient μ (for fixed d). For amorphous polymers, μ is determined by the degree of local order;⁴⁶ hence, this structural factor also determines d_f . As regards the spectral dimension d_s , it appears to be related in one way or another to the framework formed by chemical cross-links. This suggestion was based on the results of two studies by Kozlov *et al.*^{115, 133} In the former study, the relationships between v_s and the degree of local order and between d_s and d_f were elucidated. The latter study demonstrated the variation of properties of epoxy polymers with time (during physical ageing) following the change in the level of local order (or d_f) with v_s remaining invariant.

The d_s value can be calculated from Eqn (8). For estimating the dimension d_w , needed for this purpose, several relations exist;^{23, 36, 55, 60, 122, 134, 135} they give somewhat different (to within $\sim 20\%$) absolute magnitudes of this parameter. If the variant of constant d_w is chosen and the model of 'lattice animals' ($d = 3$) is used for describing branched polymers, the dependence of d_s on v_s would follow a somewhat unexpected pattern. According to this dependence, an increase in the density of cross-linking points results in lower d_s and, hence, in lower connectivity of the macromolecular framework of chemical cross-links. It is noteworthy that for great v_s , the d_s value approaches asymptotically the experimental spectral dimensions of epoxy polymers.^{22, 35, 69} This finding can be interpreted in terms of the generally accepted models of the structure (or, more precisely, morphology) of network polymers.¹³⁶

The main morphological unit of densely cross-linked epoxy polymers is a globule. It is a local thickening of a molecular space network the packing density in which is higher than the average density. During etching of fractured surfaces of epoxy polymers, this thickening is revealed as a discrete particle — a globule. The non-homogeneity of network polymers is due to both the kinetics of formation of a three-dimensional network and the presence of associates in the initial oligomers.¹³⁶

Two variants of construction of a supermolecular (globular) structure are possible: (a) accrete globules with a hexagonal or cubic packing form a strong continuous skeleton in which the role

of inter-globule defective areas is insignificant; (b) densely cross-linked globules (grains) are located in a sparse-network matrix and do not contact directly one another.

The former variant of morphology seems to be more frequently encountered. An increase in the concentration of a cross-linking agent induces simultaneous generation of a large number of chemical reaction centres; this is confirmed indirectly by a decrease in the size and the increase in the number of globules.¹¹⁶ This results in a smaller size and a greater number of inter-globule defective areas; thus, the connectivity of the skeleton diminishes (defective areas act as sorts of skeletal discontinuities) and, hence, d_s decreases.

In the case where the morphology of a network polymer corresponds to the second variant, its structure can be represented as a mixture of arbitrary polymer fractals in the vicinity of the gelation point; the spectral dimension of the globule is d_s and that of the inter-globule area is δ_s . The δ_s value can be estimated using the relation⁶⁰

$$d_f = d_s \frac{(d+1)(2-\delta_s)}{(2+d_s-2\delta_s)}.$$

As a first approximation, it was assumed in this relation that the spectral dimensions of the structures of the epoxy polymer and the globules are equal. It was found that the dependence of δ_s on v_s for epoxy polymers shows parallel variation of d_s and δ_s upon the variation of v_s provided that $d_s > \delta_s$.⁶⁰ This condition indicates that the skeleton in the inter-globular gaps is less connected than the globules themselves because it is more defective.

Thus, the density of chemical cross-linking points cannot serve as an index for the connectivity of the macromolecular skeleton of network polymers. This makes impossible the use of v_s to characterise the structure of network polymers in a computer simulation, which follows from the results presented above. The d_s value, which provides determination of elastic properties, may serve as a suitable parameter. However, to estimate other properties, one more parameter is required, which would characterise the degree of thermodynamic nonequilibrium of the structures of vitreous polymers. This role can be played by d_f or the density of the cluster network of physical entanglements V_{cl} ,⁴⁷ or by the proportion of clusters ϕ_{cl} .¹³⁷ For instance, the necessity to take into account d_s , V_{cl} or ϕ_{cl} for calculating the yield point from known elasticity modulus has been demonstrated by Beloshenko and Kozlov.⁴⁷ Therefore, the frequently encountered correlations between properties of network polymers and v_s can serve only as an illustration. The use of two parameters (for example, d_s and d_f with a constant d) is a mandatory (fundamental) condition which follows from the fractality of intermolecular frameworks of vitreous polymers; in turn, the fractality is a consequence of thermodynamic nonequilibrium of this structure.

3. Description of molecular mobility using fractal characteristics

The problems of molecular mobility in polymers have always received considerable attention.^{32,95,138} The reasons are obvious — polymers are thermodynamically nonequilibrium solids, their physical properties being determined by molecular relaxation processes occurring in them; these processes, in turn, depend on specific structural features of molecular chains and the structural organisation of polymers.¹³⁸ However, there is no consensus regarding the parameters describing these processes. In particular, it is assumed that fast relaxations are determined by the mobility of free chains located between densely packed regions, which are simultaneously the nodes of the network of physical entanglements in a macromolecule. This interpretation fully complies with the main statements of the cluster model for the structure of amorphous polymers,¹⁵ which provides quantitative description of structural elements. The relationship between the cluster model and fractal analysis can be formulated as follows: fractal analysis gives general physical parameters, while

the cluster model makes them more specific using particular characteristics of polymers.

Yet another important aspect is worth noting. The above interpretation of the structure of amorphous polymers refers to elastomers. Extension of these notions to vitreous amorphous polymers implies 'freezing' of densely packed regions, *i.e.* a sharp increase in their lifetimes. The fractal forms of macromolecules, macromolecular coils formed during nonequilibrium physico-chemical processes are retained (remain 'frozen') in polymers. This suggests that the main factor determining the molecular mobility in the vitreous state is the mobility of chain fragments between the points of fixing.¹¹¹

The fractal dimension D has been chosen as the structural factor characterising the level of molecular mobility;¹¹¹ this was done for the following reasons. First, a chain fragment between the points of fixing is a self-similar object having a dimension differing from the topological dimension, *i.e.* it is a fractal by definition.¹⁰⁷ Second, it was shown¹⁰¹ that D with the range of variation $1 < D \leq 2$ characterises exactly the molecular mobility of a chain fragment in loosely packed regions.¹³⁸ The condition $D = 1$ implies stretching of this chain fragment and loss of fractal properties and mobility. In terms of relaxation spectroscopy, this means that $\tan \delta = 0$, where $\tan \delta$ is the mechanical (or dielectric) loss tangent. The condition $D = 2$ means the maximum possible mobility of the chain section, which corresponds to a rubbery state of the polymer, *i.e.* it is consistent with the maximum value of $\tan \delta$ at the glass transition temperature T_g .

Figure 15 shows the dependence of $\tan \delta$ on D for several copolymers¹¹¹ [the D values were calculated using Eqn (48)] for a measurement frequency of 1 kHz. The dependence has clearly defined limits. For $D = 1$, it is extrapolated to $\tan \delta = 0$. When $D = 2$, $\tan \delta$ is roughly equal to the corresponding value at T_g . Thus, linear dependences with the limiting $\tan \delta$ values indicated above can be used to predict the fractal dimension.

Figure 15. Dielectric loss tangent $\tan \delta$ vs. fractal dimension D of the macromolecule section for copolyethersulfoneformals with the content of formal blocks of 0 (1), 5 (2), 10 (3), 30 (4), 50 (5) and 70 (6) mol.%. Measurement frequency 1 kHz.¹¹¹

Now we shall consider examples of using the dimension D for the solution of applied problems. When polymer samples are obtained by solid-phase extrusion, the macroscopic (extrusion) draw ratio λ_e is determined by the ratio^{119,139,140}

$$\lambda_e = \frac{\phi_b^2}{\phi_{spin}^2}, \quad (60)$$

where ϕ_b , ϕ_{spin} are the diameters of the billet and the spinneret, respectively.

However, the structure and properties of oriented polymers are characterised much more adequately by the molecular draw

ratio λ_{mol} .¹²² The following expression relating λ_e , λ_{mol} and D to one another has been obtained:¹²⁰

$$\lambda_{\text{mol}} = \frac{l_{\text{st}} \lambda_e^{2/D}}{R_s}. \quad (61)$$

It follows from this relation that the lower D , *i.e.* the more 'frozen' the molecular mobility of the chain during drawing, the greater λ_{mol} (the more efficient the orientation process), all other factors being the same.

The limiting draw ratio λ_{∞} attained by stretching a polymer is determined, in terms of the rubbery high-elasticity theory, by the equality¹²¹

$$\lambda_{\infty} = n_{\text{st}}^{1/2}, \quad (62)$$

where n_{st} is the number of statistical segments.

This equation has been applied repeatedly to vitreous polymers. The following fractal relation has been obtained:³⁸

$$\lambda_{\infty} = n_{\text{st}}^{D/4}. \quad (63)$$

It can be easily seen that an increase in D for $n_{\text{st}} = \text{const}$ enhances the deformability of polymers. Equations (62) and (63) are identical when $D = 2$, *i.e.* for rubbers.

An important difference between Eqns (62) and (63) is that in the former, λ_{∞} depends on one parameter, which is typical of equilibrium Euclidean objects, while in the latter, it is a function of two parameters, which is typical of thermodynamically nonequilibrium fractal objects. Therefore, the use of Eqn (62) in the latter case is improper.

The relationship between the statistical chain flexibility, characterised by C_{∞} , and the dimension D has been found¹⁴¹

$$D = 2 - \frac{1}{C_{\infty}}. \quad (64)$$

Using published data for C_{∞} (see, for example, Ref. 90) and Eqns (27) and (49), the lengths of chain sections between entanglements L_{en} were calculated. The results were in agreement with experimental data (Table 7). Thus, the increase in the density of the network of macromolecular entanglements following an increase in the statistical chain rigidity was confirmed within the framework of fractal analysis. By combined use of Eqns (27) and (49), one can predict the increase in the number of points of topological fixing of a macromolecule in the vitreous state with respect to the rubbery state.¹⁴¹

The fractal dimension D of a chain fragment between the points of topological fixing (entanglements, clusters, cross-links) is an important structural parameter, which controls the molec-

ular mobility and deformability of polymers. Crucial factors accounting for the use of the dimension D are clearly defined limits of variation ($1 < D \leq 2$) and dependence on the supermolecular structure of the polymer. It should be emphasised that all fractal relations contain at least two variables. Therefore, correlations between some property of polymers and the density of the network of entanglements (cross-links), which are frequently encountered in the literature, can serve only as illustrations. The necessary use of at least two parameters (for instance, d_s and d_f with a constant d) is a fundamental condition, which follows from the fractality of the intermolecular skeletons in vitreous polymers.

IV. Conclusion

The fractal properties of a macromolecule in a polymer are predetermined by thermodynamic nonequilibrium and by the presence of a certain deterministic order. Proceeding from this fact, we considered the limitations of the scope of the concept of polymer fractal, developed for polymer solutions, and the Vilgis theory for condensed media (melts and rubbers). The major drawback of these approaches is that they neglect the effects of macromolecular entanglements. It is demonstrated that a description of the fractal properties of macromolecules cannot be physically correct without allowance for entanglements. Examples are given to illustrate the diversity of fractality in polymers. In particular, it is shown that not only macromolecular coils but also sections of macromolecules between the points of topological fixing (cross-links, entanglements) are stochastic fractals.

Conditions required for the fractality to be manifested are discussed. They include the range of scales, self-similarity and fractional dimension. It is shown that a section of a macromolecule between the points of topological fixing possesses configurational fractal properties, caused by the mutual arrangement of fragments of the macromolecule, and conformational fractal properties, conditioned by the state of bonds within a section of rigidity (*i.e.* statistical segment). In this connection, a model of structure formation in network polymers is considered; this model includes a quantitative determination of the relationship between the cross-linking density and the level of local order of the structure. It is demonstrated that, in addition to the parameters of local order, fractal dimensions of the polymer structure should also be taken into account. Examples of practical use of the fractal dimension of the section of a macromolecule between chemical cross-linking points are given; it is shown that this value can serve as a measure of molecular mobility. The influence of characteristics of molecular and topological levels of the structure of cross-linked polymers on the fractal dimension is noted.

V. Syntheses based on reactions of unsaturated sulfones and sulfoxides	392
VI. Conclusion	403

Abstract. Data on the use of sulfones and sulfoxides in total stereo-, regio- and enantioselective syntheses of natural compounds published over the last 15–20 years are discussed and classified into the most important types of reactions. The bibliography includes 420 references.

I. Introduction

Sulfonyl- and sulfinyl-containing intermediates and their precursors are finding increasing use in the synthesis of natural compounds because these groups satisfy the requirements of sophisticated multistage transformations. In this review, the most important requirements are stated based on the concepts proposed by the eminent chemist and populariser of science, E Block.¹

These functional groups should be:

- (1) readily accessible;
- (2) highly reactive;
- (3) able to effect asymmetric induction;
- (4) readily removable at a particular stage of the synthesis.

Sulfoxides and sulfones are rather readily available compounds. Methods for their synthesis both from the corresponding sulfides and other precursors have been well developed.^{2–5}

Owing to their high reactivity, sulfoxides and sulfones can induce the stereo-, regio- and enantioselective formation of new C–X bonds and, what is particularly important, of C–C bonds.

Enantiomerically pure sulfoxides are excellent mediators in the asymmetric synthesis. The fact that the sulfur atom in sulfoxides containing different substituents is an ideal asymmetry center (Montanari⁶ was the first to note this fact back in the 1970s) is not the only reason. The ability of the sulfinyl group to form chelates due to complexation with other polar groups in the molecule as well as with catalysts is used in enantioselective syntheses resulting in 1 → 2, 1 → 3 and more distant asymmetry

transfer.^{5,7–13} The wide application of chiral sulfoxides is also favoured by the availability of convenient methods for their preparation in enantiomerically pure *S*- or *R*-forms.^{5,12}

Sulfonyl groups do not possess inherent asymmetry and are substantially less active complex-forming agents. However, due to their specific bulk and electronic properties, these compounds can perform regio- and stereocontrol. Reactions of sulfones proceed under rather mild conditions, which makes it possible to retain chiral carbon centres (even those located in the vicinity of the sulfonyl group) throughout the process.

A wide variety of chemoselective procedures for the removal of sulfonyl and sulfinyl groups are available (see, for example, Ref. 14). Classical heterogeneous reduction with Raney nickel (Ra/Ni) continues to be used. Mild heterogeneous desulfonation (desulfination) with metal amalgams (primarily with Na/Hg) is also often employed. However, the majority of modern procedures involve homogeneous processes, *viz.*, reactions of transition metal salts, palladium(0) complexes or solutions of alkali metals in ammonia. Since the use of lanthanides have attracted growing interest in recent years,^{15,16} mild desulfonation with SmI₂ is rather often used (see, for example, Refs 16–19). Reductive desulfurisation, elimination of sulfenic and sulfinic acids to form C=C bonds and double elimination of hydroxy and sulfonyl groups from substituted sulfones can readily be performed. Although the sulfonyl fragment is a poor leaving group (see, for example, Ref. 20), conditions were found under which this group in some compounds can be replaced by the attacking reagents.

In spite of the fact that synthetic applications of sulfones have been surveyed (see, for example, Refs 21 and 22), the data on the use of these compounds in the synthesis of natural products remain to be systematised. Applications of particular types of sulfones, such as γ -hydroxyvinyl sulfones^{23,24} and sulfolenes,^{25,26} for these purposes have been described. Examples of the use of sulfones were cited in reviews devoted to syntheses of selected groups of natural compounds (juvenile hormones²⁷ and linear polyprenols^{28,29}). Recently, Carreno¹² has reported a comprehensive analysis of the uses of chiral sulfoxides in asymmetric syntheses of biologically active compounds. Therefore, in the present review the attention is focused on sulfonyl-containing and racemic sulfinyl-containing precursors and intermediates without special reference to asymmetric synthesis, all the more so since the stereochemistry of all chiral centres has not always been reported in the original studies. Yet another aim of this review is to

demonstrate how successfully sulfones and sulfoxides complement each other in syntheses of natural compounds.

II. Brief characterisation of reactions applicable in the synthesis of natural compounds based on the use of sulfones and sulfoxides

Even a brief analysis of reactions of sulfoxides and sulfones gives an idea of their wide synthetic potential. These compounds can provide the basis for the erection of the building for the synthesis of natural compounds. Fuchs and coworkers²⁴ compared this building to a majestic pyramid.

Reactions of carbanions stabilised by α -sulfonyl or (to a lesser extent) α -sulfinyl groups are often used in the synthesis of natural compounds. Among various reagents used for α -deprotonation,^{30, 31} lithium bases (for example, alkyllithium compounds or lithium diisopropylamide LDA) predominate. In this review, these species will be sometimes described as C-lithiated species in accordance with the original reports although this is not quite correct. It has been rigorously proved³² that in the crystalline state of sulfur-containing alkyllithium compounds, the metal atom is bound to the oxygen atom of the sulfonyl (sulfinyl) group rather than to the α -carbon atom. However, this fact is not reflected in their reactions in solution. Electrophilic reagents attack exclusively the carbon atom unlike their reactions with carbanions stabilised by the carbonyl group. Alkylation with alkyl or cycloalkyl halides, tosylates or mesylates (Scheme 1, path *a*) affords

$n = 1, 2$; (a) R^3X , $X = \text{Hal, OTs, OMs}$ ($\text{Ms} = \text{MeSO}_2$); (b) $R^3\text{CHO}$;

(c) $R^3\text{CO}_2R^4$; (d) R^3 -oxirane- R^4 ; (e) CH=EWG , EWG is an electron-withdrawing group.

sulfones or sulfoxides **A** and their reductive desulfurisation leads to the elongation of a saturated chain. Elimination of fragments of acids RSO_nH ($n = 1$ or 2) from derivatives **A** results in the formation of the $\text{C}=\text{C}$ bond. For most sulfones, this process occurs under rather drastic conditions. Many sulfoxides eliminate sulfenic acid upon mild thermolysis, which provided the basis for a method of introduction of $\text{C}=\text{C}$ bonds with *E* configuration into complex molecules proposed by Trost.^{33–35}

(a) $n = 2$, **B**•; (b) $n = 1$, Δ .

Reactions with carbonyl compounds or oxiranes lead to the 1,2-addition at the carbonyl group (Scheme 1, paths *b* and *c*) or to the oxirane-ring opening (path *d*). Reactions of α -sulfonyl carbanions with aldehydes are of particular importance because the

resulting epimeric mixtures of 2-hydroxy sulfones **B** ($n = 2$) serve as an inexhaustible source for the construction of new functional groups, viz., vinylsulfonyl, oxosulfonyl, saturated hydroxy or oxo groups.

Of prime importance is the Julia olefination resulting in stereoselective construction of the $\text{C}=\text{C}$ bond with either the *E* (Ref. 36) or *Z* (Ref. 37) configuration following acylation of the hydroxy group (Scheme 2, paths *a* and *b*).

Scheme 2

(a) $n = 2$, Ac_2O ; (b) Na/Hg ; (c) $n = 1, 2$; (d) $n = 2$, **B**•; (e) $n = 2$, $[\text{O}]$; (f) $[\text{H}]$.

The most important precursors in the asymmetric synthesis, viz., 2-hydroxy sulfoxides (**B**, $n = 1$),¹² must be used only in enantiomerically pure form. Therefore, these compounds are generally prepared by selective reduction according to Solladie^{38, 39} starting from 2-oxo sulfoxides **C**. The most convenient procedure for the synthesis of the latter involves the reaction of α -sulfinyl carbanions with the carbonyl groups of esters (Scheme 1, path *c*).

α -Sulfonyl(sulfinyl) carbanions, being active C-nucleophiles, readily react with various electron-deficient multiple bonds (Scheme 1, path *e*).

Either aryl or (more rarely) *tert*-butyl groups generally serve as substituents R^1 in sulfonyl(sulfinyl) fragments. This is dictated not only by the necessity of providing conditions for regiospecific deprotonation but also for kinetic reasons. For example, benzenesulfenic acid is eliminated upon thermolysis of sulfoxides at substantially lower temperatures than methanesulfenic acid.⁴⁰

Among unsaturated precursors, vinyl sulfones are worthy of particular attention. Fuchs and coworkers^{23, 24} believed that these sulfones are ideal starting compounds (superior even to enones) for sophisticated syntheses. New $\text{C}-\text{C}$ bonds are formed upon addition of C-nucleophiles (predominantly metal alkyls) at the activated $\text{C}=\text{C}$ bonds of vinyl sulfones followed by the reaction of electrophiles with the resulting α -sulfonyl carbanionic centre (Scheme 3, path *a*). Reactions of the $\text{C}=\text{C}$ bonds of ene sulfoxides with C-nucleophiles occur successfully, if additional acceptors, for example, carbonyl groups, are introduced into the sulfoxide molecules. Reactions of heteronucleophiles with ene sulfoxides

Scheme 3

$n = 1, 2$; (a) R^3M ($M = \text{Li, MgX}$); (b) $\text{CH}_2=\text{CH}-\text{C}(=\text{O})-\text{R}^3$; (c) $n = 2$, $R^3\text{MgX}$, Ni(II) or Fe(III) ; (d) **B**•.

and ene sulfones (see Section V.1.b) as well as the Diels–Alder [4 + 2] cycloaddition (Scheme 3, path *b*) are also widely used. Cross-coupling of vinyl sulfones with Grignard reagents in the presence of transition metal salts makes it possible to replace the sulfonyl group according to Julia,⁴¹ the C=C bonds being unaffected (Scheme 3, paths *c* and *d*).

Linear and cyclic polyunsaturated structures are successfully constructed with the use of various 1,3-dienes generated from substituted 3-sulfolenes by cheletropic elimination of SO₂.²⁶

Allyl sulfoxides and, particularly, allyl sulfones are very reactive compounds. Due to abstraction of the labile allylic hydrogen, these compounds readily form ambident carbanions, which can undergo alkylation both at the α - and (more rarely) γ -positions. In the presence of palladium catalysts or Lewis acids, the sulfonyl group in allyl sulfones is replaced by various nucleophiles.^{42,43} Because of the wide diversity of their transformations, Trost⁴⁴ has named allylic sulfones ‘organic chameleons’.

Of rearrangements of sulfoxides and sulfones, the Mislow–Evans sulfinyl–sulfenate rearrangement^{45,46} (which is used for the formation of hydroxy allylic fragments), the Pummerer reaction^{47,48} (which has many applications, but is predominantly used for the construction of cyclic molecules) and the Ramberg–Bäcklund reaction^{49,50} (which is used for the introduction of C=C bonds) are most commonly used in the synthesis of natural compounds. Because of a great body of information on syntheses involving rearrangements of sulfoxides and sulfones, these processes cannot be considered in this review in detail.

III. Syntheses based on α -sulfonyl or α -sulfinyl carbanions

1. Alkylation

a. Alkylation followed by reductive removal of sulfur-containing groups

The simplest procedure for the formation of new C–C bonds involves alkylation of α -sulfonyl or α -sulfinyl carbanions followed by reductive removal of sulfur-containing groups. This strategy was used for the first time in the syntheses of components of essential oils, *viz.*, racemic α -santalene [($\pm$)-**1**] and α -santalol [($\pm$)-**2**],⁵¹ as well as for the preparation of a pure *trans*-isomer of

squalene (**3**)⁵² by alkylation of the anion of farnesyl phenyl sulfone (**4**) with farnesyl bromide (**5**). This procedure is often used for the coupling of complex polyfunctional fragments containing numerous chiral centres. Recently, this method has been used for the preparation of intermediates **6–8** in the synthesis of ambrein (the intermediate **6**⁵³), polysubstituted biologically active furan compounds, *viz.*, calicogorgins A and C (the intermediates **7a** and **7b**, respectively⁵⁴), and the antibiotic mycotrienin (the intermediate **8**⁵⁵) (the sites of coupling are indicated by arrows).

THP is tetrahydropyran-2-yl.

$n = 1$, R = Me (**a**); $n = 2$, R = H (**b**).

R¹–R³ are protective groups.

This procedure can also be used for the construction of linear enantiomerically pure pheromones, both saturated and containing isolated C=C bonds. Mori and coworkers^{56–64} performed convergent syntheses of pheromones (*ee* 97%–98%) starting from two or more enantiomerically pure building blocks. If the absolute configuration of the natural pheromone was unknown, all possible enantiomers were synthesised in amounts sufficient for biological assays. Below are presented the syntheses of four possible enantiomers of 3,7-dimethylnonadecane (**9**), which is a pheromone of tortricid *Agromyza frontella* (an alfalfa pest).⁵⁶

Other pheromones synthesised by Mori and coworkers with the use of alkylation–desulfonylation methodology are listed in Table 1 (the coupling sites are indicated by arrows).

Table 1. Pheromones synthesised by alkylation–desulfurisation.

^a Preliminary data of biological studies. ^b In the study,⁶¹ enantiomers inactive with respect to *Tribolium castaneum*, but active with respect to other species *Tribolium* were prepared.

Pheromones whose molecules contain double bonds were constructed by alkylation–desulfonation starting from allylic sulfones and (or) allylic halides. This procedure was used for the preparation of enantiomerically pure faranal (**10**), which is the pheromone of Pharaoh's ant.⁶⁴

The synthesis of the pheromone of California scale (±)-**11** in the racemic form required the use of a threefold excess of allyl bromide because deprotonation and, correspondingly, alkylation of the initial methyl sulfone occurred non-regiospecifically.⁶⁵

In the synthesis of the sex pheromone of Douglas fir tussock moth **12**, α-thiolation followed by hydrolysis was used for the simultaneous formation of the oxo group and removal of the sulfonyl group; the C=C bond was formed by stereospecific hydrogenation of the triple bond.⁶⁶

An elegant method for stepwise alkylation developed by Moiseenkov and coworkers^{28, 67–70} makes it possible to synthesise polyunsaturated natural molecules by C₅-homologation. Lithiated δ-hydroxyallylic or saturated sulfones (including those containing a chiral centre) and the corresponding unsaturated terpenoid halides served as the starting compounds. This methodology was used for the preparation not only of relatively small molecules [for example, the pheromone components of San-Jose scale, viz., α-neryl and α-geranyl propionates (**13a,b**)⁶⁷], but also of long-chain natural regulators, such as polyphenol- and dolichol-like alcohols **14**⁶⁸ or **15**.⁶⁹ The addition of a crown ether, viz., dibenzo-18-crown-6 (DB-18-C-6), to a solution of sodium in liquid ammonia in the stage of reductive desulfonation made it

Chemical reaction scheme showing the synthesis of (±)-16. The starting material is a substituted piperidine derivative with a PhSO_2 group, an OTs group, a Boc group, and a Pr^n group. It reacts with reagent a to form an intermediate bicyclic structure with a PhSO_2 group and a Boc group. This intermediate then undergoes two more steps to yield the final product, (±)-16, which is a bicyclic amine with a methyl group and a Pr^n group.

Chemical reaction scheme showing the synthesis of compound **19**. The starting material is a complex bicyclic molecule with a BnOCH_2 group, a BnO group, a SO_2Ph group, and an iodide. It is converted to an intermediate bicyclic compound with a CH_2OBn group, a BnO group, and a SO_2Ph group via step (a). The intermediate is then converted to compound **19**, which is a bicyclic molecule with a CH_2OH group and a HO group, via steps (b) and (c).

the enantiomerically pure form starting from (*S,S*)-(–)-diethyl tartrate,⁷² phomactin D (**18**), which is a 12-membered PAF antagonist,⁷³ and the 14-membered carbocycle 7(8)-deoxyasperdiol (**19**), which is a synthetic precursor of the widespread membranoid antitumor agent asperdiol.⁷⁴

Intramolecular alkylation was used in the total synthesis of 21-membered heterocyclic antibiotics (+)-trienomycins A and F⁷⁶ and for the construction of the *AB* ring system of taxol.⁷⁷

20 min (50%–98%).

Unlike the above-mentioned studies in which alkylation was generally performed with the use of bromides or iodides, the enantiomerically controlled construction of the C(1)–C(17) fragment in the total synthesis of ionophoric boromycin was carried out using the mild reaction of a chloride with an anion generated from the 2-oxosulfonyl group.⁷⁸

Oxo sulfone **20** serves as an example of additional activation of the α -sulfonyl carbanionic centre in alkylation. The sulfone **20** was used as the starting material in the synthesis of compound **21**, which is the key intermediate for the preparation of the antibiotic ($\pm$)-aplasomycin.⁷⁹ Amino-acid-derived oxo sulfones **22a–c** were successfully used in the peptide synthesis.⁸⁰

Cyclic ketones containing the sulfonyl group at the α -position undergo three-carbon ring expansion when a fluoride anion acts on the products of alkylation of enolates of these ketones with silicon-containing allylic iodides or mesylates [$\text{Me}_3\text{SiCH}_2(\text{XCH}_2)\text{C}=\text{CH}_2$], which generate trimethylenemethane.⁸¹ Trost and coworkers⁸² used this procedure for the preparation of muscone **23** from 2-sulfonylcyclododecanone **24** in high yield.

(a) $\text{Me}_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{X}$ (X = I, OSO₂Me), NaH, NaI, DME;
(b) $\text{Bu}_4\text{N}^+\text{F}^-$, THF; (c) H_2 , 5% Pd/BaSO₄; (d) Na/Hg, Na₂HPO₄, H₂O.

The application of more complex oxosulfonyl precursors made it possible to construct sterically hindered systems of the 11,11-dimethylbicyclo[5.3.1]undecane series, such as compound **25**, which is the key intermediate in the synthesis of taxane derivatives,⁸³ as well as to prepare fused cyclopentanoids of the type **26**, which serve as the starting compounds for the preparation of hirsutene, hirsutic acid and coriolin.⁸⁴

The formal total synthesis of carba-prostacyclin (**27**), which is an analogue of prostacyclin, was reported.⁸⁵ The compound **27** is more stable, but exhibits no lesser activity in the inhibition of blood coagulation. The allylic sulfone dianion **28** was alkylated with enantiomerically pure mesylate of substituted hydroxycyclopentane. The necessary side chains were introduced into compound **29** by reactions with the corresponding lithium cuprates. The reactions were accompanied by the replacement of the

R¹ = SiMe₂Bu^t; (a) LiCu[(CH₂)₃OR²]₂; R² = CH(Me)OEt.

sulfonyl group and migration of the C=C bond to form a mixture of (*Z*)- and (*E*)-isomers of compound **30**. The latter is the key intermediate in the synthesis of carba-prostacyclin (**27**).

As to α -sulfonyl carbanions, the simplest alkylation–reductive desulfonylation procedure is rather rarely used in the synthesis of natural compounds. However, the racemic juvenile hormone **31** was synthesised by two-step reduction of the compound **32**, which is an alkylation product of disulfoxide **33**, via intermediate dithioether **34**.⁸⁶

(a) LDA; (b) BrCH₂CH=CHCO₂Me; (c) SnCl₂, AcCl, DMF;
(d) Ra/Ni, DMSO; (e) *m*-chloroperbenzoic acid (MCPBA).

In the total synthesis of racemic biotin **35**,⁸⁷ an intermediate obtained by alkylation of a sulfoxide was reduced to sulfide.

R = Bn, All; (a) MeLi; (b) I(CH₂)₄CO₂Bu^t; (c) TiCl₃; (d) HBr.

Deprotection of the amino and carboxy groups was performed in two steps to produce ($\pm$)-biotin **35**.

The reactions given below exemplify the use of alkylation of the anions derived from oxo sulfoxides upon deprotonation at the α -position with respect to the carbonyl group. Due to the induction exerted by the sulfinyl group, alkylation of an enantiomerically pure derivative of 1,3-dithiane 1-oxide (**36**) proceeded selectively to form compound **37**. Its hydrolysis afforded natural (–)-(*R*)-2,6-dimethylheptanoic acid [(–)-(*R*)-**38**].⁸⁸

(a) $(\text{Me}_3\text{Si})_2\text{NLi}$; (b) 1-iodo-2,6-dimethylheptane; (c) NaOH (39%).

The total synthesis of an antimalarial drug, viz., sesquiterpenoid (+)-artemisinin (**39**), was carried out starting from sulfoxide **40**,⁸⁹ which had been prepared from pulegone. The sulfinyl group acts as an activating agent that promotes alkylation of enolate.

(a) 2 equiv. of LDA, HMPT, THF, -35°C ; (b) bromo-ether intermediate; (c) Al/Hg.

b. Alkylation of α -sulfonyl carbanions followed by elimination of sulfinic acid

Homoallylic sulfones are promising starting compounds for the introduction of C=C bonds by alkylation of α -sulfonyl carbanions followed by elimination of sulfinic acid. Julia and Arnould⁹⁰ were the first to use this approach in the synthesis of natural compounds. These authors performed a convergent ($\text{C}_{15} + \text{C}_5$)-synthesis of methyl retinoate (**41**) related to vitamin A starting from β -ionone. The key step of this scheme involves dehydrosulfinylation of homoallylic sulfone **42** prepared by alkylation of

(a) Bu^nLi ; (b) Br-ether intermediate; (c) K_2CO_3 , MeOH (73%).

sulfone **43**. However, the *E*-configurations of all C=C bonds of the final reaction product **41** have not been established reliably.⁹⁰

This study⁹⁰ gave impetus to intensive investigations aimed at developing a sulfonyl procedure for the preparation of vitamin A as retinol acetate (**44**) (the results were surveyed in Ref. 91). This approach seemed to be promising owing to a small number of steps and the possibility of recycling of the sulfinate eliminated. The most essential results were obtained by researchers of Rhone–Poulenc^{92,93} and of Hoffman–LaRoche.^{94,95} Two versions of the convergent ($\text{C}_{15} + \text{C}_5$) schemes (Scheme 4, paths I

Scheme 4

Path I

(a) Bu^tOK , THF; (b) Pr^tONa , C_6H_{14} , 30°C , 1 h (82%–86%); (c) EtONa, EtOH, Δ , 13 h (83%), (d) Ac_2O , Py.

Path II

(a) LDA, THF; (b) NaNH_2 , NH_3 (liquid), -30°C , 50 min (85%); (c) Ac_2O , Et_3N .

Path III

X = Cl, Br; (a) Bu^tOK ; (b) NaOH, Me_2NH , 20°C , 16 h (75%) (ratio **44**:**45** ~ 1:2); (c) AcCl , Py; (d) PdCl_2 (70%).

and II)^{92, 93, 95} and the (C₁₃ + C₇) scheme 4 (path III)⁹⁴ were developed together with several procedures for the elimination of sulfinic acid. The major difficulties were associated with the formation of an admixture of the biologically inactive isomer **45** with the (*Z*)-C(9)=C(10) bond and the isomer **47**. Apparently, the isomer **45** was formed as a result of isomerisation of the intermediate sulfone **46**, whereas the isomer **47** was formed upon prolonged action of a base. The best results were obtained with the use of mild heterogeneous elimination of sulfinic acid (PrⁱONa, hexane, path I *b*). However, isolation of pure retinol acetate (**44**) requires recrystallisation.⁹² Other procedures for elimination (path I *c*, path II *e* and path III *h*) call for a number of additional operations. Thus upon desulfonylation with a solution of NaOH in Me₂NH, the content of the isomer **45** in the reaction mixture reached 34%. After isomerisation under the action of PdCl₂ and recrystallisation, pure retinol acetate was obtained in 70% yield. None of the sulfonyl procedures has been used in industry, at least, before 1984.⁹⁶

In the case of less complex molecules, for example, in the formation of (*E,E*)-1,3-dienes, the reactions are not accompanied by isomerisation. Therefore, (*E*)-homoallylic sulfones of the types **48** and **49** are convenient starting compounds. Elimination of sulfonic acid was used in the synthesis of pheromone components **50** and **51**.⁹⁷

(a) BuⁿLi; (b) THPO I; (c) H₃O⁺; (d) Bu^tOK, Bu^tOH, Δ;

(e) THPO ~~XX~~ I; (f) Na/Hg.

In the total convergent synthesis of the ionophore antibiotic indanomycin **52**,⁹⁸ the formation of the (*E,E*)-diene bridge

(b) triton B (BnMe₃NOH), MeOH, 40 °C; (c) CH₂N₂, Et₂O, 0 °C.

between two cyclic fragments of the molecule occurred as elimination of sulfinic acid involving only the hydrogen atom of the acyclic part of the intermediate sulfone **53**.

The synthesis of racemic lavandulol ($\pm$)-**54** involved formal replacement of the sulfonyl group.⁹⁹ The intermediate sulfone **55** was hydrostannylated simultaneously with the elimination of sulfinic acid. The subsequent reaction of stannane **56** with trioxane in the presence of boron trifluoride etherate was accompanied by elimination of Bu_3SnH and migration of the double bond.

(a) Bu^nLi ; (b)  (97%); (c) $\text{Bu}_3^{\text{n}}\text{SnH}$, AIBN (azobisisobutyronitrile) (97%); (d) $(\text{CH}_2\text{O})_3$, $\text{Et}_2\text{O} \cdot \text{BF}_3$ (57%).

c. Alkylation of α -sulfonyl carbanions with synchronous elimination of sulfinic acid

For saturated molecules, alkylation of α -sulfonyl carbanions with elimination of sulfinic acid is exemplified by the reaction of alkylating reagents with α -carbanions derived from 2-sulfonyl-substituted cyclic ethers, *viz.*, tetrahydropyrans or tetrahydrofurans **57a,b**. The sulfonyl groups in tetrahydropyrans and tetrahydrofurans facilitate α -deprotonation. However, Ley and coworkers¹⁰⁰ found that an intermediate formed in the course of the subsequent reaction with an electrophile is stabilised due to synchronous elimination of sulfinic acid. Apparently, the driving force for this process is the formation of the endocyclic C = C bond in the reaction products **58a,b**.

$n = 0$ (**a**), 1 (**b**); (a) Bu^nLi ; (b) R^2X ; (c) R^2MgX , ZnBr_2 ; (d) R^2X , $\text{C}_{10}\text{H}_8\text{Na}$; (e) $\text{I}(\text{CH}_2)_4\text{OTHP}$; (f) H_3O^+ .

The reactions with Grignard reagents in the presence of zinc salts or with alkyl halides in the presence of sodium naphthalenide afforded tetrahydro derivatives **59a,b**, which are the formal replacement products of the sulfonyl group, instead of dihydropyrans or dihydrofurans **58a,b**. The reactions of the sulfones **57** with electrophiles containing a protected hydroxy group at the ω -position are of considerable interest for the synthesis of certain natural compounds. These reactions afford spiroketals **60** because the hydroxy group of the substituent in the intermediate **58** immediately reacts with the nucleophilic double bond after deprotection in an acidic medium. The simplest examples of this approach are the syntheses of 1,7-dioxaspiro[5.5]undecane (**61**), which is a component of the pheromone of *Dacus Olea*¹⁰¹ and of the so-called fruit flies particularly widespread in tropical countries,¹⁰² as well as the syntheses of analogous compounds **62** and **63**.¹⁰¹

synthesis, was obtained.

Chemical reaction scheme showing the synthesis of compound **64** from compound **65** and a substituted tetrahydropyran derivative.

Reaction 1: Compound **65** (a 1,3-dioxane derivative with a PhSO_2 group and an OBn group) reacts with a substituted tetrahydropyran derivative (a 2,2-dimethyl-4-iodo-2,3-dihydro-4H-pyran derivative) to form an intermediate.

Reaction 2: The intermediate reacts with compound **66** (a 1,3-dioxane derivative with a PhSO_2 group and an $\text{OSiPh}_2\text{Bu}^t$ group) and another substituted tetrahydropyran derivative (a 2,2-dimethyl-4-iodo-2,3-dihydro-4H-pyran derivative) to form compound **67**.

Reaction 3: Compound **67** (a 1,3-dioxane derivative with a PhSO_2 group and a $(\text{CH}_2)_2\text{OH}$ group) is converted to compound **64** (a complex molecule containing a 1,3-dioxane derivative, a 1,3-dioxolane derivative, and a 1,3-dioxane derivative with a PhSO_2 group and a $(\text{CH}_2)_2\text{OH}$ group).

Ley and coworkers started their studies in this field with the development of a procedure for the synthesis of substituted spiroketals by reactions of anions generated from 2-sulfonyl-tetrahydropyrans with new reagents, *viz.*, alkoxy-substituted epoxides of the type **68**. For example, this procedure was used for the synthesis of a minor component (**69**) of the pheromone of olive moth.¹⁰⁵

The key steps of the total synthesis of avermectin (**70**) containing 30 stereogenic centres, five C=C bonds with a fixed configuration and numerous functional groups are given in Scheme 5. In particular stages of the synthesis, the intermediates were compared with the degradation products of natural avermectin. The first step of the synthesis of the macrolide **70** involved

† Avermectin was isolated from actinomycete MA-46650 in 1978.¹⁰⁴

the reaction of enantiomerically pure diepoxide **71** [an important synthon for the C(17)–C(19) fragment] with a vinylic bromide **72** to form a substituted epoxide. Subsequent reactions with substituted 2-sulfonyltetrahydropyran **73** followed by transformations required for the formation of the C(22)=C(23) bond afforded spiroketal **74**, which is the ‘northern’ [C(11)–C(25)] hemispherical fragment of the macrolide **70**. The terminal C=C bond in the compound **74** was converted into the aldehyde group in two steps. The reaction of the intermediate **75** with the anion generated from allylsulfonyl synthon **76** resulted in the formation of the (*E*)-C(10)=C(11) bond (the Julia olefination, Section III.2.a). Compound **77** contained ~12% of an admixture of the (*Z*)-C(10)=C(11) isomer. The completion of the synthesis involved the macrolactonisation of the intermediate **77** following oxidation at C(1) with simultaneous formation of the C(3)=C(4) bond and the attachment of the disaccharide residue R³, which was obtained from oleandrose, at C(13).

The synthesis of a somewhat less complex molecule, *viz.*, melbemycin β₁ (**78**), was carried out according to an analogous scheme.¹⁰⁷ The major synthons in this scheme are either identical to compounds used for the preparation of avermectin (**70**) (for example, diepoxide **71**) or differ only in the functional groups (synthons **79**, **80** and **81** correspond to compounds **72**, **73** and **76**, respectively). The formation of spiroketal is also a fundamental step in the construction of the ‘northern’ fragment. The coupling of the ‘northern’ and ‘southern’ fragments to form the (*E*)-C(10)=C(11) bond was performed by the reaction of the aldehyde group of the ‘northern’ fragment with the α-sulfonyl carbanion of the ‘southern’ fragment. This reaction is not the standard olefination procedure according to Julia because the C(9)=C(10) double bond is converted into the required C(10)=C(11) bond.¹⁰⁷

The common feature in the syntheses of the macrolides **70** and **78** is the method of formation of the trisubstituted C(14)=C(15) bond. This bond is introduced upon reactions with the halide synthons **72** or **79**. This makes it possible to circumvent the difficulties encountered in earlier studies (see Section III.2.a) in attempting to construct this bond with the use of sulfonyl or sulfenyl precursors.

2. Addition to oxygen-containing electrophiles

a. Addition of α-sulfonyl carbanions to carbonyl groups of aldehydes and ketones

Lythgoe¹⁰⁸ and Kocienski^{109–111} have shown that an important problem of olefination (coupling of synthons with the stereospecific formation of the C=C bond) can be solved by reductive elimination of 2-hydroxy sulfones, which are prepared by the reactions of aldehydes with α-sulfonyl carbanions, proposed by

Julia and Paris.³⁶ This procedure is an excellent alternative to the phosphonate Wittig method. The optimum conditions for olefination were found, *viz.*, acetylation or benzylation of the hydroxy group and reductive elimination with sodium amalgam in a mixture of methanol with tetrahydrofuran or ethyl acetate.¹¹² In studies of the scope and limitations of this reaction, it was demonstrated that *E*-disubstituted double bonds can be formed with a stereoselectivity of ~80%–100%. The stereoselectivity is enhanced in the case of chain branching at the β-position with respect to the double bond, whereas a substituent at the α-position hinders the reaction.¹¹³ Trisubstituted C=C bonds are formed with difficulty and the stereoselectivity of this process is low, whereas attempts to obtain tetrasubstituted C=C bonds failed.¹⁰⁹ Since the stereochemistry of the initial acyloxy sulfone (*threo*-, *erythro*- or a mixture of both forms) has no effect on the stereoselectivity of the formation of the C=C bond, it was suggested that this process occurs *via* a common intermediate **82** formed upon reductive elimination of the sulfinate anion or from the diastereomers **83a** or **83b**.^{109, 113} The intermediate **82** is long-lived enough to assume the conformation favourable for elimination of the acyloxy anion. This may not be the case with ketones exerting steric hindrances, which explains the fact that olefination with the use of acyloxysulfonyl derivatives prepared from ketones is not always successful. Recently, a more intricate mechanism of the olefination has been proposed.¹¹⁴ However, none of the suggested reaction schemes was confirmed by quantitative methods, for example, by kinetic methods.

R¹ = H, R² = SO₂Ph (**a**); R¹ = SO₂Ph, R² = H (**b**).

Below are summarised the results of the use of this methodology in the syntheses of natural compounds performed by Kocienski and Lythgoe with their coworkers. This procedure was used for the formation of the (*E*)-C=C bond in the alcohol **84**, which is the key intermediate in the synthesis of calciferol,¹¹⁵ and for the preparation of different modifications of vitamin D,

including α -hydroxy vitamin D₃ (see Ref. 116) and vitamin D₄.¹¹⁷ (More recently,¹¹⁸ 25-hydroxy vitamin D₂ was prepared according to an analogous procedure with the use of ethylmagnesium bromide instead of BuLi for deprotonation). This scheme was applied to the synthesis of the major C₂₅ segments (**85** and **86**) for the preparation of the antibiotics moenocinol¹¹⁹ and diumycinol,¹²⁰ respectively.

Later, the Julia olefination (which is sometimes called the Julia–Kocienski or the Julia–Lythgoe olefination) has found wide application in the synthesis. Thus this procedure was used in the synthesis of botryococcene **87** (Scheme 6), which is an algae hydrocarbon. The compound **87** has a specific branched structure. The product of its exhaustive hydrogenation (**88**) is a promising biological marker in petroleum production.¹²¹

Scheme 6

Olefination is the major stage in the total syntheses of a number of biologically active long-chain compounds. This reaction has been used in the formation of the (*E*)-C(10)=C(11) bond in the antibiotic pseudomonic acid C (**89**),^{122,123} the C(16)=C(17) bond in the antibiotic ionomycin (**90**) responsible for the transport of Ca²⁺ ions^{124,125} and the C(7)=C(8) bond in the diene fragment of curacin (**91**) exhibiting antitumor activity.¹²⁶ To construct the double bond between the piperidine and decahydronaphthalene fragments in the synthesis of alkaloids (+)-himbacine (**92a**) and (+)-himbeline (**92b**), the aldehyde and sulfonyl groups should be bound to the pyrimidine and decahydronaphthalene synthons, respectively,¹²⁷ otherwise steric hindrance to olefination occurs. One of the double bonds of the 1,3-diene system of indanomycin was also formed according to this procedure.¹²⁸

The Julia olefination is often used for the introduction of C=C bonds into the starting compounds which are subsequently employed in total syntheses. For example, double bonds in the following fragments were formed according to this procedure: in the C(1)–C(22) fragment for the construction of immunodepressant FK,¹²⁹ in the C(22)–C(31) fragment of an intermediate for the macrolide antibiotic roxatidin¹³⁰ and in the triene group of the C(10)–C(27) fragment used in the synthesis of the immunodepressant rapamycin.^{131,132} In the total synthesis of the antitumor macrolide aplyronine, coupling by the reaction of the α -sulfonyl anion with the aldehyde group was employed twice.¹³³ When the C(3)–C(17) fragment was constructed in the synthesis of boromycin, the intermediate 2-hydroxysulfonyl unit was used for the stereoselective formation of the hydroxy group rather than for the introduction of the double bond.¹³⁴

The Julia olefination was also used in the total syntheses of the majority of macrolides of the avermectin — melbemycin group, for example, of avermectin B1a (Ley *et al.*,¹⁰⁶ Hanessian *et al.*¹³⁵ and White *et al.*¹³⁶), as well as of the simplest compound of this group, *viz.*, melbemycin β_3 (**93**), which served as the favourite subject in earlier synthetic studies performed by Kocienski,¹³⁷ Baker¹³⁸ and Barrett¹³⁹ with their coworkers.

The Julia procedure was used for the coupling of large fragments which have been synthesised beforehand and already contained the required chiral centres. Macrolactonisation was performed in the final stage of the synthesis. In the synthesis of these very complex systems, the previously established regularities hold on the whole. The formation of the disubstituted C(10)=C(11) bond occurs most readily and with a high stereoselectivity, particularly, when the aldehyde group is bound to the C(11) atom of the 'northern' fragment, while the sulfonyl group is bound to the C(10) atom of the 'southern' fragment.^{106,137} When the functional groups are located in the reverse order, the results are somewhat worse.^{135,138} When the ketone was used in place of the aldehyde for the formation of the C(8)=C(9) bond of avermectin B1a [the carbonyl group at the C(8) atom of the 'southern' fragment and the sulfonyl group at the C(9) atom of the 'northern' fragment],¹³⁶ the reaction was complicated by lactonisation of the intermediate. The formation of the trisubstituted C(14)=C(15) bond with the use both of the ketone¹³⁶ and aldehyde¹³⁹ versions of olefination occurs in low yield and affords an admixture of an undesirable regioisomer. With the aim of constructing this bond, more sophisticated approaches, though also based on reactions of sulfoxides and sulfones, were applied.^{136,139}

Kocienski was the first to note¹⁰⁹ that the use of olefination for the preparation of large amounts of compounds is hampered by the necessity of consuming a considerable amount of amalgam for desulfonation. Presently, a number of procedures free of this drawback are available. Thus it is believed¹⁴⁰ that reduction with magnesium in ethanol upon catalysis with mercuric chloride occurs due to *in situ* formation of magnesium amalgam. It was also recommended to use SmI₂ in THF¹⁴¹ or HMPA.^{141,142} In the latter case, a trisubstituted double bond is successfully formed from ketones and primary sulfones, though only in low-molecular-weight model compounds.

Reactions of α -sulfonyl anions with aldehyde groups have also been used for the coupling of bulky, *e.g.*, cycloaliphatic, segments. This coupling not necessarily involved the formation of the C=C bond, but sometimes occurs through hydroxy- or oxo-functionalised saturated units.

The key steps in a multistep (more than 100 steps) enantio- and stereospecific total synthesis of okadaic acid **94**, which is a

potential antitumor drug,[‡] involved couplings of the segments A, B and C, which have been prepared according to the retrosynthetic approach, in the order (B + C) + A (the atomic numbering scheme corresponds to that used for okadaic acid).^{144–147}

MOM is methoxymethyl.

D-Glucose derivatives served as chiral pools for the construction of the segments A, B and C. The OH group at C(27) was obtained by transformation of the 2-hydroxysulfonyl grouping formed by the reaction of the aldehyde group of the segment B with the anion from the sulfone C, and the C(14)=C(15) double bond was formed according to Julia with the participation of the sulfonyl centre of the segment A. The stereoselective introduction of the methyl groups at C(13) in the segment A¹⁴⁵ and at C(29) in the segment C¹⁴⁷ was performed according to 'heteroconjugate addition' to α -silyl vinyl sulfones developed by Isobe and co-workers (this procedure will be considered in more detail in Section V.1). The final steps in the total synthesis of acid **94** with the construction of all its 17 chiral centres involve deprotection of the functional groups and conversion of 1,2-acetonide into the hydroxy acid.

The use of intramolecular reactions of α -sulfonyl carbanions with aldehydes^{148–151} is exemplified by the synthesis of tetronolide **95**, which is the aglycone of the antitumor antibiotic tetrocarcin,^{148, 149} as well as by the construction of a bicyclo-[13.3.0]octadecane core **96** for the synthesis of terpestacin and of a 14-membered core **97** for the preparation of sarcophytol A.¹⁵⁰ Syntheses of the compounds **96** and **97** involved oxidation of hydroxy groups to carbonyl groups followed by reductive removal of the sulfonyl group (Scheme 7), while the synthesis of the compound **95** additionally involved stereospecific reduction of the carbonyl group to the hydroxy group. Attempts to use this approach in the synthesis of the antitumour antibiotic lankacidin were unsuccessful. Apparently, this is associated with the use of the imidazolesulfonyl group.¹⁵²

[‡] It was believed¹⁴³ that acid **94** and its esters isolated from marine algae are toxins, which cause mortality of the gastroenteritis type as a result of diarrhetic shellfish poisoning.

Scheme 7

The Z-olefination method, which has also been developed by Julia,³⁷ is applied more rarely than the E-version. In this case, a mixture of diastereomeric acyloxy sulfones generated originally was treated with a strong base followed by desulfonylation of an intermediate (Z)-vinyl sulfone to form (Z)-alkene. This procedure was used for the preparation of components of the pheromones **98a–c** [98% of the (Z)-isomers],³⁷ dehydro-(Z)-12-squalene (**99a**) and (Z)-16-phytoene (**99b**) (in both cases, the selectivity was ~ 87%).¹⁵³ In the latter case, the aldehyde component was generated *in situ* by oxidation of a portion of the α -sulfonyl carbanions **100**.

99a: R¹ = $\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CHCH}_2$, R² = Me;

Later on, Moiseenkova and Nefedov with coworkers^{154–156} slightly improved the procedure for Z-olefination and applied it to the synthesis of trideca-(4E),(7Z)-dien-1-yl acetate (**101**) (the potato moth pheromone)¹⁵⁵ and (E,Z)- and (E,E,Z)-acetogenin

R = Ac (**a**), H (**b**).

pheromones **102** and **103a,b**.¹⁵⁵ The previously unknown cyclopropane ketones **104** and **105** served as the key compounds in the syntheses of the latter compounds (in the schemes, the double bonds formed with the use of the α -sulfonyl carbanions are indicated by arrows).

Otera and coworkers^{157–160} elaborated a procedure for the transformation of ethers of 2-hydroxy sulfones through double elimination. This procedure extends the possibilities of application of reactions of sulfonyl carbanions with aldehydes. Initially, acyloxy or alkoxy groups in esters and ethers of 2-hydroxy sulfones are eliminated under the action of a strong base (generally, Bu^tOK) followed by dehydrosulfinylation of vinyl sulfone to form the acetylene bond. If allylic isomerisation can occur in the stage of generation of unsaturated sulfone, an *E,E*-diene system is formed. The latter procedure has been used¹⁵⁹ for the preparation of piperine **106**, which is one of the components of black pepper, starting from the aldehyde **107**. Yet another natural dienamide, viz., trichonine (**108**), was also prepared according to this procedure [85%, 10% and 5% of the (2*E*,4*E*)-, (2*E*,4*Z*)- and (2*Z*,4*E*)-isomers, respectively].¹⁶⁰

An ingenious convergent (C₁₀ + C₁₀) scheme for the synthesis of vitamin A was also developed.^{161,162} Tetrahydropyran-2-yl ethers of 2-hydroxy sulfones proved to be the starting compounds of choice for this sequence of reactions. In the first step, the second allylic bond was established with respect to the sulfonyl group. Elimination of sulfinic acid from the intermediate **A** occurred with the participation of the remote allylic hydrogen atom at C(12). The resulting vitamin A contained > 85% of the all-*trans* isomer;

this amount is substantially greater than those obtained with the use of other sulfonyl methods (see Section III.1.b).

b. Addition of α -sulfinyl carbanions to carbonyl groups of aldehydes and ketones

As mentioned above (Section II), epimeric mixtures of 2-hydroxy sulfoxides formed in the reactions of aldehydes with α -sulfinyl carbanions are rather rarely used in the synthesis of natural products. The synthesis of the enantiomerically pure pheromone (+)-(7*R*,8*S*)-disparlure (**109**) by the reaction of the corresponding aldehydes with enantiomerically pure (*S*)-*tert*-butyl 6-methylheptyl sulfoxide (**110**)¹⁶³ or (*S*)- α -chlorododecyl tolyl sulfoxide (**111**) is one of a few examples.¹⁶⁴

(a) Bu^tLi; (b) Me(CH₂)₉CHO (45%); (c) SnCl₂, AcCl; (d) LiAlH₄; (e) Me₃OBu^t; (f) NaOH; (g) LDA; (h) Prⁱ(CH₂)₄CHO (39%); (i) Bu^tOK, Bu^tOH; (j) BuⁿLi, THF, -100 °C; (k) Bu₂AlH; (l) MeLi; (m) C₁₀H₂₁I; (n) Zn, Me₃SiCl.

The total yield of the compound **109** was low because hydroxy sulfoxides **112** and **113** were obtained as mixtures of diastereomers. The procedure with the use of enantiomerically pure 2-hydroxy sulfoxide **114**, which is prepared by stereoselective reduction of oxo sulfoxide **115**, is approximately twice as efficient.¹⁶⁵

The ratio of the diastereomers in a mixture of 2-hydroxy sulfoxides depends on the nature of substituents in the initial sulfoxide and aldehyde. Stork and coworkers¹⁶⁶ reported that the reaction of sulfoxide **117** with ketone **118**, which was used in a rather simple synthesis of protected chiral polyol **116** containing all 10 asymmetric centres of the secoacid of the aglycone of erythromycin, afforded a mixture of 2-hydroxy sulfoxides containing 80% of the target epimer. Compound **119** was obtained [the C(1)–C(12) fragment with the required configuration; the

[illegible]

The stereo- and enantioselectivity of the reactions of α -sulfinyl carbanions with aldehydes increases in the presence of alkoxy-carbonyl groups adjacent to the carbanionic centre.¹² This can be demonstrated by syntheses of enantiomerically pure pheromone lactams¹⁶⁹ and maytansin¹⁷⁰ exhibiting antitumour activity.

Since α -sulfinyl-substituted carbonyl compounds are most commonly used as the starting materials in this reaction, the latter is abbreviated to SPAC (Sulfoxide Piperidine and Carbonyl).

In the absence of such competition, the reactions involving ester groups, including lactone groupings, proceed readily. Reactions of α -sulfonyl carbanions with esters were used for the construction of the intermediates **124a,b** in the syntheses of components of pheromones of peach moth, *viz.*, of (*Z*)-eicos-13-en-10-one (**125a**) and (*Z*)-nonadec-12-en-9-one (**125b**).¹⁷⁷ Julia and coworkers¹⁷⁸ prepared the pheromone of yellow scale (**127**) starting from enantiomerically pure lactone (*R*)-**126**. In this synthesis, advantages were taken of yet another interesting reaction, which has been discovered in the same laboratory,⁴¹ *viz.*, the replacement of the sulfonyl group in the intermediate **128** under the action of isopropylmagnesium chloride in the presence of FeCl_3 .

(a) BuⁿLi; (b)  O[(*R*)-**126**]; (c) PrⁱMgCl, FeCl₃.

The reaction of the sulfonyl anion with the ester group served as the key step¹⁷⁹ in the stereocontrolled synthesis of pseudoan-nonacin A.

The oxo sulfone **22a**, which is the reaction product of lithiated methyl phenyl sulfoxide with protected alanine methyl ester **129**,¹⁸⁰ was used in the synthesis of isosteres of peptides.⁸⁰

The reaction of α -sulfonyl anions with esters was used as the key step in the construction of the macrolide brefeldin A (**130**) (which is related to prostaglandin and is a highly active fungicidal and antitumour drug,^{181, 182}) and of the corresponding secoacid **131**.¹⁸³

The compound **130** was prepared both in racemic and optically active forms, whereas the acid **131** was obtained only in the optically active form. In all three cases, the lower branch was constructed *via* substituted oxo sulfones **132**–**134** using similar procedures (Scheme 8).

The phosphonate method was used for the construction of the (*E*)-C(10)=C(11) bond in brefeldin (**130**),^{181, 182} while Trost *et al.*¹⁸³ made use of the Julia methodology to form this bond in compound **131** following reduction of the oxo group in the intermediate **134** to the hydroxy group. The C(2)=C(3) bond and the chiral centre at C(4) were generated with the use of various procedures for the introduction of the sulfinyl group^{181, 183} followed by thermolysis. This methodology is described in more detail in Section IV.

The intramolecular reactions under consideration have also been used for the synthesis of polycyclic terpenoids, for example, trinoranastreptene¹⁸⁵ or precursors for guaiane terpenoids.^{186, 187} A general procedure for the synthesis of terpenoids with fused

medium-sized rings involving intramolecular reactions of α -sulfonyl carbanions with esters was also proposed.¹⁸⁸

d. Reactions of α -sulfinyl carbanions with esters

Owing to the development of enantioselective procedures for the reduction of oxo sulfoxides,^{12, 27} which can be readily prepared by reactions of α -sulfinyl carbanions with esters, enantiomerically pure chiral 2-hydroxy sulfoxides became readily accessible compounds and found wide use in asymmetric synthesis, including the preparation of biologically active compounds.¹²

Thus 4-substituted butenolides **135a,b** both with the *R*- and *S*-configurations of the asymmetric centre were prepared from the same oxo sulfoxide **136a** or **136b**.¹⁸⁹

The high enantioselectivity in the synthesis of 2-hydroxy sulfoxides **137a,b**, which are required for the preparation of *R*-enantiomers of butenolides **135a,b**, was achieved by the addition of ZnCl_2 in the course of hydride reduction of the oxo sulfoxides **136a,b**. In this case, a rigid chelate complex of zinc

$\text{R} = \text{Bu}^t$ (**a**), C_8H_{17} (**b**); (a) LDA; (b) Bu_2AlH , ZnCl_2 ; (c) Bu_2AlH .

involving both functional groups of the oxo sulfoxide was formed as a result of which the hydride attack occurred from the required side. Reduction of the oxo sulfoxides **136a,b** without addition of

§An analogous procedure was used for the construction of the lower branch in more recent syntheses of brefeldin.¹⁸⁴

R^1 – R^5 are protective groups; (a) $\text{PhSO}_2\text{CH}(\text{CH}_2)_3\text{CH}(\text{OBn})\text{Me}$; (b) R^2Cl , EtPr_2N ; (c) Me_2SO , NaOH ; (d) $\text{BrCH}_2\text{CO}_2\text{Me}$; (e) Δ ; (f) $\text{PhSO}_2\text{CH}(\text{CH}_2)_3\text{CH}(\text{OR}^3)\text{Me}$; (g) $\text{PhSO}_2\text{CH}(\text{CH}_2)_3\text{CH}(\text{OR}^5)\text{Me}$ (90%–96%); (h) NaBH_4 ; (i) Ac_2O ; (j) Na/Hg , Na_2HPO_4 (65%).

ZnCl₂ afforded hydroxy sulfones **138a,b** with a high diastereoselectivity. The latter were transformed into the *S*-enantiomers of the butenolides **135a,b**.

An analogous approach was used in the synthesis of macrocyclic diethers for the preparation of enantiomerically pure diethers of lasiodiplodins, (*R*)- and (*S*)-**139**.¹⁹⁰ Epimeric 2-hydroxy sulfoxides **140** were synthesised by the reduction of oxo sulfoxide **141** in the presence or in the absence of ZnCl₂. It should be noted that when the compound **141** was prepared from diester **142** and the chiral sulfinyl anion, only the methoxycarbonyl group of the aliphatic chain was involved in the reaction, while the methoxycarbonyl group in the aromatic ring remained intact and was subsequently used for the construction of the macrocyclic lactone fragment.

(a) 2.2 equiv. of $\text{LiCH}_2\text{S(O)Tol}$, THF, -78°C ; (b) ZnCl₂; (c) Bu_2AlH , 20°C (*de* > 95%); (d) Bu_2AlH , THF, -78°C , (*de* 86%).

Chiral sulfinyl groups of 2-hydroxy sulfoxides served as inductors in diastereospecific syntheses of the protected secoacids **143** and **144** representing degradation products of the macrocyclic diethers (*R,R*)-pyrenophorin and (*R*)-patulolide A, respectively.¹⁹¹ The γ -hydroxy- α,β -unsaturated fragment of the secoacid **144** was constructed by the SPAC-type reaction of aldehyde **145** with the ethyl sulfinylacetate anion.^{172–174}

MEM is (2-methoxyethoxy)methyl.

Syntheses of brefeldin A (**130**) performed predominantly with the use of sulfinyl-containing intermediates or auxiliary reagents are presented below. Solladie *et al.*¹⁹³ prepared a chiral cyclopentane precursor **148** with the use of enantiomerically pure 2-hydroxy sulfoxide **149**, which had been synthesised from substituted cyclopentane **150** in two steps. The formation of chiral centres at C(4) and C(15) in the brefeldin molecule was completely controlled by the sulfinyl group of the compound **149**. The (*E*)-C(10)=C(11) bond in the fragment **151** was formed using the Julia olefination with the participation of the aldehyde group of the precursor **148**.¹⁹³

R = MEM; (a) 2 equiv. of $\text{LiCH}_2\text{S(O)Tol}$; (b) Bu_2AlH , ZnCl₂;

Two analogous schemes proposed by Corey ($\text{R}^1 = \text{MOM}$, $\text{Ar} = \text{ToI}$, $\text{R}^2 = \text{Me}$)¹⁹⁴ and Nokami ($\text{R}^1 = \text{MEM}$, $\text{Ar} = 4\text{-ClC}_6\text{H}_4$, $\text{R}^2 = \text{Et}$)¹⁹⁵ for the construction of the γ -hydroxy- α,β -unsaturated C(4)–C(15) fragment of the brefeldin molecule are based on a simplified approach using the SPAC reaction. These schemes involve the reaction of aldehyde **152** with chiral arylsulfonylacetates in the presence of piperidine as the key step.

The first line of investigations performed by Hua and co-workers^{207–211} was devoted to the addition of allylsulfinyl anions to enones. The total enantioselective synthesis of hirsutene (**161**) (a tricyclic biogenetic precursor of the polyquinanes coriolin and hirsutic acid[¶]) is a typical example of this approach. In the first stage, the (*S*)-allylsulfinyltolyl carbanion added to 2-methylcyclopent-2-en-1-one.²⁰⁷ Reduction of the reaction product **162** to sulfide followed by cyclisation afforded substituted hexahydropentalenone **163** containing the rings *B* and *C* of hirsutene. The compound **163** was transformed in several steps and then the construction of the ring *A* was completed on the basis of bicyclic enone **164**. Attempts to perform this synthesis starting from the cyclic allylsulfinyl anion **165** failed²⁰⁸ because the anions of cyclic sulfoxides of this type reacted with 2-methylcyclopent-2-en-1-one to

form only undesirable γ -adducts. However, the molecule of equally complicated (+)-12,13-epoxytrichocet-9-ene (**166**) possessing high biological activity was constructed starting from cyclic allylic sulfoxide **167** according to a procedure which was chosen based on retrosynthetic analysis.²⁰⁹ In this case, cyclopentenone **168** additionally activated with the methoxycarbonyl group was used. An analogous, but somewhat more complicated procedure made it possible to perform the total synthesis of (+)-pentalenene related to antitumour pentalenolactone.²¹⁰

¶ Another version of the sulfonyl approach to polyquinanes is shown in Scheme 8.¹⁸⁴

Bulky substituents in the cyclic enone do not hinder the stereoselective addition of the allylsulfinyl carbanion to the double bond. The preparation of compound **169**, which is the key intermediate in the synthesis of methyl ester of ($\pm$)-pentalenolactone E, from bicyclic enone **170**²¹¹ or the construction of the prostaglandin precursor **171** from enone **172** (Pivnitskii and coworkers²¹²) serve as examples.

The second line of investigations performed by Hua and coworkers dealt with the construction of molecules of polycyclic alkaloids based on reactions of carbanions from chiral sulfinyl ketimines with α,β -unsaturated esters followed by (sometimes synchronous) cyclisation. Thus the total syntheses of parasymphomimetic agents (–)-slaframine (**173**) and (–)-6-*epi*-slaframine (**174**) were performed starting from the sulfoxide (*R*)-**175** anion and *N*-protected methyl 2-aminoacrylate.²¹³ The diastereomers **176a** and **176b** were obtained in a ratio of 3 : 2.

An analogous reaction of the anion of tricyclic (*R*)- α -sulfinyl ketimine **177** with methyl acrylate was used for the preparation of epimers of indolo[2,3-*a*]quinolizidine, viz., (+)- and (–)-**178** (the ratio was 1 : 1.9). The key step in the synthesis of pentacyclic

(a) LDA , CO_2Me ; (b) $\text{NaCN} \cdot \text{BH}_3$; (c) Ra/Ni ; (d) LiAlH_4 .

yohimbane alkaloids **179**–**181** involves the reaction of (*S*)-**177** with methoxycarbonylcyclohexene.²¹⁴

A general procedure for the synthesis of esters of racemic α -amino acids²¹⁵ is based on the addition of a carbanion generated from methyl methylthiomethyl sulfoxide at the C $\equiv$ N bond of nitriles. The unstable adducts **182a–d** were isomerised through a prototropic shift to form enamino sulfoxides **183a–d**. The Pummerer rearrangement under the action of Ac₂O yielded compounds **184a–d** from which racemic phenylglycine, alanine and valine derivatives (**185a–c**, respectively) were prepared. Treatment of the compound **184d** with substituted phenylhydrazine hydrochloride **186** afforded racemic *N*-acetyl-5-hydroxytryptophan methyl ester (**187**).²¹⁵

R = Ph (**a**), Me (**b**), Pr (**c**), (MeO)₂CH(CH₂)₂ (**d**); (a) NaH, THF, 20 °C; (b) RCN; (c) Ac₂O; (d) R = Ph, Me, Pr; MeOH, Et₃N; (e) Ra/Ni; (f) R = (MeO)₂CH(CH₂)₂, 4-BnOC₆H₄NHNH₂·HCl (**186**); (g) Ra/Ni, EtOH.

b. Reactions of α -sulfonyl carbanions with activated C=C bonds

Specific transformations of anionic intermediates formed as a result of addition of α -sulfonyl anions to activated double bonds have found use in the synthesis of natural products.

Martel *et al.*²¹⁶ found that the addition of α -sulfonyl carbanions generated from 3-methylbut-2-en-1-yl sulfones to esters of α,β -unsaturated acids afforded cyclisation products of the initially anionic intermediates rather than the usual adducts. Thus the intermediate **188** formed from sulfone **189** and ethyl 3-methylbut-2-enoate is stabilised through cyclisation with 1,3-elimination of the sulfonyl anion to produce ethyl *trans*-chrysanthemate (**190**).²¹⁷

which is a component of natural insecticides, *viz.*, pyrethroids. The optimum conditions for this reaction involve the use of components taken in a ratio sulfone:THF:Bu^tOK = 1:2:3. A large number of aryl and alkyl chrysanthemates were synthesised according to this procedure.²¹⁸ Some of these compounds are more active insecticides than natural pyrethroids.

Julia and coworkers²¹⁹ prepared the ester **190** by the reaction of the sulfone **189** with ethylmagnesium bromide and then with diethyl isopropylidenemalonate.

Later on, Campbell *et al.*²²⁰ demonstrated that the reactions of anions generated from *E*-isomers of polyunsaturated sulfones with esters of polyunsaturated acids under conditions proposed by Martel and coworkers²¹⁸ were not accompanied by isomerisation of double bonds. This procedure was used for the preparation of the key compounds in the biosynthesis of terpenoids, *viz.*, (+)-presqualene alcohol (**191**) and (+)-prephytoene alcohol (**192**). In this study, the structure of natural prephytoene alcohol was also established.

Reactions of α,β -unsaturated carbonyl compounds with α -sulfonyl carbanions generated from 3-oxo-1,3-dihydroisobenzofuran-1-yl phenyl sulfone (**193a**) ('phthalide sulfone') and its analogues play an important role in the synthesis of biologically active compounds. Hauser and Rhee²²¹ studied reactions of the model compounds **193a,b** with linear enones or α,β -unsaturated esters and demonstrated that the resulting carbanionic intermediate is stabilised in the course of cyclisation through elimination of the sulfinate anion. The resulting 1,4-dihydroxy-naphthalene is readily oxidised to naphthoquinone, whereas methylation prevents oxidation. Apparently, the driving force for this process is the formation of a thermodynamically favourable aromatic structure.

R¹ = H (**a**), OMe (**b**); R² = H, Me; R³ = OEt, Me; (a) LDA, THF, –78 °C; (b) R²CH=CHCOR³.

Owing to the possibilities of varying the structures of analogues of phthalide sulfone **193a** and, especially, of α,β -unsaturated carbonyl compounds, a flexible and rather versatile procedure was developed for stereoregular aromatic annelation, which is strictly controlled by the structures of the starting compounds. This method was successfully used by Hauser

Scheme 9

et al.^{222–234} and by other researchers^{235–238} and assumed particular importance in the synthesis of aglycones of antitumour antibiotics, for example, compounds **194**–**198**. Selected stages of the total syntheses of these compounds are shown in Scheme 9. The key reactions of the anions prepared from phthalide sulfones **193** with α,β -unsaturated carbonyl compounds generally proceed with high yields. (The exception is the reaction of phthalide sulfone **193b** with lactone **199** producing compound **200** in a yield of only 50%.) However, the multistep character of subsequent transformations impairs the efficiency of the process as a whole. Thus in the total synthesis of the antibiotic of the anthra[1,2-*b*]pyran series, *viz.*, *O*-methylkidamycinone **194**, starting from phthalide sulfone **193b** and methyl methacrylate,²²² a naphthalene derivative **201** was converted into the final antibiotic **194** in nine steps. The use of cyclic enones (such as compounds **202** or **203**) as Michael acceptors is much more efficient. Thus the reaction of phthalide sulfone **193b** with 5-acetoxymethylcyclohex-2-enone (**202**) afforded the anthraquinone derivative **204** in 81% yield.^{223, 224} Despite the fact that 11 steps were required to build up the ring *A* and to obtain the final product, *viz.*, γ -citromycinone ($\pm$)-**195**, the total yield was ~39%. A comparatively low yield of ($\pm$)-dimethyl-6-deoxydaunomycin ($\pm$)-**196** prepared from the same precursor **204** was attributed to the formation of an admixture of its C(9)-epimer in the final stage.²²⁴ The use of the simplest bicyclic enone **203** made it possible to perform a five-step

synthesis of a tetracyclic triketone **197** in good yield. The latter is a versatile precursor for the preparation of daunomycinones.²²⁵

An exceptional interest in the synthesis of antibiotics of the anthracycline series (see, for example, Ref. 239) arises from their high biological activity. Thus since the 1970s²³⁹ to the present, daunomycin and adrianomycin obtainable by microbiological methods find use in medicine as antitumour drugs.²⁴⁰

Hauser *et al.*^{227, 228} have developed additional ways of improving procedures with the use of monocyclic enones. Thus the convergent synthesis of ($\pm$)-7,9-dideoxydaunomycinone (**205**) was performed in a rather high yield.²²⁷ In the first stage, the anion generated from phthalide sulfone **193b** reacted with 5-ethoxy-2,5-dihydrofuran-2-one (**206**). Then the reaction product **207** was converted into phthalide sulfone **208** in two steps. The subsequent reaction of the anion generated from **208** with 5-acetylcyclohex-2-enone **209** afforded the tetracyclic product **210**, which was converted into the target 7,9-dideoxydaunomycinone ($\pm$)-**205**.

Disubstituted cyclohexenone **211** served as the starting compound in the synthesis of racemic aklavinone (**212**) and pyrromycinone (**213**).²²⁸

Further progress in the application of bicyclic enones to annelation was achieved^{229–234} once procedures for the synthesis of compounds **214a,b** and **215**, which contain substituents corresponding to the substituents in the rings A of anthracyclinones, had been developed.

R = Ac (a), Et (b).

Thus a new more efficient procedure was proposed²³² for the preparation of racemic aklavinone [(±)-**212**] starting from readily available compounds, *viz.*, phthalide sulfone **193b** and enone **214b** (the total yield was ~ 17% with respect to 2-ethylacrolein used as the starting compound for the preparation of the enone **214b**). The first regio- and enantiospecific synthesis of a compound of the anthracyclinone series, *viz.*, the preparation of (–)-(R)-7,11-dideoxy-13-deoxydaunomycinone (**216**) from the anion of phthalide sulfone **193d** and enantiomerically pure enone **215**, was performed.²³³

Compound (±)-**218** possessing the nonlinear benzo-*a*[naphthalene skeleton was synthesised starting from phthalide sulfone **193b** and tricyclic enone **217**.²³⁴ In this study, yet another problem was solved. Thus the nature and arrangement of the substituents in the A rings of the natural pigments G2N and G2A were established.

The procedure for annelation proposed by Hauser has been extended to the preparation of antibiotics containing five-membered rings. This procedure was used for the synthesis of compound **219**, which is a close analogue of kinafluorenone.²³⁵ For this purpose, the anion prepared from **193a** was brought into reaction with indenone **220**, which had been synthesised *in situ* by flash pyrolysis of its adduct with cyclopentadiene (**221**).

(a) flash pyrolysis (> 95%); (b) **193a**, LiOBu^t, –60 °C (73%).

Syntheses of natural 1,4-dihydroxyanthraquinones **222** using reactions of the anions generated from phthalide sulfones **223** with monoketals of substituted benzoquinones **224** provide other examples of annelation according to Hauser.²³⁶

R¹–R⁴ = Alk.

(±)-Daunomycinone was synthesised analogously from the sulfone **193a** and analogues of benzoquinone monoketals **224**.²³⁷ The reaction of the anion of 5,6-methylenedioxyphthalide sulfone with methyl methacrylate afforded functionally substituted naphthalenes necessary for the synthesis of lignins.²³⁸

c. π -Allylic alkylation with α -sulfonyl carbanions

Among processes with the use of Pd(0) complexes, π -allylic alkylation occupies a prominent place. In these reactions, soft nucleophiles react with allylic Pd(0) complexes as the cationoid components. These complexes can be prepared from allylic compounds containing good leaving groups, such as acyloxy or sulfonyl groups. This procedure became popular due to mild reaction conditions and high stereospecificity. The reaction can be performed either with the use of stoichiometric amounts of a Pd(0) complex in a basic medium or as a catalytic process in neutral or

weakly basic media. In the latter case, the Pd(0) complex can be prepared *in situ* from a Pd²⁺ salt. The introduction of phosphine or other ligands allows one to change the regio- and stereochemistry of the reaction (see the reviews^{241–243}).

In these processes, α -sulfonyl carbanions activated with the adjacent oxo, carboxy or sulfonyl groups or (more rarely) with the allylic bond are widely used along with other C-nucleophiles.

Trost and Weber²⁴⁴ were the first to use this procedure for the synthesis of biologically active compounds and they transformed simple terpenoids into more complex compounds. The reaction of an allylic palladium complex prepared from methyl geraniate **225** with the ambident anion, which has been synthesised by the reaction of methyl 4-methyl-2-phenylsulfonylbut-3-enoate (**226**) with NaH in THF, followed by transformation of the reaction product **227** afforded farnesol (**228**). An analogous reaction of the anion **226** with the allylic Pd(0) complex **229** afforded all-*trans*-geranylgeraniol (**230**).

(a) dppe is 1,2-bis(diphenylphosphino)ethane, THF, 25 °C (65%);
(b) Bu₂AlH, MePh, –40 °C; (c) Li, EtNH₂ –78 °C.

A π -allylic version of the synthesis of retinol acetate (**44**, 67% of the *trans* isomer) was carried out²⁴⁵ using the reaction of the anion generated from substituted allylic sulfone **231a** with the Pd(0) prenylacetate complex in the presence of an excess of triphenylphosphine. Its aromatic analogue **232** exhibiting antitumour activity was synthesised analogously. In the case of sulfones containing acyclic substituents R, the reactions stopped at the stage of formation of compounds **233c,d**.

(a) NaH, THF, PPh₃; (b) EtONa, EtOH.

Tsuji was the first to propose a catalytic version of this reaction^{242,246} and he recommended to employ *O*-methoxycarbonyl as the leaving group. This procedure was used for the preparation²⁴⁷ of ubiquinone-10 (**234**), which is the coenzyme Q₁₀ exhibiting cardiovascular activity, and its analogues. Compound

235 containing an allylic *O*-methoxycarbonyl group was brought into the reaction with the anion of an activated sulfone **236** containing an allylic hydroxy group, which was employed to form a new allylic *O*-methoxycarbonyl group in the intermediate **237**. The iterative reaction with the sulfone **236** and the formation of the MeO₂CO group made it possible to build up a polyunsaturated chain. The last stage of the process involved oxidation of the aromatic ring to the quinoid one.

(a) 5 mol. % of Pd(PPh₃)₄, THF; (b) MeOCOC(=O)Et, Et₂NC₆H₄, Py, PhH.

Natural compounds exhibiting analgesic activity, *viz.*, tetraprenylquinone **238** and -quinol **239**, were prepared analogously.²⁴⁸ The synthesis of *trans,trans,trans*-geranylgeraniol (**230**) from α -sulfonyl-substituted ester **240** and oxirane **241** was also performed using the catalytic version.²⁴⁹ In this scheme, the metal-complex catalysis was used for the regiospecific opening of the oxirane ring.

(a) **241**, 5 mol. % of Pd(PPh₃)₄, THF, 25 °C (90%);

(b) PhSH, Cs₂CO₃; (c) LiBHEt₃, THF, 5 mol. % of PdCl₂(dppp)
[dppp is 1,3-bis(diphenylphosphino)propane] (100% *E*).

The catalytic procedure has assumed utmost importance in intramolecular cyclisations, which offers outstanding possibilities for the construction (including diastereocontrol) of carbo- and heterocycles (see the reviews^{250,251}).

Thus the diastereoselective introduction of a cyclopropane ring into the steroid molecule was performed by the reaction of the carbanion generated from the sulfonyl(ethoxycarbonyl) fragment of compound **242** with the π -allylic Pd complex generated in the same molecule. The final product, *viz.*, glaucasterol (**243**), contains a three-membered ring at C(24)–C(25).²⁵² 2-(Hex-1-en-1-yl)-1-methoxycarbonyl-1-phenylsulfonylcyclopropane was synthesised analogously. The latter compound served as the starting material for the synthesis of dictyoptene A (**244**) containing a three-membered ring and of a seven-membered dictyoptene B (**245**).²⁵³

R = 2,4-Cl₂C₆H₃; (a) DBU, THF, Pd(dppe)₂.

Examples of the construction of more complex carbocycles are considered below. Bicyclic (±)-punctaporonin **B** (**246**) was synthesised in 12 steps starting from substituted cyclobutanone.²⁵⁴ The palladium-catalysed reaction of the allyloxirane fragment of compound **247** with the activated α-sulfonyllactone fragment afforded the intermediate **248**, which was converted into the target product **246**.

(a) Pd(Ph₃P)₄, dppe, THF, 60 °C.

In the synthesis of 14-membered (±)-isolobophytolide (**249**), the methoxycarbonyl(phenylsulfonyl) carbanion served as the anionic component of the initial compound **250** and the pivalate

(a) *O,N*-bis(trimethylsilyl)acetamide, Pd(Ph₃P)₄, dppe, THF; (b) Bu₄NF.

anion served as the leaving group. The resulting macrocyclic intermediate **251** was transformed into the target product **249**.²⁵⁵

Cyclisation catalysed by palladium complexes is of particular importance for the preparation of medium-size heterocycles, which are widespread in nature, but which have previously been difficultly accessible.^{256–261} The construction of the key intermediates in the synthesis of natural lactones, viz., 10-membered phoracantholide (**252**),²⁵⁶ 12-membered recifeolide (**253**)²⁵⁷ and 16-membered exaltolide (**254**),²⁵⁸ from acyclic precursors serve as characteristic examples.

The construction of nine- and eight-membered functionally substituted cyclic ethers **255a,b** and **256**, which are precursors of oxonins **257** and **258** isolated from the algae *Laurencia*, presented a substantially more difficult problem. The regio- and stereochemical direction of cyclisation of the acyclic precursors **259** and **260** is determined by the site of attack of the anion generated from the sulfone on the allyl palladium fragment and depends on the nature of the leaving group and, especially, on the ligand used. Thus the methoxycarbonyloxy group and triethyl phosphite appeared to be the best leaving group and ligand, respectively, for the ring closure in compound **259** required for the construction of the skeleton of nine-membered brasilenyne (**257**). The ratio of the cyclisation products, viz., *trans-trans*-**255a** (similar to the natural isomer) and undesirable *cis-trans*-**255b**, was 14 : 1.²⁵⁹

(a) 5 mol. % of Pd₂(dba)₃ (dba is dibenzylideneacetone), 50 mol. % of P(OEt)₃, CHCl₃, THF.

A chloride anion and bisphosphite **261** appeared to be the best leaving group and ligand, respectively, in the stereoconvergent synthesis of compound **256**, which is a precursor of enantiomerically pure (–)-lauthisan (**258**).²⁶⁰ Because of the formation of

(a) 5 mol. % of $\text{Pd}_2(\text{dba})_3$, CHCl_3 , KH ,
THF–dioxane, 80 °C.

the six-membered cyclic products **262**, the yield of the eight-membered reaction product **256** was only 70%.²⁶⁰

The construction of more complex heterocycles, viz., macrocides of the cytochalasin series, which possess high membrane-transport and a broad spectrum of other biological activities, presented a particularly interesting problem. Trost and coworkers performed a 12-step synthesis of the model antibiotic A 22667718 (**264**) starting from undecynal *via* the intermediate **263**,²⁶² a 9-step synthesis of (–)-aspothalasin [(–)-**265**] from *N*-protected leucine ester *via* the precursor **266**²⁶³ and construction of the 26-membered skeleton of tetrin (**267**).²⁶⁴

Z = COOBn.

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}$.

A precursor of pentacyclic allyohimbane was synthesised analogously using the Pd(0)-catalysed ring closure in compound **268** with the acetoxy group serving as the leaving group.²⁶⁵

A 12-step synthesis of the skeleton of the macrocyclic anti-tumour compound roseophillin (**269**) is yet another example of the high efficiency of palladium-catalysed cyclisation.²⁶⁶ Acyclic

compound **270** was transformed into the cyclic precursor **271** by the reaction of the methoxycarbonylsulfonyl fragment with the allylpalladium complex incorporating the oxirane ring. The groups that activate the anionic centre were not removed following cyclisation and they were employed in subsequent transformations. Thus the ester group was used in the construction of tricyclic sulfone **272**. The benzenesulfonyl group in compound **272** is homoallylic and hence it was readily eliminated in the presence of Bu^tOK as sulfenic acid. Simultaneously, the isopropyl group was attached to the adjacent carbon atom by the action of dimethylisopropylzincmagnesium chloride on the $\text{C}=\text{C}$ bond of the enone formed (attempts to use more traditional cuprates have been unsuccessful).

(a) $[\text{Pd}(0)]$ (85%); (b) an excess of Bu^tOK ; (c) $\text{Me}_2\text{Pr}^i\text{ZnMgCl}$ (51%).

IV. Formation of $\text{C}=\text{C}$ bonds by thermolysis of sulfoxides

In many cases, thermal elimination of sulfenic acid from sulfoxides leads to the formation of (*E*)- $\text{C}=\text{C}$ bonds. In 1960, Kingsbury and Cram²⁶⁷ suggested that at moderate temperatures this process occurs according to a concerted mechanism *via* a transition state **A**. More recently,²⁶⁸ this suggestion was confirmed by kinetic studies.

A modification of this reaction proposed by Trost *et al.*^{33–35, 40, 269, 270} has been widely used predominantly for the introduction of (*E*)- $\text{C}=\text{C}$ bonds at the α, β -position with respect to the carbonyl groups of ketones or esters. This procedure is convenient because a one-pot sulfonylation–sulfinylation–dehydrosulfonylation sequence can be used. Initially, an alkylthio group is introduced at the α -position with respect to the electron-withdrawing group under the action of disulfide in a basic medium. The alkylthio group is readily oxidised to the sulfinyl group, which is removed by thermolysis, most commonly, upon boiling in toluene. All steps are carried out under mild conditions; the presence of functional groups in the molecule does not hinder this process. The temperature required for dehydrosulfonylation depends on the substrate structure. Sometimes, it is necessary to add a thiophilic scavenger. This method for the directed introduction of (*E*)- $\text{C}=\text{C}$ bonds advantageously supplements the Julia olefination and dehydrosulfonylation of homoallylic sulfones.

The synthesis of components of bee pheromones is the first example of the use of the sulfonylation–sulfinylation–dehydro-sulfonylation sequence for the preparation of natural compounds.²⁷⁰ Ethyl linoleate served as the starting compound for the preparation of the attractant **273**. (*E*)-9-Oxodec-2-enoic acid (**274**) (the queen substance, *viz.*, the attractant of the queen bee and simultaneously the pheromone of termites) was prepared from an azelaic acid ester. In both cases, thermolysis was performed by boiling in toluene with the addition of calcium carbonate.

(a) cyclo-C₆H₁₁NPr⁺Li; (b) MeSSMe, THF, HMPT, –78 °C; (c) oxidation; (d) PhMe, CaCO₃, 110 °C, 16 h; (e) H₃O⁺.

The sulfinyl groups located at the allylic or propargyl positions are also readily eliminated under conditions of thermolysis because the resulting conjugated diene and enyne systems are thermodynamically favourable. This procedure was used for the preparation of dodeca-8,10-dien-1-ol (**275**)²⁷¹ (the major component of the pheromone of apple fruit moth) and polyunsaturated esters **276**, which are the key compounds in the synthesis of natural unsaturated endiandric acids involving mild cascade electrocyclicisation.²⁷²

(a) LDA; (b) Br(CH₂)₈OH; (c) ArCO₃H; (d) PhMe, NEt₃, Δ.

Endocyclic C=C bonds can also be readily constructed by this procedure. For example, all four possible enantiomers of the natural CoA inhibitor, *viz.*, acaterin (**277**), with an acetogenin-type skeleton were prepared. The latter is a promising anti-atherosclerosis drug.²⁷³ The (4*R*,1'*R*) absolute configuration was assigned to the natural inhibitor. Both compound (+)-**277a** and its C(1')-epimer **277b** were prepared by thermolysis (after oxida-

(a) LDA, MeSSO₂Me; (b) LDA, C₇H₁₅COCl; (c) NaBH₄, THF, H₂O; (d) oxidation; (e) PhMe, CaCO₃, Δ, 3 h.

tion) of substituted valerolactones isolated from a mixture of reduction products of compound **278**. The second pair of epimers of the compound **277** was synthesised according to the same procedure starting from (*S*)-γ-valerolactone.

An analogous procedure for the introduction of the endocyclic C=C bond was used²⁷⁴ in the synthesis of compounds **279a,b**, which were supposed to correspond to stereoisomers of a more complex acetogenin, *viz.*, epoxyrollin A. However, the ¹³C NMR and mass spectra of both stereoisomers **279a,b** differed from those of the natural product.

A short elegant synthesis of (+)-(*R*)- and (–)-(*S*)-muscones **23** involved asymmetric methylation of the C=C bond of the enone **280** in the presence of D- or L-camphor derivatives, respectively.²⁷⁵ The enone **280** was prepared by elimination of benzenesulfenic acid from the oxo sulfoxide **281**.

(a) PhH, CaCO₃, Δ (83%); (b) MeLi, CuI₂, PhMe, THF (*ee* 100%); (c) MeLi, CuI₂, PhMe, THF (*ee* 100%).

8-Hydroxymenth-3-ene (**282**), which is a component of mint essential oil, was prepared according to a general procedure for the transformation of saturated ketones to enones proposed by Taber and Gunn.²⁷⁶ In the first step, α-chloroethylsulfinyl carbanion was added to the carbonyl group of 4-methylcyclohexanone to form epoxide. When distilled, the latter underwent spontaneous isomerisation to give unstable oxo sulfoxide **283**, which readily eliminated sulfenic acid. The addition of MeLi to enone **284** completed the process.

(a) LDA, THF; (b) MeCH(Cl)SOPh; (c) NaOH (90%);
(d) Δ , CaCO₃; (e) MeLi.

If the sulfonyl group is located in the aliphatic chain, the direction and the rate of hydrogen abstraction upon thermolysis depend predominantly on its acidity.^{35,269} However, thermolysis of steroid sulfoxides is a stereocontrolled process due apparently to the unique features of this system of rigidly fused rings. Thus attempts to introduce the C(15)=C(16) bond into the estrone molecule according to a conventional procedure [starting from C(16)-selenoxide²⁷⁷] failed, but this bond was constructed upon prolonged heating of the methyl ether of C(16)-(phenylsulfinyl)estrone in the presence of triphenyl phosphite, which is an active thiophilic scavenger.⁴⁰ Elimination of sulfenic acid from the A ring of 5 α - or 5 β -cholestanes occurred under standard conditions.²⁷⁸ The dependence of the direction and rate of thermolysis on the stereochemistry of the sulfur atom was observed for the first time in the case of bulky thermally stable (*R*)- and (*S*)-adamantylsulfinyl groups, which are not able to undergo stereomutation. This made it possible to develop procedures for the selective synthesis of difficultly accessible 5 α - or 5 β -cholest-2-enes and cholest-3-enes.²⁷⁶

The formation of C=C bonds by thermolysis of sulfoxides was also used in more sophisticated synthetic sequences. For example, this reaction served as a stage in the construction of brefeldin A (**130**)^{181,183} and in the synthesis of hirsutene²⁰⁷ (in the latter case, thermolysis was carried out in an alkaline medium according to a procedure reported previously²⁷⁹). Other examples will be considered below.

In the course of the total enantioselective synthesis of indolizine alkaloids elaeokanines A and B, Hua *et al.*²⁸⁰ used a large number of approaches based on reactions of sulfinyl-containing intermediates. Enamino sulfoxide **285** was prepared by alkylative annelation in the reaction of 1,3-diiodopropane with the anion of (+)-(*R*)-sulfinyl ketimine **286**. Reduction of the reaction product afforded a mixture of all four possible epimeric indolizine sulfoxides represented in pairs as **287a** and **287b**. The reaction of each of these epimers with butanal in the presence of lithium diisopropylamide proceeded quantitatively, the C(8a) chiral centre, which is essential for the subsequent synthesis, remaining unchanged. Thermolysis of a 2 : 1 mixture of hydroxy sulfoxides **288a** and **288b** gave the single product, *viz.*, hydroxyindolizine **289a** with the

(a) LDA; (b) I(CH₂)₃I; (c) NaBH₄, **287a** : **287b** (1 : 1); (d) PrⁿCHO;
(e) 110 °C, PhMe (~80%); (f) PCC (>90%).

C(7)=C(8) bond. Oxidation of the hydroxy group of **289a** resulted in (+)-elaekanine A (**290a**). (–)-Elaekanine B (**289b**), which is (unlike elaeokanine A) a hydroxy derivative, was prepared by thermolysis of hydroxy sulfoxides **287c,d** obtained by the reaction of butanal with the diastereomers **287b**.

V. Syntheses based on reactions of unsaturated sulfones and sulfoxides

1. Addition at the C=C bonds

a. Addition of C-nucleophiles

The synthesis of racemates of alkaloids (**291**–**293**) of the *Aspidosperma* family from a single pentacyclic precursor provides an example of the use of unsaturated sulfones and sulfoxides as acceptors of C-nucleophiles for the transformation of the basic skeleton, which has been constructed beforehand.^{281–283} Owing to the high acidity of the hydrogen atom at C(5) of the enone fragment, the carbanion can readily be generated and involved in the Michael addition to methyl vinyl sulfone, methyl 1-methylthiovinyl sulfoxide or methyl vinyl sulfoxide. Subsequent modifications of the adducts **294** and **295** involved the formation of additional rings in the alkaloids 4-hydroxyaspidofractinine (**291**) and 1-acetylaspidoalbidine (**293**) and the introduction of the ethyl group at position 5 in 1-acetylaspidospermidine **292** (Scheme 10).

Vinyl sulfones have found substantially wider application due to the fundamental studies of Fuchs and coworkers, which have been surveyed in detail in their reviews.^{23,24} Hence, these studies will be considered in this review only briefly. Fuchs and coworkers have developed convenient procedures for the synthesis of substituted cycloalkenyl sulfones, including enantiomerically pure sulfones, containing a free or substituted hydroxy group at the γ -position. In the case of vinyl sulfones, unlike enones, the attack of even hard nucleophiles (for example, alkylolithium) occurs exclusively at the C=C bonds following a Michael addition. Owing to the high nucleophilicity of the resulting α -sulfonyl carbanion compared to enolate, the addition can be combined with a subsequent reaction of the newly formed α -sulfonyl carbanion with an internal or external electrophile resulting in additional functionalisation. The presence of γ -hydroxy groups in these vinyl sulfones allows one to control the stereochemistry of the process.

Scheme 10

(a) $\text{CH}_2=\text{CHSO}_2\text{Me}$, Bu^tOK , Bu^tOH , $n = 2$; (b) $\text{CH}_2=\text{CHSOMe}$, LDA , $n = 1$; (c) $\text{CH}_2=\text{C}(\text{SOMe})\text{SMe}$, LDA ; (d) HClO_4 , H_2O ; (e) Ra/Ni , $n = 1$.

The scheme given below outlines in general convergent total syntheses of natural or related compounds, *viz.*, (–)-prostaglandin E_2 (**296**),²⁸⁴ (+)-carbacyclin (**27**)²⁸⁵ and (±)-morphine (**297**),²⁸⁶ carried out by Fuchs and coworkers. The key steps of these syntheses involve β -addition– α -alkylation of cycloalkenyl sulfones **298**–**300** (in the scheme, the sites of the α - and β -attacks are indicated by arrows).

The synthesis of prostaglandin **296** from the vinyl sulfone **298** involves only seven steps (the total yield was 13% with respect to 2-phenylthiocyclopent-3-enol **301** with *ee* 92%).²⁸⁴ The prepara-

tion of racemic cephalotaxine **302a**,^{287, 288} is worthy of notice as an example of more complicated syntheses. The scheme under consideration is of interest from the viewpoint of the diversity of chemical transformations. The lithiated intermediate **303** prepared from vinyl sulfone **304** by consecutive reactions with the lithium derivative **305**, allyl bromide and then with Bu^nLi contains the homoallylic sulfonyl group, which is spontaneously eliminated as lithium sulfinate. The *exo*-1,3-diene group of the reaction product **306** is used in one of the major steps of subsequent transformations to produce cephalotaxine, *viz.*, for the construction of the seven-membered heterocycle. A modification of this procedure afforded 11-hydroxycephalotaxine (**302b**). However, this method, despite its elegant character, is unsuitable for the preparation of optically active forms of compounds **302a,b**.^{287, 288}

A procedure for the 'heteroconjugate addition' developed by Isobe²⁸⁹ made it possible to solve a very important problem of the efficient stereocontrol in the construction of new acyclic C–C bonds enabling, simultaneously, further carbon-chain elongation. This method was tested using model pyranosides containing α -silylated vinylsulfonyl substituents at C(5). In this case, D-glucopyranose derivatives serve as chiral pools.

Owing to the bulky α -silyl substituent, the substrate molecule adopts a conformation in which the direction of the attack of the nucleophilic reagent [*syn* or *anti* with respect to the H atom at C(5)] depends both on the nature of the reagent and the sub-

stituents in the pyran ring, which can form chelates with nucleophiles. In the absence of polar substituents (compound **307**), the reaction with alkyllithium proceeds exclusively as *syn*-alkylation.²⁹⁰ The presence of the hydroxy group at C(4) in compound **308** and the use of a Grignard reagent provide conditions for exclusive *anti*-alkylation due to the formation of a chelate with the reagent.²⁹¹ Subsequent chain elongation in the intermediates **309** and **310** was performed predominantly by alkylation of the α -sulfonyl carbanion after desilylation. This method was used for the introduction of the *syn*-methyl group at position 6 in the total syntheses of maysine and *N*-methylmaysenine²⁹² as well as of racemic maytansinol (**311**)²⁹³ and (–)-maytansinol.²⁹⁴ Vinyl sulfones **312** and **313** were used as the starting compounds for the construction of the C(4)–C(9) fragment. In the total synthesis of okadaic acid (**94**), vinyl sulfones **314** and **315** were used for the introduction of the *anti*-C(13)-methyl group and the *syn*-C(29)-methyl group into the segments *A*¹⁴⁵ and *C*,¹⁴⁷ respectively.

α -Silylated vinylsulfonyl groups at C(6) of the pyran ring were used for 'pseudoeantiomeric' addition.²⁹⁵ In the total synthesis of tautomycin (**316**), compounds **317** and **318** were employed for the spiro-fusion of rings pseudoeantiomeric with respect to okadaic acid as well as for the introduction of the methyl group at position 3 of the segment *C*. The segments *C* and *B* were coupled

R = SiMe₂Bu^t.

by the reaction of the C(16)-sulfonyl carbanion of the former with the C(17),C(18)-epoxide of the latter in the presence of BF₃·Et₂O. Esterification with the segment *A* completed the synthesis.^{296, 297}

Studies by Posner *et al.*^{11, 298} have played a decisive role in the development of asymmetric synthesis based on reactions of C-nucleophiles with enantiomerically pure vinyl sulfoxides. These reactions made use of enantiomerically pure 2-(sulfinyl)-cycloalkenones **319a,b** or 2-(sulfinyl)alkenolides **319c,d** as the substrates. Convenient procedures for the synthesis of these compounds were devised. The carbonyl group activates the double bond thus promoting Michael-type addition of C-nucleophiles. The stereochemistry of addition can be controlled by adding chelating agents. Thus conditions for the *Si*-attack of the nucleophile are created in the presence of ZnBr₂, which binds the sulfinyl and carbonyl groups to form a rigid chelate. In the absence of this additive, *Re*-attack predominantly occurs.

Posner and coworkers used not only organometallic compounds but also lithium enolates as nucleophiles. The high optical purity of the resulting compounds was attained by varying the reaction parameters and using enantiomerically pure precursors. Thus the formal synthesis of the methyl ether of (*S,S*)-11-oxoequilenin was carried out starting from (*S*)-(+)-2-(tolylsulfinyl)cyclopent-2-enone [(*S*)-(+)-**319a**] via the secosteroid **320**.^{299, 300} The reaction of the same vinyl sulfone **319a** with lithium enolate **321** gave rise to the Michael addition product **322** with a diastereoselectivity of 91%–94%. The latter compound was converted in six steps into methyl ether of estradiol (**323**) with *ee* > 97%.³⁰¹

Vinylation of vinyl sulfone **319a** in the presence of ZnBr₂ followed by methylation afforded a mixture of diastereomers of trisubstituted cyclopentanones. Reductive desulfinylation of the latter made it possible to obtain enantiomerically pure substituted cyclopentanones **324a,b**, which are required for the synthesis of steroids.³⁰²

(a) ZnBr₂; (b) CH₂=CHMgBr; (c) MeI; (d) Al/Hg.

Quaternary chiral centres can be generated using 3-alkyl-substituted tolylsulfonylcyclopentenone as the starting compound.³⁰³ For example, vinyl sulfone **326** was used in the stereoconvergent synthesis of the sesquiterpene (+)- α -cuparenone (**325**); however, the *ee* value of the resulting product was only 70%.

(a) Tol₂CuLi; (b) MCPBA; (c) Bu^tOK; (d) MeI; (e) Me₂CuLi, MeI.

The five-step synthesis of enantiomerically pure (–)-methyl jasmonate with *ee* > 98% was carried out³⁰⁴ starting from vinyl sulfone (R)-(–)-**319a**.

(a) (R₃Si)₂C(Li)CO₂Me; (b) P₂I₄; (c) KF; (d) NaH; (e) BrCH₂Et; (f) Ra/Ni.

Using enantiomerically pure (S)-(+)-tolylsulfinylbutenolide **319c**³⁰⁵ or -pentenolide **319d**³⁰⁶ as the starting compounds in the reactions with a Grignard reagent in the presence of ZnBr₂ or with substituted lithium enolates, enantiomerically pure antitumour (–)-podarhizon and 3-substituted esters of glutaric acids, respectively, were prepared. Holton *et al.*³⁰⁷ used an analogous reaction and vinyl sulfoxide **327** as the starting compound in the formal total synthesis of aphidicolin, which exhibits *in vitro* activity against the virus *Herpes simplex*.

b. Addition of heteronucleophiles

In the synthesis of natural products, reactions of vinyl sulfones or vinyl sulfoxides with alkoxides or amines resulting in the construction of C–O or C–N bonds were used almost exclusively in

the intramolecular versions regardless of the nature of the acceptor.

Thus the key step of the 15-step enantioselective total synthesis of the pheromone (1*R*,3*S*,6*R*,9*S*,10*S*)-9,10-epoxytetrahydroedulan (+)-**328** involved cyclisation of hydroxyvinyl sulfone **329** yielding compounds **330a,b** in a ratio of 3.5:1.³⁰⁸

In the synthesis³⁰⁹ of 2,3-disubstituted pyrrolidines **331a** and piperidines **331b** (the starting materials in the synthesis of biologically active compounds) from acyclic alkoxy- and hydroxy-substituted aminovinyl sulfones **332a,b**, cyclisation proceeded also nonstereoselectively. The best *cis*-stereoselectivity (~80%) was achieved with the use of the hydroxy derivatives **332a**. The protection of the hydroxy group (the best results were obtained with R³ = PrⁱSi) favours *trans*-stereoselectivity.

n = 1 (**331a**), 2 (**331b**); R¹ = H, (CH₂)₂CO₂Me; R² = H (**332a**), PrⁱSi (**332b**); (a) CF₃CO₂H, CH₂Cl₂; (b) Et₂NH, THF, –78 °C.

In more rigid systems, for example, in the synthesis of the alkaloids clavicipines A and B **333a,b** from monocyclic com-

R¹ = Troc (trityloxycarbonyl); R² = Ac (**a**), H (**b**); (a) 10% C/Pd, THF, NH₄OAc, 20 °C, 48 h (94%).

pound **334**, cyclisation through β -amination of the double bond of the vinylsulfone fragment occurs with a high stereoselectivity.³¹⁰

In the synthesis of (–)-monomorine **335**, 5-*endo-trig* cyclisation of compound **337** prepared from norleucinol **336** took place also in a highly stereoselective manner.³¹¹ The construction of the second ring from the monocyclic intermediate **338** occurred through intramolecular reductive amination.

Intramolecular addition of heteronucleophiles at the C=C bonds of vinyl sulfoxides plays a considerable role in the asymmetric synthesis.¹²

In the series of studies performed by Iwata *et al.*,^{312–315} the addition of remote hydroxy groups to the vinyl sulfoxide fragment was used for the construction of enantiomerically pure dioxaspirodecans and -undecanes, which are the major components of pheromones of many insects. The enantioselectivity of spirocyclisation is achieved owing to the asymmetric induction of the chiral sulfinyl group due to which this method has advantages over some others.^{100, 101} Dioxaspirodecans (2*R*)-**339a,b**, which are pheromones of the wasp *Paravespula vulgaris*,^{312, 313} were prepared by the action of KH on 5-hydroxydihydropyran sulfoxides **340a,b** followed by reductive desulfination of the reaction products **341a,b**. Two other diastereomers of the pheromone, *viz.*, **342a,b**, were synthesised by isomerisation of the cyclisation product in an acidic medium followed by reductive desulfination of isomeric sulfoxides **343a,b**. The closure of the six-membered rings by an analogous intramolecular reaction afforded (*R*)- and (*S*)-1,7-dioxaspiro[5.5]undecanes **61**^{313, 314} and more complex molecules of talaromycins A and B, which are metabolites of the toxic mushroom *Talaromyces stipitatus*.³¹⁵

$R^1 = \text{H}$, $R^2 = \text{Me}$ (a); $R^1 = \text{Me}$, $R^2 = \text{H}$ (b); (a) KH, THF, -78°C ; (b) Ra/Ni, MeOH; (c) TsOH.

Solladie *et al.*¹⁶⁸ used cyclisation involving a remote hydroxy group and the C=C bond of the chiral vinylsulfinyl fragment of the molecule as one of the steps in the above-considered synthesis of a vitamin E precursor, *viz.*, (+)-(*S*)-**122**.

Polycyclic alkaloids, such as (+)-carnegine (**344**) and (+)-canadine (**345**), can be prepared by intramolecular amination of vinylsulfinyl bonds in spite of the fact that this process is not always stereoselective.^{316, 317}

Monocyclic (+)- and (–)-sedamines were synthesised³¹⁶ from linear precursors, *viz.*, substituted (*E*)- and (*Z*)-alkenyl sulfoxides. Thus cyclisation of the sulfoxide (*E*)-**346** followed by chain elongation in the reaction of the α -sulfinyl carbanion of diastereomer **347a** with benzaldehyde and reductive desulfinylation of the reaction product afforded (+)-sedamine (**348**). (–)-Sedamine was prepared according to the same procedure starting from the (*Z*)-isomer of the sulfoxide **346**.

(a) $\text{PhCH}_2\text{NEt}_3\text{OH}$, -40°C ; (b) LDA; (c) PhCHO; (d) Ra/Ni.

An alternative procedure for the preparation of carnegine (**344**) was developed³¹⁸ based on the reaction of enantiomerically pure (*R*)-2,4-dinitrophenylethynyl sulfoxide (**349**) containing the highly electrophilic triple bond with 2-(3,4-dimethoxyphenyl)-

(a) 20°C ; (b) **350a**, $\text{CF}_3\text{CO}_2\text{H}$, 0°C , 100%; (c) Ra/Ni; (d) CH_2O , NaCNBH_3 ; (e) **350b**, TsOH, MeOH, -30°C (70%).

ethylamine (**350a**). The tricyclic alkaloid (+)-tetrahydroharman (**351**) was prepared with a rather high selectivity starting from amine **350b** containing the indole substituent *via* the vinyl sulfoxide **352b**.

Intermolecular addition of a nitrogen nucleophile to the vinylsulfinyl bond was used in the synthesis of structurally unique (*R,R*)- and (*S,S*)-homalines **353** from epimeric 4-phenyl-1,5-diazacyclooctan-2-ones [(*R*)-(+)-**354**] and (*S*)-(–)-**354**.³¹⁹ The reaction of pyrazolidine with enantiomerically pure substituted (*R*)- or (*S*)-(*E*)-vinyl sulfoxides **355** in an excess of Bu^tOK followed by the removal of the sulfinyl group under the action of SmI₂ afforded bicyclic compounds. The target products were prepared from these bicyclic compound in two steps after reductive cleavage of the N–N bond under the action of Na/NH₃.

(a) Bu^tOK; (b) SmI₂; (c) Na/NH₃.

2. The Diels–Alder reaction

a. Sulfonyl- and sulfinyl-containing dienophiles

The high reactivity of vinyl sulfones as dienophiles in [4 + 2] cycloaddition reactions was reported in the 1960s. Ethyl vinyl sulfone readily enters into Diels–Alder reactions not only with electron-rich dienes (the reaction with cyclopentadiene is exothermic), but also with electron-deficient dienes (for example, with hexachlorocyclopentadiene³²⁰). More recently, owing to the fact that the adducts of vinyl sulfones can readily undergo reductive desulfonation, the latter have found application as equivalents of nonactivated alkenes and alkynes, which are difficult to introduce into the [4 + 2] cycloaddition reactions.^{321, 322} However, the Diels–Alder reactions are rather rarely used for the preparation of biologically active compounds due apparently to their low stereoselectivity. The first step of the synthesis of sesquiterpenoid sterpuric acid (**356**) involved cycloaddition of cyclic vinyl sulfone to the highly electrophilic Danishefsky diene (**357**).^{323, 324} The ratio between the target isomer **358a** and the undesirable isomer **358b** was ~ 2 : 1 (the total yield of the final product was 11%). The reaction of 3-silyloxy-2-sulfolene with diene **359**, which is the key

(a) ~ 150 °C, 5 days; (b) oxidation.

R = Pr₃Si; (a) 170–180 °C, 48 h; (b) Py·TsOH, Δ (82%–85%).

(a) 150 °C, 8 days; (b) 2 M HCl, (MeO)₃CH; (c) KOH, THF; (d) EtCuMgI.

step in the formal synthesis of breynolide (**360**), also proceeded nonselectively to form a mixture of adducts **361a,b**.³²⁵ (*E*)-1,2-Bis(diphenylsulfonyl)ethene is a more efficient dienophile. Its reaction with 5-benzoyloxy-2-pyridone proceeded with a higher selectivity and was used in the synthesis of racemic ibogamine *via* the adduct **362** (the total yield was 14%).^{326, 327}

In the absence of catalysts, [4 + 2] cycloaddition involving vinyl sulfones proceeds at rather high temperature. The use of catalysts makes it possible to use milder reaction conditions and to enhance the selectivity. Thus the selectivity of the Diels–Alder reaction of tetracyclic vinyl sulfone **363** with diene **364** in the presence of EtAlCl₂ at 0 °C was higher than 90%. Such strategy for the ring buildup made it possible to perform the C(15)- and C(20)-enantioselective synthesis of racemic alkaloid 3-*epi*-allo-yohimbone (**365**) with a skeleton similar to that of reserpine.³²⁸

An application of intramolecular [4 + 2] cycloaddition involving α,β-unsaturated sulfonyl fragments has been described. Thus the stereospecific construction of the skeleton of *cis-anti-cis*-estrone was carried out³²⁹ by the reaction of the *o*-quinodimethane fragment formed upon pyrolysis of the benzocyclo-

butane moiety of compound **366** with the vinylsulfonyl group of the same molecule.

(a) 195 °C, 1,2-Cl₂C₆H₄, 6 h (~62%).

Based on their experience on intramolecular Diels–Alder reactions of polyene sulfones,³³⁰ Craig *et al.*³³¹ attempted to use this approach in the synthesis of vitamin D₃ and its analogues, which have attracted growing interest because of the discovery of new pharmacological properties of these compounds.³³² However, the construction of the block CD for the synthesis of vitamin D₃ can be performed³³³ only starting from compound **367** containing the highly reactive sulfonylethynyl fragment. Selective hydrogenation of one of the C=C bonds in the major reaction product **368b** afforded the key intermediate in the synthesis of vitamin D₃, *viz.*, sulfone containing the rings CD. Corey *et al.*^{334–336} used ethynylsulfonyl precursors for the construction of the rings AB of forskolin (**369**) possessing valuable pharmacological properties. Owing to the additional activation of the triple bonds in compounds **370a,b** with ester groups, cyclisation

R = H (a), OCO₂Et (b); (a) R = H, CH₂Cl₂, 23 °C, 36 h (64%, *ee* 97%);

(b) R = OCO₂Et, , 95 °C, 48 h (65%, *ee* 93%).

occurred in the absence of a catalyst under mild conditions with a high enantioselectivity.

The introduction of activating groups and the addition of catalysts, which allow one to perform the Diels–Alder reactions under milder conditions, are particularly necessary if less reactive vinyl sulfoxides are used as dienophiles.

The Diels–Alder synthesis involving polyfunctional racemic vinyl sulfoxides was applied, for example, in the preparation of (±)-dehydrogriseofulvin (**371**)³³⁷ starting from the sulfoxide **372** or sodium salts of prephenates **373** *via* the intermediates **374a,b**, which were generated from the sulfoxide **375**.³³⁸ When surveying his investigations, Danishefsky particularly emphasised these studies.³³⁹ The reactions of vinyl sulfoxides even with Danishefsky's silyloxydienes necessitated prolonged heating and were accompanied by elimination of sulfenic acid.

R¹ = OH, R² = H (a); R¹ = H, R² = OH (b); (a) 100 °C, 20 h; (b) AcOH, AcOEt; (c) BBN (9-borabicyclononane); (d) NaOH.

The development of procedures for efficient asymmetric synthesis starting from enantiomerically pure sulfinyl-containing dienophiles presented the major problem. The search for the optimum reaction conditions and for the chiral sulfinyl dienophile of choice for the synthesis of (+)-(1*R*,4*R*)- and (–)-(1*S*,4*S*)-enantiomers of norborn-4-enone was carried out using the [4 + 2] cycloaddition of cyclopentadiene to (+)-(*R*)-tolyl vinyl sulfoxide³⁴⁰ and its analogues^{341,342} as examples. The full selectivity was achieved only with the use of a more complex compound, *viz.*, a ketene equivalent **376**. The reaction of the latter with cyclopentadiene in the presence of BCl₃ at –70 °C gave only one adduct, which was transformed into (+)-(1*R*,4*R*)-norborn-4-enone.³⁴³ The reaction proceeded selectively due to the formation

The synthesis of (+)-*epi*- β -santalene **377** involved the reaction of cyclopentadiene with ethyl (*Z*)-(*R*)_S-2-methyl-3-(tolylsulfinyl)-prop-2-enoate (Scheme 11).^{344,345} In this synthesis, the reaction

Scheme 11

R¹ = menthyl; R² = 2-pyridyl (**380a**), R² = 3-trifluoromethyl-2-pyridyl (**380b**); (a) , 90 °C, 6 h (87%); (b) , 25 °C, 19 h (87%); (c) , ZnCl₂, -20 °C, 3.5 h (94%); (d) , Et₂AlCl, -78 °C (94%); (e) , Et₂AlCl, -78 °C (~70%); (f) , 0 °C, 6 days (~100%).

Chiral *N*-substituted sulfinylmaleimides **385a–d** are efficient dienophiles. These compounds react with cyclopentadiene in the presence of ZnCl_2 at low temperature to form almost exclusively *exo*-adducts **386a–d** in quantitative yields.³⁵² The adduct **386d** was used³⁵³ for the preparation of the bicyclic alkaloids (+)-indolizidine **387** and (+)-laburnine **388**.

The search for new types of electron-rich dienes holds promise. This will extend the scope of synthetic applications of sulfinyl-containing dienophiles. For example, condensation of 'Dane's diene' (**389**) with the sulfinyl-substituted ester of maleic acid **390**³⁵⁴ or with sulfinyl-substituted cyclopentenone **391**³⁵⁵ afforded the adducts **392** and **393**, respectively, which are precursors in the steroid synthesis, with a high diastereoselectivity.

The reaction of the diene **389** with the sulfoxide **390** was accompanied by spontaneous elimination of sulfenic acid.

b. Sulfonyl- and sulfinyl-containing dienes

As yet, sulfonyl-substituted and, particularly, enantiomerically pure sulfinyl-substituted dienes have received little use in the synthesis of natural products.

Evans³⁵⁶ was the first to propose a tandem $[4 + 2]$ cycloaddition of a racemic sulfinyl-containing diene and the sulfonyl-sulfenate rearrangement of the adduct using the synthesis of a derivative of the hasubanan series as an example.

More recently, Posner and coworkers (see the review³⁵⁷) performed systematic studies of the Diels–Alder reactions of 3-sulfinyl- (**394a**) and 3-sulfonyl-2-pyrones (**394b**) with electron-rich dienophiles, such as vinyl ethers or vinyl sulfides. Unlike other substituted pyrones whose Diels–Alder reactions proceed only at high temperatures (resulting in the degradation of the initially formed adducts), the pyrones **394a,b** at low temperatures (sometimes at high pressure) give polysubstituted bicyclic lactones, which are excellent starting compounds for the preparation of various natural products.

Thus the reaction of the sulfinyl-substituted pyrone **394a** with ethyl vinyl sulfide proceeded stereoselectively to form³⁵⁸ the *endo*-adduct **395**, which was converted into tetrasubstituted cyclohexene **396** through the sulfoxide-sulfenate rearrangement under conditions of alkaline methanolysis. Subsequent transformations afforded substituted cyclohexadiene **397**, which is the key intermediate in the synthesis of ($\pm$)-chorismic acid (**398**). A shorter synthetic path for the cyclohexadiene **397** is based on the reaction of sulfonylpyrone **394b** with 1,3-dioxole.³⁵⁹

Posner and coworkers performed asymmetric syntheses of a number of enantiomerically pure natural compounds by introducing sulfonylpyrone **394b** into the Diels–Alder reaction with optically pure vinyl ether (–)-(*S*)-**399**^{360–362} catalysed by Lewis acid **400**.³⁶⁰ The transformation of the *endo*-adduct **401**, which was obtained with a high stereoselectivity, afforded trisubstituted cyclohexene (–)-**402**. A somewhat lower stereoselectivity was achieved when this reaction was carried out in the absence of a catalyst at $25\text{ }^\circ\text{C}$.³⁶¹ The cyclohexene **402** served as the starting compound for the preparation of the key intermediate **403** (the total yield was 62%) in the total synthesis of $1\alpha,25\alpha$ -dihydroxyvitamin D_3 as well as for the synthesis of methyl (–)-tri-*O*-acetyl-4-*epi*-shikimate (**404**) (the total yield was 23.4%, $ee > 98\%$).

Readily available racemic 2-(phenylsulfinylmethyl)buta-1,3-diene (**405**) is an active diene.³⁶³ This compound reacted with dimethylcyclopropane to give a mixture of *exo*- and *endo*-adducts **406**. After reductive desulfonylation, the *exo*-adduct was converted into Δ^3 -carene (**407**). The sulfoxide-sulfenate rearrangement of compound **406** under the action of $\text{P}(\text{OEt})_3$ afforded the hydroxy derivative **408** from which racemic chaminic acid (**409**) was prepared. Thermal condensation of the diene **405** with methyl vinyl ketone gave rise to a mixture of 1,4- and 1,3-substituted cyclohexenes in a ratio of 3 : 1. The adduct **410** was converted into racemic $\Delta^{1(7)}$ -menthene-2,8-diol (**411**) in three steps.

Sulfonyl- and sulfinyl-substituted diene units can be involved in intramolecular $[4 + 2]$ cycloaddition. For example, this procedure was used for the preparation of compound **412**, which is an

(a) 80 °C, 5 kbar; (b) Li, NH₃ (liquid); (c) P(OEt)₃; (d) PhH, 80 °C.

important fragment in the total synthesis of the macrolide ikarugamycin.³⁶⁴

A short synthesis of sesquiterpenoid (+)-sterpurene (**413**) was carried out³⁶⁵ using the cascade intramolecular [4 + 2] cycloaddition involving the diene system of sulfinyl-substituted tetraene **414**.

Convenient procedures for the preparation of enantiomerically pure 2-sulfinyl-substituted butadienes have been developed recently.^{366, 367} The transformation of the *endo*-adduct (**416a**) of diene **415** with maleic anhydride in the synthesis of monoterpenoid (–)-(1*S*,5*R*)-karahana ether (**417**) (*ee* > 93%) is the first

example of an asymmetric synthesis of a natural product with the use of such dienes.³⁶⁸

(a) $\begin{array}{c} \text{CO} \\ \diagup \quad \diagdown \\ \text{O} \end{array}$, THF, Δ ; (b) Na₂CO₃, H₂O (90%), (**416a** : **416b** = 4 : 1).

3. Syntheses based on elimination of SO₂ from 2,5-dihydrothiophene 1,1-dioxides (3-sulfolenes)

3-Sulfolenes readily eliminate SO₂ to form substituted buta-1,3-dienes. This process is the cheletropic ring-opening reaction which obeys the Woodward–Hoffmann rule and occurs under conditions of pyrolysis, sometimes in the presence of bases. The introduction of substituents into the sulfolene ring, which can be readily performed, for example, by alkylation at the α -position, followed by thermolysis allows one to prepare various buta-1,3-dienes starting from 3-sulfolenes. These butadienes can be used in the synthesis of polyunsaturated linear and carbocyclic natural compounds. Thus the homofarnesene components of the fire-ant trail pheromone **418a,b** were prepared³⁶⁹ from 2,3-dimethyl-4-(phenylthio)-3-sulfolene (Scheme 12). Polysubstituted thiophene **419** was converted into 3-sulfolene **420** by electrolytic reduction followed by oxidation at the sulfur atom.³⁷⁰ The compound **420** was subjected to *in situ* thermolysis resulting in a mixture of a juvenoid methoprene **421** and its (2*Z*,4*E*)-isomer.

Sulfolene **422** was used as the starting material³⁷¹ for the preparation of tricyclic compound **423** containing the taxane ring system. 3-Methyl-3-sulfolene served as the starting compound in many syntheses of natural compounds, for example, of open-chain α -sinensal (**424**) (an important contributor to the odour of the Chinese orange oil)³⁷² or bicyclic terpenoids of the eudesmane series **425–427**.³⁷³ In the latter cases, the intramolecular Diels–Alder reactions proceeded with extremely high stereoselectivities (Scheme 13).

The use of nitrogen-containing dienophilic groups (for example, imine or enamide groups) in the intramolecular Diels–Alder reactions opens up the way to the construction of racemic alkaloids (Scheme 14). Apparently, the first to be performed was the short synthesis of racemic elaeokanine A (**289a**) *via* the

Scheme 12

Scheme 13

intermediate **428** starting from the sulfolene **429**.³⁷⁴ Elimination of SO₂ and cyclisation were carried out by passing compound **429** through a heated column (370–390 °C) filled with glass helices. Martin *et al.*³⁷⁵ performed the formal total synthesis of pentacyclic lycorine (a natural plant-growth inhibitor, which is an important alkaloid of the *Amaryllidaceae* family) via the key

precursor lycorane **430**. Sulfolene-containing enamide **431** was used as the starting compound. Short syntheses of racemic lupinine **432a** and epilupinine **432b** were performed starting from bicyclic compound **433**, which has been prepared by pyrolysis and the intramolecular Diels–Alder reaction of disubstituted sulfolene **434**.³⁷⁶ Analogous conversions of the precursors **435a,b**,

Scheme 14

which have been prepared from 3-methoxycarbonyl-3-sulfolene, afforded the bicyclic systems **436a,b**. The latter served as the starting compounds in the synthesis of heteroyohimboids.³⁷⁷

The sulfolene grouping has also been used as a protective group in modifications of vitamin D₃. For the purpose of introducing methyl groups at C(6) and C(19)³⁷⁸ or the fluorine atom at C(19),³⁷⁹ an adduct of vitamin D₃ with SO₂ at its 1,3-diene fragment has been initially prepared. After completion of the required transformations, the adduct was decomposed by mild thermolysis.

In the total synthesis of racemic estra-1,3,5(10)-trien-17-one (**437**), a mixture of epimers of substituted 1,3-dihydrobenzo[*c*]-thiophene 2,2-dioxide **438** was used as the precursor. This mixture gave rise to the quinodimethane intermediate **439** upon thermal elimination of SO₂, which underwent stereospecific cyclisation to the final product.³⁸⁰

VI. Conclusion

Among reactions of sulfoxides and sulfones playing an important role in the synthesis of natural compounds, alkylation of carbanions obtained from these compounds or the Julia olefination became conventional processes. However, the improvement of these procedures is still in progress. Thus the use of dimethoxyethane as the solvent in the first stage of the Julia olefination³⁸¹ in combination with SmI₂ (see Refs 141 and 142) made it possible to

construct trisubstituted C=C bonds, which previously failed, for example, in the synthesis of macrolides of the avermectin–melbemycin series.^{136, 139}

One would expect that considerable study will be given to the enhancement of the stereoselectivity of catalytic Diels–Alder reactions, particularly, involving nonracemic sulfinyl dienes and dienophiles, to the use of new asymmetric building blocks, for example, chiral (*ee* 95%–99%) allylic sulfones synthesised recently,³⁸² and to the development of π -allylic alkylation catalysed by transition metals based on the strategy of the transfer of the reaction centre to the remote functional group (for example, in the synthesis of tetracyclic (–)-dendrobine)³⁸³ with the participation of sulfinyl-containing nucleophiles.

Convergent syntheses (Fuchs²³ took an active part in popularisation of this method) have found a rather wide application in the reactions considered in this review. More modern methodologies, which allow one to perform one-pot syntheses of complex compounds, are not used so often. These procedures are said to be consecutive or tandem processes,^{384–386} cascade reactions,³⁸⁷ processes with the use of counterattacking reagents³⁸⁸ or poly-component condensations.³⁸⁹ The examples of multicomponent reactions considered below demonstrate that this approach to the synthesis of natural compounds is fruitful.

Thus three-component cyclisation of an allylsulfinyl anion with a substituted cyclopentenone and an aldehyde afforded compound **440**. Modification of the latter made it possible to synthesise the prostaglandin derivative **441**.³⁹⁰ Epithio- and epoxyestratetraenones **442a,b**³⁹¹ were synthesised by three-component cyclisation involving the allylsulfonyl anion, which made it possible to construct the steroid skeleton with a high stereoselectivity without isolation of the intermediates **443a,b**. The synthesis of the alkaloids apoyohimbines **444a,b**³⁹² was based on the cascade process involving the Pictet–Spengler reaction of substituted tryptamines with a sulfolene-containing aldehyde, elimination of SO₂ from the intermediates **445a,b** and the intramolecular Diels–Alder reaction. This allows one to perform one-steps introduction of the methoxycarbonyl group at C(22) yielding a pentacyclic reaction product with the stereochemistry of the natural compound (Scheme 15).

The area of these investigations would be expected to expand in the near future.

When this review had been prepared for publication, the results of new studies devoted to the applications of sulfoxides and sulfones to the synthesis of natural compounds appeared. The most interesting of them are briefly considered below.

Conventional alkylation–desulfonylation of α -sulfonyl carbanions^{393–397} (including those prepared from oxiranes³⁹⁸) along with an interesting version of reductive alkylation of 1,1-di(sulfone) with lithium naphthalenide, allyl bromide or sodium amalgam³⁹⁹ were used for the construction of C–C bonds. Endocyclic C=C bonds were formed by pyrolysis of oxo sulfoxides.^{400, 401} In addition to the coupling of fragments through the (E)-C=C bonds using the classical olefination according to M Julia in the construction of natural molecules,^{402–404} the increasing popularity has acquired a modification of this procedure developed by S Julia⁴⁰⁵ using model compounds (see Refs 406–417 and references cited therein). The procedure elaborated by S Julia involves the reactions of aldehydes with anions generated from 2-benzothiazolyl sulfones whose participation makes it possible to perform olefination as a one-pot process. Double bonds between the pyrrole rings in natural compounds are formed by successive treatment of a mixture of a sulfone and an aldehyde with DBU and $\text{P}(\text{Bu})_3$.⁴⁰⁸ The reactions of α -sulfonyl anions^{409, 410} or anions of chiral sulfoxides⁴¹¹ with carbonyl compounds were used for binding fragments through the CH_2CO or $\text{CH}_2\text{CH}(\text{OH})$ groups. Unsaturated sulfones were involved in cyclisation of acyclic γ -hydroxyvinyl sulfones,^{412–414} metallation of vinyl sulfones at the C=C bond followed by the introduction of a substituent^{415, 416} and [4 + 2] cycloaddition of ethynyl sulfones to *N*-Boc-pyrrole.^{417, 418} Free-radical $\text{Ni}(\text{acac})_2$ -catalysed arylation of optically active sulfoxide with Ph_3ZnMgCl was also reported.⁴¹⁹ The one-pot diastereoselective synthesis of a complex polycyclic compound by cascade cyclisation involving sulfones or sulfoxides under conditions of radical catalysis was described.⁴²⁰

VIII. Other agents for ‘living’ radical polymerisation	429

Abstract. The review is devoted to various types of compounds used as agents for ‘living’ radical polymerisation, such as alkoxyamines formed upon addition of the chain carrier radicals, $R^{\bullet}$, to stable nitroxyl radicals, as well as products of the addition of the radicals to transition metal complexes with different ligands, *etc.* In all cases, the mechanism of the action of these agents consists in their reversible dissociation $A \rightleftharpoons R^{\bullet} + X^{\bullet}$, where $X^{\bullet}$ is a stable free radical or a metal-containing complex which can accept radicals $R^{\bullet}$ ($R^{\bullet} + X^{\bullet} \rightarrow A$) and thus compete with the quadratic chain termination. Particular attention is paid to the studies which allowed a quantitative formulation of the mechanism of ‘living’ radical polymerisation in the form of a mathematical model suitable for predicting both the parameters of the polymerisation and the properties of the resulting polymer (molecular mass and polydispersity). The bibliography includes 359 references.

I. Introduction

‘Living’ radical polymerisation, or, more precisely, ‘living’-chain radical polymerisation is a new line of investigation in the area of radical polymerisation, known from the early 1990s. The origination and development of this area of scientific exploration has become possible owing to the discovery in the last two decades of a new elementary act of polymerisation processes involving the chain carrier radicals $R^{\bullet}$, namely, the reversible addition of $R^{\bullet}$ to several metal complexes or to stable free radicals (in particular, to nitroxyl radicals).

Numerous studies on ‘living’ radical chains (LRC) reported over the last three years (100 articles and more *per annum*) confirm that this new field is of great scientific and technological importance and appears to have considerable promise. Most prominent in this research area are Matyjaszewski’s group in the USA and Fukuda’s group in Japan. In these research groups, studies on

LRC are carried out by polymer chemists in co-operation with mathematicians and physicists, which indicates the high level of scientific co-ordination and financial backing.

This review is concerned with systematisation and critical review of a great body of data on LRC accumulated to date. The authors of the review have worked in the area of LRC since its inception. They appeared to be among the pioneers of the elementary processes which provide the basis for ‘living’-chain radical polymerisation.

II. ‘Living’-chain anionic polymerisation

The concept of a ‘living’ polymer chain or simply a ‘living’ chain (LC) appeared in studies of anionic polymerisation and goes back to Szwarc.¹ He recognised that if a growing polymer anion (a chain carrier, R_A) cannot be quadratically terminated ($R_A + R_A \rightarrow$ ‘dead’ polymer), then, in the absence of reactive impurities (X) capable of breaking the polymer chain following a linear mechanism ($R_A + X \rightarrow$ ‘dead’ polymer), anionic polymerisation proceeds without chain breaking, as a ‘living’ process. In this case, the lifetime (τ) of growing polymer chains exceeds the time necessary for complete conversion (t). In other words, the polymer anions R_A remain ‘living’ not only during the polymerisation, but also following completion of the process, *i.e.*, after complete consumption of the initial monomer. ‘Livingness’ of polymer chains is confirmed by the fact that the polymerisation process restarts upon addition of a fresh portion of the same monomer or any other monomer which can undergo anionic polymerisation at the same centres R_A .

A conventional anionic polymerisation proceeds in such a way that the initiation of R_A is a relatively fast reaction which takes a time interval τ_i much shorter than the time necessary for complete conversion (t). The condition $\tau_i \ll t$ implies that the initiation of all chains occurs nearly simultaneously and that they grow synchronously throughout the polymerisation, so that the number-average molecular mass (M_n) of the resulting polymer is proportional to time. The molecular mass distribution of the polymer chains narrows monotonically as M_n increases and reaches very low values (the polydispersity index, M_w/M_n , approaches a value of 1.0) already at not too high M_n values (several tens of monomer units). This remarkable property is inherent in the ‘living’ chains only ($\tau > t$ and $\tau_i \ll t$). In the case $\tau \ll t$ (short-lived chains), which corresponds to radical polymerisation, the lowest polydispersity of the polymer is either 1.5 or

2.0 depending on the type of chain termination reaction (disproportionation or recombination).

The use of these valuable properties of the products of 'living' polymerisation has led to design of a novel class of polymeric materials, *viz.*, block copolymers of the $A_nB_mA_n$ type, where A is a polystyrene block, B is a polyisoprene or polybutadiene block, and m and n are the numbers of monomer units in the blocks. At particular m and n values and at the temperatures which are above the glass transition temperature of the elastic block B, but below the glass transition temperature of the block A, these types of copolymers behave as vulcanised rubbers possessing very good physicochemical properties. This is due to a specific structure of the block copolymers, *viz.*, the presence of glassy domains comprising several blocks A arranged regularly in a continuous elastic B-block matrix. The domains playing the role of cross-link points of the polymer network are essentially the same size, which is provided by very low polydispersity of the blocks A. The sizes and regular spatial arrangements of the blocks, which govern the physicochemical properties of the material, depend on n and the m/n ratio. At temperatures above the glass transition temperature of the block A, the copolymer behaves as a nonvulcanised rubber. Depending on temperature, these polymers possess the properties of vulcanisate or devulcanisate. They have played an outstanding role both in the polymer technology and in ecology since in this case the recovery of wastes and exhausted products has become much easier.

At the same time, 'living' anionic polymerisation requires an extremely labour-consuming procedure for the removal of impurities X from an initial reaction system to prevent chain breaking. Additionally, the number of pairs of the monomers of the types A and B is rather limited. Thus, the idea of performing a 'living'-chain radical polymerisation appeared to be quite attractive.

III. 'Living'-chain radical polymerisation

The fundamental distinction between 'living'-chain radical and 'living'-chain ionic polymerisation is that quadratic chain termination is of great importance in the former case and plays a negligible role in the latter. In other words, 'living'-chain radical polymerisation includes deactivation of growing active centres by termination between them ($R + R \rightarrow$ 'dead' polymer).[†] Thus, implementation of 'living'-chain polymerisation requires basically different approaches, since in this case it is the main participant of the polymerisation process rather than a removable (*e.g.*, by purification) impurity that plays the role of chain terminator, which results in a situation where $\tau \ll t$. Therefore, meeting the main condition for 'living' radical polymerisation, $\tau > t$, requires the development of a procedure for extending the lifetime of active centres (chain carriers) R. This also requires the retention of their high reactivities towards the monomer molecules (M) in order to provide the possibility for the polymer chain to grow following the ' $R + M \rightarrow$ chain' mechanism. This means that radicals R should be deactivated in order to preclude quadratic chain termination and, at the same time, should retain their activities in order to provide the polymer chain propagation ($R + M$). At first glance, this problem seems to be intractable.

The main advantage of 'living'-chain polymerisation consists in the possibility of obtaining a desired product with narrow polydispersity. At the same time, the second condition necessary for exploitation of this advantage, $\tau_i \ll t$, is also not met in the case of radical polymerisation. Here, initiation of new chains occurs throughout the polymerisation process rather than during a short initial period τ_i , thus disturbing the simultaneous chain propagation and unavoidably increasing the polydispersity of the resulting polymer even in those cases where the lifetime of radical R can be extended to time intervals $\tau > t$.

Eventually, 'living'-chain radical polymerisation seems to have no chance of success. However, a new elementary act of

radical polymerisation has been discovered, namely, temporary entrapment of the chain carrier radical R by an acceptor A ($R + A \rightleftharpoons RA$) followed by release of R (the so-called reversible inhibition). This made it possible to solve both problems, *i.e.*, to extend the time interval τ ($\tau > t$) and to achieve simultaneous propagation of all chains, thus meeting the condition $\tau_i \ll t$. Later, yet another solution to the problem was found, consisting of carrying out the reactions $R^1 + A \rightarrow R^1A$ and $R^1A + R^2 \rightarrow R^2A + R^1$, where R^1 and R^2 are the growing polymer chains of the same nature but different lengths, and/or the growing chains of different nature. Mention may be made that these two solutions differ only in the type of regeneration of the entrapped (accepted) chain carrier radicals. In the former case, the RA adduct dissociates into the initial components, whereas in the latter case the entrapped chain carrier radical R^1 is released from the R^1A adduct following the radical substitution reaction $R^1A + R^2 \rightarrow R^2A + R^1$.

Among the substances suggested for the use as acceptors A are stable free radicals R_s (nitroxyl radicals, triphenylmethyl, *etc.*) and metal complexes (porphyrin, phthalocyanine and cobaloxime cobalt complexes, copper and iron complexes with halide and organic ligands, *etc.*). Active chain carrier radicals R react with stable radicals R_s to give adducts in which the $R-R_s$ covalent bond is relatively weak and thus can dissociate at 373–423 K. For instance, if R is a growing polystyrene chain and R_s is a stable nitroxyl radical, the bond strength in the $R-R_s$ adduct is estimated at $E = 125.4 \text{ kJ mol}^{-1}$, which provides a rather high rate constant for bond dissociation, $k_1 = 10^{-4} - 10^{-5} \text{ s}^{-1}$, already at 373 K.

First, let us consider the above-mentioned elementary reactions as applied to the problem of 'living' chains taking the $R + A \rightleftharpoons RA$ reaction as an example. Let us denote the rate constants for dissociation and reverse recombination as k_1 and k_2 , respectively, the acceptor A as X (in order to specify it as a stable free radical) and the adduct as RX. If RX is used instead of conventional initiators (peroxides, azodinitriles, *etc.*) of radical polymerisation, the mechanism of the process can be described by the following scheme:

Scheme 1

At particular values of rate constants k_1 , k_2 , k_p and k_t , this four-stage mechanism provides a negligible contribution of chain termination reactions. Provided that $k_1[R] \ll k_2[X]$, the prevailing chain 'termination' by the $R + X$ reaction simply makes the chain temporarily inactive (a 'dormant' chain, RX) until the next dissociation act of RX. In such a manner the condition $\tau > t$ is met. In the final stage of polymerisation (after complete consumption of the initial monomer), almost all chains, except for a small fraction of 'dead' (quadratically terminated) chains that form a conventional random (statistical) polymer P, appear to be 'dormant' in the form of RX. Obviously, the addition of a fresh portion of the initial or another monomer (if a block copolymer is synthesised) will re-activate the chain carriers R, which means that the situation will be quite adequate to a 'living' polymerisation.

To meet the second essential condition, *viz.*, simultaneous chain initiation ($\tau_i \ll t$), it is sufficient that the half-life of the adduct RX, equal to $0.69/k_1$, be much (10 to 100 times) shorter than the time necessary for complete conversion, t . Provided that $0.69/k_1 \ll t$, each growing chain manages to be both in active and 'dormant' state tens or hundreds times. This synchronising mechanism of chain propagation provides a very low polydispersity of the polymer. It should be noted that corresponding fitting procedure for numerical values of rate constants uses the k_1 and k_p

[†] Hereafter, in some instances the radical sign will be omitted for simplicity.

constants as well as the temperature (taking into account the temperature dependence of k_1 and k_p) as independent variables.[‡]

Thus, the use of acceptors X that temporarily entrap the chain carrier radical R and then release the initial species X and R makes it possible to solve the problem of implementation of a 'living'-chain radical polymerisation. Unlike anionic polymerisation in which the chain carrier cannot undergo quadratic chain termination at all, it is appropriate to call the process discussed above a pseudo-'living' polymerisation (and, correspondingly, to consider pseudo-'living' chains), since the radical chains propagate only in the form of active chain carriers R following their 'recovery' from the 'dormant' state and thus can undergo quadratic termination.

It should be noted that the four-stage process discussed above is a non-steady-state process. Therefore, correct quantitative estimates of the parameters of the process can be obtained only after solving corresponding systems of differential equations rather than algebraic equations, as is the case of a steady-state process.

Finally, mention may be made that a 'living'-chain radical polymerisation process following this mechanism is stable towards such disturbing factors as additional initiation

where I is an initiator supplied from an external source or the monomer itself (self-initiation involving the monomer molecules occurs, *e.g.*, in the styrene polymerisation at temperatures above 373 K). Provided that the $k'_1[I]$ value is at least 5 to 10 times smaller than the $k_1[RX]$ value, this disturbing factor can be ignored. This condition can be met, as will be shown in the next Sections of the review dedicated to consideration of particular experimental data.

The other type of 'living'-chain polymerisation using the following elementary stages,

differs from that discussed above (using the $R + A \rightleftharpoons RA$ reaction) only in that it requires the use of an initiator I (or the process should be performed under conditions of spontaneous initiation involving the monomer), since the R^1A adduct does not initiate polymerisation.[§]

IV. The progress in investigations on 'living'-chain polymerisation

The progress in studies on 'living'-chain radical polymerisation can be divided into three stages.

1. The discovery of temporary entrapment of chain carrier radicals R by compound A with the formation of labile adducts $R-A$ from which R can be released by dissociation (or following a radical substitution reaction, as was shown later). This phenomenon was called reversible inhibition.

2. The use of reversible inhibition for designing a 'living'-chain radical polymerisation process (theoretical analysis, experimental studies).

3. Implementation of 'living' chain radical polymerisation following a procedure which includes an exhaustive system of proofs of successful polymerisation (registration of changes in the average molecular mass, molecular mass distribution and other characteristics during monomer conversion).

It is hard to mention a pioneering work for stages 1 and 2. More correct is to consider a number of pioneering studies carried out independently by investigators from different research groups.

However, the third stage undoubtedly began with a pioneering study carried out by investigators from Canada.² Taking the radical polymerisation of styrene in the presence of a stable iminoxyl radical (X) as an example, they were the first to show that the chain carrier (the growing polystyrene chain) R is alternately present in the reaction system in the deactivated (in the form of adduct RX) and active (in the form of free radicals $R + X$) states. This was proved by corresponding kinetic studies and by measurements of molecular mass distribution and average molecular mass of the resulting polymer during the conversion. Unlike unsuccessful attempts of their predecessors, the success of investigators from this research group is due to an extremely fortunate (chance or predicted?) choice of styrene as the monomer, since the presence of a phenyl substituent in the α -position with respect to the $R-X$ bond, which undergoes dissociation, makes this bond more labile, which allows its dissociation at a sufficiently high rate at temperatures below 423 K. This fact appeared to be essential since at $T > 423$ K the contribution of hydride transfer accompanying the dissociation increases and the dissociation mechanism changes from reversible

to irreversible

where $R' (=)$ denotes the 'dead' (terminated by intramolecular disproportionation) polystyrene chain with the end group containing a double bond and XH is the corresponding hydroxylamine.

This pioneering work² initiated the appearance of numerous publications and their number seems to have no limit as yet. At the same time, it should be remembered that the communication cited was preceded by a number of experimental and theoretical studies carried out at the first two stages. A scheme of the development of investigations in the area of 'living' polymerisation is presented below (Scheme 2).

This scheme of pioneering studies may seem to be too cumbersome and overburden with details; however, it reflects the state-of-the-art in this area. First, at first glance different-type and non-related phenomena have been observed in studies of compounds of different chemical nature, such as alkoxyamines, macrocyclic cobalt compounds (later, copper and iron complexes), dithiocarbamates, *etc.* These studies were carried out concurrently and independently. Then, it was appreciated that, despite different chemical nature of compounds studied, all of them obey identical kinetic regularities as regards their ability to entrap temporarily (reversibly) active free radicals (including growing polymer chains) and release them after certain time intervals. Simultaneously, the investigators perceived the possibility of using this type of acceptors ('trappers') as agents for 'living' radical polymerisation. (This was best shown by Smirnov.⁵) Then, several types of 'living'-chain polymerisations were reported (each of these studies formed the basis for an independent investigation line). Further development of these investigation lines is based on these initial pioneering works.

In conclusion, it should be noted that we cannot say unambiguously who was the pioneer of 'living'-chain anionic polymerisation. Undoubtedly, Szwarc^{1,46,47} has not only systematised and thoroughly analysed the key phenomena related to 'living' carbanions, thus having created a well-founded scientific discipline, but was also the first who discovered many of these phenomena. Nevertheless, his studies were preceded by investigations of other researchers. As early as 1936, Abkin and Medvedev⁴⁸ developed an original procedure for the determination of the lifetime (τ) of growing carbanion polymer chains and found that for anionic polymerisation of butadiene catalysed by sodium metal the τ value is so long that it exceeds the time necessary for complete conversion of the monomer. In other words, they discovered a 'living' chain carrier carbanion and established that the polymerisation proceeded without chain breaking (in a 'living' manner). However,

[‡] The rate constants k_2 and k_t depend only slightly on both the nature of the reagents (R and X) and the temperature (their numerical values lie within the limits $10^7 \leq k_2 \leq 10^8$, $10^7 \leq k_t \leq 3 \times 10^7$ litre mol⁻¹ s⁻¹).

[§] The only exception are metal halide-alkyl halide systems in which free radicals can be generated (see Section VI).

Scheme 2

this study received little attention and in 1956 Szwarc *et al.*^{46,47} re-discovered 'living' polymerisation of vinyl monomers as though it were a new phenomenon.

V. Alkoxyamines as agents for 'living'-chain radical polymerisation

1. A brief history of investigations

As long ago as the 1970s, it was found^{36,37} that entrapment of active free (*e.g.*, polymethacrylate) radicals *R* by stable free (*e.g.*, iminoxyl) radicals *X* at moderate temperatures (below 323 K) results in the formation of stable adducts *RX* (alkoxyamines) which can release the initial radicals *X* and *R* upon raising the temperature to 373–423 K. More recently, this property of the adducts *RX* was used to perform one of the first 'living' radical polymerisations.⁵ Other stable (*e.g.*, phenylmethyl) radicals were also tried as *X*;^{49,50} however, these attempts failed. In majority of studies, nitroxyl radicals were used, which react with hydrocarbon chain carrier radicals to give the corresponding alkoxyamines.

First of all, mention should be made of the pioneering works^{5,37,38} (see Scheme 2), as well as of the studies in which alkoxyamines were used as initiators.^{34,51–55} It is these studies that best showed the salient features of 'living'-chain polymerisation, namely, a reduction of polydispersity and an increase in molecular mass during monomer conversion and the correspondence between the number of growing polymer chains (*n_c*) and that of alkoxyamine molecules introduced into the system (*n_a*). This correspondence means that at any degree of conversion (*Γ*), the following relationship is valid

$$\Gamma[M]_0 \frac{M_M}{M_n} = n_c = n_a,$$

where $[M]_0$ is the concentration of A monomer in the initial system, M_M is the molecular mass of the monomer and M_n is the number-average molecular mass of the polymer at a given degree of conversion.

These publications^{34,51–54} were followed by a number of studies^{2,56–61} in which alkoxyamines were synthesised *in situ* from nitroxyl radicals introduced into the polymerisation system and radical initiators (peroxides, azodinitriles). The initiators were chosen so that their half-lives would be a factor of several tens or even several hundreds shorter than the time necessary for

complete conversion. Polymerisation of monomers in the presence of nitroxides (without added initiators) also belongs to processes in which alkoxyamines are synthesised *in situ*. The reaction is self-initiated by the monomer, as is the case of autopolymerisation of styrene.^{61–65}

Studies dealing with the development of procedures for modification of alkoxyamines by catalytic amounts of strong organic acids or other compounds aimed at improving their efficiency occupy a special place.^{61,66–68} However, such a modification has little effect and its mechanism is still to be clarified.

The most serious drawback of alkoxyamines as agents for 'living' polymerisation is that they are effective only in the polymerisation of styrene and its derivatives.^{69–72} For other monomers, alkoxyamines appear to be rather ineffective. They find a limited application to homopolymerisation of polar monomers (acrylates, methacrylates)^{61,73–78} and their copolymerisation with some other monomers.^{79–83} The most plausible reason for reduction of the efficiency of alkoxyamines in the polymerisation of polar monomers is that the C–ON bond in their molecules is too strong. The temperature necessary for dissociation of this bond at sufficient rate is too high, so that irreversible intramolecular disproportionation occurs instead of reversible dissociation into the initial radicals *R* and *X*. This irreversible reaction results in the formation of inert products, *viz.*, a hydroxylamine and an unsaturated compound *R*(=) with the terminal double bond. In styrene and its derivatives, as well as in the copolymers of styrene with polar monomers, the C–ON bond is weakened because of the effect of phenyl substituent.^{84,85} In the copolymerisation of styrene with polar monomers, the weakening effect of the styrene unit is achieved through the polar monomer unit⁸⁵ (the effect of the penultimate unit).

2. Synthesis of alkoxyamines

Several methods for the synthesis of adducts R_iM_nX , where R_i is the initiator radical (*e.g.*, $\text{Ph}-\text{CO}-\text{O}^\bullet$ formed upon decomposition of dibenzoyl peroxide, or BPO), *M* is the monomer (*e.g.*, styrene) and *X* is the nitroxyl radical (*e.g.*, 2,2,6,6-tetramethyl-1-piperidinyloxy, or TEMPO) have been reported.^{34,51–55} Depending on the composition, *i.e.*, the $[R_i]:[X]:[M]$ ratio in the reaction mixture, adducts with different content of *M* (from *n* = 1 to *n* ≈ 10) can be obtained. Obviously, these methods are effective only under the reported reaction conditions.^{34,51–55} Later, the

possibility of designing the syntheses of any adducts of the R_iM_nX type has been demonstrated.⁸⁶ A mathematical method was developed for calculation in the steady-state approximation of the yields of the adducts synthesised in the polymerisation processes described by the simplified Scheme 3 which includes the initiation, chain propagation and chain termination stages. This scheme assumes that only a linear chain termination occurs in the system (quadratic chain termination can be ignored because of a very high concentration of an agent X responsible for the linear chain termination).

Scheme 3

Initiation (zeroth stage)

Chain propagation (first stage)

Chain termination (second stage)

Here I is the initiator; X^* is the stable free radical; M is the monomer; R_i^* , R_iM^* , ..., $R_iM_{n-1}M^*$ are active free radicals and A_n are products of the corresponding reactions.

Analysis of Scheme 3 makes it possible to derive the following expressions for instantaneous rates of formation of any adduct, from A_0 to A_n , during the synthesis.

$$\frac{d[A_0]}{dt} = k_x[X][R_i] = \frac{W_i k_x [X]}{k_{pi}[M] + k_x[X]} = W_i \frac{1}{k_{pi}[M]/k_x[X] + 1}, \quad (1)$$

$$\begin{aligned} \frac{d[A_1]}{dt} &= k_x[X][R^1] = \frac{W_i k_x [X] k_{pi} [M]}{(k_{pi}[M] + k_x[X])(k_p[M] + k_x[X])} = \\ &= \frac{d[A_0]}{dt} \frac{1}{k_p/k_{pi} + k_x[X]/k_{pi}[M]}, \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{d[A_2]}{dt} &= k_x[X][R^2] = \frac{W_i k_x [X] k_{pi} [M] k_p [M]}{(k_{pi}[M] + k_x[X])(k_p[M] + k_x[X])^2} = \\ &= \frac{d[A_1]}{dt} \frac{1}{k_x[X]/k_p[M] + 1}, \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{d[A_n]}{dt} &= k_x[X][R^n] = \frac{W_i k_x [X] k_{pi} [M] (k_p [M])^{n-1}}{(k_{pi}[M] + k_x[X])(k_p[M] + k_x[X])^n} = \\ &= \frac{d[A_1]}{dt} \left(\frac{1}{k_x[X]/k_p[M] + 1} \right)^{n-1}, \end{aligned} \quad (4)$$

where W_i is the rate of initiation and $R^1 = R_iM$, $R^2 = R_iM_2$, ..., $R^n = R_iM_n$.

For any stage of the synthesis, the yield (Y) of each adduct A_n at instant t is calculated by the formula

$$Y = \int_0^t \frac{d[A_n]}{dt} dt, \quad (5)$$

where the form of the function describing the dependence of $d[A_n]/dt$ on t is given by formulae (1)–(4) which take into account the dependences of the concentrations of all reagents on time.

The dependence of $[I]$ on t is described by the familiar integral of the rate of a unimolecular reaction

$$[I]_t = [I]_0 \exp(-k_i t), \quad (6)$$

while the dependence of $[X]$ on t is given by the equation

$$[X]_t = [X]_0 - 2f([I]_0 - [I]_t) = [X]_0 - 2f[I]_0[1 - \exp(-k_i t)], \quad (7)$$

where f is the fraction of free radicals that did not undergo intracage recombination (this quantity is also called the efficiency of initiation, $f \approx 0.5$). From Eqn (7) it follows that the concentration of stable radical X at instant t is equal to the difference between the initial concentration of this radical, $[X]_0$, and the concentration of free radicals generated by the time t as a result of the decomposition of the initiator I.

If the synthesis is carried out under standard conditions (the monomer is taken in a large excess, $[M]_0 \gg [I]_0 \approx [X]_0$), the concentration $[M]$ is constant at any instant. If the synthesis is performed either under specific conditions (without a large excess of M) or in such a way that the adducts R_iM_nX with large n values are obtained, the form of the function $[M]_t$ is determined by the integral of the stationary rate $d[M]/dt$. For long chains ($n > 10$), the following approximation is valid

$$-\frac{d[M]}{dt} \approx \frac{k_p[M]}{k_x[X]} W_i, \quad (8)$$

whence, taking into account expressions (6) and (7), it follows that

$$[M] = [M]_0 \exp\left(-\frac{k_p k_i}{k_x} \psi\right), \quad (9)$$

where

$$\psi = \int_0^t \frac{[I]_t}{[X]_t} dt = \int_0^t \frac{[I]_0 \exp(-k_i t)}{[X]_0 - 2f[I]_0[1 - \exp(-k_i t)]} dt. \quad (10)$$

This calculation procedure makes it possible to predict the results of synthesis and to choose optimum conditions, since the values of all constants (k_i , k_{pi} , k_p and k_x) appearing in Eqns (1)–(10) can be rather accurately estimated from the reported data (see, e.g., Ref. 87). The results of calculations for the styrene–TEMPO–BPO system, obtained for three temperatures, are listed in Table 1.

The reliability of the calculations has been confirmed experimentally. Both the type of the main adduct ($A_1 = R_iMX$) and its content ($[A_1]/100 \sum_n [A_n] > 90\%$) in the overall product $\sum_n A_n$

nearly coincide with the corresponding calculated data. As can be seen from Table 1, the target product A_1 is the main product in the temperature range 348–368 K.

According to calculations, non-peroxide compounds (e.g., azonitriles) are unsuitable for use as initiators since only peroxide radicals R_i with the free valence at the oxygen atom ensure a rather high value of the k_{pi}/k_p ratio (several orders of magnitude). If the values of k_{pi} and k_p are comparable, the adduct R_iX ($n = 0$) is formed as the main product instead of the target R_iM_nX adduct. However, R_iX cannot be used as the agent for ‘living’ polymerisation because its C–ON bond energy is too high.

The results of calculations for the styrene–TEMPO–dicyclohexyl peroxydicarbonate (DCPDC) system⁸⁶ (Table 2) imply that the main adduct is

Dicyclohexyl peroxydicarbonate decomposes into radicals much faster than BPO (for DCPDC, the k_i value is 100 times greater than for BPO). This allows implementation of syntheses at lower temperatures, which is an additional 'insurance' against the risk of possible side reactions due to dissociation of R_iM_nX and ignored in Scheme 3.

According to calculations, there is little point in synthesising the adducts with long polystyrene chain ($n \approx 10$) using a one-step process. In this case, a considerable amount of hard-to-remove contaminating adducts of nearly identical compositions can be formed, even if a very carefully 'adjusted' procedure with optimum 'recipe' is employed. Because of this, long-chain adducts R_iM_nX ($n = 10$) should be synthesised using a two-step procedure which includes (i) the synthesis of R_iMX ($n = 1$) and (ii) a controlled 'living' bulk polymerisation of M (in order to extend the M_n block until desired molecular mass value) at a higher temperature at which the rate of reversible dissociation of R_iMX is high enough. In such a manner, it is possible to extend the polymer chains by about 10 units over a period of 3–4 h at 393 K and to obtain the $R_iM_{10}X$ adducts with a polydispersity index of 1.15 and more (GPC data).

It thus follows that currently the synthesis of alkoxyamines is developed to the extent that it can be performed as a kinetically controlled process with accurate prediction of results.

3. Determination of the rate constant of reversible dissociation of alkoxyamines at the C–ON bond

Reversible dissociation of R_iM_nX (BX), which is the 'heart' of the mechanism of 'living'-chain radical polymerisation, is described by Scheme 4.

Scheme 4

where P is the recombination (or disproportionation) product of radicals $\text{B}^\cdot$ and $k_2 \approx k_t \approx 10^7\text{--}10^8$ litre mol⁻¹ s⁻¹.

Since dissociation of BX is a non-steady-state process, running concentrations of all compounds involved in the process can only be found after solving the system of differential equations (11)–(13).

$$\frac{d[\text{B}]}{dt} = k_1[\text{BX}] - k_t[\text{B}]([\text{B}] + [\text{X}]), \quad (11)$$

$$\frac{d[\text{X}]}{dt} = k_1[\text{BX}] - k_t[\text{B}][\text{X}], \quad (12)$$

$$\frac{d[\text{BX}]}{dt} = -k_1[\text{BX}] + k_t[\text{B}][\text{X}], \quad (13)$$

$$[\text{BX}] = [\text{BX}]_0 - [\text{X}], \quad (14)$$

$$[\text{P}] = [\text{X}] - [\text{B}]. \quad (15)$$

The following analytical solutions of the system of equations (11)–(15) were obtained for a time interval $(k_1 k_t [\text{BX}]_0 / 3)^{-1/2} \ll t \ll (k_t [\text{BX}]_0 / 24 k_1^2)$ which covers almost entirely the range of practically significant t values (from fractions of a second to tens of days)⁸⁸:

$$[\text{X}] = [\text{BX}]_0 \left(\frac{3 k_1^2 t}{k_t [\text{BX}]_0} \right)^{1/3}, \quad (16)$$

$$[\text{B}] = [\text{BX}]_0 \left(\frac{k_1}{3 k_t^2 [\text{BX}]_0^2 t} \right)^{1/3}. \quad (17)$$

From Eqn (16) it follows that if the k_t value is estimated to sufficient accuracy, the value of

$$k_1 = \frac{[\text{X}]^{3/2} k_t^{1/2}}{[\text{BX}]_0 (3t)^{1/2}} \quad (18)$$

can be determined in the experiments on the decomposition of BX in inert media from the ESR measurements of the kinetics of accumulation of radicals $\text{X}^\cdot$. The most reliable k_t estimate is $k_t \approx 10^7\text{--}10^8$ litre mol⁻¹ s⁻¹. From Eqn (15) it follows that the data on the kinetics of accumulation of P can be used instead of the corresponding data for $\text{X}^\cdot$ if time t is rather long and $[\text{X}] \gg [\text{B}]$. This can be done if for any reason it is more convenient to perform experimental measurements of [P].

In most cases, ESR measurements of the kinetics of accumulation of radicals $\text{X}^\cdot$ in order to determine the k_1 value are carried out under conditions of reversible decomposition of alkoxyamines.^{85, 89–91}

Recently,⁹² yet another procedure for the measurement of the k_1 values has been developed. It includes measurements of the

consumption of radical $B^{\bullet}$ in the reaction with benzoquinone (BQ), which is a highly efficient acceptor of radicals $B^{\bullet}$, instead of measuring the consumption of $B^{\bullet}$ in the reaction $B^{\bullet} + X^{\bullet}$. Each BQ molecule entraps two radicals $B^{\bullet}$ with the rate constant $k_x \approx 10^5 \text{ litre mol}^{-1} \text{ s}^{-1}$ (for styryl radical at $T = 333\text{--}353 \text{ K}$). If benzoquinone ($\sim 10^{-2} \text{ mol litre}^{-1}$) is introduced into the system, then, according to Scheme 4, the deactivation rate of radicals $B^{\bullet}$ by BQ will be $W_x = k_x[BQ][B] = 10^3[B]$ while the rate of the reverse transformation of $B^{\bullet}$ into BX will be $W_2 = k_2[X][B] = 10^2[B]$ (according to ESR data, $[X] \approx 10^{-6} \text{ mol litre}^{-1}$ at $k_2 \approx 10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$). Thus, the addition of BQ decreases the rate of the reverse reaction in Scheme 4 by at least an order of magnitude, which is tantamount to nearly complete suppression of this reaction.

Under these conditions, the rate of accumulation of $X^{\bullet}$ as obtained from ESR measurements will be virtually equal to the rate of dissociation of BX. This method for the determination of k_1 eliminates difficulties associated with side reactions ignored by Scheme 4, such as, *e.g.*, disproportionation of BX with the formation of XH and a polymer $P(=)$ with a double bond in the end group. The side reactions transform a paramagnetic species $X^{\bullet}$ into an 'ESR stealth', thus disturbing the results of measurements. The new method⁹² is also more advantageous than that reported by Fischer⁸⁸ because the k_1 constant is determined here without using the k_t value, which can only be determined with an accuracy of an order of magnitude. Therefore, the accuracy of the new method is higher by an order of magnitude.

An original method for measurement of the constant k_1 was suggested.⁹³ Here, the k_1 value is determined separately rather than in combination with the k_t value. This is achieved by performing the measurements in the bulk of the monomer. In this case, owing to the reaction with the monomer, the active dissociation product of the initial alkoxyamine (RM_nX), *viz.*, a hydrocarbon radical $RM_n^{\bullet}$, manages to extend its chain by several monomer units before the next act of conversion into alkoxyamine as a result of the reaction with iminoxyl.

This procedure makes it possible to distinguish between the initial alkoxyamine RM_nX and 'heavy' alkoxyamines $RM_{n+k}X$, $RM_{n+2k}X$, ..., $RM_{n+mk}X$ and allows determination of k_1 from the data on the decrease in the concentration of the initial RM_nX . The reversible character of the dissociation presents no problems to determination of the constant k_1 , since only the first acts of dissociative decomposition of each initial molecule RM_nX are measured experimentally. The next decomposition acts that follow the reversible reduction involve compound $RM_{n+mk}X$ ($m = 1, 2, \dots$) for which no measurements have been performed.

A procedure for separate determination of the concentration of the initial alkoxyamine RM_nX (M is styrene, $n = 1$) in the mixture with 'heavy' alkoxyamines $RM_{n+mk}X$ using gel-permeation chromatography has been developed.⁹³ For $n = 1$, the peak of the initial alkoxyamine on the chromatogram of the mixture can be resolved to an accuracy of 10%–20%, which is correspondingly the accuracy of the determination of k_1 . The k_1 values thus obtained [$k_1 = 2.0 \times 10^{13} \exp(-124200/RT) \text{ s}^{-1}$] should be considered the most reliable. The limitation inherent in this method is due to the fact that it can only be applied to alkoxyamines containing one monomer unit per molecule. For $n > 1$, the resolution of the peak of the initial compound in a mixture of substances containing $n + mk$ monomer units decreases substantially. From this viewpoint, the use of the new method⁹² discussed above (competitive entrapment of active hydrocarbon radicals by benzoquinone) seems to be more convenient for $n > 1$, since it has no limitations as regards the n values for the initial alkoxyamine.

The method for assessing the constant k_1 in combination with k_p and k_t , based on measurement of the k_1k_p/k_t ratio appears to be

the most popular.^{58,89,94–101} This requires plotting the kinetic curve $W_M(t) = -d[M]/dt = k_p[M][R]$ and the curve of accumulation of the iminoxyl radical $[X]_t$. If the equilibrium in a system

is established much faster than any perturbation (*e.g.*, the reaction $R^{\bullet} + R^{\bullet}$) is developed, the function $[X]_t$ can be calculated using the formula $[X]_t = k_1[RX]/k_2[R]$, where the concentrations of RX and $R^{\bullet}$ depend on t . The $[RX]$ value is determined from the relationship $[RX] = [RX]_0 - [X]_t$, where $[RX]_0 \approx 10^{-2} \text{ mol litre}^{-1}$ and $[X]_t \approx 10^{-6}\text{--}10^{-5} \text{ mol litre}^{-1}$. Hence to sufficient accuracy we get $[RX] \approx [RX]_0$.

For a fixed $t = t_f$, the $[R]$ value is determined from the kinetic curve $[R] = W_M(t_f)/k_p[M]$, where $[M]$ is the running concentration at the same instant $t = t_f$. Then, by comparing the $W_M(t)$ and $[X]_t$ curves for the same t we can calculate the ratio

$$\frac{k_1k_p}{k_2} \approx \frac{[X]_t W_M(t)}{[RX]_0[M]}.$$

Reliability of calculations can be checked for independence of the parameter k_1k_p/k_t on the conversion time t . The accuracy of the estimate of the constant k_1 by this method is also obviously dependent on the reliability of the values chosen for k_p and k_t . Usually, the values $k_p = 2 \times 10^3$ (for $T = 393 \text{ K}$)¹⁰² and $k_t = 10^7\text{--}10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$ are used. As a rule, calculations of 'living' polymerisation processes are carried out using the constant k_1 in the form of the ratio $K = k_1/k_2$ (the equilibrium constant), thus it is the equilibrium constant value that is the main goal of quantitative estimates reported in many studies.

Nevertheless, it should be noted that the scatter of k_1 values reported by different authors is extremely wide and, which is most important, the reasons for this phenomenon are unclear. For instance, the rate constant of dissociation of 1-phenyl-1-(2,2,6,6-tetramethylpiperidinyl-1-oxy)ethane (**1**) in deuterated styrene was reported to be $\sim 10^{-3} \text{ s}^{-1}$ at 396 K.¹⁰³ On the other hand, the k_1 value obtained for the dissociation of the same compound at a higher temperature (413 K) was reported¹⁰⁴ to be equal to $\approx 8 \times 10^{-5} \text{ s}^{-1}$ (dissociation in tetrachlorobenzene). Such a wide scatter in the k_1 values can hardly be explained by the solvent effect alone.

In conclusion, let us dwell on the side reaction of irreversible dissociation of alkoxyamines which occurs at high temperatures (above 408–433 K). Apparently, it is this reaction that makes alkoxyamines with increased (as compared to styrene-containing derivatives) strength of the C–ON bond 'inoperative'.

This side reaction was first studied taking a model alkoxyamine **1** as an example.¹⁰⁴

It was concluded that dissociation of this alkoxyamine with the cleavage of the C–ON bond follows two pathways resulting in (i) an active hydrocarbon radical and the TEMPO stable radical and (ii) hydride transfer to give an unsaturated hydrocarbon and hydroxylamine.

The competition between the two types of cleavage of the C–ON bond was studied in detail by high-resolution NMR spectroscopy¹⁰⁵ taking alkoxyamines obtained upon radical decomposition of dibenzoyl peroxide in styrene as examples.

3 (PS-TEMPO with $M_n = 1100$, $M_w/M_n = 1.03$)

Thermal decomposition of alkoxyamines **2** and **3** was performed in perdeuterated toluene in the temperature range 393–433 K. The products obtained during the conversion were analysed by ^1H NMR spectroscopy. This required preliminary assignment of the ^1H NMR spectra of mixtures using the ^1H NMR spectra of model compounds and specially developed auxiliary calibrations. The obtained rate constants (k_{dec}) of irreversible decomposition of alkoxyamines **2** and **3** were $4.7 \times 10^{14} \exp(-157\,000/RT)$ and $5.7 \times 10^{14} \exp(-153\,000/RT) \text{ s}^{-1}$, respectively.

Most probably, the irreversible decomposition reaction competes with reversible dissociation, *i.e.*, the former occurs concurrently rather than sequentially (as the second stage after the dissociation of alkoxyamines into an active hydrocarbon radical and TEMPO). One can calculate the ratio $k_{\text{dec}}/k_1 = P_{\text{dec}} = 29 \exp(-29\,000/RT)$, which characterises the contribution of the side reaction of irreversible decomposition of alkoxyamines as a function of temperature, using the value $k_1 = 2.0 \times 10^{13} \exp(-124\,200/RT) \text{ s}^{-1}$ (Ref. 93). At 433 K, we have $P_{\text{dec}} \approx 10^{-2}$, which means that no more than 1% of the dissociating alkoxyamine molecules undergo irreversible decomposition. At first glance, this is a negligible value. However, taking into account the half-life of alkoxyamine (at this temperature $\tau_{1/2} = 0.69/k_1 \approx 0.5 \text{ min}$), we obtain that the alkoxyamine manages to enter into a reversible dissociation $\rightleftharpoons$ recombination cycle hundreds of times over the time necessary for complete conversion (several hours). Therefore, at first glance small losses of the alkoxyamine due to the irreversible decomposition in each cycle are accumulated and become comparable with its initial concentration (complete deactivation). As temperature decreases (*e.g.*, down to 393 K), the P_{dec} value becomes nearly halved; however, the $\tau_{1/2}$ value increases dramatically (by about a factor of 40) with concomitant sharp decrease in the number of reversible cycles and losses due to deactivation of the alkoxyamine.

4. Kinetics of alkoxyamine-mediated polymerisation of styrene

The kinetics of styrene polymerisation in the presence of alkoxyamines was reported in most detail by Greszta and Matyjaszewski.¹⁰⁶ The main goal of this study was to reveal key features of the process, which make it possible to infer the details of the mechanism of 'living'-chain polymerisation. A short list of the most important characteristics of 'living'-chain styrene polymerisation is presented below.

— The rate of polymerisation is proportional to the concentration of the monomer (*i.e.*, the process is first-order with respect to the monomer) and independent of the concentration of alkoxyamine (a zero order process with respect to alkoxyamine) or of the concentration of a stable nitroxyl radical (as a rule, TEMPO), if the alkoxyamine is synthesised *in situ*.

— The molecular masses of polymers increase linearly with the degree of polymerisation (conversion). This is valid until at least $M_n \approx 20\,000 - 30\,000$.

— The polydispersity of the resulting polymer, which is characterised by the M_w/M_n ratio, decreases usually with conversion and then increases at later stages of the process. The M_w/M_n value varies depending on the reaction conditions, but, as a rule, remains less than 1.3.

— Throughout the polymerisation, the concentration of the stable nitroxyl radical, as determined by ESR spectroscopy, is 0.1%–1.0% from the initial concentration of alkoxyamine (or its precursor, TEMPO) introduced into the reaction system.¹⁰⁷

This makes it possible to draw some conclusions. The fact that the polymerisation rate, W , of the monomer is independent of the

concentrations of alkoxyamine and the stable nitroxyl radical (TEMPO) and coincides with the rate of self-initiated polymerisation of the monomer shows that self-initiation is primarily responsible for maintaining the concentration of active centres $[R]$, which, in turn, controls the polymerisation rate ($W \sim [R]$). Thus, the rate of self-initiation (W_i) (or, generally, any radical initiation) controls the polymerisation rate.

Despite the controlling effect of W_i with respect to W , alkoxyamine used as the agent for 'living' polymerisation controls almost completely the length of growing polymer chains so that they grow throughout the polymerisation process (at least, most of them do not undergo termination). This can only occur if $W_i \ll W_A$ (W_A is the dissociation rate of alkoxyamine, $W_A = k_1[A]$), *i.e.*, if each chain initiation act corresponds to many dissociation $\rightleftharpoons$ recombination acts of alkoxyamine, so that each newly initiated chain manages to be involved repeatedly in this reversible cycle.

The narrowing of molecular mass distribution of the resulting 'living' polymer down to a M_w/M_n value of 1.3 (*cf.* $M_w/M_n = 1.5 - 2.0$ for conventional radical polymerisation) also suggests the 'living' character of polymer chains. On the other hand, the increase in the M_w/M_n ratio at later stages of polymerisation indicates some side reactions.

The fact that the relative concentration of a stable nitroxyl radical $X^{\bullet}$ is low ($[X]/[A] = 10^{-2} - 10^{-3}$) and changes only slightly during the time necessary for nearly complete conversion of the monomer indicates that the equilibrium constant $K = k_1/k_2$ of the following process is very low.

This equilibrium is shifted rather slowly under the action of disturbing factors (first of all, quadratic chain termination, $R^{\bullet} + R^{\bullet}$) which are developed during the polymerisation; hence, it may be always thought that $k_1[A] \approx k_2[R][X]$, where $[A] \approx [A]_0$. If K can be measured independently, then, using this value, one can assess the concentration of active centres $[R]$ over a period necessary for nearly complete conversion. For instance, the equilibrium constant of alkoxyamine-mediated 'living' polymerisation performed under standard conditions ($T = 393 \text{ K}$) is $10^{-11} \text{ mol litre}^{-1}$,¹⁰⁶ hence $[R] = k_1[A]/k_2[X] = 10^{-9} - 10^{-8} \text{ mol litre}^{-1}$. Usually, the concentration of alkoxyamine is $10^{-2} \text{ mol litre}^{-1}$ and that of the nitroxyl radical is $10^{-5} - 10^{-4} \text{ mol litre}^{-1}$. Therefore, the polymerisation process proceeds almost entirely at $[X] \gg [R]$, which provides a complete control of the reversible dissociation $\rightleftharpoons$ recombination cycle over the chain propagation, since quadratic chain termination makes a negligible contribution in this case. Actually, in the presence of dissociating alkoxyamine each growing chain undergoes either a linear termination following the mechanism

(a fictitious, temporarily termination, since the adduct A can dissociate, thus retaining the 'livingness' of the chain) or a quadratic termination following the pathway

The contribution of the latter process determines the extent to which the alkoxyamine-mediated chain propagation can be not in control. Quantitatively, the contributions of linear and quadratic termination are characterised by the probabilities α_1 and α_2 .

$$\alpha_1 = \frac{k_2[R][X]}{k_2[R][X] + k_t[R]^2},$$

$$\alpha_2 = \frac{k_t[R]^2}{k_2[R][X] + k_t[R]^2}.$$

Thus, taking into account that $[X] \gg [R]$ and $k_2 \approx k_t$, we get $\alpha_1 \approx 1$ and $\alpha_2 \ll 1$.

5. Kinetics of alkoxyamine-mediated 'living' radical polymerisation

Initially, the kinetic analysis of a polymerisation process proceeding in the presence of alkoxyamines (as well as other reversible inhibitors, iniferters and other agents) was performed in the framework of rather rough approximations which oversimplified the situation under consideration. Most concisely, the mechanism of this polymerisation process is described by Scheme 1. This scheme should only be augmented with a new stage to describe the generation of active radicals upon decomposition of initiators I (organic peroxides, hydroperoxides, azonitriles, *etc.*) with the initiation rate $W_i = k_i[I]$ (Scheme 5).

For a self-initiated polymerisation of the monomer, $W_i = k_{im}[M]^n$, where n can take any value depending on the specific generation mechanism of $\text{R}^\bullet$. For styrene, this mechanism involves the reactions^{108, 109}

which proceed at 393 K with the rate constants $k_d = 3 \times 10^{-8}$ (see Refs 110 and 111) and $k_i' = 5 \times 10^{-8} \text{ litre mol}^{-1} \text{ s}^{-1}$ (see Refs 106 and 112). The n value lies between 2 and 3.

Reversible inhibition steps are the key stages of the reactions. Competitive entrapment of radical $\text{R}^\bullet$ by a stable free radical $\text{X}^\bullet$ prevents the growing chains $\text{R}^\bullet$ from being terminated quadratically. During the time interval between acts of chain initiation (or regeneration) the radicals $\text{R}^\bullet$ manage to react with the monomer, thus extending the polymer chain.

It is an easy matter to perform the kinetic analysis of such a polymerisation scheme (Scheme 5). In the steady-state approximation, the polymerisation rate W is calculated as follows

$$W = k_p[M] \left(\frac{W_i}{k_t} \right)^{1/2} \quad (19)$$

This expression for W is the same as that used to describe a conventional radical polymerisation without reversible inhibition. This result is obvious. Indeed in the steady state the reversible inhibition reactions responsible for 'living' polymerisation make no contribution to the stationary concentration of growing polymer chains $[\text{R}]_s$ (and, correspondingly, to the W value), since all radicals $\text{R}^\bullet$ and $\text{X}^\bullet$ generated in the stage $\text{RX} \rightarrow \text{R}^\bullet + \text{X}^\bullet$ leave the reaction system by the stage $\text{R}^\bullet + \text{X}^\bullet \rightarrow \text{RX}$. Therefore, if the time necessary for establishment of a steady state in the polymerisation system (τ_s) is much shorter than that necessary for complete conversion (t), the alkoxyamine present in the system has no effect on the polymerisation kinetics from the moment

$\tau_s \ll t$ onwards, *i.e.*, nearly from the beginning of the polymerisation process.

However, the chain propagation regime in the presence of alkoxyamine differs fundamentally from that in conventional radical polymerisation. Actually, in the latter case the average integrated chain length (v) at instant t is given by the following expression

$$v = \frac{\int_0^t W dt}{\int_0^t W_i dt} \quad (20)$$

where $\int_0^t W dt$ is the total number of monomer units in the chains and $\int_0^t W_i dt$ is the total number of the initiated chains. In a

particular case, for $W \simeq \text{const}$ and $W_i \simeq \text{const}$, we get $v \simeq W/W_i \simeq \text{const}$. On the other hand, for 'living' polymerisation the average integrated chain length (v_x) at instant t will be determined by the total number of 'dead' and 'living' chains accumulated by the instant t

$$v_x = \frac{\int_0^t W dt}{\int_0^t W_i dt + [\text{RX}]_t} \quad (21)$$

where $[\text{RX}]_t$ is the stationary (quasi-stationary) concentration of alkoxyamine at instant t , which in turn is equal to the concentration of 'living' chains.

'Living'-chain polymerisation proceeds if $\int_0^t W_i dt \ll [\text{RX}]_t$. In this case, the v_x value is calculated by the formula

$$v_x \simeq \frac{\int_0^t W dt}{[\text{RX}]_t} \simeq \frac{\Gamma}{[\text{RX}]_t} \quad (22)$$

Here, $[\text{RX}]_t \simeq \text{const}$; if an iminoxyl is used as alkoxyamine, then $k_1/k_2 \ll 1$ and $[\text{RX}]_t \simeq [\text{RX}]_0$. Unlike conventional radical polymerisation in which the chain length remains virtually unchanged throughout the process [Eqn (20)], 'living' polymerisation in the presence of alkoxyamine is characterised by linear increase in v_x with the degree of conversion Γ [Eqn (22)] provided that the overall concentration of chains generated by the initiator throughout the polymerisation process is much lower than the equilibrium (initial) concentration of the additive RX .

These are the results of the simplest and obvious analysis of the steady-state 'living'-chain polymerisation process described by Scheme 5. It should be noted that in the absence of additional initiation the system cannot reach the steady state and the analysis is complicated.

Theoretical studies on the mechanism of 'living' radical polymerisation can be divided into two groups.

1. Early studies^{5, 113} aimed at revealing salient features of the mechanism responsible for the transformation of usual radical polymerisation into 'living' polymerisation.

2. More recent studies^{88, 106, 114–118} on the kinetic analysis of the polymerisation mechanism and molecular mass distributions of polymeric products formed in the system carried out with the use of supercomputers and sophisticated mathematical procedures. Obviously, the mechanism presented in Scheme 5 is unsuitable for analysing the molecular mass distributions (MMD). To this end, Scheme 5 should be augmented with equations for chains of different length containing v ($v = 1, 2, \dots$) monomer units instead of the equations for a growing chain of an infinite length, while the chain propagation reaction should be written as a sequence of v stages. Reversible inhibition and quadratic termination reactions should also be divided into a variety of identical

stages in which reagents R of different chain length are involved. The chain length effect of the reagent R on the rate constants can be ignored by assuming that they are the same for identical reactions. However, the number of differential equations to be integrated numerically increases by two orders of magnitude and more (instead of 5 equations shown in Scheme 5) even if the analysis is restricted to not very long chains. Calculations of MMD for the chains up to 500 monomer units long ($v = 500$) have been reported,¹¹⁵ as well as some artificial simplifying procedures (introduction of special subsystems and 'closure reactions').¹¹³

Let us consider the results obtained in three theoretical studies^{88, 106, 114} in which the results of calculations were compared in detail with the latest experimental results.

Computer simulation¹⁰⁶ of a process described by Scheme 5 for M = styrene and X = TEMPO was performed using the PREDICI programme package.^{119–121} The numerical values of the rate constants and concentrations of reagents (for 393 K) are listed below.

Parameter	Numerical value	Ref.
Rate constants of reactions/litre mol ⁻¹ s ⁻¹		
k_p	2000	102, 122
k_d	3×10^{-8}	110, 111
k'_i	5×10^{-8}	112
k_t	10^7	123, 124
Concentration/mol litre ⁻¹		
[M]	10	106
[RX]	10^{-2}	106

Unlike the values of rate constants k_p , k_d , k'_i and k_t , the values of k_1 , k_2 and some other rate constants were attenuated in the course of computer simulation because of a wide scatter of the data reported in different publications.

According to calculations,¹⁰⁶ Scheme 5 adequately describes all experimentally observed characteristic features of the process (see previous Section) assuming that $K = k_1/k_2 \leq 10^{-10}$ mol litre⁻¹. Based on detailed quantitative comparison of calculated and experimental dependences of the polydispersity index, M_w/M_n , on the degree of polymerisation, the values of the constants k_1 and k_2 were refined to be $K \simeq 10^{-11}$ mol litre⁻¹; $k_1 = 8 \times 10^{-4}$ s⁻¹ and $k_2 = 8 \times 10^7$ litre mol⁻¹ s⁻¹. This also made it possible to augment Scheme 5 with new stages necessary for improving the agreement between calculated and experimental data.

Here, P(=) is the polymer with a double bond in the end group, XH is hydroxylamine, $k_{t,D} = 50$ litre mol⁻¹ s⁻¹ is the rate constant of chain transfer to dimer D formed in the self-polymerisation of the monomer (see above), k_{dec} is the rate constant of dissociation reaction accompanied by hydride transfer and $k_{dec} \simeq 10^{-5}$ s⁻¹ (see Ref. 104).

These calculations have also confirmed that the reactions shown in Scheme 5 satisfy the principle of stationary concentrations. Using the above-mentioned values of rate constants, concentrations and temperature, the steady state is reached at a degree of polymerisation of less than 1%, i.e., nearly from the beginning of the polymerisation process. The calculated stationary concentrations of growing chains [R] and stable iminoxyl radical [X] were found to be 10^{-8} and 10^{-5} mol litre⁻¹, respectively.

Similar results have also been obtained¹¹⁴ for the same styrene–TEMPO reaction system using another type of computational procedure (the Monte Carlo stochastic algorithm^{125–128}). This makes it possible to perform calculations without recourse to supercomputers. The results of calculations for $T = 393$ K were supplemented with those obtained for $T = 363$ K¹¹⁴ which were then compared with the experimental results obtained at the same

temperature.⁷⁸ The parameters listed below provided the best fit between the calculated and experimental data.

Parameter	Numerical value
Concentration/mol litre ⁻¹	
[M]	8.75
[RX]	$3.7 \times 10^{-3} - 4.4 \times 10^{-2}$
Rate constants of reactions	
k_1/s^{-1}	2.5×10^{-3}
$k_2/\text{litre mol}^{-1} s^{-1}$	2.5×10^8
$k_p/\text{litre mol}^{-1} s^{-1}$	950
$k_t/\text{litre mol}^{-1} s^{-1}$	10^7
$k_d/\text{litre mol}^{-1} s^{-1}$	1.5×10^{-9}
$k'_i/\text{litre mol}^{-1} s^{-1}$	4.5×10^{-9}
k_{dec}/s^{-1}	8×10^{-6}

The polydispersity indices, M_w/M_n , obtained analytically^{90, 129} and found from simulation have also been compared.¹¹⁴

The M_w/M_n ratio was calculated using the formula

$$\frac{M_w}{M_n} = \frac{1}{\gamma x} + \frac{1}{x} \left[2 + \frac{(\beta - 1)(2 - x)}{\alpha - \beta} \right] - \frac{2\alpha(1 - \alpha)}{(\beta^2 - \alpha^2)x^2} \left[1 - (1 - x)^{\frac{1+\beta}{\alpha}} \right], \quad (23)$$

where x is the degree of monomer conversion, $\gamma = [M]_0/[RX]$, $\alpha = [R]/[RX]$ and $\beta = k_2[X]/k_p[RX]$. It was found that the results of computer simulation fit well the theoretical curve.

Fischer⁸⁸ reported the most detailed computer simulation. He analysed two types of 'living'-chain polymerisation, without additional initiation (Scheme 1) and with varied intensity of initiation in order to establish the range of the effect of the initiation on polydispersity M_w/M_n (Scheme 5). Different versions of syntheses of the adducts RX were also considered, including the synthesis *in situ* and those with different dynamics of reversibility (this was achieved by varying the constants k_1 and k_2 over a wide range).

The first case (see Scheme 1) corresponds to a non-steady-state process. For very short times, $t \ll [k_1^2(k_t[RX]_0/k_1 - 1)]^{-1/2} \simeq (k_1 k_t [RX]_0)^{-1/2}$, the following relation is valid

$$[R] = [X] = k_1[RX]_0 t. \quad (24)$$

For the time interval $(k_1 k_t [RX]_0/3)^{-1/2} \ll t \ll k_t [RX]_0/24k_1^2$, which covers almost entirely the range of practically significant t values, one obtains

$$[R] = [RX]_0 \left[\frac{k_1}{3(k_t[RX]_0)^2 t} \right]^{1/3},$$

$$[X] = [RX]_0 \left(\frac{3k_1^2 t}{k_t[RX]_0} \right)^{1/3},$$

$$[RX] = [RX]_0 - [X] \simeq [RX]_0,$$

$$[P] = [X] - [R] \simeq [X], \quad (25)$$

$$[M] = [M]_0 \exp \left\{ -\frac{3}{2} k_p [RX]_0 \left[\frac{k_1 t^2}{3(k_t[RX]_0)^2} \right]^{1/3} \right\}.$$

For very long times, $t \gg 2k_t[RX]_0/k_1^2$, the concentrations vary as follows:

$$[R] = \frac{[RX]_0}{k_1 t},$$

$$[X] = [RX]_0 \left(1 - \frac{k_t [RX]_0}{k_1^2 t} \right) \simeq [RX]_0, \quad (26)$$

$$[RX] = \frac{[RX]_0^2 k_t}{k_1^2 t},$$

$$[P] = [X] - [R] \simeq [X] \simeq [RX]_0.$$

Expressions (24)–(26) were derived assuming equal values of the constants k_2 and k_t in Scheme 1 ($k_2 \equiv k_t$). Successful applicability of relationships (25) throughout the polymerisation process (from $t_0 \approx 10^2$ to $t_f \approx 10^4$ s),[¶] for a conventional $[\text{RX}]_0$ value of about 10^{-2} mol litre⁻¹ requires that the condition $k_1 \ll 2 \text{ s}^{-1}$ (or 0.7 s^{-1}), depending on the choice of k_t value, 10^8 or 10^7 litre mol⁻¹ s⁻¹, be met. Since the k_1 values for alkoxyamines used in 'living' polymerisation do not exceed 10^{-2} s^{-1} at the operating temperatures, the conditions for the upper (t_f) and lower (t_0) bounds of the time interval are always met.

Using analytical expressions (24)–(26), one can assess the time taken to reach the maximum concentration of growing polymer chains $[\text{R}]_{\text{max}}$. We have $t_{\text{max}} = (2k_1k_t[\text{RX}]_0)^{-1/2} \approx 0.02 \text{ s}$ for $k_1 = 10^{-2} \text{ s}^{-1}$, $k_t = 10^7$ litre mol⁻¹ s⁻¹ and $[\text{RX}]_0 = 10^{-2}$ mol litre⁻¹. Substituting this value into Eqn (24) gives $[\text{R}]_{\text{max}} \approx 2 \times 10^{-6}$ mol litre⁻¹.

No practical implementation of the polymerisation mechanism described by Scheme 1 has been reported so far. This is due to self-initiation observed for those monomers which can undergo alkoxyamine-mediated 'living' polymerisation, such as styrene and several its derivatives, or mixtures of styrene with other monomers. Therefore it is reasonable to use the analytical solution of Eqns (24)–(26) for establishing the mechanism of the action of alkoxyamines (as well as any other agents which can reversibly accept growing polymer chains) as agents for 'living' polymerisation.

In particular, it seems to be very convenient to use expression (25) for the determination of the constant k_1 (in combination with k_t) of alkoxyamines from the data on the kinetics of the accumulation of X, which can be obtained from ESR measurements. Obviously, the corresponding experiments should be carried out using such solvents in which no self-initiation is developed in the temperature range chosen (the use of styrene and its derivatives is of course impermissible). For inert solvents, the absence of chain propagation step is of no significance since it is not considered in deriving Eqn (25).

For Scheme 1, analysis of MMD leads to the following interesting results. The contribution of quadratic chain termination ($\text{R}^* + \text{R}^* \rightarrow \text{P}$), which produces 'dead' chains and broadens the MMD, can be reduced to the extent that the value M_w/M_n will approach unity to the second decimal place. The conditions for minimisation are governed by the constant k_1 . Assuming that the k_1 value for $[\text{RX}] = 10^{-2}$ mol litre⁻¹ varies between 3×10^{-3} and $3 \times 10^{-2} \text{ s}^{-1}$ and taking $k_p = 2000$ litre mol⁻¹ s⁻¹, $k_t = 2.5 \times 10^{-8}$ litre mol⁻¹ s⁻¹ and $[\text{M}] = 10$ mol litre⁻¹, we find that the ratio M_w/M_n lies in the range 1.01–1.03. As k_1 increases by one and two orders of magnitude, the polydispersity, M_w/M_n , increases to 1.107 (for $k_1 = 3 \times 10^{-1} \text{ s}^{-1}$) and 1.412 (for $k_1 = 3 \text{ s}^{-1}$), respectively. However, it should be noted that no k_1 values meeting the condition $k_1 \geq 10^{-1} \text{ s}^{-1}$ have been reported for alkoxyamines, so they seem to be unrealistic.

Varying the $[\text{RX}]$ value at a given k_1 ($k_1 = 10^{-2} \text{ s}^{-1}$) has virtually no effect on the polydispersity, that is, the M_w/M_n ratio decreases by about 0.01 as $[\text{RX}]$ increases by a factor of 30 (from 3×10^{-3} to 10^{-1} mol litre⁻¹).

All the above-mentioned values of the ratio M_w/M_n were obtained for 90% conversion (Γ). The dependence of the polydispersity index, M_w/M_n , on Γ is determined by the numerical values of k_1 and $[\text{RX}]$. For small k_1 and high $[\text{RX}]$, the polydispersity is high in the early stages of polymerisation and then it decreases as Γ increases. For instance, calculations with $k_1 = 10^{-2} \text{ s}^{-1}$ and $[\text{RX}] = 10^{-1}$ mol litre⁻¹ show that the M_w/M_n ratio varies from 1.308 for $\Gamma = 5\%$ to 1.026 for $\Gamma = 50\%$ and reaches 1.017 for $\Gamma = 90\%$. On the contrary, for large k_1 the polydispersity increases as Γ increases. According to calculations with $k_1 = 3 \text{ s}^{-1}$ and $[\text{RX}] = 10^{-2}$ mol litre⁻¹, the

M_w/M_n ratio is 1.079, 1.256 and 1.412 for $\Gamma = 5\%$, 50% and 90%, respectively.

The results of calculations make it possible to predict the efficiency of the use of adducts RX as agents for 'living' polymerisation. Actually, the early stages of the polymerisation process (at times t not too long compared with t_{max}) are characterised by comparable concentrations of growing polymer chains R^* and scavengers X^* (both of them are products of dissociation of the adducts RX) and by a large contribution of 'dead' polymer (the product of quadratic chain termination). Correspondingly, the polydispersity is also high ($M_w/M_n \rightarrow 1.5\text{--}2.0$). As $[\text{R}]$ decreases and $[\text{X}]$ increases, both the contribution of 'dead' polymer and the polydispersity decrease. The rate of the decrease is governed by the constant k_1 since both the decrease in $[\text{R}]$ and the corresponding increase in $[\text{X}]$ are due to the irreversible consumption of radicals R^* in the reaction of quadratic chain termination $\text{R}^* + \text{R}^* \rightarrow \text{P}$, which is responsible for the shift of the dissociation equilibrium toward the formation of X. Therefore, an increase in the number of dissociation $\rightleftharpoons$ recombination cycles per unit time (*i.e.*, an increase in the k_1 constant) leads to accelerated accumulation of X (and to a decrease in $[\text{R}]$). In turn, a decrease in $[\text{R}]$ and an increase in $[\text{X}]$ lead to a decrease in the amount of 'dead' polymer produced in the reaction $\text{R}^* + \text{R}^* \rightarrow \text{P}$ and to an increase in the fraction of the polymer produced by 'living' polymerisation, $\text{R}^* + \text{X}^* \rightarrow \text{PX}$. Correspondingly, the polydispersity will decrease from values corresponding to large contributions of 'dead' polymer (1.5–2.0) to those typical of 'living'-chain polymerisation (~ 1.0).

However, in parallel with the positive effect (shortening of the time interval necessary for passage from the early stages of the process with large contribution of 'dead' polymer to the stage in which this contribution is small) there is also a negative effect of high k_1 values. For large constants k_1 , the contribution of 'dead' polymer increases since the reaction of permanent chain termination, $\text{R}^* + \text{R}^* \rightarrow \text{P}$, is of higher order with respect to $[\text{R}]$ than the reaction of temporary chain termination, $\text{R}^* + \text{X}^* \rightarrow \text{PX}$. In addition, for too high k_1 values, the polydispersity will increase with increase in the degree of polymerisation. Therefore it is necessary to find an optimum k_1 value. The limits for the optimum range of k_1 values can be evaluated using the results obtained by Fischer.⁸⁸

The results of calculations for a polymerisation process described by Scheme 5 which includes an additional initiation stage have also been reported.⁸⁸ Both self-initiation (for styrene, this is a termolecular initiation with the rate constant $k_s = 2 \times 10^{-10}$) and initiation using a conventional radical initiator (a unimolecular initiation with the rate constant $k_i = 5 \times 10^{-3} \text{ s}^{-1}$, the initiator concentration $[\text{I}] = 4 \times 10^{-2}$ mol litre⁻¹) were considered. These results were obtained by computer simulation rather than using analytical methods.

The numerical estimate of the time t_s necessary for establishment of the steady state in the reaction system is one of the most important results reported by Fischer.⁸⁸ Unlike conventional radical polymerisation with $t_s < 1 \text{ s}$, in the presence of RX the t_s value increases substantially and reaches 10^2 to 10^4 s depending on the ratio between the initiation rate of chain propagation reaction and the dissociation rate of RX. This numerical estimate shows that under certain conditions the steady-state approximation can actually be used to analyse Scheme 5.

Of great importance is also the establishment of the fact that the polymerisation rate and the polydispersity of the resulting polymer depend on the initiation rate in a different manner. As the initiation rate W_i increases, under certain conditions the polymerisation rate W increases faster than the polydispersity index M_w/M_n . Because of this, the polymerisation can be accelerated substantially with virtually no increase in the M_w/M_n ratio. Calculations for styrene ($T = 393 \text{ K}$, $k_p = 2000$, $k_t = 2.5 \times 10^8$ litre mol⁻¹ s⁻¹) with $[\text{RX}] = 10^{-2}$ mol litre⁻¹ ($k_1 = 10^{-2} \text{ s}^{-1}$) show that without initiation ($W_i = 0$) the time necessary for 90% conversion is 165 h and the M_w/M_n ratio equals 1.017. For the initiation rate $W_i = 2 \times 10^{-4}$ mol litre⁻¹ s⁻¹,

[¶] In this case, the upper (t_f) and lower (t_0) bounds for the time interval meet the conditions $t_f \ll k_t[\text{RX}]_0/24k_1^2$ and $t_0 \gg (k_1k_t[\text{RX}]_0/3)^{-1/2}$, respectively.

the average polymerisation rate is nearly doubled so that a 90% conversion is reached after 81 h, the polydispersity of the polymer being very low ($M_w/M_n = 1.04$).

Summing up the results of theoretical studies,^{88, 106, 114} one can draw the following conclusions.

'Living' radical polymerisation in the presence of alkoxyamines (either supplied 'as is' from an external source or synthesised *in situ*) follows the mechanism shown in Scheme 1 with no additional initiation. The initiation is due to reversible dissociation ($RX \rightleftharpoons R^\bullet + X^\bullet$) only. Here, we are concerned with the transformation of a usual radical polymerisation into 'living' polymerisation owing to conversion of a short-lived chain carrier R ($\tau < 1 \text{ s} \ll t$, where t is the time necessary for complete conversion) into a long-lived one ($\tau > t \approx 10^4 \text{ s}$).

The process which includes only the stages shown in Scheme 1 is an 'ideal' process as regards the polydispersity of the resulting polymer. That is, at particular $K = k_1/k_2$ values characteristic of the known alkoxyamines and constants k_p and k_t typical of the known monomers there is a temperature range suitable for performing a polymerisation to yield a virtually 'monodisperse' product ($M_w/M_n = 1.0$). However, this mechanism is impracticable.

The real mechanism is described by Scheme 5. This is characterised by a higher polymerisation rate as compared to the rate of the process described by Scheme 1. If the rates of the initiation reactions, $I \rightarrow R^\bullet$ and $RX \rightarrow R^\bullet + X^\bullet$, lie within particular limits, the polymerisation process leads to nearly the same 'monodisperse' product ($M_w/M_n = 1.0$) as that obtained in the 'ideal' case (see Scheme 1).

Comparison of calculated and experimental results shows that the mechanism presented in Scheme 5 adequately describes all experimentally observed characteristic features of 'living'-chain radical polymerisation (see previous Section), except for specific details of the evolution of the polydispersity (M_w/M_n) at deep stages of polymerisation. Rigorous quantitative description of these details was performed in the framework of a sophisticated mechanism augmented with side disproportionation reactions (see above).

Comparison of calculated and experimental results was also used for the evaluation of the numerical values of the reported (or measured independently) rate constants k_i , k_1 , k_2 , k_p , k_t , k_{tD} and k_{dec} for the styrene-TEMPO reaction system. If the difference between the known K values exceeded an order of magnitude, their values were corrected and the most plausible K were used.

Thus, the results of thorough quantitative studies^{88, 106, 114} of the polymerisation processes proceeding in the presence of alkoxyamines or other compounds possessing similar properties can serve as a theoretical basis for designing various 'living' polymerisation processes because these have made it possible to find correlations between the reaction parameters (temperature and the concentrations of reagents) and the properties of agents for 'living' polymerisation (the values of the constants k_1 and k_2 at a given temperature). On the other hand, these results can be used for choosing optimum reaction conditions for conducting a polymerisation process in the styrene-TEMPO reaction system instead of performing labour-consuming experiments on 'adjusting' technological details of the process.

Very recently, ESR studies of the mechanism of 'living' polymerisation of styrene in the presence of alkoxyamines (a styrene-dibenzoyl peroxide-TEMPO system with alkoxyamine synthesised *in situ*) revealed^{99, 100} the appearance of a doublet ESR spectrum of a system under study at medium degrees of conversion instead of the conventional singlet ESR spectrum of TEMPO. The additional component was attributed to an iminoxyl of unknown nature (we will denote it as $X^\bullet$). The same phenomenon was also observed^{85, 130, 131} in studies of the polymerisation of styrene in the presence of alkoxyamine preliminarily synthesised from styrene and TEMPO.

The ESR spectrum of the 'additional' iminoxyl $X^\bullet$ is characterised by broader lines and a smaller hyperfine coupling constant $a_N = 13.6 \text{ G}$, whereas for 'normal' TEMPO $a_N = 15.6 \text{ G}$. This

substantial change in the parameters of the ESR spectrum indicates essential changes in the nature of the substituents at the 'O-N group. Appreciable decrease in a_N accompanied by broadening of spectral lines could, *e.g.*, be observed if $X^\bullet$ contains the phenyl substituent [then the a_N value should lie between 12.1 and 13.5 G (see Ref. 132)]. This is also indicated by the fact that the 'additional' iminoxyl $X^\bullet$ is observed only if styrene is used as monomer. Neither the chemical mechanism of the formation of $X^\bullet$ nor the role it plays in the polymerisation process have been established so far. Probably, $X^\bullet$ is not involved in the reversible dissociation $\rightleftharpoons$ recombination cycle and the accumulation of $X^\bullet$ merely increases⁸⁵ the overall concentration of iminoxyls. However, it is even more probable that $X^\bullet$ does participate in the reactions of the reversible cycle and forms an adduct $RX^\bullet$ which is characterised by higher equilibrium constant $K' = k'_1/k'_2$ than that of RX adduct.

Finally, experimental results obtained by Boutevin and Bertin¹³³ differ substantially from the calculated data obtained using the extended Scheme 5. The reasons for such discrepancies have also been discussed.¹³³

6. Extension of the area of application of alkoxyamines. Copolymerisation of styrene and its derivatives with other monomers

Alkoxyamines appeared to be efficient agents for 'living' radical polymerisation only of such monomers as styrene and its derivatives (4-hydroxy-, 4-acetoxystyrenes,⁶⁹ 4-bromostyrene,⁷⁰ 3- and 4-chloromethylstyrene,⁷¹ 4-ethyl-4'-vinylbiphenyl, 1,4-divinylbenzene,⁷⁴ *etc.*). Numerous attempts^{61, 73-78} to perform 'living' polymerisations of other monomers (acrylates, methacrylates, vinyl acetate, *etc.*) in the presence of alkoxyamines either failed or were of little value, resulting in low yields and very low molecular masses of polymers. Synthesis of polyacrylates based on *n*-butyl acrylate and other monomers at 428 K in the presence of hydroxy-substituted TEMPO (4-HO-TEMPO) was the most successful, the polymers were obtained with $M_n = 10\,500 - 27\,000$ and $M_w/M_n \geq 1.53$.⁷³

The most plausible reason for unsuccessful polymerisations is that, unlike styrene and its derivatives, the molecules of the above-mentioned monomers have no phenyl substituent which affects the strength of the C-ON bond in RX subject to reversible dissociation (see Section IV). The aromatic ring is known⁸⁴ to be responsible for the redistribution of the electron density in the vicinity of the nearest covalent bond in such a manner that this bond is weakened and the corresponding binding energy decreases by several tens of kJ. However, the C-ON bond in alkoxyamines RX based on (meth)acrylates and related monomers is too strong. Because of this, the attainment of a dissociation rate of this bond suitable for performing a 'living' polymerisation requires elevated temperatures. This may change the dissociation mechanism from a reversible process with the formation of $R^\bullet$ and $X^\bullet$ to irreversible transformation of RX into $R(=)$ and hydroxylamine, XH . Possibly, this is the reason why polymerisations of acrylates at elevated temperature (428 K instead of 383-403 K for styrene) were, in general, unsuccessful.⁷⁵

The ability of (meth)acrylates and related monomers to undergo 'living' polymerisation following the mechanism shown in Scheme 5, *i.e.*, by extending the polymer chains $R^\bullet$ at the instant of their release from adducts RX ($R^\bullet + M \rightarrow RM^\bullet$) is beyond question. This is supported by, *e.g.*, the possibility of producing block copolymers of styrene with (meth)acrylates by two-step polymerisation.⁷⁸ The first stage of the process is 'living' polymerisation of styrene in the presence of alkoxyamine until complete consumption of the monomer to give poly(styryloxyamine) RX (the polystyrene chains R capped with the end group X). The second stage is copolymerisation of poly(styryloxyamine) with a new monomer, *viz.*, (meth)acrylate. This stage is performed at the same or higher temperature. As a result, one obtains not only polystyrene, but also a rather large amount of poly[styrene-*b*-(meth)acrylate] block copolymer, which indicates that the second

stage of the synthesis proceeds at least in part as a 'living' polymerisation. The addition of a mixture of (meth)acrylate with styrene instead of neat (meth)acrylate in the second stage increases the yield of the block copolymer, which reaches $\sim 100\%$ at high styrene content in the mixture. In this case, the second block of the block copolymer is a poly[styrene-*co*-(meth)acrylate] random (statistical) copolymer.^{60, 89–91, 95, 134–140}

The effect of styrene additives to (meth)acrylates introduced in order to improve the efficiency of alkoxyamines as agents for 'living' polymerisation has been studied in detail.^{78, 79, 85} It was found that a nearly 'living' polymerisation can be implemented at a sufficiently high content of styrene in the mixture. In particular, it was shown⁷⁹ that the double bonds of methacrylates are involved in 'living' polymerisation controlled by alkoxyamines if the content of styrene was 50 mol.% and more. This result is nontrivial and not obvious. Actually, consideration of reversible dissociation $\rightleftharpoons$ recombination, $RX \rightleftharpoons R^{\cdot} + X^{\cdot}$, as a process which proceeds with involvement of only those polymer chains which bear the styrene unit as the end group at the instant of recombination, $R^{\cdot} + X^{\cdot}$, suggests very fast extinguishment of 'living' polymerisation. This is associated with the fact that both copolymerisation constants, r_1 and r_2 , for the methacrylate–styrene system are less than unity ($r_1 \simeq 0.45$ and $r_2 \simeq 0.55$).¹⁴¹ Close values of r_1 and r_2 result in distinct alternation of the styrene and methacrylate units, so they have nearly equal probabilities of being the end group at the instant of recombination. If the assumption that the aromatic substituent affects the strength of the C–ON bond in RX subject to dissociation (henceforth, R_M and R_S denote the chain with the methacrylate and styrene end group, respectively) is valid, nearly half of the polymer chains will return to the initial state RX in the form of inactive adducts R_MX after each dissociation $\rightleftharpoons$ recombination cycle, thus resulting in fast extinguishment of 'living' polymerisation.

The time τ_d taken for complete deactivation ($R_SX \rightarrow R_MX$) of alkoxyamine R_SX introduced into the methacrylate–styrene mixture can be assessed from the repetition frequency of dissociation $\rightleftharpoons$ recombination cycles determined by the value of the constant k_1 . For $k_1 = 10^{-3} - 10^{-2} \text{ s}^{-1}$, we get $\tau_d \leq t \simeq 10^4 \text{ s}$, where t is the time necessary for complete conversion. Actually, during the time interval nearly equal to three half-lives of R_SX ($\tau = 3 \times 0.69/k_1 = 2 \times 10^2 - 2 \times 10^3 \text{ s}$), almost all molecules of the initial adduct R_SX are, on the average, involved in the dissociation act and nearly half of them are deactivated in the form of R_MX . When this cycle is repeated many times, the concentration of R_SX will decrease by a factor of 2^n (n is the number of cycles) compared to the initial value, $[R_SX]_0$. For instance, for $n = 3$ the $[R_SX]$ value will decrease by a factor of 8, which is adequate for nearly complete deactivation of alkoxyamine as agent for 'living' polymerisation. Then, $\tau_d \simeq 3\tau = 6 \times 10^2 - 6 \times 10^3 \text{ s}$, which means that deactivation occurs far before complete polymerisation.

This suggests that if complete conversion t takes $\simeq 10^4 \text{ s}$, then copolymerisations of methacrylates with styrene in the presence of alkoxyamines at monomer ratios close to equimolar ones will proceed as 'living' polymerisations only in the initial stages of the processes. Then, the polymerisation process either undergoes transformation into conventional radical polymerisation (if the initiation rate, W_i , is sufficiently high) or is extinguished (if W_i is too low) because of the deactivation of the initial adduct R_SX . The absence of experimental data on such an evolution⁷⁹ was explained as follows.⁸⁰ It was assumed that not only the end group, but also the penultimate unit of the polymer chain affects the strength of the C–ON bond. If so, the aromatic ring substantially weakens this bond even if it is separated by the methacrylate unit and the adduct R_MX is not completely deactivated. Because of partial deactivation of R_MX , the rate constant for dissociation, k_d , remains rather high.

Copolymerisation of styrene with acrylates in the presence of TEMPO has been studied taking butyl acrylate as an example.¹⁰¹ Here, both copolymerisation constants, r_1 and r_2 , also are less than unity, but their values differ substantially ($r_1 = 0.15$ and

$r_2 = 0.76$; M_1 is butyl acrylate and M_2 is styrene). This indicates that growing chains react mainly with the styrene rather than acrylate molecules. For acrylates, the deactivation frequency of the adducts R_SX in each dissociation $\rightleftharpoons$ recombination cycle is lower than for methacrylates. Probably, that is why the results obtained for acrylates^{82, 83, 101, 142} were encouraging. It was shown¹⁰¹ that copolymerisation of styrene with butyl acrylate at 393 K with a styrene:butyl acrylate ratio of 77:23 (azeotrope) and $[\text{TEMPO}] = 6 \times 10^{-3} \text{ mol litre}^{-1}$ exhibits distinct indications of a 'living' process. The M_n value increases as the degree of conversion increases. The best polydispersity index $M_w/M_n = 1.29$ (at $\Gamma = 65\%$ and $M_n = 59\,100$) differs appreciably from that typical of conventional radical polymerisation, while the process, according to ESR data, proceeds at a nearly stationary concentration of free iminoxyl, $[X] = (1.7 - 2.6) \times 10^{-5} \text{ mol litre}^{-1}$ (at least in the range $20\% < \Gamma < 45\%$). Considering the concentration $[X]$ and the polymerisation rate W in the 'steady-state' stage of polymerisation, one can evaluate the equilibrium constant, $K = k_1/k_2 = W[X]/k_p[M][X]_0$ ($[M]$ is the overall running concentration of both monomers, $k_p = 2040 \text{ litre mol}^{-1} \text{ s}^{-1}$).¹⁰¹ If $20\% < \Gamma < 45\%$, the $K \times 10^{11}$ value varies between 2.7(1.8) and 3.7(3.4) mol litre^{-1} (the data obtained in the experiments with the alkoxyamine synthesised *in situ* are given in parentheses). For the homopolymerisation of styrene under the same conditions, the K value reported by investigators from the same research group was found to be equal to $K = (1.50 \pm 0.3) \times 10^{-11} \text{ mol litre}^{-1}$.⁹⁹

It is believed¹⁰¹ that the observed decrease in K values during the copolymerisation is due to the deactivation of the adduct R_SX because of the substitution of the acrylate end group in R for the styrene end group. This assumption is confirmed by an increase in the polydispersity index at deep stages of the process ($M_w/M_n = 1.5\% - 1.7\%$ for 80% conversion). This also seems to be the reason why the M_n value increases nonlinearly with conversion and goes beyond the limits for $\Gamma > 70\%$. Unsuccessful attempts to perform homopolymerisation of acrylate under analogous conditions also indirectly confirm that R_SX is deactivated.

A procedure for improving the efficiency of 'living' polymerisation of dimethacrylate in the presence of alkoxyamines by performing its copolymerisation with styrene under conditions of three-dimensional radical polymerisation has been reported.¹⁴³ This includes the addition of a two- or threefold excess of styrene to the network-forming monomer (dimethacrylate) in order to perform a 'living' copolymerisation. It is essential that the number of cross-links per unit volume in the polymer network, ν , in the copolymer decreases only slightly compared to the homopolymers of dimethacrylate. The point is that, because of cyclisation in the macromolecules of homopolymers,^{144–146} the effective ν value is much smaller than the 'nominal' one, so copolymerisation of dimethacrylate with monomers which cannot form polymer networks (e.g., styrene) and contain only one double bond in the molecule increases the effective ν value.

To sum up, we can say that copolymerisation of (meth)acrylates and related monomers with styrene appears to be quite an efficient procedure for extending the area of application of alkoxyamines as agents for 'living' polymerisation.

7. Synthesis of block copolymers in the presence of alkoxyamines

A trivial method for the synthesis of block copolymers by 'living'-chain polymerisation includes two stages. The first stage is 'living'-chain polymerisation of the first monomer (M_1) to give a homopolymer with the desired molecular mass M_n and the lowest polydispersity (ideally, $M_w/M_n = 1.0$, block A). The second stage involves the extension of 'living' chains grown in the first stage with the other monomer (M_2) to give the second block (also with controlled M_n and M_w/M_n values, block B). Obviously, this approach can only be used if the 'living' end group of the chain A can initiate 'living' polymerisation of M_2 . Taking into account the limitations on the activity of alkoxyamines as agents for 'living'

polymerisation (see above), this procedure allows only the synthesis of AB block copolymers based on styrene and its derivatives. Usually, polystyrene is used as the block A while a homopolymer of a substituted styrene is used as the block B, or *vice versa*.

Synthesis of an AB block copolymer with 'living' poly(*p*-bromostyrene) as the block A and polystyrene as the block B has been described.⁷⁰ Block A was obtained by polymerisation of *p*-bromostyrene in the presence of 4-methoxy-2,2,6,6-tetramethyl-1-piperidinyloxy and dibenzoyl peroxide. 'Living' poly(*p*-bromostyrene) thus obtained was used in the second stage to perform 'living' polymerisation of styrene (block B). The overall process resulted in the preparation of the AB block copolymer.

Yet another block copolymer was synthesised, with the homopolymer of 3- and 4-chloromethylstyrene (a mixture of isomers in a 2:1 ratio) as the block A and polystyrene as the block B.⁷¹ Alkoxyamine was synthesised *in situ* from TEMPO and dibenzoyl peroxide in the bulk of 3(4)-chloromethylstyrene.

Blocks A and B can be synthesised not only from homopolymers, but also from copolymers with a rather high content of styrene or its derivatives (in order to ensure high efficiency of alkoxyamines as agents for 'living' polymerisation).^{51, 55, 73, 76, 79, 140, 147–157} This allows substantial extension of the range of AB block copolymers.

This can be done⁷³ by performing, *e.g.*, polymerisation of alkyl acrylates (including butyl acrylate) at elevated temperatures (428 K) in the presence of an iminoxyl radical, such as 4-oxo-2,2,6,6-tetramethyl-1-piperidinyloxy.[†] This procedure was used for the synthesis of not only the AB diblock copolymers (A is poly(alkyl acrylate) and B is polystyrene), but also the ABA and BAB triblock copolymers, as well as the AA' diblock copolymers, where A and A' are alkyl acrylates differing in the type of the alkyl substituent.

The use of different types of polymerisation for the synthesis of blocks A and B was proposed.^{73, 158–160} In this case, stable iminoxyl radicals are modified by incorporation of additional functional groups with retention of the atomic group carrying the unpaired spin. 4-HO-TEMPO synthesised using the known procedure¹⁶¹ is the most appropriate for such a modification. In this case, the hydroxy group is modified. For instance, a poly(tetrahydrofuran-*b*-styrene) block copolymer was synthesised¹⁶² using a combination of cationic polymerisation to obtain poly(tetrahydrofuran) followed by 'living' radical polymerisation of styrene. First, 4-HO-TEMPO was treated with sodium hydride at room temperature to give 4-NaO-TEMPO which reacts with 'living' chains grown in the cationic polymerisation of tetrahydrofuran.

Being 'dead' in cationic polymerisation, poly(tetrahydrofuran) chains capped with the iminoxyl end group (block A) 'revive' in the bulk of styrene (or styrene derivatives and their mixtures with other monomers) and help the chain extension of the block B following the 'living' radical polymerisation mechanism. For instance, synthesis of the block B was performed in the presence of dibenzoyl peroxide (with alkoxyamine synthesised *in situ*) at 368 K over a period of 3.5 h and followed by heating at 398 K for 64 h.¹⁶² The molecular masses, polydispersities as well as the lengths of blocks A and B expressed in the numbers of THF

[†] Here,⁷³ the corresponding alkoxyamine was synthesised using azobis(isobutyronitrile) instead of dibenzoyl peroxide and polymerisation was performed at 378 K rather than at a conventional temperature of 363–368 K.

(block A) and styrene units (block B) for three specimens of the AB block copolymers were as follows:

Parameter	Specimen 1	Specimen 2	Specimen 3
Block A			
M_n	1520	3300	10 600
M_w/M_n	1.38	1.43	1.26
n (THF)	14	24	77
Block B			
M_n	9690	12 600	38 800
M_w/M_n	1.22	1.25	1.40
n ($\text{CH}_2 = \text{CHPh}$)	103	112	337

The use of anionic polymerisation in conjunction with 'living' radical polymerisation for the synthesis of a block copolymer based on ϵ -caprolactone and styrene has been reported.¹⁶³

First, anionic polymerisation of ϵ -caprolactone was performed at room temperature in toluene solution for 3 h using tris(2,2,6,6-tetramethyl-1-piperidinyloxy-4-oxy)aluminium as catalyst.

According to NMR data, this stage resulted in the formation of poly(ϵ -caprolactone) (block A) capped with the iminoxyl end group:

After isolation and purification, this block A was placed in the bulk of styrene, the iminoxyl group was *in situ* converted into the alkoxyamino group in the presence of dibenzoyl peroxide and a 'living' radical polymerisation of styrene (block B) was performed. The molecular masses and polydispersities varied respectively in the range $3200 \leq M_n \leq 6700$ and $1.28 \leq M_w/M_n \leq 1.33$ for blocks A and $20\,000 \leq M_n \leq 26\,200$ and $1.37 \leq M_w/M_n \leq 1.42$ for blocks B.

Yet another example of a combination of 'living' polymerisation performed in the presence of alkoxyamines with other types of polymerisation in order to prepare block copolymers has been reported.¹⁶⁰ Block A was prepared from poly(dimethylsiloxane) ($M_n = 5000$) telomerised with propylamine in the presence of 4,4'-azobis(4-cyanopentanoyl) dichloride. The macroinitiator (block A) thus formed was used for the initiation of 'living' polymerisation of styrene in the presence of 4-methoxy-2,2,4,4-tetramethyl-1-piperidinyloxy¹⁶⁴ (MTEMPO) to grow the polystyrene block B.

The degree of styrene conversion was varied between 70% and 85%. The 'living' AB block copolymer prepared in this manner

was used for chain extension of the next block B' built of *p*-methoxystyrene units.

After 9 h, conversion of *p*-methoxystyrene reached 96%, which indicated that it is much more reactive than styrene during 'living' radical polymerisation.

According to NMR data, the ratio of dimethylsiloxane (block A), styrene (block B) and *p*-methoxystyrene (block B') units in the ABB' block copolymer was 1 : 6.67 : 44.5. The molecular masses and polydispersities of the macroinitiator, AB and ABB' copolymers were as follows (GPC data):

Product	M_n	M_w/M_n
Block A (macroinitiator)	33 000	2.39
Copolymer AB	66 000	1.90
Copolymer ABB'	135 000	1.43

In addition to poly(dimethylsiloxane), poly(isobutylene),¹⁶⁵ poly(ethylene glycol),¹⁶⁶ polyethers,¹⁶⁷ polycarbonate¹⁶⁸ and polyamide¹⁶⁹ were also used as macroinitiators. There is a review dedicated to the synthesis of block copolymers by 'living' polymerisation using alkoxyamines.¹⁷⁰

Summing up, studies on the use of alkoxyamines for the synthesis of unusual block and graft copolymers (including grafting onto fullerenes) should be mentioned^{54, 70, 71, 151, 171–194} as well as those dedicated to the preparation of star-like and dendritic structures.^{54, 151, 171, 175, 187, 190–192, 195, 196}

8. Prospects for the use of alkoxyamines and related compounds

Very recently (in the year 1999), it became possible to alleviate many problems in the use of alkoxyamines as agents for 'living' polymerisation. It was shown^{52, 137, 185, 197–199} that the dissociation rate of the C–ON bond in alkoxyamines can be increased not only by introducing a phenyl substituent at the C atom of the monomer, but also by varying the nature of substituents at the nitrogen atom.

It was found that the use of di-*tert*-butylnitroxyl instead of traditionally used nitroxides, TEMPO or its derivatives, leads to weakening of the bond subject to dissociation in the alkoxyamine molecule to the extent that the rate constant for dissociation, k_1 , appears to be high enough for performing a 'living' polymerisation of monomers devoid of aromatic rings at 393 K. For *tert*-butyl acrylate, the rate constant k_1 equals 10^{-3} s^{-1} at 393 K. Polymerisation of *tert*-butyl acrylate in the presence of di-*tert*-butylnitroxyl and cumyl peroxide (with alkoxyamine synthesised *in situ*) was performed at 393 K. The 'living' type of the process was confirmed by both the increase in M_n with conversion and by the narrowing of MMD.

These examples indicate that the possibilities of the use of alkoxyamines in 'living' polymerisation can be extended.

Obviously, other adducts RX which can decompose during polymerisation into two free radicals, *viz.*, an active radical R', which can react with the monomer M ($R' + M \rightarrow RM'$), and a stable radical X', which only can recombine with R' ($R' + X' \rightarrow RX$), can also act like alkoxyamines. Some of these compounds (*e.g.*, dithiocarbamates^{40, 41, 200}) were used well before

alkoxyamines. Currently, they are used much more rarely than alkoxyamines, most likely because of a larger number of side reactions which make 'living' polymerisation difficult. However, these and related compounds collectively called iniferters also have a number of advantages, the most important of which is photoactivity upon homolytic cleavage under the action of photoirradiation.

The search for new agents for 'living' radical polymerisation capable of undergoing a reversible photodissociation is one promising investigation line which seems to provide the possibility of substantial reduction of the operating temperature of the process (in the limit, down to room temperature). Low-temperature 'living' radical polymerisation of methyl methacrylate in the presence of RX containing piperidinothiocarbonylthio groups by photodissociation of the adduct RX instead of its thermal decomposition was attempted.²⁰¹

At present, intensive search for compounds capable of undergoing reversible homolytic cleavage in polymerisation systems is being carried out. 'Living' copolymerisation of styrene with methyl acrylate at 393 K in the presence of di(isopropoxythiocarbonyl) disulfide as RX was reported in 1997.²⁰² The polydispersity of the copolymer obtained in this manner was lower than that of its analogue synthesised by conventional radical polymerisation. (A linear increase in M_n with conversion was also observed in this study.)

Very recently, halogen-containing organic compounds have been evaluated for use as agents for 'living' polymerisation. 'Living'-chain radical polymerisation of styrene at 353 K in the presence of ω -polystyryl iodide as a mediator and dibenzoyl peroxide as an initiator has been reported.²⁰³ It was found that activation of the 'dormant' chains, RI, follows a radical substitution mechanism with the rate constant $k_{ex} = 3.1 \times 10^7 \exp(-27.8/RT) \text{ litre mol}^{-1} \text{ s}^{-1}$

rather than a reversible dissociation mechanism, $RI \rightleftharpoons R^\bullet + I^\bullet$. As can be seen, the activation energy of radical substitution reaction (27.8 kJ mol^{-1}) is much lower than that of thermal dissociation of alkoxyamines (124 kJ mol^{-1}).

Thus, the approach described above and based on the use of reversible homolytic cleavage of adducts RX remains rather promising. This is indicated by both an incessant stream of communications and the appearance of studies in which technological aspects are touched on.^{81, 204–211} To mention just a few: studies dedicated to the search for procedures for performing not only bulk polymerisation, but also polymerisation in aqueous solutions, as well as emulsion and dispersion polymerisation.^{81, 204–206, 210}

VI. Transition-metal halide complexes with organic ligands as agents for 'living'-chain radical polymerisation

Currently, an alternative approach to 'living' radical polymerisation is also being developed. This approach uses transition-metal compounds with mixed ligands including halogen atoms and organic ligands as agents for polymerisation. For brevity, we will call them transition-metal halides (TMH). The most commonly used compounds are transition-metal chlorides or bromides with the general formula $M^nY_nL_m$, where M is the transition metal, n is the valence of the transition metal, Y are the Cl^- or Br^- anions and L are organic ligands (as a rule, strong donors such as cyclic amines, linear polyamines, triphenylphosphine, *etc.*). The progress in this field is mainly associated with the studies by Matyjaszewski (USA).

Rapid development of the investigations on 'living' radical polymerisation controlled by the $M^nY_nL_m$ complexes is due to the fact that the new agents have three advantages over stable free radicals discussed in the previous Sections.

1. The most important is that, unlike TEMPO, the action of compounds $M^nY_nL_m$ is not confined to styrene and its derivatives, butyl acrylate, *etc.* as the monomers. On the contrary, these compounds can be used with almost all known monomers.

2. Compounds $M^nY_nL_m$ act at much lower temperatures (333–363 K)^{212, 213} than the TEMPO-type agents (393–428 K). It should be noted that the decrease in the operating temperatures makes it possible not only to solve the technologically important problem of reduction of power consumption, but also to reduce the risk of side reactions.

3. Using agents of the $M^nY_nL_m$ type, one can synthesise polymers with much narrower MMD and lower polydispersities ($M_w/M_n = 1.04–1.05$) than those of the polymers obtained with the TEMPO-type agents where $M_w/M_n \geq 1.15$ and often exceeds a value of 1.20.

Yet another (the most technologically important) advantage of compounds $M^nY_nL_m$ is that 'living' radical polymerisation can easily be carried out in friendly and environmentally safe aqueous solutions. Recently, the first studies on 'living' radical polymerisation in emulsions and dispersions in aqueous solutions have been reported.^{214, 215}

'Living' radical polymerisation controlled by agents of the $M^nY_nL_m$ type was called the Atom Transfer Radical Polymerisation (ATRP).

1. The mechanism of action

The mechanism of the action of $M^nY_nL_m$ compounds as agents for 'living' radical polymerisation is based on the known Kharasch reaction.²¹⁶ It was found that halides of transition metals in the lowest oxidation state n can react with alkyl halides RX to give alkyl radicals $R^\bullet$. This is accompanied by oxidation of the transition-metal atom. An essential feature of this reaction is its reversibility.

Obviously, performing the reaction in the bulk of a monomer (we will denote it Mm) initiates polymerisation by the mechanism $R^\bullet + Mm \rightarrow (R^1)^\bullet$, where $(R^1)^\bullet$ is the primary growing polymer chain, followed by incremental propagation of the primary chain by the reaction

where x is the number of the monomer molecules which to add to $R^\bullet$ during the time interval between the instant of appearance of the active polymerisation centre (as a result of the reaction between alkyl halide and $M^nY_nL_m$) and the instant of deactivation of this centre as a result of the reverse reaction with $XM^{n+1}Y_nL_mX$. Since activation occurs at regular time intervals, the deactivation is temporary, so that alkyl halide-induced polymerisation in the presence of $M^nY_nL_m$ is in essence implemented as a 'living'-chain process.

What actually happens is that the activation $\rightleftharpoons$ deactivation cycle proceeds in a more complicated manner rather than follows a simplified scheme discussed above. The reverse reaction involves a stage of addition of the free radical $R^\bullet$ to $M^{n+1}Y_nL_mX$ with the formation of an intermediate $R-M^{n+1}Y_nL_mX$, which is a mediator of stepwise growth of the polymer chain. Chain propagation occurs as the monomer addition to the radical $R^\bullet$ formed upon reversible decomposition of the intermediate rather than monomer insertion into the $R-M^{n+1}$ bond. The intermediate undergoes deactivation by decomposing into the alkyl halide RX and the initial complex $M^nY_nL_m$.

To initiate a 'living' radical polymerisation, one has to start either a forward or a reverse reaction of the activation $\rightleftharpoons$ deactivation cycle. When alkyl halides and $M^nY_nL_m$ are used as initiators, the forward reaction proceeds to give the active intermediate, $R-M^{n+1}Y_nL_mX$, which decomposes into the growing radical $R^\bullet$ and a complex $M^{n+1}Y_nL_mX$. If a halide of the transition metal in the highest oxidation state $[M^{(n+1)}]^\bullet$ is used, the active intermediate should be obtained in the reaction of

the complex $M^{n+1}Y_nL_mX$ with the radicals formed in the decomposition of the initiator [*e.g.*, azobis(isobutyronitrile)]. In both cases, 'living' radical polymerisation proceeds in the presence of the monomer. The most commonly used initiators are alkyl halides RX and complexes $M^nY_nL_m$;^{4, 212–214, 217–257} however, polymerisation can also be initiated by azobis(isobutyronitrile) in the presence of $M^{n+1}Y_nL_mX$ complexes.^{224, 227, 237, 258}

It should be noted that the process of 'living' radical polymerisation is often described using the concepts of a 'living' radical chain and a 'dormant' chain. If polymerisation is performed in the presence of stable nitroxyl radicals (TEMPO), a 'living' radical chain and a 'dormant' radical chain respectively mean a propagating radical $R^\bullet$ and an adduct (alkoxyamine TEMPO-R). For a polymerisation process proceeding in the presence of TMH, a 'living' radical chain also means a propagating radical $R^\bullet$ while a 'dormant' chain means an alkyl halide RX in the presence of $M^nY_nL_m$, where RX is either the initial alkyl halide or a polymeric product with the halogen atom in the end group. Polymer chains immobilised in the form of intermediates $R-M^{n+1}Y_nL_mX$ can be ignored since their concentrations are much lower than that of RX.

Thus, in both cases 'living' radical polymerisation is performed under conditions of dynamic equilibrium between the 'living' and 'dormant' radical chains.

The term 'living' chain, as applied to radical polymerisation, can also be used in another sense, much as in the case of, *e.g.*, anionic polymerisation. All chains which can grow are considered 'living'. These are all chains RX with the end group X which, under given conditions, can undergo homolytic cleavage to release an active free radical $R^\bullet$ (a growing polymer chain). In this case, it is believed that 'living' chains can be either 'dormant' in the form of RX or active in the form of $R^\bullet$.

An essential distinction between TEMPO- and TMH-based agents for 'living' radical polymerisation is that the latter are catalytic systems and, unlike the former, are not incorporated into the polymer chains after completion of the polymerisation process. TMH-based agents can be separated from the polymer and re-used. However, this type of compound has a drawback consisting in the ability to initiate redox processes of polymer destruction.

The necessity of using well-defined terms can be illustrated taking calculations of the average lengths of polymer chains from the data on the degree of polymerisation, $\bar{P}$, as an example. As is known, $\bar{P} = \Delta[Mm]/[Mm]_0$, where $\Delta[Mm]$ is the concentration of polymer and $[Mm]_0$ is the initial monomer concentration. In this case, the chain length ν is defined by the ratio $\nu = \bar{P}[Mm]_0/[C]$, where $[C]$ is the concentration of chains. This implies that the $[C]$ value refers to all polymer chains grown in a given polymerisation system during the time interval $\Delta\tau$ needed to reach the specified $\bar{P}$ value. In other words, $[C]$ is the sum of the $[RX]$ value averaged over $\Delta\tau$ with averaged $[R^\bullet]$ value. If quadratic chain termination during time interval $\Delta\tau$ can be ignored, then, taking into account that $[R^\bullet]$ is negligible as compared to $[RX]$, it is admissible that $[C] \simeq [RX]_0 \simeq \text{const}$. Following this reasoning, all chains with the end group X are considered 'living'. The majority of calculations of ν rest on this consideration.

2. 'Living' radical polymerisation controlled by transition-metal halides

The simplest scheme of a 'living' radical polymerisation controlled by TMH is presented below (Scheme 6).^{259, 260}

Scheme 6

Here $P_k^\bullet$ is the growing polymer chain, X is a halogen, and k_a , k_d and k_p are the rate constants for chain activation, deactivation and propagation, respectively.

For $10^{-3} \text{ s} < t < 10^2 \text{ h}$, theoretical analyses^{88, 261} of Scheme 6 have led to a number of analytical expressions which

describe the kinetics of (i) polymerisation, (ii) reduction of instantaneous concentration of growing chains and (iii) increase in the instantaneous concentration of growing chain acceptor (a complex of the transition metal in the highest oxidation state, $X-M^{n+1}Y_nL_m$) throughout the process. The corresponding formulae are as follows:

$$\ln \frac{[Mm]_0}{[Mm]} = \frac{3}{2} k_p ([RX]_0 [M^n]_0)^{1/3} \left(\frac{k_a t^2}{3k_d 2k_t} \right)^{1/3}, \quad (27)$$

$$[P_k^*] = ([RX]_0 [M^n]_0)^{1/3} \left(\frac{k_a}{3k_d 2k_t} \right)^{1/3}, \quad (28)$$

$$[M^{n+1}] = ([RX]_0 [M^n]_0)^{2/3} \left(\frac{3k_a^2 2k_t}{k_d^2} \right)^{1/3}. \quad (29)$$

Comparison of the results obtained after solving the system of differential equations (27)–(29) with the experimental results²⁵⁸ revealed considerable quantitative and qualitative (the shape of the kinetic curves) discrepancies between them.

To establish the reasons for such a sharp distinction between theory and experiment, computer simulation of a more detailed Scheme 7 was performed²⁵⁹ for Mm = styrene and M = Cu using the PREDICI programme package²⁶² and the results of reported studies.^{106, 262–266}

The numerical values of rate constants k used in computer simulation of a styrene polymerisation at 383 K with $[Mm]_0^*$, $[RX]_0^*$, $[M^n]_0^*$ and $[M^{n+1}]_0$ equal to 8.7, 0.087, 0.087 and 0 mol litre^{−1}, respectively, are shown below:

k /litre mol ^{−1} s ^{−1}	Numerical value	Ref.
k_i	1.6×10^4	267, 268
k_p	1.6×10^3	102
$2k_{tc}(0)$	10^9	267
$2k_{td}(0)^*$	10^8	267
$2k_{to}$	10^9	267
k_{tr}	0.22	269
k_d^*	1.1×10^7	270
k_a	0.45	270
k_{tp}	10^9	267, 271
k_{term}^*	4.8×10^{-11}	112

(the asterisked parameters were used as independent variables).

The discrepancies between the results of computer simulation and the known experimental data²⁵⁸ appeared to be as substantial as in the case of comparing with the results of analytical solutions of Eqns (27)–(29). Variation of the initial k values over a wide

range under assumption that they remain unchanged during the process does not make the situation better. It was found that calculated data can fit experimental results only assuming that the numerical values of particular rate constants vary during the process, *i.e.*, that they are dependent on the degree of conversion Γ (degree of polymerisation).

The appearance of the $k = f(\Gamma)$ dependence during polymerisation is largely caused by an increase in the viscosity of the reaction mixture. This prevents the reagent molecules A and B from approaching each other in the bimolecular reaction $A + B$ to the extent that the reaction becomes diffusion-controlled.^{267, 268, 272–290} In other words, after the viscosity of the reaction medium reaches a particular threshold (because of accumulation of the polymer), the rate of the bimolecular reaction $A + B$ appears to be controlled by the diffusion characteristics of A and B rather than their reactivities. Quantitatively, a bimolecular reaction goes under diffusion control if the condition $k > k_D$ (k_D is the rate constant for pairwise collisions between molecules A and B) is met. Evaluation of k_D according to Smoluchowski^{272, 277–283, 291}

$$k_D = 4\pi R(D_A + D_B)$$

(R is the distance between the centres of gravity of the colliding molecules and D_A and D_B are the diffusion coefficients of molecules A and B in the reaction medium) shows that for low-molecular mass compounds ($D \approx 10^{-5}$ cm² s^{−1}) the k_D value is $\sim 4 \times 10^9$ litre mol^{−1} s^{−1} for $\Gamma \approx 0$. This implies the absence of diffusion control over every elementary act (all k values are much less than 4×10^9). For dilute polymer solutions ($0 < \Gamma < 10\%$), the D value ($D \approx 10^{-7}$ cm² s^{−1}) is about two orders of magnitude smaller than for low-molecular mass compounds. Here, the threshold k_D value decreases down to $\sim 4 \times 10^7$ litre mol^{−1} s^{−1}, which is comparable with the rate constant for quadratic chain termination. For $\Gamma > 10\%$, polymer solutions become so viscous that the diffusion coefficients do not exceed 10^{-9} cm² s^{−1} and $k_D \leq 4 \times 10^5$ litre mol^{−1} s^{−1} even for low-molecular mass compounds. Thus, not only quadratic termination reactions of growing chains, but also elementary bimolecular reactions between small molecules (provided that their rate constants meet the condition $k \geq 4 \times 10^5$ litre mol^{−1} s^{−1}) go under diffusion control at $\Gamma > 10\%$.

The $k = f(\Gamma)$ dependence for high rate constants for quadratic chain termination, due to diffusion control of the corresponding elementary reactions, was also suggested.²⁵⁹ The corresponding formula is as follows^{292, 293}

$$k_T = k_0 \left(\frac{\Gamma [Mm]_0}{[RX]_0} \right)^{-(0.65+0.02 \frac{\Gamma [Mm]_0}{[RX]_0})},$$

where k_T is the current k value at a given degree of polymerisation Γ , expressed as the $[Mm]/[Mm]_0$ ratio ($\Gamma = \Delta[Mm]/[Mm]_0$), and k_0 is the k value at $\Gamma = 0$. Calculations performed using this model gave reasonable agreement with the experimental data.

Taking into account the known data on the diffusion kinetics,^{267, 268, 271–290, 292–294} the necessity of considering the diffusion-controlled character of quadratic chain termination reactions seems to be quite natural. Rather it is unclear why the neglect of this factor in the description of the mechanism of ‘living’ radical polymerisation in the presence of alkoxyamines causes no discrepancies between the calculated and the experimental data.

Clearly, there is no basic distinctions between the mechanism of the action of alkoxyamines and TMH (*cf.* Schemes 7 and 5). In both cases, pseudo-‘living’ chains (growing free radicals) are formed. At regular intervals, they are ‘revived’ and can react both with the monomer and with one another (unlike true ‘living’ chains which never react with one another).

It seems likely that the main distinction between TMH and alkoxyamines as agents for ‘living’ polymerisation has a purely quantitative character and lies in the fact that for TMH the rate constants for activation of ‘dormant’ chains are two orders of

magnitude higher than the corresponding rate constants for alkoxyamines. Because of this, the repetition frequency of the dissociation $\rightleftharpoons$ recombination cycle responsible for the initiation of 'living' radical polymerisation increases substantially in the presence of TMH (see Scheme 7). This leads to a decrease in the 'sensitivity' of the polymerisation process to additional initiation (e.g., thermal initiation in the case of styrene) and to reduction of the polydispersity ($M_w/M_n \approx 1$). Probably, the increase in the 'sensitivity' of the process to the dependence of the rate constants for quadratic chain termination reactions on the degree of conversion is also due to an increase in the repetition frequency of the cycle, which necessarily requires consideration of the diffusion control of the rates of these reactions.

Detailed studies of the mechanism of ATRP showed first of all that, generally, the reaction follows a radical mechanism. It was found that introduction of strong inhibitors (galvinoxyl) results in complete suppression of polymerisation, whereas the additives of poisons of anionic and cationic polymerisation (alcohols and water) have no effect on the process.^{213,295} This undoubtedly confirms that ATRP follows the radical mechanism.

The question may also arise as to whether the polymer chain propagation occurs in this case by insertion of the monomer molecule into the $R-M^{n+1}Y_nL_mX$ bond (a conventional mechanism involves homolysis of the $R-M^{n+1}$ bond followed by the reaction of the released free radical with the monomer). Obviously, it is impossible to answer this question experimentally; however, most of investigators believe that chain propagation occurs in a normal manner rather than involving the monomer insertion.^{213,231,296}

It should also be noted that, according to Scheme 7, the reaction of chain termination should result in a polymer with halogen atoms as the end groups. This was observed experimentally.^{295,297} In addition, it was shown that polymerisation of a fresh portion of the monomer can be initiated by introducing the polymers with Cl or Br atoms as the end groups (of course, in the presence of catalytic amounts of $M^nY_nL_m$).²⁹⁵

An interesting study aimed at elucidating the mechanism of ATRP was carried out by Matyjaszewski and co-workers²⁹⁸ who investigated a catalytic system based on $CuBrL_m$. The addition of finely dispersed copper to the components of the system resulted in the transformation of $CuBr_2$ formed in the course of the reaction into active $CuBr$ which rapidly reacted with RX (RBr).

This redox reaction promoted a substantial increase in the initiation rate. As a result, the rate of polymerisation increased by more than an order of magnitude and complete conversion was reached after 55 min. The redox reaction between Cu^{2+} and Cu^0 was confirmed by ESR spectroscopy. There is no question that this approach and related investigations into the processes of activation of 'living' radical polymerisation are also technologically important.

3. Catalytic systems based on transition-metal halides and the assortment of polymeric products formed

Studies on 'living' polymerisation using TMH are primarily dedicated to the search for the most efficient catalytic systems using semiquantitative evaluation procedures. It was found that the most efficient systems are based on copper bromide.^{212,219,231} It is these catalytic systems that allowed the synthesis of polymers with $M_w/M_n = 1.04-1.05$ and molecular masses $M_n = (50-100) \times 10^3$. This has initiated intensive search for novel catalytic systems without accompanying detailed kinetic studies. However, systems based on other transition metals appeared to be less efficient as regards both the polydispersity index, M_w/M_n , and the molecular mass M_n . Currently, catalytic systems containing chlorides and bromides of $Cu(I)$ and $Cu(II)$,^{4,212-214,217-249,299,300} $Fe(II)$,^{250,301-303} $Ni(II)$,³⁰⁴⁻³¹⁰

$Ru(II)$,^{215,295,296,311-320} $Rh(II)$,^{221,321} acetates of $Pd(II)$ ³²² and $Cr(II)$,³²³ as well as ReO_2 (see Ref. 324) have been studied (Table 3). For all the salts, except for $CuBr$ and $CuCl$, the polydispersity indices, M_w/M_n , lie between 1.1 and 1.3.

Syntheses of polymers with $M_w/M_n = 1.04-1.05$ have clearly demonstrated that quadratic chain termination contributes insignificantly to the MMD of the polymers. A semiquantitative procedure developed for the analysis of experimental results is based on the determination of the dependences of $\ln([Mm]_0/[Mm]_t)$ on t , where $[Mm]_0$ and $[Mm]_t$ are the initial and running concentrations of the monomer, respectively. The results of testing were accepted if both dependences were linear.

This procedure was used to analyse a large number of catalytic systems. For instance, organic ligands (L) were varied in studies of the catalysts based on $CuBr$. If both the above-mentioned dependences were linear, the effect of the nature of the ligand on the polydispersity index was followed and those ligands were chosen which gave polymers with the smallest M_w/M_n ratios. The effect of ligands on the solubility of TMH in the monomers (solvents) was also taken into account^{212,213,231} and then the ligands which were the best to stabilise the ions of metals in the highest oxidation state were chosen from the group of preliminarily selected compounds. This made it possible to choose the systems with the highest concentrations of active intermediate $R-M^{n+1}Y_nL_mX$. As follows from the data listed in Table 3, bipyridines and polyamines appeared to be the best ligands, whereas triphenylphosphine appeared to be the worst one. This is likely due to the fact that triphenylphosphine *per se* can be involved in the redox cycle.

Apparently, ligands can also suppress a number of possible side reactions such as (presumably) oxidative chain termination (for simplicity, the ligands at TMH are not shown):

and (or) hydride transfer:

where $P_n(=)$ is the polymer with the end group containing a double bond. Such radical reactions are known for transition-metal salts and complexes.³²⁵ Both reactions result in chain termination and, hence, in broadening of MMD and an increase in M_w/M_n . (Scheme 7 discussed in the previous subsection ignores these reactions since it corresponds to the case $M = Cu$ where the neglect of these side processes is well substantiated.)

A similar procedure was used for studying and choosing alkyl halides (RX). In this case, the results of bulk polymerisations and polymerisations in solvents were compared. The M_w/M_n ratio was analysed as a function of the degree of conversion.

Almost all catalysts listed in Table 3 make it possible to obtain better values of M_n and M_w/M_n than TEMPO. In addition, these catalytic systems allow polymerisation of almost all vinyl monomers at lower temperatures.

In addition to catalytic systems, activators have also been studied. Aryl and sulfonyl halides were found to be the best activators of 'living' polymerisation, alkyl halides are less efficient. In the latter case, the role of activator is played by the second component of the binary system, which 'works in pair' with the catalyst ($M^nY_nL_m$ or $M^{n+1}Y_nL_mX$). For compounds $M^nY_nL_m$, alkyl halide RX acts as activator (the initial pair is $RX + M^n$), whereas for compounds $M^{n+1}Y_nL_mX$ this role is played by the source of free radicals, such as azodinitrile, *etc.* (the initial pair is $R^* + M^{n+1}$).

It is believed^{212,213,231} that the rate of the redox reaction between the activator and catalyst should be high enough to provide nearly simultaneous initiation of all chains; this is one of the main conditions for the preparation of polymers with narrow MMD and very low polydispersity M_w/M_n . The choice of compounds to be used as activators is performed to meet this condition.

Table 3. Catalytic systems for ATRP based on transition-metal compounds.

4. ‘Living’ radical polymerisation performed in emulsions, suspensions and with the use of immobilised catalysts

As was mentioned above, intensive studies on ‘living’ radical polymerisation have led to the discovery of relatively simple and cheap catalytic systems which make it possible to accomplish the

polymerisation process in several hours and to obtain well-defined polymers with molecular masses as high as 10⁵ monomer units and narrow MMD (*M_w/M_n* ≈ 1.05–1.1).

It is obvious that bulk polymerisation faces some problems associated with fast heat transfer from the reaction zone and with

an increase in the viscosity of the reaction media during the process. Additionally, catalysts should be removed from the polymer after completion of the process, since usually they have an intense colour and can oxidise polymers under operating conditions.

Polymerisation in solvents also has essential drawbacks such as fire hazard, necessity of solvent regeneration and environmental costs.

Suspension or emulsion polymerisation in water-borne systems seems to be best suited to overcoming all the above-mentioned problems.

However, no studies on the emulsion^{214, 326} and suspension²¹⁵ 'living' radical polymerisation had been reported until 1999. The results obtained recently are encouraging, since emulsion polymerisation is at least as efficient as bulk polymerisation.

Matyjaszewski *et al.*²¹⁴ found that emulsion polymerisation of butyl methacrylate using CuBr_2L as catalysts allows reduction of the temperature of the process from 363 to 343 K and shortening of the polymerisation time from 20 to 4–5 h. The monomer conversion reached $\sim 90\%$, as is the case of bulk polymerisation. However, it should be noted that MMD was somewhat broader and varied between 1.1 and 1.2 instead of being equal to 1.05.

The new approach has of course posed some problems associated with the choice of initiators and emulsifying agents, buffer solutions, *etc.*, including the problem of stability of the latex species against aggregation as well as the problem of confining the catalysts to the monomer phase. Nevertheless, there is reason to believe that all these problems will be successfully solved since the mechanism of the action of catalysts in binary systems remains essentially the same.

'Living' radical polymerisation in suspensions have also been studied by investigators from Japan.²¹⁵ Polymerisation of MMA was performed at 353 K using $\text{RuCl}_2(\text{PPh}_3)_3$ as the catalyst. Monomer suspensions in a toluene–water mixture as well as in alcohols with additives of CH_2Cl_2 and water were used. Fairly good results were obtained, the polymers were characterised by $M_n \approx 10^5$ and $M_w/M_n = 1.1–1.3$. Stability of suspensions was achieved by vigorous stirring of the mixtures.

Finally, Matyjaszewski²¹³ attempted to immobilise CuBr_2L_2 -based catalytic systems using silica gel and cross-linked polystyrenes as catalyst's supports. However, polymerisations of styrene in the presence of immobilised catalysts were unsuccessful, namely, the M_w/M_n ratio varied in different experiments between 1.5 and 10 (for $M_n = 10^4–10^5$). The reasons why MMD is so broad are likely associated both with the diffusion from the matrix supporting the immobilised catalyst and with the increase in the molecular mass of 'living' chains during conversion. Despite the failure, the author intended to continue his studies since immobilisation of catalysts results in considerable reduction of contamination of the polymeric products by metal-containing impurities.

5. Synthesis of block, graft, star and hyperbranched copolymers using atom transfer radical polymerisation

It is well known that block copolymers, as well as star and other copolymers were first synthesised using a 'living' cationic and anionic polymerisation of vinyl monomers (their number is limited, however). Obviously, 'living' radical polymerisation would favour the extension of the assortment of different types of copolymers and, correspondingly, the broadening of the spectrum of their consumer properties.

A procedure for the preparation of block copolymers by 'living' chain polymerisation is simple. First, polymerisation of a monomer A is performed until complete conversion. Then, the other monomer (B) is introduced into the reaction system to yield a block copolymer AB. The blocks can alternate in any manner.

Star copolymers are synthesised using polyfunctional activators (alkyl halides, sulfonyl halides, *etc.*) with more than one active halogen atom. In the reaction with a catalyst (*e.g.*, $\text{Cu}^{\text{I}}\text{BrL}_2$), these halides are transformed into 'living' chains so that each polyfunctional (with respect to the halogen) molecule becomes the initial point for the growth of several polymer chains which form a star-

like structure. Synthesis of star copolymers with two, three, five^{213, 311} and even eight arms has been reported.²¹²

Graft copolymers are prepared using the reaction of chain transfer to polymer. In this case, the monomer simultaneously plays the role of an activator since halogen atoms are constituents of the monomer molecules. Almost all of them can be the initial points for chain propagation. A number of studies on the synthesis of this type of polymers has been reported.^{223, 327, 328}

It is known that both anionic and cationic polymerisation require extremely pure reagents and solvents with complete exclusion of water. 'Living' radical polymerisation allows nearly complete elimination of these limitations. Recently, numerous syntheses of almost all types of copolymers by 'living' radical polymerisation of a broad spectrum of monomers have been reported.^{229, 231, 235, 305, 306, 311, 329, 330} For instance, diblock and triblock copolymers of alkyl methacrylates,^{305, 331} styrene and acrylates,^{213, 312} polysulfones and styrene²²² and some other linear copolymers have been prepared.^{212, 213, 296, 314}

An interesting procedure for the synthesis of block and graft copolymers involves a combination of cationic polymerisation with ATRP.^{233, 246, 249, 332–334} In the first stage, cationic polymerisation of a monomer A is used to grow the chains with halogen-containing end groups (macromonomers), which are then involved in the ATRP process which proceeds in the bulk of a monomer B. This procedure was used for the preparation of various diblock copolymers of the AB type, where A is poly(tetrahydrofuran),²⁴⁶ ϵ -caprolactone,³³² vinyl ethers,²³³ norbornene or cyclopentadiene,²⁴⁹ as well as bicyclic alkenes such as bicyclo[2.2.1]heptene and bicyclo[2.2.1]heptadiene³³³ (cationic polymerisation), and B is polystyrene or poly(meth)acrylates (ATRP process).

VII. Three-dimensional 'living'-chain radical polymerisation

Polyfunctional unsaturated oligomers are compounds the molecules of which contain more than one double bond (glycol dimethacrylates, divinylbenzene, oligoester acrylates,^{335–338} oligoester maleates,³³⁹ *etc.*). Polymerisation of these compounds results in the formation of polymer networks (three-dimensional structures). Unlike linear polymerisation of conventional vinyl monomers, three-dimensional radical polymerisation proceeds according to a specific (the so-called microheterogeneous) mechanism^{336, 337} to give a specific type of topological and supramolecular (morphological) structure of the polymeric product. A salient feature of the topological structure of the polymer is that a large number of small rings is formed in the polymer network.^{144–146} These rings play the role of defects in the continuous network. A peculiarity of the morphology is that a 'grain' structure is formed in the polymer and the inter-'grain' spacings are considered as defects of the supramolecular structure.

The appearance and development of topological and morphological defects during three-dimensional radical polymerisation is due to the chain character of the polymerisation process.^{336, 337} That is, the chains initiated upon decomposition of the initiator rapidly (nearly instantaneously in the time scale of complete conversion) grow until the final length and undergo termination. The reaction system built of branched, cross-linked and aggregated polymer chains is thermodynamically and kinetically unstable in the bulk of the initial oligomer. Because of this, microphase separation occurs in the system, enhanced by a local gel effect. Eventually, this is the reason for the formation of defects, which affects physicomechanical characteristics of this type of polymer and materials based on them.

Since unsaturated oligomers have found wide and technologically important use,^{335–339} investigators are in continuous search for the ways of eliminating the reasons for the formation of defects during their polymerisation. In this regard, 'living' chains play a special role. Actually, transformation of a conventional three-dimensional chain polymerisation into 'living' chain polymer-

isation makes the process stepwise, which is typical of such well-known oligomers as epoxides, urethanes and polycondensation resins. A small distinction between 'living'-chain polymerisation and stepwise process is only that each initiation act causes the propagation of growing polymer chains by several monomer units rather than one unit. Thus, the increment value for stepwise 'living' radical polymerisation exceeds unity (one monomer unit), which makes it possible to call this process a pseudostepwise one. In this case, the reasons for intense formation of defects, inherent in three-dimensional radical polymerisation, are eliminated.^{336, 337}

Only a few studies on three-dimensional 'living'-chain radical polymerisation have been reported to date.^{72, 143, 340–343}

Ide and Fukuda^{72, 340} studied three-dimensional 'living' radical copolymerisation of styrene with 4,4'-divinylbiphenyl at 398 K in the presence of alkoxyamine synthesised from styrene and a TEMPO-like nitroxide. They determined the copolymerisation constants including that of styrene with 'pendent' double bonds of 4,4'-divinylbiphenyl, $r_p = k_{11}/k_{1p} = 1.0 \pm 0.1$ (the subscripts 'l' and 'p' correspond to styrene and divinyl oligomer, respectively). Since $r_1 = k_{11}/k_{12} = 0.38$, it was concluded that intense cyclisation on 'pendent' bonds, inherent in conventional radical chain polymerisation in this system, ceases nearly completely upon transformation of the process into 'living' polymerisation. It was also found that the end product, a cross-linked polystyrene (or a polystyrene network), was almost free from small-cycle topological defects.

A comparative study of the properties of polystyrenes cross-linked with 4,4'-divinylbiphenyl synthesised using conventional radical polymerisation (without TEMPO) and 'living' radical polymerisation (in the presence of TEMPO) has been reported.³⁴⁰ Specimens of identical composition prepared in the presence and in the absence of TEMPO possessed substantially different properties. These differences were interpreted in terms of the microheterogeneous model.³⁴⁰ The specimens synthesised by 'living'-chain polymerisation were identified as 'homogeneous'. They were characterised by nearly random distribution of cross-link points of the polymer network in the bulk of the copolymer. The specimens prepared in the absence of TEMPO were identified as 'microheterogeneous'. Their structure comprised a loose network built of highly cross-linked microgel aggregates. It was also found that, for the same concentration of cross-link points of the polymer network per unit volume, 'homogeneous' specimens had appreciably larger modulus of elasticity and greater swelling and, hence, longer fragments between the cross-link points of the polymer network (calculations by the Flory–Renner method) than 'microheterogeneous' specimens.

'Living' three-dimensional radical homopolymerisation and copolymerisation of diethyleneglycol dimethacrylate with different monomers and oligomers in the presence of *p*-xylylenebis(*N,N*-diethyl dithiocarbamate), which undergoes reversible dissociation upon photoirradiation ($\lambda = 365$ nm), has been studied.^{341–343} Temperature and frequency dependences of the modulus of elasticity and the loss factor $\tan \delta$, as well as the spectra of relaxation times and thermal characteristics of the homo- and copolymers were measured using dynamic mechanical analysis. Judging from the pattern of the distribution of relaxation times, it was concluded that microheterogeneity in the specimens increases as the density of the three-dimensional polymer network increases.

However, it is impossible to evaluate the extent to which the defectiveness of the specimens prepared by 'living' polymerisation decreases using the results obtained in these studies. An indirect confirmation of the efficiency of 'living'-chain polymerisation can be obtained from the results of ESR measurements of the concentrations of stabilised methacrylate radicals (chain carriers). According to ESR data, the concentration of chain carrier radicals in the specimens of highly cross-linked methacrylates is low, while specimens prepared by conventional radical polymerisation are characterised by high concentrations of methacrylate radicals. Moreover, these radicals do not recombine at room temperature over a long time (days and even months). Such a high stability of

methacrylate radicals is due to inhomogeneous distribution of the cross-link points of the polymer network in the bulk of the material and to the presence of microscopic domains with extremely dense polymer network in which stabilisation ('freezing') of chain carrier radicals occurs.^{336, 337, 344}

Three-dimensional radical copolymerisation of styrene with dimethacrylates in the presence of alkoxyamines was also studied.¹⁴³ It was established that the process under study was 'living'-chain polymerisation and specimens were synthesised for studying their microheterogeneities using the known procedure^{336, 337} and for measuring their physicochemical characteristics. It is believed that further comparison of these polymers with related materials obtained by conventional radical polymerisation will make it possible to solve the problem of the efficiency of three-dimensional 'living'-chain polymerisation of unsaturated oligomers.

VIII. Other agents for 'living' radical polymerisation

Most of the studies discussed in the previous Sections have been devoted to two (the main, in our opinion) investigation lines in the area of 'living' radical polymerisation. These are implementation of 'living'-chain polymerisation in the presence of (i) alkoxyamines (or stable nitroxyl radicals introduced into the polymerisation system in order to synthesise alkoxyamines *in situ*) and (ii) halide transition-metal complexes with organic ligands (or their components for the *in situ* synthesis). The choice of the investigation lines to be reviewed was dictated by two reasons, namely, the number of studies reported to date and, which is more important, the reliability of experimental results (all the data mentioned above were repeatedly reproduced by several independent research groups). This made it possible to give reliable formulations of the main kinetic features and the mechanism of the polymerisation processes under study. However, the list of studies carried out in these two investigation lines is far from being exhaustive. Below, we will outline some other lines of scientific exploration in the area of 'living' radical polymerisation.

Currently, studies of 'living' radical polymerisation have been carried out for a wide range of compounds capable of forming reversible adducts with labile bonds (e.g., C–S,^{345–348} C–Co,^{10, 349} C–Al^{350–352} and C–X (X = Cl, Br, I)^{313, 353–356} bonds) upon reactions with growing polymer chains.

Compounds with the C–S and C–X bonds were called iniferters, since they simultaneously act as the chain *initiators*, *transfer* agents and *terminators*. Thermal and photo-iniferters are known; their studies began in the 1980s.³⁵⁷

In writing the review 'living' radical polymerisation in the presence of iniferters was deliberately excluded from consideration. The development of this investigation line is associated with the studies by Otsu (Japan) who seems to be the pioneer of this area. Our decision was due to the fact that a comprehensive review covering the problem was published in 1998.³⁵⁸ All classes of iniferters were considered which were found to be the most efficient agents for 'living' polymerisation. The review concerns mono-, di-, tetra- and polyfunctional iniferters which reversibly dissociate being exposed to light (photo-active agents) or on heating, as well as monomeric, polymeric or microdisperse (microgel) iniferters used for the synthesis of monofunctional, telechelic or polyfunctional polymers, block and graft copolymers, branched (dendritic), star and cross-linked polymers. Thermally active iniferters were considered taking phenylazotriphenylmethane and tetraphenylethane derivatives as examples. The group of photo-active iniferters was represented by organosulfur compounds. Mention was made that compounds with the *N,N*-diethyldithiocarbamoyl groups were found to be the most efficient.³⁵⁹

The use of macrocyclic cobalt compounds (MCCC) appeared to be quite efficient for performing a 'living' radical polymerisation of acrylic monomers. This procedure was used for the synthesis of, e.g., well-defined poly(methyl acrylates) with

$M_n \approx 50\,000$ and $M_w/M_n = 1.1$.³⁴⁹ It was found that the mechanism of the action of MCCC is essentially different from that of mixed-valence metal compounds (see Section VI) since cobalt is not involved in the redox reactions during reversible formation and decomposition of the labile adducts of MCCC with growing polymer chains.

Detailed study of porphyrin-based MCCC showed that the active intermediate R—CoPorph formed upon trapping by cobalt porphyrin complexes can decompose in different ways depending on the type of trapped radical and reaction conditions. Possible pathways of the decomposition are three catalytic reactions described in a monograph¹⁰ (see also Refs 6–9 and 11–33).

Here, CoPorph is a cobalt porphyrin (phthalocyanine, or gly-oxime) complex; R'_n , R'_m and R'_l are radicals with the degree of polymerisation equal to n , m and l , respectively; M_m is monomer, $P_n(=)$ is macromolecule with the double bond in the end group, $[R_n \dots \text{CoPorph}]$, $[R_{n+1} \dots \text{CoPorph}]$ are reactive intermediates with the C—Co bond and $[\text{HCoPorph}]$ is porphyrin cobalt hydride.

Reactions (30)–(32) were called catalytic chain transfer, catalytic inhibition and reversible inhibition reactions. The last-named reaction was observed in the polymerisation of acrylates; however, the process showed some but not all features of 'living' polymerisation, apparently because it was accompanied by side reactions (30) and (31). More recently,³⁴⁹ suppression of side reactions by introducing axial ligands into CoPorph was reported by researchers from the United States.

Porphyrins and related ligands seem to be of limited use in the polymerisation of acrylates only. At least, our studies showed that effective control of chain propagation can be achieved only in this case.

Vigorous catalytic chain transfer reactions were observed in the case of polymerisation of MMA and styrene. Using this reaction, one can obtain oligomers up to a dimer (at CoPorph concentrations of $\sim 10^{-2}$ mol litre⁻¹). At first glance, introduction of axial ligands into CoPorph could promote transformation of this reaction into reversible inhibition. However, polymerisation of both MMA and styrene in the presence of CoPorph with axial ligands (quinoline, pyridine, etc.) revealed the catalytic inhibition reaction. The nature of the radical seems to play the key role in the reactions with CoPorph and related compounds, so that only the nature of the polymer radical dictates which of reactions (30)–(32) will actually occur.

In conclusion, mention may be made that studies concerned with purely technological problems, except for a few references in the Sections concerning emulsion, suspension and solution polymerisation, have not been covered in this review.

VI. The nature of the effect of mechanochemical activation on the reactivity of solids	446

Abstract. Data on the use of mechanochemical activation for the preparation of catalysts and supports are generalised. The effect of mechanochemical activation on the catalytic properties of various systems is noted. Catalytic reactions occurring under conditions of mechanochemical activation are discussed. The hypotheses concerning the nature of the effect of mechanochemical activation on the reactivity (including catalytic properties) are considered. The bibliography includes 197 references.

I. Introduction

An interesting, though, in our view, insufficiently studied problem is the application of mechanochemistry to heterogeneous catalysis. In both these fields, investigators are still on the way to creating general theories which would allow prediction of the behaviour of solids in various chemical and catalytic processes. In mechanochemistry as well as in catalysis, much is dependent on the solution of the problem of revealing catalytically active and reactive centres. For this reason, studies carried out at the borderline of the two sciences can favour to a considerable extent their mutual enrichment.

The development of mechanochemistry has begun with studies of grinding processes. It was found that grinding changes not only the sizes of particles of a material, but also their physicochemical properties. This provided the ground for introducing the term 'mechanochemical activation' (MCA). Grinding of substances is widely used in the chemical industry, including preparation of catalysts. The processes occurring under mechanical treatment of solids are described in sufficient detail in a number of monographs and reviews,^{1–5} and we will not dwell upon them. Let us only note the consequences of mechanochemical treatment on catalytic properties of solids or on the synthesis of catalytic systems.

Physicochemical changes resulting from MCA are the consequence of relaxation of the field of stresses in a solid after

mechanical impact on it. In all cases, irrespective of the relaxation mode, changes in the thermodynamic potentials of compounds under activation occur. The physicochemical properties of substances are related to the free energy G , for example,

$$\Delta G = -RT \ln \frac{k_2}{k_1},$$

$$\Delta G = RT \ln \frac{c}{c_\infty},$$

$$\Delta G = RT \ln \frac{p}{p_\infty},$$

$$\Delta G = \frac{-\lambda \Delta T}{T_p},$$

where k_1 and k_2 are the rate constants of forward and reverse reactions, c and c_∞ are the current and equilibrium solubilities, p and p_∞ are the current and equilibrium vapour pressures, λ and T_p are the heat and temperature of a phase transition, respectively. The free energy in turn depends on the sizes of particles of a compound and the presence of defects in it.

$$\Delta G = 2\sigma V \left(\frac{1}{r_1} - \frac{1}{r_2} \right),$$

where σ is the surface tension, V is the molar volume, r_1 and r_2 are the radii of the particles of fine and coarse fractions, respectively;

$$\Delta G = -kT \ln W,$$

where k is the Boltzmann constant, W is the thermodynamic probability equal to the possible modes of the distribution of defects in the lattice. It should be noted that the symbols r_1 and r_2 refer not only to the real physical size of particles but also to the sizes of ordered areas between the extended defects.⁵

The relaxation channel of the stress field related to the formation of fresh surface was studied most thoroughly. Many studies were devoted to the investigation of the kinetics of this process. Both the simplest regularities of coarse grinding (see Khodakov's monograph⁶) and more advanced models of fine grinding were considered which take into account the pulsed character of the mechanical impact and the effect of mechanical activation on the formation of fresh surface.^{7–11} These models have a formal character and are far from being capable of describing all experimental results, particularly those derived from studies of compounds with anisotropic properties. Detailed investigation of the chemical properties of the fresh surface

showed^{2,5,12} that MCA of silicon, germanium, tin and magnesium oxides leads to the formation of different centres on their surfaces which have predominantly a radical nature. Interactions of these centres with various gases were described. The data obtained may be used for the prediction of processes occurring in the synthesis of catalytic systems and modification of their surfaces.

Yet another general channel of relaxation of the stress field is the formation of defects of the crystal structure and the exit of these defects onto the surface of crystallites. Numerous studies systematised in monographs^{1,3,4} showed that it was the formation of defects rather than fresh surface, that was the cause of higher, MCA-induced reactivities and catalytic activities of compounds. There is a suggestion (based on indirect data) that it is the defects of the crystal structure that are the catalytically active centres. In our opinion, in order to elucidate the effect of MCA on the catalytic activity, it is necessary to relate physicochemical features of defects to the nature of the catalysis considered as a sequence of chemical transformations of the catalyst and reagents.

The process of formation of defects has a thermodynamic nature: the system tends to minimise its free energy, while the localisation of the excess energy on defects is thermodynamically more advantageous than the regular distribution of elastic stresses over all the bonds of the crystal lattice. The appearance of defects is, as a rule, accompanied by changes in the electronic properties of activated compounds. For example, electronic levels are formed in the forbidden bands, the forbidden bands become narrower, the conductivity electrons appear in semiconductors, and the electron-donor properties are enhanced in semiconductors and dielectrics. The electronic theory of catalysis considers the influence of all these changes on the catalytic properties.

These are the basic channels of relaxation of the field of stresses arising upon mechanical impact on solids. Other emissive phenomena also take place; however, their influence on the catalytic properties and peculiarities of the synthesis of catalysts is not very obvious, and we will consider them henceforth only where necessary.

Studies devoted to the investigation of the effect of mechanical treatment on catalysts may be divided into three groups. In the first group the MCA effect is used for the synthesis of catalytic systems: in the second group the effect of MCA on the catalytic properties of compounds is dealt with and in the third group catalytic reactions under MCA conditions are considered.

II. Synthesis of catalytic systems

The methods of mechanochemistry can be used for both synthesis of catalysts, supports and sorbents and control of their performance.

One of the first examples of the systematic and purposeful use of MCA for the preparation of catalysts is the preparation of a polymerisation catalyst based on titanium and aluminium chlorides. It was found that grinding of titanium(III) chloride in a ball mill increases its catalytic activity in the propylene polymerisation.¹³ It turned out that in this case the α - and γ -TiCl₃ phases pass to the δ -modification, which is more active in this reaction.¹⁴ Aluminium–titanium chloride catalysts are prepared by joint grinding of either metallic aluminium and TiCl₄¹⁵ phases or titanium and aluminium chlorides,^{16,17} or the chlorides with the addition of trialkylaluminium.¹⁸ In all probability, this technological technique was discovered purely empirically, and its scientific substantiation was started only after the publication of the corresponding patents.^{15–18} The processes occurring during mechanical treatment of catalysts were described in Refs 19–21. Somewhat later, an analogous study of titanium–magnesium chloride catalysts was carried out.^{22–24} Summing up the results obtained, one can state that upon MCA of mixtures of TiCl₃ with AlCl₃ and TiCl₄ with MgCl₂ an interaction between the components takes place. In the former case, this leads to the formation of solid solutions with the structure of δ -TiCl₃, while in the latter case

titanium chloride is fixed on the surface of magnesium chloride. Discrepancy between some results should be noted: the catalyst prepared by joint activation of titanium and magnesium chlorides possesses high activity according to Kashiwa,²² while Zakharov *et al.*²⁴ found that it is not very active, although the conditions and duration of activation were similar in both studies.

Systematic studies on the application of MCA for the preparation of catalysts were carried out at the Ivanovo Institute of Chemical Technology. These studies were aimed at solving the problem of intensification of the interaction between solids and solutions containing other components of the catalysts. Mechanical treatment accelerated the interaction of iron, zinc and aluminium oxides with a solution of chromic acid.^{25–27} Upon treatment of aluminium oxide in an ammonium-carbonate solution of zinc,²⁸ of α - and γ -aluminium oxides²⁹ and of magnesium oxide³⁰ in an ammonium-carbonate solution of copper, sorption of ions from the solution onto the surface of the solid component was observed. This technological approach both favoured the interaction of components and allowed regulation of some operational properties of the catalysts: their catalytic activities, strength and mouldabilities. The activities of chromium catalyst in the methanol synthesis,²⁷ of complex oxide and magnesium–copper catalysts in the vapour conversion of CO,^{29,30} of aluminium–nickel catalyst in the vapour conversion of hydrocarbons³¹ increased. The enhancement of the strength of iron–chromium,²⁶ aluminium–copper–zinc–chromium²⁹ and aluminium–nickel³¹ catalysts, zinc–aluminium spinel and aluminium oxide used as supports^{28,29} was also observed. In addition, α -aluminium oxide acquired mouldability by the extrusion method, which allowed the preparation of granules of complex shape.³²

Studies aimed at the development of a sulfur sorbent were carried out at the same Institute. Dispersion of zinc oxide in solutions of carboxymethylcellulose and poly(vinyl alcohol) enhanced its mouldability by the extrusion method, increased its specific surface and sorption capacity with respect to sulfur-containing compounds.³³ An analogous effect was achieved upon dispersion of zinc oxide with aluminium oxide in an ammonium-carbonate solution.³⁴ According to Shirokov and Il'in,²⁸ the enhancement of the sorbent strength results from the hydration of the surface of aluminium oxide and formation of zinc aluminate, which plays the role of a binding agent. Treatment of zinc oxide in a planetary or vibratory mill led to an increase in its static and dynamic sulfur sorption capacity and enhancement of its cleavage strength and abrasion resistance.^{35,36} Based on these studies, a technology of production of a sulfur absorbent was developed.³⁷

The method of MCA was applied for the preparation of catalysts of deep oxidation used for the after-burning of flue gases. Studies by Bulgarian investigators were aimed at the enrichment of the surface of cobalt oxide with copper oxide owing to local overheating arising during MCA.^{38,39} Upon treatment of a mixture of cobalt and copper oxides, the copper oxide phase disappeared as a result of formation of a mixed oxide compound on the surface.³⁸ Comparison of different techniques of grinding of a mixture of oxides (in a planetary or vibratory mill, in a mechanical mortar) showed that the use of the vibratory mill is the most efficient.³⁹ Presumably, the copper ions are incorporated into the voids in the layer of the cobalt cations. An attempt was made to perform the mechanochemical synthesis of analogous systems using magnesium, zinc and manganese oxides⁴⁰ instead of copper oxide; however, these oxides did not interact in a vibratory mill. The cobalt–copper oxide catalysts prepared using MCA possessed higher activities in the CO oxidation and were more resistant to poisoning with sulfur dioxide^{38,39} than the catalysts obtained by conventional methods.

Massive copper and cobalt oxides are efficient catalysts of deep oxidation. However, practical application of these oxides is problematic because it is difficult to mould them. This problem may be solved by subjecting the oxides to a short-time MCA in a planetary mill before moulding.^{41–43} The authors relate the

positive effect to hydration of the surface of copper oxide upon interaction of a mechanically activated oxide with water^{41, 43} and to changes in the morphology of cobalt oxide particles.⁴¹

The use of MCA for the synthesis of lanthanum cobaltites and manganites proved to be successful.^{44, 45} Activation of mixtures of oxides and carbonates made it possible to reduce the temperature of formation of the corresponding perovskites by 250–300 K; the interaction at lower temperatures was more complete when the initial components were in the form of carbonates. As regards the specific surface and catalytic activity, the catalysts prepared using MCA were superior to the analogous systems obtained by traditional ceramic technology and were close to the catalysts prepared by the co-precipitation method; the advantage of the MCA consists in the absence of deleterious wastes.

The preparation of skeletal catalysts is very energy-consuming since the initial alloys of the corresponding metals with aluminium are obtained by the pyrometallurgical method. Besides, definite difficulties are associated with the completeness and rate of aluminium leaching. The use of MCA solves both these problems.

The beneficial influence of MCA on the properties of skeletal nickel was reported for the first time over four decades ago.⁴⁶ Treatment of an aluminium–nickel alloy in a vibratory mill increased the activity of the catalyst obtained after leaching in the reactions of cyclohexene hydrogenation and propan-2-ol dehydrogenation. Comparatively recently, methods were developed for the preparation of nickel–aluminium alloys by the so-called ‘mechanical alloying’, *i.e.* by mechanochemical activation of a mixture of powders of nickel and aluminium metals.^{47, 48} The use of ‘mechanical alloys’ makes it possible to increase the degree of aluminium leaching and to prepare Raney catalysts which are more active in the reactions of hydrogenation of phenylacetylene, potassium maleate and nitrobenzene.^{47, 49, 50} The skeletal catalysts prepared from the alloys obtained by the ‘mechanical alloying’ method may have a more complex composition and contain modifying additives.⁵¹ It should be noted that not any composition of the ‘mechanical alloys’ makes them advantageous. Thus the pyrometallurgical alloys containing > 80% of aluminium are better leached and ensure higher catalytic activity. The advantages of MCA are most clearly manifested in the regeneration of worked-out skeletal catalysts: its use for the preparation of ‘mechanical alloys’ makes it possible not only to restore the properties of skeletal nickel but also to achieve the activity several times higher than that before regeneration.⁵² The higher activity of the catalysts prepared from ‘mechanical alloys’ is possibly explained by the fact that after leaching nickel passes to a metastable state with the structure NiAl, whereas leaching of pyrometallurgical alloys leads to the formation of the face-centred cubic lattice.⁵³

The ‘mechanical alloying’ method was also used for the preparation of hydrides of intermetallic magnesium compounds.⁵⁴ The ‘mechanical alloys’ are hydrogenated more easily than the pyrometallurgical ones, and hydrogen present in the hydrides obtained is more mobile. Hydrides of magnesium intermetallics proved to be efficient hydrogenation catalysts.⁵⁵ Compared to conventional catalysts, their advantage is particularly noticeably manifested in the reactions of selective hydrogenation of alkynes and dienes to alkenes. Thus the hydride with composition Mg₂FeH₆ provides a nearly 100% selectivity of hydrogenation of butadiene to butenes,⁵⁶ while Mg₂CoH₅ ensures the 100% selectivity of hydrogenation of acetylene to ethylene.⁵⁷ It should be noted that such a high selectivity in these reactions is reached on none of the known traditional catalysts. Preparation of hydrides through the ‘mechanical alloying’ stage is a waste-free energy-saving method which was used for the synthesis of new catalytic systems, *e.g.*, Mg₂FeH₆, Mg₂CoH₅ and Mg₃CoH₅.

The application of MCA for the preparation of iron–potassium dehydrogenation catalysts is described in sufficient detail in the literature. These catalysts are traditionally obtained by mixing iron oxide with potassium carbonate and potassium silicate. Thermal treatment of the paste obtained in water vapour leads

to the formation of the active component, *viz.*, potassium ferrite. Pretreatment of iron oxide in a disintegrator makes it possible to reduce the temperature of its reaction with alkali metal carbonates, to increase the yields of the corresponding ferrites and the rates of their formation. Higher degrees of conversion of ethylbenzene to styrene and a higher selectivity of styrene formation are reached⁵⁸ on the catalysts obtained from iron oxide treated in a disintegrator. Both these parameters are improved as the specific energy of treatment is increased.^{59, 60} In addition, such catalysts are better mouldable and possess higher strength.⁵⁹ Upon treatment of a mixture of iron oxide and potassium carbonate in a planetary mill, potassium ferrite is formed directly in the drum.⁶¹ If dehydrogenation is performed with the catalyst obtained after thermal treatment of a mixture activated in water vapour, the process begins at 670 K, whereas on the initial catalysts it starts only at 800 K. The mechanically activated catalyst exhibits an increased activity until 880 K at which it drops to the activity level of the initial specimen, which is associated with the annealing of defects in the crystal structure.⁶¹

Numerous studies were devoted to the use of MCA for the preparation of alumina-based catalysts and supports. Shirasaki *et al.*⁶² showed that grinding of corundum in water facilitates its formation; analogous data were obtained later by Il'in *et al.*³² The mouldability of alumina increases after MCA of the initial aluminium hydroxide.⁶³ In this case the resulting alumina is not inferior in its strength and sorption properties to the oxide formed from precipitated aluminium hydroxide the production of which provides large volumes of wastes. The possibility of regulation of some operational properties of catalysts with the aid of MCA was noted.^{32, 62, 63}

The possibilities of the use of MCA for the preparation of alumina-based catalysts and supports based on aluminium oxide are described in more detail in a series of papers from the Institute of Catalysis of the Siberian Branch of the Russian Academy of Sciences. Transformations of aluminium hydroxide in the course of MCA and during subsequent treatments were studied in detail. Upon activation of hydrargillite, grinding of crystals, shift of hydroxylic packs, cleavage of crystals into plates and dehydration with formation of molecular water which remains in the bulk among activation products occur.^{64–66} Analogous processes also take place upon MCA of bayerite.⁶⁷ The maximum quantity of excess energy accumulated in hydrargillite is 33 kJ mol^{–1}. This value is reached at the thickness of plates commensurable with the size of the unit cell of hydrargillite;⁶⁸ in this state hydrargillite manifests its maximum chemical activity. In studies of thermal transformations of activated hydrargillite, a new state of alumina was revealed and denoted as π -Al₂O₃.^{69, 70} This is characterised by the presence of aluminium cations in the pentacoordinated state. The structure of this oxide was established, and it was found that π -Al₂O₃ is capable of dissociative chemisorption of ammonia.⁷¹ Thermal transformations of all aluminium hydroxides subjected to MCA proceed in the same manner:⁷²

where GG, BE and BA are hydrargillite, boehmite and bayerite, respectively; M_η is the spinel-like phase of alumina.

On the other hand, non-activated aluminium hydroxides are transformed into corundum each in its own mode which is more complex than that considered above. It should be noted that the temperature of phase transition of activated hydroxides into corundum is 200 K lower than that of non-activated ones.⁷²

Detailed investigation of the processes which occur during MCA of aluminium hydroxides has allowed the development of techniques for the preparation a wide range of alumina-based catalysts, supports and sorbents. Thus depending on conditions, hydration of activated hydrargillite and π -Al₂O₃ leads to the formation of bayerite or pseudoboehmite from which different

aluminas are formed after thermal treatment.⁷³ The mechanism of hydration of the hydrargillite and π - Al_2O_3 MCA products has been established.^{74, 75}

Methods for the preparation of hydroxyaluminates of a number of divalent metals on the basis of the products of MCA of aluminium hydroxides were developed. Interaction of activated hydroxides with solutions of magnesium and zinc salts or with zinc oxide leads to the formation of the corresponding hydroxyaluminates.^{76–78} Under the same conditions, π - Al_2O_3 also enters into analogous interactions.⁷⁷ Presumably, hydroxyaluminates are formed through the stage of intercalation of salts.^{77, 78}

Yet another field of application of activated aluminium hydroxides is the synthesis of various aluminosilicates. In the MCA of kaolinite, processes analogous to those revealed in the activation of hydrargillite occur, *viz.*, shift and turn of layers as well as dehydration with the formation of molecular water remaining within the compound's structure.⁷⁹ In contrast to MCA of hydrargillite, mechanical activation of kaolinite does not alter the pathways of its thermal transformations.⁸⁰ The initial stage of thermal treatment includes formation of metakaolinite containing pentacoordinated aluminium cations.^{70, 80}

Upon MCA of a mixture of hydrargillite and silica gel, hydrated aluminosilicate is formed^{81, 82} from which an aluminosilicate spinel is formed first upon heating and then mullite. A non-activated mixture undergoes transformations which differ in many aspects. By varying conditions of hydration and thermal treatment of activated mixtures of hydrargillite and silica gel, it is possible to obtain amorphous aluminosilicates, kaolinite, montmorillonite, aluminosilicate spinel of high purity and mullite with large specific surface and without admixtures of corundum and cristobalite.⁷³ Furthermore, zeolites of types A, X, Y were obtained,^{73, 83} and the possibility of synthesis of over 100 other zeolites is predicted,⁸⁴ *i.e.*, good prospects are open for the development of little-waste methods for the preparation of zeolites.

Some aluminosilicates were synthesised using the so-called 'soft mechanochemical synthesis',⁸⁵ which involves MCA of hydrated or moist mixtures. It is suggested that in this case conditions are close to hydrothermal ones. The use of this method allows preparation of mullite without admixtures of other phases, a number of other aluminosilicates, as well as aluminates, titanates, zirconates, tungstates and vanadates of alkaline-earth metals. According to Avvakumov,⁸⁵ the method of 'soft mechanochemical synthesis' may be used for performing acid–base reactions proceeding with liberation of water.

New methods, including MCA, were developed for the synthesis of heteropolyacids (HPA) and catalysts based on them. A broad spectrum of HPA was obtained using mechanical activation of molybdenum and tungsten oxides and their mixtures with vanadium, silicon, aluminium and iron oxides. The most successful proved to be the use of MCA for the preparation of phosphomolybdic and phosphomolybdenovanadic HPA,^{86–89} in particular high-purity $\text{H}_6\text{P}_2\text{Mo}_{18}\text{O}_{62}$ and $\text{H}_{3+n}\text{PMo}_{12-n}\text{V}_n\text{O}_{40}$ with $n = 0–4$. The process is characterised by the total absence of deleterious wastes and flue gases, the time of synthesis is substantially reduced, energy consumption is decreased, losses of expensive raw materials are precluded, fire-hazard stages are absent, while the yield of HPA reaches the quantitative level.

When developing methods for the preparation of HPA, we revealed new oxide compounds of molybdenum and vanadium in the system $\text{V}_2\text{O}_5\text{--}n\text{MoO}_3$.⁹⁰ It is their formation that is the reason for such a smooth synthesis of HPA. Reactions of compounds of the system $\text{V}_2\text{O}_5\text{--}n\text{MoO}_3$ with phosphoric acid and its salts under conditions of MCA lead to the formation of HPA with composition $\text{H}_{3+n}\text{PMo}_{12-n}\text{V}_n\text{O}_{40}$, where $n \geq 3$, or their salts.⁸⁷ Apparently, an important role in these reactions is played by water of crystallisation since activation under the same conditions of a mixture containing anhydrous phosphates does not lead to the formation of HPA salts.

A waste-free method for the preparation of a catalyst for L-sorbose acetonation (one of the stages in the synthesis of vitamin C) was developed.⁸⁹ The catalyst is a mixture of phosphomolybdic heteropolyacids and provides higher yields of isopropylidene-L-sorbose than does oleum, which is normally used for this purpose, and precludes harmful acidic wastes. Mechanochemical activation is also used for the regeneration of the catalyst after isolation of the target product.⁸⁹

The application of MCA for the synthesis of nickel catalysts of decomposition of hydrocarbons proved to be rather effective. The reaction proceeds with the elimination of hydrogen and formation of filamentous carbon which is a material possessing specific, and in a number of cases, unique, physicochemical properties. Catalysts for these reactions are traditionally obtained by co-precipitation from solutions of nickel, copper and aluminium salts. MCA of nickel oxide or its mixtures with other oxides together with compounds of lamellar structure (magnesium and aluminium hydroxides, graphite) produces more efficient catalysts of decomposition of hydrocarbons than those obtained by co-precipitation.^{91–93} They operate for a long time without losing their activities, which provides higher degrees of transformation, *e.g.*, of methane. This makes cost-effective the production of hydrogen from hydrocarbons. The carbonaceous material formed can be used as a sorbent, a support for catalysts and as a catalyst.

Besides synthetic purposes, MCA is also used for improving certain operational characteristics of catalysts and supports. Thus treatment of a suspension of zeolite in a bead mill in the presence of surfactants made it possible to increase its strength.⁹⁴ Treatment of aluminium hydroxide in a vibratory mill facilitates its moulding and enhances the strength of granules of the final product.⁶³ As noted above, analogous results were obtained upon treatment of iron–chromium²⁶ and aluminium–zinc²⁸ catalysts, catalyst of vapour conversion of CO ,²⁹ aluminium, zinc, copper and cobalt oxides.^{34, 35, 41–45} The reasons for the increase in the strength of a phosphate catalyst of dehydrogenation resulting from the application of MCA were considered by Molchanov and Goidin. In the non-activated catalyst processes of baking, phase transition and recrystallisation of calcium phosphate occur⁹⁵ at virtually the same temperature. The last two processes induce mechanical stresses in the catalyst pellets which decrease their strength. Prior MCA reduces the phase transition temperature by 300–350 K and favours the completion of recrystallisation before the beginning of baking, which enhances substantially the strength of pellets.

Modification can also occur as a result of changes in sorption properties of a specimen due to grafting of various groups, formation of fresh surface and outcrops of defects to the surface. Mechanochemical grafting is used for the preparation of fillers for rubbers and plastics (see, *e.g.*, Ref. 96). We failed to find in the literature any examples of this kind of modification of surfaces of catalysts, supports or sorbents, though, in our opinion, this method is promising. However, the effect of formation of fresh surface upon MCA is used for the preparation of catalysts.^{25–30} The influence of defects in the crystal structure on properties of the surface was also revealed.^{97, 98} Mechanochemical activation of a number of oxide supports leads not only to the increase in their sorption capacity but also to a substantial decrease in the temperature of reduction of supported salts to metals and also to a higher catalytic activity of supported nickel in the ethylene hydrogenation. Data on the use of MCA for the preparation of catalysts are presented in Table 1.

We made an attempt to generalise the regularities of mechanochemical synthesis, *i.e.*, the interaction of compounds directly in the mill without any additional treatment. The mechanochemical synthesis occurs in the cases where the reagents have similar crystal structures; in the acid–base interaction, where one of the reagents is a strong acid or base (such a process is considered in sufficient detail by Avvakumov⁸⁵); in the formation of pseudomelts where an intense mechanical stirring can increase the

Table 1. Application of MCA for the preparation of catalysts.

Initial products	Final product obtained or the result	Apparatus for MCA	Additional effects	Ref.
α -TiCl ₃ , γ -TiCl ₃	δ -TiCl ₃	BM	increased activity in the propylene polymerisation	13, 14
TiCl ₃ + AlCl ₃ + R ₃ Al	δ -TiCl ₃	"	—	18
TiCl ₃ + AlCl ₃	solid solution with δ -TiCl ₃ structure	"	increased activity in the ethylene polymerisation	19–21
TiCl ₄ + MgCl ₂	fixation of TiCl ₄ on the MgCl ₂ surface	"	the same	22–24
α -Fe ₂ O ₃ or α -Al ₂ O ₃ + H ₂ CrO ₄ , Fe ₂ O ₃ + H ₂ CrO ₄	catalysts of vapour conversion of CO	BdM	increased activity, enhanced strength	25, 26
ZnO + H ₂ CrO ₄	catalyst of methanol synthesis	—	increased activity	27
Al ₂ O ₃ + Zn ²⁺ in ACS	sorption of Zn ²⁺ , formation of ZnAl ₂ O ₄	BdM	increased strength of the catalyst for desulfurisation	28
H ₂ CrO ₄ + Al(OH) ₃ + ZnO + + CuCO ₃ ·Cu(OH) ₂	catalyst of vapour conversion of CO	—	increased activity	29
MgO + Cu ²⁺ in ACS	the same	—	the same	30
CuAl ₂ O ₄ + ethanol or acetone solution	improved quality of binding agent	—	Enhanced strength	31
α -Al ₂ O ₃	possibility of moulding by extrusion	BM, VM	—	32
ZnO + CMC (or PVA or PEG)	sulfur adsorbent	USD	improved capability for moulding, increased sulfur capacity	33, 37
ZnO + Al ₂ O ₃ in ACS	the same	—	enhanced strength, increased sulfur capacity	34, 35
ZnO	"	VM, PM	the same	36
CoO + CuO	catalyst of after-burning	the same	increased activity in CO oxidation, resistance to poisoning with SO ₂	38, 39
CuO, Co ₃ O ₄	improved capacity for moulding by extrusion	PM	increased CuO activity in butane oxidation	41–43
La ₂ O ₃ + Co ₃ O ₄ , La ₂ (CO ₃) ₃ + CoCO ₃ ·Co(OH) ₂	LaCoO ₃ (catalyst of after-burning of flue gases)	"	—	44
La ₂ O ₃ + Mn ₂ O ₃ (or MnO ₂ or Mn ₃ O ₄)	LaMnO ₃ (catalyst of after-burning of flue gases)	"	—	45
Al–Ni (alloy)	Ra/Ni	VM	increased activity in cyclohexene hydrogenation	46
Ni + Al	alloys, precursors of Ra/Ni	PM	increased activity in hydrogenation reaction	47–50
Ni + Al + M (M = V, Cr, Mn, Fe, Co, Mo, W)	modified Raney nickel	"	the same	51
Ra/Ni (used) + Al	Ra/Ni	"	"	52
Mg + Ni (or Fe or Co)	alloys, precursors of intermetallic hydrides	"	high selectivity of hydrogenation of dienes and acetylenes to alkenes	55–57
M ₂ CO ₃ + Fe ₂ O ₃ (M = K, Rb, Cs)	catalyst of ethylbenzene dehydrogenation	DS	Increased activity, enhanced strength	58–60
Aluminium hydroxides	various crystalline modifications of Al ₂ O ₃	PM	—	64–75
	formation of hydroxyaluminates through intercalation of Mg and Zn salts	"	—	76–78
Aluminium hydroxides + SiO ₂	aluminosilicates, zeolites	"		73, 81–85
MoO ₃ or its mixture with V ₂ O ₅	heteropolyacids	"	total absence of waste	86–89
NiO + Al(OH) ₃ or CuO + Mg(OH) ₂	catalysts of decomposition of hydrocarbons to C and H ₂	"	high activity and stability	91–93
Ca–Cr–Ni-phosphate catalyst IM-2204	regulation of the processes of crystallisation and baking	"	enhanced strength	95
ZnO, TiO ₂ , Al ₂ O ₃ , ZnAl ₂ O ₄	changes in sorption properties	"	decrease of the temperature of reduction of deposited salts, increased activity of supported metals	97, 98

Note. Abbreviations: ACS, ammonium-carbonate solution; CMC, carboxymethylcellulose; PVA, poly(vinyl alcohol); PEG, poly(ethylene glycol); Ra/Ni, Raney nickel; BM, ball mill; BdM, bead mill; UD, ultrasonic disintegrator; VM, vibratory mill; PM, planetary mill; DS, disintegrator.

mobilities of molecules of at least one of the reagents to the level of their mobilities in a melt.

But even if no reactions occur in the mill, MCA all the same facilitates substantially other stages of the catalyst's preparation. This is determined by changes in the thermodynamic potentials due to the formation of defects, changes in electronic properties, appearance of fresh surface, *etc.* The most substantial effect is

observed for high degrees of homogenisation of mixtures of reagents, which facilitates appreciably mutual diffusion.

The interaction of components in the MCA is determined by different properties of solids, such as chemical compositions and reactivities, hardness and fragility, crystal structure and bond strength, melting temperatures and others. For this reason, there is no integral theory or any versatile reference points so far which

would make it possible to predict the result of joint MCA of at least binary systems. So far one can be satisfied solely with some specific speculations.

In our opinion, a kind of activated state arises in the MCA of mixtures of compounds. Relaxation after discontinuing of load results either in the formation of new compounds or in the return to the initial compounds which are however characterised by higher dispersion and excess energy. Naturally, the former is only possible in the absence of thermodynamic restrictions for the reaction of components. But even if the formation of new compounds is possible in principle, one cannot be sure that this possibility is realised under the MCA conditions. A substantial importance has the transition of at least one of the compounds subjected to activation to the viscous-fluid state. Here, it is possible to draw an analogy with the processes of adhesion of liquids or melts or mixing of liquids where several interacting components pass to the viscous-fluid state. In this state, the number and area of contacts between reagents increase substantially, and in the case of chemical affinity, interaction between them becomes possible. If we continue to draw an analogy with the processes of adhesion, then the phase passing to the viscous-fluid state should be called adhesive, while the other phases should be termed substrates. Correct methods for the calculation or determination of thermodynamic potentials in the adhesion or mixing of melts could also be used for predicting the possibility of the occurrence of mechanochemical synthesis. In particular, one can use the known expressions for the adhesion and cohesion works (W_{ad} and W_c , respectively), *i.e.*, the energies that should be spent for the separation of the adhesive and substrate over the interface or for the separation of components of the adhesive to an infinite distance.

$$W_{ad} = \gamma(1 + \cos \theta),$$

$$W_k = 2\gamma,$$

where γ is the surface energy of adhesive (in our case, for the phase which passed to the viscous-fluid state), θ is the angle of wetting.

In the mechanochemical synthesis, the following processes presumably take place successively. First, one or several components pass to the viscous-fluid state. As this process is not momentary, grinding and activation of other components occur simultaneously. After formation of the viscous-fluid phase its adhesion on the surface of other components occurs. If $W_{ad} > W_c$, total wetting takes place. This condition is always fulfilled in the case of formation of chemical bonds between the adhesive and substrate. As a rule, the adhesion forces are stronger than the cohesion forces, *i.e.*, than the forces of intermolecular attachment in the viscous-fluid phase. Because of this, relaxation of stresses in repeated loading of substrate–adhesive particles is manifested in the cleavage of bonds inside the viscous-fluid phase rather than in the separation over the interface. The separated part of the adhesive wets the free surface of the substrate which is formed as a result of grinding. Mechanical loading of the substrate phase with the fixed adhesive should lead to phenomena analogous to the effect of adsorption-induced dispersion since the surface energy of the interface (an analogue of the surface tension for solids) tends to a minimum upon complete wetting. Intensification of the dispersion processes leads to an increase in the surface of wetting. Atoms and molecules belonging to the interface possess high mobilities due to both the viscous-fluid state and the external mechanical impact. This favours an increase in the rates of mutual diffusion. All the above-mentioned factors result in the formation in MCA of lamellar structures either at the molecular level, as in the system V_2O_5 – MoO_3 , or at the micro-level, as in the mechanical alloying of metals⁹⁹ or upon application of metals onto solid supports by means of MCA of their mixtures^{100, 101} (see below).

If complete wetting does not occur, *i.e.*, none of the interacting phases passes to the viscous-fluid state, the phases undergone activation are dispersed and their particles several nanometres in

size prove to be homogeneously mixed, which facilitates substantially the diffusive transfer which is necessary for the interaction of components during subsequent treatments of activated mixtures. Owing to the changes in thermodynamic potentials, the reactivities of components increase in both cases.

Thus, MCA can successfully be used for the direct synthesis of catalytic systems, for facilitating the interaction of components during further treatments (calcination, hydration, sorption, *etc.*) and for the improvement of performances of the products obtained (their mouldability, strength, sorption and catalytic properties). The most important advantage of the mechanochemical methods is the possibility to develop wasteless technologies of the production of catalysts based on them. The importance of the development of wasteless methods is determined by the fact that at present the world production of catalysts is estimated at hundreds of thousands of tons. A considerable part of catalysts is obtained using precipitation methods, which are accompanied by large volumes of wastes. Over half the elements of the Periodic system, including highly toxic ones, are used in the production of catalysts and supports. It may be said without exaggeration that the preparation of catalysts, supports for them and adsorbents are environmentally most deleterious industries. The application of wasteless methods can not only improve the environmental situation in areas of production of catalysts but also decrease their cost owing to lower expenses for neutralisation of wastes. Examples of successful replacement of precipitation methods by wasteless methods based on the use of MCA are the preparation of supports and catalysts based of alumina^{64–84} and the synthesis of catalysts of decomposition of hydrocarbons.^{91–93} The use of wasteless methods of HPA synthesis is environmentally friendly.^{86–89}

Yet another advantage of mechanochemical methods is the decrease in energy consumption. This is achieved owing to the reduction of temperature and time of interaction of components. Thus the preparation of aluminides of several metals, which are precursors of skeletal catalysts, by pyrometallurgical methods requires heating to melting temperatures and in some cases multiple alternations of fusion and grinding are needed. Alloying under the MCA conditions is completed within a few minutes, and in this case the possibilities of variation of the composition of alloys are substantially extended.^{47–53} The same advantages are realised in the preparation of hydrides of intermetallic compounds from ‘mechanical alloys’.^{54–57} Heteropolyacids are formed by reactions of metal oxides with phosphoric acid at its boiling temperature (~ 373 K) for several hours, whereas the application of MCA makes it possible to decrease the temperature to 323–343 K and the reaction time to a few minutes (some HPA can be prepared at room temperature within a few seconds).^{86–89} There are numerous other examples of a substantial decrease in the temperatures of interaction of components and phase transitions. The reduction of energy consumption improves indirectly the environmental situation since energy production is one of the most deleterious for the environment.

With the use of MCA novel catalysts have been synthesised, including those never isolated earlier in the form of individual chemical compounds. Often such systems possessing unique catalytic and chemical properties cannot be synthesised by other methods. This is exemplified in the preparation of alumina π - Al_2O_3 ^{69, 70} and Raney nickel with the structure of the type $NiAl$,⁵³ as well as in the synthesis of hitherto unknown hydrides of magnesium intermetallides⁹⁹ and new compounds in the system V_2O_5 – MoO_3 .⁹⁰ The application of new catalytic systems prepared using MCA makes it possible to increase the efficiency of catalytic processes, which is often difficult or impossible to achieve by conventional methods.

Broad possibilities are opened by the use of MCA for the regulation of processes which occur in the course of formation of catalytic systems (crystallisation, baking, phase transitions, *etc.*). The temperatures of all these processes and their rates can be varied with the aid of MCA. This makes it possible to govern the

strength, parameters of a porous structure and the specific surface area of catalysts.

Mechanochemical modification of catalysts and supports is not described in sufficient detail in the literature. It is, however, clear that MCA increases the strength of specimens, improves their mouldability and regulates sorption properties. It should be noted that structures formed upon mechanochemical synthesis are non-equilibrium and possess increased reactivities, including those in the target reactions. This phenomenon will be considered in more detail below.

However, a broad range of issues has not been duly described as yet. Thus the possibilities of the use of short-living active sites for the modification of catalytic and sorption systems were not virtually studied. Few studies were devoted to the methods of mechanochemical grafting of various functional groups onto the surface of solids to be used in processes of sorption and catalysis. Potential possibilities of the methods of mechanochemistry are tremendous, as regards the search for novel catalytic systems hitherto unknown as chemical compounds. The list of similar topics could be continued but even those cited above are sufficient for becoming aware of the advisability of intensification of studies in this field.

III. Effect of mechanochemical activation on catalytic properties of compounds

1. Metal catalysts

Apparently, the effect of mechanical impact on catalytic properties of compounds was first revealed by Eckell¹⁰² who has compared the activity of nickel foil in the ethylene hydrogenation before and after rolling. The rolling led to a substantial increase in the nickel activity which decreased after annealing the foil at 473–573 K. Analogous results were obtained in studies of formic acid decomposition.^{103, 104} Correlation of the catalytic activities of the specimens studied^{102, 103} with the physical properties of mechanically treated metals made it possible to suggest that the catalytically active centres are dislocations.¹⁰⁵ This suggestion was confirmed later in numerous examples by Japanese investigators. It was shown^{106–112} that cold treatment of metals (twisting, rolling, moulding) increased the catalytic activity of copper, nickel, silver, gold and platinum in decomposition reactions of diazonium chloride, formic acid and hydrogen peroxide, dehydrogenation of ethanol, hydrogenation of cinnamic acid, oxidation of ethanol and *ortho*–*para* conversion of hydrogen. It was concluded that both dislocations and point defects are responsible for the increase in catalytic activity. Thermal annealing led in all cases to a decrease in activity to the level of activity of untreated metals; and properties of catalysts such as hardness, electroconductivity and thermo-EMF changed simultaneously. Many investigators^{106–112} relate this to the disappearance of defects.

The reasons for the increase in the catalytic activity of metals resulting from mechanical impact were elucidated in more detail in studies of the effect of treatment of nickel and cobalt powders in ball and vibratory mills on their activities in the hydrogenation of benzene and fats. An extreme dependence of cobalt activity on the time of treatment was revealed and the transition of the cubic form of metal to the hexagonal one was established.^{113, 114} Examination of a cobalt powder subjected to treatment in mills with subsequent heating, using a set of physicochemical methods, showed that the increase in the catalytic activity of the metal in benzene hydrogenation is determined by the presence of defects and a distorted crystal lattice, as well as by the density of defects.^{115–118} Deactivation of catalysts upon heating was associated with dislocation and annihilation of vacancies.¹¹⁸

A nickel powder treated in a ball mill increased its activity in the hydrogenation of benzene,^{113, 119} phenol and higher alcohols¹²⁰ and fats.¹²¹ Correlation of the nickel activity in the above-mentioned reactions with changes in its physicochemical properties suggests that the increase in activity is to a larger extent associated with disordering of the crystal lattice than to the

surface area increase.^{120, 121} In their completing study, the authors attempted to relate changes in the catalytic properties of mechanically activated nickel to changes in its crystal structure.¹²² Specific rate constants of hydrogenation of fats and *ortho*–*para* conversion of hydrogen were found to be linearly dependent on the number of distortions of the crystal lattice and the density and energy of dislocations. The activation energy of reactions was inversely proportional to the energy of dislocations.¹²² The data obtained would seem to provide an unambiguous proof that dislocations in metals are catalytically active centres. However, the method of determination of specific activities of catalysts used by the authors cannot unfortunately be regarded as correct. The rates of reactions were estimated from the degree of conversion referred to a unit surface. But the degree of conversion is an integral (as regards time and concentrations) magnitude and cannot serve as a measure of the catalytic activity. The models used for the determination of the number and density of dislocations were far from being perfect. Analogous drawbacks are also inherent in the above-cited studies by Japanese researchers.^{116–122} Nonetheless, all these publications made a substantial contribution to the understanding of the nature of the effect of mechanical impact on the catalytic activities of metals.

2. Oxide catalysts

The effect of mechanical treatment on the catalytic properties of oxide systems was revealed for the first time in studies of the catalytic activity of lead oxide in the decomposition of hydrogen peroxide as a function of time of treatment in a ball mill.¹²³ The effect of mechanical treatment on the activity of V₂O₅, Fe₃O₄ and Fe₂O₃ in the oxidation of sulfur dioxide was studied more than two decades later.^{124, 125} The dependence of the catalytic activity of vanadium oxide on the time of treatment has two maxima,¹²⁴ while the activities of both iron oxides pass through one maximum.¹²⁵ The increase in catalytic activity is presumed to be related to distortions of the crystal lattice rather than to a larger surface area. Mechanical activation of iron oxides was also used in the oxidation and vapour conversion of CO.^{126, 127} The dependences of the Fe₂O₃ activity on the treatment time has an extremal character in both reactions, whereas the same dependence for Fe₃O₄ is described by a curve with saturation. Fe₃O₄ subjected to mechanical treatment is more active than the industrial catalyst of vapour conversion of CO;¹²⁷ however, no satisfactory explanation of this effect has been given so far.

Mechanical treatment of vanadium and iron oxides leads to an increase in their adsorption capacity with respect to sulfur dioxide and hydrogen sulfide;^{124, 128, 129} the positions of the maxima of the catalytic activities and adsorption capacities virtually coincide on the time dependence curves.

An attempt was made to elucidate the reasons for the effect of mechanical activation on the catalytic properties of calcium and copper oxides in the decomposition of N₂O and *ortho*–*para* conversion of hydrogen.^{130–132} There is a quantitative dependence between the catalytic activity of calcium oxide in the decomposition of N₂O and the concentration of defects in the crystal lattice. This is evidenced by the same degree of decrease, resulting from thermal treatment, of both the catalytic activity and some parameters (determined by the X-ray diffraction method) which characterise the defectiveness of activated samples. The increase in the copper oxide activity is rationalised within the framework of the electronic theory of catalysis. It is presumed that as a result of mechanical treatment the conductivity of *n*-type passes to the conductivity of *p*-type, while the activity of the catalyst in the decomposition of N₂O is determined by the ease of electron transfer in elementary stages.¹³² Changes in the catalytic properties of copper oxide in the *ortho*–*para* conversion of hydrogen are related to magnetic properties,¹³¹ while no mention is made about electronic properties.

Mechanical treatment can not only increase, but also decrease catalytic activity. Examples of this type, though not numerous, are the decrease in the zinc oxide activity in the decomposition of

hydrogen peroxide and photooxidation of propan-2-ol after treatment in a ball mill.^{133–135} The activity of zinc oxide drops linearly as the degree of disorderliness of the crystal lattice increases. The activation energy of hydrogen peroxide decomposition on mechanically treated zinc oxide decreases with the increase in the number of paramagnetic centres which are edge dislocations.¹³⁶

The increase in the activity of zinc oxide, treated under analogous conditions, in the decomposition of hydrogen peroxide is related to a distortion of the crystal lattice.^{137–139} A comparative study of the effect of nickel and zinc grinding in a ball mill on the activation energy of hydrogen peroxide decomposition¹³⁹ made it possible to conclude that the differences observed are determined by the type of conductivity of these semiconductors possessing the *p*-type and *n*-type conductivities, respectively.

Changes in catalytic properties occur not only upon treatment in a mill, but also under other types of mechanical impact. Thus the effect of compacting pressure on the properties of a number of catalysts was reported.^{140–150} The accompanying changes in acidic properties of potassium hydrogensulfate and tungstic acid induce an increase in their activities in the acetylene polymerisation and propylene hydration, respectively.^{140–141} The activities of chromium-containing oxide catalysts in the dehydrogenation of alcohols^{142–148} and of an aluminium–cobalt–molybdenum catalyst in hydrogenolysis of thiophene^{149,150} show extremal dependences on the compacting pressure. The changes in catalytic activities are rationalised with the use of data on porous structures and variation of the interplanar distances. However, it should be noted that the methods used for the determination of the activity of catalysts in the studies cited are incorrect.^{140–150}

Yet another type of mechanical impact is the treatment of materials with shock waves. The activity of numerous simple and complex oxides as well as their mixtures in the CO oxidation increases after the application of shock waves.¹⁵¹ This is related to the appearance of anionic vacancies and other perturbations of the crystal structure. The increase in the titanium dioxide activity is not associated with the presence of paramagnetic centres Ti^{3+} and paramagnetic defects.¹⁵² It should be noted that upon application of shock waves appreciable admixtures of the reactor construction material are introduced into catalysts, and these admixtures can affect their catalytic properties.¹⁵¹ Therefore, it is not excluded that high activity of titanium dioxide observed by Golden *et al.*¹⁵² is explained by the presence of copper oxide compounds of which the reactor was made. By varying conditions of shock load one can regulate catalytic properties of fluorite;¹⁵³ not only an increase in the degree of transformation on this catalyst was observed, but also wide-range changes in the ratio of propan-2-ol dehydrogenation and dehydration rates.

Activation of supported catalysts is of definite interest. Thus treatment of a mixture of metallic nickel and quartz in a vibratory mill results in coating of quartz with nickel, and this makes it possible to reach a high rate of benzene hydrogenation.¹⁰⁰ The increase in catalytic activity is explained by distortions of the crystal lattice of nickel. Schulz *et al.*¹⁰¹ treated a mixture of nickel–ruthenium alloy and aluminium oxide in a similar manner. The system obtained was studied in detail by physicochemical methods; however, no data on its catalytic properties were reported. Of some interest is the preparation of alloys with non-equilibrium composition which preserve their thermal stabilities up to 673–773 K. Chromium, vanadium and molybdenum oxides supported on silica gel were also subject to mechanical treatment.^{154–156} Their catalytic activities in ethylene polymerisation,¹⁵⁴ propylene metathesis¹⁵⁵ and methane oxidation to formaldehyde¹⁵⁶ increased after activation in a vibratory mill in different media. Possible mechanisms of formation of active centres of these catalysts involving radical centres of silica were considered. Though, the authors do not provide any conclusive evidence of these mechanisms. A possible mechanism of the catalytic oxidation of methane is also discussed.¹⁵⁶ Of interest is the fact of an increase in the selectivity of formaldehyde formation

resulting from a virtually complete suppression of the reactions of deep oxidation of methane on activated catalysts; however, this effect is observed only at low degrees of methane conversion (1%–2%).¹⁵⁶ Unfortunately, in all studies the activity of deposited catalysts was determined without due account for the specific surface of the active component. In a number of cases, indeed, there are no corresponding methods, but they do exist for supported metals. Without knowledge of the specific surface of active component, it is impossible to establish the reason for the effect of mechanical activation on catalytic properties; furthermore, there is a risk of reaching conclusions which are opposite to the real situation.

Analysis of a large body of available experimental data allows one to avoid mistakes made in some works and to continue studies of the effect of mechanical treatment on catalytic properties of compounds at a more perfect level using modern methods. This concerns primarily the methods for the determination of catalytic activity. In the studies discussed below, the catalytic activity was determined, in our opinion, in the most correct manner, *viz.*, in the gradient-free (with regard to temperature and concentrations) conditions, while the reaction rates were referred to a catalysts unit surface. In addition, a set of modern research methods were used in these studies in order to determine the nature and concentration of defects formed in the MCA.

Oxides which are effective catalysts of deep oxidation were the subjects of studies. Activation of copper oxide in a planetary mill even for a few seconds increased 2–5-fold the specific rate of butane oxidation.^{43,157} Presumably, the reasons for this are structural perturbations in the subsurface layer and the increase in the surface concentration of Cu^+ ions, which are the centres of chemisorption.¹⁵⁷ On the contrary, cobalt oxide decreases its activity in the oxidation of butane,¹⁵⁸ and this is explained by the removal of excess oxygen in the course of mechanical treatment. A decrease in activity was also observed upon mechanical treatment of iron(III) oxide¹⁵⁹ having a defective structure. It is presumed that the treatment results in the disappearance of surface and subsurface defects with a local spinel symmetry. It was reported¹⁵⁹ that specific catalytic activity of $\alpha-Fe_2O_3$ depended almost linearly on the concentration of extended defects determined by the method of small-angle X-ray scattering. The graph which we plotted on the basis of these data (Fig. 1) confirms the conclusion made by the authors. Activation of manganese oxides induced a 2–5-fold increase in the specific rate of CO oxidation depending on the chemical composition of the oxide.¹⁶⁰ An increase in the activity of Mn_2O_3 is explained, as for Mn_3O_4 , by the appearance of extended defects. In this case, an increase in the oxygen content is also observed. The authors relate the appearance of active centres of Mn_2O_3 to the formation of steps on the faces $\langle 120 \rangle$, whereas the activity of MnO is believed to be associated with the formation of $\gamma-Mn_2O_3$ on the surface. Sadykov *et al.*¹⁶¹ have generalised and analysed the data on the effect of MCA on the defectiveness and reactivity of oxide catalysts of deep oxidation.

Figure 1. Dependence of the specific rate of CO oxidation on $\alpha-Fe_2O_3$ (w) on the integral intensity of small-angle scattering (I) (according to the data of Ref. 159).

In the MCA of zinc oxide the following three processes occur successively, *viz.*, accumulation of shear defects, relaxation of the structure resulting from grinding and agglomeration of particles formed upon grinding.¹⁶² Accumulation of defects is accompanied by the increase in the specific activity of the catalyst for the oxidation of CO; upon fissuring or breaking of crystallites over shear defects the activity returns to the preactivation level.^{163, 164} A catalytic act is supposed to involve oxygen chemisorbed at sites of the exit of shear defects onto the surface.¹⁶⁴ Accumulation of defects occurs in a very narrow range of activation times; apparently, it is due to the fact that the effect of activation was not revealed in the above-cited studies.^{133–136}

An unambiguous evidence of the role of defects as the centres responsible for the increase in catalytic activity was obtained in studies of titanium dioxide. Figure 2 shows the linear dependence of the specific rate of CO oxidation on TiO₂ on the concentration of planes of crystallographic shear.¹⁶⁵ To our knowledge, there are only three studies which revealed experimentally the quantitative dependence of the specific catalytic activity on the concentration of defects.^{122, 159, 165} Only this dependence may be regarded as a strict proof that defects are the active centres of catalysis. How-

Figure 2. Dependence of the specific rate of CO oxidation on TiO₂ on the concentration of planes of crystallographic shear (C_{PCS}).

ever, Schrader *et al.*¹²² used an incorrect method for the determination of specific catalytic activity, and in this case such a conclusion cannot be regarded as correct. The data on the effect of mechanical impact on the activity of catalysts of different nature are presented in Table 2.

Table 2. The effect of MCA on catalytic properties of various compounds.

Catalyst	Reaction	Active centre	Ref.
Ni	hydrogenation of ethylene	—	102
	decomposition of formic acid	dislocations	103–105
Cu	decomposition of diazonium chloride	the same	106, 107
	dehydrogenation of ethanol	"	107
Ni	hydrogenation of cinnamic acid, dehydrogenation of ethanol, decomposition of H ₂ O ₂ , <i>ortho</i> – <i>para</i> conversion of hydrogen	vacancies, dislocations	108, 109
Ag	decomposition of formic acid, decomposition of H ₂ O ₂ , oxidation of ethanol	dislocations	110
Au	decomposition of H ₂ O ₂	the same	111
Pt	decomposition of formic acid, hydrogenation of cinnamic acid	point defects, dislocations	112
Co	decomposition of H ₂ O ₂ , hydrogenation of benzene	defects and distortions of the structure	113–118
Ni	hydrogenation of benzene	distortions of the lattice	113, 119
	hydrogenation of phenol and mixtures of higher unsaturated alcohols	the same	120
	hydrogenation of fats, <i>ortho</i> – <i>para</i> conversion of hydrogen	dislocations	121, 122
PbO	decomposition of H ₂ O ₂	—	123
V ₂ O ₅	oxidation of SO ₂ to SO ₃	distortions of the lattice	124
Fe ₂ O ₃ , Fe ₃ O ₄	the same	the same	125
	oxidation of CO	—	126
	vapour conversion of CO	distortions of the lattice	127
CuO	decomposition of N ₂ O, <i>ortho</i> – <i>para</i> conversion of hydrogen	defects of the lattice	130, 131
CaO	decomposition of N ₂ O	the same	132
NiO	decomposition of H ₂ O ₂	distortions of the lattice	137–139
KHSO ₄	polymerisation of acetaldehyde	new acidic centres	140
H ₂ WO ₄	hydration of propylene	new proton centres	141
Cr ₂ O ₃ + CuO or/and ZnO	dehydrogenation of Pr ⁱ OH	distortions of the lattice	142–148
TiO ₂ , ZnO, BaTiO ₃ , NiO, TiO ₂ + WO ₃ , TiO ₂ + Fe ₂ O ₃	oxidation of CO	anionic vacancies	151
TiO ₂	the same	distortions of the lattice	152
CaF ₂	dehydrogenation and dehydration of Pr ⁱ OH	—	153
Ni + SiO ₂	hydrogenation of benzene	distortions of the lattice	100
CrO ₃ + SiO ₂	polymerisation of ethylene	≡SiO [•] + Cr ⁿ⁺ ($n < 6$)	154
MoO ₃ + SiO ₂	metathesis of propylene	≡SiO [•] + Mo ⁴⁺	155
V ₂ O ₅ + SiO ₂	oxidation of methane to formaldehyde	—	156
CuO	oxidation of butane	surface Cu ⁺ ions	43, 157, 161
Co ₃ O ₄	the same	excess oxygen	158, 161
Fe ₂ O ₃	oxidation of CO	defects with a local symmetry of spinel	159, 161
MnO ₂ , MnO, Mn ₃ O ₄ , Mn ₂ O ₃	the same	extended defects, steps	160, 161
ZnO	"	shear defects	162–164
TiO ₂	"	planes of crystallographic shift	165

3. Annihilation of defects as a factor of deactivation of catalysts

In the process of operation, catalysts are known to lose gradually their activity and selectivity, to degrade, *etc.* The reason for deterioration of properties of catalysts, which can also be differently manifested in the use of systems subjected to MCA, were examined in detail.¹⁶⁶ The problem of the lifetime of systems with increased reactivities resulting from MCA has an independent significance and is fairly topical.

In a number of instances, the mechanism of the disappearance of defects resembles in many respects mutual annihilation of particles and antiparticles. For example, this seems to be the case of the interaction of dislocations with the counter-directed Burgers vectors of the same magnitude or the interaction of vacancies with the internodal ion. In virtually all of the studies cited in this section, a decrease in catalytic activity resulting from the disappearance of defects was noted. Most often, the annihilation of defects is induced by thermal annealing. This concerns both metal^{106–122} and some oxide^{123, 130, 138} catalysts.

The activity of mechanically activated copper oxide in the butane oxidation decreases when a specimen is stored for a long time and as a result of catalytic reaction.¹⁵⁷ In our opinion, this occurs due to processes which are analogous to those taking place in the course of annealing, although the rate of the disappearance of defects is substantially lower due to a decreased temperature. Sometimes, other factors are also found to play a role. Thus the degradation of crystallites of zinc oxide over shear defects leads to relaxation of the crystal structure.¹⁶² For iron oxide, a mechanism was proposed for the disappearance of defects due to the shear of layers.¹⁵⁹ The recovery of the initial stoichiometry of compounds can be yet another reason for deactivation. For instance, the removal of excess oxygen from cobalt oxide in the process of MCA leads to a decrease in its activity in the butane oxidation,¹⁵⁸ while the disappearance of the planes of crystallographic shear in titanium dioxide in oxidative media makes it less active in the oxidation of CO.¹⁶⁵ All these facts altogether gave us ground for supplementing the existing list of reasons for deactivation of catalysts¹⁶⁶ with one more factor, *i.e.*, annihilation of defects of the crystal structure.^{163, 167}

In some cases, mechanical treatment can lead to a complete and irreversible inactivation of catalysts. Thus mechanical treatment of zeolite FeZSM-5 destroys its crystal structure and leads to the total loss of activity in the phenol oxidation by dinitrogen oxide.¹⁶⁸ For the same reason, aluminium oxide loses its ability for coke formation after mechanical treatment,¹⁶⁹ which is a positive factor under the condition of preservation of useful properties by this material, *e.g.*, high sorption capacity.⁹⁷

It is commonly assumed that the defects disappear at sufficiently low temperatures, so the effect of increase in activity upon MCA cannot be used for practical purposes. However, there are many well known chemical processes which occur at temperatures substantially lower than the temperatures of annealing of defects. For example, skeletal catalysts prepared with the use of mechanical melting are effective in the hydrogenation reactions at temperatures of 373 K and below. The catalysts of deep oxidation preserve their elevated activities acquired upon MCA for at least tens of hours.¹⁵⁷ In a number of cases, annealing of defects requires unusually high temperatures. For example, the activity of iron–potassium catalyst in the dehydrogenation of *n*-butenes is decreased only upon heating to temperatures above 903 K,⁶¹ which is the operation conditions of an industrial reactor. Thus, the increase in the catalytic activity by MCA may be used for practical purposes, too.

4. Effect of mechanochemical activation on the selectivities of catalysts

Very few studies have been devoted to the investigation of the effect of MCA on the selectivities of catalysts. Treatment of molybdenum disulfide in a vibratory mill changes its selectivity in the thiophene hydrodesulfuration, the direction of this change

being dependent on the composition of the medium in which this treatment is carried out.¹⁷⁰ This is attributed to changes in the ratio of crystallographic facets possessing different catalytic properties. Upon grinding in heptane, the ratio of the surfaces of basal and lateral facets of molybdenum disulfide is 72 : 28, whereas upon grinding in air it is 5 : 95. At close degrees of thiophene conversion the ratios of concentrations of butane and butenes formed on these samples reach 0.7 and 3.0, respectively. In addition, the sample with a larger proportion of lateral facets is capable of sorbing a larger amount of hydrogen, chemisorption beginning at substantially lower temperatures. The use of fluorite subjected to MCA increases the selectivity of acetone formation from propan-2-ol.¹⁵¹ Treatment of a suspension of VOHPO₄ in ethanol in a planetary mill leads to the increase of the portion of the surface formed by the facets {001} of vanadium hydrogen-phosphate, which are transformed into the facets {100} of vanadyl pyrophosphate upon thermal treatment.¹⁷¹ The elevated content of the latter favours an increase in the selectivity of maleic anhydride formation upon oxidation of *n*-butane. We observed a decrease in the selectivity of butadiene formation upon dehydrogenation of *n*-butenes on a mechanically activated iron–potassium catalyst.⁶¹ Iron carbide Fe₃C subjected to MCA increases the selectivity of formation of hydrocarbons C_{*n*}, where *n* ≥ 2, and decreases the alkene : alkane ratio in the reaction of CO₂ hydrogenation. Analogous effects are observed with a carbide catalyst synthesised by mechanochemical interaction of metallic iron with carbon.¹⁷² The authors do not discuss the nature of this phenomenon.

In virtually all the cases, changes in selectivity are related to the changes in the nature of the crystallographic facets upon grinding, while the influence of defects is not considered in any of the cited studies. In our opinion, it is necessary to take into account that the selectivity of multiroute reactions is determined by the ratio of several reactions, one of which yields the target product. Each reaction occurs on its own active centres, and by varying their ratio one can regulate selectivity. MCA can be a possible way of regulating the selectivity of catalysts. The increase in the selectivity of formation of target products is favoured by higher activity and a larger number of active centres responsible for the occurrence of major reactions and by a lower activity or a lower concentration of centres on which side reactions take place. By studying the dependence of the yield of various products on structural changes, one can establish the relationship between the occurrence of specific reactions and the presence of the corresponding structures, and this will contribute to the development of the theory of prediction of catalytic action.

Thus, the relevant, sufficiently numerous literature data point to a substantial influence of mechanical impact on the activities and selectivities of catalysts. Despite the long-standing opinion that it is impossible to use this effect for practical purposes because of the metastability of defects, some studies revealed high thermal stability of active states resulting from MCA and a substantial increase in the activities of catalysts of a number of industrially important low-temperature reactions. This is promising for the development of industrial technologies for increasing the activities of catalysts by MCA.

The reasons for the effect of MCA on the catalytic properties of compounds cannot nowadays be regarded as elucidated. The overwhelming majority of studies only state the facts of changes in catalytic properties resulting from mechanical impacts. The catalytically active centres are usually denoted with general terms, *viz.*, defects, distortions of the crystal lattice, *etc.*, without definition of their structures. Sometimes, changes in the activity (as a rule, its increase) are attributed to the appearance of specific defects: dislocations in the structure of various metals,^{105–112, 122} planes of crystallographic shear in the lattice of titanium dioxide,¹⁶⁵ steps on the facets {120} of Mn₂O₃,¹⁶⁰ dislocations with the known Burgers vectors in some oxides.¹⁶¹ We know only three studies^{122, 159, 165} which provided direct experimental evidence of the participation of defects of definite type in the increase in the

catalytic activity. The results of these studies allow description of the structure of active centres at the atomic level. In our view, the best successes in the investigation of the influence of defects on the activity of catalysts were achieved in the study of N_2O decomposition on copper oxide (the electronic theory of catalysis¹³² was used for its description) and in the investigation of the nature of the chemisorbed or surface oxygen involved in elementary catalytic acts.^{157–161, 164}

IV. The role of defects as active centres for chemical processes

Analysis of the literature data shows that compounds subjected to MCA exhibit increased reactivities in various chemical processes, *viz.*, simple chemical transformations, sorption processes and catalytic reactions. This indicates that defects are the active centres of all above-mentioned transformations. Let us consider a few examples of the versatile character of MCA action. Thus MCA of iron oxides increases both their catalytic activities in the CO oxidation and vapour conversion of $\text{CO}^{125–127}$ and the sorption capacity with respect to hydrogen sulfide.^{128, 129} Mechanochemical activation of vanadium(V) oxide induces symbatic modification of its sorption capacities with respect to sulfur dioxide and its activity in the SO_2 oxidation to SO_3 .¹²⁴ In addition, vanadium oxide manifests an increased activity in the reactions with hydrogen peroxide and alkalis after MCA.¹⁷³ Zinc and titanium oxides the structure of which contains shear defects, exhibit an increased activity in the CO oxidation^{162–165} and at the same time increased sorption capacities with respect to nickel and copper salts.^{97, 98} In addition, MCA increases the sorption capacity of zinc oxide with respect to hydrogen sulfide,³⁶ while titanium dioxide becomes more reactive in reactions involving oxygen¹⁶⁵ and sulfuric acid.³ The increase in reactivity is manifested also in a lower temperature of reduction, by hydrogen, of nickel chloride deposited on oxide supports subjected to MCA.^{97, 98} After activation of zinc ferrite with the structure of spinel, the rate of its dissolution in hydrochloric acid is substantially increased¹⁷⁴ together with the sorption capacity of zinc ferrite with respect to hydrogen sulfide.¹⁷⁵ In this state, zinc ferrite exhibits higher catalytic activity in the oxidation of CO.

Thus, if the sites of the exit of defects on the surface are catalytically active centres, they play simultaneously the role of sorption centres for salts from solutions and chemisorption of various gases, as well as of the reaction centres where simple chemical reactions take place. This refers not only to those defects which result from MCA but also to other defects. Thus the appearance of planes of twinning in the particles of metallic nickel in the formation of filamentous carbon leads to the increase in the specific rate of butadiene hydrogenation.¹⁷⁶ The reactivity of such nickel in the reaction with molecular bromine is also increased. As a result of interaction of silver supported on corundum with the reaction medium, one observes formation of interblock boundaries. These defects are the active centres of ethylene oxidation to ethylene oxide.¹⁷⁷ In the above-mentioned systems the character of oxygen chemisorption on silver and of hydrogen on nickel is changed.¹⁷⁸ Among uranium nitrides used as catalysts in the synthesis of ammonia, the maximum activity is characteristic of the sample with composition $\text{UN}_{1.7}$ with an ordered structure, *i.e.*, it has defects in the crystal structure of a definite type.¹⁷⁹ This nitride is also distinguished by a special character of chemisorption of nitrogen and a higher reactivity in the reaction with hydrogen.

These data show that the mechanically induced defects of the crystal structure exhibit higher activity in the three chemical processes differing in their nature and mechanisms: simple chemical transformations, sorption and catalysis (Table 3).

The increase in the sorption capacity of different oxides with respect to gases and the concomitant increase in their catalytic activities in the CO oxidation with formation of the same active centres is well explicable since chemisorption is an elementary

Table 3. Chemical processes depending on defects in the catalyst's structure.

Catalyst	Chemical transformation	Sorption	Catalytic reaction
ZnO	oxidation – reduction	O_2 , H_2Se , Ni^{2+}	oxidation of CO
TiO_2	oxidation, dissolution in acids	Ni^{2+}	the same
ZnAl_2O_4 , ZnFe_2O_4	leaching	Ni^{2+} , H_2S	"
Fe_2O_3	dissolution in acids	H_2S	"

stage of a catalytic reaction. But the fact that the increase in the activities of oxides in chemical reactions and stronger sorption of ions from solutions on them correlates with these two effects is surprising. Taking into account the versatility of active centres, one may suggest that the increase in chemical activity is explained not by changes in the mechanism of processes, but has a more common origin. It is changes in the thermodynamic potentials of compounds as a result of MCA that can be such a reason.

V. Catalytic reactions under conditions of mechanochemical activation

Scarce data on catalytic reactions occurring under MCA conditions may be divided into two groups: some of them are regarded as pseudocatalytic (the term proposed by P Yu Butyagin) and all other as really catalytic reactions. The so-called pseudocatalytic reactions represent a recurrent sequence of simple chemical transformations of reagents involving a solid. Each of these transformations may be regarded as an analogue of an elementary act in the stepwise mechanism of a catalytic reaction. Their motive forces are continuous induction of active centres as a result of mechanical impacts. For the reaction to continue after the interaction of reagents with the centre, the latter should be regenerated due to the supply of mechanical energy. In contrast to this, in the catalytic reactions the active centres are regenerated in subsequent elementary acts as a result of chemical transformations. Oxidation of carbon, hydrogen and CO under the conditions of mechanical activation of quartz^{180–182} represents examples of pseudocatalytic reactions. The mechanism of CO oxidation was described by Butyagin.⁵ Apparently reactions of polymerisation occurring upon mechanical activation of various materials in the medium of the corresponding monomers belong to the same type.^{183–185} Radical or charged centres of freshly formed surface act as initiators of the growth of polymeric chains.

The truly catalytic reactions include, *e.g.*, the synthesis of ammonia which takes place upon treatment of the catalyst with carborundum particles¹⁸⁶ in a jet mill¹⁸⁶ and in a ball mill,¹⁸⁷ hydrogenation of benzene on nickel in a vibratory mill,^{188–190} and of ethylene on iron,¹⁹⁰ and oxidation of SO_2 on vanadium(V) oxide.¹²⁴ All the above-listed reactions, except for the last mentioned one, proceed with high conversion degrees at room temperature. To accelerate the reactions of hydrogenation, solids possessing high hardness, *e.g.* corundum, were introduced into the reaction volume; these reactions can proceed even in the presence of catalytic poisons (thiophene).¹⁸⁸ The activation energy of sulfur dioxide oxidation in the temperature range 623–773 K under conditions of MCA was 5 kcal mol^{-1} , this energy being much lower than that in the conventional catalysis ($32–34 \text{ kcal mol}^{-1}$). Methanation of CO_2 on metal catalysts under mechanical activation is also carried out at elevated temperatures.¹⁹¹ Catalytic hydrogenation of CO to methane on the inert alloy $\text{Zr}_{0.5}\text{Ni}_{0.5}$ saturated with hydrogen is believed to follow two pathways.¹⁹² One of them includes the stage of dissociative chemisorption of CO with the liberation of elementary carbon and its subsequent hydrogenation; this is confirmed by studies of individual stages of the process under the MCA conditions. The

occurrence of the reaction through the second pathway is presumably associated with the generation of short-living active states on the catalyst surface.

We undertook systematic studies of catalytic reactions under the MCA conditions. This refers to many reactions: CO oxidation on oxides and metals, synthesis of ammonia on the industrial catalyst CA-1B, pyrolysis of butane on magnesium oxide, hydrogenolysis of butadiene on hydrides of magnesium intermetallides, synthesis of boric acid esters with the use of spherical granules of zeolites as catalysts, grinding bodies and absorbents of water formed in the reaction, as well as numerous reactions of hydrogenation and reduction of functional groups.^{163, 193} These reactions do not occur in the absence of catalysts, while the composition of the catalysts themselves is not changed in the course of the process. This indicates that they are indeed the accelerators of the process rather than mere reagents.

The reactions of hydrogenation and reduction of solid organic compounds have been studied in sufficient detail. The most efficient catalysts of such processes proved to be hydrides of intermetallic compounds. The mechanochemical reactions of catalytic hydrogenation or reduction involve only the terminal unsaturated bonds and functional groups; no reactions take place when these bonds and groups occupy internal positions. By varying conditions of mechanical activation, one can regulate the selectivity of reactions which has been clearly exemplified in transformations of caryophyllene α -oxide.¹⁶³ Apparently, in many cases, the mechanisms of reactions differ under the MCA conditions from those in traditional catalysis. Thus in the hydrogenation of butadiene under usual conditions on the hydride Mg_2FeH_6 the selectivity of formation of butenes is close to 100%,⁵⁶ whereas under the MCA conditions complete hydrogenolysis occurs on this catalyst.¹⁹³

How can MCA affect the course of catalytic reactions? One of the most important advantages of catalysis is the possibility of an easier overcoming the reaction activation barrier or, more precisely, its elementary act. This is as a rule achieved by supplying the catalyst and reagents with external energy, most often in the form of heat. The energy can also be supplied by sonication (sonocatalysis) or as electromagnetic radiation (radiation-induced catalysis or photocatalysis depending on the radiation wavelength).

We took the liberty of introducing a new term 'mechanochemical catalysis', *i.e.*, the catalysis in which the energy is supplied by mechanical impact on catalysts and reagents. As a result of such impact, not only the activities of catalysts are increased, but also the chemical reactivities of solid reagents and, besides, the regularities of activation of catalysts are changed. Since any measurements inside the working chambers of mills are not technically feasible, it may only be suggested what kind of processes occur during mechanical activation.

The simplest way is to suppose that the energy is supplied by means of transformation of the mechanical energy to thermal energy, after which a catalytic reaction occurs in a usual manner. Indeed, some investigators believe that the temperatures up to 1500–2000 K are developed at the sites of contact of grinding bodies with the compound under activation (the theory of magmaplasma). However, this view is not corroborated by valid experimental evidence. A conclusion based on calorimetric measurements which states that during grinding the temperature reaches 650–900 K seems to be better substantiated. Nonetheless, in this case, too, it is difficult to explain why at these temperatures either ammonium nitrate (published data) or some organic compounds (own results) virtually do not decompose. Apparently, introduction of compounds which can be readily activated changes the friction coefficients, while the temperatures in the working chambers are substantially lower under conditions of mechanochemical catalysis than those mentioned above. Hence, the transformation of the mechanical energy to thermal energy can explain only some of experimental data.

We believe that the most probable way of activation of reagents is the transfer of excess energy concentrated in the short-living centres formed in the course of cleavage of the catalyst's crystallites. Such centres have, as a rule, a radical nature, and the thermodynamic requirement for the reduction of their energy is fulfilled at the expense of bonding. The reactants situated in the immediate proximity of such a centre react with the unsaturated bond and pass to the activated state. In this case, the vibratory and electronic levels are excited, electronic levels appear in the forbidden bands (especially when defects of the crystal lattice are available), and the forbidden band becomes narrower. It is these processes that are the result of energy redistribution according to the scheme: mechanical energy $\rightarrow$ excess energy of the catalyst $\rightarrow$ excess energy of a reactant.

In contrast to other types of catalysis, the mechanochemical catalysis induces continuous formation of defects, their migration, interaction and annihilation. It is known that compounds are sorbed predominantly on sites of the exit of defects onto the surface and migrate together with these defects. Even dislocations of molecules into the bulk of solids were detected. Migration of point defects and dislocations is described in sufficient detail in the literature, but there is little information about the migration of planar defects. The planar defects are formed upon shear and turn the layers of cations and anions relative to each other. Apparently, recovery of the normal packing in some places and formation of shear defects in others occur in the MCA. In this situation, the places of exit of such defects migrate over the surface of crystallites. Interaction and annihilation of defects result in release of energy, and since the reactants are localised basically on defects, a part of the released energy is most probably spent in the activation of reactants.

We believe that the three modes of energy transfer mentioned above are the most probable since they are indirectly confirmed experimentally. One should not however rule out other ways of energy transfer to reactants. For example, the acceptor compounds may be activated by capturing the so-called mechanoelectrons. Several reports discuss the problem of participation of high-frequency phonons in the activation processes. Upon mechanical activation of solids, different types of electromagnetic radiation arise which can also induce activation of reactants in the mode similar to that of the radiation-induced catalysis or photocatalysis. Concomitant realisation of several described channels of energy redistribution is not precluded either.

VI. The nature of the effect of mechanochemical activation on the reactivity of solids

Using theoretical concepts, it is possible to predict to some extent, and in a number of cases to make approximate quantitative estimates of the effect of MCA on the properties of catalysts and catalytic reactions. Changes in the thermodynamic potentials of catalysts should induce changes in the equilibrium constants of formation of intermediate products, *e.g.*, chemisorbed compounds, towards their higher concentrations. With correct data on the values of thermodynamic potentials, it is possible to establish how changes in the catalyst's state influence its activity. To this end, use is made of the known expressions which relate the rate of a catalytic reaction to thermodynamic parameters. Such an approach is described, for example, by Boreskov.¹⁹⁴ At the qualitative level, one may say that the shift of equilibrium towards higher concentration of intermediates should lead to an increased reaction rate. It is obvious that both the magnitude of activity and its increment due to MCA have definite limits which are determined by the chemical nature of the compound subject to activation. The maximum of stored excess energy is determined by the type of crystal structure of a compound and by the nature of defects arising during MCA. In addition, if the appearance of defects results in changes in the heat of chemisorption of the

reactants, the activation energy of reaction (E) is also changed in conformity with the equation of Brønsted and Polanyi:

$$E = E_0 \pm \alpha q,$$

where the activation energy E_0 and the coefficient α depend on the type of reaction and q is the heat of chemisorption. This will also affect the rate of catalytic reactions. Upon formation of fresh surfaces by crystal splitting, localised free valences appear, the number of which may be close to the number of surface atoms. The presence of free valences favours the increase in the adsorption and chemical activities of the catalyst with respect to the gas and liquid phases and also solutes. Within the lifetime of such states, which ranges from 10^{-4} to 10^{-7} s (see Ref. 3), all processes of 'chemical relaxation' have enough time to occur, including chemical reactions with contacting compounds.⁴

The appearance of defects leads to changes in the electronic properties of a solid, which will be discussed below, and to changes in the geometry of the surface due to the appearance on it of sites for the exit of extended defects. Changes in the regular structure affect not only the sites of the exit of defects onto the surface themselves but also considerable areas around them. Relevant calculations indicate that at fairly moderate concentrations of dislocations (10^{11} – 10^{12} cm⁻²) the part of distorted structure amounts to 70%–80% of all the surface.³ For this reason, the defects of the crystal structure will substantially influence the processes of adsorption and hence the catalytic properties of a substance. This influence is realised through the geometric factor, *i.e.*, the geometric correspondence of the structure of reactants to the surface of catalysts. Apparently, the selectivity of multiroute reactions should vary most substantially. The sorption properties of the surface in the places of the exit of the defects of crystal structure should differ from those of the remaining surface, first, because of changes in the surface geometry and, second, due to the fact that such places serve as traps of electrons and possess special electronic properties.¹⁹⁵ The effect of defects on the catalytic properties of compounds is apparently also manifested in the variation of the energy of bonding between atoms in the lattice of catalysts which is determined by changes in the interatomic distances in the course of formation of extended defects. For example, the strength of the oxygen bond in oxides is well known to correlate with the catalytic activity of oxides in the reactions of oxidation. It is not excluded that the appearance of defects can result in changes in the nature of the chemisorbed reagents. Thus upon MCA of quartz the activated catalyst generates singlet oxygen; an analogous phenomenon is observed with the reduced and hence defective vanadium oxide.¹⁹⁶ This induces changes in the catalytic properties of this oxide in the oxidation reaction of naphthalene to phthalic anhydride.

Changes in the electronic properties of catalysts resulting from MCA can have a substantial effect on the redox and other reactions requiring transfer of electrons. We have already noted above that chemisorption is possibly influenced by changes in the surface properties in the places of the exit of defects where electrons are localised. It may also be expected that during the occurrence of both catalytic and ordinary reactions the conductivity electrons and the electrons belonging to anions with enhanced electron-donor properties will be involved in the elementary acts with electron transfer. According to the literature data, the catalytic properties of compounds can be influenced by the peculiarities of transition of electrons from one electronic level to another, work of electron release, position of the Fermi level, width of the forbidden band, availability of electronic levels in it, *etc.* All these parameters may be influenced by means of MCA.

All the changes listed above favour the increase in the reactivities of components in the synthesis of catalysts, modification of their sorption properties due to the formation of new surface and the appearance of places for the exit of defects onto the surface, as well as changes in the specific catalytic activity. By now, a considerable body of experimental data has been accumulated on the dependence of the catalytic activity on the mechanical impact.

However, the authors of the overwhelming majority of works confine themselves either to a trivial statement of such influence or to attempts to explain specific situations that they have observed.

Comparison of different viewpoints would possibly allow interpretation of experimental observations, formulation of general theoretical concepts and creation of the scientific ground for the purposeful control of the processes occurring. Of special interest is the elucidation of the reasons of the effect of MCA on the catalytic activity of compounds and selectivity of reactions of different nature (redox, acidic and other reactions). To this end, physical theory of mechanical impact should be combined with concepts of the chemical nature of the catalytic activity. It is possible that this will not however allow creation of an integral theory, as it is still the case in the heterogeneous catalysis on the whole, but there is a possibility to formulate local theoretical conceptions relevant to individual types of catalysis.

The problem of estimation of the specific activity of a catalyst is of crucial importance. The well known Boreskov's rule on the approximately constant specific activities of catalysts of the same chemical compositions¹⁹⁴ may be regarded only as a statement of the chemical nature of a catalytic act which was formulated by Berthelot as far back as 1877: 'Owing to a chemical impact of contacting substances, intermediate compounds are formed which in turn are degraded as they emerge and eventually vanish in the final metamorphosis.'¹⁹⁷ If the catalytic properties of compounds were determined solely by the chemical composition of active centres, then it would be absurd to expect that the same centres could display different activities, and no additional experiments would have been required.

The constancy of specific catalytic activity is approximate in the extent to which the total set of properties of the surface of catalysts is reproduced. The actual level of the development of the scientific bases underlying the preparation of catalysts does not allow high reproducibility. However, from the viewpoint of applied science this is not required in most cases. The term 'approximate constancy' means that the activity of catalysts is also influenced by other factors which were not denied by Boreskov either (see his monograph,¹⁹⁴ p. 47). In his opinion, these factors can induce differences in properties of individual facets of crystals and the non-equilibrium states of the catalyst's surface. But even the catalysts with completely the same chemical, structural and other characteristics would possess an approximate rather than absolute constancy of specific activity.

It is the role of additional factors which influences the specific catalytic activity that was the topic of our review. The activity of a catalyst with defects is somewhat higher than its activity in the equilibrium state. The degree of increase in activity depends on the amount of excess energy which is stored in defects and influences the catalytic properties through the variation of thermodynamic potentials. This amount of energy is determined by the physico-chemical nature of the catalytically active sites.

The non-equilibrium structural and phase states of catalysts arising in the process of their preparation should be subject to annealing in the course of reaction, and the catalysts should pass to the steady state. However, there are numerous examples of rather high stability of such states of solid catalysts at elevated temperatures in real reaction media. This is explained by the fact that thermal annealing of defects is an activation process, and if the conditions do not permit overcoming of the activation barrier, some metastable structures of higher reactivity may exist for a rather long time.

Further studies of the nature of the structural factors and of their role in a chemical act will allow a deeper insight into the detailed mechanism of catalysis. The progress in this field can be achieved using novel MCA techniques and modern physical methods of research.

The review was supported by the Russian Foundation for Basic Research (Project No. 00-15-97440).

IV. Mixtures of starch with synthetic polymers	455
V. Conclusion	458

Abstract. The effects of low-molecular-weight additives, temperature and mechanical action on the structure and properties of starch are discussed. Special attention is given to mixtures of starch with synthetic polymers, *e.g.*, co-polymers of ethylene with vinyl acetate, vinyl alcohol, acrylic acid, cellulose derivatives and other natural polymers. These mixtures can be used in the development of novel environmentally safe materials (films, coatings, packaging materials) and various articles for short-term use. The bibliography includes 105 references.

I. Introduction

Modern-day technology calls for the development of polymeric materials the properties of which do not change even after long-term use. The effects of environmental factors (*e.g.*, water, atmospheric oxygen, sunlight and biological agents, such as microbes, fungi, insects, *etc.*) reduce the service life of many articles prepared from polymeric materials. All this raises the problem of creation and application of special-purpose stabilisers and bioprotectors.¹ However, the immense bulk of polymeric materials and articles made thereof puts forward a problem of their further destruction or disposal after the termination of their service life. Many polymers are decomposed in the environment over a relatively long period of time; therefore, the production of biodegradable materials is as important as their stabilisation. Polymers, particularly household plastics and films, must be rapidly decomposed after use under the influence of chemical (atmospheric oxygen, water), physical (sunlight, heat) and biological (bacteria, fungi, yeasts, insects, *etc.*) environmental factors.^{2,3} These factors produce a synergistic effect, eventually resulting in the fragmentation of the polymer owing to the destruction of its macromolecules and their conversion into low-molecular-weight compounds that can be further involved in the natural circulation of substances. In the strict sense, the term 'biodegradation of a polymer' implies deterioration of its physical and chemical properties and a decrease of its molecular mass

down to the formation of CO₂, H₂O, CH₄ and other low-molecular-weight products under the influence of microorganisms in both aerobic and anaerobic conditions.^{4,5}

Microorganisms or enzymes produced by them cause the decomposition of natural polymers (*e.g.*, cellulose, starch, chitin, polypeptides, *etc.*) into low-molecular-weight compounds which are further involved in the metabolism of the elemental forms of life.⁶ Enzymes play the role of catalysts favouring the degradation of the main polymeric chain. Specific enzymes evolved in the course of evolution can selectively destroy natural high-molecular-weight compounds, such as cellulose, proteins and other natural polymers. For example, amylase induces the degradation of the starch molecule. Enzymes causing the destruction of synthetic polymers, *e.g.*, polyalkenes or polyvinyl polymers, are absent in Nature. However, these classes of polymers are especially extensively used in the production of packaging materials and articles for short-term use. These wastes constitute the greater part of municipal garbage in all industrially developed countries.^{2,7–9} The interest in materials based on natural polymers (*e.g.*, starch, chitin) has increased considerably in the recent years, because owing to their structural features these compounds can be involved in natural circulation and thus be environmentally safe.

The problem of development of biodegradable polymeric materials has been considered in detail in reviews.^{10–13} It was shown that the use of natural renewable polymers is the most promising and economically advantageous approach. The synthesis of novel biodegradable polymers and chemical modification of natural polymers were described by Vasnev.¹⁴ The methods for estimating the biodegradability of polymeric materials based mainly on the analysis of products of the activity of bacteria which decompose polymers have been developed and standardised in many countries.^{4,15–17}

Here we survey the most recent data concerning the properties of materials prepared from starch or its mixtures with synthetic polymers.

II. The structure of starch

Starch is a natural polysaccharide which is accumulated in plant tubers, seeds, stalks and leaves in the course of their vital activity. The main sources for the commercial production of starch are potatoes, wheat, corn and rice. Starch comprises two polymeric components, *viz.*, amylose and amylopectin, they are built of α -D-glucopyranose residues but differ in both structure and function. The amylose content in native starch usually varies from 20 mass % to 30 mass %, while amylopectin constitutes the greater part (70%) of the starch molecule. At the same time, the

A I Suvorova, I S Tyukova, E I Trufanova Urals State University, prosp. Lenina 51, 620083 Ekaterinburg, Russian Federation.
Fax (7-343) 261 59 78. Tel. (7-343) 261 60 46.
E-mail: Anna.Suvorova@usu.ru (A I Suvorova),
Irina.Tyukova@usu.ru (I S Tyukova)

amylose content in high-amylose starch can reach 50 mass % to 70 mass %.¹⁸

Amylose (**1**) is a linear polymer, which consists of α -(1,4)-D-glucopyranoside residues with the average molecular mass of $\sim 10^2$ to 10^3 kg mol⁻¹. In cellular starch, the helical chains of amylose form complexes with lipids. Amylopectin (**2**) contains α -(1,4)- and α -(1,6)-linked glucose residues. Extended linear chains involve α -(1,4)-bonds and a great number of shorter branchings are linked through α -(1,6)-bonds.

The molecular mass of amylopectin is approximately 10^5 kg mol⁻¹. The branchings in the starch molecule may contain, on the average, up to twenty glucose residues. Amylopectin molecules also form helices; it is noteworthy that shorter side chains form double helices.^{19,20}

The spatial structure of amylopectin has not been clearly understood yet. A number of models have been proposed²¹ in order to establish a correlation between the character of branchings in the chains of amylopectin and its ability to form regular crystalline regions. The Robin–Mercier scheme²² (Fig. 1) pro-

Figure 1. A structural model of amylopectin; A are crystalline regions, B are amorphous regions.²²

Figure 2. The structure of native starch;²⁰ (1) helices of amylopectin, (2) hybrid helices of amylose and amylopectin, (3) free lipids, (4) free amylose, (5) V-structures of amylose.

vides an example of such models. This model takes account of the presence of amorphous regions in the amylopectin molecule formed by chain branchings and of crystalline regions consisting of linear, parallelly stacked fragments.

The degree of crystallinity of natural starch depends on its origin and varies from 15% to 45%. The structure of starch formed by regular stacking of the double chains of amylose and amylopectin and incorporating lipid molecules which form complexes with them is schematically represented in Fig. 2. Using wide-angle X-ray scattering,^{19,23} it was shown that the crystalline structures of starch isolated from different parts of plants differ considerably. This polysaccharide was found to exist in three polymorphous modifications. Starch from gramineous seeds has the so-called A-structure, tuber starch has the B-structure, while starch extracted from roots and stalks of plants has the C-structure. The crystalline structures of the A- and B-types are associated with the amylose fragment and consist of parallel coiled right double helices with anti-parallel packing. Each turn of the helix comprises six α -D-glucose residues. The conformations of the double helices of amylose in A- and B-structures are identical, but the A-structure is represented by a unit cell of the orthorhombic type ($a = 1.190$ nm, $b = 1.770$ nm, $c = 1.052$ nm), whereas the B-structure is represented by a hexagonal unit cell ($a = b = 1.85$ nm, $c = 1.04$ nm). Besides, in natural starch amylose complexes with lipids form structures of the V-type. The content of crystalline structures of the A- and B-type in starch samples of different origin was found to be 56% and 44%, respectively.²⁴ The presence of these structures was confirmed by IR spectroscopy.²⁵

Starch contains a large proportion of amorphous regions. However, the glass-transition temperature (T_g) of dry starch cannot be measured because it lies above the temperature at which the decomposition of the polymer occurs; its calculation is based on the estimation of the plasticising effect of water which penetrates into the amorphous regions of the starch molecule and decreases T_g . The concentration dependence of T_g of the starch – water system can be described by the equation²⁶

$$T_c = 244.9 - 1565\omega + 2640\omega^2,$$

where ω is the content of water (w/w) in swollen starch. Extrapolation of these data for T_g of the starch samples plasticised with water to various degrees gave T_g values ranging from 230 to 250 °C.^{20,26}

Starch is present in plants in the form of granules having the diameter from 2 to 100 μ m.²⁷ The structure of these supramolecular granules is complex and has not yet been finally elucidated. It is known that starch granules comprise both crystalline and amorphous regions. The amorphous regions form a continuous phase and incorporate crystals of a lamellar type.²⁷ Microscopic analysis of the supramolecular structure of starch granules²⁸

revealed that the lamellae predominantly consist of amylopectin. Their sizes depend on the origin of starch and their localisation in the granules and vary from 20 to 500 nm.

Starches isolated from different natural sources differ in their sensitivities to destructive factors, such as temperature and enzymic hydrolysis. Thermolysis of starch granules isolated from potatoes, wheat, barley, rice, corn and tapioca was studied at fixed temperatures (170–325 °C).²⁹ It was found that corn starch exhibits the highest resistance to heating, whereas barley starch is the least thermostable. This may be due to the differences in the molecular masses and ratios of linear and branched components of starches having different biological origin.

III. Effects of water and plasticisers on the properties of starch

Starch is a typical hydrophilic polymer; it may contain up to 30 mass %–40 mass % of bound water. It is known²³ that different structures of starches of the A- and B-types bind differently to water. In structures of the B-type, water is mobile and can easily enter and leave the complex (Fig. 3). In crystallites of the A-type, water of hydration forms a layered structure and is firmly bound to the surrounding double helices of amylose. Therefore, A-structures are less sensitive to the atmospheric moisture than B-structures.

Figure 3. The schematic representations of the crystalline structures of amylose with water. (a) A-amylose complex, (b) B-amylose complex. The hatched areas designate absorbed water.

Studies of the effect of water on starch provide additional information about the structure of this polymer. Dissolution of starch in water is a complex process, which strongly depends on temperature. Swelling of starch in saturated water vapour at room temperature results in the formation of a gel which retains the predominant polymer-to-polymer contacts.³⁰ This process does not result in complete dissolution of starch as is evidenced by the shape of the isotherm of water vapour sorption³¹ characteristic of systems with limited swelling of a polymer. However, the mobility of starch molecules increases with an increase in the amount of absorbed water as a result of which the linear component of the polymer, *viz.*, amylose, forms a true solution with water. This is accompanied by the formation of a two-phase swollen gel–solution system.

A high-energy interaction with water of several samples of amylose starch having a crystalline structure of the B-type and the chain length of 12–55 residues was established by scanning calorimetry and sorption.³² However, at room temperature the energy of the interaction of the components is too low to compensate for the oppositely directed entropic contribution. Therefore, complete destruction of the polymer-to-polymer contacts and solubilisation of starch do not occur. Water is a poor solvent for amylose starch at room temperature.

The solubility of starch increases with temperature. The swelling of dispersions (2.6 mass %) of corn and pea starches in water was studied by laser diffractometry.³³ It was found that heating above gelatinisation temperatures significantly changes both the sizes of starch granules and their distribution according

to size. The maximum increase in the diameter of starch granules is ~ 3.5-fold.³³ The behaviour of the starch–water system at a wide range of temperatures was studied by differential scanning calorimetry (DSC), dilatometry, rheology and polarisation microscopy using rice,³⁴ potato^{26,35} and wheat³⁵ starches as examples. The sizes of starch granules first increase slightly in excess of water at 35 to 55 °C and then increase sharply (by 55%) at 65 °C, reaching the maximum at 75 °C. At temperatures above 75 °C, starch granules are destroyed and crystallinity disappears. The viscosity of the system kept at the temperatures indicated above increases until the gelatinisation step is reached. At higher temperatures, amylose is separated from amylopectin due to partial destruction of the physical lattice nodes after which starch dissolution begins. Cooling of aqueous solutions of starch again results in the formation of gels which contain swollen granules consisting predominantly of amylopectin; the amylose component of starch is predominantly localised in the intergranular space.

The dissolution of rice starch was studied by DSC and was interpreted³⁴ as a phase transition, since the thermograms displayed a peak of heat absorption at 75 °C corresponding to the gel transition. Using DSC, it was shown that the increase in the water content in wheat starch from 2.8 mass % to 90 mass % and subsequent heating induced several structural transitions due to melting of amylopectin crystallites and its complexes with lipids as well as due to melting of amylose in the swollen samples.³⁶

The content of amylose and amylopectin, their molecular masses and the content of lipids depend on the origin of starch. These factors affect the interaction of starch with water. The gel-forming abilities of starches isolated from the grains of hard and soft corn,³⁷ hard wheat and potatoes grown in different geographical zones, from rice³⁴ and green herbs³⁸ have been studied. It was shown that starches isolated from gramineous plant seeds contain less amylose than potato starch and have lower values of the temperature and enthalpy of gelatinisation. In contrast, starches isolated from green herbs, which contain more amylose (up to 30 mass %) of high molecular mass (up to 4.5×10^3 kg mol⁻¹) and highly branched amylopectin, have higher values of these parameters.

Studies on the structure and gelatinisation of amylopectin samples ($M_w = 0.2 \times 10^3 - 1 \times 10^3$ kg mol⁻¹) specially prepared from yellow corn revealed²¹ that the gels kept at constant temperature (4 °C) are typical representatives of thermoreversible gels formed by physical lattice nodes. The crystallinity of such gels increases upon storage as can be evidenced from wide-angle X-ray scattering data²¹ and the increase in the area of the endothermal peak on the DSC curves^{21,39} resulting from the increase in the enthalpies of melting of starch crystallites. Apparently, water which plays the role of a plasticiser by increasing the mobility of starch granules increases the crystallinity as in the case of the synthetic polymers.⁴⁰ It was also shown²¹ that the structural perfection of amylopectin crystallites depends on the conditions of gel crystallisation.

The interaction of starch samples differing in the amylose content with water was studied by Shogren and Jasberg.¹⁸ The behaviour of corn starch containing 28 mass % of amylose in the swelling and subsequent gelatinisation differs considerably from the behaviour of starch with the amylose content of 50 mass % to 70 mass % at equal molecular masses of the polymers. These differences affect starch concentrations at which gelatinisation begins, enthalpies of gelatinisation and the syneresis rates of the gels.

The effect of the molecular mass of the amylose starch on its solubility was studied by Moates *et al.*³² With a change in the molecular masses from 2 to 10 kg mol⁻¹ in systems with the same degree of swelling (0.8), the dissolution temperature of starch increases from 57 to 119 °C. Extrapolation to infinitely high molecular mass gives a dissolution temperature of 147 °C.

It was found^{41,42} that homogenisation of wheat or potato starch in water is facilitated by mechanical action on the system, *e.g.*, by extrusional stirring of the components. It was shown⁴²

that the threshold of a twin-screw extruder of the mixer driver is 120–150 kW h⁻¹ below which the system cannot pass into the fluid state. This limiting value depends on the viscosity of the mixture, which is proportional to the molecular masses of amylose and amylopectin.

Plasticisation of starch with water and its simultaneous exposure at elevated temperature and under mechanical stress makes it possible to change considerably the physical and mechanical properties of the starch–water system. The reason for these changes is in irreversible destruction of starch granules, mechanical stress being the crucial factor in this process. Reprocessing of plasticised starch on standard technological equipment for moulding of plastic materials (*e.g.*, extruders, casting machines, *etc.*) permits one to obtain materials possessing different physical properties.

Glycerol and oligomeric polyglycols can also exert a plasticising effect on starch. These plasticisers are generally used in combination with water. The thermoplastic properties of materials obtained by extrusion of mixtures of potato starch with glycerol and water were studied by van Soest *et al.*⁴³ Two specimens were studied based on the native starch, *viz.*, that with $M_w = 37\,000\text{ kg mol}^{-1}$ and that with $M_w = 1900\text{ kg mol}^{-1}$ prepared by partial acid hydrolysis. The specimens containing less than 9 mass % of water were glass-like and had elasticity moduli from 400 to 1000 MPa. If the water content in these materials was from 9 mass % to 15 mass %, they acquired elastic properties but became soft and fragile with an increase in the water content above 15 mass %. The differences in the thermoplastic properties of these materials are due to the presence of water rather than to the differences in the molecular weights of the starches. Thermo-mechanical analysis revealed that T_g of the extruded samples decreased appreciably with an increase in the water content (Table 1). It was assumed^{43,44} that the properties of starch-based thermoplastic materials are determined by the formation of a complex network consisting of linear chains of amylose and branched molecules of amylopectin in which hydrogen bonds play a crucial role. A lower value of the fracture energy of an elastic material prepared from low-molecular-weight starch can be attributed both to the shorter length of the amylose chain and to smaller molecular mass and branching of the amylopectin molecules.

Table 1. The changes in T_g of extruded samples of potato starch plasticised with water.⁴³

Water content (mass %)	T_g / °C	
	material prepared from native starch	material prepared from hydrolysed starch
14	5	—
11	25	—
8	42	—
5	59	58

The effects of glycerol (14 mass %–39 mass %) and water (1 mass %–28 mass %) on the phase behaviour of barley starch were studied using DSC and dynamic thermomechanical analysis.⁴⁵ Samples with low content of water and glycerol formed homogenous monophasic systems. Strong interaction of starch with glycerol in samples containing less than 20% of water presumably impedes crystallisation of amylopectin as a result of which the system remains amorphous and monophasic. With an increase in the concentration of the plasticising agents, the mixture separates into a starch-enriched and a starch-depleted phases as evidenced from the appearance of mechanical loss peaks corresponding to T_g of the individual phases.

Simultaneous use of water and glycerol as plasticisers makes it possible to obtain flexible starch-based thermoplastic materials by

compression moulding⁴⁶ and extrusion.⁴⁷ The materials prepared from corn, potato and wheat starches were characterised by constant (with respect to starch) content of glycerol (1:0.3), contained from 8 mass % to 25 mass % of water and were elastic ($T_g < 20\text{ °C}$). Studies of mechanical properties of such materials established a dependence of the elasticity modulus and breaking stress (σ_p) both on the content of the plasticising agents and on the origin of starch.^{46,47} The difference in mechanical properties is presumably due to the higher content of amylopectin in corn starch, which is plasticised with water more readily than potato starch enriched with high-molecular-weight amylose.⁴⁷

The mechanical properties of plasticised starch depend on the storage time prior to testing.^{48,49} Storage of thermoplastic materials prepared from corn⁴⁸ and potato⁴⁹ starch at high relative humidity (up to 90%) results in an increase in their breaking stress, while their elongation at disruption decreases. The reason for this phenomenon is the time-dependent post-crystallisation of starch in the presence of water and glycerol; the degree of crystallinity of B-type structures in the tested samples increases from 5% to 30%.

The amylose and amylopectin components of starch plasticised with water and glycerol manifest different abilities for structural rearrangements.⁵⁰ Analysis of extrusion samples of specially prepared high-amylose and high-amylopectin starches (the amylose content varied from 0% to 70%) revealed⁵⁰ that in amylose-enriched materials further crystallisation occurs much faster than in amylopectin-enriched ones.

The higher ability of plasticised amylose for post-crystallisation was also established in samples of the amylose starch obtained by compression moulding.⁵¹ The elasticity moduli of plasticised, partially crystallised samples comprising structures of the V- and B-types were practically the same immediately after moulding. After storage, the elasticity moduli of the samples prepared from normal corn starch was ~100 MPa, whereas those of the high-amylose starch were of about 700 MPa. These differences seem to be due to the fact that high-amylose starches contain more amorphous structures capable of additional crystallisation.⁵¹

Storage of samples also causes certain changes in T_g due to the condensation of amorphous regions of starch as a result of formation of additional nodes on the physical lattice and conformational rearrangement of the macromolecules, leading to the formation of molecular and intramolecular double helices of amylose and amylopectin.³⁹

In addition to glycerol and polyglycols, other substances can exert a plasticising effects on starch. Calorimetric determination of T_g of starch films containing water and additives (10%–20%) of glycerol, sorbitol, sodium lactate, urea, ethyleneglycol, diethyleneglycol, polyethyleneglycol (PEG-200) and glycerol diacetate was carried out by Lourdin *et al.*⁵² All these compounds, with the exception of glycerol diacetate, formed homogeneous systems with starch; their T_g decreased monotonically with an increase in the concentration of the plasticisers. The glycerol acetate–starch system was characterised by phase separation; the value of T_g did not change in the presence of the plasticiser.

The water in the starch not only transfers the system into a thermoplastic state upon extrusion, but also partly protects the polymer from destruction. For example, sage starch which contained from 34% to 47% of water was incapable of dextrinisation (*i.e.*, degradation leading to low-molecular-weight and oligomeric carbohydrates) but was easily gelatinised, if the extrusion was carried out under drastic conditions (150 °C, high screw speeds).⁵³ According to other investigators, the processing of this polysaccharide into a thermoplastic material is always accompanied by destruction. Thus, mixing of yellow corn starch⁵⁴ with water (18 mass % or 23 mass %) in a two-screw extruder decreases its molecular mass from 3.36×10^5 to $4 \times 10^4\text{ kg mol}^{-1}$. After repeated extrusion in a single-screw extruder at 110 or 130 °C, the decrease in the molecular mass is less pronounced. It was proposed⁵⁴ to use the value of specific mechanical energy applied to the polymer on moulding for the calculation of the expected

decrease in the molecular mass when choosing the type of the extruder and the regime of moulding of thermoplastic materials.

Water and other agents containing hydroxy groups are used as additives in the preparation of thermoplastic materials for single or short-term use. A significant drawback of these materials is their low resistance to water. Therefore, in recent years starch mixtures with synthetic polymers have acquired increasing importance together with thermoplastic materials prepared from starch without additives. These materials combine characteristic properties of their synthetic component with biodegradability owing to the presence of a natural biodegradable component, *viz.*, starch.

IV. Mixtures of starch with synthetic polymers

Composite starch mixtures with various synthetic polymers were first proposed in the 1970–1980's.^{55–59} Most often, starch is used for the modification of polyethylene (PE), a film material designed for short-term use (*e.g.*, packaging of food stuffs, agriculture and medicine, *etc.*). In these mixtures, starch usually plays the role of a filling agent, which ensures the biodegradation of the polymeric item after its service life is over.⁶⁰ Thermoplastic mixtures of synthetic polymers with starch are typically prepared from starch plasticised with glycerol and water. The components are mixed in an extruder at $\sim 150^\circ\text{C}$, which temperature ensures good gelatinisation of the polysaccharide⁶¹ and leads to the formation of two-phase mixtures the biodegradation of which begins from the surface of a starch-enriched film. Small amounts of pro-oxidants favour biodegradation by inducing oxidative decomposition of the material under natural conditions.⁶² A PE–starch–vegetable oil mixture is an example of such a composition.⁶³ Vegetable oil plays the role of a pro-oxidant and simultaneously facilitates the mixing of the natural and synthetic polymers in the course of moulding.

Starch is poorly compatible with non-polar PE; therefore, investigations into improvement of the affinity of the natural and synthetic polymers should be aimed at preparing starch mixtures with co-polymers of ethylene with other more polar monomers as well as at producing modified starches with enhanced affinity for PE.

1. Mixtures of starch with ethylene co-polymers

Co-polymers of ethylene with vinyl acetate (EVAc) or the products of saponification of acetate groups in these co-polymers are most commonly used as components of starch mixtures. These mixtures are prepared from yellow or native corn as well as from high-amylose starch Hylon VII by extrusion with the ethylene–vinyl alcohol co-polymer [EVAL, 56% of $\text{CH}_2\text{CH}(\text{OH})$ units]. Their structural characteristics were studied by wide-angle X-ray scattering, scanning and transmission electron microscopy and DSC.⁶⁴ Heterogeneous mixtures of EVAL with yellow corn starch displayed a clearly defined boundary between the phases; the sizes of the domains were proportional to the extrusion time. In heterogeneous mixtures of EVAL with native corn and Hylon starches, the inhomogeneities decreased faster than in the case of yellow corn starch; the boundaries between the phases as seen in the electron micrographs were diffuse. There was a decrease in the melting temperature of the synthetic polymer, which testified to partial miscibility of the components at the interphases. Simmons and Thomas⁶⁵ prepared phase-separated mixtures of various compositions, which contained domains (0.1–3 μm) enriched either with starch or with EVAL depending on the composition. At the starch content of 55 mass %–60 mass %, the phase reversal was accompanied by drastic changes in the domain sizes. An analysis of the phase compositions of starch mixtures revealed that the compatibility of the components increased with an increase in the amylose content in the starch.

Fibres cast from these mixtures manifested reduced sensitivity to moisture and low initial rates of enzymic biodegradation even in starch-enriched systems. The surface of these fibres was coated with a layer of a synthetic co-polymer, since the matrix phase of

the system was EVAL with the starch content of up to 70 mass %.^{64,65}

The water resistance and mechanical properties of starch mixtures are determined by the ratio of their constituents. Absorption of moisture by films⁶⁶ prepared by blowing of mixtures of native corn starch pre-plasticised with glycerol and water and EVAL [1:1 (mixture A); 2:1 (mixture B)] varied from 2% to 11% and was greater in the films prepared from mixture B. The breaking strength of the films prepared from mixture A was one-third of that for films prepared from pure EVAL and even less for films prepared from mixture B.

The use of electron irradiation (flux energy 2.5 MeV, 2500 Gray s^{-1}) in the formation of thermoplastic EVAL–starch mixtures makes it possible to modify the structure and rheological properties of these compositions.^{67,68} EVAL was shown to be resistant to irradiation, which causes predominantly destruction of starch macromolecules by changing their supramolecular organisation and thus facilitating the mixing of starch with EVAL. The mechanical and rheological properties of irradiated mixtures differ substantially from those of the original samples. The mixtures containing high-amylose starch appeared to be the most resistant to irradiation, which can be attributed⁶⁸ to chemical reactions of the linear molecules of the amylose starch with the synthetic polymer under the influence of irradiation.

The conditions for moulding of starch mixtures with EVAL strongly influence their degradability. The favourable effect of the structural anisotropy of starch–EVAL mixtures which appears in the injection moulding on the resistance of the mixtures to the action of physiological solutions (estimated from the mass loss and changes in the mechanical properties upon ageing for 80 days) and ethylene oxide used for the sterilisation of materials in clinical practice was demonstrated by Reis *et al.*⁶⁹

In-depth studies into the properties of starch mixtures with EVAc and with EVAc modified with maleic anhydride (EVAMA) were carried out by Ramkumar *et al.*^{70–74} Mixtures of commercial corn starch (25 mass % of amylose, 75 mass % of amylopectin) with co-polymers containing 18 mass % (EVAMA-18) and 28 mass % (EVAMA-28) of CH_2CHOAc units and about 0.8 mass % of anhydride fragments were prepared by extrusion carried out at different temperatures, screw speeds and mixing times. A dynamic mechanical analysis⁷² performed at different shear rates (0.005–0.5 s^{-1}) and frequencies (0.1–100 s^{-1}) in a broad range of temperatures revealed that all the mixtures under study displayed two regions of relaxation transition temperatures, *i.e.*, -30°C for the synthetic polymer and 40°C for starch, which testifies that these systems are heterogeneous. The introduction of anhydride fragments into the co-polymer macromolecule causes a shift in the transition temperatures, which suggests improved compatibility of the components.

The changes in the crystallinity of starch granules in the course of mixing were demonstrated by DSC.⁷² The starch–EVAMA mixtures are characterised by lower values of heats of melting (Table 2), *i.e.*, the structure of starch granules in these mixtures changes to a greater degree. Repeated compression moulding of the mixtures also decreases the heat of melting.

With an increase in the starch content in the mixtures, the viscosity of the systems changes, reaching a maximum level at 70 mass % of starch. The absolute viscosities of the mixtures containing EVAMA-18 are higher than those of starch–EVAMA-28 mixtures. It is noteworthy that the viscosities of starch mixtures of any composition exceed the additive values.^{72,73}

The ability of starch mixtures to absorb water strongly depends on the moulding conditions, *e.g.*, temperature, screw speed and injection pressure. Starch–EVAMA mixtures absorb water more readily than starch–EVAc mixtures (22 mass %–37 mass % or 20 mass %–27 mass % of water, respectively). Contrariwise, in the presence of water the values of diffusion coefficients and structural relaxation times calculated from the anomalous sorption model were higher for starch–EVA mixtures. These differences were attributed to the different degree of

Table 2. The heats of melting of starch mixtures with ethylene co-polymers.⁷⁰

Sample	Heats of melting ^a of samples /J g ⁻¹	
	following extrusion	following additional compression moulding
Starch–EVA ^b		
20:80	—	75.8
40:60	101.0	95.5
Starch–EVAMA-18 ^b		
40:60	46.9	19.7
70:30	—	98.0
Starch–EVAMA-28 ^b		
40:60	56.6	26.0
70:30	—	68.7

^aThe heat of melting of dry starch is 35.9 J g⁻¹; ^bThe figures in parentheses designate the starch:co-polymer ratios.

starch destruction during the formation of mixtures with EVAc and EVAMA rather than to the presence of anhydride groups in the co-polymer.⁷⁰

Using wide-angle X-ray scattering, it was shown⁷³ that 20-week storage of starch mixtures with a synthetic polymer leads to structural rearrangements resulting in the restoration of the crystalline structure of starch, which was completely lost in the course of moulding. The changes in crystallinity are especially well-pronounced during the first five weeks following moulding; as a result, the resistance of starch samples to rupture increases. After storage of the samples at 10 °C, the structural changes become less apparent, but are manifested on storage at 50 °C, since relaxation transitions in starch occur around this temperature.⁷²

From the data taken altogether, Ramkumar *et al.*^{70–74} concluded that the presence of anhydride fragments in the co-polymer chain is favourable for the improvement of compatibility of the starch mixture constituents. Mixtures of co-polymers of EVAc and EVAMA with the starch content of 70 mass % manifest good mechanical and moulding properties and are fairly resistant to water.

Mixtures of starch with an ethylene–propylene co-polymer (EP), polystyrene (PS), an ethylene–propylene–maleic anhydride co-polymer (0.8 mass %, EPMA) as well as with a styrene–maleic anhydride co-polymer (8 mass %, SMA) obtained by extrusion at 120–180 °C were studied at different effective mechanical moulding energies.^{75–79} In these studies, the effects of the composition (40 mass %–70 mass % of starch) and moulding conditions on the structure and properties of starch mixtures were analysed. As in the case of starch–EVAMA mixtures,^{70,72} the miscibility of components improved in the presence of anhydride fragments in the synthetic polymer chain. This phenomenon was interpreted^{75–79} as the chemical reaction between starch and the synthetic polymer under the influence of high temperatures and shear stress in the extruder on moulding. This reaction results in the formation of ester bonds between the carboxy groups in the co-polymer chain and the primary hydroxy groups of starch.

Comparison of mechanical characteristics of the mixtures suggests that the co-polymers containing anhydride fragments react more strongly with starch (Table 3).⁷⁶ The breaking strength of starch–SMA mixtures is lower than that of pure SMA or PS but higher than that of starch–PS mixtures. In EPMA-containing compositions, the increase in the starch content up to 70 mass % increases the breaking strength of the systems. The increased resistance of starch mixtures with polymers containing anhydride groups is a result of enhanced interphasic adhesion at the boundary between the structural inhomogeneities caused by the reaction of the anhydride groups of the synthetic polymer with the hydroxy groups of starch.

Table 3. The breaking strengths of polymers and polymer–starch mixtures.⁷⁶

Sample	Starch:co-polymer ratio	σ_p /MPa
SMA		33.2
Starch–SMA	60:40	18.4
	70:30	17.7
PS		31.0
Starch–PS	60:40	9.6
EPMA		6.2
Starch–EPMA	60:40	6.4
	70:30	8.3
EP		> 8.9
Starch–EP	70:30	2.8

Starch mixtures with EPMA and SMA are easy to mould, display satisfactory mechanical characteristics and are biodegradable by spores of the fungus *Penicillium funiculogum*, which is facilitated with an increase in the starch content. At low starch content, starch granules remain encapsulated within the synthetic polymer and are thus hardly accessible to microorganisms.⁷⁶

Starch–EPMA and starch–SMA films are highly hydrophilic. Adsorption of water by these specimens depends on the method for the preparation of the mixtures and the moulding regime, since mechanical action induces decomposition of starch granules. Both compositions are rather resistant to water at room temperature despite high starch content (50 mass %–80 mass %); after keeping in water for two months, they absorb as little as 10 mass %–30 mass % of H₂O. The resistance of starch mixtures with EPMA to water under conditions mimicking sterilisation (121 °C, 10 min) is higher than that of starch mixtures with SMA.⁷⁶

Using scanning electron microscopy, it was shown⁷⁸ that a material possessing good mechanical properties can be prepared by varying the compositions of three-component mixtures (starch–SMA–EPMA) and moulding conditions. Starch granules in this material have a size of 1 to 5 µm.

A thermoplastic material was obtained⁸⁰ by extrusion of a mixture of wheat, potato, corn or rice starch (36 mass %) with an ethylene–acrylic acid co-polymer (used as ammonium salt, EAA, 41 mass %), water (12.5 mass %), urea (8.4 mass %) and polyethylene glycol (PEG, 2,1 mass %). Mechanical characteristics of films depended on the origin of starch as well as on the contents of water and PEG. The films based on wheat starch possessed the highest values of the elasticity modulus (~180 MPa). The mechanical characteristics deteriorate with an increase in the concentration of the plasticiser.

Thermooxidation resistance of mixtures of low-pressure polyethylene (LPPE) with a methyl methacrylate–butadiene–styrene co-polymer (MBS), with EAA and plasticised starch at 190 °C was studied^{81–83} using thermogravimetry, DSC and IR spectroscopy both upon continuous heating and in the isothermal regime. It was shown that MBS and EAC accelerate, whereas starch

decelerates thermooxidation of LPPE. A ternary LPPE–EAA–starch system appeared to be the most resistant to temperature, apparently due to the stabilising effect of the co-polymer at the PE–starch interface.

2. Mixtures of starch with cellulose derivatives and other natural polymers

A great number of investigations of the past decade^{84–92} were devoted to studies of starch mixtures with other natural polymers, such as pectins, cellulose, *etc.*, or products of their chemical modification. The feasibility of production of biodegradable packaging films for food stuffs as well as for biomedical purposes from starch–gutta-percha mixtures was studied by Arvanitoyannis *et al.*⁸⁴

Biodegradable starch mixtures with natural water-soluble polysaccharides, *viz.*, pectins, were studied^{85–87} using dynamic mechanical analysis, dilatometry, scanning electron microscopy and IR spectroscopy. Plant cell wall pectins contain esterified polygalacturonic acid residues, the degree of esterification depending on the origin of pectin. The pectins studied were isolated from citrus plants, sugar beet, almonds and water-melon rinds.^{85–87} The rupture strength and elasticity modulus of films cast from aqueous solutions practically do not depend on the origin of pectin. The rupture strengths of glycerol-plasticised films of pectin–starch mixtures change only slightly with an increase in the plasticiser content up to 45 mass %. Further increase in the glycerol content up to 75% sharply decreases the rupture strength and increases 10-fold the chain elongation at break. The increase in the starch content in the mixtures attenuates the plasticising effect of glycerol and thus makes the films more rigid. The level of mechanical properties of pectin–starch–glycerol films correspond to the mean values of the mechanical characteristics of films prepared from ordinary synthetic polymers ($\sigma_p = 27$ MPa, elasticity modulus 2×10^3 – 3×10^3 MPa). A change in the dynamic strain at a constant frequency of 1.6 Hz over a broad range of temperatures (from -100 to -200 °C) causes the appearance of three regions of mechanical relaxation, *viz.*, at -50 , 25 and ~ 100 °C. The position of mechanical losses peaks depends on the amount of the plasticiser (glycerol) added, *viz.*, the transition temperature decreases with an increase in the glycerol concentration. Using IR spectroscopy, it was shown⁸³ that the position of the band corresponding to the carboxy group of pectin changes noticeably after addition of glycerol, whereas the positions of the absorption bands characteristic of starch change to a lesser degree. The results of spectral studies⁸³ suggest that plasticised films prepared from starch mixtures are highly compatible with pectin. However, phase homogeneities of the systems under study were not proved.

Extrusion of corn starch mixtures with microcrystalline cellulose and methyl cellulose (MC) in the presence of additives, *e.g.*, plasticisers (polyols), or without them was used to produce edible films.⁸⁸ The increase in the concentration of the cellulose component increases the rupture strength and decreases the elongation at break and the permeability of films for water vapour.

Thermoplastic films plasticised with triacetyl glycerol were obtained by hot moulding of mixtures of potato or corn starch with cellulose diacetate (CDA).⁸⁹ The ratio of the polymeric components in the mixtures was varied at a constant concentration of triacetyl glycerol (35 mass %) relative to the total polymer mass. It was shown that the effective viscosity of the mixture decreases with an increase in the starch content from 10 mass % to 80 mass %, while the fluidity index of the melt increases from 2 to 70 g within 10 min, which was interpreted as an increase in the plasticiser content relative to CDA with a rise in the starch content in the system. Potato starch forms more viscous compositions with CDA than corn starch.

Commercial plasticised films were prepared from starch–CDA mixtures by injection moulding.⁹⁰ In their mechanical properties, these films are similar to polystyrene films but are additionally biodegradable. In these mixtures, biodegradation

first affects starch and the plasticiser and only afterwards involves CDA. The compositions containing starch and cellulose acetate are unstable in sea water but can be used as biodegradable non-toxic plastics for short-term use in air.

Using static sorption of water vapour, it was shown^{91,92} that water-soluble starch forms mixtures with MC and carboxymethylcellulose (CMC), which are thermodynamically compatible if the starch content is below 25 mass %; with an increase in the starch content, the systems become microheterogeneous. The rate of biodegradation of such films by microorganisms in water–soil suspensions as determined by the evolution of carbon dioxide depends on the degree of swelling and solubility of the components of the polymeric mixture in water, which facilitates their biodegradation. The rate of biodegradation of MC and CMC mixtures with starch in aqueous media does not depend on the phase state of the system and increases with an increase in the starch content.

Starch mixtures with ternary co-polymers based on caprolactam, dodecalactam and salts of adipic or sebacic acids with hexamethylene diamine were obtained by compression moulding.⁹³ The mixtures of components containing up to 30 mass % of starch are compatible as evidenced from the negative iodine test and the presence of a single relaxation dielectric loss peak around 50 °C. The resistance of these mixtures to water depends on the number of non-polar methylene groups between the amide bonds of the co-polymer. In systems with the same content of starch, the stability of the mixture containing a dodecalactam-based co-polymer is higher. The biodegradation of these films in water, as in the majority of starch-containing mixtures, is facilitated with an increase in its concentration in the system.

Extrusion of a mixture of starch, EVAI and inorganic compounds, *e.g.*, hydroxyapatite, was used to obtain biodegradable materials.⁹⁴ These compositions contain more than 30 mass % of natural or synthetic hydroxyapatite and resemble bone both in exterior and in mechanical properties. Scanning electron microscopy and X-ray diffractometry data testify to the homogeneity of their microstructure.

All the polymeric mixtures mentioned above could find practical application in the future. The thermoplastic materials (*e.g.*, Mater Bi, Novon, Bioflex) manufactured in Italy, USA, Canada and Germany (predominantly for ‘fast food’ enterprises) provide examples of commercial compositions based on starch.^{7,95–97}

Novon, a thermoplastic material prepared from plasticised starch, usually contains modified derivatives of polysaccharides.

Mater Bi represents a mixture of starch with polycaprolactone or EVAI and usually contains glycerol as the plasticiser.

The materials prepared from these compositions are highly stable and compete favourably with PE films in mechanical properties.^{96,97} The films prepared by extrusion and blowing can be used in the production of plastic bags for carrying small loads (~ 3 to 5 kg).

The biodegradability of Mater Bi materials under aerobic and anaerobic conditions in water and in compost has been studied in detail.⁹⁵ It was shown that the plasticiser is washed out rapidly in aqueous media. The starch : polycaprolactone ratio remains constant (54 : 46) under aerobic conditions during biodegradation with bacteria; under anaerobic conditions, the biodegradation predominantly affects starch.

3. Chemical modification of starch

Yet another method for the preparation of starch-based materials is chemical modification of starch, which consists in polymer-analogous transformations (most commonly, by esterification of the hydroxy groups) or introduction of fragments of different chemical origin into the polysaccharide macromolecule (*e.g.*, the synthesis of the so-called graft co-polymers). In this review, we shall consider the properties of the compositions containing the products of polymer-analogous conversions of starch and their mixtures with other polymers.

Starch acetates differing in the degree of substitution (from 1.5 to 2.5) were obtained from high-amylose corn starch.⁹⁸ According to DSC data, their T_g values changed from 165 to 185 °C; after plasticisation with water, T_g decreased to 35–95 °C. Extrusion of highly substituted starch acetate containing 15 mass % of water was used to obtain foamed materials, which surpassed foamed polystyrenes in plasticity and stability on compression. It is assumed⁹⁸ that such materials can be used in the production of packaging materials for agricultural and food industries.

Mechanical properties of films prepared from acetylated starch are determined by the origin of starch,⁹⁹ being dependent on the content of amylose and amylopectin in the original polymer.¹⁰⁰ The films with a high content of branched amylopectin acetate display high rupture strengths but are fragile.¹⁰⁰

Starch acetates are much less hygroscopic than non-modified starch.¹⁰⁰ Using four samples of acetylated corn starch with a fixed (from 3.3 mass % to 66 mass %) content of amylose as examples, it was shown that esterification increases the solubility and swelling capacity of starch in organic media.⁹⁹ Acetylated starch gels are less rigid and more elastic and transparent than the gels formed by the original starch. The low-amylose starch acetate is an exception. However, in contrast to native starch, the acetylated products are less biodegradable, since esterification prevents the action of enzymes on starch.⁹⁹

Mixtures of acyl derivatives of starch with yet another biodegradable polymer, viz., poly-3-hydroxybutyrate (PHB), are highly recommended as candidates for starch compositions.¹⁰¹ The components of the polymeric composition are incompatible as evidenced from the independence of the positions of their characteristic absorption bands in the IR spectra on their ratio. However, the temperature and enthalpy of melting of partially crystallised PHB decrease after the addition of starch acetate, which affects the morphological properties of PHB crystallites and increases its ability for crystallisation.

Carboxymethyl starch was obtained by treatment of yellow corn starch and pigweed starch (the degree of substitution = 0.1–0.2) with chloroacetic acid.¹⁰² Small additions of carboxymethyl starch were used for the extrusion of various food stuffs derived from semolina. It was found that modified starch improves processing of these products.

Elastic edible films were prepared from hydroxypropyl starch mixed with gelatine and plasticised with polyols and water (up to 25 mass %) by Arvanitoyannis *et al.*¹⁰³ The permeability of these films for oxygen and CO₂ increases with an increase in the content of the plasticiser in the system, which deteriorates the quality of packaging materials for food stuffs.

Higher fatty acid esters of starch are promising reagents for mixing with non-polar polymers, such as PE and polypropylene.¹⁰⁴ The reaction of starch with the corresponding acid chlorides in DMSO gave starch octanoates and dodecanoates with the degree of substitution of 1.8 and 2.7. The ester groups containing higher alkyl radicals improve the affinity of starch for the non-polar synthetic polymer and act as internal plasticisers. The compatibility of starch dodecanoate with PE is higher than that of starch octanoate. The starch dodecanoate–PE mixtures manifest higher thermal stabilities, greater elongation at break upon rupture and lower moisture absorption than starch octanoate–PE mixtures. However, being introduced into PE at any ratios, these substances decrease the rate of biodegradation of the mixture in comparison with starch–PE mixtures.

Starches modified by the introduction of cholesterol residues¹⁰⁵ and mixed with high-pressure PE were used for the production of blown films. In comparison with non-modified starch, these materials are more homogenous and more stable. Biodegradation in a compost of films prepared from these mixtures occurs even faster than that of non-modified starch–PE mixtures, apparently due to the loosening of the starch structure caused by bulky cholesterol fragments.

The preparation and investigation of properties of the systems based on chemically modified starch has found lesser application

than the preparation of systems from mixtures of native starch with other polymers.

V. Conclusion

Studies carried out in the past decades have demonstrated that biodegradable materials should combine high mechanical and other essential operational and technological properties (*e.g.*, stability, low gas permeability, environmental safety, easy moulding, *etc.*) with biodegradability. Biodegradable materials based on starch or starch mixtures with synthetic polymers are the most readily available and have found wide practical application.

The properties of starch-based polymeric materials including their biodegradability depend on the compatibility of the mixture components and the structure of the systems thus prepared. However, the thermodynamic and energetic characteristics of the interaction of starch with synthetic polymers within the mixtures and the structure of such systems are still poorly known. It is these properties of starch mixtures with synthetic polymers that must be subject of comprehensive analysis in order to establish the general regularities with the ultimate goal to select the components and technologies for the preparation of polymeric materials, which are stable in various media and biodegradable.

The widening of the range of biodegradable polymeric systems is very important for future studies; therefore it is hoped that the results described in this review will be useful for further studies based on the use of this environmentally important scientific approach.

V. Conclusion	478

Abstract. The published data on the methods of synthesis and chemical transformations of nitrogenous heterocyclic compounds spiro-fused with a cyclopropane fragment are described systematically and generalised. The bibliography includes 146 references.

I. Introduction

Synthesis and studies of the properties of highly strained carbocyclic compounds, including those incorporating a cyclopropane ring, is a field of organic chemistry which is developing most intensely. Today, many methods for the synthesis of cyclopropanes are known; their chemical transformations have been studied, and diverse spheres of practical use of these compounds have been found by now. The introduction of a spiro-fused cyclopropane fragment in a heterocyclic molecule changes the reactivity of the heterocycle. The high strain of the three-carbon ring predetermines its ability to undergo facile opening with a change in the spiro-carbon atom hybridisation from sp^3 to sp^2 . Since heterocyclic compounds (including mono- and polynitrogen-containing ones) find use as medicines and as chemical means for plant and animal protection, synthesis of their analogues with a spirocyclopropane fragment is interesting both from the theoretical viewpoint and for the preparation of new biologically active compounds, in particular, potential pharmaceuticals.

Synthesis of heterocycles containing a spiro cyclopropane fragment involves either the formation of a heterocyclic structure from compounds that already possess a three-carbon ring or the formation of a cyclopropane ring in structures incorporating the required heterocycle. The first approach is primarily based on various [3 + 2]- and [4 + 2]-cycloaddition reactions that can be carried out using either cyclopropane-containing dipolarophiles (dienophiles), e.g., methylenecyclopropanes, or nitrogen-containing 1,3-dipoles or dienes in which one atom of the cyclopropane ring is involved in the reactive fragment. Diazocyclopropane generated *in situ*, which readily reacts with

certain unsaturated compounds to give spiro[cyclopropanedihydropyrazoles], is a promising building block of the latter type.

The second approach is based on the addition of aliphatic diazo compounds to the activated exocyclic double bond in a heterocycle followed by dedinitrogenation of the resulting dihydropyrazoles, as well as on the addition of carbenes or ylides to methylenesubstituted heterocycles.

This review is a first attempt at generalisation of the published data on the synthesis and some chemical transformations of heterocyclic compounds incorporating a spirocyclopropane fragment and at least one nitrogen atom in the ring. The presented material is mostly arranged according to the class of the key compounds used for the construction of the spirocyclopropane-containing azaheterocycles. The structures in which the cyclopropane fragment is not spiro-fused directly with the azaheterocycle are not considered.

II. The formation of nitrogen-containing heterocyclic systems from compounds with a cyclopropane fragment

1. Cycloaddition involving diazocyclopropane

Diazocyclopropane (**1**) is a promising compound for the synthesis of compounds incorporating a spiro-fused cyclopropane fragment which are difficult to access.^{1–4} Generally, diazocyclopropane (**1**) is generated by decomposition of *N*-cyclopropyl-*N*-nitrosourea (**2a**)^{1,4} or *N*-cyclopropyl-*N*-nitrosocarbamate (**2b**)^{2,3} on treatment with strong bases, by analogy with the synthesis of aliphatic diazo compounds.⁵ Unlike the majority of the known aliphatic and cyclic diazo compounds, both diazocyclopropane (**1**) and all of its derivatives mentioned in the literature^{6–9} are quite unstable compounds which have not been detected in individual form. Nevertheless, the formation of diazocyclopropanes *in situ* follows from the methods used for their generation and chemical trapping. For example, its reactions with unsaturated compounds result in 1,3-dipolar cycloaddition products, *viz.*, the corresponding spiro[cyclopropane-4,5-dihydro-3*H*-pyrazoles].

Y = NH₂ (**a**), OEt (**b**).

Uspekhi Khimii 69 (6) 507–527 (2000); translated by S S Veselyi

The reaction of diazocyclopropane (**1**) with oxosteroids^{2,3} should be noted as one of the first examples of the trapping of compound **1** with unsaturated compounds. For example, diazo-

cyclopropane (**1**) generated *in situ* undergoes selective addition to the Δ^{16} bond of the diene **3** to give dihydropyrazole **4**. The reaction of an excess of the diazo compound **1** with the carbonyl group of the adduct **4** results in oxaspiropentane **5**. Thermolysis² of the dihydropyrazole **4** isolated in individual form, as in the case of similar dihydropyrazoles obtained by the addition of other diazoalkanes,¹⁰ occurs non-selectively: in addition to the usual reaction product, *viz.*, the spirocyclopentane derivative **6**, the β -substituted α,β -enone **7** is formed (the ratio **6**:**7** is 3.5:1).

It should be noted that the reaction of diazocyclopropane (**1**) with the cyclohexenone fragment of steroids under the same conditions occurs in a different way.³ For example, the reaction of compound **8** gives not only the expected addition product to the Δ^{16} bond, *i.e.*, the adduct **9**, but also compound **10** due to the six-membered ring expansion, which is similar to homologisation of cyclic ketones on treatment with diazomethane.¹¹ Cyclobutanone **11** formed upon formal addition of cyclopropylidene to the carbonyl group of the cycloheptane fragment of compound **10**³ was identified as a minor product.

Although diazocyclopropane (**1**) can in principle be trapped by alkenes to give spiro[cyclopropanedihydropyrazoles], this reaction did not find synthetic application for a long time, primarily because the nature of unsaturated substrates which can enter into 1,3-dipolar cycloaddition with compound **1** was not

determined with certainty. In fact, there are several examples where generation of diazocyclopropane (**1**) in the presence of unsaturated compounds, such as cyclohexa-1,4-diene,¹² bicyclopentylidene,¹³ or cycloalkyl-substituted bicyclopentylidenes,^{14–16} resulted in spirane hydrocarbons rather than dihydropyrazoles which were formed due to [1 + 2]-cycloaddition of cyclopropylidene to these compounds. Generation of diazocyclopropane from compounds **2a,b** can produce, in addition to cyclopropylidene, other unstable species. The pathways of transformation of cyclopropyl nitrosourea **2a** and cyclopropyl nitrosoureas substituted at the cyclopropane ring on treatment with reagents of different basicity and nucleophilicity were studied in a series of works by Kirmse *et al.*^{1,17–27} It was assumed that their reactions give rise to cyclopropyldiazonium salts, as well as cyclopropyl and allyl cations due to the dedinitrogenation of these salts.

(a) weak base; (b) strong base.

Systematic studies of 1,3-dipolar cycloaddition of diazocyclopropane (**1**) to alkenes, first of all a systematic search for efficient traps for compound **1** to give spiro[cyclopropanedihydropyrazoles], date back to the beginning of the 1990s. It was found that reactions of diazocyclopropane (**1**), generated *in situ* on treatment of cyclopropyl nitrosourea (**2a**) with sodium methoxide, with norbornene⁴ and other compounds containing the bicyclo[2.2.1]heptene fragment²⁸ mostly result in spiro[cyclopropanedihydropyrazoles] of the types **12** and **13**, exclusively as *exo*-isomers. Good yields (50%–70%) are achieved if a molar excess as low as 1.5-fold of the unsaturated substrate with respect to cyclopropyl nitrosourea (**2a**) is used.

The asymmetrically substituted hydrocarbon **14** gives a mixture of isomeric spiro[cyclopropanedihydropyrazoles] **15a** and **15b** due to the different approach of diazocyclopropane to the double bond; their ratio was ~1:1 and the overall yield was 55%–58%. The polycyclic diene **16** reacts with diazocyclopropane (**1**) in a similar way.²⁸ Despite the steric hindrance created by the spirocyclopropane fragment in the norbornene moiety, dihydropyrazoles **17a** and **17b** (in a ratio ~1.4:1) are also formed exclusively as *exo*-isomers, although their overall yield (23%) is markedly lower than that of norbornene unsaturated at position 7. It should be noted that this reaction did not give any addition products of diazocyclopropane (**1**) (or cyclopropylidene) to the cyclopentene double bond.

The reaction of norbornadiene with diazocyclopropane (**1**) generated *in situ* also occurs as 1,3-dipolar cycloaddition, although less selectively, and results in a mixture of isomeric mono- (**18**) and bisadducts (**19**) in 32%–35% and 35%–38% yields, respectively.⁴

Unlike the adducts **12**, **13**, **15** and **17**, monospiro[cyclopropanedihydropyrazoles] **18** are a mixture of *exo*- and *endo*-isomers in the ratio $\sim 4:1$, while the bisadducts **19** formed from them are a mixture of four isomers in the ratio $\sim 10:7:1.3:1$. Although a two-fold excess of norbornadiene is used, bisadducts **19** are formed in an even greater quantity than monoadducts **18**; the addition of the second diazocyclopropane molecule to monoadducts **18** occurs exclusively at the *exo* position.

Benzvalene and 3,3-disubstituted cyclopropenes are also efficient trapping agents for diazocyclopropane (**1**).^{4, 28, 29}

R = Me; R–R = (CH₂)₃.

The reaction of diazocyclopropane (**1**) with alkynylcyclopropane **20** results in regioisomeric dihydropyrazoles **21a** and **21b** in the ratio $\sim 3:1$; this reaction does not involve the triple bond.²⁹

1,3-Dipolar cycloaddition products are formed in reactions of diazocyclopropane (**1**) with methyl cyclopropenecarboxylates **22**

and **23**.^{28, 29} The regioselectivity is low in the case of the cyclopropene **23**.

In the synthesis of dihydropyrazoles from cyclopropenes **20** and **22**, alternate addition of cyclopropylnitrosourea (**2a**) and the corresponding cyclopropene to a suspension of MeONa in a MeOH–ether mixture at -20 to -30 °C was found to be the method of choice.²⁹

It should be noted that the majority of the resulting polycyclic spiro[cyclopropanedihydropyrazoles] possess rather high thermal stability.³⁰ For example, dihydropyrazoles **12** and **13** are stable when heated to 200 °C. In the gas phase at 410–450 °C, they undergo dedinitrogenation to give a mixture of strained hydrocarbons, *viz.*, spiro[tricyclo[3.2.1.0^{2,4}]octane-1,3'-cyclopropane] (**24**) or spiro[pentacyclo[4.4.0.0^{2,8}.0^{3,5}.0^{7,9}]decane-4,1'-cyclopropane] (**25**), as well as isomeric compounds **26** or **27** containing a fused cyclobutane fragment (overall yield 30%–70%). An increase in temperature favours the isomerisation of the spirane hydrocarbons **24** and **25** to the corresponding unsaturated compounds **26** and **27**.

The unsaturated 4,5-dihydro-3*H*-pyrazole **18** obtained by the addition of diazocyclopropane (**1**) to norbornadiene eliminates cyclopentadiene instead of N₂ on thermolysis to give 3(5)-vinylpyrazole (**28**).³⁰

In addition to strained cyclic unsaturated compounds, conjugated aliphatic dienes such as buta-1,3-diene can also play the role of trapping agents for diazocyclopropane (**1**).²⁸ At -25 °C, 6-vinyl-4,5-diazaspiro[2.4]hept-4-ene (**29**) is formed as the major product; unlike polycyclic dihydropyrazoles, it readily undergoes polymerisation to give a rubber-like substance. The reaction of diazocyclopropane (**1**) with 2-methylbuta-1,3-diene also occurs as 1,3-dipolar addition, but 6-isopropylidene-4,5-diazaspiro[2.4]hept-4-ene (**31**) rather than 5-isopropenyldihydropyrazole **30** is formed in this case as the main reaction product. Apparently, the addition of diazocyclopropane occurs mostly to the unsubstituted

double bond, while the resulting dihydropyrazole **30** undergoes isomerisation under the reaction conditions.²⁸

It is well known that the reactivity of alkenes with respect to diazomethane and other aliphatic diazo compounds in 1,3-dipolar cycloaddition reactions is largely determined by the nature of the double bonds and that the reaction accelerates upon introduction of electron-withdrawing substituents.³¹ Successful 1,3-dipolar cycloaddition in the case of low-activity alkenes is usually provided by keeping the reaction mixture for a long time. This technique cannot be employed in reactions with diazocyclopropane because of its instability, which undoubtedly decreases the number of potential unsaturated partners of this reaction. It has recently been established that styrene³² and vinyl bromide³³ are rather good trapping agents for diazocyclopropane (**1**) generated *in situ*.³³ 1,3-Dipolar cycloadditions involving these alkenes occur regioselectively to give 5-phenyl- (**32a**) and 5-bromospiro[cyclopropane-1,3'-dihydropyrazoles] (**32b**), respectively. However, unlike the majority of spiro[cyclopropanedihydropyrazoles] considered above, including compound **32a**, bromodihydropyrazole **32b** is unstable and undergoes partial resinification and partial transformation to 3(5)-(2-bromoethyl)pyrazole (**33**) upon storage in an inert atmosphere at 15 °C for 8–10 days.³³ The reaction of the compound **32b** with MeONa in MeOH at 25 °C for 2 h results in a mixture of 3(5)-(2-methoxyethyl)- (**34**) and 3(5)-vinylpyrazoles (**28**) [overall yield ~ 80%, ratio (3–4) : 1].³³

R = Ph (**a**, 67%), Br (**b**, 60%).

It should be noted that the reaction of diazomethane with vinyl bromide in ether readily results in pyrazole hydrobromide due to the facile dehydrobromination of the bromodihydropyrazole formed initially.³⁴ Thus, the spirocyclopropane moiety in the compound **32b** reduces the ability of the heterocyclic fragment to undergo deprotonation.

Acrylic acid derivatives are good substrates for reactions involving diazocyclopropane (**1**); for example, the addition of cyclopropylnitrosourea (**2a**) to a mixture of methyl methacrylate and sodium methoxide (ratio 1 : 1.5 : 1.5) affords dihydropyrazole **35** in a yield up to 70%.³⁵

Diazocyclopropane (**1**) reacts with acrylonitrile and methyl acrylate with equal efficiency. However, in this case the composition of the reaction products depends on the conditions and the reagent ratio.³⁶ In particular, generation of diazocyclopropane (**1**) by the addition of cyclopropylnitrosourea (**2a**) to a mixture of an unsaturated compound and MeONa in a solvent was found to be unacceptable due to a side reaction of methanol addition to the electron-deficient double bond of acrylonitrile or methyl acrylate. The side reaction can be inhibited almost completely by changing the order of addition of the reagents.³⁶ At the ratio **2a** : acrylate ~ 1 : 1, the expected spiro[cyclopropane-1,5'-4,5-dihydro-1*H*-pyrazoles] **36a,b** are formed as the main reaction products (yields ~ 70%).³⁶

R = CN (**a**, 70%), COOMe (**b**, 69%).

It was shown later³⁷ that the synthesis of dihydropyrazole **36a** can be carried out with equal success with the use of K₂CO₃ instead of MeONa, but in this case complete decomposition of cyclopropylnitrosourea (**2a**) at 0–5 °C takes as long as 1–2 h.

Dihydropyrazoles **36a,b** (especially **36b**) are rather labile compounds which undergo partial decomposition even under the conditions of preparative TLC.

An increase in the amount of acrylonitrile or methyl acrylate to 2–2.5 equiv. with respect to cyclopropylnitrosourea decreases the fraction of dihydropyrazoles **36a,b** to ~ 15% and results in new reaction products, *viz.*, functionally substituted dihydropyrazoles **37a,b**, which, as shown in special experiments,^{36–38} are formed upon reaction of dihydropyrazoles **36a,b** with the excess of unsaturated substrates. The generation of the anions **38a,b** is probably the driving force of the observed transformations. This procedure makes it possible to obtain spiro[cyclopropanedihydropyrazoles] containing functional substituents in the side chain and in the dihydropyrazole ring (see Section III).

R = CN (**a**, 84%), COOMe (**b**, 80%).

Diazocyclopropane (**1**) undergoes regioselective addition to *trans*-β-nitrostyrene (**39**) to give 3-nitro-4-phenylspiro[cyclopropane-1,5'-4,5-dihydro-1*H*-pyrazole] (**40**).³⁷

1,3-Dipolar cycloaddition of diazocyclopropane (**1**) to phenyl vinyl sulfide,³⁸ divinyl ether³⁷ and methylenecyclopropane⁴ occurs with low efficiency (the yields of dihydropyrazoles are 5%, 13% and 12%, respectively). The reaction with methylenecyclopropane gave a mixture of two regioisomers **41a,b** in the ratio ~ 3 : 1; in addition to dihydropyrazoles, the reaction of cyclopropylidene with methylenecyclopropane also gave dispiro[2.0.2.1]heptane (**42**). As it could be expected, cyclopropyl methyl ether and allene were the main side products of decomposition of cyclopropylnitrosourea (**2a**).⁴

2. Cycloaddition involving substituted diazocyclopropanes

Along with the cycloaddition of diazocyclopropane (**1**) generated *in situ* to the unsaturated compounds considered above, there are examples of [3 + 2]-cycloaddition of substituted diazocyclopropanes to activated C=C bonds. For example, in the beginning of the 1960s, American authors obtained *N*-(2,2-diphenylcyclopropyl)-*N*-nitrosourea (**43**) and studied its decomposition in the presence of bases or on heating.^{7, 39, 40} On treatment with lithium ethoxide in saturated hydrocarbons, nitrosourea **43** is decomposed with evolution of N_2 but without the yellow coloration typical of diazo compounds; this reaction gives 1,1-diphenylallene (**44**) in high yield. In the presence of diethyl fumarate, the corresponding dihydropyrazole **45** is formed upon 1,3-dipolar cycloaddition of 2,2-diphenyldiazocyclopropane (**46**) to the double bond.⁷

Thermal decomposition ($60\text{--}82^{\circ}\text{C}$) of nitrosourea **43** in heptane or in an excess of diethyl fumarate results in the same compounds **44** and **45** (yields 95% and 44%, respectively);⁴⁰ this is untypical of other *N*-alkyl-*N*-nitrosamides.

The reaction of 2,2-dimethyl- and 2,2-dichlorodiazocyclopropanes, generated *in situ* from the corresponding *N*-nitroso-*N*-cyclopropylureas **47a,b**, with a reactive dipolarophile, *viz.*, 3,3-dimethylcyclopropene, was studied.⁸ In both cases, a mixture of two isomeric dihydropyrazoles was formed in $\sim 70\%$ yield; the ratio of the *anti* and *syn* isomers was 2.2 : 1 for compound **48a** and 1 : 1.3 for compound **48b**.

R = Me (a), Cl (b).

Generation of substituted diazocyclopropanes from substituted *N*-nitroso-*N*-cyclopropylureas is a promising method for the synthesis of nitrogenous heterocycles containing a polyspiran

fragment. It has been shown recently^{9, 41, 42} that diazospirlopentane (**49**) generated *in situ* from *N*-nitroso-*N*-spiropentylurea (**50**) reacts with 3,3-dimethylcyclopropene or methyl methacrylate to give 4,5-dihydro-3*H*-pyrazoles **51a,b** or **52a,b** fused with the spiropentane fragment (as mixtures of isomers in the ratio $\sim 1 : 1$).

The yields of the 1,3-dipolar cycloaddition products **51** and **52** increase considerably with a decrease in the temperature of the reaction. For example, the yield of dihydropyrazoles **52** is $\sim 20\%$ at -20°C and increases to 72% at -50°C .⁹ Evidently, diazospirlopentane (**49**) is even less stable than diazocyclopropane (**1**).

Unlike strained cycloalkenes or alkenes with electron-withdrawing substituents, bicyclopopylidene (**53**) reacts with diazocyclopropanes generated *in situ* to give polyspirocyclopropane-containing hydrocarbons, in particular, triangulans **54–56**, instead of dihydropyrazoles ([3 + 2]-cycloaddition products).^{13–16, 43} Evidently, diazocyclopropanes cannot react with bicyclopopylidene (**53**) according to 1,3-dipolar cycloaddition due to a specific nature of the double bond in this compound, which manifests itself, in particular, in a noticeable shortening of this bond;⁴⁴ these compounds undergo dedinitrogenation to give the corresponding cyclopropylenes **57–59**, which are mostly isomerised into allenes. The reaction of cyclopropylenes **57–59** with the original bicyclopopylidene (**53**) occurs as [1 + 2]-cycloaddition to give triangulans **54–56**.

Diazocyclopropane and cyclopropylidene do not react with alkynes, such as $\text{PhC}\equiv\text{CH}$, $\text{MeO}_2\text{CC}\equiv\text{CCO}_2\text{Me}$ and $\text{HC}\equiv\text{CC}(\text{Me})=\text{CH}_2$.^{29, 37}

3. Cycloaddition to methylenecyclopropane and its derivatives

Syntheses of spirocyclopropane-containing azaheterocycles make use of cycloaddition of nitrogen-containing 1,3-dipoles to methylenecyclopropane and its derivatives with substituents both in the cyclopropane ring and at the double bond.

For example, the reaction of diazomethane with methylenecyclopropane at 3 °C for two weeks results in a mixture of two regioisomeric dihydropyrazoles **60a,b** (overall yield 90%, ratio 55 : 45).⁴⁵ The addition of diazomethane and 3-diazoprop-1-ene to 2,2-difluoromethylenecyclopropane also occurs non-selectively; a mixture of three regioisomeric 4,5-dihydro-1*H*-pyrazoles **61a–c** (~ 3.7 : 1 : 1) is formed in the latter case.⁴⁶

Phenyl azide slowly adds to methylenecyclopropane (**62a**), benzylenecyclopropane (**62b**) or (diphenylmethylenecyclopropane) (**62c**) to give the thermally stable spiro[dihydrotriazolecyclopropanes] **63a–c**. It is assumed^{47, 48} that the reaction occurs through a concerted mechanism with the addition of the terminal nitrogen atom of phenyl azide to the tetrasubstituted carbon atom of the cyclopropane ring. Photolytic dedinitrogenation of 4,5-dihydro-1*H*-1,2,3-triazoles **63a–c** (Pyrex, high-pressure mercury lamp) affords new azaheterocycles **64a–c**, which are derivatives of 1-phenylazaspiropentane (yields 90%, 99% and 90%, respectively).^{47, 48}

Compound	R ¹	R ²	T /°C	t /days	Yield of 63 (%)
a	H	H	20	60	70–80
			50	1	70–80
b	H	Ph	100	1–2	38
c	Ph	Ph	100	1–2	51

Apparently, the azaspiropentane fragment can also be formed upon direct addition of nitrenes to the double bond of methylenecyclopropanes. At least, this is how the photochemical reaction of methyl azidoformate with methylenecyclopropane

to give 1-(methoxycarbonyl)azaspiropentane (**65**) is believed to occur.⁴⁸

Unlike phenyl azide, cyanogen azide and *p*-nitrobenzenesulfonyl azide do not give any stable dihydrotriazoles in reactions with cyclopropylidenecycloalkanes: they readily undergo dedinitrogenation. The addition of cyanogen azide to cyclopropylidenecyclohexane (~ 20 °C, 7 days) probably occurs non-regioselectively, since hydrolysis of the reaction mixture gives spiro[2.6]nonan-4-one and spiro[3.5]nonan-1-one (yields 46% and 30%, respectively).⁴⁹ The reactions of *p*-nitrobenzenesulfonyl azide with cyclopropylidenepolyspiroalkanes **66** occur regioselectively *via* dihydrotriazoles **67** which readily undergo dedinitrogenation with simultaneous ring expansion to give imides **68**.^{50–52}

$m = 0$ (a), 1 (b), 2 (c).

Similarly, diazocyclopropane (**1**) probably adds to the imide **68a** *via* an unstable dihydrotriazole, which is transformed into the imide **68b**.⁵²

Diverse heterocyclic compounds containing a spirocyclopropane fragment are obtained by treatment of methylenecyclopropanes with dihydrotriazoledione **69**; the reaction pathway depends considerably on the nature of the substituents at the cyclopropane ring. In particular, [2 + 2]-cycloaddition of *trans*-2,3-dimethyl-1-methylenecyclopropane to dihydrotriazoledione **69** at room temperature to give the adduct **70** occurs slowly.⁵³

With benzylenecyclopropane, dihydrotriazoledione **69** reacts much faster. However, in this case compound **71** formed in the first step, *i.e.*, a product of formal [4 + 2]-cycloaddition involving the benzene ring of the substituent, contains a cyclohexadiene fragment and readily adds the second molecule of dihydrotriazoledione **69** to give the bisadduct **72**.⁵³

The cycloaddition of dihydrotriazolodione **69** to bicyclopopylidene (**53**) occurs in an unexpected way; simple closure of the four-membered heterocycle in the resulting zwitter-ion **73** does not occur in this case. After an alkyl shift, the carbon atom in the cyclopropane fragment that was involved in the formation of the first C–N bond is attacked by the nucleophilic nitrogen atom. Diaziridine **74** is the only reaction product that was isolated.⁵⁴

Unlike the methylenecyclopropanes considered above, conjugated alkenylidenecyclopropanes react with dihydrotriazolodione **69** as true dienes to give [4 + 2]-cycloadducts. For example, the reaction with bis(cyclopropylidene)ethane occurs almost instantaneously and gives high yield of the cycloadduct **75** where both cyclopropane fragments are retained in the molecule.⁵⁵

1-Methyl-2-silyloxyprop-2-enylidenecyclopropane (**76**) can act as a 1,3-diene in the reaction with the dihydrotriazolodione **69**, giving a heterocyclic compound **77** in 55% yield.⁵⁶

Synthesis of polycyclic heterocycles with a spirocyclopropane fragment in the molecule is carried out using the reaction of the dihydrotriazolodione **69** with cyclic dienes **78a,b** or with their derivatives. The [4 + 2]-cycloadducts **79a,b** are formed in high yields under mild conditions.^{57–61} Subsequent transformations of the heterocyclic adduct **79b** afforded highly strained dispiro[2.0.2.4]decane **80**.^{59, 60}

$n = 1$ (a), 2 (b).

(a) H_2 , Pd/C, MeOH; (b) Bu^tOK, DMSO, H_2O ;
(c) CuCl_2 , H_2O , EtOH; (d) KOH.

Both linear and cyclic nitrones can act as 1,3-dipolar compounds in reactions with methylenecyclopropanes.^{62–66} The reaction of methylenecyclopropane with nitrones **81a–c** occurs as [3 + 2]-cycloaddition with retention of the cyclopropane fragment; in this case, mixtures of regioisomers **82a–c** and **83a–c** are

formed in the ratio (2–9):1 in 69%–86% yield,⁶² which are difficult to separate. Spiro[cyclopropane-1,4'-isoxazolidines] **83a–c** are more thermally stable than their regioisomers **82a–c**. The latter undergo rearrangement (400 °C, 0.2 mm Hg) to derivatives of 4-piperidones **84a–c** and enaminones, which allows one to isolate the isoxazolidines **83a–c** from the reaction mixture.

$\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$ (a); $\text{R}^1 - \text{R}^2 = \text{CH}_2\text{CH}_2\text{C}(\text{Me})_2$ (b), $(\text{CH}_2)_4$ (c).

The use of alkyl- and aryl-substituted methylenecyclopropanes and derivatives of cyclopropylidenecetic acid in these transformations makes it possible to obtain various fused spiro[cyclopropaneisoxazolidines] which are of interest as starting compounds in the syntheses of isoquinoline, quinolizidine, indolizidine and some other heterocyclic structures.^{63–72} Electron-donating substituents at the double bond favour the formation of spiro[cyclopropane-1,4'-isoxazolidines], whereas the 1,5'-regioisomers are formed in the presence of electron-withdrawing substituents. For example, the addition of cyclic nitrone **81b** to substituted methylenecyclopropane **85** results exclusively in isoxazolidine **86**, whereas the reaction of the same nitrone **81b** with the methyl ester **87a** or cyclopropylidenecetonitrile (**87b**) affords stereoisomeric spiro[cyclopropane-1,5'-isoxazolidines] **88a,b** and **89a,b**.^{63, 72}

Compound	R	Yield of 88 (%)	Yield of 89 (%)
a	CO ₂ Me	21	42
b	CN	70	17

The nitrones **81a–c** react with bicyclopopylidene (**53**) at 20–60 °C to give high yields of isoxazolidines **90a–c**, in which both spirocyclopropane fragments are retained. However, heating of the reaction mixture in aromatic hydrocarbons as solvents at 80–130 °C results in isomerisation of the isoxazolidines obtained to the corresponding spiro[cyclopropane-1,3'-piperidin]-4-ones **91a–c**; only the cyclopropane ring adjacent to the labile N–O bond is involved in the rearrangement.^{73, 74}

Compound	R ¹	R ²	Yield of 90 (%)	Yield of 91 (%)
a	Ph	Me	93	63
b	(CH ₂) ₂ CMe ₂		80	80
c	(CH ₂) ₄		60	65

Isomerisation of isoxazolidines **90a–c** to piperidones **91a–c** probably occurs by homolytic cleavage of the N–O bond in the heterocycle followed by fast rearrangement of the radicals and ring closure.

Only reactions with nitrones with symmetrically substituted bicyclopopylidenes, where isoxazolidines incorporating a spirocyclopropane fragment are formed selectively, are of preparative value. Otherwise, a complex mixture of isomeric compounds is formed, as is the case, *e.g.*, of the cycloaddition of the nitrone **81b** to monosubstituted bicyclopopylidenes **92a,b**. Mixtures of isomers **93** and **94** (overall yield 65%–85%) could not be separated chromatographically or after their thermal rearrangement to the corresponding piperidones.⁷⁴

R = CO₂Me (**a**), SPH (**b**).

The cycloaddition of nitrones to the double bond of the methylenecyclopropane fragment can occur in an intramolecular manner as well. The reaction with nitrone **95a** containing a trisubstituted double bond (25 °C, 24 h, yield 87%) occurs regioselectively to give the cycloadduct **96a**. The presence of an additional methyl group in the nitrone **95b** decreases the polarity of the double bond and the reactivity of the nitrone. At 80 °C (2 h), a mixture of two isomers **96b** and **97** in the ratio ~ 2 : 1 is formed.⁷⁵

R = H (**a**), Me (**b**).

Unsaturated analogues of isoxazolidines, *viz.*, spiro[cyclopropanedihydroisoxazoles], can be obtained by 1,3-dipolar cycloaddition of nitrile oxides to methylenecyclopropanes. The reaction of nitrile oxides **98a–c** with non-substituted methylenecyclopropane occurs regioselectively to give spiro[cyclopropane-1,5'-dihydroisoxazoles] **99a–c**.⁷⁶ Only in the case of acetonitrile oxide (**98c**) was the formation of a different regioisomer (~ 3%) observed.

R = Ph (**a**, 65%), Bn (**b**, 35%), Me (**c**, 60%).

R = Ph (**100a**, 64%), 2,4,6-Me₃C₆H₂ (**100d**, 100%).

Spiro[cyclopropane-1,5'-dihydroisoxazoles] substituted in the cyclopropane ring are obtained in a similar way from nitrile oxides **98a–d** and substituted methylenecyclopropanes.⁷⁷ Reactions of methylenespiropentane with nitrile oxides **98a** (20 °C, 16 h) and **98d** (60 °C, 4 h) in benzene results in dihydroisoxazoles **100a,d**, thermal rearrangement of which to ketones **101a,d** occurs regioselectively, exclusively with opening of the inner cyclopropane ring at the C(5)–C(2') bond.⁷⁸

The cycloaddition of nitrile oxides **98a–c** to bicyclopopylidene (**53**) occurs less efficiently than to methylenecyclopropane.^{73,74} Because of this, partial dimerisation of nitrile oxides to furoxans occurs. The yields of dispirano dihydroisoxazoles **102** can be increased by performing slow generation of nitrile oxide *in situ* (*e.g.*, in the synthesis of nitrile oxide **98a** by treatment of benzohydroxymoyl chloride with NaHCO₃) or by using spatially hindered nitrile oxides, *e.g.*, **98d**. However, the presence of extremely bulky substituents in the nitrile oxide molecule, *e.g.*, in compound **98e**, again decreases the yield of the target product. It should be noted that in the case of the nitrile oxide **98a** the resulting dihydroisoxazole **102a** partially reacts with it to give compound **103**.⁷⁴

Compound	R	T / °C	t / days	Yield of 102 (%)
a	Ph	66	7	40
c	Me	20	7	10
d	2,4,6-Me ₃ C ₆ H ₂	110	2	67
e	Ph ₃ C	110	7	17

Bicyclopopylidene (**53**) undergoes [2 + 2]-cycloaddition to chlorosulfonyl isocyanate to give the β-lactam **104**, but this is not the main product. Evidently, the reaction can occur as a two-step process to give the 1,4-zwitter ion **105**. The main reaction product is methylenecyclopropane-γ-lactam **106** formed by opening of one cyclopropane ring in the intermediate **105**.⁵⁴

Bicyclopopylidene (**53**) readily undergoes [4 + 2]-cycloaddition to heterodienes such as 1,2,4,5-tetrazine and its derivatives. The primary cycloaddition product readily undergoes dedinitrogenation, while the resulting 8,9-diazadispiro[2.0.2.4]deca-7,9-diene (**107**) undergoes trimerisation to the fused heterocyclic

compound **108** with six spiro-fused cyclopropane fragments in the molecule (a mixture of two stereoisomers).⁷⁹ Attempts to trap the heterodiene **107** failed.

Synthesis of fused azaheterocycles with a spirocyclopropane fragment can be carried out by the reactions of cyclopropylideneacetates with imines. For example, the ester **87a** undergoes formal [4 + 2]-cycloaddition to imine **109a** to give spiro[cyclopropane-1,3'-dihydroisoquinoline] **110**. The reaction of chloro-substituted methylenecyclopropane **87c** with imines **109b,c** in methanol gives the Michael adducts **111b,c** in almost quantitative yields. These adducts are thermally stable, but in the presence of lithium diisopropylamide or potassium *tert*-butoxide, carbenes are generated; the latter are transformed to compounds **112b,c** with a dihydro-2-azaazulene skeleton due to intramolecular cycloaddition to the benzene ring followed by isomerisation.^{80,81} This bicyclic system has been studied much less than the 1-azaazulene derivatives.

The cyclopropyl substituent at position 1 of azaazulenes **112b,c** can be opened on treatment with electrophilic reagents, which enables intramolecular cyclisation of the salts **113b,c** to give derivatives **114b,c**.⁸¹

Unlike 1-alkenylidenecyclopropanes which react with dihydrotriazolodione **69** or with chlorosulfonyl isocyanate with opening of the cyclopropane ring,⁸² *N*-mesitylcyclopropylideneazomethine (**115**) reacts with *N*-(dicyanomethylidene)aniline or phenyl isocyanate to give spiro[azetidinecyclopropanes] **116** and **117**. In the latter case, a considerable amount of the cycloadduct **118** is formed.⁸³

4. Other methods for the synthesis of azaheterocycles incorporating a spirocyclopropane fragment

Heterocyclic compounds incorporating a spirocyclopropane fragment in the molecule can be obtained by typical cyclocondensations involving cyclopropane derivatives. However, certain conditions have to be observed in order to keep the cyclopropane fragment unchanged in the course of the reaction. For example, the reaction of pyrazolidine-3,5-dione **119** with 1,1-cyclopropanedicarbonyl dichloride in the presence of an equimolar amount of triethylamine results in compound **120** containing a three-carbon ring. On the other hand, this reaction carried out with heating in THF in the absence of a base is accompanied by the three-carbon ring opening and results in the chloroethyl derivative **121**.⁸⁴

Intramolecular cyclisation of 1,1-disubstituted cyclopropane **122** on treatment with $\text{Ba}(\text{OH})_2$ results in lactam **123** containing a spirocyclopropane fragment. The latter undergoes heterocycle opening to give 1-(2-aminoethyl)cyclopropanecarboxylic acid on refluxing in aqueous dioxane in the presence of $\text{Ba}(\text{OH})_2$.⁸⁵

The cyclocondensation method with the use of 1-aminocyclopropanecarboxylic acid or its derivatives as structural blocks was used for a directed synthesis of a series of spiro compounds, *e.g.* **124**–**126**, which may be interesting as potential medicines.^{86–88} For example, benzodiazepine **125** was obtained in 48% yield by cyclocondensation of methyl 1-aminocyclopropanecarboxylate with *o*-nitrobenzaldehyde.⁸⁸

The 1-methylamino-2-methylcyclopropanecarboxylic acid moiety spiro-fused with the macrocycle is a constituent of cyclic octadepsipeptides, which are bifunctional antibiotics of the quinomycin series that can be intercalated into DNA.^{89, 90}

R = Buⁱ, Prⁱ, Me.

The incorporation of the spirocyclopropane fragment in the benzoxazine heterocycle of ofloxacin (a well-known antibacterial compound belonging to the fluoroquinolone series) was carried out according to the following scheme: condensation of β -oxoester **127** with triethyl orthoformate to give unsaturated ester **128**; formation of the 1,4-oxazine ring containing a spirocyclopropane fragment by treating compound **128** with 1-(hydroxymethyl)cyclopropylamine hydrochloride followed by heating of the reaction product **129** with anhydrous potassium fluoride in DMSO. Acid hydrolysis of the ester group followed by selective replacement of a fluorine atom by cyclic amines afforded the target compounds **130**.⁹¹

In the reaction of ninhydrin (indan-1,2,3-trione hydrate) (**131**) with 1-aminocyclopropanecarboxylic acid (**132**) (molar ratio 1 : 2) in boiling benzene, decarboxylation of the acid **132** occurs to give spiro[cyclopropane-1,5'-pyrrolidine] **133**. The reaction of equimolar amounts of the acid **132**, ninhydrin (**131**) and *N*-phenyl-

maleimide in acetonitrile under reflux results in spiro[cyclopropane-1,5'-pyrrolidine] **134**.⁹² It is assumed⁹² that these reactions involve the intermediate 1,3-dipole **135**.

In certain cases, the corresponding cyclopropane derivatives were deliberately obtained for the directed syntheses of biologically active compounds containing a spirocyclopropane fragment. For example, (1-benzyloxycarbonyl-1-bromomethylidene)cyclopropane (**137**) was obtained for the synthesis of the cyclopropane analogue of norpenicillin **136**.⁹³ The reaction of compound **137** with 4-mercaptoazetidin-2-one **138** in the presence of K₂CO₃ results in epimeric 2-bisnorpenicillanates **136** (ratio ~ 4 : 1, yield ~ 25%).⁹⁴

Although the yields of the adducts are low, this method is considered to be convenient⁹⁴ because it does not give rise to side transformations of the cyclopropane ring.

HMPT is hexamethylphosphorous triamide.

It is well known⁹⁵ that 1-azirines are widely used in the synthesis of heterocyclic systems containing a nitrogen atom in the ring. Highly strained 2-phenyl-1-azaspiropent-1-ene (**139**) is a useful starting compound for the synthesis of azaheterocycles containing a spirocyclopropane fragment. This compound is obtained by pyrolysis of the addition product of benzonitrile oxide **98a** to cyclopropylidenephosphorane.⁹⁶ The reaction of the spirane **139** with benzonitrile-4-nitrobenzylidene (**140**) generated *in situ* from *N*-(4-nitrobenzyl)benzimidoyl chloride occurs regioselectively to give the spiro{cyclopropane-1,6'-1,3-diazabicyclo[3.1.0]hex-3-ene} derivative **141**, the structure of which was

established from spectroscopic data and by its hydrolysis into 3,4-dihydro-5,6-diphenyl-2-pyridone.⁹⁷

Ar = 4-NO₂C₆H₄.

It is well known⁹⁸ that nitrones undergo 1,3-dipolar cycloaddition to compounds containing C=N bonds. Aziridine **139** also reacts with nitrones **142a,b**; however, the resulting cycloadducts **143a,b** are unstable under the reaction conditions (benzene, Δ) and are transformed into cyclopropylamides **144a** or **144b**.⁹⁷

R = Ph (a), 4-NO₂C₆H₄ (b).

III. Formation of a cyclopropane ring spiro-fused with a heterocycle

Cycloaddition of various reagents to methyldene derivatives of the corresponding heterocycles is one of the general ways to form a spiro-fused cyclopropane ring in heterocyclic compounds. Cyclopropanation of the double bond, which is usually activated by electron-withdrawing substituents, is mostly carried out by reactions with diazo compounds and ylides. In some cases, an opposite approach is used, where the required azaheterocycle contains a diazo group capable of reacting with an unsaturated substrate. In any case, the originally formed dihydropyrazoles, *i.e.*, 1,3-dipolar cycloadducts, are then transformed into cyclopropane derivatives upon elimination of a nitrogen molecule; depending on the nature of the substituents, this either occurs spontaneously at room temperature or requires elevated temperatures. In a number of cases, the choice of the target heterocyclic compounds, *e.g.*, indolinones or cephalosporins, is dictated by the search for new biologically active compounds.^{99–104}

1. Construction of a cyclopropane ring based on the formation and dedinitrogenation of dihydropyrazoles

The addition of diazomethane to methyldeneindolin-2-one derivatives **145a–d** results in spiro[indoline-3,3'-dihydropyrazoles] **146a–d** with high regioselectivity.^{102,103} Their thermolysis in boiling dioxane or treatment with HCl in MeOH at room temper-

ature involves elimination of nitrogen to give spiro[cyclopropane-1,3'-indolin]-2-ones **147a–d**. Chromatography of dihydropyrazoles **146a,b** on Al₂O₃ is accompanied by their transformation to conjugated enones **148a,b** (yields 57% and 74%, respectively) rather than to compounds **147a,b**.¹⁰³

R¹ = H, R² = Ph (**146a**, 92%), Me (**146b**, 90%), OEt (**146c**, 62%);

R¹ = CH₂N(CH₂)₂O, R² = OEt (**146d**, 74%).

Unlike methyldeneindolin-2-ones **145a–d**, fluoro-substituted 3-(arylmethyldene)indolin-2-ones **149** react with an ethereal solution of CH₂N₂ at 20 °C to give directly spiro[cyclopropaneindolin]ones **150**.¹⁰⁴

X = H, 5-F, 6-F; R¹ = H, COMe, CH₂N(CH₂)₂O; R² = 2-F, 4-F; R³ = H, 2-Me, 3-Me, 5-Me, 3-Cl, 3-F.

As in the example considered above, 1,3-dipolar cycloaddition of diphenyldiazomethane to methyldeneindolin-2-ones **145c,d** in DMF at 20 °C involves nitrogen elimination from the dihydropyrazoles formed originally to give spiro[cyclopropaneindolin]ones **147e,f**.¹⁰²

R = H (**147e**, 53%), CH₂N(CH₂)₂O (**147f**, 76%).

A similar approach to the construction of a spiro-fused cyclopropane fragment is also applicable to other heterocyclic systems; depending on the nature of the azaheterocycle and the substituents in the ring, the reaction of diazo compounds with the exocyclic double bond can involve both the formation of the intermediate dihydropyrazoles and their spontaneous dedinitrogenation.

The methods (including enantioselective ones) for the synthesis of 1-aminocyclopropanecarboxylic acid derivatives were

developed using 1,3-dipolar cycloaddition of diazomethane to 4-alkylidene(arylidene)-5(4*H*)oxazolones,^{105–108} thiazolones¹⁰⁹ and piperazinediones.^{110–112} The reaction with oxazolones **151** occurs at 20–45 °C with nitrogen elimination and formation of spiro[cyclopropanoxazolines] **152**. On the other hand, the reaction of CH₂N₂ with piperazinediones **153a,b** gives spiro-fused azaheterocycles **154** in high yields and with high diastereoselectivity (> 95%). Photolysis of the latter results in azaheterocycles **155** in > 90% yields. Acid splitting of the six-membered heterocycle in the resulting compounds on treatment with 6*M* HCl in AcOH at 100 °C results in 1-aminocyclopropanecarboxylic acid derivatives.^{110, 111}

R = Ph, 4-ClC₆H₄, 4-MeC₆H₄, 4-MeOC₆H₄ (45%–60%), Me (25%), Cl (75%), Br.

R¹ = Ac, R² = Ph (**a**); R¹ = Bu^tOCO (Boc), R² = Et (**b**).

If the oxazolone ring contains both substituted methylidene and vinyl fragments (*cf.* compounds **156a,b**), the addition of diazomethane occurs mainly to the methylidene fragment and the corresponding cyclopropane derivatives **157a,b** are formed as the reaction products even at room temperature.¹¹³ The addition of diazomethane to the vinyl group occurs only in compound **156b** and only to a minor extent to give the dihydropyrazole **158b**, which is stable under these conditions.

Ar = Ph (**a**), 3,4-(MeO)₂C₆H₃ (**b**).

The formation of a cyclopropane fragment spiro-fused with the heterocyclic system of cephalosporins is documented.¹¹⁴ For example, diphenyldiazomethane adds to the exocyclic double bond of 2-methylidenecephemes **159** (30 °C, 30 min) to give two isomeric spiro derivatives **160a** and **160b** in the ratio ~ 3 : 1. It is believed¹¹⁴ that the reaction occurs through regioselective formation of the dihydropyrazole **161**.

1,3-Dipolar cycloaddition of diazomethane to 3-methylidenecephemes **162** occurs at 5 °C in 1 week and only with a great excess of diazomethane.¹¹⁵ 1,3-Dipolar cycloaddition products **163** containing a spiro-fused dihydropyrazole fragment is formed in the first stage.

n = 0 (**a**), 1 (**b**); R¹ = PhOCH₂CO; R² = 4-NO₂C₆H₄CH₂.

Subsequent thermolysis of the resulting 1-dihydropyrazoles **163a,b** occurs non-selectively and results in both products with a cyclopropane fragment, *i.e.*, spiro[cephame-1,3'-cyclopropanes] **164a,b** (yields 60% and 64%, respectively), and their isomers, *i.e.*, 3-vinylcephemes **165a,b** (20% and 15% yields, respectively).¹¹⁵

Pure *E*- and *Z*-isomers of 2,2,2-trichloroethyl penicillanates **166** containing an exocyclic double bond react with diphenyldiazomethane to give stable 4,5-dihydro-3*H*-pyrazoles **167a** or **167b**, pyrolysis of which occurs stereospecifically and results in penicillanates **168** with a spirocyclopropane fragment.¹¹⁶

Compound	R ¹	R ²	Yield of 167 (%)	Yield of 168 (%)
a	CO ₂ Bn	H	72	89
b	H	CO ₂ Bn	87	15

The cyclopropane fragment spiro-fused with a heterocycle also results from the addition of the corresponding diazo hetero-

cycles to activated alkenes followed by dedinitrogenation of the resulting dihydropyrazole. For example, the reaction of 3-diazoindoles **169** with methyl acrylate or acrylonitrile in boiling benzene results in nitrogen elimination to give substituted spiro[cyclopropane-1,3'-indoles] **170** with the preferential formation of *anti*-isomers.¹¹⁷ It should be noted that diazo compounds **169** are rather stable under the same conditions in the absence of unsaturated substrates. It is therefore assumed that their reactions with methyl acrylate and acrylonitrile occur as 1,3-dipolar cycloaddition; the intermediate dihydropyrazoles undergo spontaneous dedinitrogenation.

Exhaustive 1,3-dipolar cycloaddition of aliphatic diazo compound to allenes followed by partial dedinitrogenation of the resulting spiro-fused bis(dihydropyrazoles) makes it possible to form fragments of an azaheterocycle and a spirocyclopropane simultaneously.^{118,119} For example, bis(dihydropyrazole) **171** synthesised by the addition of 2-diazopropane to allene is transformed into spiro[cyclopropanedihydropyrazole] **172** on heating to 100 °C. The loss of the second nitrogen molecule to give tetramethylspiropentane (**173**) occurs only at 200 °C.¹¹⁸

2. Cyclopropanation of unsaturated compounds with sulfur carbenes and sulfur ylides

Although the cyclopropanation of unsaturated compounds with carbenes and their synthetic equivalents is a popular modern method for the construction of three-carbon rings, there are but a few examples of such reactions resulting in azaheterocycles fused with a spirocyclopropane fragment.

Cyclopropanation of alkenes with heterocyclic diazo compounds in the presence of catalysts is an example. Diazopenicillanates and diazocephemes have been reported as cyclopropanating reagents.¹¹⁶ This method is an alternative to the reaction of aliphatic diazo compounds with methylenepenicillanates or methylenecephemes in the construction of the same structural fragments. Cyclopropanation of unsaturated compounds activated by electron-donating substituents occurs successfully. For example, the reaction of benzyl 6-diazopenicillanate (**174**) or 7-diazoceph-3-ene (**175**) with ethyl vinyl ether in the presence of copper acetylacetonate results in ethoxycyclopropanes **176** or **177** (each as a mixture of four isomers).¹²⁰

The reaction of diazo compounds **174** and **175** with vinyl acetate in the presence of Cu(acac)₂ occurs similarly, but the yields of the products do not exceed 10% due to the low stability of the resulting spiro-fused acetoxycyclopropanes.¹²⁰ The reaction of diazo compounds **174** and **175** with alkenes containing electron-withdrawing groups, both in the presence and in the absence of Cu(acac)₂, occurs as 1,3-dipolar cycloaddition and results only in the corresponding spiro-fused 4,5-dihydro-1*H*-pyrazoles.¹²⁰

Refluxing of trichloromethyl derivatives of imidazolidines **178** in xylene is presumably accompanied by the abstraction of CHCl₃ and generation of a nucleophilic heterocyclic carbene which can add to activated double bonds. For example, the reaction with *N*-phenylmaleimide affords spirocyclopropane-containing adducts **179**.¹²¹

Ar = Ph (85%), 4-MeC₆H₄ (57%), 4-MeOC₆H₄ (77%).

The reaction of dihydropyrazine **180** with butyllithium and tosyl azide at –70 °C in the presence of cyclohexene results in the spirane adduct **181** (overall yield > 70% with respect to the starting dihydropyrazine **180**) due to generation and [1 + 2]-cycloaddition of the heterocyclic carbene **182**.¹²²

(a) BuLi; (b) TsN₃, –70 °C; (c)

Dichlorocyclopropanation of 2-methylquinoline at 25 °C (CHCl₃, 50% NaOH, Et₃N⁺ BnCl[–]) occurs in rather high yields to give compounds **183** and **184** with a spiro[cyclopropane-1,2'-quinoline] structure. Probably, dichlorocarbene first adds to the nitrogen atom to give an ylide, which generates 1-formyl-2-methylidenedihydroquinoline (**185**) in alkaline medium; the latter undergoes the usual dichlorocyclopropanation.¹²³

The method for building the cyclopropane ring by addition of reactive sulfur ylides to double bonds is commonly used in synthetic organic chemistry.¹²⁴ Unlike the reactions with electrophilic carbenes, alkenes activated with electron-withdrawing groups (Michael acceptors) are used in these processes.

Back in 1973, Spry¹²⁵ demonstrated the possibility of using sulfur ylides for the cyclopropanation of 2-methylidenecephalosporins. For example, the reaction of sulfonylmethylide **186** with functionally substituted methylidenecephemes **187** occurs exclusively at the exocyclic double bond to give spiro[cephalosporin-cyclopropanes] **188** in high yields.¹²⁵

R ¹	R ²	Yield (%)
PhOCH ₂	H	80
PhOCH ₂	OAc	85
Me	OAc	64

The reaction of 3-methylidene-2,3-dihydrothiazin-4-one derivatives **189** containing an enone system with ylides **190** results in spiro[cyclopropanedihydrothiazines] **191**.¹²⁶ If ylide **190** contains a benzoyl substituent, a mixture (~1:2) of spirocyclopropane and dihydrofuran derivatives **191b,c** and **192b,c** is formed. Unsaturated ylide **190** (R² = H) reacts with the enone **189** (R¹ = Ph) to give only spiro[cyclopropanedihydro-1,2-benzothiazine] **191a**. It is believed¹²⁶ that the process starts with nucleophilic attack of ylides **190** on the β-carbon atom of the C=C bond in the enones **189**; this results in resonance-stabilised betaines, which then undergo cyclisation at the carbon or oxygen atoms to give three- or five-membered rings. The direction of betaine cyclisation is determined by both electronic and steric factors.¹²⁶

R¹ = Ph, Me; R² = H, COPh.

Compound	R ¹	R ²	Yield of 191 (%)	Yield of 192 (%)
a	Ph	H	80	—
b	Me	COPh	22	52
c	Ph	COPh	24	55

A common method for the introduction of the spirocyclopropane fragment in a morpholinone structure is the reaction of their methylenes derivatives **193**, which are obtained from the phosphonate **194** using the Wittig reaction, with sulfur ylides.¹²⁷ It should be noted that the diastereoselectivity of methylenation of the double bond by the ylide **195** is higher than that by the ylide **190a**; diastereomers of spirane derivatives **196a-f** are formed preferentially (or exclusively) in yields higher than 82% (with the exception for compound **196e**). It should be noted that the addition of diazomethane to ethylenemorpholinone **193b** followed by photolysis of the resulting dihydropyrazole affords a diastereomeric mixture of spirane **196b** (ratio 1:1.6, overall yield 91%).¹²⁷

R = H (**a**), Me (**b**), Et (**c**), Prⁿ (**d**), Prⁱ (**e**), Ph (**f**);

(a) RCHO, NaH, THF; (b) PhS(O)(NEt₂)CH₂⁺ (**195**).

3. Decarboxylation and γ-elimination leading to cyclopropane ring formation

The formation of a spiro-fused cyclopropane fragment is carried out by decarboxylation of γ-lactones **197** spiro-fused with a heterocyclic system, besides elimination of an N₂ molecule from dihydropyrazoles. This method was used for the synthesis of spiro[cyclopropane-1,2'-indolin]-3-ones **198** with substituents both in the benzene ring and at the nitrogen atom aimed at the search for novel compounds with antiinflammatory and analgesic effects.^{99, 100, 128}

Spiro-fused γ-lactones **197a-f** are obtained in two steps by condensation of the corresponding anthranilic acids with α-bromo-γ-butyrolactone. Decarboxylation of the lactones **197a-f** is carried out by heating (150–160 °C) in the presence of an alkali metal chloride to give the heterocycles **198** in 75%–94% yields.^{100, 128} Functionalisation of the benzene ring in the spiro-lactone **197a** is carried out before the decarboxylation step.

R = H (**a**), Me (**b**), OMe (**c**), Cl (**d**), Br (**e**), I (**f**).

1,3-Elimination from the corresponding functional derivatives is a useful method for the formation of a spiro-fused cyclopropane fragment applicable to various azaheterocyclic structures. In particular, this type of reaction includes cycloalkylation of compounds containing reactive hydrogen atoms with 1,2-dibromoethane. For example, the reaction of indolin-2-one with 2 equiv. of dibromoethane in the presence of sodium hydride results in compound **199**, subsequent reduction of which with magnesium in boiling THF gives unsaturated spiro[cyclopropane-1,3'-indolin]-2-one, which was later used for the synthesis of compounds with potential pharmacological activity.^{129, 130}

A scheme for the synthesis of spiro[1,4-benzothiazine]cyclopropan-3-one **200** with the use of 2-aminobenzethiol as the starting compound is presented below. The required functionalised ethyl group is introduced in the initial condensation step, while the spirocyclopropane fragment is formed in the last step, *i.e.*, cyclisation of mesylate **201**.¹³¹

(a) $\text{BrCH}_2\text{CH}_2\text{OH}$, K_2CO_3 , EtOH; (b) $\text{OCH}_2\text{CH}_2\text{OH}$, H^+ ; (c) $\text{BrCH}_2\text{CO}_2\text{Me}$; (d) MeOH, TsOH; (e) MsCl, Et₃N, CH₂Cl₂; (f) NaH, 20 °C, 30 min; (g) 70 °C, 15 min.

Alkylation followed by 1,3-elimination was successfully used for a stereoselective synthesis of (*R*)- and (*S*)-isomers of 1-amino-2,2-dideuteriocyclopropanecarboxylic acid. Spiranes **202** were used as the starting compounds which were then hydrolysed with HCl. These transformations could also be performed starting from chiral dihydropyrazine **203** and selectively deuterated 2-bromoethyl triflates.^{132, 133} Metallation of compounds **203** followed by alkylation with deuterated 2-bromoethyl triflate first gives (2-bromoethyl)dihydropyrazine **204a,b** (yield 86%–88%); in this case, an isomer with a *cis* arrangement of the benzyl and bromoethyl substituents is formed as the main product. Subsequent cyclisation of compounds **204a,b** on treatment with BuLi in THF affords spiro[cyclopropanedihydropyrazines] **202a,b** (yield 46%–55%).^{132, 133}

(a) $\text{BrCD}_2\text{CH}_2\text{OTf}$; (b) $\text{BrCH}_2\text{CD}_2\text{OTf}$.

In some cases, consecutive chemical transformations result in the formation of heterocyclic and then cyclopropane fragments. For example, the reaction of substituted thioureas **205a–e** with 2,4-dibromobutanoyl chloride occurs on treatment with 5% NaOH in the presence of benzytriethylammonium chloride

and results in a mixture of spiro[cyclopropane-1,5'-dihydrothiazol]-4-one derivatives **206a–e** (yields 18%–40%) and tricyclic compounds **207a–e**.¹³⁴ The reaction occurs in two steps, as shown for cyclohexylthiourea **205b**.

R = Bu (a), cyclo-C₆H₁₁ (b), Bn (c), Ph (d),  (e).

4. Miscellaneous methods for the formation of a spiro-fused cyclopropane fragment

A particular case of the formation of a cyclopropane ring spiro-fused with a thiazine fragment is represented by the transformation of tricyclic benzothiazine salts **208a,b**, which are obtained by chlorination of benzothiazine **209** followed by treatment of the resulting α -chloro derivative **210** with 1,3-dienes in the presence of AgClO₄.¹³⁵ Treatment of the benzothiazinium salts **208a,b** with reducing agents or bases results in 2'-vinylspiro[cyclopropane-1,2'-thiazines] **211a,b** in 56%–90% yields. Electrolysis of the salt **208a** in acetonitrile (1 h) also results in spiro[cyclopropane-1,2'-thiazine] **211a** in ~60% yield. It was found by X-ray diffraction analysis that the vinyl group and the sulfur atom in compound **211a** are *syn*-arranged. It was assumed¹³⁵ that the formation of spiro[cyclopropane-1,2'-thiazines] **211a,b** can follow both an ionic and a radical mechanism, although it was not specified which particular intermediates of radical nature can be generated in this system.¹³⁵

R = Me (a), H (b); (a) 20 °C: Mg, THF, or NaBH₄, EtOH, or Zn, AcOH; (b) B[–].

A spirocyclopropane fragment is formed in the reaction of bromomalonodinitrile with the electron-deficient exocyclic double bond of 2-methylidene-substituted dihydrobenzoxazole **212**.

Spiro[cyclopropane-1,2'-dihydrobenzoxazole] **213** is formed when an equimolar mixture of the reactants is kept for 2 h at 25 °C in 95% ethanol in the absence of bases.¹³⁶

The reaction of polycyclic enamines **214** with methyl 1-bromoacrylate or 1-chloroacrylonitrile results in spirocyclopropane-containing hexahydroindolindolizine (**215a**) or hexahydroindolindolizine (**215b**) salts. Treatment of these salts with NaBH₄ or other reducing agents results either in compounds **216** containing a spirocyclopropane fragment (in moderate yields) or in deeper reduction with the cyclopropane ring opening.^{137, 138}

$n = 1$ (**a**), 2 (**b**); $X = \text{Cl}, \text{Br}$; $Z = \text{COOMe}, \text{CN}$.

Desulfurisation of thietane derivatives can serve as yet another method for the formation of a cyclopropane fragment spiro-fused with an azaheterocycle. In particular, photolysis of a mixture of *N*-methylmonothiophthalimide (**217**) with 1,1-diphenylethylene or *trans*-stilbene results in spiro-fused thietanes **218** or **219a,b**,¹³⁹ desulfurisation of which with Raney nickel (Ni/Ra) in ethanol affords spiro[cyclopropane-1,3'-isindolin]-1-ones **220** and **221**; a mixture of two isomeric compounds, viz., *trans*- and *cis*-**221**, is formed from the isomer **219a** under these conditions. However, only one derivative, viz., *trans*-**221**, is obtained in almost quantitative yield if thietane **219a** is first oxidised with hydrogen peroxide in acetic acid to give sulfone **222**, which is then subject to photolysis.¹³⁹

IV. Functionalisation of heterocyclic compounds containing a spirocyclopropane fragment

In this Section, we consider chemical transformations of aza-heterocycles containing a spirocyclopropane fragment, which is preserved in these reactions. In particular, chemical modifications of 5-bromospiro[cyclopropane-1,3'-4,5-dihydro-3*H*-pyrazole] (**32b**) and 3-*R*-spiro[cyclopropane-1,5'-4,5-dihydro-1*H*-pyrazoles] **36a,b**, which have recently become accessible (see Section II), were studied.^{33, 36} It was found^{33, 140} that the bromine atom in compound **32b** can be replaced by nucleophiles such as PhO, PhS or N₃ to give compounds **223**, in which the spiro[cyclopropane-1,5'-dihydropyrazole] structure remains intact.

$X = \text{OPh}$ (**a**), SPh (**b**), N_3 (**c**).

It was shown recently^{32, 140} that 4,5-dihydro-3*H*-pyrazoles **32a,b**, **35** and **223c** add phthalimidonitrene, which is obtained *in situ* upon oxidation of *N*-aminophthalimide with Pb(OAc)₄, to give pyrazolinio-*N*-phthalimidoamides (azimines) **224a,b**–**227a,b** with retention of the cyclopropane ring. In this case, the regioisomers **a** are formed preferentially from all 4,5-dihydro-3*H*-pyrazoles (or exclusively from ester **35**).

Compound	R ¹	R ²	Yield (%)	Ratio a : b
224	H	Ph	70–75	5.5 : 1
225	H	Br	30–35	see ^a
226	Me	COOMe	50–55	1 : 0
227	H	N ₃	60–65	3.3 : 1

^a The isomer **225b** is unstable under the reaction conditions.

Thermolysis of the azimines **224** and **226** (*o*-dichlorobenzene, 170 °C) results in the elimination of one nitrogen molecule to give fused heterocyclic systems (compounds **228a,b**) with retention of the cyclopropane fragment; in addition, deeper partial dedinitrogenation of the azimines to give spiropentane derivatives **229a,b** is observed.³² It is assumed¹⁴¹ that spiro[cyclopropanetetrahydropyrazolo[1,2-*b*]phthalazine}diones **228** are formed due to the preliminary dissociation of azimines **224**, **226** to the starting dihydropyrazoles **32a**, **35** and phthalimidonitrene **230**. The nitrene **230** eliminates a nitrogen molecule to give benzocyclobutenedione

231, which is in equilibrium with its open diketene form. The latter reacts with dihydropyrazoles **32**, **35** to give compounds **228a,b** in 25%–28% yields. The 4,5-dihydro-3*H*-pyrazoles formed upon the destruction of azimines undergo dedinitrogenation to give the corresponding spiropentanes **229a,b**.

$R^1 = \text{H}$, $R^2 = \text{Ph}$ (**a**); $R^1 = \text{Me}$, $R^2 = \text{COOMe}$ (**b**).

3-Cyanospiro[cyclopropane-4,5-dihydro-1*H*-pyrazole] **36a**, like other 4,5-dihydro-1*H*-pyrazoles, can be acylated with benzoyl or cyclopropanoyl chloride in the presence of pyridine to give 1-acyl-4,5-dihydro-1*H*-pyrazoles **232**.¹⁴² On the other hand, the anions **38a,b** generated from 4,5-dihydro-1*H*-pyrazoles **36a,b** add to alkenes containing electron-withdrawing substituents exclusively as C(3)-nucleophiles [compounds **37a,b** are formed similarly (see Section II)].³⁶ For example, dihydropyrazole **36a** reacts with dimethyl maleate or dimethyl fumarate in the presence of MeONa to give a mixture of diastereomeric cyanodiester **233a,b** (ratio ~ 1.5 : 1, overall yield ~ 70%).^{37,38}

$R = \text{Ph}$, cyclo- C_3H_5 .

Unexpectedly, spiro[cyclopropane-1,5'-4,5-dihydro-1*H*-pyrazoles] **36a,b** readily react with diazocyclopropane (**1**) generated *in situ*. For example, decomposition of cyclopropylnitrosourea (**2a**) on treatment with MeONa or K_2CO_3 in the presence of dihydropyrazoles **36a,b** results in hitherto unknown (*E*)-cyclopropylazodihydropyrazoles **234a,b** as the main reaction products.^{36,42} A reaction scheme was suggested which is similar to that of the formation of azo compounds through azo-coupling of aromatic diazonium salts with various substrates, including 4,5-dihydro-1*H*-pyrazoles.¹⁴³ The reaction of the **38a,b** anions can probably involve diazocyclopropane precursors such as cyclopropyldiazohydroxide or the cyclopropyldiazonium cation formed upon alkaline decomposition of nitrosourea **2a**, rather than compound **1** itself.¹ This scheme is supported by the fact that aliphatic diazo compounds, *e.g.* diazomethane or methyl diazoacetate, do not enter into similar reactions with 4,5-dihydro-1*H*-pyrazoles **36a,b**.

$R = \text{CN}$ (**a**), COOMe (**b**).

It should be noted that azodihydropyrazoles **234a,b** can be obtained in one step by treating acrylonitrile or methyl acrylate with a two- to three-fold excess of cyclopropylnitrosourea (**2a**).³⁶

An attempt at isolation of azodihydropyrazole **234b** by TLC on Al_2O_3 resulted in its transformation to cyclopropylhydrazone **235** (probably due to hydrolysis of the ester groups followed by decarboxylation); the spiro[cyclopropane-1,5'-4,5-dihydro-3*H*-pyrazole] structure is retained under these conditions.

Thermolysis of azodihydropyrazole **234a** (110 °C, 2 h) is accompanied by elimination of the ring nitrogen atoms to give 1-cyano-1-(cyclopropylazo)spiro-pentane (**236**), which undergoes azocyclopropane–dihydropyrazole rearrangement at higher temperature (180 °C, 40 min)^{144,145} to give dihydropyrazole **237** with a spirocyclopropane fragment at position 4 of the heterocycle.³⁶

Substituted diazocyclopropanes generated by decomposition of *N*-nitrosoureas **47a** or **50** on treatment with sodium methoxide react with dihydropyrazole **36a** similarly to the unsubstituted compound **1** to give (*E*)-azodihydropyrazoles **238a** or **238b** (each as a mixture of two diastereomers in the ratio ~ 1 : 1).⁴²

$R = \text{Me}$ (**238a**, 70%); $R-R = \text{CH}_2\text{CH}_2$ (**238b**, 65%).

Bromination of cyanodihydropyrazole **36a** with *N*-bromosuccinimide (NBS) at 20 °C in the absence of radical initiators occurs at position C(3) of the heterocycle to give 3-bromo-3-cyanospiro[cyclopropane-1,5'-4,5-dihydro-3*H*-pyrazole] (**239**) in high yield. However, the resulting bromodihydropyrazole **239** has low stability and is transformed to the isomeric (2-bromoethyl)cyanopyrazole (**240**) in 3–4 days at room temperature.¹⁴²

The introduction of chlorine atoms in the cyclopropane ring makes it more stable with respect to electrophilic reagents, in particular Br_2 in methanol; this enables functionalisation of the heterocyclic part of the molecule. For example, bromomethoxylation of a quinoline derivative **241** at room temperature affords a high yield of compound **242** which retains the spiro-fused cyclopropane fragment.¹⁴⁶

Certain transformations of spiro[cyclopropane-1,2'-indolin]-3-one derivatives, in particular of compounds **198**, also occur with retention of the cyclopropane fragment; some functional derivatives showing antiinflammatory and analgesic activities were synthesised from them.^{100, 128} For example, the reduction of compound **198a** with sodium borohydride results in the hydroxy derivative **243**; its reactions with Grignard reagents give alcohols **244a, b**.

Saponification of *N*-acetylindolinone **198a** on treatment with MeONa or KOH in methanol results in unsubstituted spiro[cyclopropane-1,2'-indolin]-3-one **245** in an almost quantitative yield. The latter was used as the starting compound for the syntheses of alkyl-, acyl-, alkoxy carbonyl- and sulfonylspiro[cyclopropane-1,2'-indolin]-3-ones.¹²⁸

R = Ph (**244a**, 67%), Bn (**244b**, 79%).

Nitration of compounds **198a** with copper nitrate gives the 5-nitro derivative **246**, catalytic hydrogenation of which affords 5-aminoindolinone **247**. The acetyl amino and mesitylamino derivatives of the latter show biological activities. It is of note that treatment of the spirane compound **198a** with trifluoroacetic anhydride in acetic acid results not only in cyclopropane ring opening to give substituted indole **248**, but also in skeletal isomerisation of compound **198a**, probably through Wagner–Meerwein rearrangement. The rearrangement product **249** is formed in 40% yield.¹⁰⁰

V. Conclusion

It is evident from this review that the methods for the synthesis of nitrogenous heterocycles containing a spirocyclopropane fragment are quite diverse though rather laborious; this restricts considerably the study of the properties of these compounds. The interest in heterocyclic compounds incorporating a spiro-fused cyclopropane fragment stems from the search for new medicines and biologically active compounds. Some heterocycles with a spirocyclopropane fragment, such as derivatives of dihydroisoxazoles, indoline-2(3)-ones, cephalosporins and penicillanates, are of interest as potential pharmaceutical compounds.

Incommensurate suprastructures: new problems of inorganic solid-state chemistry

V S Pervov, E V Makhonina

Contents

I. Introduction	481
II. Synthesis and structures of misfit compounds	482
III. Physical properties of misfit suprastructures	483
IV. Interactions of substructures and phase stabilities of layered misfit compounds	485
V. Conclusion	487

Abstract. Data on a new class of inorganic incommensurate intergrowth suprastructures, *viz.*, layered misfit compounds, are surveyed and systematised. Physical properties of misfit suprastructures are discussed. Possible mechanisms of the effects of the electronic structure and incommensurability on the structural elements of suprastructures and on their recognition in molecular ensembles are considered. The general criteria for self-organisation of incommensurate suprastructures are proposed and conditions for the fragmentation of one of the sublattices (*i.e.*, conditions for the formation of nanocomposites) are given. The bibliography includes 82 references.

I. Introduction

The term 'supramolecular chemistry' was introduced by the Nobel laureate J-M Lehn in 1978. He defined this field as the chemistry beyond the molecule, which describes complex aggregates formed as a result of association of two (or more) chemical species linked by intermolecular forces.¹ In succeeding years, this new interdisciplinary science whose language, definitions and concepts are still in their developmental stage has been progressing rapidly.²

It should be noted that the range of subjects studied in supramolecular chemistry is being steadily extended, which generates a need for the discussion of some limitations on their choice, in particular, restrictions imposed by the requirements of the geometric and topological correspondence of structural elements upon self-organisation of supramolecular ensembles. As shown below, these limitations are of fundamental importance particularly in the case of inorganic suprastructures because their structures are substantially affected by the rigidity of conjugated extended structural elements. Thus it was demonstrated³ that a guest–host system, which governs differences in the principles of construction of supramolecules based on the structural organisation of the host (three-, two-, one- or zero-dimensional structures),

is better suited to the classification of inorganic subjects of supramolecular chemistry.

Incommensurability between a guest and a host is rather frequently observed in inorganic guest–host systems, which can lead to structural and morphological changes in the supramolecular ensemble as a whole. The problem of incommensurability has been stated and considered in most detail within the framework of supramolecular chemistry dealing with incommensurate intergrowth structures. Studies in this field were started more than a decade ago.⁴ Among these structures are inorganic compounds with crystal lattices consisting of two (or more) sublattices whose periods are noticeably different (at least in one direction). The term 'misfit' is finding increasing use for the description of such compounds.

Two types of compounds with incommensurate structural elements, *viz.*, linear (one-dimensional) and layered (two-dimensional) structures, are known.⁵ Systems characterised by a one-dimensional (chain) structure of the guest sublattice (substructure) belong to the linear type (these structures are also said to be columnar misfit structures). Generally, the sizes of the 'columns' correspond to the size of the host matrix in the *ab* plane perpendicular to the axis of the column, whereas the incommensurability is associated with its *c* axis. These structures are exemplified in crystals of $\text{Hg}_{3-x}\text{AsF}_6$ containing $-\text{Hg}-\text{Hg}-$ chains, which are located in cavities formed by AsF_6 octahedra,⁴ and in compounds of the $\text{A}_{1-x}\text{Cr}_2\text{X}_{4-x}$ series ($\text{A} = \text{Ba}, \text{Sr}, \text{Eu}$ or Pb ; $\text{X} = \text{S}$ or Se ; $x = 0.29$).⁶ The structure of one compound of this series, *viz.*, $\text{Eu}_{1-x}\text{Cr}_2\text{Se}_{4-x}$, is shown in Fig. 1. This compound is of interest because it contains two types of one-dimen-

Figure 1. Structure of $\text{Eu}_{1-x}\text{Cr}_2\text{Se}_{4-x}$ (projection along the incommensurate axis).⁵

sional guest sublattices, *viz.*, $\text{Eu}_6\text{Cr}_2\text{Se}_6$ and Eu_3Se , which thread the framework of the host $\text{Cr}_{21}\text{Se}_{36}$.

Suprastructures with incommensurate layers belong to layered misfit structures. In these structures, as in columnar misfit substances, the incommensurability is manifested only in one crystallographic direction along which the layers are aligned. These subjects are not new, since different combinations of crystallographically incommensurate layers (for example, gallium adsorbate on the surface of single-crystal silicon⁷ and some other epitaxial systems) have long been known and have been well characterised. Among layered misfit structures, synthetic complex chalcogenides of the general formula $(\text{MX})_{1+x}(\text{TX}_2)_m$ ($\text{M} = \text{Sn, Pb, Bi, Sb}$ or Ln ; $\text{T} = \text{Ti, V, Nb, Ta}$ or Cr ; $\text{X} = \text{S}$ or Se ; $x = 0.08\text{--}0.28$; $m = 1, 2, 3, \dots$) have been studied in most detail. These compounds represent analogues of the well-known minerals, *viz.*, cylindrite $[(\text{Pb,Sb})\text{S}]_{1.38}(\text{Sn,Fe})\text{S}_2$,⁸ franckeite $\text{Pb}_5\text{FeSn}_3\text{Sb}_2\text{S}_{14}$ (see Ref. 9) and some other minerals.¹⁰

The rather high thermodynamic stability of inorganic incommensurate compounds calls for revision of the existing concepts of the topological 'laws' of construction of supramolecular structures. When constructing incommensurate structures, researchers face two problems. The first problem is associated with the limiting values of the incommensurability up to which the structural elements (substructures) retain their capacity for self-organisation. The second problem is related to the consequences of this self-organisation. In the course of self-organisation of the suprastructure, forces responsible for the retention of the rigidity of its constituent substructures compete with forces linking these substructures to form a single suprastructure. This competition leads to various structural and morphological changes in the ensembles formed.

Since the discovery of incommensurate intergrowth structures, no structures possessing the incommensurability in more than one crystallographic directions have been found, *i.e.*, the topological principles of the construction of these compounds are rejected only partially. Nevertheless, even 'one-dimensional' incommensurability gives rise to very interesting properties of inorganic crystal structures.

On the whole, problems associated with the structures, phase stabilities and properties of incommensurate intergrowth suprastructures have not been adequately investigated, though, in our opinion, these problems are of importance for both inorganic supramolecular and solid-state chemistry.

In particular, one of the fruitful lines of investigation of incommensurate structures may be associated with an apparent analogy of the mechanisms of formation of intercalates A_xTX_2 (A is a donor species and TX_2 is a layered dichalcogenide matrix) to those of layered misfit compounds (with the same matrices).

It is also worthy of note that studies dealing with layered misfit compounds have been aimed mainly at searching for new combinations of incommensurate substructures, developing procedures for their structural identification and studying their physical properties. We believe that studies of layered misfit structures are of interest not only because of unusual properties of these compounds, but primarily because of considerable prospects of their application due to evident possibility of the preparation of materials possessing unique electrophysical and magnetic characteristics (if only due to the nontrivial behaviour of conduction electrons in incommensurate crystal fields).

II. Synthesis and structures of misfit compounds

Several procedures for the synthesis of incommensurate suprastructures are known. The majority of layered misfit structures $(\text{MX})_{1+x}(\text{TX}_2)_m$ have been prepared by solid-phase high-temperature synthesis starting from the elements or the corresponding binary compounds (MX and TX_2). Generally, suprastructures with $\text{M} = \text{Sn, Pb, Bi}$ or Sb are formed at about $800\text{--}900^\circ\text{C}$,^{11–16} whereas suprastructures with $\text{M} = \text{Ln}$ are formed at 1050--

1350°C .^{17–20} In all cases, the syntheses are completed in several days.

In a number of studies, layered misfit structures were prepared by slow heating of the starting mixtures to temperatures at which the synthesis started. Then the mixtures were kept at this temperature for several days and the resulting specimens were slowly cooled. Procedures for the synthesis of layered misfit compounds involving quenching of specimens from high temperatures (see, for example, Refs 12 and 16) were also reported. Unfortunately, the dependence of the properties of the resulting specimens on the mode of cooling was not examined.

Most of the known misfit compounds were prepared using stoichiometric amounts of chalcogenides MX and TX_2 ($1:m$) based on the formula $(\text{MX})(\text{TX}_2)_m$ (*i.e.*, at $x = 0$), although the compositions of the resulting substances are described by the formula $(\text{MX})_{1+x}(\text{TX}_2)_m$, where x is distinct from zero. Generally, syntheses of misfit compounds from the elements were carried out using a small excess of the corresponding chalcogen to accelerate the reaction (see, for example, Ref. 15).

A procedure for the preparation of layered misfit suprastructures (especially, based on REE) from the corresponding ternary oxides by their heating in a graphite boat under a stream of a mixture of hydrogen sulfide and an inert gas at $1300\text{--}1350^\circ\text{C}$ was also described.⁵ In particular, this procedure was used for the preparation of $(\text{LaS})_{1.19}\text{CrS}_2$.

Single-crystalline specimens can be synthesised by the transport reaction method. Traditionally, iodine^{19,20} or chlorine¹⁴ serves as the transporting agent. (It was mentioned that crystals were formed in the cooling zone of a furnace.) Crystals of 'PbNbS₃' and 'LaNbS₃' were grown with the use of an admixture of $(\text{NH}_4)_2\text{PbCl}_6$, which decomposed at high temperature to form PbCl_2 , NH_4Cl and Cl_2 .¹⁷ Apparently, the chlorine liberated acted as the transporting agent.

As mentioned above, layered misfit suprastructures of the $(\text{MX})_{1+x}(\text{TX}_2)_m$ type consist of layers of two substructures, *viz.*, MX (guest) and TX_2 (host). The guest layer (Q layer) has a pseudocubic NaCl-type lattice and the host layer (H layer) represents a 'sandwich' of hexagonal networks built up from X atoms. Atoms of the transition metal T are either in trigonal-prismatic (Nb or Ta) or octahedral (Ti, V or Cr) environment formed by X atoms (Figs 2 and 3).^{21–24} Thus the trigonal-prismatic and octahedral environments about the T atoms are observed in the structures $(\text{SnS})_{1.17}\text{NbS}_2$ (see Ref. 24) and $(\text{PbS})_{1.18}\text{TiS}_2$,²¹ respectively.

Layered misfit compounds differ in the number of the host layers per guest layer (for example, $1\text{Q}/1\text{H}$, $1\text{Q}/2\text{H}$ or $1\text{Q}/3\text{H}$).⁵ Therefore, these compounds are described by the general formula $(\text{MX})_{1+x}(\text{TX}_2)_m$, where the index m is the number of TX_2 layers per unit cell of the suprastructure along the c axis. Mono- ($m = 1$) and bilayer ($m = 2$) structures (Fig. 4) prevail. The arrangement of the structural elements along the b axis can also be different due to the presence of two extreme stacking sequences for the substructures. In the case of a body-centred (CC) arrangement of MX and TX_2 substructures, their c axes coincide, whereas in the case of a face-centred (FF) arrangement, these axes are shifted

Figure 2. Substructures MX (Q layer) and TX_2 (H layer) with incommensurate lattice parameters (a_Q and a_H).

Figure 3. Coordination of the T atoms in the trigonal-prismatic ($2H$) and octahedral ($1T$) polytypes of the TX_2 substructure.

Figure 4. Schematic representation of monolayer (a) and bilayer (b) misfit structures.

relative to each other by $a/2$. Intermediate modes (CF and FC) of arrangement of MX and TX_2 units were also found (Fig. 5).⁵

The limiting stoichiometry of the suprastructure $(MX)_{1+x}(TX_2)_m$ as a whole is determined by the ratio between the parameters a of the host and the guest (a_H/a_Q), which can change from 0.64 [for $(YS)_{1.28}CrS_2$]²² to 0.54 [for $(BiS)_{1.08}TaS_2$].²³ Here, $x = (4/2)(a_H/a_Q) - 1$ ($4/2$ is the ratio between the numbers of the MX and TX_2 formula units in the unit cell of the suprastructure). The parameters a_H and a_Q of the unit cells of selected layered misfit compounds are given in Table 1.

The application of the X-ray powder method and X-ray structural analysis to studies of misfit structures presents problems because the symmetry of these compounds should be described by four-dimensional space groups.^{4,17} It was also demonstrated that the precise identification of misfit structures is complicated by the following interrelating facts: by the presence of

Figure 5. Different structural types of layered misfit compounds based on NbS_2 and TaS_2 (projections along the $[100]$ direction).⁵

Table 1. Limiting stoichiometric ratios for the unit cells of some layered misfit compounds.

Compound	$a_Q/\text{\AA}$	$a_H/\text{\AA}$	$x = 2a_H/a_Q - 1$	$b_Q = b_H/\text{\AA}$	Ref.
$(SnS)_{1.17}NbS_2$	5.673	3.321	0.1708	5.751	24
$(LaS)_{1.14}NbS_2$	5.828	3.310	0.1359	5.797	17
$(PbS)_{1.18}TiS_2$	5.800	3.410	0.1755	5.881	21

several polytypes in the suprastructure, which hinders the formation of single crystals, and by the difference in morphology of crystalline particles of these suprastructures. Thus it was found that the synthesis and prolonged annealing (required for the attainment of thermodynamic equilibrium) of the misfit compounds $(BiS)_{1+x}(NbS_2)_m$ and $(PbS)_{1+x}(NbS_2)_m$ gave rise both to the usual layered crystals and species with the same composition, which resemble an insulation tape bundle.^{11,15} Beginning with a particular diameter of the species, the layers are twisted and the maximum radius of the bundle does not exceed 0.1 mm.

III. Physical properties of misfit suprastructures

The complexity of incommensurate suprastructures (in particular, layered misfit structures) and the characteristic features of interactions between their constituent substructures result in the diversity of the physical properties observed. Misfit structures are studied by different physical and physicochemical methods. The electrophysical and magnetic properties of misfit compounds were examined in a large number of studies. The superconductivity of compounds based on some layered dichalcogenides with the $2H$ structure was also investigated. Valuable information on the physical properties of incommensurate suprastructures was also obtained in studies of X-ray photoelectron spectra, optical reflectance and Raman spectra as well as in studies with the use of some other methods.

1. Electrophysical properties

Misfit compounds containing NbX_2 or TaX_2 as the host substructure possess metallic conductivity.^{11,13,19,23–26} In these structures, the resistivity (ρ_{ab}) in the ab plane is $\sim 10^{-6} \Omega$.^{19,23–27} The ratio between the resistivities along the commensurate (b) and incommensurate (a) axes (ρ_a/ρ_b) is close to unity [for example, in the compound $(CeS)_{1.16}NbS_2$].²⁷ This is also evident from the number of charge carriers along the a and b axes calculated for the suprastructure $(PbS)_{1.13}TaS_2$. These values were determined from optical reflectivity measurements.²⁸ The resistivity along the c axis is substantially larger than that in the ab plane. The ρ_c/ρ_{ab} ratio is equal to 50 for compounds based on chalcogenides of rare-earth elements²⁷ and it is even larger for suprastructures with $M = Sn, Pb$ or Bi . Thus the ρ_c/ρ_{ab} ratio for $(SnS)_{1.18}NbS_2$ is 250 and 800 at 300 and 4 K, respectively.³ ($\rho_c/\rho_{ab} \approx 10^5$ determined at 300 K for this compound previously²⁴ is, apparently, overestimated).

Like some intercalates based on tantalum and niobium dichalcogenides, misfit suprastructures formed from TaS_2 or NbS_2 and PbS, SnS or BiS are characterised by a positive Hall coefficient and a negative Seebeck coefficient.^{23–26} The number of holes calculated from the Hall coefficients at 4 K^{25,26} suggest the occurrence of electron transfer from the MX layers to the TX_2 layers in incommensurate suprastructures, as in intercalates, the d_{z^2} band of the TX_2 layer being more than half-filled. Taking into account the negative Seebeck coefficients, it should be noted that these data are only tentative.

Suprastructures consisting of TaX_2 or NbX_2 layers and layers of REE chalcogenides are characterised by a substantially lower concentration of charge carriers compared to suprastructures containing Sn, Pb or Bi chalcogenides. These compounds possess positive Hall and Seebeck coefficients,^{29–31} which is indicative of p-type conductivity in these compounds. The calculated degrees of electron density transfer in suprastructures with $M = REE$ are

substantially higher than those observed in compounds with $M = \text{Sn}$ or Pb .³¹ The X-ray photoelectron spectra of these compounds^{32–35} also revealed an essential electron transfer from MX to TX_2 layers. In this case, the M atoms exist virtually in the trivalent state.

Metallic conductivity is also typical of suprastructures $(\text{MS})_{1+x}(\text{TiS}_2)$ with $M = \text{Sn}$ or Pb .^{11,36,37} The temperature dependences of ρ_{ab} observed for $(\text{MS})_{1+x}(\text{TiS}_2)$ ³⁶ is analogous to those found for the intercalates Li_xTiS_2 (see Ref. 38) and Ag_xTiS_2 .³⁹ The Hall coefficient of the former is negative and corresponds to the partial filling of the conduction band of the TiS_2 substructures by electrons from the MX substructure. However, the character of the temperature dependence of ρ_{ab} indicates that holes in the valence band of MX are not involved in the conductivity. It was thus suggested⁵ that holes are localised in the valence band of the MX substructure. This localisation occurs either due to a change in the lattice potential along the $[100]$ direction giving rise to centres of hole localisation or due to the presence of defects and vacancies in the MX sublattice.

The compounds $(\text{CeS})_{1.19}(\text{TiS}_2)_m$ ($m = 1$ or 2)³⁷ also possess metallic conductivity and exhibit antiferromagnetic ordering at 2.8 K, which is not accompanied by anomalous behaviour of the conductivity around this point. This indicates that the MX layers do not contribute to the conductivity of the above-mentioned compounds. The residual resistivities observed for the compounds $(\text{CeS})_{1.19}(\text{TiS}_2)_m$ (~ 450 and $350 \mu\Omega \text{ cm}$ for $m = 1$ and 2 , respectively) are larger than that for Li_xTiS_2 (see Ref. 38) whose structure is not incommensurate. The authors believed that this fact is indicative of a substantial effect of the incommensurability of misfit structures on the crystal lattice, which is manifested in its local modulations playing a significant role in scattering of charge carriers.³⁷

The majority of compounds with the VX_2 sublattice, for example, $(\text{PbS})_{1.12}\text{VS}_2$ (see Ref. 12) and $(\text{LnS})_{1+x}\text{VS}_2$ (see Refs 37 and 40) ($\text{Ln} = \text{La}, \text{Ce}, \text{Nd}$ or Sm), exhibit semiconducting properties. It was found that the conductivity of the compounds $(\text{LnS})_{1+x}\text{VS}_2$ ($\text{Ln} = \text{La}, \text{Ce}, \text{Pr}$ or Nd) changed from semiconducting to metallic at 150–200 K.⁴¹

The $V-V$ distances in the misfit compound $(\text{PbS})_{1.12}\text{VS}_2$ possessing semiconducting properties⁴² are close to those in the intercalates Na_xVS_2 ,⁴³ which exhibit metallic conductivity. Therefore, the semiconducting properties of $(\text{PbS})_{1.12}\text{VS}_2$ demonstrate that holes in the valence band of PbS are not involved in the conductivity. These holes are either localised or absent due to lattice defects. X-ray structural analysis of the compound $(\text{LaSe})_{1.21}\text{VSe}_2$ within four-dimensional symmetry space groups⁴⁴ established that the LaSe sublattice contains $\sim 5\%$ of lanthanum vacancies and the VSe_2 sublattice is characterised by a large modulation of the $V-V$ distances giving rise to centres of localisation of charge carriers. Therefore, holes available in the valence band of LaSe layers do not contribute to the conductivity of the compound $(\text{LaSe})_{1.21}\text{VSe}_2$. Based on the conductivity data, the temperature dependence of the thermoelectric power and the optical reflectivities for the compound $(\text{LaS})_{1.16}\text{VS}_2$, it was concluded that charge carriers are localised in LaS layers.³⁷

Misfit suprastructures with the CrS_2 host substructure were prepared only for REE. The measurements of the conductivity of $(\text{GdS})_{1.27}\text{CrS}_2$ (see Ref. 45) demonstrated that this compound exhibits semiconducting properties; the activation energy is 0.34 eV. The suprastructure $(\text{LaS})_{1+x}\text{CrS}_2$ also possesses semiconducting properties.^{45,46} The X-ray photoelectron spectra and magnetic measurements performed for the compounds $(\text{LnS})_{1+x}\text{CrS}_2$ demonstrated that chromium atoms occupying the CrS_2 sublattice points exist in the trivalent state,^{47,48} which is indicative of a substantial electron transfer from LnX layers to CrS_2 layers. In this case, a portion of electrons (x) does remain in the LnX sublattice, which seemingly should give rise to metallic conductivity in these misfit compounds (at least, for elements of the first part of the REE series whose electrons are delocalised over $5d$ and $4f$ orbitals). However, the precise chemical analysis of

the compound $(\text{LaS})_{1+x}\text{CrS}_2$ (see Ref. 45) demonstrated that the lanthanum content in this compound is less than that expected. Based on the results of the analysis, the formula $(\text{La}_{0.94}[\text{La}_{0.06}\text{S}])_{1.2}\text{CrS}_2$ was assigned to the compound $(\text{LaS})_{1+x}\text{CrS}_2$ because the charges of La^{3+} , Cr^{3+} and S^{2-} can be balanced out only if lanthanum vacancies are present in the LaS layers. An analogous situation was observed for the compound $(\text{GdS})_{1.27}\text{CrS}_2$ to which the composition $(\text{Gd}_{0.91}[\text{La}_{0.09}\text{S}])_{1.27}\text{CrS}_2$ was assigned on the basis of the data from precise chemical analysis and X-ray structural analysis. In this case, charge balance between the ions is observed. Therefore, the semiconducting character of the compounds under consideration is attributable to partial localisation of electrons in the MX layers.

2. Magnetic properties

The magnetic properties of layered misfit compounds based on TaX_2 or NbX_2 with the LnX guest substructure are determined primarily by the nature of the Ln atom. The strong effect of the crystal field was observed for mono- and bilayer misfit structures with $M = \text{Ce}$ or Nd .^{19,27,34,49} Studies of the magnetic properties of the compounds $(\text{LnS})_{1+x}(\text{TS}_2)_m$ ($T = \text{Ta}$ or Nb) demonstrated that these properties are substantially different in the directions perpendicular and parallel to the magnetic field (the direction of the field coincides with the c axis of the crystal). Thus the magnetic susceptibilities for the phases ' NdNb_2S_5 ' and ' SmNb_2S_5 ' along the field and in the transverse direction differ by factors of 1.5 and 2.5–2.6, respectively.¹⁹ The small magnetic moments of the compounds $(\text{LaX})_{1+x}(\text{TX}_2)_2$ (see Refs 19, 49 and 50) indicate that lanthanum atoms exist in the trivalent state, which is indicative of a substantial electron transfer from LaX layers to TX_2 layers. In suprastructures with $M = \text{Ce}$ ⁵¹ or Sm ,³⁴ the electron density transfer from MX layers to TX_2 layers is somewhat smaller than that observed in suprastructures with $M = \text{La}$. According to the results of measurements of magnetic moments, weak ferromagnetic interactions occur within the LnX layer and even weaker antiferromagnetic interactions occur between the LnX layers. At low temperature, antiferromagnetic ordering is observed in suprastructures (in this case, the temperature dependence of the magnetic moment does not obey the Curie–Weiss law).^{19,38,45} For the suprastructure ' GdNb_2S_5 ', the ordering occurs at 5 K.¹⁹ For the suprastructure $(\text{GdS})_{1.21}\text{NbS}_2$, the ordering occurs at 12.8 and 4.6 K.³⁸ Somewhat different results were obtained for compounds with $M = \text{Tb}$, Dy or Er . At low temperature, these compounds behave as paramagnetics and do not exhibit the anisotropy of magnetic properties.^{5,19} This was attributed to the absence of the effect of the crystal field in the case of REE atoms located in the right part of the Periodic system due to a larger contraction of their $4f$ orbitals.

The magnetic properties of the suprastructures $(\text{LnS})_{1+x}\text{VS}_2$ also substantially depend on the nature of the Ln atom^{40,52} and are in many respects similar to the properties of the corresponding structures based on NbX_2 . However, the properties of the former compounds are distinguished by stronger antiferromagnetic interactions between LnS layers. The deviation of the temperature dependence of the magnetic moment from the Curie–Weiss law at low temperatures is attributed to the effect of the crystal field. The magnetic properties of the compounds $(\text{LnS})_{1+x}\text{VS}_2$ indicate that the Ln atoms in these compounds exist in the trivalent state.

The magnetic behaviour of misfit structures containing CrS_2 layers is more complex because of the contribution of Cr^{3+} ions.^{45,47,48} Thus the compound $(\text{LaS})_{1.20}\text{CrS}_2$ behaves as a paramagnetic up to 110–300 K. At low temperatures, two magnetic transitions (at 120 and 70 K) are observed for this compound.⁴⁸ Such behaviour of $(\text{LaS})_{1.20}\text{CrS}_2$ is conditioned by the spins of the Cr^{3+} ions. The results of magnetic measurements for structures containing CrS_2 layers were interpreted taking into account the type of ordering of the magnetic structure at low temperature and possible antiferromagnetic interactions between the Cr ions in the CrS_2 layer (depending on the $\text{Cr}-\text{Cr}$ distance) (see, for example, the review⁵).

3. Superconductivity

Of the known misfit suprastructures, only the compounds $(MX)_1 + x(TX_2)_m$ ($M = \text{Sn, Pb, Bi or Ln}$; $X = \text{S or Se}$, $m = 1$ or 2) based on layered tantalum or niobium dichalcogenides, which have $2H$ structures and possess their own superconductivity, exhibit superconducting properties. The superconducting transition critical temperatures (T_c) for all these misfit compounds are lower than those for the corresponding dichalcogenides TX_2 , which is, apparently, attributable to the insulating properties of MX layers.^{53–58} For example, the T_c values for the compounds $(\text{PbS})_{1.14}(\text{NbSe}_2)_2$ and $(\text{PbS})_{1.14}\text{NbSe}_2$ are 3.4⁵⁴ and 2.475 K,⁵³ respectively, whereas T_c for $2H\text{-NbSe}_2$ is 6.3 K.⁵ Misfit compounds based on TX_2 , like dichalcogenides as such, exhibit anisotropy of the critical field, which depends on the nature of the metal M . Thus the anisotropy is ~ 1.29 and 35 for $(\text{BiSe})_{1.10}\text{NbSe}_2$ and $(\text{LaSe})_{1.14}\text{NbSe}_2$, respectively. For mono- and bilayer suprastructures, the critical fields also have differing anisotropy. For the monolayer compounds $(\text{SnS})_{1.17}\text{NbS}_2$ and $(\text{PbS})_{1.14}\text{NbS}_2$, the anisotropy is $\sim 8–10$,^{53, 56} whereas the anisotropy for the bilayer compound $(\text{PbSe})_{1.12}(\text{NbSe}_2)_2$ is $\sim 4–5$.⁵⁴ Based on the fact that the compound $(\text{PbSe})_{1.12}(\text{NbSe}_2)_2$ exhibits anisotropy intermediate between those of $(\text{PbS})_{1.14}\text{NbS}_2$ and NbSe_2 as such, it was suggested that the compound $(\text{PbSe})_{1.12}(\text{NbSe}_2)_2$ is a second-stage intercalate.⁵⁷

* * *

To sum up the discussion of the physical properties of layered misfit structures, it should be stated that these properties can be described to a first approximation by an additive scheme, *viz.*, as a result of superposition of the properties of the TX_2 and MX substructures. Thus studies of a number of misfit structures by X-ray photoelectron and Raman spectroscopy^{21, 59–62} demonstrated that these spectra can be described as a superposition of the spectra of the MX and TX_2 substructures.

In some respects, this is also true for the results of studies of the electrophysical properties of these compounds. When describing suprastructures $(MX)_1 + x(TX_2)_m$ within the framework of the rigid band model, one can use the fact that the TX_2 and MX layers in these structures are similar to the corresponding layers in crystals of TX_2 and MX , with the difference that the Fermi level for the TX_2 layer of the misfit structure is located higher than that in the crystal of TX_2 and taking into account that the changes in the MX layer compared to the analogous layer in the crystal are caused by the electron transfer to the TX_2 layer. (The charge transfer from the MX layers to the TX_2 layers was quantitatively evaluated based on the Hall and Seebeck coefficients.)

Needless to say the real situation goes beyond the scope of the simple additive scheme. For example, as mentioned above, the mutual effect of two substructures, which is manifested, in particular, in distortions and discontinuities of the crystal lattices of the TX_2 and MX layers, cannot be ignored. On the whole, the data on the physical properties of layered misfit structures confirm the correctness of their comparison with intercalates of the A_nTX_2 type.

IV. Interactions of substructures and phase stabilities of layered misfit compounds

In this Section, we consider the nature of the interaction between substructures and the possibility of deformation of their lattices. In our opinion, it is worthwhile to perform a comparative analysis of conditions of the occurrence of layered misfit structures $(MX)_1 + x(TX_2)_m$ and intercalates A_nTX_2 (A is any metal) because this analysis can be based on the use of a unified approach determining the limits of the phase stability of the layered TX_2 host matrix. Although intercalates, unlike misfit structures, do not imply incommensurability between the host and guest lattices (in the theory of intercalates,⁶³ it is assumed that cavities in the host lattice topotactically correspond to the structure of the guest),

both layered misfit structures and intercalates are characterised by $Q-H$ interactions of the same type determined by charge transfer from MX to TX_2 and from A to TX_2 , respectively.^{64, 65} The concept describing the conditions of phase stability of layered intercalates is based on the rigid band model.⁶⁶

Depending on the coordination of the T atom, the TX_2 matrix can exist in two structural modifications related to the electronic stabilisation of the conduction bands, *viz.*, $1T$ (octahedral coordination) and $2H$ (trigonal-prismatic coordination). The schemes of the conduction bands for layered dichalcogenides of Groups IV–VI transition metals are shown in Fig. 6.

Figure 6. Band structures of transition metal dichalcogenides TX_2 ($2H$ polytype).⁶⁶

It was found⁶⁶ that the valence band of the TX_2 layer consists of two subbands to which the s and p atomic orbitals (AO) of chalcogen X make the major contributions, whereas the conduction band consists primarily of nonbonding d -AO of the transition metal T . The splitting of the conduction band by the crystal field of the X atoms determines its occupation by electrons and the energetics. In the $2H$ structures of TX_2 , the band formed by the d_{z^2} -AO of the T metal has the lowest energy.

For the d^1 ions of Group V metals (for example, for Nb and Ta), this band is half-filled; the occupied and unoccupied levels of this band are not separated due to which these compounds exhibit metallic conductivity. Within the limits determined by the filling of the d_{z^2} -AO of the T atom, intercalation of the structures $2H\text{-NbX}_2$ and $2H\text{-TaX}_2$ does not lead to electron destabilisation of the system and occurs rather readily. We have demonstrated^{67, 68} that destabilisation of the conduction band in the intercalates Ga_aNbSe_2 and Ga_aTaSe_2 occurs at $a \approx 0.12$ and is accompanied by the transformation of a two-dimensional structure into a three-dimensional (spinel) structure, which is associated with a change in the valence states of gallium and niobium (tantalum) atoms caused by charge transfer from gallium to niobium (tantalum).

Layered misfit structures $(MX)_1 + x(TX_2)_m$ based on dichalcogenides of Group V transition metals have been rather well studied. It was demonstrated that the degree of charge transfer from M to T depends on the properties of the MX guest layer.^{17, 19, 25, 26, 29–35, 49–51, 62, 64} In suprastructures containing lanthanide ($M = \text{Ln}$) sulfides (selenides) as the guest, substantial charge transfer was observed. Thus based on the temperature dependence of the conductivity and the data from X-ray photoelectron spectroscopy, it was established that the filling of the d_{z^2} band in $2H\text{-TaX}_2$ for monolayer structures is 1.8–1.97 electrons per T metal atom. A different situation occurs in misfit compounds with $M = \text{Sn or Pb}$. In the latter, the charge transfer is

significantly smaller. According to the published data,^{24, 25, 64} the charge transfer in these suprastructures is 0.3–0.5 electrons per T atom.

Apparently, suprastructures with $T = V$ are a special case.^{12, 37, 40, 44, 52, 61} In the phases $(\text{PbS})_{1.12}\text{VS}_2$,¹² $(\text{LnS})_{1+x}\text{VS}_2$ ($\text{Ln} = \text{La}, \text{Ce}, \text{Nd}$ or Sm)^{37, 40} and $(\text{LaSe})_{1.12}\text{VSe}_2$,⁴⁴ vanadium atoms are in an octahedral environment. In these structures, as in compounds with $T = \text{Nb}$ or Ta , electron density is transferred from MX layers to VX_2 layers, this transfer being particularly significant for compounds with $M = \text{Ln}$.^{40, 52} As mentioned above, the $V-V$ distances in these misfit structures are close to those in intercalates Na_xVS_2 (see Ref. 43) possessing metallic conductivity. A consideration of the electronic structures of misfit suprastructures based on VX_2 within the framework of the rigid band model assumes that these structures possess metallic conductivity. However, most of the suprastructures synthesised based on vanadium chalcogenides are actually semiconductors. This behaviour may be attributed either to the formation of an energy gap in the Fermi level due to splitting of the t_{2g} orbitals³⁷ or to localisation of charge carriers in the MX layer at defects of different types^{37, 44, 61} caused primarily by the incommensurability of substructure lattices.

Layered matrices based on chalcogenides of Group VI metals, such as Mo and W, belong to the $2H$ polytype and are high energy-gap semiconductors. The d_{z^2} band in chalcogenides of Group VI metals with the $2H$ structure, unlike that in chalcogenides of Group V metals, is completely filled. The energy gap between this band and the nearest unoccupied levels is ~ 1.5 eV.⁶⁶ Hence, intercalation of these compounds with A donors is very hindered. Therefore, it is reasonable that layered misfit structures based on $2H$ layers of MoX_2 or WX_2 are as yet unknown. At the same time, misfit compounds based on chromium sulfide, *viz.*, $(\text{LnS})_{1+x}(\text{CrS}_2)_m$, with the $1T$ structure of the host matrix have been characterised in sufficient detail. These compounds are semiconductors with an energy gap of ~ 0.5 eV. In these compounds, as in the compounds $(\text{LnS})_{1+x}(\text{VS}_2)_m$, the M and T atoms exist in the trivalent states due to a substantial charge transfer from Ln to Cr and the presence of vacancies in Ln positions.^{37, 45, 46}

Layered misfit suprastructures with $M = \text{Bi}$ or Sb are a special case. Although these compounds are very similar in structure and properties to compounds with $M = \text{Pb}$ or Sn , the charge transfer in the former compounds determined from electrophysical data^{23, 26} is substantially smaller than that in misfit structures with $M = \text{Pb}$ or Sn , unless a strong acceptor, such as CrS_2 , serves as the host matrix.⁶⁴ The X-ray photoelectron spectra⁶⁹ of the compounds $(\text{SbS})_{1+x}\text{CrS}_2$ and the Bi–S bond lengths in $(\text{BiS})_{1.23}\text{CrS}_2$ (see Ref. 70) demonstrate that the Sb and Bi atoms in these compounds exist in the trivalent state. A number of characteristic structural features of the compounds $(\text{BiS})_{1.08}\text{TaS}_2$ and $(\text{BiS})_{1.09}\text{TaSe}_2$ containing short Bi–Bi bonds were mentioned.¹⁵

Of Group IV transition metals, only titanium atoms form layered dichalcogenide structures with a crystal lattice of the $1T\text{-CdI}$ type (with octahedral coordination about the T atom, see Fig. 3). Generally, their intercalation with donors (metals) is accompanied by a $1T \rightarrow 2H$ phase transition.⁶³ The atomic t_{2g} orbitals of titanium ions with the d^0 electronic configuration are unoccupied. However, intercalation of the TiX_2 matrix with A donor atoms leads to the electron transfer from A atoms to Ti ions and to the occupation of the t_{2g} orbitals. In this case, their degeneracy is eliminated because the trigonal-prismatic ($2H$) coordination about Ti atoms with the lower-energy d_{z^2} band becomes energetically more favourable. A rather surprising thing is that the Ti atoms retain an octahedral coordination in spite of the difference in the character of the MX layers and the conditions of charge transfer.

Titanium dichalcogenides form layered misfit compounds with Pb, Sn,^{11, 21, 36, 61, 71, 72} Ce³⁷ or Ag.⁷³ Electrophysical measurements^{36, 37} and analysis of photoelectron spectra^{21, 61, 74, 75} and

Raman spectra⁶¹ indicate charge transfer from MX layers to TiX_2 layers. The nature and bond strengths between the layers in such misfit structures were interpreted differently. Thus, in some studies^{3, 64, 69} it was assumed that the MX and TiX_2 layers are covalently bound (*viz.*, that there are covalent bonds between the M atoms of the MX layers and the X atoms of the TiX_2 layers). In other studies, it was reported that there are Coulombic interactions between the positively charged metal atoms M from the MX layers and the negatively charged chalcogen atoms from the TX_2 layers, as, for example, in the compounds $(\text{PbS})_{1.18}(\text{TiS}_2)_m$ ($m = 1$ or 2). Electron probe microanalysis of this compound⁷¹ revealed a deficiency of lead ions in the PbS layers, which was interpreted as the replacement of 8%–10% of Pb^{2+} ions by Ti^{3+} ions, which may lead to stabilisation of the misfit suprastructure. The stability of the compounds $(\text{CeS})_{1.19}(\text{TiS}_2)_m$ ($m = 1$ or 2) was estimated within the framework of the rigid band model based on the results of measurements of the electrical resistivity, thermoelectric power and optical reflectivity.³⁷

However, the results of the majority of studies, in our opinion, indicate that the interaction between the MX and TX_2 substructures occurs through charge transfer from the MX layers to the TX_2 layers. For example, calculations of the band structure of $(\text{LaS})(\text{SrS})_{0.2}\text{CrS}_2$ demonstrated⁴⁶ that there is no more or less significant charge density between the lanthanum atoms from the LaS layer and the sulfur atoms from the CrS_2 layer. On the contrary, the lone electron pairs of the sulfur atoms of the CrS_2 layer are directed toward the free space rather than toward the lanthanum atoms of the adjacent layer. In this case, the factors determining the polytype of the TX_2 layer in the resulting suprastructures remain unclear. In our opinion, the energy characteristics of the structures under consideration play here a decisive role. These characteristics can be described based on the concept of electronic stabilisation of the suprastructure. This concept was confirmed by the results of the study⁴⁵ in which the formation of defects in MX substructures due to the transfer of an excess charge from the MX layer to the TX_2 layer was experimentally observed and theoretically justified.

One would expect that intercalation of layered misfit structures with donor species will be accompanied by phase transitions associated with changes in substructures. Analogous processes were observed, for example, on the formation of intercalates of the $A_n\text{TX}_2$ type.^{67, 68} The formation of defects (discontinuities) in the MX substructure may be yet another consequence of intercalation.

As mentioned above, intercalates based on layered misfit compounds are formed due to charge transfer and filling of unoccupied levels of the suprastructure. Unfortunately, examples of the existence of such intercalates, their structural features and properties are limited in number. However, to a first approximation it can be stated that the rule of electronic stabilisation is fulfilled for these compounds, as in the case of intercalation of typical layered matrices. At the same time, it is important to keep in mind the differences associated with the charge transfer in the above-mentioned intercalates and in the corresponding misfit structures. Studies of intercalation of the suprastructures ' PbVS_3 ', ' PbTiS_3 ', ' PbTi_2S_5 ' and ' SnTiS_3 ' with lithium (from solutions of n-butyllithium in hexane at room temperature)¹⁴ demonstrated that intercalation of monolayer misfit structures occurs with greater difficulty than that of the corresponding bilayer structures. Analogous results were obtained in the study⁷⁶ in which the electrochemical intercalation of the compounds $(\text{PbS})_{1.18}\text{TiS}_2$ and $(\text{PbS})_{1.18}(\text{TiS}_2)_2$ with silver was examined. It was demonstrated that the insertion of silver into the structure $(\text{PbS})_{1.18}\text{TiS}_2$ resulted in disproportionation of the latter into $\text{Ag}_x(\text{PbS})_{1.18}(\text{TiS}_2)_2$ and PbS .

Similar results were obtained upon intercalation of iron and nickel into layered misfit structures based on TiS_2 and LaS or CeS.⁷⁷ Monolayer intercalates could not be prepared, whereas the bilayer structures of the $A_n(\text{LaS})_{1.18}(\text{TiS}_2)_2$ type were synthesised and studied. Presumably, the formation of intercalates (in the case

of a comparable donor ability of the intercalant) becomes easier as the charge transfer from MX to TX₂ decreases and as the electron ‘capacitance’ of the unoccupied band is increased. In this respect, the probability of intercalation of layered misfit compounds possessing the 1T structure is higher than that of compounds with the 2H structure because a metal atom with octahedral coordination can accept a larger number of electrons than an atom with trigonal-prismatic coordination.

Intercalation of metals into the synthetic matrix Ta_{1-x}Re_xSe₂ was also studied.^{78,79} The electronic structure of this matrix can be changed by varying its composition, *i.e.*, by varying the *x* value. For *x* = 0.5, this matrix is isoelectronic and isostructural to the matrix 2H-MoSe₂, *viz.*, the *d*_{z²} band in this matrix is filled and intercalation is accompanied by disproportionation of the layered structure.

The results of a study⁴⁶ in which the possibility of the replacement of a portion of lanthanum atoms in (LaS)_{1+x}CrS₂ by ‘inert’ Sr was examined can be cited as supporting evidence for the above concept of electronic stabilisation. The results obtained demonstrated that the structure (LaS)_{1+x}CrS₂ contains a substantial amount (~0.2) of lanthanum vacancies, *i.e.*, the corresponding suprastructure is a nanocomposite. This fact was indirectly confirmed by the results of another study,¹⁶ where it was attempted to obtain images of LaS layers in the suprastructure (LaS)_{1.14}NbS₂ by scanning tunnelling electron and atomic-force microscopy; however, the attempts were unsuccessful.

Probably, the differences in the morphology of the synthesised crystalline species (BiS)_{1+x}(NbS)_{*m*} are also associated with the conditions of the interaction between the constituent substructures. Among the specimens obtained, layered structures as well as structures of the ‘insulation-tape bundle’ type were found. As mentioned above, no noticeable electron density transfer was observed in layered misfit structures with M = Bi or Sb, unlike those with M = Ln. In the case of the former structures, single crystals are deformed and take the shape of an ‘insulation-tape bundle’ or a bent tube (because stresses due to the incommensurability of the layers in one direction result in the curvature) due to the incommensurability of the intercalant MS and the nonrigidity of the TS₂ matrix.^{80–82} The optimum inner and outer radii of ‘bundles’ are determined by the force balance retaining the matrix rigidity as well as by the conditions of the interaction between substructures.

Unfortunately, data on the thermodynamic properties of layered misfit structures are lacking in the literature. We suggested that the formation of defects (discontinuities) in intergrowth incommensurate substructures and the degree of additivity of the substructure contributions to the observed properties of the suprastructure can be studied by thermal analysis and differential scanning calorimetry.

We established that the specific heats of the compounds (SnS)_{1+x}TaS₂ and (PbS)_{1+x}TaS₂ cannot be described in the context of the additivity. Anomalies were also found for the temperature dependence of the specific heat due to first-order phase transition. Thus it was demonstrated that compounds with the nonextreme stoichiometry (*x* = 0) did not give a low-temperature (35–70 °C) specific-heat peak, whereas these peaks for quenched and nonquenched samples of (SnS)_{1.15}TaS₂ differ in height. For all compounds based on TaS₂, the specific-heat peak was observed at 350 °C. The peak height depends on the stoichiometry and the conditions of cooling of the samples. Probably, these effects are associated with disruptions in one of the sublattices.

Our studies demonstrated that the compounds (SnS)_{1+x}TaS₂ actively decomposed at above ~600 °C in an inert atmosphere to liberate elementary sulfur. Apparently, the intercalates Sn_{*x*}TaS₂ were the final decomposition products. In the future, we hope to confirm the fact that the observed phase transitions are associated with discontinuities in one of the sublattices (MX). In our opinion, these compounds are thermodynamically unstable due to the effect of the incommensurability on the crystal structure. Appa-

rently, strengthening of the interaction between substructures (for a given incommensurability) leads to an increase in the instability of the suprastructure due to a change in the energy of the bonds between the metal and chalcogen atoms in one of the substructures.

We have presented sufficiently convincing evidence for the possibility of fragmentation of one of the sublattices in the misfit structure (MX)_{1+x}(TS₂)_{*m*}. The equation of motion was solved within the framework of the Frenkel–Kontorova model taking into account the anharmonicity of the elastic sublattice and the incommensurability between the period of this sublattice and the corresponding lattice parameter of the crystal environment. The corrections for the known solutions of the equation of motion in the harmonic approximation were also found. It was demonstrated that under conditions of anharmonicity of the interaction between the sublattice and the host lattice, two reasons for its possible fragmentation into particles of finite length exist, *viz.*, the incommensurability and doubling of the period of solutions of the nonlinear problem describing this model. The solution obtained determines the conditions of formation of one-dimensional nanocomposite structures and the limiting parameters at which the suprastructure of the ensemble changes from regular to random.

V. Conclusion

Incommensurate suprastructures, which have been studied thus far, are limited only to compounds in which one lattice parameter of intergrowth substructures is incommensurate (a one-dimensional case). Apparently, eutectics can serve as abundant examples of suprastructures characterised by incommensurability along all three crystallographic directions. As it usually is, the transformation from a one-dimensional model to a three-dimensional system, presents problems. However, it can be said that some general criteria for the formation of suprastructures with the three-dimensional incommensurability were revealed.

First, it is apparent that the incommensurability of intergrowth substructures in real suprastructures occurs within particular limits. Apparently, for some incommensurability parameters, the interaction between sublattices can lead to the formation of defects of different types, including fragmentation of one of the substructures. We failed to find literature data on the dependence of the properties and structures of layered misfit structures on the incommensurability. However, it is apparent that the character of the interaction between substructures should depend on the stoichiometric ratio, *i.e.*, on the *x* and *m* values. As mentioned above, indirect evidence is available for the fact that monolayer structures undergo disproportionation to form bilayer and simple structures as the *x* parameter changes (see the data on intercalation of misfit structures^{14,76,77}). Other data (tubular morphology of particles,¹⁵ the results of studies by scanning tunnelling electron and atomic-force microscopy⁷⁰ and results of our investigations of thermodynamic properties of misfit structures) indicate that defects in substructures comprising the misfit structure or in one of these substructures are frequently observed.

Second, it was proved that it is important to meet the conditions of electronic stabilisation of suprastructures. Since the charge transfer is the major mechanism responsible for the interaction between structural elements in misfit suprastructures, the conditions of electronic stabilisation determine both the stabilities of substructures and the existence of a suprastructure as a whole. The above-considered differences in the character of the interaction between substructures MX and TX₂ determine both the possibility of formation of defects in the substructures and their character [see the data^{44,45,69} on the structures (LaS)_{1+x}CrS₂, (LaSe)_{1+x}VSe₂ and (PbS)_{1+x}TiS₂]. The differences in the morphology of misfit particles are also attributable to these facts.¹⁵

Third, it was established that the nonrigidity of substructures is of importance, at least it was demonstrated that deformations of sublattices due to their incommensurability should be taken into

account both in structural studies and in investigations of physicochemical properties of incommensurate compounds. For example, it can be suggested that bonds in one sublattice can be cleaved at particular tensile stresses and new bonds in another sublattice can be formed at particular compression stresses. The latter possibility is supported by the results of the study of the structures $(\text{BiS})_{1.08}\text{TaS}_2$ and $(\text{BiSe})_{1.09}\text{TaSe}_2$ ¹⁵ in which short (as in metals) Bi–Bi bonds were found. The results of the study¹⁶ provided indirect evidence for the cleavage of bonds in MX substructures.

Finally, approaches and procedures, which allow one to determine the conditions of fragmentation of substructures, were theoretically justified.

In the present review, we call attention to some apparent relationships responsible for the structural characteristics, structure imperfection and morphology of particles of crystalline suprastructures formed from incommensurate elements. Although it is evident that this problem is of importance in solid-state chemistry and in many fields of materials science, it has not been discussed previously in the literature.

Evidently, three situations can occur upon formation of incommensurate intergrowth suprastructures. In the first case, the nonrigidity of the lattices compensates for their insignificant incommensurability. In this case, the formation of a suprastructure is accompanied by stresses, but it does not disturb the stoichiometry. In the second situation, rigid substructures exist and the interaction between these substructures are rather weak. In this case, rather well-organised crystalline suprastructures are formed at any incommensurability. Their limiting stoichiometry is determined by the incommensurability, and the properties, most likely, additively depend on the properties of the constituent elements. The third situation is associated with mechanisms of structural compensation. Due to the strong interaction between substructures, their nonrigidity and substantial incommensurability, discontinuities can appear in one of the sublattices accompanied by the formation of nanocomposites. The structural compensation of the resulting stresses may lead to the formation of unusual defects or give rise to an unusual morphology of particles of suprastructural aggregates. It is also possible that particular limitations on the particle sizes occur. The last-mentioned situation is based on rather abundant experimental data. In our opinion, this situation is of prime interest within the framework of the problems under consideration.

We are grateful to Academician I I Moiseev, Corresponding Member of the Russian Academy of Sciences I V Melikhov and Professor I D Mikheikin for helpful discussion and valuable advice in the discussion of the paper.

The review has been written with the financial support by the Russian Foundation for Basic Research (Project No. 99-03-32550) and the Program of the Development of High-Priority Topics (the Direction 'Fundamental Problems of Modern Chemistry').

Some new aspects in the application of perfluoroalkyl halides in the synthesis of fluorine-containing organic compounds

G G Furin

Contents

I. Introduction	491
II. The use of perfluoroalkyl halides in the synthesis of partially fluorinated compounds	492
III. Reactions of perfluoroalkyl halides with organic substrates occurring by a single-electron transfer mechanism	496
IV. Conclusion	517

Abstract. The approaches to the activation of perfluoroalkyl halides used as intermediates in the synthesis of partially fluorinated compounds are considered. The conditions for reactions of organic compounds with perfluoroalkyl iodides in the presence of reductants ($\text{Na}_2\text{S}_2\text{O}_4$, $\text{HOCH}_2\text{SO}_2\text{Na}$), metals and metal salts, redox systems ($\text{Na}_2\text{S}_2\text{O}_8$, Bu^tOOH , $\text{Pb}(\text{OAc})_4$, H_2O_2 – FeSO_4 , $\text{Ce}(\text{SO}_4)_2$) and transition metal complexes are described. The generation of perfluoroalkyl radicals by a single-electron transfer mechanism are discussed. The introduction of perfluoroalkyl groups into aromatic and unsaturated organic compounds and functionalisation of perfluoroalkyl iodides, particularly, their transformation into perfluoroalkanesulfinic and perfluoroalkane-carboxylic acids and aldehydes, are considered. The bibliography includes 442 references.

I. Introduction

The introduction of fluorine atoms into the molecules of organic compounds not only changes their physical and chemical properties but also forms the basis for the development of new synthetic procedures, sometimes unusual for organic chemistry, for the generation of C–C bonds and cyclic systems.^{1–6}

Partially fluorinated organic compounds, particularly those containing perfluoroalkyl groups, find wide application in the synthesis of novel materials, in the design of medicinal and agricultural preparations and in different branches of technology.^{7–24} This, in turn, stimulates the development of novel, and the perfection of the existing methods for the introduction of polyfluorinated fragments into organic substrates. The interest of investigators in the possibility of direct introduction of such fragments into organic molecules is determined by diverse applicability of fluorine-containing compounds and unique physical and biological properties imparted to these compounds by fluorine, because regioselective substitution of a perfluoroalkyl group for the hydrogen atom in aromatic or heterocyclic systems may significantly influence their properties.

The introduction of perfluoroalkyl groups, in the first place, of CF_3 , into organic molecules is based on three main types of chemical transformations, viz., those involving electrophilic (see, e.g., Refs 2, 25, 26), nucleophilic²⁷ and radical^{28–30} species. Thus, the availability of perfluoroalkyl iodides and the feasibility of their use in the synthesis of organometallic compounds made it possible to develop novel procedures for the generation of perfluoroalkyl radicals and to study their reactions.^{28–30}

The addition of perfluoroalkyl halides to alkenes and alkynes is one of the most fundamental procedures for introducing perfluoroalkyl groups into the molecules of organic substrates. Perfluoroalkyl radicals are traditionally generated photochemically,^{31–41} thermally⁴² or electrolytically,^{43,44} viz., by:

(i) photolysis or thermolysis of perfluoroalkyl halides, perfluoroalkanesulfonyl chlorides and organometallic compounds containing perfluoroalkyl substituents;^{45–50}

(ii) decomposition of polyfluorinated acyl peroxides of the general formula $(\text{C}_n\text{F}_{2n+1}\text{COO})_2$ ^{51–64} and electrolysis of perfluoroalkane-carboxylic acids.^{65–69}

These methods have successfully been used in the perfluoroalkylation of alkenes, aromatic, natural and heterocyclic compounds. Their advantages and disadvantages have been described in detail.^{45,65–68} To the main disadvantages of these methods one may relate the difficulty in their implementation under conditions of large-scale manufacture, low selectivity and low yields of the target products. Moreover, the preparation of the starting building blocks, which are often toxic and expensive, demands special conditions.¹⁹ These circumstances together have made it necessary to develop efficient methods for introducing perfluoroalkyl groups† into organic molecules. The main emphasis in these studies was laid on their direct incorporation by *in situ* generation of perfluoroalkyl radicals. This, in turn, required simple, available and inexpensive reagents and simplification of the procedure of direct introduction of perfluoroalkyl groups into organic molecules.

This search culminated in the development of novel approaches to the generation of perfluoroalkyl radicals from perfluoroalkyl halides in reactions occurring by a single-electron transfer mechanism. A variety of initiators for such reactions are currently known. The ease of performance and high efficiency of the perfluoroalkylation reaction as well as high accessibility of the reagents leave hope that this reaction will be very efficient in the synthesis of fluoroorganic compounds. The present work is an overview of the published data concerning perfluoroalkylation

† The electrophilic nature of the perfluoroalkyl radical was reported by Baum *et al.*⁷⁰

reactions, it highlights the key events in the methodology of introduction of perfluoroalkyl groups into organic compounds.

II. The use of perfluoroalkyl halides in the synthesis of partially fluorinated compounds

Perfluoroalkyl iodides and bromides have recently received considerable attention owing to their accessibility, high reactivity and ability to be used in perfluoroalkylation reactions, including new ones.

These reactions can be initiated in various ways, *viz.*, thermally,^{42,71–74} electrochemically,^{43,44} photolytically,^{31–41,75,76} or in the presence of free radical inducers, *e.g.*, hydrogen peroxide,⁷⁷ α,α -azobis(dimethylpentanonitrile),^{78–80} α,α -azobis(cyclohexanecarbonitrile)⁸¹ and α,α -azobis(isobutyronitrile) (AIBN).^{79–85} By selecting appropriate reaction conditions (*viz.*, solvent, temperature, reaction time), one may carry out perfluoroalkylation of various organic compounds.

These reactions are accompanied by the cleavage of C–I and C–Br bonds, but not of C–F bonds because the latter possess greater strength. Under certain conditions, perfluoroalkyl halides act as radical reagents, which perfluoroalkylate unsaturated organic compounds. This approach was repeatedly used in the chemistry of fluoroorganic compounds.^{36,86–93}

Perfluoroalkyl iodides (R_F-I) are widely used as a source of perfluoroalkyl radicals, their addition to alkenes⁴⁶ and reactions with aromatic hydrocarbons under thermolysis conditions have been described, *e.g.*:

1. Reactions of perfluoroalkyl iodides with organic substrates in the presence of nucleophilic agents

This methodology was first used^{94–102} in reactions of alkene- and arene-thiols with perfluoroalkyl iodides in liquid ammonia upon UV-irradiation. The corresponding aryl perfluoroalkyl sulfides were isolated in high yields.

Reactions with perfluoroalkyl bromides and diiodoperfluoroalkanes were conducted in a similar way, this was further extended to selenium and tellurium derivatives and representatives of other classes.^{103–108}

Later, it was shown that reactions of perfluoroalkyl iodides with trialkylammonium and sodium salts of benzenethiols (Table 1)¹⁰² or sodium benzothiazole-2-thiolate^{108,109} do not always require UV-irradiation. These reactions may occur in bipolar aprotic solvents at room temperature and are characterised by high yields.

$R-\text{C}_6\text{H}_4-\text{SH} + R_FI \xrightarrow{NaH} R-\text{C}_6\text{H}_4-SR_F$			$R-\text{C}_6\text{H}_4-\text{SH} + R_FI \xrightarrow{NaH} R-\text{C}_6\text{H}_4-SR_F$		
R	R_F	Yield (%)	R	R_F	Yield (%)
H	C_4F_9	66	NO_2	C_6F_{13}	93
Me	C_4F_9	77	NO_2	C_8F_{17}	93
OH	C_4F_9	30	NO_2	$C_4F_9(CH_2)_2$	90
Cl	C_4F_9	83	NO_2	$C_6F_{13}(CH_2)_2$	68
NO_2	C_4F_9	99			

Alkali metal benzenethiolates are convenient reagents, but in this case substitution reactions occur only on irradiation.^{110–112} Nitrobenzene can be used as an initiator of this reaction. For example, the reactions of perfluorohexyl bromide with potassium

Ph	CF_3	45	4-CF ₃ C ₆ H ₄	CF_3	13

The reaction of $CF_3(CF_2)_9I$ with sodium 4-fluorobenzene-thiolate in DMF at 30–45 °C gives 4-FC₆H₄S(CF₂)₉CF₃ (yield 94%).¹¹⁴ On the other hand, benzenethiol,^{115,116} benzeneselenol^{117–119} and benzenetellurol^{120,121} anions, which are known to be strong nucleophiles, generate the corresponding perfluoroalkyl radicals from perfluoroalkyl iodides introduced into the reaction with alkenes. In this way, efficient perfluoroalkylselenylation (Table 2)^{117–119} and perfluoroalkyltellurylation (Table 3)^{120,121} of a series of alkenes were carried out.

In $PhSeNa - R_FX$ and $PhTeNa - R_FI$ systems, perfluoroalkyl radicals are generated from perfluoroalkyl halides at room temperature. This property was used in the development of a new approach to the generation of perfluoroalkyl radicals at low temperatures.

The yields of perfluoroalkyl phenyl sulfides (R_FSPh) depend on the length of the alkyl chain. In the case of $C_nF_{2n+1}I$, where $n = 4, 6$ and 8 , the yields are 78%, 84% and 86%, respectively. Perfluoroalkyl radicals add to the multiple bond regioselectively.¹

A procedure for the synthesis of aryl perfluoroalkyl sulfides from perfluoroalkyl halides and benzenethiols was proposed by

Table 2. Perfluoroalkylselenenylation of alkenes.^{117–119}

Koshechko *et al.*¹⁰⁵ who used MV²⁺–SO₂ (MV²⁺ is methylviologen, *N,N'*-dimethyl-4,4'-bipyridinium salt) and I₂–SO₂ systems as electron carriers.

R_F = CF₃, Hal = I: X = H (91.2%), NHCO₂Me (88.5%), Cl (53%), NO₂ (9.2%);¹⁰⁴

R_F = CF₃, Hal = Br: X = H (74%), Me (41%);¹⁰⁵

R_F = CFCl₂CF₂, Hal = Cl, X = H (34%);¹⁰⁵

R_F = CF₃, Hal = Br: X = NHCO₂Me (94%), H (78%), Br (64%), Cl (60%), NO₂ (24%) (reaction with benzenethiols).¹⁰⁷

This reaction was studied in detail using spectrophotometry and cyclic voltamperometry¹⁰⁵ and provided conclusive evidence for the intermediate formation of the 'CF₃ radical. Kinetic studies revealed that this reaction is of the second order with respect to the reagents, *i.e.*, $v = k_2[ArSH][MV^{2+}2I^-]$. The k_2 values for PhSH and 4-MeC₆H₄SH were equal to 4.6 and 7.1 litre mol⁻¹ s⁻¹, respectively, at 30 °C.

After addition of SO₂ to the system, the reaction is controlled by the radical anion SO₂^{•-} generated from SO₂ by the radical

cation MV^{•+}, which, in turn, is generated upon action of ArS⁻ on MV²⁺. The interaction of the intermediate radical anion [CF₃SPh]^{•-} with MV²⁺ gives the reaction product and MV^{•+}.

It is noteworthy that SO₂ is an efficient electron carrier in the electrochemical cathode trifluoromethylation of benzenethiols with trifluoromethyl bromide.^{106, 107}

Tetrakis(dimethylamino)ethylene (TDAE) proved to be an efficient reductant initiating the cleavage of C–I and C–Br bonds in reactions with unsaturated compounds. Thus TDAE forms a complex (*e.g.*, with CF₃I), which can act as a nucleophilic trifluoromethylating agent in polar solvents. The ionisation potential of TDAE is equal to 6.13 eV,¹²² being close to that of zinc, which is known to be a potent reductant [the standard electrode potential (E°) of zinc is –0.763 V]. TDAE is also known to be a very potent electron donor; its ionisation energy (591 kJ mol⁻¹) is lower than that of zinc (906 kJ mol⁻¹) and is close to that for lithium (521 kJ mol⁻¹). Electrochemical oxidation of TDAE in acetonitrile occurs in two reversible single-electron steps and results in [TDAE]^{•+} and [TDAE]²⁺ ($E^\circ = -0.78$ and -0.61 V, respectively).¹²³

Later, this methodology was used in the synthesis of dialkyl-(trifluoromethyl)amines by the reaction of CF₂Br₂ with secondary amines in the presence of TDAE¹²⁴ and in reactions of 2-(bromodifluoromethyl)benzoxazole¹²⁵ and chlorodifluoromethyl ketones with aromatic aldehydes in the presence of TDAE.¹²⁶

Ar	Ph	4-FC ₆ H ₄	4-PhC ₆ H ₄	4-CF ₃ C ₆ H ₄	4-CNC ₆ H ₄
Yield (%)	62	67	45	63	61

Ar	Ph	Ph	Ph	4-CF ₃ C ₆ H ₄	4-FC ₆ H ₄	
Yield (%)	55	45	55	58	55	57

The acyldifluoromethyl anion generated from chlorodifluoromethyl ketone reacts with aromatic aldehydes to give the corresponding hydroxy ketones containing a CF₂ fragment in the α-position.¹²⁶

In the presence of alcoholates, perfluoroalkyl iodides and -bromides react with alkenes to yield the addition products.^{127–131} This suggests that alcoholates, as is the case with the Cannizzaro reaction with aldehydes, act as reducing agents rather than induce splitting of perfluoroalkyl halides by the haloformic pathway.

R = n-C₃H₁₁, CH₂OH.

Phosphines [PPh₃, PBu₃ⁿ, P(NEt₂)₃, P(OEt)₃] are used as activators in the reaction of perfluoroalkyl iodides with alkenes.^{132–145}

R = n-C₄H₉, n-C₆H₁₃.

R _F	Yield (%)	R _F	Yield (%)
C ₆ F ₁₃	79	C ₈ F ₁₇	72
Cl(CF ₂) ₄	81	FSO ₂ (CF ₂) ₂ O(CF ₂) ₂	28
Cl(CF ₂) ₆	83	FSO ₂ (CF ₂) ₂ O(CF ₂) ₈	87

In the presence of P(NEt₂)₃, perfluoroalkyl iodides R(CF₂)_nI (R = CF₃, n = 4–7) react with alkenes¹⁴⁰ or benzoyl chloride derivatives¹⁴¹ with the formation of addition products at the multiple bond and the corresponding ketones (yields 32%–43%). The hexamethyldisiloxane–sodium methoxide system in THF is also effective to this goal.¹⁴²

The reaction of perfluoroalkyl iodides with nucleophiles manifests the features of a S_{RN}1 reaction^{44, 146} and proceeds smoothly under relatively mild conditions. The stereochemistry of the reaction of perfluoroalkyl iodides with alkenes suggests that it is the perfluoroalkyl radical that initially attacks the alkene. Presumably, the initiation consists in electron transfer from the nucleophile to the perfluoroalkyl iodide resulting in the generation of the radical anion [R_FI]^{•−};^{147, 148} the process is exothermic. The radical anion formed must be rapidly decomposed into the perfluoroalkyl radical and the iodide ion. The efficiency of the free-radical chain growth in the reaction with alkenes is provided under conditions such that the decomposition of the radical anion [R_FI]^{•−} is a fast reaction; apparently, the polar effect in the translocation of the iodine favours the decomposition:

The radical anion [CF₃I]^{•−} has been detected in a solid state as a stable species at 77 K. At 100 K, it dissociates into the trifluoromethyl radical and the iodide ion.^{149–155} The reaction of the perfluoroalkyl radical with an anionic substrate generates a radical anion which further reacts with perfluoroalkyl iodide to give [R_FI]^{•−} according to the S_{RN}1 mechanism.^{152–155} A more detailed description of these reactions is given in Refs 116, 156–160. Further transformations of the radical anion [R_FX]^{•−} may proceed in two pathways (routes *a* and *b*), which depends on thermodynamic factors.

Nu is nucleophile.

It was shown⁴⁷ that the R_F• and I• fragments (but not the radical anions [R_FI]^{•−}) are formed in polar solvents. Hence a question arises about the pathways of generation of the radical R_F•. It is quite probable that only the C–I bonds are involved in the formation of donor–acceptor complexes with perfluoroalkyl iodides, which favours the manifestation of electrophilic properties of R_FI in solvents of the hexamethylphosphoramide (HMPA) and DMF type. Presumably, the translocation of the radical anion centre to R_FI followed by the generation of the R_F• radical is the limiting step in this reaction.

The formation of radicals from perfluoroalkyl halides by the S_{RN}1 mechanism is one of the most characteristic features of electron transfer reactions in organic chemistry.¹⁶¹ The S_{RN}1 mechanism is especially favourable for perfluoroalkyl halides, since the latter manifest very low activity in nucleophilic reactions of the S_N1 and S_N2 type. Studies of perfluoroalkyl halides reactions occurring *via* the S_{RN}1 mechanism were begun in the 1970's.^{162–170}

The values of the radical formation energy (*E*) in the gas phase were found to be as follows:⁸⁹

Radical	<i>E</i> / eV	Radical	<i>E</i> / eV
•CF ₃	2.10	F•	3.39
CF ₃ •CF ₂	2.10	Cl•	3.61
(CF ₃) ₂ •CF	2.65	Br•	3.37
(CF ₃) ₃ C•	3.40	I•	3.06

Therefore, route *a* in the transformation of radical anions is probable for compounds CF₃X, C₂F₅X, (CF₃)₂CFX (but not for X = I), while route *b* is probable for (CF₃)₃CX (at all values of X) and R. The direction of a reaction in solution depends on the value of free energy of solvation (Δ*G*). For example, in water Δ*G* has the following values:

Anion	Δ <i>G</i> / kJ mol ^{−1}	Anion	Δ <i>G</i> / kJ mol ^{−1}
F [−]	−472	I [−]	−283
Cl [−]	−347	R _F [−]	−200
Br [−]	−321		

In this case, route *a* seems to be preferable for all R_FX [probably, with the exception of (CF₃)₃CCl] and, perhaps, (CF₃)₂CFI.

The transfer of electrons from the charged nucleophile to Bu⁺Br leads to the formation of a radical anion–radical pair; its further transformations differ from those for an analogous pair in the case of R_FBr, which is decomposed by the route *b*, resulting in the radical anion [R_FX]^{•−}. Quantum-chemical calculations using the AM1 method revealed that the formation of the radical anion generating the ternary perfluoroalkyl carbanion (CF₃)₃C[−] and the radical Br• (see Refs 146, 165) is due to higher electronegativity of the tertiary group of the perfluoroalkyl radical. The enthalpy of formation of this anion and the Br• radical (Δ*H*₁) is 17.6 kcal mol^{−1}, whereas that of the tertiary perfluoroalkyl radical and the bromide ion (Δ*H*₂) is much higher, *i.e.*, 57.9 kcal mol^{−1} (see Ref. 166).

The occurrence of this reaction through the formation of a radical anion was confirmed experimentally.¹⁶⁶ The reactions of (R_F)₃CBr with nucleophiles, *e.g.*, Na₂S, NaSH, KSCN, KCN, R₄NX (X = Cl, Br, I), in organic solvents (*e.g.*, MeCN, DMF, CH₂Cl₂, EtOAc) result in the quantitative formation of mixtures of (R_F)₃CH and perfluoroalkene. This can be attributed to the reaction of the perfluoroalkyl halide with the proton from the medium as well as to stabilisation of the perfluoroalkyl carbanion due to elimination of the fluorine anion from the CF₂ fragment in the α-position.

Nu is nucleophile, Solv is solvent.

The electron transfer from the reductant to perfluoroalkyl halide resulting in the formation of the corresponding radical anions is highly efficient, since free σ*-orbitals of the C–Hal bonds (Hal = Cl, Br, I) lie fairly low on the energy axis. Active generation of such radical anions requires a reductant the standard reduction potential (*E*_{red}^o) of which is higher than that of the

alkyl halide involved in the reaction. Depending on the structure of the alkyl fragment and the nature of the halogen, the reducing potentials ($E_{1/2}$ relative to SCE) of perfluoroalkyl halides (Pt electrode in MeCN) vary from -1.10 to $+0.71$ V.¹⁷¹

R _F Hal	$E_{1/2}$ /V	R _F Hal	$E_{1/2}$ /V
CF ₃ I	-1.10	(CF ₃) ₃ CBr	-0.14
C ₃ F ₇ I	-1.00	C ₃ F ₇ CBr(CF ₃) ₂	-0.09
I(CF ₂) ₄ I	-0.96	1-bromo-1-methylperfluoro-	0.12
(CF ₃) ₂ CFI	-0.66	cyclopentane	
cyclo-C ₆ F ₁₁ I	-0.36	1-bromoperfluorobicyclo-	0.71
I ₂	0.10	[4.4.0]decane	
(CF ₃) ₃ CI	0.14	1-chloro-1-methylperfluoro-	-1.02
C ₃ F ₇ CI(CF ₃) ₂	0.32	cyclopentane	
C ₃ F ₇ CCl(CF ₃) ₂	-0.97	1-chloroperfluorobicyclo-	-0.95
(CF ₃) ₂ CFBr	-1.05	[4.4.0]decane	

Consequently, the presence in the reaction mixture of a compound with a higher (in comparison with perfluoroalkyl halide) value of E_{red}° makes possible the generation of the radical anion $[\text{R}_F\text{X}]^{\cdot-}$; its decomposition results in the perfluoroalkyl radical. The latter can be further involved in reactions with organic compounds. In the subsequent sections, this process will be exemplified with both classical reductants and redox systems.

2. Sulfinylation of perfluoroalkyl iodides

The addition of perfluoroalkyl halides to the C=C bond of alkenes is the most promising approach to the generation of C—C bonds in the synthesis of polyfluorinated compounds. Numerous synthetic procedures for perfluoroalkylation of alkenes, especially by R_FI, have been developed. One of them includes thermal or photochemical induction of free-radical reactions.

This approach was developed by a group of Chinese investigators who studied sulfinate dehalogenation of halogen-containing hydrocarbons. Thus it was demonstrated for the first time^{54, 172–177} that perfluoroalkyl iodides react with sodium dithionite (Na₂S₂O₄) to yield sulfinic acid derivatives. The chemistry of perfluoroalkanesulfonates including their synthesis, properties, reactions and applications is described in the reviews (see Refs 158–160).

The inexpensive reducing agent Na₂S₂O₄ can be used for the preparation of perfluoroalkanesulfinic acid salts from perfluoroalkyl halides (R_FX, where X = Br, I, or R_FCCl₃) under relatively mild conditions. This method is widely employed in reactions of these salts with alkenes, dienes, alkynes and aromatic compounds. On the other hand, this system is efficient mostly for polyfluorinated alkyl halides.¹⁷² Bromine and iodine atoms in the perfluori-

nated carbon chain are easily substituted and the target product is formed in a high yield. More recent studies confirmed the efficacy of this approach.^{178–192}

Later, it was found that other nucleophilic sulfur derivatives also react with perfluoroalkyl iodides to give salts of perfluoroalkanesulfinic acid (Table 4).^{22, 143, 144, 184}

Presumably, these reactions occur *via* a single-electron transfer (SET) mechanism as can be evidenced from the trapping of perfluoroalkyl radicals by alkenes and nitroso compounds.⁵⁴

The sulfonylation with sodium dithionite gives an access to perfluoroalkanesulfonic acids, which are valuable intermediates in the synthesis of surfactants, without recourse to electrochemical fluorination and using accessible perfluoroalkyl iodides.^{134, 173, 184, 185, 193} For example, I(CF₂)₂O(CF₂)₂SO₃Na can be prepared from I(CF₂)₂O(CF₂)₂I using phase-transfer catalysis in polyethylene glycols-200 and -600 or in acetonitrile, ethanol or diglyme.

Perfluoroalkyl bromides also react with sodium dithionite.^{172–176, 194, 195} Thus, CF₃Br gives sodium trifluoromethanesulfinate in 90% yield, and sulfinylation products are formed from 1,1,1-trichloroperfluoroalkanes in yields of 90% and higher.

R = Cl, F, CF₃, Cl(CF₂)₂, Cl(CF₂)₄, Cl(CF₂)₆.

The reactions of α,ω -diiodoperfluoroalkanes¹⁸³ and α,ω -dibromoperfluoroalkanes¹⁸⁹ with 1 or 2 equiv. of Na₂S₂O₄ in aqueous MeCN in the presence of sodium hydrogencarbonate result in sulfonates, *e.g.*, I(CF₂)₆SO₂Na and NaSO₂(CF₂)₆SO₂Na, which in turn give the corresponding sulfonyl chlorides, *e.g.*, I(CF₂)₆SO₂Cl and ClSO₂(CF₂)₆SO₂Cl ($n = 3, 4, 6$) upon chlorination at 0 °C (Table 5).

Table 4. Synthesis of sodium perfluoroalkanesulfonates.

Nucleophile	R _F X	Reaction conditions		Product	Yield (%)

4	1:2	1:1	$\text{ClSO}_2(\text{CF}_2)_4\text{SO}_2\text{Cl}$	83 (100)
6	1:2	1:1	$\text{ClSO}_2(\text{CF}_2)_6\text{SO}_2\text{Cl}$	75 (> 95)

^a Molar ratio. ^b The figures in parentheses correspond to the yields according to ¹⁹F NMR spectroscopy data.

One should bear in mind that dimerisation of a perfluoroalkyl radical is also possible. For example, heating of perfluoroalkyl iodide in the presence of the $\text{Na}_2\text{S}_2\text{O}_4-\text{NaHCO}_3$ system in MeCN for 48 h gives a dimeric product.⁹³

The sulfinate dehalogenation reaction has opened up new opportunities for the synthesis of perfluoroalkanesulfinic and -sulfonic acids and their derivatives, since it permits direct transformation of perfluoroalkyl halide into perfluoroalkyl sulfinate and thus eliminates the necessity for the intermediate step, *i.e.*, the synthesis of an organometallic derivative. There is no doubt that this approach holds great promise for wide-scale technological application.^{172–175, 178–181, 189, 195}

III. Reactions of perfluoroalkyl halides with organic substrates occurring by a single-electron transfer mechanism

The addition of perfluoroalkyl iodides to alkenes and alkynes is one of the most important methods for the synthesis of commercially valuable fluorohydrocarbons used as intermediates in the preparation of novel materials and products.²⁰ In this Section, we shall consider a novel approach to the functionalisation of the accessible perfluoroalkyl iodides, which consists in the involvement of an intermediate perfluoroalkyl radical generated under the action of various initiators. This reaction is described by a well-known mechanism, $\text{S}_{\text{RN}}1$. The possibility to alter the direction of the reaction by varying reaction conditions and using appropriate initiators permits one to perform directed synthesis of fluorinated compounds of various compositions.

Reactions of perfluoroalkyl iodides with organic substrates can be initiated in three different ways, *viz.*:

(1) by treating perfluoroalkyl iodides with reductants. The key steps in this process are the initial formation of the intermediate radical anion of perfluoroalkyl iodide and its dissociation into the perfluoroalkyl radical and the iodide anion;

(2) by treating perfluoroalkyl iodides with oxidants. As a result the reactant, possessing electrophilic properties, generates a radical cation. The latter reacts with perfluoroalkyl iodide to generate a radical anion $[\text{R}_\text{F}\text{I}]^{\cdot-}$, which is further decomposed to give a perfluoroalkyl radical;

(3) by treating perfluoroalkyl iodides with systems which generate alkyl or any other radicals themselves. The reaction of the latter with perfluoroalkyl iodide yields perfluoroalkyl radicals by-passing the formation of radical anions.

A vast body of experimental evidence on each of these approaches provides a guideline for new applications of perfluoroalkyl iodides. It seems therefore expedient to lay the main emphasis on these particular pathways of chemical transformations of perfluoroalkyl halides and sodium perfluoroalkanesulfonates.

1. Reactions of perfluoroalkyl iodides in the presence of reducing systems

The presence of an appropriate reductant is a main requirement for the activation of perfluoroalkyl halides and the intermediate formation of perfluoroalkyl radicals. Its specific function consists primarily in the generation of the corresponding radical anions from perfluoroalkyl halides.

Various systems have been tested for this purpose, *viz.*, (1) formaldehyde–sodium sulfoxylate;¹⁹⁰ (2) sodium dithionite; (3) thiourea dioxide;^{170, 185} (4) metals and metal salts; (5) transition metal complexes. Each of these systems has characteristic features of its own; therefore, their effects must be considered in more detail.

a. The formaldehyde–sodium sulfoxylate system

The formaldehyde–sodium sulfoxylate system or rongalite ($\text{HOCH}_2\text{SO}_2\text{Na}$), is widely used in industry as a reductant. Its reaction with perfluoroalkyl iodides and bromides gives the corresponding salts of sulfinic acids. It was found that under special conditions this reagent can generate perfluoroalkyl radicals from both perfluoroalkyl iodides and perfluoroalkanesulfinic acid salts.

The reaction of perfluoroalkyl iodides and bromides with ethylene, ethylene derivatives and acetylene in polar solvents in the presence of compounds containing the SO_2^- anion (*e.g.*, $\text{Na}_2\text{S}_2\text{O}_4$, $\text{HOCH}_2\text{SO}_2\text{Na}$, *etc.*) (3 h, room temperature) yields addition products at the multiple bond in nearly quantitative yields.¹⁰¹

Rongalite was used for perfluoroalkylation of pyridine derivatives under the action of perfluoroalkyl iodides.^{191, 192, 196, 197}

$\text{X} = \text{I}, \text{Br};$

$\text{R}^1 = \text{H}; \text{R}^2 = \text{H}, 3\text{-Me}, 4\text{-Me}, 4\text{-NH}_2; \text{R}^1 = 3\text{-Me}, \text{R}^2 = 5\text{-Me};$

$\text{R}^1 - \text{R}^2 = 2,3\text{-CH}=\text{CHCH}=\text{CH}$ (quinoline);

$\text{R}^1 - \text{R}^2 = 3,4\text{-CH}=\text{CHCH}=\text{CH}$ (isoquinoline).

It is worth noting that the reaction of the perfluoroalkyl iodides $\text{R}_\text{F}\text{I}$ with pyridine in the presence of the $\text{Na}_2\text{S}_2\text{O}_4-\text{NaHCO}_3$ system does not result in the formation of perfluoroalkylation products in acceptable yields, whereas an addition of $\text{HOCH}_2\text{SO}_2\text{Na}$ affords a mixture of α -, β - and γ -perfluoroalkylpyridines in sufficiently good yields.^{191, 192}

$\text{R}_\text{F}\text{X} = \text{C}_6\text{F}_{13}\text{I}, \text{C}_7\text{F}_{15}\text{I}, \text{C}_8\text{F}_{17}\text{I}, \text{ClC}_8\text{F}_{16}\text{I}, \text{C}_7\text{F}_{15}\text{Br}, \text{ClC}_6\text{F}_{12}\text{Br}.$

This reaction applied to coumarin gives 3-perfluoroalkylcoumarin; its S- and N-analogues can also be prepared in good yields.^{198, 199} However, in the case of the $\text{Na}_2\text{S}_2\text{O}_4$ –cetyltrimethylammonium bromide (CTMAB) system the yield of the target product is low.⁶²

$\text{E} = \text{O}$ (63%), S, NH; $\text{R}_\text{F} = \text{F}(\text{CF}_2)_6$; $\text{X} = \text{H}, \text{OH}.$

$$\text{Pyridine} + \text{Cl}(\text{CF}_2)_4\text{I} \xrightarrow[\text{MeCN-H}_2\text{O}, 60^\circ\text{C}, 5\text{ h}]{\text{HOCH}_2\text{SO}_2\text{Na}} \text{2-(CF}_2)_4\text{Clpyridine} \quad (68\%)$$
$$\text{HOCH}_2\text{SO}_5^- \longrightarrow \text{HSO}_5^- + \text{CH}_2\text{O}.$$

The reaction of polyfluoroalkyl iodides and -bromides containing 3 to 12 carbon atoms, viz., $\text{Cl}(\text{CF}_2)_n\text{I}$ ($n = 4, 6, 8$), $\text{CF}_3(\text{CF}_2)_n\text{I}$ ($n = 5-7$) and $\text{Cl}(\text{CF}_2)_n\text{NBr}$ ($n = 4, 6$), with the rongalite- NaHCO_3 system in bipolar aprotic solvents (MeCN, DMF) results in the formation of sodium polyfluorocarboxylates in high yields.^{185, 201-205} This approach is more convenient than the conventional method based on electrochemical fluorination of carboxylic acids and their derivatives.

<i>n</i>	Hal	Yield (%)	<i>n</i>	Hal	Yield (%)
2	I	74	6	I	82
	Br	80		Br	70
3	I	82	7	I	70
	Br	—		Br	86
5	I	79	11	I	51
	Br	84		Br	—

Reactions of perfluoroalkyl iodides with ethylene and acetylene in polar solvents induced by sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) also permit the introduction of the perfluoroalkyl group into organic molecules. Thus the reaction of $\text{Cl}(\text{CF}_2)_6\text{I}$ with ethylene in the presence of the $\text{Na}_2\text{S}_2\text{O}_4\text{--NaHCO}_3$ system (3 h, room temperature) gives an addition product at the multiple bond, $\text{Cl}(\text{CF}_2)_6\text{CH}_2\text{CH}_2\text{I}$, in a nearly quantitative yield.^{186, 187, 211, 212} A similar reaction involves secondary perfluoroalkyl iodides, such as $\text{CF}_3\text{CFI}(\text{CF}_2)_4\text{SO}_2\text{F}$, $\text{CF}_3\text{CFI}(\text{CF}_2)_n\text{Cl}$ ($n = 2, 4$), $\text{CF}_3\text{CFI}(\text{CF}_2)_2\text{O}(\text{CF}_2)_2\text{SO}_3\text{Na}$ and $\text{CF}_3(\text{CF}_2)_2\text{OCFICF}_3$.^{213–215}

In the presence of sodium dithionite, perfluoroalkyl bromides react vigorously with alkenes in aqueous isopropyl alcohol at 60–70 °C to give addition products in good yields.²¹⁵

R = H, (CH₂)₃Me, (CH₂)₅Me, (CH₂)₇Me;
R_F = H(CF₂)₆, F(CF₂)₈, Cl(CF₂)₄, Cl(CF₂)₆.

In the presence of sodium dithionite, rongalite or thiourea dioxide, CF_2Br_2 and CHF_2I react with terminal alkenes in aqueous acetonitrile or *tert*-butyl alcohol at room temperature or on cooling to give the corresponding adducts.^{196, 217, 218}

$$\text{CF}_2\text{ClCFCl}_2 \xrightarrow[\text{MeCN}-\text{H}_2\text{O}]{\text{Na}_2\text{S}_2\text{O}_4-\text{NaHCO}_3}$$

In the presence of sodium dithionite, CF_2Br_2 reacts with diethylallyl malonate, alkenes and alkynes; in the latter case, mixtures of *E*- and *Z*-isomers are formed in moderate yields (Table 6).^{196, 220}

The reaction of difluorodiiodomethane with alkenes in the presence of iron at 40–50 °C gives compounds carrying the ICF₂ group.^{221, 222}

The latter also react with alkenes and alkynes in MeCN–H₂O in the presence of the Na₂S₂O₄–NaHCO₃ system at 30 °C, resulting in the formation of addition products at the multiple bond.²²²

Table 6. Reactions of alkenes and alkynes with CF₂Br₂ induced by reductants.

Substrate	Reductant	Yield (%)
Hex-1-ene	HOCH ₂ SO ₂ Na	85
	(NH ₂) ₂ C=SO ₂	80

The reaction of Cl(CF₂)₄I with α-phenylstyrene in aqueous MeCN induced by the Na₂S₂O₄–NaHCO₃ system (4 h, 40 °C) gives the products **1** and **2** which contain no iodine atom.²²³

However, if styrene is used as a substrate, fluorine-containing oligomers are formed together with compound **1**.¹⁹⁶ Cyclohexene and cyclooctene manifest similar behaviour.¹⁹⁶ Under these conditions, CF₂Br₂ also reacts with α- and β-pinenes.^{196, 220}

It was shown^{224–229} that the use of compounds containing different halogen atoms in the reaction of 1,1,1-tribromotrifluoroethane with alkenes yields addition products at the multiple bond.

The mechanism of generation of perfluoroalkyl radicals under the action of sodium dithionite and its subsequent reaction with alkenes is now well-established.¹⁵⁸ The transformations of the intermediate radical **C** were shown to occur in three different ways.

The reaction of perfluoroalkyl iodides with alkynes under sulfatodehalogenation conditions gives a mixture of *E*- and *Z*-adducts in very high yields.²³⁰ A similar reaction with alkenes was used in the synthesis of an α,α-difluoro-γ-lactone.²³¹

R¹ = R² = Alk, H.

The reaction of CF₂=CFCF₂Cl with allyl alcohol in aqueous acetonitrile in the presence of the Na₂S₂O₄–NaHCO₃ system affords an adduct (1:1); treatment of the latter with zinc at 130–140 °C in ethylene glycol results in 1,1,2,3,3-pentafluoro-1,5-hexadiene,²³² which is further used in the synthesis of poly-fluorinated polymers.

In the presence of sodium dithionite, perfluoroalkyl iodides react also with allyl alcohol and unsaturated carboxylic acids to give addition products at the multiple bonds in high yields.²³³

A convenient and efficient procedure was developed for the direct introduction of the perfluoroalkyl group into unsaturated compounds which is based on the reaction of perfluoroalkyl iodides with alkene and alkyne derivatives induced by sulfur-containing systems. The main advantages of this method are its simplicity, high variability of functional groups, easy isolation of reaction products and regioselectivity. Moreover, these reagents

are neither toxic nor explosive, which makes them environmentally safe.

The presence of two multiple bonds in the substrate molecule favours the addition of R_F and I fragments to the alkene and the formation of a five-membered heterocycle of the type **3**. This reaction is regioselective.²⁰¹ Its strategy consists in the generation of a radical centre due to the cleavage of the F_2C-I bond, the addition of the radical formed at the double bond and subsequent cyclisation involving the radical centre and the multiple bond as a donor. Polyfluoroalkylated 3-iodoalkylidenetetrahydrofuran-2-one is formed as a result of generation of the perfluoroalkyl radical initiated by the reaction of R_F with $Na_2S_2O_4$ and subsequent formation of a five-membered heterocycle. This reaction occurs with high regioselectivity.²⁰¹

R	R_F	Yield (%)	<i>E</i> : <i>Z</i>
H	CF_3	44	32 : 68
H	$Cl(CF_2)_2$	47	60 : 40
H	$Cl(CF_2)_4$	50	52 : 48

H	MeCO	$Cl(CF_2)_2$	46	0	52 : 48
Me	PhCO	$Cl(CF_2)_2$	70	0	> 97 : 3
Me	PhCO	$Cl(CF_2)_4$	60	0	> 97 : 3
Me	OTs	CF_3	72	0	> 97 : 3
Me	OTs	$Cl(CF_2)_4$	83	0	> 97 : 3

Presumably, this reaction occurs by the following scheme:

Cyclisation induced by the intermediate radical is successfully used for the construction of cyclic systems.²³⁴

It is worth noting that in reactions with alkynes perfluoroalkyl iodides form mixtures of *E*- and *Z*-adducts in the presence of sodium dithionite, whereas perfluoroalkyl bromides and trichloro-1,1,1-trifluoroethane yield exclusively sulfonates.²³⁰

Generally, if the starting compound contains a double bond, its treatment with perfluoroalkyl iodides in the presence of the $Na_2S_2O_4-NaHCO_3$ system results in the formation of addition products as is the case in the reaction of perfluoroalkyl iodides with *O*-allyl-*O*-isopropylidenglycerol and crown ethers containing multiple bonds in a $CH_2Cl_2-H_2O$ mixture.^{235, 236}

$R_F = F(CF_2)_8$ (72%), $F(CF_2)_6$ (59%), $Cl(CF_2)_6$ (55%), $Cl(CF_2)_8$ (68%).

The addition products of perfluoroalkyl iodides at the triple bond can be used in the synthesis of heterocyclic compounds, e.g., 5-perfluoroalkyl-substituted isoxazoles.^{237, 238}

$R^1 = H$, $R^2 = CH_2OH$.

Diethyl difluoroiodomethylphosphonate was also introduced in the reaction with alkynes²²² to give a mixture of isomers the ratio of which depends on the nature of the substituent at the triple bond (Table 7).

Perfluoroalkyl derivatives of alkynes are formed in the reaction of alkynes with perfluoroalkyl iodides and subsequent treatment with a base as a result of elimination of HI from the adducts formed.²³⁵⁻²⁴⁰

Note. The $\text{ICF}_2\text{P}(\text{O})(\text{OEt})_2\text{:HC}\equiv\text{CR}:\text{Na}_2\text{S}_2\text{O}_4:\text{NaHCO}_3$ ratio is 1:2:1:1.

The reaction of silylenol ethers with perfluoroalkyl iodides in the presence of the $\text{Na}_2\text{S}_2\text{O}_4\text{--NaHCO}_3$ system results in the formation of perfluoroalkylated α,β -unsaturated aldehydes and ketones.^{241–245} Heating of the latter with HNEt_2 (or piperidine) and acid hydrolysis give the corresponding β -dicarbonyl compounds.

$\text{X} = \text{Cl}; n = 4, 6, 8; \text{X} = \text{F}; n = 6, 8.$

Trimethylsilyl ethers of the enol forms of acetophenone and methyl vinyl ketone react with perfluoroalkyl iodides in the presence of the $\text{Na}_2\text{S}_2\text{O}_4\text{--NaHCO}_3$ system to give hydrogen substitution products at the double bond.²⁴²

It should be noted that the intermediate radical is capable of dimerisation; thus the dimeric products **6** and **7** are formed from butadiene derivatives in reactions involving allylic radicals **8**.²⁴⁶

$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_n (n = 2, 4), \text{CF}_3(\text{CF}_2)_3; \text{R}^1 = \text{R}^2 = \text{H}, \text{Me}.$

The rates of reactions of perfluoroalkyl halides with alkenes and alkynes can be increased by sonication.^{206, 235}

α -Perfluoroalkyl derivatives of aldehydes formed as intermediate products in the synthesis of valuable fluorine-containing blocks²²⁶ are further used in the synthesis of heterocyclic compounds.^{227, 240} Polyfluorinated aldehydes or ketones are formed in reactions of vinyl ethers with perfluoroalkyl iodides and are further transformed into either the corresponding acids **9** or alcohols **10**.²⁴⁷

Compound **11** containing the allene group, like dienes, form an intermediate radical in the reaction with perfluoroalkyl iodides; its dimerisation yields the diether **12**.²³⁶

Perfluoroalkyl iodides $\text{n-C}_6\text{F}_{13}\text{I}$ and $\text{Cl}(\text{CF}_2)_n\text{I}$ ($n = 2, 4, 6, 8$) react with 4-methylenedioxolane in the presence of the $\text{Na}_2\text{S}_2\text{O}_4\text{--NaHCO}_3$ system resulting in ring opening.²⁴⁸

Cyclic ethers (2,3-dihydrofuran and 3,4-dihydro-2*H*-pyran) react with $\text{R}_\text{F}\text{I}$ [$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_n$, where $n = 4, 6, 8$; $\text{F}(\text{CF}_2)_n$, where $n = 6, 8$]²²⁶ or with CF_2Br_2 ^{196, 225} in the presence of the $\text{Na}_2\text{S}_2\text{O}_4\text{--NaHCO}_3$ system to produce 2-polyfluoroalkylhemiacetals **13** which can be oxidised to the corresponding lactones **14** or reduced to the diols **15**.^{226, 249} On the other hand, the hydrogen substitution product at the multiple bond **16** is formed in the presence of *p*-toluenesulfonic acid (Scheme 1).

$\text{R}_\text{F} = \text{n-C}_6\text{F}_{13}, \text{Cl}(\text{CF}_2)_n (n = 2, 4, 6, 8).$

Perfluoroalkyl iodides react with heterocyclic compounds **17–20** containing an α -methylene substituent in the presence of

Scheme 1

the $\text{Na}_2\text{S}_2\text{O}_4 - \text{NaHCO}_3$ system with the formation of ring-opening products.²⁵⁰

Carbohydrates containing perfluoroalkyl substituents, *e.g.*, 2- R_F -2-deoxy-D-glucose, are prepared by perfluoroalkylation of glycals by perfluoroalkyl iodides induced by the $\text{Na}_2\text{S}_2\text{O}_4 - \text{NaHCO}_3$ system.^{197, 207, 251 - 258}

Perfluoroalkyl-substituted carbohydrates, *e.g.*, 2-iodo-3-perfluoroalkylpropyl-2,3,4,6-tetra-*O*-acetyl- β -D-glucopyranoside (**21**), can be synthesised by perfluoroalkylation of allyl glucopyranoside **22**. These compounds were found to be useful intermediates and can be used as surfactants and emulsifiers.^{250, 259 - 266}

$\text{R}_\text{F} = \text{C}_4\text{F}_9$ (86%), C_6F_{13} (83%), C_8F_{17} (78%), $\text{C}_{10}\text{F}_{21}$ (71%).

Perfluoroalkyl iodides add at the multiple bond of hex-5-enopyranose and -furanose ($\text{R} = \text{CH}_2\text{Ph}$, Me) in the presence of $\text{Na}_2\text{S}_2\text{O}_4$.²⁶²

Under ordinary conditions, benzene does not react with perfluoroalkyl iodides; however, under conditions of phase-transfer catalysis with CTMAB it yields perfluoroalkylation products and dimerisation products of intermediate cationic σ -complexes.^{212, 267 - 269} Perfluoroalkylation of aromatic compounds containing amino or hydroxy substituents with bromotrifluoro-

methane or long-chain perfluoroalkyl iodides occurs at the *ortho*- and *para*-positions.^{212, 267 - 269}

Ortho- and *para*-perfluoroalkylphenols can easily be prepared from phenol²⁷⁰ and its *para*-substituted derivatives^{252, 271} in the presence of an alkali. For example, in the presence of NaOH *p*-cresol reacts with $\text{Cl}(\text{CF}_2)_6\text{I}$ in DMF containing $\text{Na}_2\text{S}_2\text{O}_4 - \text{NaHCO}_3$ to give 2- ω -chloroperfluorohexyl-*p*-cresol in 60% yield.²⁷⁰ 2,6-Diperfluoroalkyl derivatives can also be formed.²⁷¹

The $\text{Na}_2\text{S}_2\text{O}_4 - \text{NaHCO}_3$ system was efficient in the perfluoroalkylation of biologically active compounds containing a phenolic fragment. A procedure was developed for introducing perfluoroalkyl substituents into the aromatic ring of tyrosine.²⁷²

α -Perfluoroalkyl-substituted derivatives are formed in high yields upon treatment of pyrrole with perfluoroalkyl iodides in the presence of the $\text{Na}_2\text{S}_2\text{O}_4 - \text{NaHCO}_3$ system.²⁷³ However, high hydrolytic lability of the fluorine atoms of the α - CF_2 group should be kept in mind. It is of note that 2,5-dimethylpyrrole yields both addition (**23**) and substitution products of the hydrogen atom of the pyrrole ring (**24**).^{274 - 277}

Perfluoroalkylation of other nitrogen-containing heterocyclic compounds is also possible.²⁷³

Perfluoroalkyl sulfones are synthesised in the reaction of alkenes $\text{H}_2\text{C}=\text{CHR}$ ($\text{R} = \text{CN}, \text{MeCO}$) with sodium perfluoroalkanesulfonates $\text{R}_\text{F}\text{SO}_2\text{Na}$ ($\text{R}_\text{F} = \text{C}_4\text{F}_9, \text{ClC}_4\text{F}_8$) obtained by treatment of perfluoroalkyl iodides with sodium dithionite.¹⁸⁸

It may thus be concluded that perfluoroalkyl radicals can be formed from perfluoroalkyl halides under the action of other radical anions capable of generating radical anions of perfluoroalkyl halides. Indeed, Medebielle *et al.*²³⁹ who studied the reduction of CF_3Br , $n\text{-C}_4\text{F}_9\text{I}$, $n\text{-C}_6\text{F}_{13}\text{I}$ and $\text{I}(\text{CF}_2)_4\text{I}$ using terephthalonitrile, nitrobenzene and 4-nitropyridine *N*-oxide as messengers ($E^\circ = -1.60, -1.10$ and -0.79 V rel. SCE, respectively) demonstrated the efficiency of perfluoroalkylation of *N*-anions of the heterocyclic series (*e.g.*, imidazole, adenine, xanthine, uracil, cytosine, barbituric acid, lumazine, theophylline) by intermediate perfluoroalkyl radicals.

This reaction occurs in accordance with the following scheme. The initial electrochemically generated 4-nitropyridine *N*-oxide (P) radical anion induces the reduction of perfluoroalkyl halide to the corresponding radical anion which is further transformed into the perfluoroalkyl radical. The latter reacts with the *N*-anion to yield a new radical anion which ultimately yields the final product and the radical anion of the 'messenger', *viz.*,

In the case of perfluoroalkyl halides, the reaction mechanism represents a modified version of the classical $\text{S}_{\text{RN}}1$ mechanism where the electron transfer occurs without the intermediate formation of the substrate radical anion. The perfluoroalkyl

radical thus generated attacks the carbon atom of the *N*-anion of the heterocyclic compound, eventually resulting in the formation of the reaction product.

This methodology describes the perfluoroalkylation of organic substrates by perfluoroalkyl halides as a reduction in the presence of catalysts of the 4-nitropyridine *N*-oxide type.

c. Reactions of perfluoroalkyl iodides and -bromides catalysed by transition metals and their derivatives

Catalytic effects of metals and their salts. Various initiators of addition reactions of perfluoroalkyl iodides and -bromides to the multiple bonds $\text{C}=\text{C}$ are presently known. An important role in the generation of perfluoroalkyl radicals is played by transition metal derivatives (mostly, zero-valent compounds)^{278, 279} and their complexes^{180, 280–283} used as both reagents and catalysts of diverse reactions.^{180, 278, 282, 283} Reactions of perfluoroalkyl iodides with alkenes and alkynes are especially efficient in the presence of Ru, Ni, W, Mo,^{180, 282, 283} Sn,^{284, 285} Fe,^{286, 287} Mg,^{288, 289} Cu,^{290–294} Raney Ni (RaNi),^{295–297} Pt,^{298, 299} Mn^{II}, Hg^I,³⁰⁰ Ru^{II},³⁰¹ Rh,³⁰² Me₃Al,²¹⁷ Et₃B,^{303–308} Zn,^{197, 309} and Pd⁰ (see Refs 197, 278, 310) and result in the formation of addition products at the multiple bond.^{278, 279} Reactions of perfluoroalkyl iodides with benzene in the presence of metals (Rh, Pd, Pt, Ru, Cu, RaNi, Co) and aqueous potassium hydrogencarbonate give perfluoroalkylbenzenes.^{311, 312} It is noteworthy that disubstitution occurs with low yields.

The role of metals consists in reductive generation of the radical $\text{R}_\text{F}^\cdot$ from $\text{R}_\text{F}\text{I}$. Further transformations depend on the type of the substrate and may occur either as subsequent addition of the radical $\text{R}_\text{F}^\cdot$ at the multiple bond ($\text{C}=\text{C}$) or as substitution of a halogen or hydrogen atom at the carbon atom of the multiple bond. Thus perfluoroalkyl iodides give perfluoroalkanes in the presence of zinc in sulfolane or in H_2O ;³¹³ in DMF they react with aldehydes to give the corresponding alcohols.³¹⁴

The reaction of bromotrifluoromethane with aldehydes and zinc in *N*-methylpyrrolidone yields alcohols;³¹⁵ trifluoroacetaldehyde is formed from DMF under conditions of cathode synthesis.³¹⁶

It should be noted that reactions of perfluoroalkyl iodides and -bromides with electrophiles can also be catalysed by other metals. Thus the reaction of bromotrifluoromethane with chlorotrimethylsilane in the presence of aluminium powder in *N*-methylpyrrolidone yields trimethyl(trifluoromethyl)silane (yield 62%).³¹⁷ In the presence of cadmium, perfluoroalkanes are formed in 72% to 90% yield.³¹⁸ The reaction of $\text{Cl}(\text{CF}_2)_4\text{I}$ with $\text{Bu}^n\text{CH}=\text{CH}_2$ in the presence of Mg results in the addition product $\text{Bu}^n\text{CHICH}_2(\text{CF}_2)_4\text{Cl}$ in high yield, the reaction with $\text{Bu}^n\text{C}\equiv\text{CH}$ yields a mixture of (*E*)- and (*Z*)- $\text{Cl}(\text{CF}_2)_4\text{CH}=\text{CIBu}^n$ (Ref. 288).

Various reactions of perfluoroalkyl iodides with aromatic compounds (Table 8) and alkenes in the presence of copper have been described.^{319–322} In these reactions, diethylene glycol, acetonitrile and acetic anhydride are used as solvents.

The reaction of perfluoroalkyl iodides with cyclohexene in the presence of catalytic amounts of copper gives addition products at the multiple bond and reduction products.

Table 8. Reactions of bromo- and iodoaromatic compounds with perfluoroalkyl iodides R_FI in the presence of copper.³²¹

ArHal	R_F	Reaction conditions			Product	Yield (%)
		solvent	$T/^\circ\text{C}$	t/h		
PhI	n-C ₇ F ₁₅	DMSO	125	23	n-C ₇ F ₁₅ Ph	78
	n-C ₈ F ₁₇	DMSO	130	15	n-C ₈ F ₁₇ Ph	83
C ₁₀ H ₇ Br	n-C ₇ F ₁₅	DMSO	125	34	n-C ₇ F ₁₅ C ₁₀ H ₇	45
C ₁₀ H ₇ I	n-C ₇ F ₁₅	DMSO	125	48	n-C ₇ F ₁₅ C ₁₀ H ₇	89
	n-C ₈ F ₁₇	C ₅ H ₅ N	120	16	n-C ₈ F ₁₇ C ₁₀ H ₇	96

The reactions catalysed by metals (*e.g.*, Zn, Cd) seem to occur via the intermediate formation of organometallic compounds, *viz.*, an organozinc compound of the $\text{CF}_3\text{ZnBr} \cdot L_n$ type (see Ref. 314) or an organocadmium compound,³¹⁸ which further generate perfluoroalkyl radicals.

Hence the initiation of the cleavage of the C–Hal bond under the action of metals is one of the simplest and convenient methods for the activation of reactions of R_FI with alkenes and alkynes.²⁸⁸

It would be natural to expect that a similar effect will be produced by a combination of transition metal salts and zero-valent metals. Indeed, the $\text{NiCl}_2 \cdot 6\text{H}_2\text{O} - \text{Al}$ system efficiently initiates the reactions of R_FI with $R_F\text{CH}=\text{CH}_2$ resulting in the formation of addition products at the multiple bond, albeit, in moderate yields.³²³ For example, the yields of the adducts formed in the reaction of alkenes with R_FI in MeCN in the presence of 20 mol. % of $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ and 2 equiv. Al (25–30 °C, 12 h) (Table 9) were 45%–60%.³²³ Zinc can replace aluminium in this reaction.³²⁴

An interesting transformation occurred when perfluoroalkyl iodides, -bromides and -chlorides were heated in DMF in the presence of aluminium-promoted Sn^{II} ($\text{SnCl}_2 - \text{Al}$)³²⁵ or Pb^{II} ($\text{PbBr}_2 - \text{Al}$).^{326–329} This reaction resulted in the formation of perfluoroalkylaldehyde monohydrates.^{325–329}

Reagents and conditions	R_FX	Yield (%)	Reagents and conditions	R_FX	Yield (%)
(a) SnCl_2 , Al,	$\text{Cl}(\text{CF}_2)_4\text{I}$	80	(b) PbCl_2 , Al	$\text{H}(\text{CF}_2)_4\text{Cl}$	80
20 °C,	$\text{Cl}(\text{CF}_2)_6\text{I}$	97		$\text{H}(\text{CF}_2)_6\text{Cl}$	85
10 h	$\text{Cl}(\text{CF}_2)_8\text{I}$	88		$\text{H}(\text{CF}_2)_8\text{Cl}$	88
	$\text{C}_4\text{F}_9\text{I}$	90		$\text{CH}_2=\text{CH}(\text{CF}_2)_4\text{Cl}$	82

	$\text{C}_8\text{F}_{17}\text{Br}$	89		$\text{Bu}^n\text{CHICH}_2(\text{CF}_2)_4\text{Cl}$	91
				$\text{Bu}^n\text{CHICH}_2(\text{CF}_2)_6\text{Cl}$	93

The yields of reaction products and reaction conditions are listed in Tables 10 and 11.

The perfluoroalkylation of DMF by perfluoroalkyl iodides and α,ω -dibromoperfluoroalkanes in the presence of $\text{Al}-\text{SnCl}_2$ or $\text{Al}-\text{PbBr}_2$ is strongly accelerated by sonication³³⁰ which has recently found wide application in the activation of organic reactions.^{331–333} Thus the reaction occurring under normal conditions usually lasts from 4 to 24 h, whereas that subjected to sonication is completed within 0.25–3 h. The possibility of performing perfluoroalkylation with perfluoroalkyl iodides in

the presence of metals (*e.g.*, zinc, magnesium, *etc.*) using sonication has been demonstrated.^{255, 334–337}

The reaction of cyclohexanone with $\text{C}_4\text{F}_9\text{I}$ in hexane catalysed by magnesium and activated by sonication results in 1-perfluorobutylcyclohexanol (yield ~ 81%).³³⁶

Perfluoroalkylation occurs in the presence of zinc in THF and is catalysed by the triphenylphosphine–palladium complex. In the absence of catalysts, the reactions of perfluoroalkyl iodides with compounds containing a carbonyl group are carried out using zinc in DMF. For example, the reaction of perfluoroalkyl iodides with the *o*-tolualdehyde–chromium tricarbonyl **25** complex yields the corresponding alcohols **26** which eliminate $\text{Cr}(\text{CO})_3$ to give the alcohols **27**.³³⁸

**Table 9.** Reactions of fluorine-containing alkenes $\text{CH}_2=\text{CHCF}_2\text{R}_F^1$ with perfluoroalkyl iodides R_F^2I (25–30 °C, 12 h, molar ratio $\text{R}_2\text{F}_2\text{I} : \text{NiCl}_2 \cdot 6\text{H}_2\text{O} = 2.0 : 1.0 : 0.2$ or $5.0 : 1.0 : 0.2$).³²³

More recent studies³³⁸ demonstrated that sonication can be used in reactions of perfluoroalkyl iodides and -bromides with various carbonyl compounds and alkyl halides in the presence of MnCl₂—Na and AgBr—Li systems.³³⁹ This finding has led to the development of a simple procedure for the synthesis of perfluoro-carboxylic acids and partially fluorinated secondary alcohols using carbon dioxide and aldehydes, respectively. In this case, sodium and lithium are used as reductants for the formation of active metals (manganese and silver), which yield reactive organometallic derivatives with perfluoroalkyl halides. The organometallic derivatives enter into the reaction with the carbonyl compound.

The activity of perfluoroalkyl halides decreases in the following order: R_FI > R_FBr ≫ R_FCl.

The Sn—AgOAc and Sn—Cu₂Cl₂ systems effectively catalyse reactions of perfluoroalkyl iodides with alkenes under relatively mild conditions.²⁸⁴ Methanol is the most suitable solvent for these reactions. Joint use of metallic Sn and Al produces the same effect.

R = Me(CH₂)₅, MeO(CH₂)₂, HOCH₂, PhCH₂, HO(CH₂)₄, (EtO₂C)₂CHCH₂, Me₂CHCH₂; R_F = n-C₄F₉, n-C₆F₁₃.

It was found that the copper acetate—hydrazine hydrate system catalyses reactions of perfluoroalkyl iodides with alkenes and alkynes;³⁴⁰ the yields of the target products vary from 65% to 90%.

The KI—CuSO₄ system is also active in these reactions.³⁴¹ In the presence of this system, cupric perfluoroalkanesulfonates react with alkenes with the formation of addition products at the multiple bond, viz., R_FSO₂CH₂CHIR.

Nickel complexes effectively catalyse the perfluoroalkylation of aromatic compounds under the action of polyfluoroalkyl iodides.³⁴²

It was found³⁴³ that the Cp₂TiCl₂—Fe system catalyses the reactions of perfluoroalkyl iodides XCF₂CF₂I (X = Cl, Br) with alkenes and alkynes which yield 1 : 1 adducts.^{343–345} The use of octa-1,7-diene (**28**) as an alkene results in the involvement of only one multiple bond and the formation of the adduct **29**.

R_F = ClC₄F₈ (87%), C₄F₉ (88%), (CF₂)₂CF (92%), CF₂ClCF₂ (90%).

In the presence of 30 mol.-equiv. of Fe and 2 mol.-equiv. of Cp₂TiCl₂, 1,2-dihalogenotetrafluoroethane CF₂BrCF₂X (X = I, Br) reacts with alkenes in EtOH under a nitrogen atmosphere to give addition products in excellent yields (Table 12). The experimental results provide support for a radical mechanism of this reaction. In the perfluoroalkylation induced by CF₂BrCF₂X in the presence of Cp₂TiCl₂ as a catalyst, 2-bromotetrafluoroethyl radical can be formed, apparently according to the following scheme:^{346, 347}

$$\text{CF}_2\text{BrCF}_2\text{X} + \text{R}^1\text{CH}=\text{CHR}^2 \longrightarrow \text{CF}_2\text{BrCF}_2\text{CHR}^1\text{CHXR}^2$$

Alkene	R _F X	T /°C	t /h	Product	Yield (%)

Diallyl ether	CF ₂ BrCF ₂ Br	60	8		95
	CF ₂ BrCF ₂ I	55	7		94

$$\text{CH}_3\text{C}(\text{CH}_3)=\text{CHCH}_2\text{CH}_3 + \text{R}_\text{F}\text{I} \xrightarrow[\text{Zn, THE, 20 }^\circ\text{C, 1 h}]{\text{Cp}_2\text{TiCl}_2} \text{R}_\text{F}\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$$
$$\text{CH}_2=\text{CH}(\text{CH}_2)_m\text{R} + \text{R}_\text{F}\text{I} \longrightarrow$$

The cyclopentadienyldicarbonyl iron dimer is yet another efficient catalyst of the reaction of perfluoroalkyl iodides with alkene derivatives.^{348, 349}

$$\text{CH}_2=\text{CHOEt} + \text{CF}_3(\text{CF}_2)_5\text{I} \xrightarrow[\text{Et}_3\text{N, EtOH, 25 } ^\circ\text{C}]{[\text{CpFe}(\text{CO})_2]_2} \text{CF}_3(\text{CF}_2)_5\text{CH}_2\text{CH}_2\text{OEt}$$

(63%–95%)

Successful perfluoroalkylation of alkenes containing electron-accepting substituents (*e.g.*, acrylates, acrylonitrile, methyl vinyl ketone, *etc.*) was carried out with Zn-bis(dimethylglyoximate)-pyridinecobalt(II) bromide [BrCo(dmgH)₂Py, **30**] in ethanol as a

$$\text{Cyclohexane ring with } \text{CF}_2\text{CF}_2\text{Br} \text{ and } \text{Br} \text{ substituents} + \text{CH}_2=\text{CHCO}_2\text{R} \xrightarrow[\text{EtOH, 20 } ^\circ\text{C, 24 h}]{\text{BrCo(dmgH)}_2\text{Py-Zn}} \text{Cyclohexane ring with } (\text{CF}_2)_2(\text{CH}_2)_2\text{CO}_2\text{R} \text{ and } \text{Br} \text{ substituents}$$

Zinc itself can exert a pronounced effect on the reactions of alkenes with perfluoroalkyl iodides. For example, the reaction of $\text{Me}(\text{CH}_2)_4\text{CH}=\text{CH}_2$ with $\text{CF}_3(\text{CF}_2)_3\text{I}$ yielded 90% of $\text{Me}(\text{CH}_2)_4\cdot\text{CHICH}_2(\text{CF}_2)_3\text{CF}_3$.³⁵¹

The system $\text{Co}-\text{Zn}$ was used for perfluoroalkylation of alkenes by perfluoroalkyl iodides and -bromides.^{256, 259, 344} Thus perfluoroalkylation of various cyclic, linear, symmetric or asymmetric alkenes with Freon-2402 (1,2-dibromo-1,1,2,2-tetrafluoroethane) resulted in derivatives containing a CF_2CF_2 fragment.^{354, 355} It may be noted that the activation of the $\text{C}-\text{Br}$ bond, *e.g.*, in $\text{RCF}_2\text{CF}_2\text{Br}$, by cobalt in the low valent state generated *in situ* occurs with high efficiency, which made it possible to induce reactions of these compounds with unsaturated substrates.²⁵⁹

Table 13. Perfluoroalkylation of alkenes by perfluoroalkyl iodides in the presence of the catalytic system **30** – Zn.³⁵⁴

	C ₈ F ₁₇ Br	30	10	R _F CH=CHCO ₂ Et	65 (28 : 72)

^a The reaction was carried out in the presence of the catalytic system Cp₂TiCl₂ – Fe.

The (diethoxyphosphoryl)difluoromethyl group was successfully introduced into alkenes containing electron-withdrawing substituents by the reaction with (EtO)₂P(O)CF₂Br in the presence of the system **30** – Zn.^{344, 346–348}

X = CO₂Et, CO₂H, CN, CH₂Cl, CONH₂, COMe, OAc, OEt, CO₂Me, Buⁿ.

The yield of the reaction products increases after addition of 1 equiv. of HCOONH₄. Apparently, the surface of zinc is activated by ammonium ions. Other ammonium salts, *e.g.*, NH₄Cl, NH₄Br and NH₄OAc, can also be used for this purpose; however, the yields of the reaction products are lower.

Reduction of commercial Freon-1301 (bromotrifluoromethane) to the trifluoromethyl radical possessing electrophilic character using the Zn – SO₂ system in DMF in the presence of Na₂S₂O₅ and bases (Na₂HPO₄, 2-methylpyridine) was a step forward on the way to trifluoromethylation of aromatic and heterocyclic compounds.^{138, 171, 267, 353, 355–357} Thus the reaction of CF₃Br with aniline in the presence of this system gives a mixture of *ortho*- and *para*-trifluoromethylanilines with the *ortho*-isomer prevailing.

Trifluoromethylation of pyrrole and *N*-methylpyrrole occurs at position 2.

In the presence of this system, perfluoroalkyl iodides F(CF₂)_{*n*}I (*n* = 1, 2, 4, 6, 8) efficiently react with aromatic compounds

containing electron-donor substituents (phenols, anisole, anilines, aminophenols, toluene) and pyrrole.

The reaction of perfluoroalkyl iodides with CO₂ in the presence of the Zn/Cu couple in DMSO results in perfluorinated carboxylic acid, this presents special interest.^{358–360} An analogous reaction with SO₂ gives the corresponding perfluoroalkanesulfonyl chlorides.³⁶⁰

Some metal halides can effectively catalyse perfluoroalkylation reactions. Thus the redox system CrCl₃ – Fe in ethanol promotes the perfluoroalkylation of alkenes containing electron-withdrawing substituents^{256, 347, 361, 362} under the action of CF₂Br₂ (Table 14),²⁰⁵ CF₃Cl or ICHFCO₂R (R = Me, Et) at 60–70 °C.²⁸⁷

R¹ = CO₂Me (71%), CO₂Et (78%), CN (74%), COMe (75%);

R² = Me, Et.

The CrCl₃ – Fe system is efficient in the reaction of perfluoroalkyl iodides Cl(CF₂)_{*n*}I (*n* = 2, 4, 6, 8), C₄F₉I, C₆F₁₃I and C₈F₁₇I with methyl α-acetylaminocrylate resulting in β-perfluoroalkyl-α-amino acid derivatives R_FCH₂CH(NHAc)CO₂Me in 65% to 80% yields. The reaction of perfluoroalkyl iodides with diethyl allylmalonate and its analogues in the presence of the CrCl₃ – Fe system gives perfluoroalkylmethyl-substituted derivatives of

The YbCl₃–Zn and LnCl₃–Zn systems produce a similar effect.^{138, 251, 254, 256} Thus the reaction of perfluorohexyl iodide with CH₂=CHCH₂OAc in THF in the presence of the YbCl₃–Zn system results in F(CF₂)₆(CH₂)₃OAc in 95% yield. This can be explained by the fact that the primary addition product to the double bond undergoes reductive deiodination.

The efficiency of the YbCl₃–Zn system in catalytic reactions of perfluoroalkyl iodides with alkenes was studied (Table 15).^{250–256} This reaction is completed within several minutes in tetrahydrofuran but does not take place in EtOH or benzene.

The reaction of substituted hepta-1,6-diene with perfluoroalkyl iodide in the presence of the LaCl₃–Zn or SmCl₃–Zn system is accompanied by cyclisation involving the second double bond and results in a mixture of the corresponding *cis*- and *trans*-

3-iodomethyl-4-perfluoroalkylmethyl-1,1-di(ethoxycarbonyl)cyclopentanes (**4**: **1**).¹³⁸

R_F = ClC₄F₈, ClC₆F₁₂, C₆F₁₃, C₈F₁₇.

The NiCl₂·6 H₂O–Zn system in THF proved to be efficient in the reaction of iodoacetates with alkenes resulting in δ-iodo esters in good yields.^{251–253} In the case of perfluoroalkyl chlorides, the hydrogen atom is substituted for chlorine.²⁵²

Activation of perfluoroalkyl iodides by transition metal complexes. Transition metal complexes can also efficiently activate perfluoroalkyl iodides.

Perfluoroalkanesulfonyl chlorides F(CF₂)_nSO₂Cl (*n* = 1–20) and pentafluorobenzenesulfonyl chloride can replace perfluoroalkyl iodides in perfluoroalkylation and arylation reactions of aromatic and heterocyclic compounds and alkenes with (Ph₃P)₃RuCl₂ as a catalyst.^{355, 363–367}

Perfluorophenylation of various thiophene derivatives by C₆F₅SO₂Cl in the presence of the (Ph₃P)₃RuCl₂ complex was studied under similar conditions. The results of these studies are listed in Table 17.^{366, 367}

Perfluoroalkyl iodides add to alkenes in the presence of the Wilkinson catalyst [tris(triphenylphosphine)rhodium chloride] at 80 °C.^{298, 372} This catalyst ensures high chemoselectivity under mild reaction conditions.

R_f = Cl(CF₂)₄, F(CF₂)₄, Cl(CF₂)₆, Cl(CF₂)₂;

R¹ = *n*-C₅H₁₁, *n*-C₆H₁₃, Buⁿ, Me₂CHCH₂, Et; R² = H, Me.

Perfluoroalkyl iodides R_fI [R_f = Cl(CF₂)₄, Cl(CF₂)₆, CF₃(CF₂)₃] react with alkenes and alkynes in the presence of Ir(H)(CO)(PPh₃)₃. The addition reaction to the triple bond yields predominantly *E*-isomers.³⁵⁸

The perfluoroalkyl radical R_f• generated from perfluoroalkyl iodides in the presence of metals or transition metal complexes reacts smoothly with alkenes containing both electron-donor and electron-withdrawing substituents. As in the case of sulfonatode-

Table 17. Reactions of thiophene and its derivatives with pentafluorobenzenesulfonyl chloride in the presence of (Ph₃P)₃RuCl₂.³⁶⁶

		11

halogenation, these complexes effectively catalyse the addition of perfluoroalkyl halides to both types of alkenes.

Tetrakis(triphenylphosphine)palladium is also efficient in reactions of perfluoroalkyl iodides with alkenes and alkynes in hexane.^{278, 302, 305, 310, 373 - 376}

R_f = CF₃(CF₂)₃, CF₃(CF₂)₂, CF₃(CF₂)₅; R = (CH₂)₂OH, Ph, *n*-C₆H₁₃, SiMe₃, Buⁿ, CH₂SiMe₃, (CH₂)₂CO₂Me, CH₂OH.

For example, chlorododecafluorohexyl iodide reacts with hept-2-ene in the presence of 0.5 mol. % Pd⁰ (20 min, 20 °C) resulting in the addition product (yield 97%). An increase in temperature from 20 to 100 °C has little effect on this reaction.

The trialkylstannyl group at the carbon atom of the multiple bond can be replaced by the perfluoroalkyl group by treatment with perfluoroalkyl iodide in the presence of Pd(PPh₃)₄.³⁷⁷ Thus the reaction of (*E*)-PhCH=CHSnBu₃ with perfluorobutyl iodide in the presence of Pd(PPh₃)₄ in hexane with boiling for 4 min results in (*E*)-PhCH=CHC₄F₉ in 68% yield.^{297, 377}

A mixture of *cis*- and *trans*-ethers R_fCH=CHOR (yields 51%–86%) is formed in the reaction of R_fI (R_f = CF₃, C₃F₇, C₆F₁₃) with CH₂=CHOR (R = H, Buⁿ) in hexane in the presence of Pd(PPh₃)₄ and Et₃N.³⁷⁸

α,α-Difluoro-substituted esters of carboxylic and phosphonic acids are prepared by the reaction of iodo-substituted derivatives of these acids with alkenes in the presence of Pd(PPh₃)₄. Subsequent treatment of the iodo-substituted derivative with NiCl₂·6 H₂O results in the formation of the reduction product.^{158, 250 - 256}

Zero-valent palladium also catalyses the reactions of aryl- or alkenyl halides with alkenes resulting in addition products.³⁷⁹

Most probably, the complex **34**, which is formed first, yields an organopalladium derivative **35** in reactions with alkene.³⁸⁰ Its further transformations can include reduction of palladium to Pd⁰ with the formation of an addition product to the multiple bond (route *a*) or elimination of the hydrogen atom from the β-position under the action of palladium eventually resulting in a new alkene (route *b*).

Palladium(0) is the only possible reagent in the formation of a radical anion of perfluoroalkyl iodide (reduction) which yields the perfluoroalkyl radical initiating further conversions. The formation of a cyclic system in the reaction of perfluoroalkyl iodide with diallyl ether in the presence of Pd⁰ provides strong evidence in favour of the radical mechanism of this reaction.

On the other hand, this reaction may occur *via* the generation of the perfluoroalkyl radical upon decomposition of the complex **34**. The perfluoroalkyl radical further reacts with alkene to give the target product.

The EPR spectra of perfluoroalkyl radicals generated in these reactions could not be recorded because of their high reactivity and low concentration.²⁷⁸ However, the use of *N*-benzylidene-*tert*-butylamine *N*-oxide as a spin trap made it possible to obtain well-resolved EPR spectra in which the trapped [Cl(CF₂)₄][•] radical could be detected as the radical [Cl(CF₂)₄CH(Ph)N(O[•])Bu^t].²⁷⁸ These findings provide evidence both for the electron transfer in this reaction and the oxidation of Pd⁰ by perfluoroalkyl iodide resulting in the formation of a perfluoroalkyl palladium complex of the type **34** as occurring with the formation of a transient radical.

Fluorine-containing aliphatic mono- and dicarboxylic acids were obtained by the reaction of perfluoroalkyl iodides or -bromides with CO₂ in the presence of the Group VIII transition metal complexes and subsequent hydrolysis of the reaction products.^{381, 382} Thus CF₃(CF₂)₇CO₂H was isolated in 40% yield upon hydrolysis of the reaction product of CF₃(CF₂)₇I with CO₂ in DMF in an autoclave in the presence of Pd(PPh₃)₄ at 60 °C. This suggests the intermediate formation of the perfluoroalkyl radical which further reacts with carbon dioxide.

When the reaction is carried out in the presence of alkenes and a CO₂ source, the intermediate radical formed as the product of addition of the perfluoroalkyl radical to the multiple bond reacts further with CO₂ to yield a carboxylic acid. With alcohol as a solvent, this reaction gives the corresponding ester. Thus the

reaction of hex-1-ene with C₈F₁₇I in the presence of K₂CO₃ and dichlorobis(triphenylphosphine)palladium in ethanol (12 h, 80 °C) gives C₈F₁₇CH₂CHBuCO₂Et in 67% yield.^{383, 384}

Perfluoroalkylation of aromatic compounds by perfluoroalkyl iodides can be carried out in the presence of zero-valent transition metals (*e.g.*, Rh, Pd, Pt, Ru, Cu, Ni, Re) and aqueous K₂CO₃.³⁸⁵ The yields of disubstituted products are usually low.

On the other hand, the reaction of perfluorovinyl- and polyfluoroaryl iodides with alkynes in the presence of the (Ph₃P)₂PdCl₂–CuI complex results in the formation of addition products to the triple bond and elimination of HI.^{361, 373–376}

R¹ = OMe, NMe₂, F, Br; R² = (CH₂)_{*n*}Me (*n* = 3–6), Ph, (CH₂)₃CN, CH₂Oph, CH₂OH, CH(OH)Me.

The reaction of perfluoroalkyl iodides with alkynes in the presence of a palladium catalyst and bases (*e.g.*, K₂CO₃, Et₃N) yields mixtures of enynes and alkenes.³⁸⁶ The co-catalyst CuI increases the yield of enynes. The best results are attained when the CHCl₃–EtOH mixture (5 : 1) is used as a solvent.

Similarly, perfluorooctylmethyl-substituted aziridines are obtained in the reaction of perfluorooctyl iodide with allylamines under identical conditions.

R = H (35%), Ph (41%).

On the other hand, the addition product to the multiple bond is formed in the reaction of perfluoroalkyl halides with allyl acetate in the presence of $\text{Pd}(\text{PPh}_3)_4$.³⁸²

It was found³²⁸ that the dichlorobis(η -cyclopentadienyl)titanium(IV)–iron system efficiently catalyses the reactions of perfluoroalkyl iodides and -bromides with octa-1,7-diene (**39**). This reaction gives addition products to one multiple bond (**40**).

R_F = ClC₄F₈ (87%), C₄F₉ (88%), (CF₂)₂CF (92%), CF₂ClCF₂ (90%), CF₂BrCF₂ (91%), CF₂ClCFCl (81%).

The Cp₂TiCl₂–Zn system is also efficient in reactions of allyl bromide with carbonyl compounds.³²⁹

Ethyl-4,4,4-trifluoro-3-iodo-(Z)-crotonate (**41**) is a valuable synthon in the synthesis of compounds containing the trifluoromethyl group. The reaction of alkynes with the ester **41** in the presence of $\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$ results in compound **42** which contains a conjugated system of double and triple bonds in addition to the CF₃ group.^{387, 388}

R = SiMe₃ (76%), Ph (87%), (CH₂)₇Me (92%), 4-MeOC₆H₄ (93%), 4-NO₂C₆H₄ (88%), (CH₂)₅Me (93%), (CH₂)₃Me (91%).

The reaction of (*E*)- and (*Z*)-1,2-difluoro-1-iodoalkenes and (*E*)- and (*Z*)- α,β -difluoro- β -iodostyrenes with carbon monoxide in the presence of $\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$ as the catalyst, an alcohol and trialkylamine on heating yields carboxylic acid esters.³⁸⁹

Nickel complexes also efficiently catalyse perfluoroalkylation of aromatic compounds.³⁴²

The search for novel methods for the synthesis of fluoroorganic compounds was based on the use of accessible carbonyls of zero-valent metals. It was found that carbonyl complexes of the Group VIII transition metals can efficiently catalyse the reaction of R_FI with alkenes and alkynes.^{180, 382, 383} For example, perfluoroalkyl iodides react with phenylacetylene in the presence of transition metal carbonyls, e.g., Ni(CO)₂(PPh₃)₃, resulting in β -perfluoroalkylstyrenes (yield 89%–96%) (Table 19).

Table 19. Reactions of phenylacetylene with perfluoroalkyl iodides.¹⁸⁰

Catalyst	T / °C	t / h	Conver- sion (%)	Yield (%)
Ru/C	120	12	98.6	93
Pt/C	100	12	99.8	94

Ni(CO) ₂ (PPh ₃) ₃	70	6	100	96
W(CO) ₅ [P(OEt) ₃]	90	5	95.7	89
Mo(CO) ₅ (PPh ₃)	80	5	97.9	92

Depending on the reaction conditions, iron pentacarbonyl converts the primary perfluoroalkyl iodide into 1-iodoperfluoroalk-1-ene or to a perfluoroalkyl radical which both can further perfluoroalkylate aromatic compounds and alkenes.^{233, 390, 391} The addition of I(CF₂)₄I to CH₂=CH₂ in the presence of Fe(CO)₅ and HOCH₂CH₂NH₂ in an autoclave at 100 °C results in ICH₂CH₂(CF₂)₄CH₂CH₂I (yield 78%).

Perfluoroalkyl iodides enter into addition or substitution reactions with alkenes^{346, 348} and dihydropyran³⁴⁸ in the presence of [CpFe(CO)₂]₂.

The reactions of trialkylsilyl derivatives of alkenes with perfluoroalkyl iodides in the presence of iron carbonyl, Fe₃(CO)₁₂ result in the substitution of the perfluoroalkyl group for the trialkylsilyl group.^{392, 393}

R_F = n-C₃F₇, n-C₈F₁₇, CF₂CF₂Br, CFCF₂Br, CFCF₂Cl, CHF₂CF₂Cl.

In the presence of Fe(CO)₅ in DMF, alkenes react with R_FI with the formation of addition products to the double bond.²⁸¹

$\text{R}_\text{F} = (\text{CF}_3)_2\text{CFCF}=\text{CFCF}_2, \text{NCCF}_2, \text{MeCO}_2\text{CF}_2, \text{C}_3\text{F}_7, \text{CF}_3(\text{CF}_2)_4\text{CF}_2, \text{FSO}_2\text{CF}_2\text{CF}_2, (\text{CF}_3)_2\text{CFOCF}_2\text{CF}_2$; $\text{R} = \text{Bu}^\text{n}, \text{CO}_2\text{Me}$.

It was shown³⁹⁴ that nickel carbonyls are efficient in the reaction of substitution of the perfluoroalkyl group of α -chloro-fluoroketones for chlorine. When these reactions are carried out in donor solvents, organometallic compounds possessing perfluoroalkylating properties can be formed. For example, the reaction of perfluoroalkyl iodides with nickel tetracarbonyl in acetonitrile at 25–60 °C yields either dimeric products or unsaturated compounds.³⁹²

This reaction probably occurs *via* the intermediate formation of the nickel-containing compound **43**.

The reaction of perfluoroalkyl iodide with nickel tetracarbonyl is exothermic. The nickel compound formed reacts with the original substrate to give an isomeric mixture of perfluorohexa-2,4-diene. The reaction of perfluorohexyl iodide with nickel tetracarbonyl carried out at temperatures > 120 °C yields a mixture of two dodecenes, *viz.*, *trans*-perfluorododec-6-ene and *trans*-perfluorododec-5-ene (1 : 1) and perfluorocyclohexene.

2. Reactions of perfluoroalkyl halides with unsaturated organic compounds in the presence of redox systems

Studies of reactions of perfluoroalkyl halides with unsaturated organic compounds in the presence of reducing and oxidising systems revealed many specific features in their behaviour which can be rationalised by generation of perfluoroalkyl radicals. These radicals can be formed in different ways, predominantly by the reduction of perfluoroalkyl iodide to the radical anion. Hence a question arises as to whether the radical $\text{R}_\text{F}\cdot$ can be generated by an alternative route. According to some data, the reaction of perfluoroalkyl iodides with alkenes can be efficiently initiated by some oxidants, *e.g.*, $\text{Pb}(\text{OAc})_4$, $(\text{NH}_4)_2\text{S}_2\text{O}_8 - \text{HCO}_2\text{Na}$, $\text{CrCl}_3 - \text{Fe}$. Thus lead tetraacetate initiates the reaction of diiododifluoromethane with alkenes and alkynes.³⁹⁵

$\text{R}^1 = (\text{CH}_2)_3\text{Me}$ (95%), CH_2OH (93%), SiMe_3 (95%), CH_2OEt (92%), $(\text{CF}_2)_4\text{Cl}$ (80%), $(\text{CF}_2)_4\text{Br}$ (78%);
 $\text{R}^2 = \text{Bu}^\text{n}$; $\text{R}^3 = \text{Bu}^\text{n}$ (72%), Et (78%); $\text{R}^2 = \text{C}_5\text{H}_{11}$, $\text{R}^3 = \text{Et}$ (76%);
 $\text{R}^2 = \text{CH}_2\text{OMe}$; $\text{R}^3 = \text{Bu}^\text{n}$ (70%), Me (64%).

In addition to perfluoroalkyl iodides, these reactions occur with sodium perfluoroalkanesulfonates. For example, heating of $\text{Cl}(\text{CF}_2)_n\text{SO}_2\text{Na}$ with hex-1-ene in $\text{Ac}_2\text{O} - \text{AcOH}$ in the presence of $\text{Pb}(\text{OAc})_4$ at 80 °C results in the formation of an addition

product to the multiple bond, *viz.*, $\text{Cl}(\text{CF}_2)_n\text{CH}_2\text{C}_5\text{H}_{11}$, in 45% yield.³⁹⁶

$n = 3, 5$.

Some peroxides are effective in reactions of perfluoroalkyl iodides with alkenes.³⁹⁷

$n = 1-21$; $m = 3-25$.

Potassium permanganate can also initiate the reaction of perfluoroalkyl iodides with alkenes in aqueous MeCN at 80 °C.³⁹⁸

$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_4, \text{Cl}(\text{CF}_2)_6$; $\text{R} = \text{Bu}^\text{n}, \text{CH}_2\text{OH}, \text{n-C}_6\text{H}_{13}, \text{n-C}_{10}\text{H}_{21}, \text{Me}_3\text{Si}, \text{CH}_2\text{OCH}_2\text{CH}=\text{CH}_2, \text{n-C}_{14}\text{H}_{29}$.

Some salts of Ce^IV efficiently induce perfluoroalkylation by perfluoroalkyl iodides. In the presence of $\text{Ce}(\text{SO}_4)_2 \cdot 4 \text{H}_2\text{O}$ or $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$, perfluoroalkyl halides $\text{R}_\text{F}\text{X}$ [$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_n$ ($n = 4, 6$), $\text{F}_3\text{C}(\text{CF}_2)_5$, $\text{X} = \text{I}$; $\text{R}_\text{F} = \text{CF}_2\text{Br}$, $\text{X} = \text{Br}$] react smoothly with alkenes $\text{RCH}=\text{CH}_2$ ($\text{R} = \text{Bu}^\text{n}, \text{CH}_2\text{OH}, \text{n-C}_8\text{H}_{17}$, *etc.*) (Tables 20 and 21) and alkynes to give perfluoroalkylation products.^{398, 399}

Table 20. The effect of the solvent on the reaction of but-1-ene and hex-1-ene with $\text{Cl}(\text{CF}_2)_4\text{I}$ and $\text{Cl}(\text{CF}_2)_6\text{I}$ in the presence of $\text{Ce}(\text{SO}_4)_2 \cdot 4 \text{H}_2\text{O}$.³⁹⁸

$\text{CH}_2\text{OCH}=\text{CH}_2$	65	81	—	83
$\text{n-C}_{14}\text{H}_{29}$	78	—	—	—

Note. The reaction was carried out at 80 °C for 8 h (100% conversion).

In the presence of $\text{Mn}(\text{OAc})_3 \cdot 2 \text{H}_2\text{O}$ or $\text{Ce}(\text{SO}_4)_2$, sodium polyfluoroalkanesulfonates can be used in these reactions instead of perfluoroalkyl iodides. In this case, the perfluoroalkyl radical formed reacts with aromatic compounds⁴⁰⁰ and alkenes,²⁵⁰ which results in the formation of either substitution products of the hydrogen atom in the benzene ring or in the formation of adducts to the multiple bond. This approach was used for introducing perfluoroalkyl groups into the benzene rings of benzocrown ethers under the action of sodium perfluorosulfonates.⁴⁰¹

Tetrahydrofuran **45** derivatives (see Table 21) were prepared using diallyl ether (**44**) as a substrate; this reaction resulted in the formation of a free radical intermediate as could be evidenced from the EPR spectra.²³⁴

Reactions of perfluoroalkyl iodides with alkynes in the presence of Ce^{IV} salts (Table 22) proceed at a higher temperature (120 °C) and are slower (the reaction time varies from 18 to 20 h) than the corresponding reactions with alkenes.^{398, 399}

$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_4, \text{Cl}(\text{CF}_2)_6, \text{CF}_3(\text{CF}_2)_5;$

$\text{R} = \text{Bu}^n, \text{Ph}, n\text{-C}_6\text{H}_{13}, n\text{-C}_7\text{H}_{15}, \text{CH}_2\text{OH}, \text{MeOCH}_2.$

Table 22. The reaction of acetylene derivatives $\text{HC}\equiv\text{CR}$ with $\text{Cl}(\text{CF}_2)_4\text{I}$ and $\text{Cl}(\text{CF}_2)_6\text{I}$ in the presence of Ce^{IV} salts in DMF.³⁹⁸

CH_2OMe	$\text{Ce}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$	48 (2 : 5)	—

Note. The reaction was carried out at 120 °C for 18–20 h.

Butadiene undergoes perfluoroalkylation under the action of perfluoroalkanesulfonyl bromide $\text{R}_\text{F}\text{SO}_2\text{Br}$ in the presence of dibenzoyl peroxide to give a mixture of isomeric unsaturated addition products.⁴⁰²

$\text{R}_\text{F}, \text{R}'_\text{F} = \text{Cl}(\text{CF}_2)_4, \text{Cl}(\text{CF}_2)_5, \text{F}(\text{CF}_2)_5.$

Dibenzoyl peroxide can also be used for perfluoroalkylation of aromatic compounds.²⁶⁸

The use of hydrogen peroxide, di-*tert*-butyl peroxide and dibenzoyl peroxide as inducers gave encouraging results. Thus the reaction of trimethylsilylacetylene with 1,6-diiodoperfluorohexane in the presence of di-*tert*-butyl peroxide results in 1,10-diiodo-1,10-bis(trimethylsilyl)dodecafluorodeca-1,9-diene in 92% yield.⁷⁰

$n = 6, 8, 10, 12.$

Treatment of phenylacetylene with perfluoroheptyl iodide in the presence of di-*tert*-butyl peroxide results in (*E*)-1-iodo-1-phenylpentadecafluoronon-1-ene.⁷⁰

The reaction of alkenes with perfluoroalkyl iodides in the presence of hydrogen peroxide in acetone, acetonitrile or ethanol gives addition products to the multiple bond in good yields.⁴⁰³

Potassium superoxide (KO_2) reacts with 1,4-diiodoperfluorobutane in benzene containing dicyclohexano-18-crown-6 (its role in this reaction is ambiguous) to give $\text{I}(\text{CF}_2)_3\text{CO}_2\text{H}$.^{404, 405}

Sodium perfluoroalkanesulfonates of the type $\text{Cl}(\text{CF}_2)_n\text{SO}_2\text{Na}$ ($n = 4, 6, 8$) the reduction potentials of which are equal to 0.95–1.00 V generate perfluoroalkyl radicals in the presence of oxidants, e.g., $\text{Mn}(\text{OAc})_3 \cdot 2 \text{H}_2\text{O}$, $\text{Ce}(\text{SO}_4)_2$, HgSO_4 and Co_2O_3 .^{250–256} The radicals formed react with aromatic compounds to give monoperfluoroalkylation products. For example, the reaction of 1,4-dimethoxybenzene with $\text{Cl}(\text{CF}_2)_4\text{SO}_2\text{Na}$ in the presence of $\text{Mn}(\text{OAc})_3$ in H_2O , MeCN or AcOH at 80 °C gave the adduct 1,4-(MeO)₂ $\text{C}_6\text{H}_3(\text{CF}_2)_4\text{Cl}$ -2 in 50% yield.⁴⁰⁶

The reaction of sodium perfluoroalkanesulfonates with coumarin gives the 3-perfluoroalkyl derivatives **46**,²⁵⁷ 3,6-bis(perfluoroalkyl)- (**47**) and 3,6,8-tris(perfluoroalkyl) derivatives (**48**) are formed when the perfluoroalkylating reagent is used in excess. These compounds have found applications as fluorescent dyes and for laser systems.

The reaction of perfluoroalkyl iodides $\text{R}_\text{F}\text{I}$ [$\text{R}_\text{F} = \text{CF}_3(\text{CF}_2)_5, \text{H}(\text{CF}_2)_4, \text{Cl}(\text{CF}_2)_n$ ($n = 4, 6, 8$), $\text{I}(\text{CF}_2)_m$ ($m = 4, 6$), $\text{NaO}_3\text{S} \cdot (\text{CF}_2)_2\text{O}(\text{CF}_2)_m$ ($m = 2, 4$)] with NaHSO_3 in the presence of $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$ in aqueous acetonitrile at 70 °C results in the salts $\text{R}_\text{F}\text{SO}_2\text{Na}$ in 70% to 88% yields.¹⁵⁶

The $\text{Ce}^{\text{IV}} - \text{NaHCO}_3$ and $\text{Fe}^{\text{III}} - \text{NaHSO}_3$ systems efficiently catalyse the reactions of perfluoroalkyl iodides with alkenes. These reactions give high yields of addition products to the double bond.^{353, 407} $\text{K}_2[\text{Fe}(\text{CN})_6]$ was found to be an excellent inducer of reactions of addition of perfluoroalkyl iodides to alkenes and their derivatives.²⁴⁴

Let us now discuss the tentative reaction mechanisms underlying reactions of perfluoroalkyl halides and sodium perfluoroalkanesulfonates with unsaturated compounds in the presence of redox systems. These reactions were surveyed by Hu *et al.*³⁰

Two schemes are probable. According to the first of them, a radical cation is generated from perfluoroalkyl iodide under the action of an oxidant and is transformed to a perfluoroalkyl radical. The second route includes initial oxidation of the unsaturated substrate to the radical cation, which then reacts with perfluoroalkyl iodide to produce the perfluoroalkyl radical.

The latter was proposed by Huang and Xie⁴⁰⁰ for the reaction with styrene in the presence of lead tetraacetate.

Ox, oxidant.

However, standard oxidation potentials (E°_{ox}) of the alkenes used are too high to ensure their oxidation to the corresponding radical cations. For instance, E°_{ox} of oct-1-ene is 2.70 V relative to $\text{Ag}^+/\text{AgNO}_3$,⁴⁰⁸ although polar effects can to certain degree compensate for this stability.

An alternative intermediate, *viz.*, the radical cation of perfluoroalkyl iodide $[\text{R}_\text{F}\text{I}]^{\cdot+}$, can be formed under the action of a strong oxidant. Indeed, the same radical cation is formed in the electrochemical⁴⁰⁹ oxidation of perfluoroalkyl iodide in the presence of perfluoroalkanesulfonic acid.

Efficient catalysis of the reaction of perfluoroalkyl iodide with alkenes [*e.g.*, E°_{ox} of $\text{MeOC}_6\text{H}_4\text{C}(\text{Me})=\text{CH}_2$ is 1.49 V (see Ref. 410), E°_{ox} of α -phenylstyrene is 1.22 V relative to SCE⁴¹¹] requires an oxidant with a reduction potential, E°_{ox} , of > 1.6 V (rel. SCE). In this case, the radical cation $[\text{R}_\text{F}\text{I}]^{\cdot+}$ can be formed. The radical cation $[\text{R}_\text{F}\text{I}]^{\cdot+}$ is rapidly decomposed into $\text{R}_\text{F}^{\cdot}$ and the iodonium cation. The radical $\text{R}_\text{F}^{\cdot}$ was detected in its reaction with alkene, which resulted in the generation of a new radical. The latter detached iodine from $\text{R}_\text{F}\text{I}$ to yield the reaction product and the radical $\text{R}_\text{F}^{\cdot}$.

The reduction potentials of some oxidants are listed in Table 23.^{412,413} If the reduction potential of an oxidant is ≥ 1.60 V (rel. SCE), this can efficiently initiate the reaction with alkenes.

Table 23. Standard reduction potentials (E°_{red}) of different oxidants.

Oxidant	Ion	$E^\circ_{\text{red}}/\text{V}$	Ref.
$\text{Na}_2\text{S}_2\text{O}_8$, $(\text{NH}_4)_2\text{S}_2\text{O}_8$	$\text{S}_2\text{O}_8^{2-}$	2.01	412
KMnO_4	MnO_4^-	1.695	412
$\text{Pb}(\text{OAc})_4$, PbO_2	Pb^{4+}	1.69	412
$\text{Ce}(\text{SO}_4)_2$, $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$	Ce^{4+}	1.61	412
$\text{Mn}_2(\text{OAc})_3$	Mn^{3+}	1.51	412
$\text{K}_2\text{Cr}_2\text{O}_7$	$\text{Cr}_2\text{O}_7^{2-}$	1.33	412

Chloranil		0.02	413
$[\text{N}(\text{C}_6\text{H}_3\text{Br}_2-2,4)_3]^+$		1.14	413
$[\text{N}(\text{C}_6\text{H}_4\text{Br}-3)_3]^+$		0.70	413
$[\text{C}_6\text{H}_4\text{Br}-4]_3\text{N}^+$		1.06	414

Thus, the reactions of perfluoroalkyl halides with alkenes or alkynes in the presence of oxidants appear to be a convenient method for fluoroalkylation of alkenes or alkynes.

Perfluoroalkyl iodides successfully react with alkenes in aqueous MeCN (6–8 h, 60 °C) in the presence of $\text{Na}_2\text{S}_2\text{O}_8$ or $(\text{NH}_4)_2\text{S}_2\text{O}_8$ (Table 24).³⁹⁸ Cyclohexene and cyclopentene also react with $\text{R}_\text{F}\text{I}$ to produce the 1:1 adducts in good yields. The reaction of α -chloro- ω -iodoperfluoroalkanes with alkenes in the presence of the $(\text{NH}_4)_2\text{S}_2\text{O}_8\text{--HCO}_2\text{Na}$ system gives addition products at the expense of the C–I bond without involving the

Table 24. Reactions of $\text{R}_\text{F}\text{I}$ with alkenes $\text{RCH}=\text{CH}_2$ in the presence of $\text{Na}_2\text{S}_2\text{O}_8$ in MeCN– H_2O .³⁹⁸

$\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_4, \text{Cl}(\text{CF}_2)_6, \text{CF}_3(\text{CF}_2)_5$;

$\text{R} = \text{Bu}^n, \text{CH}_2\text{OH}, n\text{-C}_6\text{H}_{13}, n\text{-C}_8\text{H}_{17}, n\text{-C}_9\text{H}_{19}, n\text{-C}_{10}\text{H}_{21}, \text{Me}_3\text{Si}, \text{CH}_2\text{OCH}_2\text{CH}=\text{CH}_2$.

Reactions of sodium perfluoroalkanesulfonates $\text{R}_\text{F}\text{CF}_2\text{SO}_2\text{Na}$ with allyl halide and propargyl halide in the presence of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ result in good yields of 3-(perfluoroalkyl)prop-1-ene and 3-(perfluoroalkyl)allene, respectively.³²⁶

An interesting transformation of perfluoroalkyl iodides and -bromides as well as of compounds containing a CCl_3 group at the end of the perfluorinated carbon chain into the corresponding perfluorocarboxylic acids was observed in the presence of a redox system.^{132–144, 159, 193, 401, 417, 418}

Ox = $(\text{NH}_4)_2\text{S}_2\text{O}_8\text{--HCO}_2\text{Na} \cdot 2\text{H}_2\text{O}$, $(\text{NH}_4)_2\text{S}_2\text{O}_8\text{--oxalate}$, $\text{H}_2\text{O}_2\text{--FeSO}_4 \cdot 7\text{H}_2\text{O}$, $(\text{NH}_4)_2\text{S}_2\text{O}_8\text{--Na}_2\text{S}_2\text{O}_4$, $\text{H}_2\text{O}_2\text{--Na}_2\text{S}_2\text{O}_4$, $\text{KBrO}_3\text{--Na}_2\text{S}_2\text{O}_4$, $(\text{PhCO})_2\text{O}_2\text{--PhNMe}_2$.

$\text{CF}_3\text{CCl}=\text{CHCH}_2\text{Cl}$ is the reaction product of CF_3CCl_3 with ethylene in the presence of Cr_2O_3 .⁴¹⁹ Perfluoroalkylation by perfluoroalkyl iodides and sodium perfluoroalkanesulfonates was performed using a variety of redox reagents and systems, *e.g.*, $\text{Ce}(\text{SO}_4)_2$, $\text{H}_2\text{O}_2\text{--FeSO}_4$, $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$, $\text{Pb}(\text{OAc})_4\text{--HOAc--Ac}_2\text{O}$, $\text{Mn}(\text{OAc})_3 \cdot \text{H}_2\text{O}$, *etc.* This reaction occurs *via* the intermediate formation of the perfluoroalkyl radical, since the introduction of compounds containing labile (C–Hal) bonds yields products of substitution of the $\text{R}_\text{F}\text{CF}_2$ group for the halogen atom.⁴²⁰

$\text{X} = \text{Cl}, \text{Br}$; $\text{R}_\text{F} = \text{Cl}(\text{CF}_2)_n$ ($n = 2, 4, 6$), $\text{CF}_3(\text{CF}_2)_n$ ($n = 3, 5, 7$).

The optimum conditions for this reaction are as follows: temperature below 40 °C and DMF as a solvent.

The use of redox systems allows for selective transformation of perfluoroalkyl iodides, α, ω -diiodoperfluoroalkanes and com-

$(\text{PhCO}_2)_2 - \text{PhNMe}_2$	DMF	30	16	25	100

The intermediate perfluoroalkyl radical not only reacts with alkenes, but can undergo other transformations depending on the reaction conditions and the oxidant type. For example, reactions of sodium chloropolyfluoroalkanesulfonates yield dimerisation products, carboxylic acids and adducts to the multiple bond.³⁹⁶

Perfluoroalkylated alkenes are the main products in the reaction of sodium perfluoroalkanesulfonates with conjugated dienes in the presence of $\text{M}_2\text{S}_2\text{O}_8$.^{159, 427, 428}

The nature of other functional groups in the molecule can influence the lability of the C—Cl bond. For example, the activity of compounds of the type $\text{Cl}(\text{CF}_2)_7\text{X}$ ($\text{X} = \text{CO}_2\text{Na}$, CO_2Me , CO_2H) in the reaction with hept-1-ene decreases in the following order: $\text{Cl}(\text{CF}_2)_7\text{CO}_2\text{Na} > \text{Cl}(\text{CF}_2)_7\text{CO}_2\text{Me} > \text{Cl}(\text{CF}_2)_7\text{CO}_2\text{H}$.

In polyhalogenopolyfluoroalkanes containing I and Cl atoms, the latter is much less active than iodine. The chlorine atom reacts with hept-1-ene only after substitution of the SO_3Na group for iodine.

The perfluoroalkylation reaction can occur with different redox reagents and systems, *e.g.*, $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$, H_2O_2 — FeSO_4 , $\text{Ce}(\text{SO}_4)_2$, $\text{Pb}(\text{OAc})_4$ — HOAc — Ac_2O , $\text{Mn}(\text{OAc})_3 \cdot \text{H}_2\text{O}$, *etc.* This reaction proceeds through the generation of the perfluoroalkyl radical and results in the products of substitution of the $\text{R}_\text{F}\text{CF}_2$ group for the halogen atom (Table 27).^{325, 326}

$(\text{CH}_2)_2\text{CO}_2\text{Et}$	100
$\text{CH}_2\text{CO}_2\text{Et}$	60
$\text{CH}_2\text{CH}(\text{NH}_3^+)\text{CO}_2\text{Me}$	47
$(\text{CH}_2)_2\text{CH}(\text{NH}_3)\text{CO}_2\text{Me}$	55

Trifluoroalkylation of vinyl esters in the presence of Bu^tOOH results in α -trifluoromethyl ketones.⁴³²

Trifluoromethyl derivatives are formed in reactions of $\text{CF}_3\text{SO}_2\text{Na}$ with vinyl sulfides. The sulfur atom effectively stabilises the carbocation, which can be trapped by the reaction with a nucleophile, particularly, with an alcohol. α -Trifluoromethyl thioketals are the end products in this reaction.

Aromatic compounds also undergo perfluoroalkylation in the presence of Bu^tOOH .⁴³³

The trifluoromethyl radical can also be generated in the oxidation of the sodium trifluoromethanesulfinate by aqueous *tert*-butyl hydroxypoxide in the presence of Cu^{2+} (Refs 326, 432) and $\text{M}_2\text{S}_2\text{O}_8$ ($\text{M} = \text{K}$, Na , NH_4).^{430, 432–435} Some of these reactions are depicted in Scheme 2.

The $\text{CF}_3\text{SO}_2\text{Na} - \text{Bu}^t\text{OOH} - \text{Cu}^{2+}$ system can be used as a formal 'cationoid' reagent in the trifluoromethylation of arenes (Table 28).^{250, 253, 430, 432}

Perfluoroalkanesulfonates react with mono- and disubstituted alkenes in air or in oxygen with UV irradiation resulting in α -perfluoroalkyl ketones.²⁵³

$\text{R}_\text{F} = \text{X}(\text{CF}_2)_n$, $n = 4, 6, 8$; $\text{X} = \text{F}$, Cl .

Scheme 2

The reactions of terminal alkenes with sodium perfluoroalkanesulfonates in the presence of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ or the Fenton reagent ($\text{H}_2\text{O}_2 - \text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) proceed rather vigorously. In the presence of additional nucleophiles, side reactions of the intermediate carbocations are possible, which has been used for the synthesis of secondary amines.⁴³⁶

$$R_F = Cl(CF_2)_n (n = 4, 6), CF_3(CF_2)_5; R = Bu^n, n-C_7H_{15}, n-C_8H_{17},$$

$$AcO, CH_3OAc, (CH_2)_8CO_2Et.$$

Pyrrole and its derivatives undergo perfluoroalkylation under the action of perfluoroalkyl iodides in the presence of the $\text{H}_2\text{O}_2 - \text{FeSO}_4$ system in DMSO (Table 29).⁴³⁷

3. Activation of perfluoroalkyl iodides by radicals

The above data suggest that under different reaction conditions perfluoroalkyl iodides can generate perfluoroalkyl radicals which further react with alkenes and aromatic compounds by a free-radical mechanism. Bravo *et al.*⁴³⁸ found that the radical Ph $\cdot$ can rapidly detach the iodine atom from secondary perfluoroalkyl iodides. This can be explained by the fact that the Ph—I bond is stronger than the R_F—I bond. The kinetics of the reaction of perfluoroalkyl iodides with the phenyl radical was studied by Kryger *et al.*⁴³⁹

sec-R is secondary alkyl.

In other words, it is the iodide ion that is responsible for the electron transfer. It was thus suggested that perfluoroalkyl iodides can be activated by radicals generated from other substrates. For example, the methyl radical can activate the C–I bond.

In turn, the methyl radical is formed in the reaction of acetone or DMSO with hydrogen peroxide in trifluoroacetic acid or in the presence of Fe^{2+} salts, respectively. The methyl radical reacts with perfluoroalkyl iodide to produce a perfluoroalkyl radical. The

latter initiates further perfluoroalkylation of unsaturated or aromatic compounds.

Perfluoroalkyl radicals were generated by the following systems: $Bu^tOOH - Fe(OAc)_2OH$, $Me_2CO - H_2O_2$, $Me_2SO - H_2O_2 - Fe^{2+}$.⁴⁴⁰ These systems effect smooth perfluoroalkylation of aromatic compounds and alkenes (e.g., oct-1-ene, cyclohexene).

The ratio of isomers formed in perfluoroalkylation of aromatic compounds and the relative rates of these reactions suggest the radical mechanism of this reaction.⁴³⁸

Reductive perfluoroalkylation of alkenes with perfluoroalkyl iodides can be carried out in the presence of *tert*-butyl hydroperoxide in acetic acid (Table 30).⁴⁴¹

Table 30. Reductive perfluoroalkylation of alkenes by perfluoroalkyl iodides $R_F I$ in the presence of Bu^tOOH .⁴⁴¹

Alkene	R_F	Yield (%)
Hex-1-ene	C_4F_9	77
	C_8F_{17}	72
Oct-1-ene	C_4F_9	73
	C_8F_{17}	71
3,3-Dimethylbut-1-ene	C_4F_9	83
	C_8F_{17}	86
Cyclohexene	C_4F_9	85
	C_8F_{17}	73

It should be noted that this approach was first used in reactions of some aromatic compounds with perfluoroalkyl iodides and equimolar amounts of the peroxide.⁴⁴² It may be expected that after optimal conditions for such reactions are found, their role in perfluoroalkylation will increase.

IV. Conclusion

The data presented above testify to the increasing interest of investigators in the development of new approaches to the introduction of perfluorinated fragments into organic molecules and the transformation of simple substituents into complex functional groups. The novel perfluoroalkylating reagents considered above can be regarded as an alternative to classical and popular reagents. In particular, perfluoroalkyl iodides are widely used in perfluorination of unsaturated and aromatic organic substrates in the presence of initiators and catalysts. Radical perfluoroalkylation, syntheses of perfluoroalkanesulfinic and perfluorocarboxylic acids and polyfluorinated aldehydes as well as electrochemical synthesis of perfluoroalkyl derivatives offer obvious advantages because of simplicity and possibility to be used on an industrial scale. It remains to be hoped that further investigations will culminate in the discovery of other approaches to the synthesis of fluorine-containing compounds.

In this review, we made an attempt to demonstrate the most recent approaches and synthetic potentialities of novel reagents and to outline the main trends in the synthesis of perfluoroorganic compounds containing various molecular backbones and functional groups. This form of presentation of the experimental material makes it possible to contemplate the problem from the unusual for traditional chemistry standpoint and to propose certain original solutions based on the use of novel approaches to the generation of perfluoroalkyl radicals and their involvement in reactions with various compounds.

Needless to say, the practical implementation of the above-mentioned ideas and processes occurring by a single-electron transfer mechanism presents special interest not only for practitioners in fluoroorganic chemistry but also for specialists in organic synthesis and investigators elaborating radically new approaches to directed synthesis of organic molecules with the ultimate goal to develop new technologies. It should be noted that perfluoroorganic compounds often represent convenient, even unique models for the formulation and solution of fundamental problems of theoretical organic chemistry. In this context, the role of perfluorinated organic materials is steadily increasing, although the number of perfluoroalkylating agents which are suitable for large-scale production is still too small. A breakthrough in this area can be expected in the nearest future. The advent of advanced methodologies for transformation of organic compounds into valuable fluorine-containing products will speed up further progress in organic synthesis.

Structure and properties of polymers in terms of the fractal approach

V U Novikov, G V Kozlov

Contents

I. Introduction	523
II. Fractal analysis of the polymer structure	523
III. Modelling of the structure and properties of polymers	537
IV. Experimental determination of the fractal dimension	544
V. Conclusion	546

Abstract. The review considers various manifestations of fractality in the description of the synthesis of macromolecules and the formation of the quasi-equilibrium state in polymers, fluctuation free volume, macromolecular frameworks, order parameters, and dissipative structures, acting as centres of shear stress in clusters. The possibility of numerical modelling of the properties of network polymers within the framework of fractal formalism is demonstrated. The methods for determination of the fractal dimension are described. The bibliography includes 248 references.

I. Introduction

The use in investigations of only Euclidean geometry, which describes objects with integer dimensions, restricts the possibility of adequate description of real (both natural and artificial) objects because it leaves numerous objects with fractional (fractal) dimensions beyond the scope of consideration. The properties of such objects can be described using fractal geometry.^{1,2}

Frequently encountered natural and synthetic polymers belong to the class of fractal objects. A polymer consists of long-chain macromolecules. Owing to this structure, polymers possess properties differing from those of other classes of solids. The most important parameters characterising a macromolecular chain are length and rigidity.^{3–5}

The structure of a vitreous polymer is thermodynamically unstable. Thermodynamically nonequilibrium processes result in the formation of fractal structures.⁶ A classical example supporting this statement is a fractured surface of a polymer. It has been found experimentally that the fractal properties of a fractured surface do not depend on the thermodynamic state of the solid.⁷ This is due to the thermodynamically nonequilibrium character of the fracture process.⁸ In the syntheses of polymers in solution (which is the most widely used variant⁹) the main structural unit is a macromolecular coil, which is known¹⁰ to be a fractal. To describe an object in terms of Euclidean geometry, only one

parameter, namely, the Euclidean dimension d , is needed, whereas description of fractal objects requires at least three parameters: the dimension d and the Hausdorff and spectral (fracton, d_s) dimensions.¹¹ Thus, the question of whether or not the methods of fractal analysis should be used to describe the structure of a macromolecular coil and a polymer is not a matter of researcher's choice but is dictated by the requirements of correct approach to the problem.[†]

The methods of fractal analysis and the models of irreversible aggregation provide a new understanding of the processes of synthesis and provide results which are difficult to obtain (or cannot be obtained) by other methods. All the foregoing has stipulated the scope of this review the purpose of which is to summarise the results of the use of fractal approach to the synthesis and analysis of the structures and properties of vitreous polymers.

II. Fractal analysis of the polymer structure

1. A model and the structure of a macromolecular coil

In order to develop a physically substantiated description for processes such as flocculation, polymerisation, *etc.*, various irreversible aggregation models, based on the physical pattern of formation of larger objects from smaller ones, have been developed.^{15–18} The necessity of using models of this type in this review is due to the fact that the processes they describe result in the formation of fractal objects.

The fractal dimension of a macromolecular coil in solution (D) is determined by two types of interaction: interactions of the coil elements with one another and solvent–polymer interactions.¹⁹ These types of interaction have been considered in detail.²⁰ In particular, the D value was found to depend on the chain rigidity, characterised by the Kuhn segment length (A). Linear $D(A)$ dependences have been found for flexible-, semirigid- and rigid-chain polymers (Fig. 1). An increase in the chain rigidity (an increase in A) is accompanied by a decrease in D ; this implies transition to less compact macromolecular coils.^{10,21} The D values obtained by extrapolation to $A = 0$ are different. The lowest value is obtained for rigid-chain polymers, which reflects the difficulty of formation of macromolecular coils in this case.²²

For flexible- and semirigid-chain polymers, the $D(A)$ plot at $A = 0$ extrapolates to $D = 2$, which corresponds to the dimension of the coil in a Θ -solvent.²⁰ Thus, only a hypothetical absolutely

Figure 1. Fractal dimension D of a macromolecular coil vs. length of the Kuhn segment A for flexible- and semirigid-chain (correlation coefficient 0.82) (1) and rigid-chain polymers (correlation coefficient 0.85) (2).

flexible macromolecule ($A = 0$) can have an ideal conformation in a good solvent. In real polymer chains (for $A > 0$, i.e. actually, for an isolated macromolecular coil), this conformation can be attained by choosing a solvent which would counterbalance the effect of excluded volume.¹⁹ A similar extrapolation to $A = 0$ for rigid-chain polymers gives $D \approx 1.67$. This corresponds to the dimension of a coil in a good solvent.¹⁰ However, it should be noted that for these polymers, Θ -conditions can be created when the index in the Mark–Kuhn–Houwink equation $a \neq 0.5$ (or $D \neq 2$). For instance, Θ -conditions for polyarylate have been attained²² at $a = 0.8$, which is equivalent to $D \approx 1.67$ in conformity with the equation

$$D = \frac{3}{1+a} \quad (1)$$

Thus, different D values obtained for the above classes of polymers by extrapolation of the $D(A)$ plot to $A = 0$ can imply different criteria for the attainment of Θ -conditions.

Two alternative analytical expressions have been reported^{20,23} for evaluation of D as a function of the molecular characteristics of a polymer, C_∞ and S (C_∞ is the characteristic ratio, which is a measure of the statistical chain flexibility²⁴ and S is the cross-section area of the macromolecule)

$$C_\infty = \frac{D}{3(2-D)} + \frac{4}{3}, \quad (2)$$

$$D = 2 - 4 \left(\frac{2}{C_\infty S} \right)^{1/2}. \quad (3)$$

The D values determined from Eqns (2) and (3) were found to be in good agreement with those determined using Eqn (1).²⁰

The polymer–solvent interactions, which also influence the D value of a macromolecular coil in solution, can be characterised in several ways. One way is to use the Huggins constant k_H , which reflects the extent of polymer–solvent interaction.²⁴ The equation derived in terms of this approach shows the variation of D as a function of molecular mass M of the polymer²²

$$D = \frac{3 \ln M}{\ln M + \ln(7.14 k_H - 1) - \ln k_\eta - \ln k_H}, \quad (4)$$

where k_η is the constant in the Mark–Kuhn–Houwink equation.

The $D(k_H^{-2})$ dependence obtained experimentally²⁰ shows that both an increase in the rigidity and improvement of the thermodynamic quality of the solvent with respect to the polymer result in

Figure 2. Fractal dimension D of a macromolecular coil for polyarylate vs. solubility parameter δ_s of the solvent used in the synthesis (1) and vs. reaction time t (2).

higher k_H . This in turn, decreases both k_H^{-2} and D . The correlation limits of $D(k_H^{-2})$ correspond to the range $1.5 < D < 2.286$; hence, this correlation can be used for predicting the structure of a macromolecular coil in dilute solutions.

Yet another parameter used to characterise the polymer–solvent interaction is the difference between the solubility parameters of the polymer and the solvent.²⁵ The plot for the variation of D of polyarylate vs. the solubility parameter of the solvent used in the synthesis of the polymer has a dome-like shape, typical of this type of dependence (Fig. 2, curve 1); this confirms the increase in D (an increase in the compactness of the macromolecular coil) following deterioration of the thermodynamic quality of the solvent.

The fractal dimension of a macromolecular coil D can serve simultaneously as a measure of volume interactions of this coil: for a coil in a Θ -solvent, D equal to 2 implies the absence of these interactions (the interaction parameter $\epsilon = 0$), $D < 2$ corresponds to repulsive interactions ($\epsilon > 0$), and $D > 2$ means attractive interactions ($\epsilon < 0$). A simple procedure for the determination of D is based on the equation²⁶

$$D = \left(\frac{5[\eta]}{[\eta]_\Theta^{2/3}} - 3 \right) \left(\frac{3[\eta]}{[\eta]_\Theta^{2/3}} - 2 \right)^{-1}, \quad (5)$$

where $[\eta]$ and $[\eta]_\Theta$ are intrinsic viscosities of the polymer dissolved in an arbitrary solvent and in a Θ -solvent, respectively.

By virtue of fractal analysis, one can gain some useful information, in addition to the data on molecular hydrodynamics, from the same experimental data.²⁷ This statement is illustrated below by some examples.

The fractal dimension D characterises the degree of ‘openness’ of the fractal structure — the lower D , the more efficient the penetration of particles into a fractal cluster (the more ‘accessible’ is the cluster for a reaction).²⁸ This is expressed analytically as follows:²⁹

$$Q \propto t^{(3-D)/2}, \quad (6)$$

where Q is the degree of conversion of a polymer and t is the current reaction time.

Equation (6) is the main scaling relation used to describe polymerisation kinetics.^{30–37} It is noteworthy that the process cannot take place for Euclidean coils (compact globules) because for them, $D = d = 3$ and $Q = \text{const}$. It is clear that in the general case, Eqn (6) should also contain diffusion parameters and the initial reactant concentrations.

An aspect related directly to the problem of macromolecular coil structure considered here is the dependence of aggregation processes on the concentration of aggregating particles c (initial concentration c_0) in some space.³⁸ If the density ρ of a cluster (macromolecular coil) decreases during the growth down to the density of the surrounding medium (the polymer–monomer solution), one type of universality of diffusion-limited aggregation

(DLA) is replaced by another type, namely, the particle–cluster aggregation switches to aggregation according to the Eden model;³⁹ subsequently, growth of the macromolecular coil ceases, having reached the critical radius R_c .³⁷ This variation of ρ is possible only for fractals because their density depends on the radius of gyration R_g , which is the critical radius for them³⁷

$$\rho \propto b R_g^{D-d}, \quad (7)$$

where b is a proportionality factor.

In the case of Euclidean objects, $D = d$ and $\rho = \text{const}$. The transition between the classes of universality considered in terms of the DLA model is preceded by yet another transition, namely, the cluster–cluster aggregation is replaced by the particle–cluster aggregation; this markedly decreases the rate of the reaction but does not stop it.⁴⁰

In terms of the cluster–cluster DLA, the synthesis of a polymer can be described using the relation^{40–42}

$$R_g \propto \left(\frac{4c_0 k T}{3\eta_0 m_0} t \right)^{1/D}, \quad (8)$$

where k is the Boltzmann constant, T is temperature, η_0 is the initial viscosity of the medium, t is the reaction time, and m_0 is the mass of a unit.

An increase in D implies an increase in the degree of branching of a macromolecular coil.²² This statement is illustrated by calculation of the spectral dimension d_s , which characterises the degree of connectivity of a fractal. The d_s value for a swollen fractal with allowance for the effect of excluded volume can be estimated from the following equation:⁴³

$$D = d_s \frac{d+2}{d-2}. \quad (9)$$

Note that for linear polymers, $d_s = 1$, while for branched polymers, $d_s = 1.33$.^{42, 43} The coil structure formed during the synthesis largely determines the molecular mass of the polymer formed. As D increases, the coil becomes more compact and the density of the coil diminishes.⁴⁴ The main models suitable in this case include the formation of a close packing of macromolecular coils, the appearance of an entanglement network, and the description of the self-acceleration effect with allowance for the concept of free volume. According to each of these models, the increase in the viscosity in the monomer–polymer system is the main reason for the formation of a macromolecular coil.⁴⁵

To describe the limiting regimes of the dynamics of the growth of aggregates in a reaction vessel with the initial monomer concentration c_0 , the characteristic length scale ξ was introduced,⁴⁶ which determines the qualitative transition from a fractal object to a non-fractal object

$$\xi \propto c_0^{-1/(d-D)}. \quad (10)$$

The former regime is realised for $R_g \ll \xi$, for a coil density much greater than the density of the medium in the reaction vessel and for the aggregate size (the degree of polymerisation for a macromolecular coil) N ; it can be written that⁴⁶

$$N(c_0, t) \propto (c_0 t)^{D/(2+D-d)}. \quad (11)$$

The latter regime is observed when $R_g \gg \xi$, the densities of the aggregate and the medium in the reaction vessel are nearly equal, and

$$N(c_0, t) \propto c_0^{(1+d)/(d-D)} t^d. \quad (12)$$

The relationship between N and Q in terms of the irreversible aggregation models can be elucidated using the main scaling relation (6) and relation (8), in which all the parameters, except for c_0 , η_0 and t , are assumed to be constant,

$$Q \propto c_0^{(D-1)/2} \eta_0^{(5-D)/2} N^{(3-D)/2}. \quad (13)$$

The resulting equation can be used to estimate the dependence of Q on t for the two regimes considered above. All these depend-

ences are non-linear and imply an increase in the reaction rate with an increase in t , that is, a self-acceleration effect.

A possible reason for self-acceleration is interpenetration of macromolecular coils compressed to the Θ -size with the formation of a stable network of molecular entanglements.^{47, 48} In some cases, under certain conditions of synthesis, in particular, for low c_0 and η_0 , the absence of self-acceleration is assumed.⁴⁵

It should be noted that the above variant for the calculation of $Q(t)$ does not take into account the exhaustion of the monomer during the reaction. Exhaustion of the monomer appreciably decreases the reaction rate. In other words, the effects of self-acceleration and exhaustion of the monomer act in the opposite directions. When c_0 values are low, the latter effect can suppress the former one.

An important process occurring during the synthesis of polymers is gelation; traditionally, it attracts considerable attention. However, there are several definitions of the gelation point and several methods for locating it on the $Q(t)$ curve. For example, the gelation point is found as the point in which the solution starts to exhibit some properties of a solid (elasticity, fragility, etc.).⁴⁸ In polymer syntheses, transition from the initial stage of polymerisation to the self-acceleration stage is referred to as gelation point.⁴⁹ The concept of gelation point used in polymer physics implies the point where the cluster which tightens the system (and extends from one system edge to the other) is formed.³⁶ Kolb and Herrmann⁵⁰ calculated the gelation point on the $Q(t)$ curve in terms of an approach based on the DLA models. Different approaches and different definitions of gelation cause uncertainty in its interpretation.

If the gelation effect is interpreted as the formation of a cluster tightening the system, the parameters describing this system change substantially.³⁶ Thus the velocity v of the migration of clusters (macromolecular coils) with mass m is assumed to be⁵⁰

$$v = m^\alpha, \quad (14)$$

where α is a scaling index.

At the point of gelation, the sign of α changes from negative to positive. This means that below the gelation point, smaller clusters are more mobile, whereas after the gelation point, the tightening cluster has the highest mobility.

Statistical geometric characteristics of the system also change in the gelation point. It has been shown both theoretically and experimentally³⁶ that D values of about 1.6–2.1, typical of a macromolecular coil in a solution, increase to ~ 2.5 (see Ref. 21), which is a value characterising a Witten–Sander cluster.¹⁵ In terms of the cluster–cluster DLA, the time dependence of R_g is written as⁵¹

$$R_g \propto t^{1/z}, \quad (15)$$

where the index z is related to D and α by the expression

$$z = D(1 - \alpha) - (d - 2). \quad (16)$$

Polymeric systems are often described using the size distribution function of clusters (macromolecular coils). In the physical chemistry of polymers, this function is defined as the molecular-mass distribution (MMD) function. The fractal dimension D provides little information on aggregation (polymerisation); this is a static value which does not describe the aggregation dynamics. In addition, D characterises the geometric properties of only one cluster (macromolecular coil) and cannot be used to describe sets of clusters in the system. For this purpose, one has to study the cluster size distribution function $n_s(t)$, where n_s is the number of clusters consisting of s units at time t .⁵²

The description of the cluster size distribution in the cluster–cluster DLA model has been analysed.^{40, 50, 52, 53} This model is completely suitable, for example, for the description of polymerisation of polymethyldiammonium chloride (PMDAC). The D value of this polymer, estimated to be 1.65 using Eqn (1), is a typical fractal dimension of aggregates formed during the clus-

ter-cluster DLA.³⁷ In view of this fact, the molecular mass distribution of PMDAC is described using the function⁵²

$$n_s(t) \propto s^{-2} t^z. \quad (17)$$

Let us consider methods used to estimate the parameters appearing in relation (17). The $n_s(t')$ values for the gelation point are found from the experimental MMD curves, $W_i(N)$, in the following way. It is assumed that $N = s$ and the part of the polymer corresponding to s_i is roughly equal to the total weight proportion of the polymer fraction W_i . By dividing W_i into s_i and by multiplying the ratio by the maximum degree of conversion Q_i , we obtain the $n_s(t')$ value. The index z is found from Eqn (16). In terms of the DLA model, the diffusion coefficient D_s is usually represented, by analogy with Eqn (14), in the form^{51,52}

$$D_s \propto s^\alpha. \quad (18)$$

In view of the definition of D_s (see Ref. 54), it can be easily found from Eqn (18) that

$$\alpha \propto -\ln \eta_0. \quad (19)$$

It was shown^{51,52} that α determines the pattern of the MMD function. For $\alpha < -0.5$, dome-shaped distribution curves having a maximum were obtained, and for $\alpha > -0.5$, the curves decay monotonically. The MMD curves for PMDAC are also dome-shaped. If we assume the equality sign in relation (19), α would vary from -1 to -3 , which completely complies with the experimental MMD curves. The position of the MMD maximum $N_{\max}$ is determined by the relation⁵⁵

$$N_{\max} \propto \frac{-\alpha}{1-\alpha}. \quad (20)$$

An increase in c_0 results in an increase in η_0 as well as in α and $N_{\max}$.

Figure 3 presents the variation of $\ln(s^2 n_s)$ vs. $\ln(st^z)$ for PMDAC samples synthesised at different c_0 . It can be seen that all experimental points fit in one curve. This is the most important result which confirms the legitimacy of using irreversible aggregation models for the description of polymerisation.

Figure 3. Generalised MMD curve as the function $\ln(s^2 n_s)$ vs. $\ln(st^z)$ for PMDAC synthesised at c_0 of 1.0 (1), 2.5 (2), 4.0 (3) and 5.0 (4) mol litre⁻¹.

The general curve shown in Fig. 3 can be used to predict the kinetics of MMD as a function of t . For this purpose, the $s = N$ value is first specified and the st^z value is determined for an arbitrary t . After that, the corresponding $s^2 n_s$ value is found using the plot in Fig. 3 and then W_i is calculated. The same calculation should be repeated for a different s , and so on.

The relationship between the structures of the macromolecular coil and a solid polymer and its influence on the glass transition temperature T_g have been analysed in relation to a series of vitreous amorphous copolymers — aromatic copolyestersulfon-formals (APESF). Transition to the condensed state implies a change in the environment of a macromolecular coil; the solvent

molecules surrounding the coil are replaced by similar coils. This changes the fractal dimension of the coil⁴⁴ and, correspondingly, the fractal dimension of the polymer structure as a whole.⁵⁶

To derive an analytical expression representing the relationship between the structure and properties of polymers, a definite quantitative model of the structure is required. The cluster model for the structure of the amorphous state of polymers was used for this purpose.⁵⁷ This model is based on the concept of local (short-range) order. The proportion of segments densely packed in the clusters φ_{cl} is a parameter of order, which is related to T_g by the following expression:⁵⁸

$$\varphi_{cl} \approx 0.03(T_g - T)^{0.55}, \quad (21)$$

where T is the testing temperature.

Within the framework of the cluster model, the glass-liquid transition is regarded as the thermofluctuational decomposition of clusters at $T = T_g$.⁵⁹ Fractal concepts are interrelated with the cluster model; the relationship between the main characteristics of these models is given in the form⁶⁰

$$d_f = d - 6 \left(\frac{\varphi_{cl}}{SC_\infty} \right)^{1/2}, \quad (22)$$

where d_f is the fractal dimension of the supermolecular (super-segmental) structure of the polymer

$$d_f = (d - 1)(1 + \mu), \quad (23)$$

where μ is the Poisson coefficient.

The S values for the sulfone and formal fragments which constitute APESF were assumed to be 35 and 23 Å², respectively,⁴⁸ and S values for copolymers were estimated using the condition of additivity. The C_∞ values were calculated from the equation⁶⁰

$$C_\infty = \frac{d_f}{d(d - d_f) + 4/3}. \quad (24)$$

Using Eqns (21)–(24), one can calculate T_g proceeding only from the structure of the macromolecular coil in solution, which is characterised by D , and from the molecular parameter S . The T_g values calculated by this procedure are in good agreement with experimental values; the discrepancy between them does not exceed 4% (Fig. 4).

Figure 4. Glass transition temperature T_g vs. the content of sulfone fragment. The curve corresponds to experimental results and the points are calculated values.¹⁴

2. Hierarchy and evolution of dissipative structures in polymers

In recent years, principles of synergetics of nonequilibrium systems and fractal analysis have been used to study the relationship between the structures and properties of vitreous polymers,^{61–64} because an amorphous polymer is a thermodynamically nonequilibrium system.

The main feature distinguishing polymers from other classes of solids is that they consist of long-chain macromolecules. Therefore, it is natural to assume that the structural hierarchy of polymers (including network polymers) should be based on their molecular structure. In recent years, the characteristic ratio C_∞ has been used more and more frequently as a molecular parameter to describe the properties of polymers, instead of some other characteristics such as a/σ (a is the chain 'thickness' and σ is the chain rigidity).^{65,66} According to Boyer and Miller,⁶⁷ this is due to the fact that σ has greater uncertainty than C_∞ . Indeed, σ depends on the bond angles in the macromolecule, while C_∞ depends on the bond lengths, which are normally determined much more precisely than the bond angles. Without objecting to the legitimacy of this conclusion, we believe, nevertheless, that the reasons for the wide use of the parameter C_∞ are much more fundamental (see, for example, a number of studies^{60–64,68–71}). This can be demonstrated in relation to the epoxy polymers based on bisphenol A and cured by diamine (EP-1) and anhydride (EP-2). For example, to estimate the Bragg interval d_B for these polymers, wide-angle X-ray diffractometry has been used.⁷¹ The resulting value was used to determine the diameter ϕ (and, hence, the cross-section area S) of the molecule, simulated by a cylinder, from the following relation:

$$\phi \approx 1.22 d_B. \quad (25)$$

Subsequently, using the empirical relation⁷¹

$$T_g \approx 129 \left(\frac{S}{C_\infty} \right)^{1/2}, \quad (26)$$

where T_g is expressed in Kelvins and S is expressed in $\text{\AA}^2$, one can calculate the C_∞ values for epoxy polymers.

The behaviour of a solid subjected to mechanical treatment is determined by the processes of formation (disintegration) and evolution of dissipative structures (DS), which ensure the optimum mode of dissipation of the supplied energy.^{60,72,73} This general statement is valid for all polymers. Polymers have local order, which occurs as DS.^{74,75} However, direct application of the fundamental principles of thermodynamics and statistical physics of nonequilibrium systems to the investigation of the deformation of materials of a particular class is often difficult or even impossible without the knowledge of a definite quantitative model for the structure of this material. In the case of amorphous polymers, the cluster model is suitable for this purpose.^{57,74}

A specific feature of the DS formed in polymers is the existence of a universal hierarchy of space scales (structural levels), which is also reflected in the hierarchy of linear dimensions of the structure.^{60,63} Even elastically isotropic solids are characterised by at least three independent length scales, l_1 , l_2 and l_3 , which are related to one another⁷³

$$l_1 = a, \quad (27)$$

$$l_2 = aA_0, \quad (28)$$

$$l_3 = aA_0A_i, \quad (29)$$

where a is the minimum scale, A_0 and A_i are automodelling coefficients.

When choosing these length scales as applied to polymers, one should reject the atomic-size level because a polymer consists of long macromolecules. Therefore, the bond length in the macromolecular backbone l_0 , which is of the order of several angstroms, should be taken as the minimum scale a for polymers.^{62,76} Then the next (segmental) structural level would be determined by the length of statistical segment l_{st} , which is found from the equation

$$l_{st} = l_0 C_\infty.$$

Hence, provided that $l_1 = l_0$, it can be written for this structural level that^{77–79}

$$A_0 = C_\infty.$$

The next structural level for polymers is the topological level, the parameters of which are determined by characteristics of the network of macromolecular entanglements ('loops') in linear polymers or the network of chemical cross-links in cross-linked polymers. The characteristic length for this level is the distance between the entanglement points or chemical cross-linking points R_s

$$R_s = 18 \left(\frac{2V_{cl}}{F} \right)^{-1/3}, \quad (30)$$

where V_{cl} is the density of the cluster network of entanglements, F is the cluster functionality.

If the equality $A_0 = C_\infty$ is retained for the subsequent structural levels, Eqns (27)–(29) for polymers can be written in the form

$$l_1 = l_0, \quad (31)$$

$$l_2 = l_{st} = l_0 C_\infty, \quad (32)$$

$$l_3 = R_s = l_0 C_\infty^2. \quad (33)$$

Figure 5 shows the dependence of R_s vs C_∞^2 . Splitting of the plot into two straight lines is due, first, to the great scatter of the published data^{62,76,80} and, second, to different approaches to the interpretation of the $l_2 = l_{st}$ value.^{62,81} Nevertheless, the fact that R_s is proportional to C_∞^2 confirms that C_∞ is the automodelling coefficient for the transition of the scale of DS dimensions from l_{st} to R_s .

Figure 5. Distance between entanglements (chemical cross-linking points) vs. characteristic ratio for amorphous vitreous (1), amorphous-crystalline (2) and cross-linked (3) polymers.⁷⁹

Figure 6 illustrates the relationship between the R_s values calculated from Eqns (30) and (33). Aharoni⁷⁶ noted an increase in R_s following an increase in the chain flexibility (increase in C_∞) for a large number of linear polymers

Figure 6. Relationship between the distances between entanglements (chemical cross-linking points) R_s calculated from Eqns (30) and (33) for amorphous glassy (1), amorphous-crystalline (2) and cross-linked (3) polymers.⁷⁹

$$R_s \approx 10 C_{\infty}. \quad (34)$$

A similar relation holds for cross-linked polymers

$$R_s \approx 5 C_{\infty}. \quad (35)$$

Thus, the C_{∞} value, which is correlated with R_s , appears to be controlled by the polymer topology, which can be varied by varying the cross-linking density v_s .

Polymers are characterised by one more, specific length scale; this is the section of a macromolecule between entanglement points or chemical cross-linking points L_s , which can be determined from the equation

$$L_s = \frac{F_{ch}}{2Sv_s}, \quad (36)$$

where F_{ch} is the functionality of a chemical cross-linking point ($F_{ch} = 4$).¹⁴

Figure 7 shows the variation of L_s vs. C_{∞}^3 , which can be approximated by a straight line passing through the origin of coordinates. The L_s/C_{∞}^3 ratio has the order of l_0 .^{62, 76} Hence, for this structural level, typical of polymers, C_{∞} can be accepted as the automodelling coefficient.^{82–84}

Figure 7. Length of the section of a macromolecule between entanglements (chemical cross-linking points) L_s vs. characteristic ratio C_{∞}^3 for amorphous glassy (1), amorphous-crystalline (2) and cross-linked (3) polymers.⁷⁹

Let us consider the evolution of DS in network polymers during deformation. It has been shown⁷⁴ that plastic yield in amorphous polymers occurs exactly in clusters, the yield point being dependent only on the density of the cluster network of entanglements (v_{en}), i.e. on the number of closely packed segments in unit volume of the polymer. Yield can be regarded as the loss of stability of clusters in the field of mechanical stress, while cold flow is the deformation of a devitrified loosely packed matrix in which the role of chemical cross-links is played by the cluster network of entanglements.⁸⁵ This interpretation permits one to specify the structural changes occurring during deformation of network polymers in terms of the percolation cluster model.^{60, 72–74}

As noted above, the DS formed (or existing) in a solid subjected to deformation are distinguished by a universal hierarchy of structural levels.⁸⁶ Balankin^{87, 88} suggested that the hierarchical structure of the DS in a solid is based on a fundamental feature, i.e. shear stability, which stipulates the difference between the characteristic space scales of the regions of localisation and dissipation of energy ‘pumped’ into the solid on external treatment. The characteristic scale of the regions (l_s) in which excess energy is dissipated is proportional to the shear modulus G . Since, in terms of the cluster model, these regions can be associated with clusters, it is expedient to use the characteristic size l_{st} as l_s . Figure 8 illustrates the relationship between G and l_{st} , which is approximated by a straight line that passes through the origin of coordinates. This confirms the legitimacy of using l_{st} as l_s .

Figure 8. Relationship between the length of statistical segment l_{st} and the shear modulus G for EP-1 (1), EP-2 (2) and for EP-1 (3) and EP-2 (4) samples cured at a hydrostatic pressure of 200 MPa.⁷⁸

With allowance for the above interpretation of cold flow and for Eqn (30), the distance between the clusters R_{cl} should be accepted as the next level in the hierarchy of structural levels. The characteristic size of the regions of localisation of the ‘pumped-in’ energy is

$$l_e \propto B + \frac{4}{3}G, \quad (37)$$

where B is the bulk modulus.⁷³ The possibility of equating R_{cl} and l_e is verified in the following way. The ratio of the space scales of the DS of adjacent structural levels, L_i and L_{i+1} , is expressed as follows:⁷³

$$\frac{L_{i+1}}{L_i} = \frac{l_e}{l_s} = \left(B + \frac{4}{3}G \right) G^{-1} = A_i. \quad (38)$$

It is clear that the multiplication of the ratio $[B + (4/3)G]/G$ by l_s , which is equal to l_{st} , gives l_e . The R_{cl} value can be estimated using Eqn (30).

The dependence of l_e on $[B + (4/3)G]$ also proved to be linear (Fig. 9), which implies that the parameter l_e can, in principle, be used as the characteristic size of the regions of localisation of the pumped-in energy. However, this assumption can be ultimately confirmed by comparing l_e and R_{cl} . A correlation between these parameters has been found;⁶⁰ it was shown that R_{cl} regularly exceeds l_e by ~ 0.8 nm. This relationship between l_e and R_{cl} can be interpreted by virtue of the cluster structure model for an amorphous polymer (Fig. 10).⁸⁹ Evidently, the decrease in R_{cl} by ~ 0.8 nm, which is roughly equal to l_{st} , means that the pumped-in energy does not spread throughout the whole polymer bulk but is localised only in the loosely packed matrix because a cluster with the characteristic size l_{st} is excluded from consideration. Compar-

Figure 9. Relationship between the characteristic size of the regions of localisation of the pumped-in energy l_e and the parameter $[B + (4/3)G]$. For designations, see Fig. 8.⁷⁸

Figure 10. Parameters of the cluster structure model for an amorphous polymer.

Figure 11. Relationship between the characteristic size of the regions of localisation of the pumped-in energy l_e and the $(R_{cl} - l_{st})$ value. For designations, see Fig. 8.

ison of the l_e value and the difference $R_{cl} - l_{st}$ (Fig. 11) confirms this conclusion. Hence, the structural characteristics l_e and $R_{cl} - l_{st}$, estimated within the framework of the cluster model and regarded as the space scales of the DS of adjacent levels [see Eqn (38)], allow one to estimate the automodelling coefficient for the mechanical deformation of a network polymer A_i , which is equal to the fractal dimension D_f of the regions of localisation of excess energy in a plastically deformed medium. In a first approximation, the D_f value can be expressed in terms of the Poisson coefficient μ in the following way:⁷²

$$D_f = 2 \frac{1 - \mu}{1 - 2\mu}. \quad (39)$$

The relationship between the dimension D_f and the automodelling coefficient A_i for the network polymers under consideration is illustrated in Fig. 12. It can be seen that both the magnitudes

Figure 12. Relationship between the fractal dimension of the regions of localisation of excess energy D_f and the automodelling coefficient A_i . For designations, see Fig. 8.

and the patterns of variation for these parameters coincide. Thus, plastic yield and cold flow of network polymers are adequately described in terms of the thermodynamics of nonequilibrium processes and the cluster model of amorphous polymers provides a correct description of the structure of network polymers. It is also evident that clusters are identified as DS.

Similar results have been obtained for film samples of a linear polymer — polyarylatesulfone.⁹⁰ Using Eqn (38) and the ratio¹⁴

$$\frac{L_s}{l_{st}} = \left(\frac{R_s}{l_{st}} \right)^D, \quad (40)$$

it can be shown that

$$A_i = D_f \approx \left(\frac{L_s}{l_{st}} \right)^{1/D}. \quad (41)$$

Figure 13 shows that the L_s values estimated from Eqns (36) and (41) are in good agreement with each other. This implies that the sections of a macromolecule between entanglements and between clusters also obey (are controlled by) the DS hierarchy.⁹⁰

Figure 13. Relationship between the lengths of macromolecule sections between entanglements determined using Eqns (36) and (41) for polyarylatesulfone.⁹⁰

In view of the foregoing, it can be suggested that the automodelling coefficient A_i in Eqn (38) is equal to C_∞ . Then this equation assumes the form

$$\frac{B}{G} + \frac{4}{3} = C_\infty. \quad (42)$$

The B and G values can be expressed in terms of Young's modulus (E) and the fractal dimension of the polymer structure d_f in the following way:⁹¹

$$B = \frac{E}{d(d - d_f)}, \quad (43)$$

$$G = \frac{E(d - 1)}{2d_f}, \quad (44)$$

where $d = 3$.

Using Eqns (42)–(44), one can estimate quantitatively the relationship between the molecular parameter C_∞ and the fractal dimension d_f .⁹²

$$\frac{2d_f}{d(d - 1)(d - d_f)} + \frac{4}{3} = C_\infty. \quad (45)$$

The dependences of d_f found from Eqns (23) and (45) for various classes of polymers are presented in Fig. 14. It can be seen that the results are in good agreement with each other. It is noteworthy that the methods of calculation are completely independent — Eqn (23) employs the results of mechanical testing, while Eqn (45) is based on published data for C_∞ .⁹²

Figure 14. Fractal dimension of the structure d_f of polymers vs. characteristic ratio C_∞ .

Solid line — calculation from Eqn (45); dots — calculation from Eqn (23): (1) linear polymers, impact testing; (2) linear polymers, calculation of d_f from the data of Ref. 60; (3) cross-linked epoxy polymers; (4) super-high-molecular-mass polyethylene produced by solid-phase extrusion; (5) polyarylate prepared by solid-phase extrusion at $T > T_g$; (6) linear polymers, stretching testing; (7) linear polymers, calculation of d_f from small-angle X-ray diffraction data. For sample (7) experimental data on the inaccuracy are given.⁶⁰

The evolution of DS induced by various types of treatment of the polymer has been considered.^{64,93,94} Figure 15 shows the dependence of the cluster functionality F on the curing agent: oligomer ratio (K_{st}) for epoxy polymers in deformed and non-deformed states. The most characteristic distinction between the plots being compared is the substantial increase in F after the yield point. The simultaneous decrease in V_{cl} and increase in F upon deformation of polymers up to the yield point^{63,64} implies decomposition of unstable clusters characterised by relatively low F to leave only stable clusters with large F .⁹⁵ The decay of unstable clusters induces mechanical devitrification of the loosely packed matrix; this explains the plastic behaviour of the polymer in the plateau of forced rubber-like elasticity (cold flow).^{96,97}

The opposite situation is observed during heat ageing, namely, the local order (V_{cl}) increases and the molecular mobility of chains is suppressed (D decreases).⁹⁴

Experimental evidence for the fractality of the cluster structure (or DS) has been obtained using wide-angle X-ray diffraction analysis.^{98–100} The integral intensity of the amorphous halo I_{cl} can be regarded as a measure of distributed particles (clusters), while its half-width can be taken as a measure of their effective size; the relationship between these values is illustrated in Fig. 16

Figure 15. Functionality of clusters vs. the curing agent: oligomer ratio for epoxy polymers EP-1 (1, 3) and EP-2 (2, 4) before (1, 2) and after (3, 4) the yield point has been attained.

Figure 16. Reciprocal integral intensity of X-ray scattering vs. cluster half-width for EP-1.⁹⁸

in relation to EP-1. The $I_{cl}^{-1}(l_{cl})$ dependence presented in the logarithmic coordinates is readily transformed into the form⁹⁸

$$I_{cl}^{-1} \propto l_{cl}^{d_f}, \quad (46)$$

where $d_f \simeq 2.70$.

This type of dependence is typical of fractal structures; it can serve as experimental evidence confirming the fractality of the polymer structure. In addition, the d_f value is in good agreement with the fractal dimensions found for other epoxy polymers (see, for example, Ref. 69).

A fundamental description of the process of polymer fracture which includes the dilaton concept^{101–103} as a constituent has been proposed.¹⁰⁴ The dilaton model assumes the formation of a negative density fluctuation, dilaton, the length of which is determined by the free path of phonons Λ_f . In this case, the overload factor χ on the bonds being ruptured depends on Λ_f and on the interatomic distance a_{at} .¹⁰¹

$$\chi = \frac{\Lambda_f}{a_{at}}. \quad (47)$$

The Λ_f values found for oriented polymers are about 10 nm and χ are about 30–40.¹⁰³ However, for nonoriented polymers, it was found that $\chi \leq 1$, i.e. $\Lambda_f \leq a_{at}$. These dilatons were called ‘degenerate’ (practically, this means that phonons have no free path).^{105–107}

The use of the fracton concept²⁸ provided a fundamental interpretation for this seeming contradiction. Fractons are vibrational excitations localised on a fractal. Since the chain section between entanglements or cross-links is a fractal, a phonon localised on this section becomes a fracton. Localisation of a phonon means that it has no free path; this accounts for the fact that $\chi \leq 1$.

During orientation of a polymer, the chain section in question is stretched; finally, it becomes straight. In this case, its Hausdorff dimension is equal to the topological dimension

$$D = d_t = 1 \quad (48)$$

and the fractal behaviour switches to the Euclidean behaviour: the phonon becomes delocalised and acquires some free path controlled by the structure of the oriented polymer. Now $\chi > 1$. Thus, the dilaton concept is actually a specific case of the fracton theory (for $D = 1$).¹⁰⁴

The following relationship between the parameters χ and D has been obtained.¹⁰⁴

$$\chi \simeq D^{-2}. \quad (49)$$

An increase in the molecular mobility (increase in D) results in stress relaxation on the non-oriented polymer chains ($\chi < 1$).¹⁰⁸

Since characteristics of fractal analysis are general, the relationship between the structures of different aggregation (physical) states of the polymer can be established. For example, a macromolecular coil (cluster) in solution and the polymer structure in the condensed state are fractals with the dimensions D and d_f , respectively.^{44,109} This fact can be used to predict the structure of a solid polymer even at the stage of synthesis.^{110–112} The D value,

with allowance for the effect of excluded volume, is determined by Eqn (9). For linear polymers, it should be accepted that d_s in this equation is equal to 1.⁴³ Transition to the condensed state is accompanied by the change in the environment of a macromolecular coil; a coil becomes surrounded by similar coils instead of solvent molecules. This results in the change of the fractal dimension d_f for the condensed state⁴⁴

$$d_f = \frac{d_s(d+2)}{2}. \quad (50)$$

For linear polymers, provided that $d_s = 1$ and $d = 3$, it follows from Eqns (9) and (50) that¹¹¹

$$d_f = 1.5D. \quad (51)$$

Equation (51) clearly demonstrates the relationship between the coil structure in solution and the structure of the condensed polymer.

3. Quasi-equilibrium state of polymers

Neither completely ordered nor completely disordered polymers have been obtained to date. One reason for this situation is the chain nature of polymer molecules (in particular, the formation of loops during crystallisation).¹¹³ The tendency for transition to a more equilibrated state in polymers is often attributed to an increase in the degree of ordering.¹¹⁴ Therefore, it can be assumed that processes in which this tendency is manifested (for example, heat ageing, thermosetting, *etc.*) are subject to a competition of two opposing mechanisms. An increase in the degree of ordering is counteracted by the entropy of 'stretching' of macromolecules. When the thermodynamic forces of these mechanisms have been balanced, the polymer reaches some quasi-equilibrium state.⁶⁰ Perturbation of the balance in either direction governs the pattern of changes in the polymer structure. In other words, under certain conditions, a polymer can be transformed not only towards a more equilibrated state but also away from equilibrium. According to its physical essence, the latter process can be called 'antirelaxation'. Some causes and consequences of this process are considered below in terms of the cluster model of the structure of the amorphous state of polymers and cluster analysis.

Thermosetting of extruded specimens of polyarylate occurs in the loosely packed matrix;¹¹² therefore, the D_f value should be taken as the fractal dimension which determines the process in a structural element (for example, in a tube). Figure 17a shows the variation of the thermosetting ψ as a function of D_f for extrudates, which implies that the thermal shrinkage changes its sign when $D_f \approx 3$. This fact is very interesting by itself. In the case of extrudates with $D_f > 3$, a less closely packed structure (having greater D_f) is transformed during relaxation (thermosetting) into a more closely packed structure (having smaller D_f), which is, therefore, closer to equilibrium. The behaviour of specimens with $D_f < 3$ requires clarification. At the first glance, it seems that as D_f decreases and the structure changes, $\psi = 0$ should imply termination of thermosetting. However, this does not occur; instead, ψ only changes its sign. This effect can be easily explained

Figure 17. Thermosetting ψ vs. the dimension of the regions of localisation of excess energy D_f (a) and extrusion draw ratio λ (b) for polyarylate extrudates.

by two specific features of the cluster model — arbitrary orientation of the cluster axes in space and connection of clusters by 'interpenetrating' chains, which are subject to the limitations of the Gaussian statistics.⁹⁷ This means that it is impossible to attain a close packing of clusters, *i.e.* conditions of thermodynamic equilibrium cannot be reached in an amorphous polymer. This has been the reason for the introduction of the above-mentioned concept of 'quasi-equilibrium state',¹¹⁵ in which forces due to which a polymer tends to a thermodynamic equilibrium and, hence, to an increase in the degree of local ordering are counterbalanced by entropy forces of the 'interpenetrating chains'. The last-mentioned fact can induce transition of an amorphous polymer from a thermodynamically more equilibrated state to a less equilibrated state. Experimental dependence of ψ on the draw ratio λ confirms this direction of the thermosetting process (Fig. 17b).

The most characteristic feature of the relationship between D and d_f (Fig. 18) is the fact that the limiting value $D = 1$ is attained at $d_f = 2.5$ rather than at $d_f = 2$. Recalling that the dimension D characterises the mobility (deformability) of the section of a macromolecule between chemical cross-linking points (entanglement points) and $D = 1$ implies the loss of molecular mobility by this section. The quasi-equilibrium state corresponds to 'freezing' of the molecular mobility of polymer chains and, as a consequence, to the transition to brittle fracture, which is realised at $D_f < 3$.⁸⁷ Since D_f and d_f are related to each other as follows⁸⁷

$$D_f = 1 + \frac{1}{3 - d_f}, \quad (52)$$

it can be readily seen that $d_f = 2.5$ corresponds to $D_f = 3$.

When examining the dependence of d_f on the relative portion of the loosely packed matrix ϕ_{lp} in poly(methyl methacrylate), high-density polyethylene, polycarbonate, and polyarylate (Fig. 19), attention is drawn by the fact that for $\phi_{lp} = 0$ (the hypothetical state characterised by full local ordering), the d_f values are extrapolated to certain d_f^0 values (which are different for different polymers), exceeding the lower limiting value, equal to 2. Using published data for C_∞ (see, for example, Ref. 113), one can calculate the theoretical d_f^0 values from Eqn (45) and compare them with the limiting d_f^0 value (see Fig. 19). The parameters d_f^1 and d_f^0 are well correlated (Table 1), which reflects the occurrence of a quasi-equilibrium state. Using Eqn (45) and the relation

$$\phi_{cl} = C_\infty l_0 S V_{cl}, \quad (53)$$

the following limits can be identified: for $C_\infty > 3$, a quasi-equilibrium state cannot be attained at all; for $C_\infty = 2-3$, it may happen that $D_f < 3$; the value $d_f = 2$, corresponding to $D_f = 2$ is reachable only for a polymer with $C_\infty = 2$. Analysis of the results obtained in terms of Eqn (45) as well as the data given in Fig. 19 and in Table 1 show that Eqn (45) determines the minimum d_f values possible for a given C_∞ .

Figure 18. Relationship between the fractal dimensions of the macromolecule section between cross-linking points D and of the structure d_f for epoxy polymers EP-1 (1) and EP-2 (2).

Figure 19. Fractal dimension of the structure d_f vs. proportion of the loosely packed matrix ϕ_{lp} for poly(methyl methacrylate) (1), high-density polyethylene (2), polycarbonate (3), polyarylate (4), and polyarylate extrudates (5).

Table 1. Fractal dimensions of the polymer structures d_f^1 and d_f^0 .

Polymer	d_f^1	d_f^0
Poly(methyl methacrylate)	2.55	2.60
High-density polyethylene	2.53	2.49
Polycarbonate	2.29	2.31
Polyarylate	2.23	2.27
Epoxy polymer	2.58	2.51

This accounts for the discrepancies between the d_f values found from relations (23) and (45) — the former gives the real d_f value and the latter gives the minimum possible one.

The dependences of D_f on the curing agent : oligomer ratio (Fig. 20) for EP-2 specimens immediately after the manufacture (curve 1) and after keeping at room temperature for 1.5 years (physical ageing) (curve 2) show that during ageing, D_f approaches 3, this effect being more pronounced for nonequilibrium systems with a deficiency or an excess of a curing agent. The minimum C_∞ value for the epoxy polymer with $K_{st} = 1.0$ is equal to 3.38.⁷¹ With allowance for this fact, an estimate of the minimum D_f value also gave ~ 3.38 . This estimate is in good agreement with the experimental D_f value for the aged polymer ($D_f \approx 3.16$).

The existence of the quasi-equilibrium state is also confirmed by the temperature dependences of the density fluctuations $\langle \Delta\rho/\rho \rangle^2$ (Fig. 21), which diminish as the temperature rises and tend to zero for $T = 0$, which corresponds to an ideal structure. However, there occurs a transition at temperature T^* below which $\langle \Delta\rho/\rho \rangle^2$ deviates from the predicted pattern¹¹⁶ and remains constant as the temperature varies. The density fluctuations above T^* are supposed to be due to the local mobility of the sequences in the polymer backbone but below T^* this mobility becomes ‘frozen’. This interpretation is fully consistent with the concept

Figure 20. Dimensions of the regions of localisation of excess energy D_f vs. the curing agent : oligomer ratio K_{st} for EP-2 samples immediately after preparation (1) and after physical ageing (2).

Figure 21. Temperature dependences of the density fluctuations $\langle \Delta\rho/\rho \rangle^2$ for poly(methyl methacrylate) (1) and poly(ethylene terephthalate) (2).¹¹⁷

of quasi-equilibrium state ($D = 1$). The nature of the temperature T^* has been considered in detail.¹¹⁷

Thus, the introduction of the concept of quasi-equilibrium state in polymers provides interpretation of some experimental facts. The application of the cluster model and fractal analysis makes it possible to specify the direction of the process of synthesis and to estimate its main characteristics.

4. Fluctuation free volume in polymers

The properties of polymers are mainly related to the molecular mobility and structure, which is determined by the degree of ordering of macromolecules.¹¹⁸ Free volume, or, more precisely, one of its components, fluctuation free volume, is one of the parameters most suitable for phenomenological description of a structure.¹¹⁹ As a rule, the fraction of the fluctuation free volume f_{iv} is estimated on the basis of polymer properties rather than from structure characteristics. Within the framework of the cluster model of the amorphous state of polymers,^{74, 120, 121} it has been shown⁵⁷ that a microcavity of fluctuation free volume is formed upon detachment (dissociation) of a segment from a region of local order (cluster) and ‘collapses’ upon attachment of a segment to a cluster. If this mechanism is accepted, at least two aspects need to be considered. One aspect concerns the energy characteristics of the process. The cluster model for the structure of the amorphous state of polymers postulates the thermofluctuational character of local ordering, according to which the number of segments in clusters diminishes as the temperature increases;¹²² this results in the formation of new microcavities of the fluctuation free volume (their nature has been considered in detail¹²³) and in an increase in f_{iv} . It is evident that the energy of thermal fluctuations is of the order of kT ; the energy of formation of a microcavity (ϵ_h) can be estimated from the equation

$$\epsilon_h = kT_g \ln \frac{1}{f_{iv}}. \quad (54)$$

Since the maximum f_{iv} value expected in the vitreous state is 0.159 (according to the most ‘rigorous’ estimates¹²⁴) and $T < T_g$, it is obvious that the energy of thermal fluctuations is insufficient for the formation of a microcavity.

The second point is determination of the f_{iv} value. This can be done by virtue of the following equation:

$$f_{iv} \approx 0.017 \frac{1 + \mu}{1 - 2\mu}. \quad (55)$$

For amorphous vitreous polymers, $f_{iv} \approx 0.050 - 0.090$,¹²¹ which is much greater than the value $f_{iv} \approx 0.025 \pm 0.003$, which has been found in terms of the Williams–Landell–Ferry (WLF) concept and is generally accepted for most polymers.¹¹⁸

Evaluation of some polymer properties requires not only the integral characteristic f_{iv} but also the parameters of a separate

microcavity of fluctuation free volume, which is traditionally represented as a sphere with volume V_h .¹¹⁹

Recalling that the fractal dimension of the polymer structure is in the range $2 \leq d_f \leq 3$, it can be suggested that the fluctuation free volume as a structural unit also possesses fractal properties. Using relations (55) and (23), the dependence of f_{fv} on d_f has been elucidated⁶⁰

$$f_{fv} \approx 8.5 \times 10^{-3} \frac{d_f}{3 - d_f}. \quad (56)$$

If the above assumption is correct, the following general relation should hold:¹²⁵

$$N_h \propto r_h^{D_{fv}}, \quad (57)$$

where N_h is the number of microcavities, r_h is their characteristic size, and D_{fv} is the fractal dimension of the fluctuation free volume.

As a first approximation, the r_h value can be expressed in terms of the microcavity volume as $V_h^{1/3}$, the volume being found from the equation

$$V_h = \frac{3(1 - \mu)kT_g}{f_{fv}E}. \quad (58)$$

Although this approximation introduces some inaccuracy to the quantitative results, it does not deteriorate the generality of the conclusions.

The number of microcavities N_h is expressed as the ratio¹¹⁹

$$N_h = \frac{f_{fv}}{V_h}. \quad (59)$$

Figure 22 presents the variation of $\ln N_h$ as a function of $\ln V_h^{1/3}$ for specimens of three epoxy polymers, EP-1, EP-2, and aged EP-2, which is designated by EP-3. It can be seen that the plots are linear; this is a typical feature of fractal behaviour. The D_{fv} values found from relation (57) for EP-1 and EP-2 were 5.9; that for EP-3 was 2.7.

It is clear that D_{fv} calculated in this way are averaged values; nevertheless, they provide grounds for an important conclusion: in the general case, a microcavity of fluctuation free volume can be represented by a D_{fv} -dimensional sphere, modelling by a three-dimensional sphere being a specific case. The D_{fv} values are close to the corresponding dimensions D_f of the regions of localisation of excess energy, which are determined from Eqn (39). In addition, D_f is equal to the automodelling coefficient A_i and, hence, to C_∞ . The fractal dimension D_{fv} interpreted in this way is closely related to the characteristics of the polymer structure.

Now we consider the energy criterion for the formation of a microcavity with the volume V_h . For this purpose, we use the concept of free fracture of solids,¹²⁶ according to which a limited amount of potential energy with density A^* can be accumulated in

a limited volume V and the formation of a new surface requires work equal to the product of the surface area S_n and the specific surface energy σ_n . In the case of free fracture,¹²⁷

$$A^*V = \sigma_n S_n. \quad (60)$$

As applied to the formation of a microcavity with the volume $V = V_h$, relation (60) can be represented as follows:⁸⁷

$$\frac{V}{S_n} = \frac{\sigma_n}{A^*}. \quad (61)$$

For a D_{fv} -dimensional sphere, it can be written that⁸⁷

$$\frac{V}{S_n} = \frac{r_h}{D_{fv}}. \quad (62)$$

The σ_n value can be represented as follows:¹¹⁹

$$\sigma_n = \frac{\epsilon_h}{2V_h^{2/3}}, \quad (63)$$

where ϵ_h is estimated from Eqn (54).

Finally, by determining A^* as the ratio

$$A^* = \frac{kT}{V_h}, \quad (64)$$

and using Eqns (61) and (63), we obtain

$$D_{fv} = \frac{4\pi T}{T_g \ln(1/f_{fv})}. \quad (65)$$

Since ageing can be interpreted as a tendency towards thermodynamic equilibrium,¹¹⁴ it is assumed that the condition $D_{fv} = 3$ corresponds to a certain quasi-equilibrium state of the polymer. This allows one to draw several conclusions. First, an increase in temperature, all other factors being the same, implies an increase in D_f and, hence, enhancement of the thermodynamic nonequilibrium of the polymer as a system. It follows from Eqn (39) that an increase in D_f is accompanied by an increase in μ ; this accounts for the well-known fact that the Poisson coefficient of polymers increases with temperature.^{74, 127, 128} Second, an increase in μ implies a decrease in the degree of local ordering of amorphous polymers,^{70, 129} which is manifested as a decrease in the density of the cluster network of entanglements V_{en} . In other words, an increase in V_{en} reflects the trend of a polymer towards thermodynamic equilibrium.¹¹⁴ Third, in the case where $D_{fv} = 3$, one can calculate the relative portion of the 'quasi-equilibrium' free volume (f'_{fv}); for the epoxy polymers in question, it falls in the range $\sim 0.028 - 0.042$, which is rather close to the f_{fv} value in the WLF equation mentioned above. Thus, the estimation of f_{fv} using Eqn (55) is correct and the considerable magnitudes of f_{fv} reflect a relatively high degree of thermodynamic nonequilibrium in epoxy polymers.

Let us consider the general statements of the concept of fluctuation free volume in relation to cross-linked systems. Figure 23a illustrates the relationship between the fractal dimensions of the regions of localisation of excess energy D_f [see Eqn (39)] and the fluctuation free volume D_{fv} [see Eqn (65)]. It can be seen that these two values are fairly close to each other.[‡] Thus, the f_{fv} value can actually be used to characterise the polymer structure.

The formation of a microcavity with the volume V_h requires local critical deformation ϵ_c ¹³⁰

$$\epsilon_c = \frac{1}{3} \frac{\ln(1/f_{fv})}{3\gamma}, \quad (66)$$

where γ is the Grüneisen parameter, characterising the anharmonicity of the intermolecular bonds in a polymer and the factor 3 was introduced under the assumption that a microcavity is three-dimensional. In view of this fact, this factor should be replaced by D_{fv} and thus Eqn (66) assumes the form

[‡] Some discrepancy is due to the fluctuation nature of free volume.

Figure 22. Number of microcavities of fluctuation free volume vs. their size for EP-1 (1), EP-2 (2) and EP-3 (3).

Figure 23. Relationships between the fractal dimensions of the regions of localisation of excess energy D_f and the fluctuation free volume D_{ffv} (a) and between the dimension of the fluctuation free volume and the critical deformation in the formation of microcavities ϵ_c (b) for EP-1 (1), EP-2 (2) and EP-3 (3).

$$\epsilon_c = \frac{\ln(1/f_{fv})}{3\gamma D_{ffv}}. \quad (67)$$

Thus, the more pronounced the fractality of the fluctuation free volume (the greater D_{ffv}), the smaller ϵ_c and the easier the formation of the microcavity. This fact is reflected in the dependence of ϵ_c on D_{ffv}^{-1} (Fig. 23 b). The γ value was found from the relation¹³⁰

$$\gamma \simeq 0.74 \frac{1 + \mu}{1 - 2\mu}. \quad (68)$$

It is noteworthy that the Grüneisen parameter varies in parallel with D_{ffv} and is related to the dimension of the fluctuation free volume by the following simple relation:

$$\gamma \simeq D_{ffv} - 1. \quad (69)$$

In other words, the Grüneisen parameter is also a fractal characteristic; for quasi-equilibrium conditions, $\gamma = 2$. The values $\gamma > 2$ mean an enhanced nonequilibrium character of the system.¹³¹

Figure 24 shows the dependence of γ on D_{ffv} and the dependence of V_h on K_{st} for three epoxy polymers. The V_h values for EP-1 and EP-2 vary from 0.97 to 7.31 nm³ but those for EP-3 are greater and lie in the range of 5.45–10.1 nm³. In terms of the free fracture concept, this implies that the formation of a microcavity in a system the state of which is close to quasi-equilibrium requires more thermal fluctuations with the energy kT than that in non-equilibrium systems (EP-1 or EP-2). The same requirement is valid for each particular composition, which is confirmed by the presence of a maximum on the dependence of V_h on K_{st} at $K_{st} = 1$. The degree of equilibration can be estimated as the difference

Figure 24. Relationship between the Grüneisen parameter γ and the dimension of the fluctuation free volume D_{ffv} (a) and the dependence of V_h on K_{st} (b) for EP-1 (1), EP-2 (2) and EP-3 (3).

Figure 25. Variation of f_{fv} vs. K_{st} (a) and of the density of the cluster network of entanglements V_{en} vs. Δf_{fv} (b) for epoxy polymers.

(a): (1) EP-1, $f_{fv}(K_{st})$; (2) EP-1, $f'_{fv}(K_{st})$; (3) EP-3, $f_{fv}(K_{st})$; (b): (1) EP-1, (2) EP-2, (3) EP-3.

$$\Delta f_{fv} = f_{fv} - f'_{fv}. \quad (70)$$

The meaning of this estimate becomes evident if one compares the $f_{fv}(K_{st})$ and $f'_{fv}(K_{st})$ plots for EP-1 and EP-3 (Fig. 25 a). As noted above, samples with $K_{st} = 1$ are closest to the quasi-equilibrium state. The aged EP-3 samples at $K_{st} = 1$ have already reached this state and further ageing does not change the structure. The samples with $K_{st} \leq 0.50$ and those with $K_{st} \geq 1.50$ possess the lowest stability during physical ageing, which is displayed as the corresponding change in their properties. The decrease in the elastic modulus during ageing of EP-1 amounted to 1.7 GPa for $K_{st} = 1.50$ and 1.1 GPa for $K_{st} = 1.0$. Thus, by comparing the $f_{fv}(K_{st})$ and $f'_{fv}(K_{st})$ plots, one can demonstrate the degree of thermodynamic nonequilibrium of cross-linked systems and predict the possible changes in their structure and properties during physical ageing.

The closeness of a polymer to the equilibrium state can be characterised by the degree of ordering. Using the cluster model, this trend can be quantitatively described fairly easily in terms of the parameters V_{en} or ϕ_{cl} .^{57,132} The dependence of V_{en} on Δf_{fv} (Fig. 25 b) shows that the degree of local ordering can serve as an indication of the thermodynamic nonequilibrium of the polymer structure. Extrapolation of the straight line $V_{en}(\Delta f_{fv})$ to $\Delta f_{fv} = 0$ gives $V_{en} \simeq 3.8 \times 10^{27} \text{ m}^{-3}$, which is about 1.5 times lower than the maximum V_{en} value found as the ratio of the total length of the macromolecule per unit volume of the polymer to the length of the statistical segment.¹³³ This discrepancy stipulates the legitimacy of applying the term ‘quasi-equilibrium state’ to the polymer structure with $\Delta f_{fv} = 0$. It is clear that an equilibrium state implies that all macromolecules are packed in the regions of local ordering. It has been shown⁷⁰ that the condition $\Delta f_{fv} = 0$ cannot be attained for the epoxy polymers in question even for the maximum possible V_{en} value. Yet another important feature of the quasi-equilibrium state is temperature dependence of parameters, in particular, f_{fv} [see Eqn (65)]. When $V_{en} = 0$, the straight line $V_{en}(\Delta f_{fv})$ is extrapolated to $\Delta f_{fv} \simeq 0.077$, which also has a definite physical meaning. For $f'_{fv} = 0.035$ (see Fig. 25 a) and $\Delta f_{fv} \simeq 0.077$, the f_{fv} value is equal to 0.112, which is close to the fluctuation free volume at T_g .^{118,119} Thus, the destruction of clusters can be identified with glass transition of cross-linked polymers.

Thus, the above results point to the fractality of the fluctuation free volume in cross-linked polymers. In this connection, one important fact should be noted, which has not received adequate attention before. In accordance with Eqn (58), V_h decreases with an increase in f_{fv} . For pores with sizes of the order of several nanometers, it has been shown^{134,135} that

$$-\frac{dV}{d\rho} \propto \rho^{2-D'}, \quad (71)$$

where V is the total pore volume, ρ is the average pore radius, and D' is the fractal dimension of the structure of a porous material.

Figure 26. Relative fluctuation free volume f_{fv} vs. radius of the free volume microcavities r_h for EP-1 (1) and EP-2 (2).

According to different estimates, the linear sizes of microcavities of free volume r_h vary from 0.2 to 1.5 nm.^{136–142} If we assume that $V_h = f_{fv}$ and $r = r_h$, for Eqn (71) to have a physical meaning, it is evidently required that the slope of the $f_{fv}(r_h)$ plot be negative. The calculated D' values for EP-1 and EP-2 vary from 4.78 to 5.31, which is consistent with the above estimates of D_{fv} and D_f . Figure 26 presents the dependence of f_{fv} on r_h , which is linear and has a negative slope. Figure 27 illustrates the relationship between D_f and D' . It can be seen that D' values are regularly greater than D_f but both values vary according to the same pattern and the deviations do not exceed 25%. This also attests to the fractality of the free volume the dimension of which reflects the extent of ‘pumping’ of energy into the polymer and does not coincide with the corresponding dimension of the polymer structure.

Figure 27. Relationship between the fractal dimensions D' and D_f calculated from Eqns (71) and (39), respectively, for EP-1 (1) and EP-2 (2).

Let us consider the influence of the ‘pumping’ of energy (mechanical or thermal) on the formation of free volume in epoxy polymers. Within the framework of the Frenkel’ kinetic theory,¹¹⁵ the radius of a microcavity of free volume r_h depends on the surface tension σ

$$r_h^2 = \frac{\varepsilon_h}{4\pi\sigma}. \quad (72)$$

Equation (72), which is an analogue of relation (63), permits calculation of σ provided that r_h and ε_h are known. The dependence of the σ values thus found on D_f for EP-1 and EP-2 is plotted in Fig. 28. An increase in D_f (enhancement of energy pumping from the outside) results in a decrease in σ , which facilitates the formation of a microcavity of the fluctuation free volume. Note that for $D_f = 7.7$, the σ value becomes equal to zero. This is unlikely from the physical viewpoint; nevertheless, it is evident that σ sharply diminishes on moving towards $D_f \approx 7.7$. This D_f value is matched by $\mu \approx 0.425$ [according to Eqn (39)], which corresponds to the mechanical⁷⁴ and thermal¹⁴³ glass transition process. It has been shown experimentally that V_h sharply increases (and, hence, σ decreases)¹³⁶ and the yield point increases¹⁴⁴ at T_g .

Figure 28. Surface tension vs. fractal dimension of the regions of localisation of excess energy for EP-1 (1) and EP-2 (2).

The variation of f_{fv} as a function of D_f is presented in Fig. 29. The straight line was drawn with the assumption that for $\mu = 0$ (which corresponds to close packing of an amorphous polymer¹²⁹), $D_f = 2$ and $f_{fv} = 0$, whereas for the maximum possible f_{fv} value at T_g [$f_{fv}^t \approx 0.159$ (see Ref. 124)], $\mu \approx 0.44$ and $D_f^t \approx 9.3$. The f_{fv} values found using relation (55) for EP-1 and EP-2 correspond to the proposed model. Thus, ‘pumping’ of energy into a polymer increases the dimensions of the regions in which it is localised and increases the fluctuation free volume.

Figure 29. Relationship between the relative fluctuation free volume f_{fv} and the dimension of the regions of localisation of excess energy D_f . The points correspond to the calculation of f_{fv} from Eqn (55) for EP-1 (1) and EP-2 (2). The explanations are in the text.¹⁵³

Thus, the fluctuation free volume in vitreous polymers has a fractal structure; therefore, the microcavities that constitute the free volume can be modelled by a D_{fv} -dimensional sphere. The sizes of microcavities are controlled by the volume in which the energy of thermal fluctuations needed for their formation is accumulated. The absolute magnitudes of f_{fv} can characterise the thermodynamic nonequilibrium of the polymer structure. For quasi-equilibrium structures, it is assumed to be equal to f_{fv} in the known WLF equation. The dimension of the free volume regions (which coincides with the corresponding dimension of the regions of localisation of energy pumped from the outside) reflects the extent of energetic excitation of the polymer structure.

5. Fractal characteristics of polymers in time-dependent processes

Polymers obey the principle of temperature–time superposition,^{145, 146} according to which structural (including fractal) characteristics of polymers are functions of the time scale of testing. In this connection, we shall consider the influence of the

time factor on the fractal characteristics in processes typical of polymers such as thermal ageing or relaxation.

The dependences of the dielectric loss tangent ($\tan \delta$) on the Hausdorff dimension for several copolymers have different slopes at measurement frequencies of 1 and 10 kHz. This hampers correct prediction of $\tan \delta$. This difference can be easily explained in terms of the cluster model. The φ_{cl} value is a parameter of the order of the polymer structure;⁶⁰ due to the thermodynamic nonequilibrium of the structure, it is also a function of the time scale t . In the general case, the time-dependent order parameter $\varphi_{cl}(t)$ is determined as follows:¹⁴⁷

$$\varphi_{cl}(t) = \varphi_{cl}^0 \exp\left(-\frac{t}{\tau_0}\right), \quad (73)$$

where φ_{cl}^0 is the φ_{cl} value at very large t and τ_0 is the relaxation time under normal conditions.

If the time scale of the experiment is expressed in terms of π/ω (ω is the frequency of measurements) and the relaxation time is assumed to be $\tau \approx 10$ ms, the φ_{cl} value can be estimated as a function of frequency and, hence, different D values for frequencies of 1 and 10 kHz can be obtained. An increase in D (decrease in t) results in higher φ_{cl} [according to Eqn (73)] and in lower D .¹⁴ Therefore, the dependence of $\tan \delta$ on D is described by one straight line for both frequencies mentioned above.²⁶ Thus clusters can be generally defined as regions in which relaxation processes are impossible.

Physical ageing of amorphous vitreous polymers consists in the variation of the structure and properties with time, which reflects the thermodynamically nonequilibrium nature of these polymers.¹¹⁴ At relatively low temperatures (about room temperature), this process is fairly slow; it takes several years for substantial changes in the properties to occur.^{94, 148} Therefore, forecasting of these phenomena should be performed with allowance for both spatial and temporal disorder of systems. The spatial non-uniformity of the structure of amorphous vitreous polymers accounts for the rather broad range of the rates of relaxation processes. Spatial disorder results in temporal disorder. The variation of the properties and structure of polymers during ageing can be described quantitatively within the framework of fractal analysis.

Study of the reaction dynamics in disordered systems has shown that for most reactions at long times, subordination expressed by the following general relation is obeyed:¹⁴⁹

$$\Phi \propto t^{\alpha\gamma}, \quad (74)$$

where Φ is an arbitrary function dependent on time t and α and γ are coefficients taking into account the spatial and temporal disorder.

As applied to physical ageing, the variation of structure with time can be described, on the basis of general relation (74), in the following way:¹⁵⁰

$$V_{cl} = C V_{cl}^0 t^{\alpha\gamma}, \quad (75)$$

where V_{cl} and V_{cl}^0 are the densities of the cluster network of entanglements in the aged and initial polymers, respectively; C is a proportionality coefficient. The index α can be defined in terms of fractal analysis as the difference $d_f - 2$, where d_f is the fractal dimension of the structure of the initial epoxy polymer, with allowance for the following considerations: the $2 < d_f \leq 3$ range characterises the degree of disorder of the polymer structure;¹⁵¹ most information on this point is carried by the fractional part of d_f : the greater the magnitude of d_f , the lower the local order and, hence, the higher the spatial disorder of the system.¹⁵²

The quasi-equilibrium state of polymers is characterised by $d_f \approx 2.5$. This value corresponds to a fully relaxed polymer with a narrow size distribution of free volume cavities¹⁵³ and, hence, to the least temporal disorder, characterised by a spectrum of relaxation times. Therefore, the following approximation has been used:¹⁵⁰

$$\gamma = d_f - 2.5. \quad (76)$$

Thus, Eqn (75) can be finally written in the form

$$V_{cl} = V_{cl}^0 C t^{(d_f-2)(d_f-2.5)}, \quad (77)$$

where the coefficient C determined empirically is equal to ~ 0.14 and the time of ageing is expressed in seconds.

Figure 30 shows the dependences of φ_{cl} on K_{st} for the initial (EP-2) and aged (EP-3) epoxy polymers. In the case of EP-3, the φ_{cl} values determined experimentally and calculated using Eqn (77) are given. It can be seen that the experimental and calculated values are in good agreement. The maximum deviations for K_{st} equal to 0.50 and 1.50 do not exceed $\sim 25\%$. It is assumed¹⁵⁰ that the main reason for the inaccuracy is the high power dependence of V_{cl} on d_f in Eqn (77).

Figure 30. Relative portion of clusters φ_{cl} vs. the curing agent: oligomer ratio K_{st} for EP-2 (1) and EP-3 (2, 3); (1, 2) experimental data, (3) calculation using Eqn (77).¹⁵⁰

Yet another important aspect of physical ageing is also associated with the dependence of φ_{cl} on K_{st} (see Fig. 30). The ageing rate expressed as the difference between the φ_{cl} values for EP-2 and EP-3 varies substantially for different K_{st} (and, hence, for different chemical cross-linking densities v_s). The minimum ageing rate is observed for a system with $K_{st} = 1.0$;¹⁵² deviations from this value towards both greater and lower values result in an increase in the ageing rate.¹⁰¹ This is due to an increase in both α and γ [see Eqn (77)] or, in other words, to an increase in the fractal dimension of the structure d_f .

Parameters which vary during physical ageing include not only supermolecular structure characteristics (d_f and D_f) but also the statistical chain flexibility index C_∞ . Using Eqns (39) and (41), it can be written that

$$A_i = C_\infty = D_f = 2 \frac{1 - \mu}{1 - 2\mu}. \quad (78)$$

The physical ageing results ultimately in the formation of similar structures for all the epoxy polymers considered, irrespective of the density of chemical cross-linking points (v_s varies by approximately an order of magnitude).¹⁵⁴ Naturally, this structure equalisation also determines substantial convergence of the properties of EP-2 and EP-3.⁹⁴

From the practical viewpoint, it is important to predict the properties of polymers during physical ageing. A procedure suitable for this purpose has been reported.¹⁵⁰ This procedure is based on Eqn (77). Knowing the V_{cl} and C_∞ values, one can estimate D_f and calculate E .¹⁵⁵ Then the yield point σ_p ^{142, 148} and some characteristics of polymers^{64, 156} can be determined.

In recent years, considerable attention has been paid to investigation of the relaxation processes in complex condensed systems. An example of this type of system is amorphous-crystalline polyethylene, the structure of which under normal conditions consists of crystalline regions, regions of local ordering and a devitrified loosely packed matrix.^{157, 158} The interest in these

studies is caused by the experimental fact that the correlation functions for many different systems vary in accordance with the same exponential dependence

$$\varphi(t) = \exp \left[- \left(\frac{t}{\tau} \right)^\beta \right], \quad 0 < \beta < 1. \quad (79)$$

The parameters β and τ depend both on the material and on the environmental conditions, for example, temperature.

The law described by Eqn (79) was first proposed by Kohlrausch and has later been used by Williams and Watts to describe the dielectric relaxation in polymers (M Schlesinger, J Klafter, see Ref. 149, p. 553). The main difficulty in the case of polymers is to identify the parameters of Eqn (79) in terms of characteristics describing the polymer structure. This identification has been performed within the framework of fractal analysis.³⁹

In the impact testing of polymers, the elastic modulus decreases with an increase in the time scale of testing (in the case of brittle fracture, this is time to fracture t') and can be described by the empirical relation^{159, 160}

$$E = E_0(t')^{-m}, \quad (80)$$

where E_0 is the 'unity' modulus, *i.e.* the E value for $t' = 1$ on the time scale chosen, and m is an empirical index characterising the degree of completeness of relaxation processes.

Figure 31 shows the variation of E as a function of t' corresponding to Eqn (80) for high-density polyethylene samples with different lengths of a sharp notch (an increase in the length decreases t') at a testing temperature of 293 K. The slope of the straight line can be used to estimate the index m , while extrapolation of the plot to $t' = 1$ gives the E_0 value. It should be noted that at certain t' values (for example, τ), the variation of $\ln E$ vs. $\ln(1/t')$ has a break — at $t' < \tau$ the elastic modulus increases faster than at $t' > \tau$, which reflects an increase in m . This finding is related to the extent of completeness of relaxation processes: at $t' > \tau$ this extent is high and, correspondingly, the increase in E is insignificant.

Figure 31. Elastic modulus E vs. time to fracture t' [see Eqn (80)] for high-density polyethylene samples with a sharp notch; $\tau = \tau_0$ is relaxation time.¹⁵³

The difficulty in describing the variation of E according to Eqn (80) is due to the presence of two empirical constants (E_0 and m), which, moreover, can change discretely. Therefore, an alternative approach based on the use of the Kohlrausch equation (79) has been chosen.¹⁵³ To describe E , this equation should be written in the form

$$E = E'_0 \exp \left[- \left(\frac{t'}{\tau_0} \right)^\beta \right], \quad 0 < \beta < 1, \quad (81)$$

where E'_0 is a constant.

Let us consider the physical meaning of the parameters appearing in Eqn (81). It is evident that the τ value can be taken

as τ_0 (see Fig. 31). The constant E'_0 determines the maximum elastic modulus $E_{\max}$ which can be attained for a given polymer without relaxation. The range of variation of this parameter for very high testing frequencies (several megahertz) was found¹⁶¹ to be 1.1–2.6 GPa for high- and low-density polyethylene. Finally, the index β , characterising the width of the relaxation spectrum (spatial disorder of the system), can be associated with the fractional part of d_f , *i.e.* it is taken to be equal to $d_f - 2$. Note that both β and $d_f - 2$ vary over the same limits. Thus, the final form of the Kohlrausch equation for determining the elastic modulus of polymers under high-speed loading (brittle fracture) can be written as follows¹⁵³

$$E = E_{\max} \exp \left[- \left(\frac{t'}{\tau} \right)^{d_f - 2} \right], \quad 0 < (d_f - 2) < 1. \quad (82)$$

Figure 32 shows the dependences of the E values, both experimental and calculated from Eqn (82), on the sharp notch length l for high-density polyethylene samples at different temperatures. Good agreement between the theoretical and experimental results is obvious.

Figure 32. Experimental (1–4) and calculated [Eqn (82)] (5–8) elastic moduli E vs. length of the sharp notch l for high-density polyethylene at testing temperatures of 293 (1, 5), 313 (2, 6), 333 (3, 7) and 353 K (4, 8).¹⁵³

Thus, methods of fractal analysis in combination with the cluster model of the structure of amorphous polymers provide a quantitative description of time-dependent processes. The fact that the fractal dimension of the structure d_f takes into account both the spatial and temporal disorder accounts for the simplicity of the resulting equations.¹⁵⁰

III. Modelling of the structure and properties of polymers

1. Modelling in terms of the percolation theory

Percolation models are widely used to describe critical phenomena¹⁶² including those in polymers.^{162–166} Percolation clusters are homogeneous fractals when $x \neq x_c$ (x is the current coordinate, x_c is the coordinate of the percolation transition). For example, the structure of vitreous polymers is a fractal when $T \neq T_g$ or, with allowance for the foregoing, when $T < T_g$.

It should be borne in mind that the fractal properties of the polymer structure are due to the presence of the cluster structure or, more precisely, of 'frozen' ordering. However, as has already been mentioned, the magnitude of the fractal dimension of the structure d_f for amorphous polymers is debated, the overall range being $2 \leq d_f \leq 3$.¹²⁵ Thus on the basis of theoretical statements of Alexander and Orbach,⁴³ it has been concluded¹⁶⁷ that for an ideal disordered linear polymer, d_f is equal to 2, while for real amorphous polymers, this value is 2.0–2.2. Let us make several rather simple estimates of d_f for epoxy polymers EP-1 and EP-2. For a percolation system, the following relation holds:¹⁶²

$$d_f = d - \frac{\beta}{\nu}, \quad (83)$$

where d is the dimension of the Euclidean space in which the fractal is inserted and β and ν are critical indices of a percolation system related to each other as

$$d\nu = 2\beta + \gamma_c, \quad (84)$$

where γ_c is also a critical index of the percolation system. The parameters calculated from Eqn (83) are listed in Table 2.

Table 2. Parameters of percolation systems for epoxy polymers.

Parameter	Experiment		Calculation using Eqn (83)
	EP-1	EP-2	
ν	0.67	1.15	0.88
β/ν	0.537	0.504	0.455
d_f	2.46	2.50	2.545

The evaluation of the index ν for EP-1 and EP-2 for $d = 3$ using Eqn (84) and the β and γ_c values determined previously gives 0.67 and 1.15, respectively, which is consistent with the theoretical value $\nu = 0.88$ (see Table 2).

The d_f values for epoxy polymers estimated using Eqn (23) fall in the range from 2.56 to 2.73, which is in good agreement with the estimates made in this review but is substantially greater than has been assumed previously.^{43, 167}

The following ratio for percolation clusters has been reported:

$$d_{\text{super}} = \frac{d_f}{d_s}, \quad (85)$$

where $d_{\text{super}} > 1$ is so-called superlocalised index.

Using the d_{super} and d_s values found experimentally for epoxy polymers based on bisphenol A,^{167, 168} we calculated d_f , which proved to be 2.55. This value is close to the above estimates. Note that the application of Eqn (85) to the calculation of d_{super} of epoxy polymers became possible owing to the representation of their structure as a percolation system.

The d_f value can also be estimated without experimental d_s but using only the index d_{super} . For example, the random walk dimension d_w can be represented, with allowance for Eqn (85), in the following form:

$$d_w = 2d_{\text{super}}. \quad (86)$$

The d_f values for the epoxy polymer at $d_{\text{super}} = 1.85$ ¹⁶⁷ amounted to 2.47 and 2.70 in accordance with the Alexander–Orbach and Aharoni–Stauffer hypotheses,⁴⁸ respectively. These values are close to the estimates made using Eqn (23).¹⁶⁷

The fractal dimension is determined by the disorder which is generated by deterministic chaos. This statement can be expressed in the analytical form¹⁶⁹

$$d_f = \frac{S}{\lambda}, \quad (87)$$

where S is the entropy of the system, λ is the Lyapunov index.

The entropy change ΔS in a chaotic process can be determined using the following simple formula:^{170, 171}

$$\Delta S \approx 3kf_{iv} \ln f_{iv}, \quad (88)$$

where f_{iv} is determined from Eqn (55) and k is the Boltzmann constant.

Figure 33 shows the variation of d_f [calculated in terms of Eqn (23)] as a function of ΔS [calculated using Eqn (88)] for the epoxy polymers under consideration. This plot has some interesting features. First, extrapolation of the $d_f(\Delta S)$ straight line to $\Delta S = 0$ yields the value $d_f = 2$. Relation (88) indicates that the condition $\Delta S = 0$ is matched by $f_{iv} = 0$. This implies close packing

Figure 33. Fractal dimension d_f of the structure vs. entropy for EP-1 (1) and EP-2 (2).¹⁷⁰

of the structure of epoxy polymers. In other words, the value $d_f = 2$ is attained for an amorphous polymer in the case of close packing rather than in the case of ideal disorder, as has been suggested in a previous publication.¹⁶⁷ Second, $d_f = 3$ is attained at a ΔS value corresponding to $f_{iv} \approx 0.157$. This is known to be the greatest theoretical value relative to the free volume at T_g .¹²⁴ This means that $d_f = 3$ corresponds to the devitrified state of the polymer, *i.e.* to destruction of the local ‘frozen’ order. This fact confirms the relationship between local order and fractality of amorphous polymers. Third, in accordance with relation (87), the linear dependence of d_f on ΔS means that $\lambda = \text{const}$. Thus, the chaotic component of the dynamics of structure formation is the same for the epoxy polymers considered.¹⁷²

Thus, the structure formed in epoxy polymers at the glass transition temperature T_g is a percolation cluster, which is described adequately in terms of the cluster model.^{57, 173} Therefore, it can be assumed that glass transition of a polymer is a phase transition and ϕ_{cl} is an order parameter. In addition, this fact can serve as evidence confirming fractality of the structure of network polymers (for $T < T_g$) in the range of length scales of ~ 0.3 – 5.0 nm. The fractal dimension of the structure of epoxy polymers is much greater than it has been believed previously (see, for example, Ref. 60); it is determined by the disorder generated by deterministic chaos. The loss of fractality by the epoxy polymer structure, *i.e.* the situation when $d_f = d$ is attained at the glass transition temperature.

It is worth noting that the model of percolation cluster proposed by Kozlov *et al.*^{166, 170} is similar in essence to the concept of critical thermal transition.¹⁹ According to this concept, the portion of system elements belonging to the greatest cluster is proportional to the order parameter, which varies near the critical temperature T^* as ε^β , where $\varepsilon = (T - T^*)/T^*$.

2. The model of diffusion-limited aggregation

The general description of the models of irreversible aggregation has been reported in several publications.^{12, 162, 174} Here we shall consider particular aspects of using the model of diffusion-limited aggregation (DLA) for describing the structure of amorphous polymers. Note that the computer simulation procedures, widely used for this purpose, should be made more specific. If the cluster model of the structure of amorphous polymers^{173–175} can be described as the Witten–Sander (WS) cluster, this means that the model and the WS cluster belong to the same class of universality.

There exist numerous reasons for representing the structure of an amorphous polymer as WS clusters and for assigning them to one class of universality. These reasons have been considered in detail;⁶⁰ here we mention only three most important ones.¹⁷⁶ The first reason is that the aggregation mechanism belongs to one class of universality; for WS clusters, this is attachment of separate particles to the growing clusters (aggregation of the particle–

cluster type). In terms of the cluster model, this mechanism is attachment of a statistical segment to a region of local order; this event is equivalent to the ‘collapse’ of a microcavity of the fluctuation free volume.^{57,121} The second reason follows from the first one: due to the identical aggregation mechanisms, the structures of amorphous polymers and the WS clusters have the same scaling indices, namely, the dimensions d_f (see Refs 170 and 171) and D (see Ref. 172), respectively. The third reason is as follows. It is known⁴⁴ that during the synthesis of polymers, the class of universality changes in the gelation point, namely, the cluster–cluster mechanism is replaced by the particle–cluster mechanism; the latter affords WS clusters.

The model representation (in terms of the DLA model) made it possible to describe the structures of EP-1 and EP-2; this was done using the same scaling index, namely, the dimension d_f .¹⁷⁵ It should be mentioned that the word ‘cluster’ is interpreted in different ways in the cluster model¹⁷⁷ and in the WS cluster model. In terms of the latter, the term ‘cluster’ denotes both the region of local ordering and the chains protruding from it, while in the former case, only statistical segments incorporated in the region of local ordering are meant. It is evident that the structure of a polymer sample cannot be regarded as a single WS cluster. Therefore, by analogy with Belousov *et al.*,¹⁷⁷ who proposed a modified variant of the WS model, we represent the structure of epoxy polymers by a set of WS clusters, the size of each cluster ranging from l_{st} to R_{cl} . Therefore, the model of multiple growth sites is the most plausible modification of the WS model. According to the WS model, the growth of a WS cluster takes place on a large number of seeds, the cluster size R_{cl} being related to the concentration of free diffusing particles N in the following way:

$$N \simeq R_{cl}^{D-d}. \quad (89)$$

Only those statistical segments that are located in the loosely packed matrix are able to join the region of local ordering. An increase in the degree of local ordering decreases the temperature; for $R_{cl} = \text{const}$, this means a decrease in the difference $D-d$ or a decrease in D . The N value was taken to be equal to the product of the number of particles (statistical segments) per unit volume and the proportion of the loosely packed matrix. Figure 34 shows the plots for the variation of the fractal dimensions of the epoxy polymer structures¹⁵⁶ and of the WS cluster, calculated using relation (89), *vs.* the curing agent : oligomer ratio. One can notice good correspondence between d_f and D .¹⁷⁵

Thus, a modified version of the particle–cluster aggregation model¹⁷⁸ allows the structures of network polymers to be described in terms of D . This stipulates the assignment of the structure of network polymers to the given class of universality and, hence, description of its properties by relations developed for this class of universality.¹⁷⁵

Description of the local ordering of the structure of amorphous polymers (in relation to polycarbonate and high-density polyethylene) in terms of the WS model has been reported.¹⁷⁶ The following equation characterises the variation of the density of the

Figure 34. Fractal dimensions of the structure d_f (1, 2) and of the WS clusters D (3, 4) *vs.* the curing agent : oligomer ratio K_{st} for EP-1 (1, 3) and EP-2 (2, 4).¹⁵⁶

WS cluster ρ_{ws} as a function of its radius R_{ws} and the dimension D :¹⁷⁹

$$\rho_{ws} = \rho \left(\frac{R_{ws}}{a} \right)^{D-d}, \quad (90)$$

where ρ is the density of the material of the WS cluster in the state of close packing, a is the lower boundary of the fractal behaviour of the WS cluster, which can be identified with the length of an elementary unit in the polymer chain.

A WS cluster obeys the relations $D < d$ and $\rho_{ws} < \rho$, which determine the condition $a < R_{ws}$. Replacement of the signs in the first two inequalities by equality signs implies transition of the cluster to another class of universality, for example, transition to the Eden cluster.⁸⁷ Meanwhile, since $\rho_{ws} \neq 0$ and $\rho \neq 0$, a cannot be equal to zero. Thus, a compact region ($D \simeq d$) with size a , identified as a region of local ordering for the structure of an amorphous polymer, always exists in the centre of the WS cluster. This statement is a necessary condition for the existence of the WS cluster.¹⁸⁰ Two remarks on this point are pertinent.

First, the cause for the appearance of the compact region at initial stages of formation of a WS cluster can be easily understood. Indeed, the fractal nature of the WS cluster is determined by the shielding effect of its ‘branches’, which prevent the access of particles into the inner regions of the cluster.^{180,181} However, in initial stages of the growth, these ‘branches’ are poorly developed and the shielding effect is low. Second, the polymer structure, as any real (physical) fractal, possesses fractal properties only in a particular range of length scales.⁸⁷ It has been shown experimentally^{167,182} that this range for polymers is from several Ångström to several tens of Ångström. This implies the presence of a density gradient in the polymer in this range of length scales, which, in turn, means alternation of blobs and rarefied sections in the material.¹⁸³ The cluster model^{173,177} satisfies this condition, whereas, for example, the ‘felt’ model of the polymer structure proposed by Flory¹¹³ cannot account for the experimentally observed fractal properties.^{167,182,183}

Thus, interpretation of the structure of an amorphous polymer as a WS cluster (more precisely, as a set of these clusters) assumes necessarily the existence of regions of local order. This has been confirmed¹⁷⁶ by comparing the a values calculated from Eqn (90) and the size of the region of local order r_{cl} (Fig. 35). The r_{cl} value can be found from the following equation (under the assumption of close packing):¹⁸⁴

$$r_{cl} = \left(\frac{n_{cl} S}{\pi \eta} \right)^{1/2}, \quad (91)$$

where n_{cl} is the number of statistical segments in the cluster, η is the density of packing of the element, equal to 0.74.¹⁸⁴

Figure 36 shows the variations of the size of the regions of local order r_{cl} in the cluster model¹⁷³ and the compact regions a in the WS model *vs.* testing temperature for polycarbonate and high-density polyethylene. In studies by Kozlov *et al.*,^{176,185} the density of the loosely packed polymer matrix, which coincides with the density of the polymer above the glass transition (melting) temperature, was taken as ρ_{ws} and the density of the crystalline

Figure 35. Cross-section of the region of local order incorporating seven statistical segments (d_m is the diameter of the polymer macromolecule).¹⁷⁵

Figure 36. Size of the regions of local ordering r_{cl} (curve) in the cluster model and size of the compact regions a (dots) in the WS model vs. temperature for polycarbonate (a) and high-density polyethylene (b).

regions of polycarbonate and polyethylene was used as ρ . In addition, it was assumed in calculations that

$$R_{cl} = R_{WS}, \quad (92)$$

$$D = d_f. \quad (93)$$

The absolute magnitudes and the patterns of temperature variation of the parameters r_{cl} and a are in good agreement. Some scatter in the a values relative to r_{cl} is due to the inaccuracy in the determination of d_f using Eqn (23), caused by the power dependence of a on D , which markedly affects the accuracy of comparison.

Thus, it can be inferred that experimental results also indicate the obligatory existence of regions of local order in the structure of an amorphous polymer in terms of the DLA model. The structure of amorphous polymers can also be studied using the method of autocorrelation functions¹⁷⁶

$$C(r) = \langle p(r') - p(r' + r) \rangle, \quad (94)$$

where $p(r')$ and $p(r' + r)$ are probabilities that particles composing a cluster are located at points r' and $r' + r$ (the probability is equal to unity when the point does contain a particle and to zero when no particle is present). The autocorrelation function for distances r greater than several lattice spacings can be represented by the scaling relation¹⁸⁶

$$C(r) \propto r^{-\alpha}, \quad (95)$$

where

$$\alpha = d - D. \quad (96)$$

In the case of a linear autocorrelation function, having determined α , one can estimate the fractal dimension D of the object.

The autocorrelation function for the structure of an amorphous polymer (in particular, polycarbonate) is shown schematically in Fig. 37; the density variation is presented as a function of distance, the reference point ($r = 0$) being placed at the centre of a local order region (see Fig. 35). Over an interval from 0 to r_{cl} the ρ value remains constant and equal to the density of the region of local order, which has been assumed, as a first approximation, to be equal to the ρ_{cr} value for crystalline polycarbonate.¹⁸⁷ In the range from r_{cl} to R_{cl} , the density is supposed to decrease linearly to reach ρ_{min} , which is estimated as follows. Litt *et al.*¹⁸⁷ have reported the averaged density of amorphous polycarbonate ρ_a ,

Figure 37. Autocorrelation function $\rho(r)$ for polycarbonate. The explanations are in the text.

which corresponds to the centre of the sloping section in Fig. 37. From simple geometric considerations, we obtain

$$\rho_{min} = \rho_a - (\rho_{cr} - \rho_a). \quad (97)$$

Now one can estimate the α value from the relation

$$(\rho_{cr} - \rho_{min})^{-\alpha} \simeq \left(\frac{R_{cl}}{2} - r_{cl} \right)^{-\alpha}, \quad (98)$$

and then calculate the d_f value for the polymer structure using Eqn (96) because modelling of this structure by a WS cluster assumes that equality (93) is valid.¹⁷⁸

The temperature dependences of the fractal dimension of the polycarbonate structure obtained experimentally and calculated in terms of the WS model taking account of relations (95) and (98) are presented in Fig. 38. It can be seen that the results correspond rather well to each other. However, the agreement can be improved by using so-called 'true' yield point. Kozlov *et al.*¹⁶⁶ determined d_f for polycarbonate at 293 K using five different procedures; the average value was found to be $d_f \simeq 2.51$. This result is in good agreement with the value $d_f \simeq 2.56$ determined for 293 K in terms of the WS model.

Figure 38. Fractal dimensions d_f of the structures of polycarbonate (1, 2) and WS cluster (3) vs. temperature. Determined with allowance for real (1) and 'true' (2) yield point.

Recalling that the quasi-equilibrium state of a polymer structure is characterised, in the general case, by $d_f = 2.5$, the same fractal dimension is typical of a WS cluster in a three-dimensional space when $N \rightarrow \infty$.¹⁸⁶ Therefore, below we consider the correspondence between the conditions of formation of a quasi-equilibrium state in the cluster model of an amorphous polymer structure and in the WS model. The modification of the WS model discussed above (growth on a large number of 'seeds')¹⁷⁷ uses the term 'diffusion distance' ξ , which depends on the local environment of each 'seed'. The growth of a WS cluster

continues until the condition $\xi \simeq R_{cl}$ is attained. The ξ and R_{cl} values are related to the concentration of free particles (c_{fr}) in the following way:¹⁷⁸

$$\xi \simeq c_{fr}^{-1} R_{cl}^{D-d+2}. \quad (99)$$

Taking into account the condition for termination of the cluster growth, it can be written that

$$c_{fr} \simeq R_{cl}^{D-d}. \quad (100)$$

This relation allows one to determine the concentration of free particles at the moment when the WS cluster stops growing having reached the size R_{cl} (subsequently, this concentration is designated by c_{WS}) or when the quasi-equilibrium state in terms of the WS model has been attained because in this case, too, the diffusion growth is restricted by interaction of the neighbouring WS clusters.

The concentration of particles in the cluster can be determined in terms of the cluster model.¹⁷³ Using relations (45) and (53), d_f can be related to the fraction of clusters ϕ_{cl} . Assuming that $d_f = 2.5$, one can estimate the ϕ_{cl} value for the quasi-equilibrium state of polymers.¹⁵

The R_{cl} value in the model¹⁷⁸ is limited by the number of 'seeds', which is, in turn, equal to the number of WS clusters, n_{WS} . According to the cluster model, the number of statistical segments incorporated in the regions of local order per unit volume of the polymer is assumed to be equal to the density of cluster network V_{cl} . The functionality F of such a region is the number of chains protruding from it. Since this region (cluster) is an analogue of a crystallite with extended chains, the number of segments in one cluster is equal to $F/2$. The number of regions of local order N_{cl} , equal to n_{WS} , in unit volume of the polymer can be found from the equation¹¹³

$$N_{cl} = \frac{2V_{cl}}{F}. \quad (101)$$

In addition to the cluster network of entanglements, polymers are known to contain a network of traditional 'loops'; unlike the cluster network, the latter is retained above T_g .¹⁴⁶ The numbers of entanglements in this network, determined above T_g , have been reported (see, for example, Refs 62, 76, 188). The density of the network of these 'loops' (V_{en}) can be found from the equation

$$V_{en} = \frac{\rho N_A}{M_{en}}, \quad (102)$$

where M_{en} is the molecular mass of the chain between entanglements.

Figure 39. Relationship between the densities of clusters N_{cl} and the network of macromolecular 'loops' V_{en} for various polymers; (1) poly(ethylene terephthalate), (2) polyamide-6, (3) polyethylene, (4) polypropylene, (5) polystyrene, (6) poly(methyl methacrylate), (7) poly(vinyl chloride), (8) polycarbonate.

Figure 39 illustrates the relationship between the N_{cl} and V_{en} values for eight polymers. It can be seen that these parameters correspond to each other both in magnitude and in the pattern of variation. The rather large scatter is due to the discrepancies between the M_{en} values taken from different sources for the same polymer [for instance, for polyethylene, $M_{en} = 737 \text{ g mol}^{-1}$ (see Ref. 62) or 1900 g mol^{-1} (see Ref. 188)]. Nevertheless, under the assumption that $N_{cl} \simeq V_{en}$, the V_{en} value can be identified as the density of 'seeds' and the R_{cl} value can be found using Eqn (30).

The use of dimensional R_{cl} values in relation (100) results in the c_{WS} value being dependent on the dimension of R_{cl} . Therefore, the lower limit (b) at which the fractal properties are manifested ($b \simeq 0.5 \text{ nm}^{173}$) was chosen as the scale, and the dimensionless parameter R_{cl}/b was used in Eqn (100). When a different b value is employed, c_{WS} somewhat changes but the trend of its variation is retained.

It has been shown¹⁸⁹ that the minimum value $d_{fmin} = 2.5$ is typical only of polymers with $C_\infty = 3$. The d_{fmin} value can be determined by modification of the equation¹⁹⁰

$$\frac{d_{fmin}}{3(3 - d_{fmin})} + \frac{4}{3} = C_\infty. \quad (103)$$

For polymers with $C_\infty > 3$, the calculation gives incorrect ϕ_{cl} values (greater than unity). Therefore, the d_{fmin} values found for polymers using Eqn (103) are greater than 2.5. Thus, the chain rigidity has a substantial influence on the formation of the polymer structure.

Only segments incorporated in the loosely packed matrix have the opportunity to join the regions of local ordering. Thus, in terms of the WS model, it is these segments that should be considered as free particles. Therefore,

$$c_{sf} = 1 - \phi_{cl} = \phi_{lp},$$

where ϕ_{lp} is the volume fraction of the loosely packed matrix.

Figure 40 illustrates the good correspondence between the c_{WS} and c_{sf} values for twelve polymers, which attests that the interpretations of the quasi-equilibrium state of the polymer structure in the cluster model¹⁷³ and in the WS model¹⁷⁸ are equivalent. The c_{WS} values are somewhat greater than c_{sf} because the scale b was chosen arbitrarily.

Thus, the concepts of quasi-equilibrium state involved in the DLA and cluster models of the structure of amorphous polymers are similar in physical essence, the quantitative estimations in terms of these two models providing consistent results. The

macromolecular ‘loops’, which restrict the mobility of polymer chains act as the ‘seeds’ in the WS model.¹⁷⁸

3. Order and fractality in polymers

The temperature dependences of V_{cl} for different polymers are similar. Raising the temperature results in a decrease in V_{cl} , the rate of thermofluctuational decomposition of clusters sharply increasing as T approaches T_g (or T_m). This general regularity is illustrated by the plots for V_{cl} vs. testing temperature for polycarbonate, poly(methyl methacrylate) and high-density polyethylene (Fig. 41). Note that similar temperature dependences are obeyed by the mechanical properties of polymers (elastic modulus, yield point, *etc.*).¹⁹¹ This similarity implies the possibility of superposition of the $V_{cl}(T)$ curves for different polymers, which is due to the common pattern of variation of the degree of local ordering vs. temperature. Below we construct this superposition and consider some its consequences in terms of the cluster model resorting to percolation theory and fractal analysis.⁶⁰

Figure 41. Density of the cluster network of entanglements V_{cl} vs. reduced testing temperature $\Delta T = T_g - T$ for polycarbonate (1), poly(methyl methacrylate) (2) and $\Delta T = T_m - T$ for high-density polyethylene (3).⁶⁰

The dependences of V_{cl} on the reduced temperature $\Delta T = T_g - T$ for some polymers follow similar patterns (see Ref. 41); therefore, a scaling relation of the following type can be applied:

$$V_{cl} \propto \Delta T^x, \quad (104)$$

where x is a generalised index.

However, the degree of local ordering is reflected more precisely by the relative portion of clusters φ_{cl} , determined from Eqn (53). An obvious advantage of Eqn (53) is the fact that it includes the main molecular characteristics of polymers. Figure 42 shows the $\ln \varphi_{cl}(\ln \Delta T)$ plots for the three polymers mentioned above and for the epoxy polymer EP-1, which are approximated by a common straight line. It can be easily seen that

Figure 42. Relative portion of the clusters φ_{cl} vs. reduced testing temperature ΔT for polycarbonate (1), poly(methyl methacrylate) (2), high-density polyethylene (3) and EP-1 (4).⁶⁰

these data comply well with the known relation of percolation models in the case of critical transition¹⁶²

$$P_\infty \propto (T_g - T)^\beta. \quad (105)$$

In this interpretation, the φ_{cl} value corresponds to the ‘power’ of an infinite cluster, *i.e.* the probability P_∞ that a unit belongs to the infinite cluster. Thus, at T_g (or T_m), the cluster network of entanglements appears (or vanishes); simultaneously, the structure of a vitreous polymer sample as a system is formed (or destroyed). Several other important points related to the possibility of describing a polymer structure in terms of Eqn (105) deserve attention. In the cluster model, the statistical segment l_{st} is taken as the ‘section of rigidity’ of a chain. The l_{st} value is several times smaller than the Kuhn segment length A , which characterises the rigidity of a freely jointed chain.⁹¹ When the A value is chosen as the ‘section of rigidity’, the φ_{cl} values prove to be greater than unity in most cases, which is devoid of physical meaning. The relationship between A and l_{st} can be written in the following form:

$$l_{st} = A \cos \frac{\theta_v}{2}, \quad (106)$$

where θ_v is the bond angle.

Thus, the shorter length of the chain section of rigidity l_{st} in the vitreous state is due to the conformational rearrangements peculiar to this state.

In the case of amorphous-crystalline high-density polyethylene, the reduced φ'_{cl} value was used; this parameter characterises φ_{cl} with respect to the whole polymer bulk rather than to the amorphous phase alone

$$\varphi'_{cl} = \frac{\varphi_{cl}}{1 - k}, \quad (107)$$

where k is the degree of crystallinity.

The relation modified for the case of amorphous-crystalline polymers is represented by Eqn (53). Using Eqns (53) and (23), one can elucidate the relationship between d_f and φ_{cl}

$$d_f = d - 5.98 \times 10^{-10} \left(\frac{\varphi_{cl}}{C_\infty S} \right)^{1/2}, \quad (108)$$

where S is expressed in $\text{\AA}^2$.

As has been shown above, Eqn (45) provides the minimum values for the fractal dimension of structure ($d_f^\dagger$) possible for a given polymer, which are in good agreement with the d_f^0 values (see Table 1). Hence, by substituting $d_f^\dagger$ or d_f^0 into Eqn (108), one can estimate the limiting degree of local ordering (φ_{cl}^0) possible for a given polymer as a function of the most important molecular characteristics of the polymer, C_∞ and S . When the temperature decreases below T_0 (at which the φ_{cl}^0 value is attained), the degree of local ordering does not change; therefore, T_0 can be regarded as an analogue of the temperature T_∞ at which the polymer reaches a constant free volume.^{106, 173, 191, 192} Meanwhile, T_0 can be found from Eqn (104) provided that $\varphi_{cl} = \varphi_{cl}^0$. The T_0 and T_∞ values thus obtained, together with the temperatures of transition to a state with a constant value of density fluctuations T^* ,^{106, 193} for eight polymers are listed in Table 3. It can be seen that T_0 and T_∞ are in good agreement for all polymers except polycarbonate, for which the calculation gave $\Delta T = 670$ K, which has no physical meaning. For real polymers, the tendency towards a thermodynamically more equilibrium state should be counterbalanced at a certain point by the force of chain ‘tightening.’ Therefore, the value $d_f = 2.5$ should be used instead of $d_f^\dagger$. In addition, the value $\varphi_{lp} = 1$ (*i.e.* $\varphi_{cl} = 0$) is attained at $d_f = 2.92$ rather than at $d_f = 3$, as could be suggested in view of Eqn (108). With allowance for these corrections, calculation in terms of Eqn (105) affords $T_0 \approx 318$ K for polycarbonate, which is consistent with the value $T_\infty = 323$ K (see Table 3). The correspondence between T_0 and T^* is poorer than that between T_0 and T_∞ but the patterns of their variation for polymers fully coincide.

Table 3. Temperatures of the transitions to the 'frozen' free volume T_∞ , quasi-equilibrium state T_0 and a constant density fluctuation T^* .

Polymer	T_∞ / K	T_0 / K	T^* / K
Poly(ethylene terephthalate)	280	300	220–250
Polyamide-6	277	304	200
Polyethylene	227	243	140–150
Polypropylene	227	199	210
Polystyrene	324	320	270
Poly(methyl methacrylate)	290	269	250–280
Poly(vinyl chloride)	270	333	220
Polycarbonate	323	318	200–220

The following empirical relation between the change in the specific Gibbs function of the formation of the supermolecular structure ΔG during the self-assembly of the cluster structure and φ_{cl} has been derived¹⁹⁴

$$\Delta G \propto \varphi_{cl}. \quad (109)$$

Substitution of this relation into Eqn (108) gave the expression

$$\Delta G \propto C_\infty S(3 - d_f)^2. \quad (110)$$

The ΔG value for the supercooled liquid–solid nonequilibrium phase transition has been reported.¹⁹⁵ It follows from relation (110) that $\Delta G = 0$ when $d_f = 3$, *i.e.* when the fractal properties are lost. In other words, the fact that fractal structures are formed only in nonequilibrium processes has been confirmed once again.¹²

4. The possibility of numerical modelling of polymer properties

Little is known about a polymer synthesised from monomers or prepared by curing an oligomer; as a rule, the known data include the trademarks of monomers, oligomers, and curing agents and their ratios. Evidently, in this situation, for example, in the case of network polymers, the main initial parameter — cross-linking density v_s — can be either calculated¹⁵⁴ or determined experimentally.¹⁹² In the latter case, the molecular mass of the chain section between the cross-linking points M_s is calculated using the equation

$$\frac{1}{M_s} = \frac{F_i m}{2W}, \quad (111)$$

where F_i is the functionality of the curing agent, m is the number of moles of the curing agent in the sample, and W is the sample weight.

Comparison of the $T_g(v_s)$ plots for different epoxy polymers for which the v_s values were determined by both methods mentioned above shows that the experimental values are somewhat lower than the calculated ones. This discrepancy can be eliminated by introducing the correction factor C . The discrepancy is due to two reasons; one reason is the use of different batches of epoxy resins and curing agents and the other reason is that the calculation implies completeness of the curing reaction, *i.e.* that the curing agent has been entirely consumed, which does not occur in reality.

Apart from v_s , it is necessary to estimate the cross-section area of the macromolecule S and the length of a real bond in the backbone l_0 . The S value is either taken from reference data (if they do exist) or estimated by comparison with the S value of a linear polymer with a similar chemical structure. For example, the chemical structures of the epoxy resins and polycarbonate are similar because they both are based on bisphenol A. Therefore, the value $S = 0.31 \text{ nm}^2$, determined for polycarbonates, was used for these epoxy polymers.⁷⁶ Experimental estimates have shown⁷¹ that this approximation is correct to within $\sim 5\%$. As regards the l_0 value, it characterises a class of polymers rather than a

particular polymer, which makes its determination easier. Since epoxy resins are heterochain polymers, $l_0 = 0.125 \text{ nm}$.⁷⁶

Using the above parameters, one can estimate the length of the section of a macromolecule between chemical cross-linking points and the distance between chemical cross-linking points.¹⁴ The subsequent stage is to solve a set of three equations with three variables, namely, the characteristic ratio C_∞ and the fractal dimensions of the macromolecule section between chemical cross-linking points D and of the cluster structure d_f . By solving this set of equations, one can find these structural characteristics of the epoxy polymers. After that, the Poisson coefficient should be found from Eqn (23) and the cluster network density V_{cl} should be determined from the relation

$$\mu = 0.5 - 2.98 \times 10^{-10} (V_{cl} l_0)^{1/2}. \quad (112)$$

Finally, the relative portion of clusters is calculated as

$$\varphi_{cl} = \frac{V_{cl}}{V} \quad (113)$$

where V is the polymer volume.

For the loosely packed matrix,⁶⁰

$$\varphi_{lp} = 1 - \varphi_{cl}. \quad (114)$$

Thus, we have obtained a complete set of characteristics of the molecular, topological, and supermolecular levels of the structure of cross-linked polymers, which permits one to model and predict their properties. The properties chosen include three characteristics for applications (elastic modulus E , yield point σ_p and glass transition temperature T_g), which are needed to develop new materials, and three characteristics which are regarded conventionally as theoretical (Grüneisen parameter γ , thermal expansion coefficient α_t and yield strain ϵ).

It should be taken into account that one order parameter (for example, φ_{cl}) is inadequate to describe the structure and properties of an amorphous polymer. It has been shown in relation to linear polymers¹⁹⁶ that the need for a second order parameter is due to the thermodynamic nonequilibrium of the loosely packed matrix. In other words, $f_{iv} \neq f'_{iv}$. Therefore, a second order parameter was introduced for linear polymers, namely, $(f'_{iv} - f_{iv})/f_{iv}$. In the case of cross-linked polymers, the constant contribution to f_{iv} caused by the presence of chemical cross-linking points should be additionally taken into account as f_{iv}^* ($f_{iv}^* = 0.024$, see Refs 70, 185). The use of percolation models¹⁹⁷ results in the relation

$$G \propto \left(\varphi_{cl} - \frac{f'_{iv} - f_{iv}^* - f_{iv}}{f_{iv}} \right)^A, \quad (115)$$

where G is the shear modulus, $A \simeq 1.5$.

Having determined f'_{iv} from relation (70) and f_{iv} from relation (55), one can find the shear modulus and then, using Eqn (44), the elastic modulus.

The relation for determining the yield point derived using relations (23) and (44) has the form

$$\sigma_p = \frac{E(3 - d_f)}{3d_f}. \quad (116)$$

The σ_p value can also be estimated using the equation^{198, 199}

$$\sigma_p = \frac{3^{1/2} G b (l_{st} V_{cl})^{1/2}}{2\pi}, \quad (117)$$

where b is the Burgers vector, determined from the empirical relation¹²⁹

$$b = \left(\frac{52.2}{C_\infty} \right)^{1/2}. \quad (118)$$

The glass transition temperature T_g can be found either using an empirical equation⁷¹ or in terms of the fractal approach to glass transition. This is done either using a general model or a

model which takes into account the stabilising influence of chemical cross-links *via* the factor $v_s^{1/2}$ (see Ref. 200).

The Grüneisen parameter γ can be determined by one of the following methods: calculation in terms of relation (69) using the parameter D_f (equal to D_{fv}), determined previously from Eqn (39); calculation in terms of Eqn (68); or calculation using the relation

$$\gamma = \frac{9\pi^2}{4(S^{1/2} + l_0)(l_{st} V_{cl})^{1/2}} - 0.25. \quad (119)$$

The thermal expansion coefficient a_t can be found from the equation

$$\gamma = \frac{3 + a_t T(3 + a_t T)}{6a_t}. \quad (120)$$

The yield strain ε is found from relation (67) provided that $\varepsilon = \varepsilon_c$.

Thus, the approach making use of the cluster model of the structure of amorphous polymers and fractal analysis provides the possibility of numerical modelling of the structures and properties of network polymers. An obvious advantage of this procedure is the fact that only v_s and S are actually used as calculation parameters. It should be noted that the simplicity of choosing the input data is combined with the strict physical interpretation of these data and, hence, no empirical adjusting coefficients are required.

IV. Experimental determination of the fractal dimension

1. A brief survey of the methods

Various methods are used to determine the fractal dimension,^{61, 201} which can be conventionally divided into two groups: fractographical and physical methods, based on the relationship between the fractal dimension and physical properties. The former group includes the methods of horizontal sections (cut islets),^{202–207} vertical sections,^{13, 208–211} profile Fourier analysis,^{203, 212} decantation, expansion, and cell counting,^{61, 213} similarity transformation,^{214, 215} *etc.* The fractographic methods used to gain fractal information on the irregularity of fractured surfaces make it possible to investigate profiles as horizontal or vertical sections of the surface. This requires additional hypotheses to attain reliability of the relationships between the surface fractal properties and size.^{208, 216, 217}

The main goal of fractographic measurements is to determine the fractal dimension of, for example, chipped (fractured) surface and the limits in which the surface exhibits fractal properties. The main problem is the legitimacy of measuring the fractal dimension of self-affine fractured surfaces. The horizontal profile of a fractured surface can be statistically self-similar but the vertical profile is usually self-affine.^{218, 219} Thus, the horizontal and vertical surface sections have absolutely different scaling characteristics, which need to be estimated using different procedures of measurements.

In the case of statistically self-similar horizontal contours, any sensible procedure for determination of the fractal dimension should give the same value.⁸⁷ The question is how this fractal dimension is correlated with the fractal properties of the self-affine fractured surface. Self-affine vertical profiles can be characterised by many fractal dimensions, for example, local and global fractal dimensions. The latter are always equal to the topological dimension of the profile, while the local dimensions of the profile irregularities can be represented as exponential functions.²²⁰

The second group of methods comprises various physical methods used most often for fractal analysis of surfaces (mainly, fractured surfaces). They include porometry,^{211, 222} scattering procedures (*e.g.*, small-angle neutron scattering),¹³ optical diffraction methods,^{13, 61, 182, 223} secondary electron emission measurement,¹³ adsorption–desorption measurements (adsorption

probe method),^{13, 224–227} methods of thermodynamics,²²⁸ the deposit experiment method,²²⁹ electro- and thermochemical methods,^{229, 230} NMR measurements of the pore distribution,²³¹ procedures based on the results of mechanical measurements,^{61, 232} *etc.*[§]

2. Small-angle X-ray diffraction

As an example, we shall consider the practical application of one method, small-angle X-ray scattering (SAXS), which is widely used to study the fractal structure of solids.^{227, 233–245} Polymers are mainly studied by this method during cross-linking in solutions.^{233–235} The theoretical grounds of the method have been developed fairly well by now.^{238, 241, 242} The fractal structures of block polystyrene, poly(methyl methacrylate), and polycarbonate have been studied by the SAXS method.¹⁵³ These particular polymers were chosen because they are often used as model systems and, therefore, they are well characterised and because the structures of macromolecules⁷⁶ and, as a consequence, the properties of these polymers are different.²⁴⁴

The use of the SAXS method is based on the characteristic power dependence of the scattering intensity I on the scattering vector

$$I(k) \propto k^{-x}, \quad (121)$$

where x is a Porod index, the interpretation of which depends on the nature of the scattering source

$$k = 4\pi\lambda^{-1} \sin \frac{\theta}{2}, \quad (122)$$

where λ is the X-ray radiation wavelength and θ is the scattering angle.²²⁴

In the case of bulk fractals (*i.e.* structures like polymers), this index coincides with the fractal dimension of the structure d_f .^{224, 242}

For a fractal phase interface with the dimension D_i , the following relation holds:²³⁸

$$I(k) \propto k^{D_i-6}, \quad 2 < D_i < 6. \quad (123)$$

Figure 43 shows the $\ln I(k)$ plots, while Fig. 44 presents the dependences of $\ln I$ on k^2 for the polymers mentioned above.²⁴⁵ Two linear sections present for each polymer of Fig. 43 point to the existence of two regions with different fractal dimensions. These plots differ from the analogous plots for silicates, for which the slope of the $\ln I(k)$ plots increases discretely with an increase in k (which implies the loss of fractal properties), but are similar to the dependences obtained for amorphous chalcogenide films.²⁴² To identify the structural regions responsible for the observed change in the slope, the cluster model for the structure of

§ Experimental methods for determining the fractal dimension are considered in detail, for example, in a monograph.²³⁷

Figure 43. SAXS intensity *vs.* scattering vector k for poly(methyl methacrylate) (1), polystyrene (2), polycarbonate (3).³⁹

Figure 44. SAXS intensity vs. k^2 for poly(methyl methacrylate) (1), polystyrene (2), polycarbonate (3).³⁹

amorphous polymers was used. The region of local order and the sections of macromolecules protruding from it should be considered as the fractal cluster.¹²⁵ The size of this cluster is twice the distance between the regions of local order, and its fractal dimension characterises the structure of the whole polymer, which is a set of generalised fractal clusters. Another structural region is represented by the loosely packed matrix located between the local order regions; all the fluctuation free volume is accumulated in this region. The R_{cl} values for the polymers considered are listed in Table 4. Using the plots presented in Fig. 44 one can calculate the Guinier radii.²⁴⁵ Attention is drawn by the facts that R_G and R_{cl} are close in magnitude and that R_G increases twofold on passing from one linear section to the other (Fig. 43), which corresponds to the transition from R_{cl} to $2R_{cl}$. This suggests that the R_G and R_{cl} values reflect the same structural parameter. The condition for the fractality of particles which scatter X-rays in the range of small angles is known²²⁴ to be represented by the inequality $R_G k \geq 1$.

Table 4. Structural and fractal characteristics of amorphous polymers.

Polymer	R_{Cl}/nm		$d_{\text{fp}} \quad D_{\text{fp}} \quad d_{\text{f}} \quad D_{\text{f}}$				
	$k < 0.028^{-1} \quad k > 0.028^{-1}$						
Polystyrene	4.1	10.0	5.0	2.80	5.12	2.75	5.0
Poly(methyl methacrylate)	3.7	10.0	5.0	2.80	5.20	2.70	4.33
Polycarbonate	3.0	8.0	4.0	2.40	4.40	2.62	3.63

The presence of two R_G values implies the existence of a boundary between fractal structural regions, which can be found from the condition $R_G k \geq 1$. For a fractal cluster with the size $2R_{cl} \approx 7.0$ nm, this corresponds to $k \approx 0.00143$ nm⁻¹ or $\ln k \approx 4.25$, which is the upper limit of fractality of the polymer structure. When $R_G \approx R_{cl} \approx 3.5$ nm, we have $\ln k \approx -3.56$, which is consistent with the $\ln k$ value at which the slope of the plots in Fig. 43 changes.

Thus, the section of the dependence of $\ln I$ on $\ln k$ for $\ln k$ ranging from 4.25 to -3.56 can be associated with the cluster structure of an amorphous polymer and the section for $\ln k > -3.56$ is matched by the loosely packed matrix.

The existence of these boundaries is due to a known feature of real fractals — the fractal behaviour is realised only within a definite scale range. Several ranges have been determined for amorphous solids;²⁴² we shall distinguish two of them which correspond to the k values used. If the size of a cluster of pores[¶] is designated by η_p and the size of a pore is designated by a_p , the

¶ In amorphous polymers, the term ‘pores’ is used in relation to microcavities of free volume and the term ‘cluster of pores’ refers to the loosely packed matrix in which they are concentrated.

dimension of structural elements will be estimated in the following ranges of k . When $k < \eta_p^{-1}$, the dimension of the structure itself is determined, while for $\eta_p^{-1} < k < a_p$, the dimension of the cluster of pores is found. It has been shown¹⁸⁹ that the fluctuation free volume in a polymer is a fractal object, its dimension being equal to the dimension of the regions of localisation of excess energy D_f .²⁴⁶ In other words, D_f characterises the degree of energy excitation of the loosely packed matrix. The dimensions d_f and D_f can be found from relations (23) and (39), respectively.

The d_{fp} values estimated from Eqn (123) with allowance for the slope of the plots shown in Fig. 43 ($\ln k$ is -4.25 to -3.56) are summarised in Table 4. The d_f values found using Eqn (23) are given for comparison. The fact that the values thus obtained are close confirms the validity of this interpretation.

The slope of the plot sections for $\ln k > -3.56$ is close to unity; it cannot be interpreted as the fractal dimension of a structural element if for no other reason than its magnitude. Therefore, Eqn (123) was used to determine the fractal dimension. Comparison of the D_{fp} and D_f values obtained in this way [see Eqn (39)] showed that they are in good agreement (see Table 4). Note that a slope of the order of unity (-0.75 to -0.80) has also been obtained for a similar k range for amorphous chalcogenide films; however, this result was not interpreted.²⁴²

The condition $R_G k \geq 1$ is usually obeyed for larger angles in the small-angle region. However, in the case of relatively large structural elements, the region of fractality and the Guinier region can overlap. Apparently, this overlap also takes place for the polymers under consideration. The range of linearity of the plots shown in Figs 43 and 44 is $(1-3) \times 10^3$ nm⁻¹ and $R_G \approx 10$ nm, i.e. the product $R_G k$ falls in the range from 1 to 3. The overlap of the fractality and Guinier regions may imply a relationship between the fractal dimension d_f and the Guinier radius R_G . This can be demonstrated analytically in the following way. According to the small-angle Guinier approximation, the following relation holds:²⁴⁵

$$I = I_0 \ln \left(-\frac{R_G^2 k^2}{3} \right), \quad (124)$$

while in the range of the Porod large angles, the relation¹⁵³

$$I = C k^{-d_f}, \quad (125)$$

is valid, where I_0 and C are constants. For equal I , there exists a formal relationship between d_f and R_G ¹⁵³

$$d_f = \frac{(R_G^2/3)k - \ln(I_0/C)}{\ln k}. \quad (126)$$

It is noteworthy that this relationship is not obligatory in terms of the cluster model. An increase in R_G means an increase in the distance between the clusters, a decrease in V_{cl} , an increase in μ , and the corresponding increase in d_f , which is reflected by relation (126).

We would like to note yet another important aspect of determination of d_f by the SAXS method. Based on the data of previous publications,^{238, 246} Novikov *et al.*^{167, 182} estimated the d_f values for amorphous vitreous polymers to be 2.0–2.2. In another study,²⁴⁷ polystyrene has been tested at 16 K; as shown above, transfer of this result to the temperature range of about 293 K is improper. Studies of the silicate colloid aggregates^{224, 241, 248} showed that their porosity influences appreciably the d_f value. Thus pressing (i.e. an increase in the density) of samples results in markedly higher d_f ranging from 2.55 to 2.65.²⁴¹ Feder¹³ obtained $d_f = 2.56$ for protein aggregates. These results are in good agreement with the data obtained in terms of Eqn (23) and with the above SAXS data. Therefore, any estimates assuming *a priori*, without sufficient grounds, $d_f \approx 2$ for amorphous vitreous polymers can induce substantial errors, for example, in the calculation of d_s .^{167, 182}

Thus, the SAXS methods make it possible to confirm the fractality of different structural components of amorphous vitreous polymers and to measure their fractal dimensions. The upper limit of the fractal behaviour of polymers, equal to $\sim 2R_{cl}$, is also in good agreement with the estimate of this value reported by Novikov *et al.*¹⁶⁷

V. Conclusion

A feature distinguishing the fractal approach from the physical models of polymer synthesis developed previously is that it takes into account the structure of the macromolecular coil, which determines the polymer structure, and characterises simultaneously the fractal dimension of the coil and the particular mechanism of the coil formation. The results obtained along this line indicate that the growth of macromolecules during the polymer structure formation stops when the macromolecular coil has reached the density of the reaction medium rather than due to exhaustion of the chemical reactants, *i.e.* the reaction is terminated by purely physical factors. This conclusion is impossible in terms of the Euclidean geometry.

Based on fundamental physical principles, the multilevel polymer structure has been described and the equations relating the molecular characteristics, topology, and parameters of the supermolecular structure of polymers are analysed. The application of principles of nonequilibrium thermodynamics and treatment of vitreous polymers as structurally inhomogeneous solids provided understanding of the fact that the mechanical energy applied during deformation is 'pumped' into the loosely packed regions of the polymer and dissipated in the closely packed regions (clusters). The dissipation of mechanical energy induces shear stress in the clusters; the clusters lose their stability, which causes the polymer to yield.

Analysis of the concept of the fluctuation free volume in a vitreous polymer has shown that it possesses fractal properties; hence, the microcavities composing this volume can be modelled by a D_{fr} -dimensional sphere. The microcavity size is restricted by the volume in which the energy of thermal fluctuations needed for their formation is accumulated. It is shown that 'stretching' of macromolecules hampers an increase in the degree of ordering. When the thermodynamic forces inducing these effects are counterbalanced, the polymer reaches a certain quasi-equilibrium state, which is explained by a density fluctuation above a particular temperature below the glass transition temperature. The introduction of the concept of the quasi-equilibrium state of polymers provides a better understanding of several experimental findings.

The results of modelling the polymer structure using percolation and aggregation theory showed that the structure formed at the glass transition temperature is a percolation cluster. Glass transition is assumed to be a phase transition. The fractal dimension of these structures is determined by the disorder generated by deterministic chaos. Simultaneously, it was shown that the polymer structure can be modelled by a modified model of the diffusion-limited irreversible aggregation. The superposition of the cluster volume-temperature curves for amorphous and amorphous-crystalline polymers and the relationship between fractality and local order in the structure of vitreous polymers were described within the framework of the cluster model resorting to the percolation theory. The importance of calculation of the properties of polymers is demonstrated by presenting a procedure based on the cluster model of the amorphous state structure and fractal analysis. This procedure allows one to perform numerical modelling of properties of, for example, cross-linked polymers. An obvious advantage of this method is the simplicity of choosing the input data in combination with strict physical interpretation and the absence of adjusting coefficients.

This brief survey of the methods of determination of the fractal dimension and the practical application of the SAXS procedure for determining the fractal dimension demonstrates

the prospects for using the fractal approach for the investigation of the structure and properties of polymers.

VI. Vibrational spectra of ternary oxides	558

Abstract. Phase relations in the subsolidus region are considered for 54 ternary systems including $M_2O_3-V_2O_5-R_2O_5$, $Y_2O_3(La_2O_3, Sc_2O_3)-Nb_2O_5-Ta_2O_5$, $M_2O_3-B_2O_3-R_2O_5$, $M_2O_3-Ga_2O_3-R_2O_5$, $Al_2O_3-V_2O_5-R_2O_5$ (where M is a rare-earth element and $R = \text{Ta, Nb}$). The criteria determining the formation of ternary oxide compounds were found to include the cation sizes and the ratios between the radii of the ions constituting the anionic part of the compounds. The crystal-chemical characteristics are presented for MR_2VO_9 , $LaRB_2O_7$, La_4VBO_{10} , Ln_7VBO_{17} ($Ln = \text{La, Pr, Nd}$), $La_3Ga_{5.5}R_{0.5}O_{14}$. The vibrational spectra of polycrystals of ternary compounds and solid solutions based on them are described in detail. The bibliography includes 154 references.

I. Introduction

One of the primary tasks of chemistry is the development and creation of new materials. Simple and complex oxides have found very wide use in many branches of industry. Synthesis of new materials based on complex oxides and the improvement of existing technologies for the production of these materials are based both on the study of the phase diagrams of oxide systems and on fundamental investigations into the 'composition-structure-properties' relationships.

Owing to the vast diversity of their properties, complex oxides of V, Ta, Nb and elements of the Group III of the Periodic Table are of special interest. For example, oxide crystals of Group III and VB elements are used as photo-, cathodo- and X-ray active luminophores. A topical task is the search for medical and luminescent materials that possess new spectroscopic parameters which might be expected among compounds of transition elements.

For instance, efficient tantalum-based X-ray active luminophores have acquired ever growing importance in recent years.^{1–3} They possess higher specific density $[(7.5–9.7) \times 10^3 \text{ kg m}^{-3}]$ than other X-ray active luminophores used in common practice and a number of other advantages allowing the production of intensifying X-ray screens with higher resolution and speed. This

makes it possible to decrease significantly the radiation dose that affects the patients during X-ray examinations, a feature especially important for X-ray diagnostics of children.

Rare-earth element (REE) tantalates are crystals which efficiently absorb X-ray radiation with a quantum energy from 10 to 150 keV and are widely used in medicine. Complex tantalum-containing REE oxides are used as novel X-ray contrast agents (RCA) that are precipitated on body tissues and absorb X-ray radiation. This enhances contrast, which allows one to perform more accurate diagnostics at lower irradiation doses absorbed by the patient.^{4–8} The physicochemical properties of these compounds have not been studied sufficiently yet. Studies of the phase diagrams of complex oxides and their solid solutions used as RCA will aid in filling this gap.

Compounds of the general formula MR_2VO_9 exist in ternary systems $M_2O_3-V_2O_5-R_2O_5$ ($M = \text{REE}$; $R = \text{Nb, Ta}$).⁹ Based on these compounds, a new type of complex-oxide phosphor crystal has been developed. Synthesis of these compounds is accompanied by spontaneous formation of optical centres VO_4^{4-} owing to which the crystals of MR_2VO_9 possess narrow-band luminescence, predominantly in the red region of the spectrum. These phosphor crystals have an unusual temperature dependence of irradiation: the intensity of red luminescence of the centres increases on heating, whereas that of the support is quenched.¹⁰ This effect contradicts the law of thermal luminescence quenching and has not been rationalised yet.

A physicochemical substantiation of the properties of complex oxides listed above requires primarily a detailed study of the regularities of their formation by considering phase relations in ternary systems. The types of phase diagram often vary for REE-containing systems:¹¹ purely eutectic systems exist in equilibrium with chemical compounds. In addition, one or several compounds can exist only for some of the elements rather than for the entire REE series. As a result, isostoichiometric series are formed which are grouped in complete or incomplete morphotropic and isostructural series. The change in the type of phase diagrams of ternary systems depending on the nature of the REE is shown below.

The purpose of this review is to generalise data on the phase relations in ternary[†] oxide systems of Group III and VB elements

[†] The phase composition of restriction-type binary systems, viz., $M_2O_3-R_2O_5$ ($M = \text{B, Al, La, Y, Sc, Ln}$; $R = \text{Ta, Nb, V}$), $M_2O_3-B_2O_3$ ($M = \text{La, Y, Sc, Ln}$), $La_2O_3-Ga_2O_3$, $V_2O_5-R_2O_5$ ($R = \text{Ta, Nb}$), $Ta_2O_5-Nb_2O_5$, as well as the chemistry of the compounds formed from them have been described in detail elsewhere.^{12–82}

in a subsolidus region, to reveal the regularities of the formation of ternary oxide systems and to analyse their vibration spectra. The vibration spectra not only provide information on the structure of the crystal lattices of ternary compounds but also make it possible to predict the luminescent properties of phosphor crystals. Based on the analysis of vibration spectra with the use of the concept of elementary lattice excitations (phonons), one can make conclusions on the filling of the energy gaps between the excited states of optical centres and describe the processes responsible for the excitation energy transfer in phosphor crystals.

II. Phase relations in $M_2O_3 - V_2O_5 - Ta_2O_5$ systems ($M = \text{REE}$)

Figure 1[†] shows phase relations in tantalum-containing $M_2O_3 - V_2O_5 - Ta_2O_5$ systems in a subsolidus region up to 1200 °C.^{83–98} For each REE, ternary oxides with the composition MTa_2VO_9 (henceforth referred to as vanadatotantalates) were found in these systems. When a mixture of the starting compounds is heated, thermodynamic equilibrium is established faster the higher the temperature. Under isothermal sintering conditions at temperatures > 1100 °C, the $M_2O_3 - V_2O_5$ systems are equilibrated in 6–8 h, while the $M_2O_3 - Ta_2O_5$ systems require 30–70 h (for comparison: the equilibrium in the $M_2O_3 - Ta_2O_5$ system at 900 °C is established in > 100 h). It takes more than 10 h to equilibrate the $V_2O_5 - Ta_2O_5$ system.^{18,44} Equilibration of the ternary systems $M_2O_3 - V_2O_5 - Ta_2O_5$ takes approximately the same time as that of the $M_2O_3 - Ta_2O_5$ systems.⁹ Vanadatotantalates decompose above 1200 °C to give the corresponding REE metatantalates and an unknown phase.⁸⁶ In a subsolidus region, all compounds of the ternary system are stable. The difference in triangulation depends only on the existence of certain binary compounds in the $M_2O_3 - V_2O_5$ (up to 50 mol. % M_2O_3) and $M_2O_3 - Ta_2O_5$ systems (50 mol. %–100 mol. % Ta_2O_5).

According to the data of laser radiation second harmonics generation (SHG) measurements, ternary oxides of scandium and cerium subgroup elements can be assigned centrosymmetrical crystals.⁹ X-Ray diffraction data⁹ suggest that the structures of MTa_2VO_9 ($M = \text{La, Y, Pr, Nd, Sm, Eu}$) are close to those of the corresponding tantalates MTa_7O_{19} which possess hexagonal symmetry. For this reason, solid solutions can be formed in the $MTa_2VO_9 - MTa_7O_{19}$ system. Table 1 lists the unit cell parameters for MTa_2VO_9 crystals. It should be noted that YTa_2VO_9 has two crystal modifications conventionally designated as α and β . The α modification is structurally similar to $LaTa_2VO_9$, while the β modification is similar to $ScTa_2VO_9$.

Table 1. Unit cell parameters of hexagonal crystals of MTa_2VO_9 .

M	a^a /nm	c^a /nm	V /nm ³
La	0.6231	1.9573	0.658
Ce	0.6152	0.9932	0.653
Pr	0.6124	1.9831	0.643
Nd	0.6143	1.9864	0.648
Sm	0.6192	1.9723	0.654
Eu	0.6121	1.9812	0.643
Y ^b	0.6189	1.9831	0.655

^a The error of determination is ± 0.0005 nm. ^b The α - YTa_2VO_9 phase.

ters for MTa_2VO_9 crystals. It should be noted that YTa_2VO_9 has two crystal modifications conventionally designated as α and β . The α modification is structurally similar to $LaTa_2VO_9$, while the β modification is similar to $ScTa_2VO_9$.

The structures of vanadatotantalates of scandium and yttrium subgroup elements differ from those of compounds of cerium subgroup elements. The structure of MTa_2VO_9 crystals has not been determined yet.

One can see from Table 1 that the parameters a and c and the unit cell volumes of vanadatotantalates do not depend linearly on the lanthanide ionic radii, as opposed to simple tantalates⁹⁹ and mixed-cation compounds.¹⁰⁰ It is believed⁹⁹ that the decrease in the unit cell parameters of tantalates with the decrease in the REE ionic radii can be explained by a decrease in the degree of covalence of the M–O bond, which changes essentially along the series from scandium to yttrium, lanthanum and from cerium to lutetium. Evidently, other factors are important in the case of vanadatotantalates.

It is well known that REE compounds display periodicity of structural and structure-dependent properties. These properties change non-monotonically for several reasons; the major of these include the energetic and spatial deepening of orbitals, the alteration of the type of exchange interactions between unpaired electrons, spin-orbital stabilisation, the nephelauxetic effect and the stabilising effect of the crystal field.¹¹

Table 1 shows that praseodymium and europium vanadatotantalates have the smallest parameters a and unit cell volumes. Hence, it can be assumed that an additional decrease in the energy of the $4f$ orbitals occurs in $PrTa_2VO_9$ and $EuTa_2VO_9$ due to spin-orbital interaction. This affects the contribution of the f orbitals to the formation of chemical bonds and probably the shape of the coordination polyhedra of these compounds. It is noteworthy that there is a small ‘gadolinium’ inflexion of a values for $LnTa_7O_{19}$ crystals ($Ln = \text{Ce} - \text{Lu}$).¹⁰¹

No sharp changes in the X-ray diffraction parameters are observed in the series $LnTa_2VO_9$ ($Ln = \text{Gd} - \text{Lu}$). These crystals are isostructural, which is corroborated by the data from vibrational spectra (see Section VI).

Some crystal-chemical features of vanadatotantalates were established using NMR spectroscopy.⁸³ In particular, the type of coordination polyhedra formed by oxygen around the vanadium ions was determined. The spectra were assigned using NMR data for known compounds.^{102–106} The spectra for a sample of YTa_2VO_9 were recorded at frequencies of 105.2 and 78.86 MHz without and with magic-angle spinning (MAS). The spectrum consisted of a single line. The magic-angle spinning enabled fairly accurate determination of the isotropic shift. The MAS spectra recorded at two operating frequencies of the spectrometer display quadrupole splitting of the central transition. Figure 2 (curve 1) shows a ⁵¹V NMR spectrum for YTa_2VO_9 measured at 78.86 MHz without consideration of the quadrupole correction $\delta_{\text{iso}} = -665 \pm 2$. The small anisotropy of the chemical shift and the value of δ_{iso} indicate that the vanadium atom is located in an almost regular tetrahedral environment. According to data reported elsewhere,¹⁰⁷ the insignificant distortion of the tetrahe-

[†] Hereinafter, isothermal sections are shown in the phase diagrams.

Figure 1. Phase relations in the $M_2O_3 - V_2O_5 - R_2O_5$ systems ($M = \text{REE}$, $R = \text{Ta, Nb}$).

(1) $M_{12}V_2O_{23}$ ($M = \text{Pr, Nd}$); (2) M_5VO_{10} ($M = \text{Y, Sm, Eu, Er}$); (3) $M_{1.62}V_{0.38}O_{3.38}$ ($M = \text{La, Nd, Eu, Gd, Tb}$); (4) $M_8V_2O_{17}$ ($M = \text{Y, La, Ce-Eu, Dy-Yb}$); (5) M_3VO_7 ($M = \text{La, Nd, Eu}$); (6) $La_{1.42}V_{0.58}O_{3.58}$; (7) M_3RO_7 ($R = \text{Ta, M} \neq \text{Ce}$; $R = \text{Nb, M} \neq \text{Sc, Ce}$); (8) MR_3O_9 ($R = \text{Ta, M} \neq \text{Sc}$; $R = \text{Nb, M} = \text{La-Sm}$); (9) MR_5O_{14} ($R = \text{Ta, M} = \text{La, Ce}$; $R = \text{Nb, M} = \text{La-Nd, Er}$); (10) MR_7O_{19} ($R = \text{Ta, M} \neq \text{Sc, Yb, Lu}$; $R = \text{Nb, M} = \text{La, Ce}$).

Figure 2. ^{51}V NMR spectra of YT_2VO_9 (1), YNb_2VO_9 (2), ScNb_2VO_9 (3), $\text{La}_4\text{VBO}_{10}$ (4).

dron can suggest that one of its oxygen atoms simultaneously belongs to an adjacent VO_4 tetrahedron. The NMR spectrum of the vanadatotantalate GdT_2VO_9 could not be recorded, probably due to quadrupole effects resulting in line broadening.

Thus, it is possible to distinguish a full isostoichiometric series in the LnTa_2VO_9 class of compounds (where Ln indicates lanthanides) existing at normal temperature and pressure. However, this is not a full isostructural series: for $\text{Ln} = \text{Gd}$, there is a morphotropic transition from one structural type ($\text{LnTa}_7\text{O}_{19}$) for $\text{Ln} = \text{Y}$, $\text{La} - \text{Eu}$ to another one for $\text{Ln} = \text{Gd} - \text{Lu}$.

III. Phase relations in the systems $\text{M}_2\text{O}_3 - \text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5$ ($\text{M} = \text{REE}$) and Y_2O_3 ($\text{La}_2\text{O}_3, \text{Sc}_2\text{O}_3$) - $\text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$

Figure 1 shows phase relations in the $\text{M}_2\text{O}_3 - \text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5$ systems in the subsolidus region up to 1100°C (for $\text{M} = \text{Sc}$, up to 1000°C).^{83, 89, 94, 108–114} Compounds with the composition MNb_2VO_9 (henceforth referred to as vanadatoniobates) were found in ternary systems for every M.

Under isothermal annealing conditions at temperatures $> 900^\circ\text{C}$, the time required to establish equilibria in the $\text{M}_2\text{O}_3 - \text{Nb}_2\text{O}_5$ and $\text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5$ systems is the same as in the corresponding tantalum-containing systems. Ternary $\text{M}_2\text{O}_3 - \text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5$ systems come to equilibrium in 30–70 h.⁹ Vanadatoniobates decompose above 1150°C to give ortho- (Sc , Y) and metaniobates (La , Ln) and an unknown phase.⁸⁶ In the subsolidus region, all compounds of the ternary systems are stable.

The structure of vanadatoniobates has not been determined yet. According to SHG measurements, Sc , Y and La vanadatoniobates are centrosymmetrical crystals. It follows from comparison of the X-ray diffraction characteristics of MTa_2VO_9 and MNb_2VO_9 ($\text{M} = \text{Sc}$, Y , La) that ScTa_2VO_9 and ScNb_2VO_9 are isostructural; the structures of vanadatoniobates YNb_2VO_9 and LaNb_2VO_9 differ from each other and from those of vanadatotantalates YT_2VO_9 and LaTa_2VO_9 , respectively.

The structure of vanadatoniobates formed by cerium subgroup lanthanides differs from that of the corresponding vanadatotantalates. Within the series LnNb_2VO_9 ($\text{Ln} = \text{Ce} - \text{Eu}$), the structures of PrNb_2VO_9 and NdNb_2VO_9 are similar and differ from the structures of CeNb_2VO_9 , SmNb_2VO_9 and EuNb_2VO_9 , which have similar lattice symmetry. Probably, as in vanadatotantalates of cerium subgroup elements, the additional decrease in the energy of the f orbitals participating in the chemical bonds in vanadatoniobates of the elements of this subgroup affects the shape of the coordination polyhedra of the crystals.

The structure of vanadatoniobates of yttrium subgroup elements has some specific features. In the X-ray diffraction patterns of compounds in the series $\text{Gd} - \text{Lu}$, the interplanar distance (d) between the most intense reflexions decreases from 0.359 [relative

intensity (I/I_0) 69%] to 0.354 nm (relative intensity 68%) in the case of GdNb_2VO_9 and to 0.350 (relative intensity 100%) in the case of EuNb_2VO_9 . For TmNb_2VO_9 , YbNb_2VO_9 and LuNb_2VO_9 , only one reflexion with 100% intensity and $d = 0.351$ nm is observed. Thus, the vanadatoniobates LnNb_2VO_9 , where $\text{Ln} = \text{Gd}$, Tb , Dy , Ho , Er , are isostructural, and the structures differ from those of compounds with $\text{Ln} = \text{Tm}$, Yb , Lu . This behaviour is probably determined by the Ln^{3+} ionic radius and the degree of covalency of the $\text{Ln} - \text{O}$ bond. It should be noted that the structures of the cerium- and yttrium-subgroup compounds are different. The type of coordination polyhedron of the vanadatoniobate lattice was determined using NMR spectroscopy (see Fig. 2, curves 2,3).⁸³ In polycrystals of YNb_2VO_9 , the V^{5+} ions occupy two non-equivalent crystallographic positions. The isotropic shifts $\delta_{\text{iso}1}$ and $\delta_{\text{iso}2}$ are -665 ± 2 and -604 ± 2 , respectively, without the quadrupole correction. The small anisotropy and the magnitudes of the isotropic shifts suggest that the vanadium atom is located in an almost regular tetrahedral environment and can have one common atom with the adjacent VO_4 tetrahedron. It is of note that compounds YNb_2VO_9 and YT_2VO_9 are not isostructural but have almost similar tetrahedral environments with $\delta_{\text{iso}} = -665$.

Two lines are observed in the ^{51}V NMR spectrum of ScNb_2VO_9 . The use of the MAS technique made it possible to determine the isotropic shifts for these lines: -581 ± 5 (line I) and -603 ± 2 (line II). The presence of two lines in the spectrum suggests that the lattice contains two non-equivalent vanadium ions. The shape of line I implies an axial anisotropy of the chemical shift tensor equal to $\delta_{\perp} = -350$, whereas line II is almost symmetrical. The magnitude of anisotropy, its type and the magnitude of the isotropic shift make it possible to assume that line I belongs to the vanadium ions in a distorted octahedral environment, while line II belongs to the vanadium ions in a slightly distorted tetrahedral environment. The tetrahedral environments in ScNb_2VO_9 and in YNb_2VO_9 ($\delta_{\text{iso}} = -604$) are almost the same. In the vanadatoniobate ScNb_2VO_9 , the VO_4 tetrahedra are linked to each other through one common oxygen atom. The reason for distortion of the VO_6 octahedra is that each VO_6 octahedron has two common oxygen atoms with the adjacent octahedron.¹⁰⁷

Based on the X-ray diffraction characteristics obtained for LnNb_2VO_9 ($\text{Ln} = \text{REE}$), it can be stated that this isostoichiometric series of compounds is not a full isostructural series. Five different structure types exist in the series of LnNb_2VO_4 vanadatoniobates: the first one for $\text{Ln} = \text{La}$, the second one for $\text{Ln} = \text{Pr}$ and Nd , the third one for $\text{Ln} = \text{Ce}$, Sm and Eu , the fourth one for $\text{Ln} = \text{Gd}$, Tb , Dy , Ho , Er and the fifth one for $\text{Ln} = \text{Tm}$, Yb and Lu . Thus, a morphotropy phenomenon is observed.

The $\text{Y}_2\text{O}_3 - \text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$ system.¹¹⁵ Figure 3 presents phase relations in the $\text{Y}_2\text{O}_3 - \text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$ system in a subsoli-

Figure 3. Phase relations in the $\text{Y}_2\text{O}_3 - \text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$ system. (1) $\alpha\text{-Nb}_{2(1-x)}\text{Ta}_{2x}\text{O}_5$; (2) $\beta\text{-Ta}_{2(1-x)}\text{Nb}_{2x}\text{O}_5$.

dus region up to 1350 °C. Solid solutions in this system were studied by optical-immersion analysis. A continuous series of solid solutions with the compositions $Y_3Nb_xTa_{1-x}O_7$ with a probable structure of the pyrochlore type was found in the quasibinary section Y_3TaO_7 – Y_3NbO_7 , and solid solutions of two types were found in the quasibinary section $YTaO_4$ – $YNbO_4$. The first type has the composition $YNb_xTa_{1-x}O_4$ and is based on the fergusonite M' -modification in the concentration range $0 \leq x \leq 0.15$, while the second type has the same composition and is based on the fergusonite M -modification in the concentration range $0.3 \leq x \leq 1$. A mixture of solid solutions of the first and second types is formed in the intermediate region, viz., $0.15 < x < 0.3$. Above 1400 °C, a continuous series of solid solutions with M -fergusonite structure exists in this section.

The La_2O_3 – Nb_2O_5 – Ta_2O_5 system.¹¹⁶ In order to determine the location of the quasibinary sections and to perform the triangulation of the La_2O_3 – Nb_2O_5 – Ta_2O_5 system, physicochemical analysis was used to study the phase composition of 30 points located in various hypothetical sections and regions of the system. Figure 4 presents phase relations in the La_2O_3 – Nb_2O_5 – Ta_2O_5 system in a subsolidus region up to 1250 °C. Various solid substitution solutions were found in the region containing more than 50 mol. % La_2O_3 . The hatched regions 1 and 2 contain solid solutions based on $LaNbO_4$ and La_3NbO_7 , respectively. In addition, a limited series of solid solutions of the general formula $LaTa_{1-x}Nb_xO_4$ ($0 \leq x \leq 0.15$) based on $LaTaO_4$ was found in the $LaNbO_4$ – $LaTaO_4$ section. A continuous series of solid solutions of the general formula $La_3Nb_{1-y}Ta_yO_7$ ($0 \leq y \leq 1$) exists in the La_3NbO_7 – La_3TaO_7 section.

Figure 4. Phase relations in the La_2O_3 – Nb_2O_5 – Ta_2O_5 system. The hatched zones indicate the areas of existence of solid solutions based on $LaNbO_4$ (1) and La_3NbO_7 (2).

The Sc_2O_3 – Nb_2O_5 – Ta_2O_5 system.[§] The phase composition of the system was studied up to 1400 °C; no ternary compounds were found (Fig. 5). A continuous series of solid substitution solutions of the general formula $ScTa_{1-x}Nb_xO_4$ with the wolframite structure exists in the quasibinary section $ScNbO_4$ – $ScTaO_4$.

Figure 5. Phase relations in the Sc_2O_3 – Nb_2O_5 – Ta_2O_5 system.

IV. Phase relations in systems containing B, Al and Ga

The M_2O_3 – B_2O_3 – Ta_2O_5 systems.^{83, 117–119} Figure 6a,b presents phase relations in the Sc_2O_3 – B_2O_3 – Ta_2O_5 and Y_2O_3 – B_2O_3 – Ta_2O_5 systems in a subsolidus region up to 1100 °C. No ternary compounds were found in these systems.

Figure 7 demonstrates phase relations in the La_2O_3 – B_2O_3 – Ta_2O_5 system in a subsolidus region up to 1000 °C. A ternary compound with the composition $LaTaB_2O_7$, which exists in

Figure 6. Phase relations in the Sc_2O_3 – B_2O_3 – Ta_2O_5 (a) and Y_2O_3 – B_2O_3 – Ta_2O_5 (b) systems.

Figure 7. Phase relations in the La_2O_3 – B_2O_3 – Ta_2O_5 system.

§The system was studied by E V Arkhipova (Institute of Solid State Chemistry of the Urals Branch of the Russian Academy of Sciences).

equilibrium with LaBO_3 , $\text{La}(\text{BO}_2)_3$, B_2O_3 , LaTa_3O_9 and LaTaO_4 , was found in the quasibinary section $\text{La}(\text{BO}_2)_3$ – LaTa_3O_9 . Lanthanum boratotantalate decomposes at $\sim 1200^\circ\text{C}$ in accordance with the peritectic reaction

In the M_2O_3 – B_2O_3 systems, thermodynamic equilibrium at temperatures above 1000°C is established in several tens of hours.⁶⁶ The time required to reach equilibrium in ternary systems is even longer, viz., ~ 200 h.⁹ All phases of the systems described above are stable in a subsolidus region.

According to SHG laser irradiation measurements, lanthanum boratotantalate has centrosymmetrical crystals. X-Ray diffraction studies suggest that it has orthorhombic symmetry. The unit cell parameters a , b and c for LaTaB_2O_7 are 1.28692, 1.17562 and 1.13692 nm, respectively; the unit cell volume is 1.72004 nm^3 ; the number of formula units in the lattice (z) is 14; the picnometric density is $6.16 \times 10^3\text{ kg m}^{-3}$.

The coordination of boron in these crystals was studied by NMR spectroscopy.¹²⁰ Figure 8 shows the ^{11}B NMR spectrum of the boratotantalate LaTaB_2O_7 (relative to aqueous H_3BO_3 , magic-angle spinning). The spectrum is a superposition of two doublet components ($\delta = -7.96$ and -21.59) and a narrow central peak ($\delta = -16.53$). The assignment was made using the known literature data (see, e.g., Ref. 121). It was found that the doublet belongs to the boron nuclei located in a trigonal oxygen environment (the quadrupole coupling constant is 2.5 MHz), while the narrow line belongs to the boron nuclei in a tetrahedral environment. It should be noted that the central component in the spectra is shifted by 7 ppm, and the doublet is shifted by 14 ppm with respect to diamagnetic compounds. This is probably caused by paramagnetic admixtures in the samples.

The ternary M_2O_3 – B_2O_3 – Ta_2O_5 systems with the following lanthanides were studied: cerium, praseodymium, neodymium, samarium and europium.^{122,123} No ternary compounds were found in these systems. Figure 9 *a, b* presents phase relations in

Figure 8. ^{11}B NMR spectrum of boratotantalate LaTaB_2O_7 .

Figure 9. Phase relations in the Ce_2O_3 – B_2O_3 – Ta_2O_5 (*a*) and Ln_2O_3 – B_2O_3 – Ta_2O_5 ($\text{Ln} = \text{Pr}, \text{Nd}, \text{Sm}, \text{Eu}$) (*b*) systems.

these systems in a subsolidus region up to 1000°C . It is seen that borates are in equilibrium with lanthanide tantalates.

The M_2O_3 – B_2O_3 – Nb_2O_5 systems.^{83,118,119} These systems, where $\text{M} = \text{REE}$, are similar to the corresponding tantalum-containing ternary systems in many respects. The equilibrium in these systems is also established in ~ 200 h.⁹ No ternary compounds were found in the Sc_2O_3 – B_2O_3 – Nb_2O_5 and Y_2O_3 – B_2O_3 – Nb_2O_5 systems, the phase relations in which in a subsolidus region up to 1000°C are presented in Fig. 10 *a, b*.

Figure 10. Phase relations in the Sc_2O_3 – B_2O_3 – Nb_2O_5 (*a*) and Y_2O_3 – B_2O_3 – Nb_2O_5 (*b*) systems.

More complex phase relations are observed in the La_2O_3 – B_2O_3 – Nb_2O_5 system.^{117,119} The ternary compound LaNbB_2O_7 is formed in this system; this compound exists in equilibrium with LaNbO_4 , LaNb_3O_9 , LaBO_3 , $\text{La}(\text{BO}_2)_3$ and B_2O_3 . The boratonio-bate LaNbB_2O_7 is isostructural to the boratotantalate LaTaB_2O_7 . It decomposes peritectically above 1200°C to give LaNbO_4 and B_2O_3 . Figure 11 shows phase relations in this system in a subsolidus region up to 1000°C . The unit cell parameters a , b and c of LaNbB_2O_7 are 1.2771(5), 1.1722(5) and 1.1223(5) nm; the unit cell volume is 1.679231 nm^3 .

Figure 11. Phase relations in the La_2O_3 – B_2O_3 – Nb_2O_5 system.

The M_2O_3 – B_2O_3 – V_2O_5 systems. The equilibrium in these systems is established in more than 800 h,⁹ which is much longer than in the M_2O_3 – B_2O_3 – R_2O_5 systems ($\text{R} = \text{Ta}, \text{Nb}$).

Figure 12 demonstrates phase relations in the Y_2O_3 – B_2O_3 – V_2O_5 system in a subsolidus region up to 1000°C . No ternary compounds were found in this system.¹²⁴

Figure 13 presents phase relations in the La_2O_3 – B_2O_3 – V_2O_5 system in a subsolidus region up to 900°C .¹²⁵ It was found that lanthanum orthovanadate is in equilibrium with all compounds of the binary systems La_2O_3 – B_2O_3 and B_2O_3 – V_2O_5 except La_3BO_6 . A ternary compound with the composition $\text{La}_4\text{VBO}_{10}$ is formed in this system in the region with high La_2O_3 content; this compound

Figure 12. Phase relations in the Y_2O_3 – B_2O_3 – V_2O_5 system.

Figure 13. Phase relations in the La_2O_3 – B_2O_3 – V_2O_5 system.

is in equilibrium with La_2O_3 , La_3BO_6 , LaBO_3 and LaVO_4 . The melting point of $\text{La}_4\text{VBO}_{10}$ is unknown. According to SHG measurements, this compound has centrosymmetrical crystals.

Figure 2 (curve 4) shows the ^{51}V NMR spectrum of $\text{La}_4\text{VBO}_{10}$ polycrystals. The spectrum is a single line with $\delta_{\text{iso}} = -674$. The magnitude of the quadrupole correction indicates that vanadium is located in a nearly regular tetrahedral environment.¹²⁶ As in vanadatoniobates, the VO_4 tetrahedra can have one common oxygen atom with the adjacent tetrahedra. The signal of the boron nuclei is very weak, probably due to quadrupole effects.

Hence, LaTaB_2O_7 , LaNbB_2O_7 and $\text{La}_4\text{VBO}_{10}$ are merely the first members of the corresponding isostoichiometric series under ordinary conditions. An attempt to obtain compounds of scandium, yttrium and lanthanides with compositions indicated above failed.⁸³

Gokhman *et al.*¹²⁷ synthesised ternary oxides with the composition $\text{Ln}_7\text{V}_2\text{BO}_{17}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$). The samples were obtained in air by multi-step sintering of the starting oxides Ln_2O_3 , V_2O_5 and H_3BO_3 . The temperature of the final sintering step was 1240°C ; the overall sintering time was 30 h. The melting points of the compounds are unknown. Ternary oxides for $\text{Ln} = \text{Sm}, \text{Eu}, \text{Gd}$ and Tb could not be obtained. Table 2 lists the unit cell parameters for the crystals of $\text{Ln}_7\text{V}_2\text{BO}_{17}$, which possess monoclinic symmetry.

Table 2. Unit cell parameters of $\text{Ln}_7\text{V}_2\text{BO}_{17}$ crystals.

Ln	<i>a</i> /nm	<i>b</i> /nm	<i>c</i> /nm	β /deg	<i>V</i> /nm ³
La	0.695(1)	1.786(1)	1.227(1)	99.6(1)	1.501(2)
Pr	0.687(1)	1.747(7)	1.205(3)	99.7(3)	1.425(7)
Nd	0.680(1)	1.723(2)	1.205(1)	99.4(1)	1.392(2)

Figure 14. Phase relations in the Al_2O_3 – V_2O_5 – Ta_2O_5 (a) and Al_2O_3 – V_2O_5 – Nb_2O_5 (b) systems.

The Al_2O_3 – V_2O_5 – R_2O_5 systems. Figure 14a shows phase relations in the Al_2O_3 – V_2O_5 – Ta_2O_5 system in a subsolidus region up to 1350°C , and Fig. 14b shows phase relations in the Al_2O_3 – V_2O_5 – Nb_2O_5 system in a subsolidus region up to 1100°C . The times required to establish equilibria in these systems are the same as those for M_2O_3 – V_2O_5 – R_2O_5 ($\text{M} = \text{REE}$, $\text{R} = \text{Ta}, \text{Nb}$). No ternary compounds were found in these systems.^{9, 128–130}

It was found that the AlTaO_4 phase has two crystal modifications in the section AlTaO_4 – V_2O_5 (see Fig. 14a). In the vicinity of the section point where the concentrations of the components, *i.e.*, Al_2O_3 , V_2O_5 and Ta_2O_5 , are 38 mol.%, 24 mol.% and 38 mol.%, respectively, the AlTaO_4 crystals are isostructural to alumotantite (its formula is $\text{Al}_{0.98}\text{Ta}_{0.99}\text{Nb}_{0.02}\text{O}_4$) with orthorhombic symmetry.¹³¹ In the other points of this section studied, the AlTaO_4 crystals have a structure different from that of alumotantite.¹³² It should also be noted that for all points of this section containing less than 50 mol. % V_2O_5 (except for the point specified above), the diffractograms of freshly prepared AlTaO_4 samples recorded at room temperature contain additional lines. These lines disappear after storage of the samples in air for a month. These reflexions probably originate from structural ordering of AlTaO_4 crystals with involvement of lattice defects.

The AlNbO_4 structure is described in the database of X-ray spectra.¹³³

The M_2O_3 – Ga_2O_3 – Nb_2O_5 (Ta_2O_5) systems ($\text{M} = \text{La}, \text{Pr}$).⁴² The isothermal sections in these systems have not been studied. It was found that the La_2O_3 – Ga_2O_3 – Nb_2O_5 system contains a ternary compound with the composition $\text{La}_3\text{Ga}_{5.5}\text{Nb}_{0.5}\text{O}_{14}$ having the structure of $\text{Ca}_3\text{Ga}_2\text{Ge}_4\text{O}_{14}$ ($a = 0.8218$ nm, $c = 0.5122$ nm; the densities obtained from X-ray estimation and from experimental measurement are 5.934×10^3 and 5.903×10^3 kg m^{−3}, respectively). The compound has a narrow homogeneity range and is stable up to 1450°C .

The compound $\text{La}_3\text{Ga}_{5.5}\text{Ta}_{0.5}\text{O}_{14}$ ($a = 0.8151$ nm, $c = 0.5105$ nm) is formed in the La_2O_3 – Ga_2O_3 – Ta_2O_5 system, and the compounds $\text{Pr}_3\text{Ga}_{5.5}\text{Nb}(\text{Ta})_{0.5}\text{O}_{14}$ exist in the Pr_2O_3 – Ga_2O_3 – Nb_2O_5 (Ta_2O_5) systems. Starting with $\text{M} = \text{Nd}$, no similar compounds isostructural to $\text{Ca}_3\text{Ga}_2\text{Ge}_4\text{O}_{14}$ are formed.

V. Phase formation regularities in ternary systems

It follows from the experimental phase relation diagrams that vanadatoniobates MNb_2VO_9 exist in equilibrium preferentially with compounds which have the structural type of fergusonite, perovskite, zircon, wolframite (ScNbO_4) and with compounds α - $\text{LaNb}_5\text{O}_{14}$ and $\text{MNb}_7\text{O}_{19}$ ($\text{M} = \text{La}, \text{Ce}$). Vanadatotantalates MTa_2VO_9 coexist with such compounds as fergusonite, perovskite, wolframite (ScTaO_4), LaTaO_4 , $\text{MTa}_5\text{O}_{14}$ ($\text{M} = \text{La}, \text{Ce}$) and with compounds of hexagonal symmetry such as $\text{MTa}_7\text{O}_{19}$. All vanadatotantalates and -niobates exist in equilibrium with tetragonal phases such as VR_9O_{25} and RVO_5 ($\text{R} = \text{Ta}, \text{Nb}$). Lanthanum boratotantalate and -niobate LaRB_2O_7 ($\text{R} = \text{Ta}, \text{Nb}$) coexist

Table 3. Ionic sizes (Ref. 134) of Group III and VB elements and ratios of ionic radii.

Ion (1) ^a	Radius (r_1) /nm	Ion (2) ^a	Radius (r_2) /nm	r_1/r_2
B^{3+} (3)	0.01	V^{5+} (4)	0.0355	~ 0.3
		Nb^{5+} (4)	0.048	~ 0.2
		Nb^{5+} (6)	0.064	~ 0.16
		Ta^{5+} (6)	0.064	~ 0.16
V^{5+} (4)	0.0355	Nb^{5+} (4)	0.048	~ 0.74
		Nb^{5+} (6)	0.064	~ 0.55
		Ta^{5+} (6)	0.064	~ 0.55
Ga^{3+}	0.047–0.062 ^b			

^a The numbers in parentheses indicate the coordination numbers. ^b Values for different coordination numbers are given.

with such compounds as perovskite, aragonite, fergusonite, $LaRO_4$ and monoclinic $La(BO_2)_3$, whereas lanthanum boratovanadate La_4VBO_{10} coexists with such compounds as monazite, aragonite and monoclinic La_3BO_6 . All ternary compounds described above exist in equilibrium with simple oxides R_2O_5 ($R = Ta, Nb, V$), B_2O_3 , La_2O_3 .

Solid solutions in the $Y_2O_3-Nb_2O_5-Ta_2O_5$ system coexist with such compounds as fergusonite, pyrochlore, perovskite, Y_2O_3 , R_2O_5 ($R = Ta, Nb$); those in the $La_2O_3-Nb_2O_5-Ta_2O_5$ system coexist with such compounds as weberite, perovskite, $LaTaO_4$ and La_2O_3 , and those in the $Sc_2O_3-Nb_2O_5-Ta_2O_5$ system coexist with such oxides as Sc_3TaO_7 and R_2O_5 ($R = Nb, Ta$).

Thus, it can be stated that ternary phases formed in systems of Group III and VB oxides (except for $La_2O_3-B_2O_3-V_2O_5$) exist in equilibrium with compounds that have the fergusonite and perovskite structural types and with compounds characteristic of each individual system.

It is well known that no theory formulating the phase formation criteria in complex systems exists at present. The phase formation in quasi-binary vanadate systems was analysed by estimation of cation radii and with the use of the spatial-energetical P parameter.⁴⁴

Let us consider the regularities in the formation of mixed crystals for Group III and VB elements depending on the ion sizes and on the ionic radii ratios in ternary compounds (Table 3).

If the ratio of the ionic radius of boron to that of tantalum or niobium is ~ 0.2 , no ternary compounds of lanthanides, scandium and yttrium are formed in the $M_2O_3-B_2O_3-Ta_2O_5$ (Nb_2O_5) systems ($M = Sc, Y, Ce-Lu$). The existence of the starting

Table 4. Ratios of ionic radii in ternary compounds.

Compounds	M	Ion (1)	Ion (2)	r_1/r_2
MR_2VO_9 ($R = Nb, Ta$)	Sc, Y, La–Lu	V^{5+}	R^{5+}	0.55–0.74
MRB_2O_7 ($R = Nb, Ta$)	La	B^{3+}	R^{5+}	0.2
M_4VBO_{10}	La	B^{3+}	V^{5+}	0.3
$M_7V_2BO_{17}$	La, Pr, Nd	B^{3+}	V^{5+}	0.3
$M_3Ga_{5.5}R_{0.5}O_{14}$ ($R = Nb, Ta$)	La, Pr	Ga^{3+}	R^{5+}	0.97

members of the series with $M = La$, viz., $LaTaB_2O_7$ and $LaNbB_2O_7$, can be explained by the fact that the radius of the La^{3+} ion is larger than those of scandium and lanthanides. In the $Al_2O_3-V_2O_5-Ta_2O_5$ (Nb_2O_5) systems, ternary compounds with hypothetical composition $Al_xTa(Nb)_yV_zO_k$ are not formed, either. Probably, the cation radii should also be taken into account in addition to the ionic radii ratios in the anionic parts of the compounds. The ion radius of Al^{3+} is 0.0390 to 0.0535 nm depending on the coordination number; it is smaller than the ion radii of scandium, yttrium, lanthanum and lanthanides. This is probably the reason why ternary compounds are not formed in the $Al_2O_3-V_2O_5-Ta_2O_5$ (Nb_2O_5) systems [unlike in the $M_2O_3-V_2O_5-Ta_2O_5$ (Nb_2O_5) systems ($M = Sc, Y, La-Lu$) where the MR_2VO_9 compounds exist]. In the $M_2O_3-B_2O_3-V_2O_5$ systems ($M = La, Pr, Nd$) at temperatures $> 900^\circ C$, the $M_7V_2BO_{17}$ compounds exist (see Ref. 127), whereas only one compound, namely, M_4VBO_{10} with $M = La$, was found at temperatures $< 900^\circ C$. Hence, one can probably expect the formation of compounds with molecular composition M_4VBO_{10} for $M = Pr$ and Nd .

Thus, the dimension-related criterion for the formation of ternary compounds in oxide systems includes two conditions: (1) the cation radius should be larger than 0.0535 nm; (2) the radii ratios for the ions forming the anionic parts should be greater than 0.2 but smaller than 1. It follows from the data in Table 4 that if the ionic radii ratio is $r_1/r_2 \approx 0.2$, ternary compounds exist only in the case of $M = La$, whereas if this ratio is 0.55–0.74, these exist in the case of $M = Sc, Y, La-Lu$. However, if the radius of the M ion is smaller than that of the Sc ion, ternary compounds are not formed for $r_1/r_2 = 0.55-0.74$ [where $ion(1) = V^{5+}$; $ion(2) = Ta^{5+}, Nb^{5+}$]. In the $M_2O_3-Nb_2O_5-Ta_2O_5$ systems, no ternary compounds with hypothetical composition $M_xNb_yTa_zO_r$ are formed either if $r_1/r_2 = 1$ and $M = Sc, Y, La$.

Thus, the following classification of ternary oxide systems of Group III and VB elements can be made: (1) systems with an equilibrium between the original components and binary compounds; (2) systems where ternary phases are formed. In turn,

Scheme 1

ternary phases can have a constant composition (chemical compounds) or a variable composition (solid solutions). The arbitrary character of this classification is due to the fact that constant composition phases always contain very narrow homogeneity regions which can be neglected. Scheme 1 shows the classification of ternary oxide systems; this classification can apparently be used to predict the existence of phase equilibria, *e.g.*, in the $\text{Ln}_2\text{O}_3\text{--Nb}_2\text{O}_5\text{--Ta}_2\text{O}_5$ and $\text{Ln}'_2\text{O}_3\text{--Nb}_2\text{O}_5\text{--Ta}_2\text{O}_5$ systems, where Ln and Ln' are lanthanides belonging to the yttrium and cerium subgroups, respectively.

VI. Vibrational spectra of ternary oxides

Using NMR spectroscopy in MR_2VO_9 ($R = \text{Ta}, \text{Nb}$) and $\text{La}_4\text{VBO}_{10}$ crystals, the VO_4 and VO_6 anionic groups were revealed; they are generally linked through one or two oxygen atoms with the adjacent VO_4 or VO_6 groups, respectively. The LaTaB_2O_7 crystals were shown to contain BO_3 triangles. Thus, one of the goals in the analysis of the vibrational spectra of ternary oxides is to determine whether the anionic part of a compound is a united complex anion or it consists of anionic groups.

1. MTa_2VO_9 crystals

The IR spectra of the MTa_2VO_9 crystals, where M indicates cerium subgroup elements, contain narrow intense bands in the range of $430\text{--}437\text{ cm}^{-1}$, whereas the remaining bands in the spectrum are broad and have medium intensity. The band positions in the range of $600\text{--}900\text{ cm}^{-1}$ depend on the nature of the M^{3+} ion: the vibration frequencies are shifted to the long-wave region with a decrease in the ionic radii in the series Ce–Eu (Fig. 15). It is well known that a decrease in the ionic radius increases the covalence of bond between a lanthanide ion and the environment and enhances the effect of the crystal field,¹¹ hence these bands can originate from the stretching vibrations of the Ta–O bonds involving the M–O bonds. The shape of the IR spectra of MTa_2VO_9 crystals, where M indicates yttrium subgroup elements, depends on the nature of the metal and changes non-monotonically (Fig. 16).⁸⁸

The most significant differences between the spectra of MTa_2VO_9 , where M indicates yttrium and cerium subgroup elements, are observed in the region of $200\text{--}500\text{ cm}^{-1}$, which probably corresponds to the deformation vibrations of the lattice polyhedra. The IR spectra of LaTa_2VO_9 (Fig. 17, spectrum 1) and ScTa_2VO_9 (Fig. 17, spectrum 3) are similar to the spectra of MTa_2VO_9 , where M indicates yttrium and cerium subgroup elements, respectively. Replacement of 50% of yttrium in YT_2VO_9 by europium stabilises the α -phase, and the IR spectrum of the solid solution $\text{Y}_{0.5}\text{Eu}_{0.5}\text{Ta}_2\text{VO}_9$ (Fig. 17, spectrum 2)

Figure 15. IR spectra of MTa_2VO_9 , where M = Ce (1), Pr (2), Nd (3), Sm (4), Eu (5).

Figure 16. IR spectra of MTa_2VO_9 , where M = Gd (1), Tb (2), Dy (3), Ho (4), Er (5), Tm (6), Yb (7), Lu (8).

Figure 17. IR spectra of LaTa_2VO_9 (1), $\text{Y}_{0.5}\text{Eu}_{0.5}\text{Ta}_2\text{VO}_9$ (2) and ScTa_2VO_9 (3).

resembles that of LaTa_2VO_9 . Tables 5–8 list the frequencies of vibrational spectrum maxima for compounds of the general formula MTa_2VO_9 ($M = \text{Sc}, \text{Y}, \text{La--Lu}$). The bands in the regions of $865\text{--}900$, $790\text{--}835$, $455\text{--}485$ and $370\text{--}385\text{ cm}^{-1}$ can probably be assigned to the ν_1 , ν_3 , ν_4 and ν_2 vibrations of the VO_4 tetrahedra, respectively, while the bands in the regions of $910\text{--}930$, $580\text{--}710$ and $430\text{--}455\text{ cm}^{-1}$ can be assigned to the ν_1 , ν_3 and ν_5 vibrations of the TaO_6 octahedra, respectively. Only the most intense lines in the Raman spectra of LaTa_2VO_9 and TbTa_2VO_9 were recorded.[¶] The Raman spectra of the vanadotantalates CeTa_2VO_9 and ScTa_2VO_9 could not be recorded, probably due to strong absorption of radiation.

The Raman spectra of MTa_2VO_9 , where $M = \text{Pr}, \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}, \text{Dy}, \text{Tm}, \text{Yb}, \text{Lu}$, in the region of $780\text{--}1000\text{ cm}^{-1}$ are similar (Fig. 18–20): each of them contains an intense line at $855\text{--}900\text{ cm}^{-1}$ and two lines around $780\text{--}835\text{ cm}^{-1}$. The differences between the spectra of the compounds containing cerium and yttrium subgroup elements are mostly observed in the range below 780 cm^{-1} . The Raman spectra of the vanadotantalates HoTa_2VO_9 and ErTa_2VO_9 differ from those described above (see Fig. 19, spectra 2 and 3). The spectrum of HoTa_2VO_9 was recorded using argon laser excitation (excitation with a helium–neon laser results in a weak vibrational spectrum at the background level). It contains a group of narrow high-intensity lines at

[¶]All Raman spectra were recorded with excitation by a helium–neon laser ($\lambda = 632.8\text{ nm}$) unless stated otherwise.

contains a group of intense lines in the region of $340\text{--}455\text{ cm}^{-1}$. Probably, resonance phenomena involving virtual states due to diffusion of laser light near the $^4\text{F}_{9/2}$ state of the Er^{3+} ion also occur in this case. Similar phenomena were reported for the $^7\text{F}_0$ state of the Eu^{3+} ion and the $^4\text{I}_{9/2}$ state of the Nd^{3+} ion in $\text{EuTa}_7\text{O}_{19}$ and LnTaO_4 crystals ($\text{Ln} = \text{Nd}$, Eu).¹³⁵

The empirical assignment of frequencies in the vibrational spectra of YTa_2VO_9 is based on the fact that its lattice contains almost regular VO_4 tetrahedra.^{136,137} The region of the stretching vibrations of these tetrahedra [$730\text{--}900\text{ cm}^{-1}$, cf. the assignment of the stretching vibration frequencies of VO_4 tetrahedra^{138,139} for the $[\text{VO}_4]^{3-}$ ion and for the $\text{Na}_3\text{M}(\text{VO}_4)_2$ compounds, where

$\text{M} = \text{Sc}$, Y , La – Lu] displays quite a few maxima (see Table 8), which may be due to vibrations of VO_4 groups linked through one oxygen atom.

The tantalates $\text{MTa}_7\text{O}_{19}$ ($\text{M} = \text{La}$, Ce) with the structures similar to that of YTa_2VO_9 are characterised by the presence of distorted TaO_6 octahedra. Probably, the structure of MTa_2VO_9 also contains distorted TaO_6 octahedra. The presence of vanadium-based polyhedra in the lattice of vanadatotantalates primarily results in variation of the frequencies originating from internal vibrations of the TaO_6 octahedra (ν and δ for $\text{Ta}-\text{O}$ and $\text{Ta}-\text{O}-\text{Ta}$) and in elongation of the bonds in the octahedra

Figure 20. Raman spectra of MTa_2VO_9 , where $\text{M} = \text{Tm}$ (1), Yb (2), Lu (3), and the Raman spectrum of vanadatotantalate YTa_2VO_9 (4).

accompanied by a decrease in the vibration frequencies of the Ta–O terminal bonds.

Some frequencies in the spectra of YTa_2VO_9 were assigned to vibrations of distorted TaO_6 octahedra (see Table 8 and the frequency assignment in Refs 140 and 141). The spectra of orthovanadates MVO_4 and the assignment of the vibration frequencies of VO_4 tetrahedra have been documented.¹⁴² For example, the frequencies for YVO_4 are as follows: $\nu_1 = 888$, $\nu_2 = 376$, $\nu_3 = 836.8$, $\nu_4 = 487 \text{ cm}^{-1}$. Taking into account the line shapes in the Raman spectrum of the vanadatotantalate YTa_2VO_9 , some of the lines were assigned to the vibration frequencies of the VO_4 tetrahedron: $\nu_1 = 885$, $\nu_2 = 375$, $\nu_3 = 830$, $\nu_4 = 485 \text{ cm}^{-1}$. It is well known that for some tetrahedra, such as VO_4^{3-} , ReO_4^{3-} , FeO_4^{2-} , RuO_4^{2-} , FeO_4^{2-} ,¹⁴³ and for MTa_2VO_9 the frequency ν_3 is smaller than ν_1 .

2. MNb_2VO_9 crystals

The structures of MNb_2VO_9 crystals have not been determined. Tables 9–12 list the frequencies of the maxima in the vibration spectra of the vanadatoniobates MNb_2VO_9 ($\text{M} = \text{Sc}$, Y , La – Lu).⁹ The bands at 865 – 890 , 795 – 840 , 470 – 490 and 370 – 385 cm^{-1} can probably be assigned to the ν_1 , ν_3 , ν_4 and ν_2 vibrations of the VO_4 tetrahedra, respectively.

The bands in the IR spectra of these compounds differ in shapes and intensities. For vanadatoniobates of cerium subgroup lanthanides, comparatively intense medium-width bands at 200 – 600 cm^{-1} and one broad band at 600 – 1000 cm^{-1} are observed (Fig. 21). For instance, the NdNb_2VO_9 spectrum has some specific features: the band at 828 cm^{-1} is particularly intense. In the spectra of MNb_2VO_9 , where $\text{M} = \text{Ce}$, Pr , Sm , Eu , this band is less intense and is shifted from 828 cm^{-1} towards

Figure 21. IR spectra of MNb_2VO_9 , where $\text{M} = \text{Ce}$ (1), Pr (2), Nd (3), Sm (4), Eu (5).

higher or lower frequencies. Such frequency shifts are less pronounced in the deformation vibration region. The IR spectra of yttrium subgroup compounds are similar: the frequency region characteristic of deformation vibrations displays comparatively intense medium-width bands; the stretching vibration bands merge into one broad band (Figs 22, 23). It should be noted that the IR spectra of LaNb_2VO_9 (Fig. 24, spectrum 1) and vanadatoniobates of yttrium subgroup elements are similar to the spectra of vanadatoniobates of cerium subgroup elements. The spectra of YNb_2VO_9 and ScNb_2VO_9 (Fig. 24, spectra 2, 3) mainly differ in the intensity of the absorption bands. It is noteworthy that for compounds with $\text{M} = \text{Gd}$, Tb , Dy , Ho the broad band in the region of deformation vibrations splits into two narrow bands at

260–270 cm^{-1} . This can be due to distortion of the polyhedra formed by the M^{3+} ions ($\text{M} = \text{Gd, Tb, Dy, Ho}$). The positions of certain bands depend on the nature of the M^{3+} cation: the decrease in the ionic radii in the Ce^{3+} – Lu^{3+} series is accompanied by a shift of the band at 420 cm^{-1} to 412 cm^{-1} (Ho^{3+} is an exception). This may originate from an increase in the covalency of the bond of the lanthanide with the environment and enhancement of the crystal field effect as the M^{3+} ionic radius decreases. The Raman spectra could be recorded only for the compounds with $\text{M} = \text{La, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er}$; only the most intense lines were recorded for NdNb_2VO_9 . In the spectra of lanthanum, praseodymium, samarium and gadolinium vanada-

toniobates, the most intense narrow band is shifted from 850 to 880 cm^{-1} (Fig. 25). Similarly, the decrease in ionic radius in the series La^{3+} , Pr^{3+} , Sm^{3+} , Gd^{3+} results in displacement of the relatively broad band at 670 cm^{-1} to 685 cm^{-1} . The pair of lines at 650 and 690 cm^{-1} in the spectrum of HoNb_2VO_9 has the highest intensity (Fig. 26, spectrum 2). This is probably due to the resonance enhancement of the Raman spectrum upon helium–neon laser excitation of the holmium ion near the $^5\text{F}_5$ state. The enhancement of the line at 940 cm^{-1} occurs due to resonance effects, viz., laser light scattering near the $^4\text{F}_{9/2}$ state of the erbium ion in ErNb_2VO_9 . The bands at 850–880 and 670–690 cm^{-1} in the spectra of vanadatoniobates, like those in the case of vanada-

totantalates, originate from the stretching vibrations of the $\text{Nb}-\text{O}$ bonds involving the $\text{M}-\text{O}$ bonds.

NMR data were used for empirical assignment of certain frequencies in the vibrational spectra of MNb_2VO_9 . In the vanadatonibate YNb_2VO_9 , vanadium occupies two non-equivalent regular tetrahedral positions; the vanadium environment in one of them coincides with the tetrahedral environment of

**Figure 25.** Raman spectra of MNb_2VO_9 , where $\text{M} = \text{La}$ (1), Pr (2), Sm (3), Gd (4).**Figure 26.** Raman spectra of MNb_2VO_9 , where $\text{M} = \text{Tb}$ (1), Ho (2), Dy (3), Er (4).

vanadium in the vanadatotantalate YT_2VO_9 . In ScNb_2VO_9 crystals, vanadium occupies two non-equivalent crystallographic positions: one position corresponds to a distorted octahedral environment while the other corresponds to a slightly distorted tetrahedral environment; the type of the VO_4 tetrahedra in ScNb_2VO_9 is similar to one of the types of tetrahedron in YNb_2VO_9 . The YNb_2VO_9 and YT_2VO_9 compounds have different structures. On the other hand, YNb_2VO_9 and ScNb_2VO_9 have niobium-formed polyhedra of the same symmetries.

The IR and Raman spectra of the vanadatonibates MNb_2VO_9 , where $\text{M} = \text{Sc, Y, La}$, are virtually similar and mostly differ in the band intensities. Therefore, the structures of MNb_2VO_9 are likely to contain the same set of polyhedra, namely VO_4 , VO_6 and NbO_m ; the structural difference between these compounds is that the polyhedra in the lattices of MNb_2VO_9 crystals are connected in different ways. The existence of vanadium polyhedra in YNb_2VO_9 and ScNb_2VO_9 was established reliably; probable assignment of bands in the IR spectra of these compounds was made on this basis (see Table 12).^{138, 140, 144, 145}

The majority of lines in the Raman spectra of MNb_2VO_9 are broadened. This implies that the lattice atoms occupy non-equivalent crystallographic positions and form several types of similar polyhedra with different symmetries. The lines in the Raman spectra of MT_2VO_9 crystals are less broadened, hence the MT_2VO_9 structure has fewer non-equivalent atomic positions.

As in the case of vanadatotantalates, certain frequencies in the Raman spectra of vanadatonibates were assigned based on the intensities, shapes and positions of particular lines. Comparison of these data with those for MVO_4 orthovanadates (see Refs 146, 147) resulted in the assignment given in Tables 9–12 ($\nu_3 < \nu_1$, as in the case of MT_2VO_9).

The changes in the ν_1 and ν_3 frequencies in the Raman spectra of MT_2VO_9 and MNb_2VO_9 polycrystals were analysed (see Ref. 9). The spectral lines are sufficiently narrow, hence it is quite reasonable to construct various functional dependences for them. Figure 27 presents the dependences of the ν_1 and ν_3 frequencies in the Raman spectra of LnTa_2VO_9 and LnNb_2VO_9 on the atomic number (z) and the ionic radius (r_{Ln}) of Ln^{3+} (the ionic radii were taken from Ref. 134). The ν_1 frequency is given only for LnTa_2VO_9 crystals. Figure 27a clearly shows the scatter of experimental points near the straight line drawn using the least-

Figure 27. Dependence of vibration frequencies ν_1 and ν_3 of VO_4 tetrahedra on the atomic number in LnTa_2VO_9 (a) and the Ln^{3+} ionic radius in LnTa_2VO_9 (1, 2) and LnNb_2VO_9 (3) (b). The experimental points refer to the frequencies ν_1 (1, 3) and ν_3 (2); the calculated curves are drawn for the frequencies ν_1 (solid line) and ν_3 (dashed line).

squares method. The ν_1 frequency for the LnTa_2VO_9 compounds increases as the lanthanide atomic number changes in the series Pr–Lu. This phenomenon can be explained by the lanthanide contraction. The scatter of ν_1 values around the straight line is different for different lanthanides. The greatest deviations are observed for Tb, Nd and Lu. It is well known that non-uniform spreading of f orbitals, which depends on z and originates from spin-orbital coupling, is superimposed on the lanthanide contraction.¹¹ This effect might explain the scatter of ν_1 for the compounds under consideration. Figure 27b shows the same kind of scatter of experimental data and an increase in ν_1 and ν_3 with a decrease in the Ln ionic radius; in addition, the straight lines have sharp breaks around $r_{\text{Ln}} = 0.094$ nm (the ionic radius of Gd^{3+}). The dependences of other properties in the series of f elements are also characterised by similar breaks.¹¹ As shown by Muck *et al.*,¹⁴⁸ the $\nu_1(\text{VO}_4)$ frequency in the IR spectra of $\text{Y}(\text{PO}_4)_x(\text{VO}_4)_{1-x}$ mixed crystals increases as x changes from 0 to 0.7. This can be due to the effect on the bond vibrations in VO_4 tetrahedra exerted, for example, by other VO_4 groups.

3. LaTaB_2O_7 , $\text{La}_4\text{VBO}_{10}$, $\text{Ln}_7\text{V}_2\text{BO}_{17}$ crystals and solid solutions based on them

Table 13 lists the frequencies of maxima in the vibrational spectra of solid solutions based on LaTaB_2O_7 . The bands in the regions of 718–720 and 610–620 cm^{-1} can probably be assigned to the ν_2 and ν_4 vibrations of the BO_3 triangles. Frequencies up to

^a Raman spectroscopy data.

1000–1100 cm⁻¹ correspond to the fundamental lattice vibrations of the simple rare-earth element tantalates (see Ref. 141). The vibrations of the B—O bonds occur in the region up to 1400 cm⁻¹ (see Ref. 149). Thus, the frequencies in the region of 1170–1412 cm⁻¹ in mixed-anion crystals probably correspond to vibrations of the B—O bonds in BO₃. The bands in the region of 155–1100 cm⁻¹ belong to the vibrations of groups containing tantalum, boron and lanthanum. The bands at 1170–1270 cm⁻¹ probably arise from ν_3 antisymmetric stretching vibrations of isolated BO₃ triangles.

It is well known that the isolated BO₃³⁻ anion is characterised by vibrations in the region of 1100–1300 (degenerate antisymmetric stretching vibration) and 700–900 cm⁻¹ (nonplanar degenerate deformation vibration). The reduction of boron symmetry in the case of LaBO₃ or the L-modification of SmBO₃ causes the frequency of 940 cm⁻¹ to appear, which corresponds to symmetric stretching vibrations.^{150, 151} Association of anions in rings or chains distorts their structures, which leads to broadening and splitting of bands, overlap of regions of different vibrations and often to a high-frequency shift of the stretching vibration bands. The character and span of frequencies of this group of vibrations in the IR spectra of La_{1-x}Sm_xTaB₂O₇ is not inconsistent with association of borate anions in rings and chains. Comparison of the spectra presented here with the results obtained for REE tantalates provides a reason to assume that the frequencies 600–830 cm⁻¹ include the stretching vibrations of TaO_n polyhedra in addition to the deformation vibrations of the BO₃ groups, whereas vibrations at 200–500 cm⁻¹ can be due to various deformation modes of O—B—O and O—Ta—O. The

Raman spectrum of the boratotantalate LaTaB₂O₇ contains a dominant line with $\nu = 370$ cm⁻¹ (Fig. 28 a). The presence of an intense line in the region of 370–430 cm⁻¹ of the Raman spectrum is characteristic of REE tantalates and comes from the deformation vibration of O—Ta—O.

The IR spectra of La_{1-x}Sm_xTaB₂O₇ solid solutions lack certain frequencies that are present in the spectra of LaTaB₂O₇ (Fig. 28 b); in addition, a series of frequencies appears (see Table 13). This means that replacement of lanthanum ions with samarium ions results in deformation of lattice polyhedra in solid solutions. This probably changes the selection rule of the vibrations. The same is true for the vibrational spectra of La_{1-x}Eu_xTaB₂O₇ solid solutions (see Ref. 152). Table 14 presents the frequencies of maxima in the vibrational spectra of La_{4(1-x)}Ln_{4x}VBO₁₀ solid solutions (Ln = Sm, Eu). According to NMR data, the lattices of the crystals indicated above contain almost regular VO₄ tetrahedra which have one common oxygen atom with the adjacent VO₄ tetrahedra. The IR spectra of the pure compound and its solid solutions are characterised by the presence of three intense absorption bands at 400–600, 650–950 and 1150–1350 cm⁻¹ (see Ref. 153). The spectra of solid solutions lack some frequencies and contain some new frequencies in comparison with the spectrum of La₄VBO₁₀ (Fig. 29 a).

The bands in the region of 480–486 cm⁻¹ can be assigned to the ν_4 vibrations of the VO₄ tetrahedra, while those in the regions of 1275–1280, 941–945, 715–748 and 592–621 cm⁻¹, to the ν_3 , ν_1 , ν_2 and ν_4 vibrations of the BO₃ triangles, respectively.

The Raman spectrum of the (La_{0.09}Sm_{0.01})₄VBO₁₀ solid solution contains five high-intensity lines (Fig. 29 b) and two

Figure 28. Vibrational spectra of LaTaB_2O_7 . (a) Raman spectrum; (b) IR spectrum.

Figure 29. IR spectrum of $\text{La}_4\text{VBO}_{10}$ (a) and Raman spectrum of $(\text{La}_{0.99}\text{Sm}_{0.01})_4\text{VBO}_{10}$ (b).

medium-intensity lines. Using the data for the vibration frequencies of BO_3 groups (see Refs 138, 150), a series of IR bands were assigned to the vibrations of BO_3 borate triangles (see Table 14). It follows from the assignment presented in Table 14 that $\text{La}_4\text{VBO}_{10}$ is a mixed-anion compound. Probably, the La—O

bond in the complex borates in question is essentially ionic, as shown for $\text{LaMgB}_5\text{O}_{10}$, LaBO_3 , etc.¹⁵⁴

The IR spectra of $\text{Ln}_7\text{V}_2\text{BO}_{17}$ contain bands ascribed to deformed BO_3 groups;¹²⁷ in particular, at 1172, 1215, 1310 and 1350 cm^{-1} for $\text{Ln} = \text{Nd}$.

* * *

Thus, the possibility of formation of ternary oxide compounds in ternary oxide systems of Group III and VB elements depends both on the ratio of the ionic radii of elements in the anionic part of the compound and on the cation radius. The vibrations of complex anionic groups in ternary oxide crystals can be interpreted as vibrations of quasi-isolated polyhedra, such as VO_4 , VO_6 and RO_n , and BO_3 triangles. The chemical bonds of solid solutions with complex anions involve the f orbitals, as is evident from the lattice dynamics of these objects. As a rule, ternary compounds decompose to binary ones on heating. This is also characteristic of ternary compounds of other Groups of the Periodic Table. For example, titanoniobates and -tantalates, $\text{LnTiNb}(\text{Ta})\text{O}_6$, undergo peritectic decomposition to give rutile and the corresponding niobates and tantalates, $\text{LnNb}(\text{Ta})\text{O}_4$.¹³ The decomposition products of compounds with mixed cations, e.g., $\text{Ln}_2\text{Ca}_3(\text{BO}_3)_4$ or $\text{LnAl}_3(\text{BO}_3)_4$, contain double borates, viz., LnBO_3 and AlBO_3 .⁶⁶

The data presented in this review can serve as a basis for studies of more complex multicomponent oxide systems, e.g., $\text{M}_2\text{O}_3 - \text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$, $\text{M}_2\text{O}_3 - \text{M}'_2\text{O}_3 - \text{V}_2\text{O}_5 - \text{Nb}_2\text{O}_5 - \text{Ta}_2\text{O}_5$, etc. The use of spectroscopic methods allows one to understand the regularities of the formation of phases and their structures in the systems under consideration.

IV. Syntheses of insect sex pheromones	578

Abstract. Stereo- and regiocontrolled methods for the construction of a (Z)-trisubstituted C=C bond and for the regiospecific introduction of a chiral fragment are exemplified in total syntheses of insect pheromones belonging to (Z)-trisubstituted alkenes. The bibliography includes 113 references.

I. Introduction

In the last two decades, it was found that the biological activities of a series of important natural compounds, such as low-molecular-weight bioregulators, viz., polyprenols, dolichols, antibiotics of a strobilurin family and pheromones of different species of insects, are associated with the presence of a (Z)-trisubstituted alkene fragment in these molecules. In this connection, the problem of the regio- and stereocontrolled synthesis of (Z)-trisubstituted alkenes is of substantial methodological and practical interest. A rather small group of insect pheromones containing this structural fragment represents a 'proving ground' for the elucidation of the synthetic potential of methods developed for the formation of (Z)-trisubstituted C=C bonds. In the total syntheses of these pheromones, all known procedures for the stereoselective construction of (Z)-trisubstituted alkenes were employed. These methods can find use in the preparation of other biologically active compounds. In addition, the approaches developed for the formation of chiral centres are also of obvious interest.

In the present review, methods for the regio- and stereocontrolled construction of (Z)-trisubstituted C=C bonds and the regiospecific introduction of a chiral centre, which are of importance for organic synthesis, are exemplified in total syntheses of pheromones of the above-mentioned group.

We believe that the solution of this problem calls for systematisation of the available data on the syntheses of the target structures, which are ranked in the order of increasing difficulty. Attention will be focussed on procedures for the construction of (Z)-trisubstituted alkene fragments and methods for the formation of chiral centres.

II. Synthesis of the alarm pheromones of the mold mite *Tyrophagus putrescentiae*, the astigmatid mite *Glycyphagus domesticus* and the ant *Oecophylla longinoda*

In the late 1970s, Kuwahara *et al.*^{1,2} demonstrated that neryl formate (**1**) is the alarm pheromone of one of the major pests of cereal crops, viz., the mold mite *Tyrophagus putrescentiae*. Later,³ this conclusion was confirmed by bioassays of synthetic neryl formate (**1**) prepared from nerol (**2**).

Later, Kuwahara and Koshii⁴ have found that neral (**3**), which can also be readily prepared from nerol (**2**), is the alarm pheromone of the astigmatid mite *Glycyphagus domesticus*.

α,β -Unsaturated aldehyde **4**, which is a hexanal dimerisation product, was isolated by Baker and coworkers in 1975.⁵ This is the alarm pheromone of the African weaver ant *Oecophylla longinoda*. Although, in strict accordance with the IUPAC nomenclature, aldehyde **4** is the (E)-isomer, the carbon substituents at the C=C bond are in *cis* positions with respect to each other. Disubstituted α,β -unsaturated aldehydes of this type are precursors of (Z)-methylalkenes. Hence, we believe that it is reasonable to consider the synthesis of the aldehyde **4** in the present review. In 1966, Basavaian and Hyma⁶ synthesised the aldehyde **4** with the use of the Baylis–Hillman reaction⁷ for the regio- and stereoselective construction of its trisubstituted alkene fragment.

Hydroxy ester **5**, which was prepared by the condensation of hexanal with methyl acrylate under conditions proposed by Baylis and Hillman,⁷ was converted into acetate **6**. The reaction of the latter with PrMgBr afforded ester **7** as the only product. Reduction of the ester group and oxidation of the resulting alcohol **8**

N Ya Grigorieva, P G Tsiklauri N D Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky prosp. 47, 117913 Moscow, Russian Federation. Fax (7-095) 135 53 28. Tel. (7-095) 938 36 96. E-mail: ves@carc.ioc.ac.ru

with pyridinium chlorochromate gave rise to the aldehyde **4** (the overall yield was 20.5%).

(a) AcCl, Py; (b) Pr^nMgBr ; (c) Bu_2^iAlH ; (d) PCC (pyridinium chlorochromate), CH_2Cl_2 .

A simpler yet highly stereoselective procedure for the synthesis of the aldehyde **4**⁸ involves condensation of *N*-*tert*-butylhexanimine with hexanal yielding β -hydroxy imine **9**. Acid scission of the latter afforded thermodynamically more favourable⁹ aldehyde (*E*)-**4** in 70% yield (the stereoselectivity was ~ 98%). The aldehyde (*E*)-**4** was also identified by Baker *et al.*¹⁰ as a component of the alarm pheromone of the beetle *Amblypelta nitida*.

(a) Bu^tNH_2 ; (b) LDA (lithium diisopropylamide); (c) $\text{C}_5\text{H}_{11}\text{CHO}$; (d) H_3O^+ .

III. Syntheses of ant trail pheromones

1. Trail pheromones of the fire ant *Solenopsis invicta*

As early as 1959, Wilson¹¹ demonstrated that fire ants produce a special trail pheromone, which allows members of the community to find routes to sources of food, new areas, *etc.*

Van der Meer and coworkers¹² isolated this pheromone, established that it represents a mixture of at least five closely related compounds and separated these compounds by preparative GLC. Based on the results of studies of the physicochemical properties of individual components of this mixture, two compounds were assigned to the α -farnesene series and one compound was assigned to the allofarnesene series. The configurations of the pheromone components were established by comparing the spectral data (UV, ^1H NMR and mass spectra) of natural and authentic samples of α - and allofarnesenes synthesised in an unequivocal way. Thus dehydration of (*Z*)-nerolidol **10** in a POCl_3 -Py system at 160 °C afforded a mixture of isomeric α -farnesenes, (*Z,Z*)- and (*E,Z*)-**11**, and (*Z*)- β -farnesene, (*Z*)-**12**. Dehydration of the isomer (*E*)-**10** under the same conditions gave rise to a mixture of (*E,E*)- and (*Z,E*)- α -farnesenes (**11**) and (*E*)- β -farnesene [(*E*)-**12**].¹²

Based on comparison of the physicochemical characteristics of farnesenes **11** and the components of the fire ant trail pheromone, it was reliably established that the major component of this pheromone has the structure (*Z,E*)-**11** and one of the minor components has the structure (*E,E*)-**11**. It should be noted that α -farnesene (*Z,E*)-**11** was identified as a component of trail pheromones also of other ant species.¹³

With the aim of establishing the stereochemistry of the components of the fire ant trail pheromone belonging to the allofarnesene series, all eight possible isomeric allofarnesenes were synthesised using the Wittig reaction.¹⁴

It appeared that the condensation of ylides **13** and **14** generated from geranyl- and nerylphosphonium bromides, respectively, with tiglic aldehyde (**15**) proceeded stereoselectively to form allofarnesenes (*E,E,E*)-**16** and (*E,E,Z*)-**16**, respectively. To the contrary, the condensation of triphenylphosphonium ethylide **17** with isomeric pseudoionones (*E,E*)-**18** or (*E,Z*)-**18** was non-stereoselective.

The reaction of the isomer (*E,E*)-**18** afforded a mixture of (*E,E,E*)- and (*Z,E,E*)-**16**, whereas the isomer (*E,Z*)-**18** gave a mixture of (*E,E,Z*)- and (*Z,E,Z*)-**16**. The condensation of the (*Z,E*)-pseudoionone, (*Z,E*)-**18**, with the ylide **17** yielded a mixture of (*E,Z,E*)-**16** and (*Z,Z,E*)-**16**, whereas the reaction of the

(Z,Z)-pseudoionone [(Z,Z)-18] with the ylide **17** afforded a mixture of (E,Z,Z)-**16** and (Z,Z,Z)-**16**. Comparison of the spectral properties (UV, ^1H NMR and mass spectra) of the individual allofarnesenes isolated by preparative GLC with those of the third component of the fire ant trail pheromone demonstrated that the latter is the stereoisomer (Z,Z,Z)-**16**. Bioassays of the allofarnesene isomers demonstrated that the compounds (E,Z,E)-, (Z,Z,E)- and (E,Z,Z)-**16** with the (Z)-configuration of the C(4)=C(5) bond exhibit the trail pheromone activity.

The fourth and fifth components of the trail pheromone of *S. invicta* were identified¹⁵ as (Z,E)- and (E,E)-homofarnesenes **19** by comparing the physicochemical characteristics of these pheromone components with those of the compounds (Z,E)-, (E,E)-, (E,Z)- and (Z,Z)-**19**, which have been specially synthesised from nerol or geraniol.

(a) PBr_3 , Py; (b) $\text{MeCH}(\text{SPh})_2$; (c) HgCl_2 ; (d) $\text{H}_2\text{C}=\text{C}(\text{Me})\text{MgBr}$; (e) PCC, CH_2Cl_2 ; (f) $\text{Ph}_3\text{P}=\text{CH}_2$.

2. Trail pheromone of the ant *Leptogenys diminuta*

In 1991, Attygalle *et al.*¹⁶ isolated the trail pheromone of the ants *Leptogenys diminuta*. Based on the results of physicochemical studies, the authors assigned the structure of (Z)-isogeraniol (**20**) to this pheromone. To decide between the (Z)- and (E)-configurations of compound **20**, the retention times (GLC) of the

natural pheromone and the samples of (Z)- and (E)-**20** synthesised from citral enol acetates were compared.

3. Trail pheromone of Pharaoh's ant *Monomorium pharaonis* (faranal)

In 1977, Ritter *et al.*¹⁷ isolated the trail pheromone of Pharaoh's ant *Monomorium pharaonis*, which is a pest of food and a dangerous carrier of wound infections. Based on the results of physicochemical studies, the structure of 3,4,7,11-tetramethyldeca-(6E,10Z)-dienal was assigned to this pheromone named faranal. However, the absolute configurations of the C(3) and C(4) centres in the molecule remained an open question up to 1980 when Kobayashi and coworkers¹⁸ synthesised isomeric aldehydes **21** and demonstrated that only the compound (3S,4R)-**21** exhibited biological activity and, hence, the natural faranal had this configuration.

The key step of the synthesis involved condensation of (2E,6Z)-homogeraniol pyrophosphate **22** with (3E)- or (3Z)-3-methylpent-3-enyl pyrophosphate catalysed by farnesyl-pyrophosphate synthetase leading to chiral pyrophosphates (4S)- and (4R)-**23**, which was in accord with the results obtained previously.^{19,20} These compounds were converted into aldehydes (4S)- and (4R)-**24**, respectively. Selective reduction of the C(2)=C(3) double bond in the aldehydes (4S)-**24** and (4R)-**24** afforded a mixture of the diastereomeric aldehydes (3R,4S)- and (3S,4S)-**21**

PP is $\text{P}_2\text{O}_6\text{H}_3$; (a) $\text{farnesyl-pyrophosphate synthetase}$; (b) alkaline phosphatase; (c) MnO_2 ; (d) Et_3SiH , $(\text{Ph}_3\text{P})_3\text{RhCl}$; (e) H_3O^+ ;

(f) $\text{farnesyl-pyrophosphate synthetase}$

and a mixture of the diastereomers (3*R*,4*R*)- and (3*S*,4*R*)-**21**, respectively. The individual compounds were isolated by HPLC.

Homogeraniol **25** required for the preparation of the pyrophosphate **22** was synthesised²¹ using a reaction sequence in which the key step of chain elongation (*a*) was non-stereoselective and, hence, it was necessary to separate isomers by rectification or chromatography.

(*a*) (EtO)₂P(O)CH₂CO₂Me, MeONa; (*b*) LiAlH₄; (*c*) PBr₃, Py; (*d*) Mg, MeCOCH₂CO₂Me; (*e*) NaOH; (*f*) H₃O⁺.

Generally, the synthesis of faranal [(3*S*,4*R*)-**21**] involves coupling of two building blocks. One of these blocks contains either only (*Z*)-trisubstituted alkene fragments or simultaneously (*Z*)- and (*E*)-trisubstituted fragments, while the second block contains the chiral portion of the molecule. The construction of the blocks of both types and their coupling to form the target faranal molecule [(3*S*,4*R*)-**21**] are considered below.

Mori and Ueda^{22, 23} used an allylic alcohol **26** as the (*Z*)-trisubstituted alkene synthon. Its synthesis involved isomerisation of 3-methylpent-1-en-4-yn-3-ol (**27**) under the action of lithium acetylide and reduction of the triple bond in the alcohol (*Z*)-**28** isolated from its mixture with (*E*)-**28** (the ratio 85 : 15).

(*a*) HC≡CLi, (*b*) NH₂NH₂·H₂O; (*c*) H₂O₂, EtOH.

Baker *et al.*²⁴ performed a highly stereoselective synthesis of the alkene synthon **29** based on the *cis*-addition of organocopper compounds to terminal alkynes (this reaction had been discovered by Corey and Katzenellenbogen²⁵). The reagent **30** was added to the starting propyne to give (*Z*)-homoallylic alcohol **31**. The alcohol **31** was converted into enyne **32** via tosylate. Successive treatment of compound **32** with a cuprate complex **33**²⁶ and iodine gave the target iodide **29** in 33.7% overall yield with a stereoselectivity exceeding 96%.

(*a*) EtCu(Me₂S)·MgBr₂ (**30**); (*b*) PrC≡CLi, , (*c*) TsCl, Py; (*d*) HC≡CLi; (*e*) MeCu(Me₂S)·MgBr₂ (**33**); (*f*) I₂.

An analogous scheme was used in the synthesis of faranal performed by Mori and coworkers.²⁷ They succeeded in increas-

ing substantially the yield in the step of conversion of the enyne **32** into the iodide **29** by applying Wipf's modification²⁸ of carbocationic aluminination.

The synthon **34** was prepared employing the cuprate procedure for the construction of the (*Z*)-alkene fragment of faranal.²⁹

(*a*) **30**; (*b*) BuC≡CLi, H₂C=CHCOMe.

An alternative procedure for the construction of the (*Z*)-trisubstituted alkene fragment was used in the synthesis of bromide **35**, which is a key intermediate in the synthesis of faranal.^{30, 31} Epoxide **36**, which can readily be prepared from benzyl ether of geraniol, was converted into allylic alcohol **37** in high yield. Sharpless's epoxidation of the latter, scission of the epoxy group in the resulting epoxide **38** with lithium dimethyl cuprate and, finally, elimination of the hydroxy groups from diol **39** according to a procedure proposed by Tanaka *et al.*³² afforded benzyl ether **40**. The latter was converted into the bromide **35** according to standard procedures in a yield of 24% with respect to geraniol.

(*a*) *m*-Chloroperbenzoic acid (MCPBA); (*b*) (PrⁱO)₃Al, PhMe; (*c*) BuⁱO₂H, VO(acac)₂; (*d*) Me₂CuLi; (*e*) HC(OMe)₂NMe₂, Ac₂O; (*f*) Li/NH₃; (*g*) PBr₃, Py.

Conversions of the above-described alkene synthon blocks **26**, **29**, **34** and **35** into faranal [(3*S*,4*R*)-**21**] involved their coupling with blocks containing the 3,4-dimethylbutanal fragment. In many cases, an adduct of butadiene with maleic anhydride **41**, which was smoothly converted into *cis*-dimethylcyclohexene (**42**), was used as the starting compound for the preparation of these blocks. The ring-opening in the compound **42** and the transformation of dicarboxylic acid **43** giving rise to the target synthons have been performed in two ways. The path *I*²⁹ involved

Path *I*

(*a*) LiAlH₄; (*b*) MeSO₂Cl, Py; (*c*) KMnO₄, Bu₄NHSO₄, H₂O-PhH; (*d*) EtOH, H₂SO₄, H₂O; (*e*) TsCl, Py; (*f*) LiI, MeCN; (*g*) NaOH; (*h*) Ph₃P, PhH.

oxidation of dimethylcyclohexene **42** with potassium permanganate under conditions of phase transfer catalysis followed by the transformation of the carboxy groups in the dicarboxylic acid **43** to form phosphonium salt **44**.

The path *II*²⁴ involved ozonation of dimethylcyclohexene **42** to form the acid **43**. Its pyrolysis afforded ketone **45** whose Baeyer–Villiger oxidation gave rise to lactone **46** (the total yield was 42.8% with respect to the adduct **41**). Treatment of the lactone **46** with anhydrous HBr in EtOH afforded bromo ester **47**, which was converted into iodide **48** according to standard procedures. The iodide **48** is a synthon for the construction of (±)-faranal.[†]

Path *II*

THP is tetrahydropyran-2-yl; (a) O₃; (b) CrO₃; (c) Ba(OH)₂, Δ; (d) MCPBA; (e) HBr, EtOH; (f) LiAlH₄; (g) 3,4-dihydro-2H-pyran (DHP), TsOH; (h) LiI, MeCN.

The target racemic faranal [(±)-**21**] was synthesised²⁹ by condensation of the ylide generated from the phosphonium salt **44** with the ketone **34**. The resulting 54:46 mixture of isomeric acids (6*E*)- and (6*Z*)-**49** was converted into a mixture of the racemic faranal [(±)-**21**] and its (6*Z*)-isomer through the corresponding ethyl esters and alcohols. The isomer (±)-**21** was isolated from the latter mixture by preparative GLC in 9.1% total yield.

(a) NaH, DMSO; (b) **34**; (c) CH₂N₂; (d) LiAlH₄; (e) PCC, CH₂Cl₂.

To reach the same goal, Baker *et al.*²⁴ used condensation of a lithium derivative **50**, which was prepared from the iodide **29**, with the iodide **48**. This condensation is highly stereoselective. The resulting tetrahydropyranyl ether **51** was converted into the (±)-faranal [(±)-**21**] in a total yield of 18% with respect to the iodide **48**.

(a) Bu^tLi, Et₂O, −90 °C; (b) **48**, Et₂O–THF (1 : 3); (c) H₃O⁺; (d) PCC, CH₂Cl₂.

Mori and Ueda^{22,23} were the first to synthesise natural (3*S*,4*R*)-(+)-**21**. The key step of this scheme involved asymmetric resolution of hydroxy acid (±)-**52**, which was prepared from the lactone (±)-**46**, using treatment with (*S*)-(-)-α-phenylethylamine. Acidification of the resulting salt **53** afforded the lactone (+)-**46** whose (3*R*,4*R*)-configuration was confirmed by conversion into (*R*)-citronellic acid.

(a) NaOH; (b) (*S*)-(-)-α-phenylethylamine; (c) HCl; (d) Bu₂AlH; (e) (EtO)₂P(O)CH(Me)CO₂Et, NaOEt; (f) DHP, TsOH; (g) LiAlH₄; (h) BuLi; (i) TsCl; (j) LiBr, Et₂O–HMPA (hexamethylphosphoric triamide); (k) PhSO₂Na, DMF; (l) BuLi, THF–HMPA, (5*R*,6*R*)-**56**; (m) Li/NH₃; (n) H₃O⁺; (o) TsCl, Py; (p) NaCN, DMSO; (q) NaOH, EtOH; (r) PCC, CH₂Cl₂.

Reduction of (3*R*,4*R*)-**46** into chiral lactol **54** followed by the Horner–Emmons reaction of the latter with triethyl 2-methyl-2-phosphonoacetate afforded hydroxy ester (5*R*,6*R*)-**55**, which was converted into bromide (5*R*,6*R*)-**56** using a sequence of standard reactions. The chiral bromide (5*R*,6*R*)-**56** was condensed with sulfone **57** prepared from the alcohol **26**. Desulfation of the resulting sulfone **58** followed by the replacement of the protective group afforded tosylate (2*R*,3*R*)-**59**, which was the starting product in the final steps of the synthesis of faranal [(3*S*,4*R*)-(+)-**21**] identical with the natural specimen.

[†] Recently, Tolstikov and coworkers³³ have reported an efficient synthesis of methoxymethyl analogues of the compound **48**.

Later, Mori and Murata²⁷ developed a shorter synthetic route to faranal [(3*S*,4*R*)-(+)-21]. The key chiral synthon for this compound, *viz.*, iodide **60**, was prepared in five steps starting from dimethylcyclohexene **42**. The asymmetric resolution of *meso*-epoxide **61** using the lithium derivative of (*S*)-pyrrolidin-2-ylmethylpyrrolidine (**62**) afforded allylic alcohol **63**, which was purified by recrystallisation of the corresponding 3,5-dinitrobenzoate to *ee* ~ 100%. Ozonation of the compound **63**, reduction and protection of the hydroxy groups at C(1) and C(2) in the resulting triol followed by substitution of the hydroxy group at C(6) gave rise to the iodide **60**. Condensation of **60** with 6-ethyl-2-methylhepta-1,5-dienyllithium (**50**) resulted in enantiomerically pure acetal **64**. Hydrolysis of **64** followed by periodate oxidation of the resulting diol gave rise to (3*S*,4*R*)-21 (in a total yield of 12.5% with respect to propyne), which was used for the preparation of the lithium derivative **50**.

The chiral fragment of faranal was constructed also with the use of lactone (3*S*)-**65** formed from methyl hydrogen (3*R*)-3-methylglutarate [(3*R*)-**66**].^{30,31} Enzymic hydrolysis of the dimethyl ester **67** using pig liver esterase (PLE) afforded the ester **66** with an optical purity of 85%. This ester was purified by recrystallisation of 1-cinchonidinium salt to *ee* 100%.

Alkylation of the enolate prepared from lactone **65** with the bromide **35** gave rise to lactone (2*R*,3*S*)-**68** containing ~ 6% of the (2*S*,3*S*)-isomer. Transesterification of the lactone **68** followed by protection of the hydroxy group in the resulting hydroxy ester afforded ester **69** whose methoxycarbonyl group was converted into the methyl group in three standard steps. The resulting tetrahydropyranyl ether **70** was converted into (3*S*,4*R*)-21 in a total yield of ~ 2% with respect to geraniol, which was the starting compound for the preparation of the bromide **35**.

IV. Syntheses of insect sex pheromones

1. Synthesis of sex pheromones of scales

a. Sex pheromone of the California red scale

Roelofs *et al.*^{34,35} isolated the female-produced sex pheromone of the California red scale *Aonidiella auranti*, which is the major pest of citrus crops distributed throughout the tropical and subtropical regions. This pheromone was found to consist of two components. Based on the data of physicochemical studies, it was proposed that these components have structures **71** and **72**.

Due to the deficiency of the isolated natural substance, the absolute configurations of these compounds were established only by comparing the physicochemical characteristics of the pheromone components with those of all possible isomers synthesised starting from (*S*)- and (*R*)-carvone. It was found that only the (3*S*,6*R*)-acetate **71** and the (3*Z*,6*R*)-acetate **72** exhibit the pheromone activity.

The retrosynthetic analysis of the molecule **72** shows that the simplest approach to its construction involves the Wittig reaction between synthon blocks **73** and **74**. This approach was used in the first synthesis of the compound **72**.³⁶

The aldehyde (3*R*)-**73** was prepared by oxidative scission of (*S*)-carvone (**75**) *via* epoxide **76** and diol **77**. Ethoxy lactone **78** prepared from the diol **77** was converted into compound **79** and then into bromide **80** in three standard steps. Treatment of the bromide **80** with vinyl lithium followed by hydrolysis afforded the aldehyde **73**.

(a) H₂O₂, NaOH; (b) HClO₄, H₂O, THF; (c) Pb(OAc)₄, EtOH; (d) HC(OEt)₃, TsOH, EtOH; (e) LiAlH₄; (f) TsCl, Py; (g) NaBr, HMPA; (h) CH₂=CHLi; (i) H₃O⁺; (j) Ph₃P⁺CH(Me)(CH₂)₂OH Br[−] (**81**), 2 equiv. of BuLi; (k) Ac₂O, Py.

The reaction of the aldehyde **73** with ylide obtained from phosphonium salt **81** gave rise to a 52:48 mixture of isomeric alcohols. Separation of a mixture of (3*Z*)- and (3*E*)-acetates **72**

obtained from these alcohols by preparative GLC afforded compound (3Z,6R)-**72** in 2.53% total yield.[‡]

The acetate (3Z,6R)-**72** was also synthesised³⁷ starting from (R)-limonene **82** according to a similar strategy, but using a more efficient procedure. Ozonolysis of limonene **82** yielded oxo acetal **83**, which was converted into enyne acetal **85** through hydroxy acetal phosphate **84** according to Negishi.³⁸ Hydrolysis of the latter yielded aldehyde, which was subjected to hydrogenation to form the diene aldehyde (3R)-**73**. Condensation of the latter with ylide generated by the reaction of (Me₃Si)₂NLi with the phosphonium salt **81** afforded a 2:1 mixture of isomeric alcohols, which were separated by chromatography. Acetylation of the (3Z)-isomer produced (3Z,6R)-**72** in 37% total yield.

A substantial drawback of the above-considered syntheses of the acetate **72** is the non-stereoselectivity of the key step of the construction of the (Z)-trisubstituted C=C bond by the Wittig reaction. Caine and Crews³⁹ have overcome this drawback using another synthetic scheme. It appeared that when treated with the ylide, which was generated from the salt **81** under the action of BuLi in a mixture of THF and HMPA, β-hydroxy α-phenylthio ketone **86** prepared from the oxirane **76**⁴⁰ underwent the retro-aldol reaction followed by the Wittig olefination to form alcohol (3Z)-**87**. This compound did not contain an admixture of the (3E)-isomer but was contaminated with desmethyl analogue **88** (~15%). The resulting mixture was converted into a mixture of the corresponding acetoxy sulfoxides from which sulfoxide **89** was isolated by chromatography. Thermal desulfinylation of the sulfoxide **89** afforded trienone **90**, which was converted into a mixture of diacetates **91**. Hydrogenolysis of the acetates **91** yielded a 89:11 mixture of the pheromone (3Z,6R)-**72** and its regioisomer **92**. Separation of this mixture was a very tedious procedure. Thus, in spite of the stereoselectivity of the construction of the (Z)-trisubstituted C=C bond, this scheme has no advantages over the scheme proposed by Becker and Sahali³⁷ as regards both the number of steps and the yield of the target compound **72**.

Still and Mitra⁴¹ developed a more efficient procedure for the stereoselective construction of the (Z)-trisubstituted alkene fragment in the compound **72**. It was found that the reactions of BuLi with allylic trialkylstannylmethyl ethers of the type **93** were

(a) PhSH, Et₃N, MeCN; (b) **81**, 2 equiv. of BuLi, THF, HMPA; (c) Ac₂O, Py; (d) MCPBA; (e) 135 °C, 0.15 mm Hg; (f) LiAlH₄; (g) HCO₂NH₄, PdCl₂(PPh₃)₂, dioxane.

accompanied by a [2,3]-sigmatropic rearrangement yielding (Z)-trisubstituted homoallyl alcohols.

R = Alk; (a) KH, Bu₃SnCH₂I; (b) BuLi.

This finding has been used in the synthesis of the racemic acetate **72**. The key intermediate, viz., alcohol **94**, was prepared in four steps starting from ethyl 3-methylcrotonate. The transforma-

(a) LDA, CH₂=CH(CH₂)₂Br; (b) LiAlH₄; (c) N-bromosuccinimide (NBS), PPh₃; (d) Mg, H₂C=C(Me)CHO; (e) KH, Bu₃SnCH₂I; (f) BuLi; (g) Ac₂O, Py.

[‡] Simultaneously, the isomer (3E,6R)-**72** was isolated; the isomers (3Z,6S)-**72** and (3E,6S)-**72** were prepared analogously starting from (R)-carvone.

tion of the skeleton of the alcohol **94** through organotin compound **95** followed by acetylation afforded ($\pm$)-**72** in 32% total yield with the stereoselectivity exceeding 95%.

The acetate (3*Z*,6*R*)-**72** was also synthesised^{42,43} using the Still rearrangement. The required alcohol (5*R*)-**94** was prepared⁴² from (+)-camphor. An efficient enantiospecific procedure developed previously^{44–46} for the cleavage of 9,10-dibromocamphor **96** yielding bromoacid **97** has been employed.

(a) Br₂, ClSO₃H; (b) Zn, AcOH; (c) KOH, DMSO, H₂O; (d) LiAlH₄; (e) O₃, MeOH; (f) Me₂S; (g) Bu^tMe₂SiCl, 4-Me₂NC₃H₄N; (h) NaOMe, MeOH; (i) PDC, CH₂Cl₂; (j) H₂C=PPh₃; (k) Bu₄NF; (l) H₂C=C(Me)MgBr.

Substituted cyclopentanone **98**, which was synthesised from compound **97** according to standard procedures, is (like compound **96**) a β -bromo ketone and underwent smooth ring-opening following protection of the hydroxy group to form acyclic ester **99**. The latter was transformed into dienol **100** and then into the aldehyde (3*R*)-**73** according to standard procedures. The reaction of the aldehyde (3*R*)-**73** with isopropenylmagnesium bromide afforded the alcohol (5*R*)-**94** in 8% total yield. Since the conversion of the alcohol ($\pm$)-**94** to the acetate ($\pm$)-**72** had been already performed by Still and Mitra,⁴¹ the above-described procedure for the preparation of (5*R*)-**94** can be formally considered as the first total stereoselective synthesis of (3*Z*,6*R*)-**72**.

Oppolzer and Stevenson⁴³ synthesised the acetate (3*Z*,6*R*)-**72** also with the use of (+)-camphor, but this was used as a chiral matrix rather than as a synthon. This approach was based on the known fact⁴⁷ that alkenyl cuprates stabilised by Bu₃P add with high stereoselectivity to enoates of the type **101** prepared from camphor. In this case, the induced chirality is completely retained after removal of the matrix.

R = (CH₂)₂CH=CH₂; (a) Bu₃P, CuI, -70 °C; (b) BF₃·Et₂O; (c) **101**; (d) NaOH, EtOH, H₂O; (e) LiAlH₄; (f) (COCl)₂, DMSO, Et₃N; (g) H₂C=C(Me)Li; (h) KH, Bu₃SnCH₂I; (i) BuLi; (j) Ac₂O, Py.

Thus enoate **101** [prepared from (+)-camphor in seven steps] added the complex of diisopropenyl cuprate with Bu₃P to form ester **102** with an enantioselectivity of ~95%. Saponification of the ester **102** afforded chiral acid **103**. This acid was converted into the alcohol (5*R*)-**94** according to standard procedures. The latter was transformed into (3*Z*,6*R*)-**72** using the Still rearrangement in 20% total yield.

The synthesis of the triene **72** still attracts interest. This pheromone serves as a test substance for examining every new method proposed for the construction of (*Z*)-trisubstituted C=C bonds.

Thus the compound **72** was chosen⁴⁸ as one of the subjects for the comparison of the reactivities of allylic organoiron nucleophiles with those of allylsilanes and allylstannanes. The synthesis of ($\pm$)-**72** involved the conversion of the commercially available diene **104** into a mixture (~1 : 1) of organoiron compounds (2*Z*)- and (2*E*)-**106** via allylic chloride **105**. The second synthon required for the construction of the triene **72**, viz., iodide **107** (a ~1 : 1 mixture of the isomers), was prepared from 4-methyl-5,6-dihydro-2*H*-pyran **108** according to standard procedures.

Fp = C₅H₅Fe(CO)₂; (a) Ca(OCl)₂; (b) NaFp; (c) **107**, MeNO₂; (d) AcCl, K[PtCl₃(C₂H₄)]; (e) NaI, Me₂CO.

In spite of the geometric inhomogeneity of the iodide **107**, its condensation with organoiron derivatives **106** at ~20 °C afforded ($\pm$)-**72** (the yield was 42%) containing <1% of an admixture of the (3*E*)-isomer. The selectivity of the reaction was attributed to the high reactivity of the (3*Z*)-iodide **107** due to the anchimeric assistance to ionisation provided by the acetoxy group. This scheme is attractive because it involves a small number of steps and does not require the introduction and removal of protective groups.

The syntheses of the aldehyde (3*R*)-**73** and the alcohol (3*R*)-**100**,⁴⁹ which are the key intermediates in the synthesis of (3*Z*,6*R*)-**72**, were carried out with the use of a previously discovered 1,4-addition of complex organocopper compounds of the type **109** to acetals **110** prepared from α,β -enals and (*R,R*)-butane-2,3-diol. Dienol ethers **111** prepared by the highly regio- and diastereoselective reaction were subjected to hydrolysis to form aldehydes **112** in quantitative yields.

This scheme was tried out in the synthesis of the aldehyde (3*R*)-**73** starting from propargylaldehyde diethyl acetal (the yield was 50%, *ee* 85%). The aldehyde (3*R*)-**73** was reduced to the alcohol (3*R*)-**100** in quantitative yield.

(a) [H₂C=CH(CH₂)₂]₂CuLi; (b) (2*R*,3*R*)-HOCH(Me)CH(Me)OH, TsOH; (c) H₂C=C(Me)Cu·LiBr·BF₃·PBu₃; (d) Ac₂O, Py; (e) HCO₂H; (f) NaBH₄.

The aldehyde (3*Z*,6*R*)-**72** was also synthesised⁵⁰ using a highly stereoselective procedure developed by one of the authors^{51–53} of the present review for the construction of (*Z*)-tri-substituted alkenes based on the facts that (*E*)-isomers of α,β -disubstituted acroleins are thermodynamically favourable and that they are stereospecifically converted into (*Z*)-trisubstituted alkenes.

According to this methodology, Baudouy and Prince⁵⁰ chose the aldehyde (3*R*)-**73** and α -(triethylsilyl)imine **113** as synthons for the construction of (3*Z*,6*R*)-**72**. The aldehyde (3*R*)-**73** was prepared from limonene according to a scheme reported previously.³⁷ However, Baudouy and Prince⁵⁰ developed a direct procedure for the conversion of the hydroxy acetal phosphate **84** into diene acetal **114**, which made it possible to reduce the scheme by two steps. The aldehyde (3*R*)-**73** was formed upon hydrolysis of the acetal **114** in quantitative yield. The second synthon, *viz.*, silylated imine **113**, was prepared in three standard steps starting from the monobenzy ether of butane-1,4-diol.

(a) O₃, MeOH; (b) (H₂N)₂CS; (c) HC(OMe)₃, CeCl₃·6 H₂O; (d) LDA, CIP(O)(OEt)₂, THF; (e) Li/NH₃, THF; (f) HClO₄, THF, H₂O; (g) (COCl)₂, DMSO, Et₃N; (h) Bu^tNH₂, 4 Å molecular sieves; (i) LDA, Et₃SiCl; (j) Bu^sLi, (3*R*)-**73**; (k) H₃O⁺; (l) C₅H₅N·HCl, CH₂Cl₂; (m) LiAlH₄, Et₂O; (n) C₅H₅N·SO₃, THF; (o) LiAlH₄, THF; (p) Ac₂O, HClO₄.

Condensation of the imine **113** deprotonated under the action of Bu^sLi with the aldehyde (3*R*)-**73** afforded acrolein **115**. The mixture formed initially was kept in a CH₂Cl₂ solution containing pyridinium chloride for 4 h after which the content of the (*Z*)-isomer was no higher than 1%. The carbonyl group in compound **115** was reduced to the methyl group in three standard steps. The replacement of the protective benzyl group in the resulting ether **116** by the acetate group gave rise to (3*Z*,6*R*)-**72** in 30% total yield.

The construction of the pheromone (±)-**72**⁵⁴ based on a method for the generation of allyllithium compounds by reductive lithiation of readily available allyl phenyl sulfides with aromatic radical anions^{55–57} has proved the utility of this procedure. The regiocontrolled addition of unsymmetrical allyllithium derivatives to carbonyl compounds (which had been developed by the authors previously) employed in this synthesis is of particular interest. Thus treatment of the allyllithium intermediate with Ti(OPr)₄ allows one to perform the subsequent reaction with an aldehyde at the more substituted position of the allylic system, whereas treatment with CeCl₃, on the contrary, makes it possible to perform this reaction at the less substituted position.

(a) Bu^sLi; (b) H₂C=CH(CH₂)₂Br; (c) lithium 4,4'-di(*tert*-butyl)bi-phenylide (LDBB), –78 °C, Ti(OPr)₄, CH₂O; (d) CBr₄, Ph₃P; (e) **117**; (f) LDBB, –78 °C, CeCl₃, CH₂O; (g) Ac₂O, Py.

Thus alkylation of the anion **117** generated from isobutenyl phenyl sulfide under the action of Bu^sLi with but-3-enyl bromide occurred exclusively at the α position to form sulfide **118**. Reductive lithiation of the latter with lithium 4,4'-di(*tert*-butyl)-

biphenylide followed by *in situ* treatment of the reaction product with $\text{Ti}(\text{OPr})_4$ and the reaction of the resulting organotitanium compound with formaldehyde afforded alcohol **119**, which was converted into allyl sulfide **120**. The sulfide **120** was subjected to reductive lithiation. The successive treatment of the resulting alkyllithium intermediate with CeCl_3 and formaldehyde gave rise to alcohol (3*Z*)-**121** from which the acetate ($\pm$)-**72** was obtained in 22.4% total yield.

In 1995, Serebryakov and coworkers⁵⁸ synthesised the acetate ($\pm$)-**72** using the highly selective 1,4-*cis*-hydrogenation of conjugated dienes in the presence of carbonyl chromium complexes⁵⁹ for the construction of the (*Z*)-trisubstituted $\text{C}=\text{C}$ bond. This method had been employed previously^{60,61} in the synthesis of natural compounds. The triene **122** required for this synthesis was prepared in five steps from ethyl acetoacetate.

(a) EtONa , EtOH , $\text{H}_2\text{C}=\text{CH}(\text{CH}_2)_2\text{Br}$; (b) $\text{HO}(\text{CH}_2)_2\text{OH}$, TsOH ; (c) LiAlH_4 ; (d) PCC , CH_2Cl_2 ; (e) $(\text{EtO})_2\text{P}(\text{O})\text{CH}_2\text{CH}(\text{Me})=\text{CHCO}_2\text{Et}$ (**124**), KOH , PhH , 18-crown-6 (18-C-6); (f) H_2 , $(\text{PhCO}_2\text{Me})\text{Cr}(\text{CO})_3$, Me_2CO , 120°C ; (g) H_3O^+ ; (h) $\text{Ph}_3\text{P}=\text{CH}_2$; (i) Ac_2O , Na_2CO_3 , 100°C .

Alkylation of ethyl acetoacetate with but-3-enyl bromide, the conversion of the resulting oxo ester (after protection of the carbonyl group) into hydroxy ketal and oxidation of the latter afforded aldehyde **123**. Condensation of **123** with triethyl 3-methyl-4-phosphonocrotonate (**124**) under conditions of phase transfer catalysis according to a procedure developed previously⁶² gave rise to a 2:1 mixture of the trienes (2*E*)- and (2*Z*)-**122**. Hydrogenation of the conjugated diene system in the presence of a chromium complex afforded (3*Z*)-ester **125**, which virtually did not contain an admixture of the (3*E*)-isomer. The ester **125** was converted into hydroxy ketone **126** by standard procedures. The reaction of the ketone **126** with methylidenetriphenylphosphorane followed by acetylation of the resulting alcohol completed the synthesis of ($\pm$)-**72** (the total yield was 4.3%).

In the synthesis of the compound **72**, Cooke and Burman⁶³ did not develop a new approach to the construction of the (*Z*)-trisubstituted $\text{C}=\text{C}$ bond but used the available (*Z*)-alkene fragment in chlorohydrin **127** (*Z* > 98%), which had been described previously⁶⁴ and which was converted into bromide **128** in two steps.

(a) DHP , HCl ; (b) NaBr , *N*-methylpyrrolidone; (c) $\text{Cl}(\text{CH}_2)_2\text{COCl}$; (d) MeONa ; (e) $\text{H}_2\text{C}=\text{CHCH}_2\text{Li}$; (f) **128**; (g) AcOH , 90°C ; (h) NaOH ; (i) Ac_2O , Py ; (j) $\text{Ph}_3\text{P}=\text{CH}_2$.

In the study cited (Ref. 63), an ingenious method for the assembly of the molecule ($\pm$)-**72** was used. Phosphorane **129** was used as the key compound in this synthetic scheme. The compound **129** was generated from phosphonium salt **130**, which was prepared by acylation of *tert*-butoxycarbonylmethylidenetriphenylphosphorane **131** with β -chloropropionyl chloride. Successive treatment of the phosphorane **129** with prop-2-enyllithium and the bromide **128** afforded the phosphorane **130** containing the major structural fragments of the pheromone ($\pm$)-**72**. The phosphorane **130** was converted into hydroxy ketone **132** by a procedure developed previously.⁶⁵ Acetylation of the latter followed by the reaction of the resulting acetate with methylidenetriphenylphosphorane gave rise to ($\pm$)-**72** in 8.5% total yield.

b. Sex pheromone of the white peach scale

Subsequent to the pheromone of the California red scale **72**, a structurally similar female-produced sex pheromone of the white peach scale *Pseudaulascaspis pentagona*, viz., propionate **133**, was isolated.⁶⁶

The structure of compound **133** was established by physicochemical methods and the absolute configuration of the C(6) centre was determined based on the results of bioassays of both enantiomers, which have been synthesised starting from (+)- and (−)-limonenes according to a scheme analogous to that used in the synthesis of the acetate **72** (see Section IV.1.a). Only the (3*Z*,6*R*)-propionate **133** appeared to be the active attractant.⁶⁷

Serebryakov and coworkers⁵⁸ performed a highly stereoselective synthesis of the compound **133** according to a procedure analogous to that developed by them for the pheromone **72**.

c. Sex pheromone of the yellow scale

Gieselmann *et al.*⁶⁸ isolated the female-produced sex pheromone of the yellow scale *Aonidiella citrina*, a species morphologically very similar to *A. auranti*, and established its structure. Although the pheromone of the yellow scale (3*R*,5*E*)-**134** is formally the (5*E*)-isomer, we consider this compound in the present review because the branches of its major hydrocarbon chain, like those in the pheromones of the California red scale and the white peach scale, are in the *cis* positions with respect to each other. Because of this, (3*R*,5*E*)-**134** was synthesised according to procedures analogous to those used for the preparation of pheromones containing the (*Z*)-trisubstituted $\text{C}=\text{C}$ bond. Based on the results of physicochemical studies,⁶⁸ the structure (5*E*)-**134** was assigned to this pheromone [with the accuracy of the absolute configuration of the C(3) centre]. This structure was confirmed by two independent syntheses. One of these syntheses⁶⁹ involved the Horner–Emmons reaction of aldehyde **135** with an anion generated from phosphonate **136**.

MOM is methoxymethyl; (a) PCC, AcONa, CH_2Cl_2 ; (b) $(\text{EtO})_2\text{P}(\text{O})\text{CH}(\text{Pr}^i)\text{CO}_2\text{Et}$ (**136**), EtONa; (c) Bu_2AlH ; (d) Ac_2O , Py; (e) $(\text{Me}_2\text{C}=\text{CH})_2\text{CuLi}$; (f) $\text{Cl}_3\text{CCO}_2\text{H}$.

The resulting mixture (4 : 1) of the esters (Z)- and (E)-**137** was converted into a mixture of acetates **138** through the corresponding alcohols. Treatment of the compounds **138** with diisobutyl-lithium cuprate afforded a mixture of isomers **139**, which was converted into a mixture of acetates (E)-**134** and (Z)-**134** in two standard steps also in a ratio of 1 : 4. Bioassays of the isomers separated by preparative GLC demonstrated that only the compound (E)-**134** exhibited the attractant activity.

Suguro *et al.*⁷⁰ reached the same conclusion when performing the stereoselective synthesis of the isomeric acetates **134** from the common precursor, *viz.*, ester (E)-**140**. This ester was prepared with a stereoselectivity of 92% by the *in situ* Claisen–Johnson [3,3]-sigmatropic rearrangement of orthoester **141** (Scheme 1).

Treatment of the ester **140** with MeMgI afforded alcohol **142**, which was dehydrated to form a mixture of regioisomeric trienes **143**. Hydroboration of this mixture under standard conditions gave rise to a mixture of the corresponding alcohols from which

the (5Z)-isomer was isolated by chromatography. Acetylation of the latter afforded the acetate (5Z)-**134** in ~ 1% total yield.

The ester (E)-**140** required for the preparation of the acetate (E)-**134** was synthesised *via* epoxide **144** by the Vedejs method.⁷¹ Successive treatment of the epoxide **144** with lithium diphenylphosphide and methyl iodide afforded the corresponding tetrahydropyranyl derivative, which was converted into alcohol **145**. Oxidation of the hydroxy group in the alcohol **145** and methylation of the resulting carboxylic acid gave rise to the ester (E)-**140**, which was converted into (E)-**134** in 0.5% total yield by an analogous procedure.

Mori and coworkers⁷² established the absolute configuration of the C(3) centre in the acetate **134** and performed the synthesis of (3S,5E)-**134** exhibiting the high attractant activity. For this purpose, chiral monoester (R)-**146**, which was synthesised from (R)-citronellic acid, was used as the starting compound. The Hunsdiecker reaction of the monoester (R)-**146** afforded bromide **147**, which was transformed into acid **149** *via* selenide **148**. The acid **149** was smoothly converted into aldehyde **150**. The reaction of the aldehyde **150** with an organomagnesium compound prepared from bromide **151** gave rise to alcohol **152**, which was subjected to the Still rearrangement. The alcohol **153** containing the trisubstituted alkene fragment was obtained with a stereoselectivity of > 95%. The reaction of an aldehyde prepared from **153** with isopropylidenetriphenylphosphorane afforded triene **154**. Hydroboration–oxidation of the terminal double bond in the triene **154** followed by acetylation of the resulting alcohol **155** completed the synthesis of (3S,5E)-**134** (the total yield was 0.2%).

Later, Mori and Kuwahara⁷³ performed a more efficient synthesis of (3S,5E)-**134**. According to this scheme, the trisubstituted alkene fragment was also constructed by the Still rearrangement. The key intermediate, *viz.*, benzyloxy alcohol **156**, was prepared by the reaction of the organomagnesium derivative of the bromide **151** with aldehyde **157**. The latter was synthesised by the seven-step transformation of methyl (R)-citronellate [(R)-**158**]. The conversion of the benzyloxy alcohol **156** according to Still giving rise to benzyloxy alcohol **159**, oxidation of the latter and treatment of the resulting aldehyde with isopropylidenetriphenylphosphorane afforded benzyl ether **160**. The target acetate (3S,5E)-**134** was prepared from **160** in 7% total yield.

Simultaneously, Mori and Kuwahara⁷³ prepared (3*R*,5*E*)-**134** in 10% total yield. Bioassays demonstrated that only the (3*S*)-enantiomer exhibited the attractant activity.^{73, 74}

Although Mori and coworkers^{70, 72, 73} succeeded in performing stereoselective synthesis of (3*S*,5*E*)-**134**, the synthetic schemes involved many steps and, as a result, the target compound was prepared in low yield. Later, more efficient syntheses of the acetate (5*E*)-**134** were performed.^{75–77}

Julia and coworkers⁷⁵ constructed the chiral fragment in the acetate (5*E*)-**134** by the reaction of an anion generated from sulfone **161** with (3*R*)-methylvalerolactone (**162**). When treated with *tert*-butyldimethylchlorosilane, the resulting mixture of hydroxy oxo sulfone **163** and hemiketal **164** was quantitatively converted into the silyl derivative of hydroxy oxo sulfone **163**. Reduction of the carbonyl group in **163** followed by acetylation of a mixture of the resulting alcohols afforded a mixture of acetates **165**. Elimination of AcOH from the acetates **165** resulted in sulfone **166** containing an admixture (< 2%) of the (5*Z*)-isomer.

(a) BuLi, **162**; (b) LDA, Me₂Bu^tSiCl; (c) NaBH₄; (d) Ac₂O, dimethylaminopyridine (DMAP), Py; (e) NaOH; (f) PrⁱMgBr, FeCl₃; (g) Bu₄NF; (h) Ac₂O, Py.

The reaction of the sulfone **166** with PrⁱMgBr in the presence of FeCl₃ afforded, like other analogous reactions studied previously,⁷⁸ a 1 : 1 mixture of products of replacement and elimination of the sulfonyl group. After removal of the silyl protection, chromatographic separation of the resulting mixture of the acetates (3*S*,5*E*)-**134** and **167**, (3*S*,5*E*)-**134** was isolated in 17.2% total yield.

Millar⁷⁶ constructed the trisubstituted alkene fragment in the compound (5*E*)-**134** based on the above-mentioned highly stereoselective addition of cuprates to alkynes. Thus successive treatment of 3-methylbut-1-yne with (PhMe₂Si)₂CuLi (Ref. 79) and 3-methylbut-2-enyl bromide gave rise to vinylsilane containing 16% of the S_N2'-addition product. This mixture was converted into the corresponding iodides. Flash chromatography of the latter afforded iodide **168** in 39% total yield. This iodide was transformed into the target acetate (±)-(5*E*)-**134** by cross-coupling with an organozinc reagent synthesised from iodide **169**. The reaction product was converted into the target acetate (±)-(5*E*)-**134** (the total yield was ~ 16%).

(a) 2 equiv. of PhMe_2SiLi , CuCN , THF; (b) $\text{BrCH}_2\text{CH}=\text{CMe}_2$; (c) I_2 ; (d) HCl , EtOH ; (e) LiAlH_4 ; (f) $\text{I}_2 \cdot \text{Ph}_3\text{P}$, imidazole; (g) Zn , THF; (h) **168**, $(\text{Ph}_3\text{P})_4\text{Pd}$; (i) NaOAc , HMPA.

The pheromone (3*S*,5*E*)-**134** was also synthesised⁷⁷ starting from (*S*)-citronellyl pivalate (**170**). The highly stereoselective construction of the trisubstituted alkene fragment took advantage of thermodynamic predominance of the (*E*)-isomers of α,β -disubstituted acroleins,⁵³ *i.e.*, it is based on the approach used previously⁵⁰ in the synthesis of the pheromone of the California red scale **72**. The first synthon, *viz.*, aldehyde **171**, was prepared from the ester **170** by oxidation of its phenylselenenyl derivative with di-*tert*-butyl peroxide.

$\text{R} = \text{COBu}^t$; (a) $(\text{PhSe})_2$, H_2O_2 ; (b) Bu^tO_2 ; (c) O_3 , -78°C ; (d) $\text{EtOCH}=\text{CH}_2$, H_3PO_4 , 150°C ; (e) Bu^tNH_2 , 4 Å molecular sieves; (f) LDA , Et_3SiCl ; (g) Bu^tLi , **171**; (h) $\text{CF}_3\text{CO}_2\text{H}$, H_2O ; (i) $\text{C}_5\text{H}_5\text{N} \cdot \text{HCl}$; (j) MeMgI ; (k) $(\text{COCl})_2$, DMSO , Et_3N ; (l) $\text{Ph}_3\text{P}=\text{CH}_2$; (m) Bu_2AlH ; (n) H_2 , $(\text{Ph}_3\text{P})_3\text{RhCl}$; (o) Ac_2O , Et_3N .

Subsequent ozonolysis of the resulting tertiary alcohol **172** afforded the aldehyde **171**. The second synthon, *viz.*, silylated imine **173**, was prepared by condensation of 2-methylbut-3-en-2-ol with ethyl vinyl ether followed by successive treatment of the resulting aldehyde **174** with Bu^tNH_2 and Et_3SiCl . Condensation of the imine **173** with the aldehyde **171** under conditions used previously⁵⁰ in the synthesis of the pheromone **72** yielded acrolein **175**, which virtually did not contain the (*Z*)-isomer. The carbonyl group in the aldehyde **175** was converted into the isopropyl fragment in six steps. The target acetate (3*S*,5*E*)-**134** was prepared in 25% total yield. This is the best result obtained in the synthesis of the sex pheromone of the yellow scale.

d. Sex pheromone of the San Jose scale

Almost simultaneously with the pheromone of the yellow scale, the female-produced sex pheromone of the San Jose scale *Quadraspidiotus perniciosus*, which is a widespread polyphagous pest of fruit and decorative trees, was isolated.⁸⁰ Two major components

of this pheromone, *viz.*, esters **176** and (*Z*)-**177**, were identified by physicochemical methods. More recently,⁸¹ the ester (*E*)-**177** was also found. It was demonstrated that the pheromone contains these components in a ratio of 47.55:47.75:4.70.⁸¹ Each of these components exhibits approximately the same biological activity.

The ester (*Z*)-**177** was synthesised for the first time⁸² with the use of the above-mentioned highly stereoselective addition of dialkyl cuprates to alkynes in the key step of the construction of the (*Z*)-trisubstituted alkene fragment.

(a) Mg ; (b) $\text{CuBr} \cdot \text{Me}_2\text{S}$; (c) $\text{HC}\equiv\text{CMe}$; (d) CO_2 , $(\text{EtO})_3\text{P}$, HMPA; (e) CH_2N_2 ; (f) Bu_2AlH ; (g) $(\text{EtCO})_2\text{O}$, Py .

The reaction of cuprate obtained from the magnesium derivative of bromide **178** with propyne proceeded as *cis*-addition. Treatment of the reaction mixture with CO_2 afforded (*Z*)-acid **179**. The latter was converted into the target pheromone (*Z*)-**177** in 29% total yield using standard procedures.

Alderice *et al.*⁸³ synthesised the ester (*Z*)-**177** using the stereoselective conversion of enol phosphates of β -oxo esters into (*Z*)-trisubstituted α,β -unsaturated esters.⁸⁴

(a) NaH , BuLi ; (b) $\text{H}_2\text{C}=\text{CH}(\text{Me})\text{CH}_2\text{CH}_2\text{OTs}$ (**181**); (c) $(\text{EtO})_2\text{P}(\text{O})\text{Cl}$, Et_3N ; (d) MeMgCl , MeCu ; (e) Bu_2AlH ; (f) $(\text{EtCO})_2\text{O}$, Py ; (g) $(\text{EtO})_2\text{P}(\text{O})\text{Cl}$, NaH .

Thus dianion **180** generated from methyl acetoacetate underwent smooth alkylation under the action of tosylate **181** to form β -oxo acid ester **182**. The latter was converted into enol phosphate (*E*)-**183**. Treatment of (*E*)-**183** with MeMgCl in the presence of a catalytic amount of MeCu afforded ester (*Z*)-**184**, which was transformed into the target pheromone (*Z*)-**177** through the corresponding alcohol in ~40% total yield. Deprotonation of the oxo ester **182** with NaH instead of Et_3N afforded the (*Z*)-enol phosphate **183**. The latter was converted into the component of the pheromone of the San Jose scale, *viz.*, the propionate (*E*)-**177**, in three steps.

Nerol is a convenient starting compound for the synthesis of the ester (*Z*)-**177**. However, isomerisation of the $\text{C}(6)=\text{C}(7)$ double bond appeared to be a difficult problem. Only after several

unsuccessful attempts,⁸⁵ an efficient reagent for this isomerisation, *viz.*, *tert*-butyl hypochlorite, was found.^{86,87} The propionate (*Z*)-**177** was synthesised according to this scheme in three steps in 40% total yield.

(a) (EtCO)₂O, Py; (b) Bu^tOCl, SiO₂; (c) NaBH₄, LiI.

Moiseenkov *et al.*⁸⁸ synthesised the propionate (*Z*)-**177** starting from isoprenoid (*Z*)-hydroxy sulfonamide **185**.⁸⁹ The synthetic scheme involved alkylation of the sulfonamide **185** with 3-methylbut-3-enyl iodide **186** to form sulfonamide **187** and reductive desulfurization of the latter in the presence of dibenzo-18-crown-6 (DB-18-C-6). The reaction proceeded virtually without migration of the C=C bond to form alcohol (*Z*)-**188**, which was converted into the propionate (*Z*)-**177** in 51% total yield.

(a) BuLi, THF; (b) H₂C=C(Me)(CH₂)₂I (**186**); (c) Na/NH₃, C₆H₁₄, DB-18-C-6; (d) (EtCO)₂O, Py.

A mixture of propionates (*Z*)- and (*E*)-**177** was synthesised by Chinese chemists.^{90–92} The synthesis involved the Wittig reaction of ketone **189** with ylide generated from phosphonium salt **190** followed by the conversion of the resulting mixture of alcohols **188** into a mixture of propionates (*Z*)- and (*E*)-**177**. The key intermediate, *viz.*, the ketone **189**, was prepared in two ways. The first route^{90,91} involved oxidation of alcohol **191** formed in the reaction of diisopentenyl cuprate with propylene oxide. The second route⁹² involved the conversion of heptane-2,6-dione monoketal into the ketone **189** *via* ketal **192**.

(a) Li; (b) CuI; (c) $\text{Me} \begin{array}{c} \diagup \diagdown \\ \text{O} \end{array}$; (d) PCC, CH₂Cl₂; (e) BnO(CH₂)₃OH on a polymeric support; (f) Ph₃P=CH₂; (g) H₃O⁺; (h) (Ph₃P⁺CH₂CH₂OH)Cl[–] (**190**), B[–]; (i) (EtCO)₂O, Py.

2. Synthesis of the male-produced sex pheromone of the southern green stinkbug *Nezara viridula*

The southern green stinkbug *Nezara viridula* is a pest of cotton, citrus, cereal and vegetable crops, which is widely distributed in tropical and subtropical regions. The first data on the structure of the male-produced sex pheromone of *N. viridula* were published in 1971.⁹³ However, its major component was isolated only in 1987.⁹⁴ Based on the results of physicochemical studies, the structure of epoxybisabolene (**193**) was assigned to this component. With the aim of establishing the stereochemistry of the natural pheromone, eight of its isomers were synthesised⁹⁴ starting from (*R*)- and (*S*)-limonenes using the modified Julia procedure⁷⁵ in the step of construction of the trisubstituted alkene fragment.⁹⁵ The approach used in the cited study⁹⁴ is exemplified in the syntheses of the (*Z*)- and (*E*)-isomers of (1*S*,2*R*,4*S*)-**193** considered below. The necessary key intermediate, *viz.*, epoxy ketone **194**, was prepared in the individual state with the use of a reaction sequence involving epoxidation of (*S*)-limonene and conversion of the resulting mixture of α - and β -epoxides into a mixture of amino alcohols **195** and **196**. The latter compounds were converted into the corresponding tosylates and separated by chromatography.

(a) MCPBA; (b) Me₂NH, H₂O; (c) TsCl, Py; (d) MeI; (e) KOH; (f) O₃, CH₂Cl₂; (g) Ph₃P; (h) Me₂C=CH(CH₂)₂SO₂Ph (**198**), BuLi; (i) PhCOCl, Py; (j) Na/Hg, THF, MeOH.

Amino tosylate corresponding to the amino alcohol **196** was transformed into the quaternary ammonium salt and then into individual epoxide (1*S*,2*R*,4*S*)-**197**. Ozonation of the double bond in (1*S*,2*R*,4*S*)-**197** followed by the reaction of the resulting epoxy ketone (1*S*,2*R*,4*S*)-**194** with deprotonated sulfone **198** afforded β -hydroxy sulfone. The latter was converted into benzoate. Subsequent reductive elimination gave rise to a 1:1 mixture of the (*Z*)- and (*E*)-isomers of epoxybisabolene (1*S*,2*R*,4*S*)-**193**. The individual isomers were isolated by HPLC. The (*Z*)- and (*E*)-iso-

mers of epoxybisabolene (1*S*,2*S*,4*R*)-**193** were prepared analogously from epoxy ketone (1*S*,3*S*,4*R*)-**194**. Four other isomeric epoxybisabolenes were prepared starting from (*R*)-limonene. Based on comparison of the physicochemical characteristics of the isomers synthesised with those of the male-produced pheromone of stinkbugs of the Brazilian population, it was reliably established that the pheromone is epoxybisabolene (Z,1*S*,3*R*,4*S*)-**193**. Bioassays demonstrated that only this isomer was attractive to *N. viridula* females.

Later, it was shown^{96–99} that other isomers of epoxybisabolene **193** with the (*Z*)-configuration of the C(5)=C(6) double bond as well as (*Z*)-bisabolene are sex pheromones of stinkbugs from other regions. The ratio between the components in the pheromone mixture varies depending on the habitat. In this connection, synthesis of racemic epoxybisabolene (Z)-**193** starting from racemic limonene (patented by Mori *et al.*¹⁰⁰) is of interest. The individual epoxybisabolene (Z)-**193** was isolated from a mixture with the (*E*)-isomer by chromatography.

(a) MCPBA; (b) $\text{Ph}_3\text{P}=\text{CHCH}_2\text{CH}=\text{CMe}_2$.

The major component of all pheromone mixtures of the southern green stinkbug, *viz.*, epoxybisabolene (Z,1*S*,2*R*,4*S*)-**193**, was synthesised¹⁰¹ from commercially available perillyl alcohol **198**. The key step of this scheme involved the Horner–Emmons reaction of the ketone **194** with phosphine oxide **199**. Epoxidation of perillyl alcohol **198** according to Sharpless afforded hydroxy epoxide **200**. The hydroxymethyl group of **200** was reduced to the methyl group through the corresponding mesylate. The resulting epoxide **197** was converted into the corresponding epoxy ketone **194** (the total yield was 47%). The reaction of the latter with an anion generated from the phosphine oxide **199** gave rise to a mixture of *erythro*- and *threo*-phosphine oxides **201**. The former was isolated by chromatography from a mixture with (*E*)-epoxybisabolene, which was formed due to decomposition of the unstable *threo*-**201**, and was converted into the epoxybisabolene (Z,1*S*,2*R*,4*S*)-**193** (the total yield was 18%).

(a) (D)-(–)-tartaric acid, $\text{Ti}(\text{OPr})_4$, $\text{Bu}^t\text{O}_2\text{H}$; (b) MeSO_2Cl , Py; (c) LiAlH_4 ; (d) KMnO_4 , DB-18-C-6, CH_2Cl_2 ; (e) $\text{Me}_2\text{C}=\text{CH}(\text{CH}_2)_2\text{P}(\text{O})\text{Ph}_2$ (**199**), BuLi; (f) NaH, DMF.

Efficient syntheses of the isomers (Z,1*S*,2*R*,4*S*)-, (Z,1*S*,2*S*,4*R*)-, (Z,1*R*,2*S*,4*R*)- and (Z,1*R*,2*R*,4*S*)-**193** were carried

out¹⁰² starting from the commercially available mixture of α - and β -epoxides of (*S*)- and (*R*)-limonenes. The (*Z*)-trisubstituted alkene fragment was constructed using the highly stereoselective *cis*-addition of dialkyl lithium cuprates to acetylenecarboxylic esters. The scheme of the synthesis is exemplified below in the preparation of the isomer (Z,1*S*,2*R*,4*S*)-**193**.

(a) LDA; (b) $(\text{EtO})_2\text{P}(\text{O})\text{Cl}$; (c) 2.5 equiv. of LDA; (d) BuLi, ClCO_2Me ; (e) Me_2CuLi ; (f) Bu_2^tAlH ; (g) CBr_4 , PPh₃; (h) Bu^tLi, $\text{Me}_2\text{C}=\text{CHBr}$.

Substituted acetylenecarboxylic ester **202** was prepared from the epoxy ketone (1*S*,2*R*,4*S*)-**194** in four steps. The addition of dimethyl lithium cuprate to the ester **202** afforded ester (2*Z*)-**203**. The latter was transformed into (Z,1*S*,2*R*,4*S*)-**193** in 24% total yield according to standard procedures. Analogously, the isomer (Z,1*S*,2*S*,4*R*)-**193** was prepared from the ketone (1*S*,2*S*,4*R*)-**194** and the isomers (Z,1*R*,2*R*,4*R*)- and (Z,1*R*,2*R*,4*S*)-**193** were prepared from α - and β -epoxides of (*R*)-limonene, respectively.

(Z,1*S*,2*S*,4*R*)-Epoxybisabolene was also synthesised¹⁰³ starting from acid **204**, which was prepared by the asymmetric Diels–Alder reaction.¹⁰⁴ Bromolactonisation of the acid **204** gave rise to a mixture of bromo lactones **205** and **206**. Treatment of this mixture with 4-methyl-1-phenylthiopent-3-enyllithium (**207**) afforded phenylthio ketone **208** in high yield. The reaction of the compound **208** with MeLi gave rise to a mixture of *threo*- and *erythro*-hydroxy sulfides (**209**) separated by flash chromatography. Treatment of *threo*-**209** with P_2I_4 in the presence of Et_3N produced the target epoxybisabolene **193** in a total yield of 18% with respect to the acid **204**.

(a) NBS, Na_2CO_3 ; (b) $\text{Me}_2\text{C}=\text{CHCH}_2\text{CH}(\text{Li})\text{SPh}$ (**207**); (c) MeLi; (d) P_2I_4 , Et_3N , CH_2Cl_2 .

3. Synthesis of the sex pheromones of the dry bean beetles *Callosobruchus analis* and *C. maculatus*

The female-produced sex pheromone of the dry bean beetle *Callosobruchus analis* was isolated in 1991.¹⁰⁵ Based on the data

of GLC-mass spectrometry, the structure of 3-methylheptenoic acid containing a double bond at position 2 or 3 was assigned to this pheromone. Comparison of the physicochemical properties of the pheromone isolated with those of authentic 3-methylheptenoic acids containing a double bond at different positions (which were synthesised by the Reformatsky, Wittig or Horner–Emmons reactions) demonstrated that the pheromone of *C. analis* females is 3-methylhept-(2*Z*)-enoic acid (**210**). Bioassays of isomeric 3-methylheptenoic acids demonstrated that 3-methylhept-(3*Z*)-enoic acid is also the attractant for males of the dry bean beetle *C. analis*. This acid was identified as the major component of the sex pheromone of the dry bean beetle *C. maculatus*.^{105, 106}

A highly stereoselective synthesis of 3-methylhept-(2*Z*)-enoic acid (**210**) was carried out according to two procedures. The first procedure¹⁰⁷ was based on the fact that the (*E*)-isomers of α,β -disubstituted acroleins are thermodynamically favourable.

In this scheme, the key intermediate was the (*E*)-isomer of substituted acrolein **211**, which was formed with a stereoselectivity of > 95% upon condensation of the trimethylsilyl derivative of *N*-*tert*-butylhexanimine (**212**) with glycolaldehyde benzyl ether (**213**).¹⁰⁷ Stereospecific reduction of the carbonyl group in the aldehyde **211** to the hydroxymethyl group and then to the methyl group *via* sulfate afforded benzyl ether **214**. Deprotection followed by oxidation of the resulting alcohol **215** gave rise to the acid **210** (the total yield was 12%).

(a) Bu^tNH_2 ; (b) LDA; (c) Me_3SiCl ; (d) OHCCH_2OBn (**213**); (e) H_3O^+ ; (f) NaBH_4 ; (g) $\text{Py} \cdot \text{SO}_3$; (h) LiAlH_4 ; (i) Li/NH_3 ; (j) MnO_2 ; (k) Ag_2O .

The second procedure¹⁰⁸ was based on our version of the highly stereoselective Peterson olefination^{109, 110} of methyl ketones. The method involves the introduction of a bulky phenylthio substituent at the C(3) atom. This substituent can be readily removed from the reaction product.

$\text{R} = \text{Me}$ (**a**), Bu^t (**b**); (a) $\text{Me}_3\text{SiCH}_2\text{CO}_2\text{R}$, LDA; (b) $[\text{AlH}_3]$; (c) Na/NH_3 , C_6H_{12} , DB-18-C-6.

Olefination of α -phenylthio ketone **216**, which was prepared according to Warren's method,¹¹¹ with alkyl trimethylsilylacetates afforded a mixture of 4-phenylthio esters (2*Z*)- and (2*E*)-**217a,b** (the ratios of the isomers were 92 : 8 and 85 : 15 for **217a** and **217b**, respectively). Reduction of the (*Z*)-ester **217b** isolated by chromatography with AlH_3 *in situ* gave rise to 4-phenylthio alcohol (2*Z*)-**218** desulfation of which afforded the alcohol **215** in 10.3% total yield. It should be noted that the yield of the alcohol **215** prepared according to the first procedure reached 26%.

3-Methylhept-(3*Z*)-enoic acid **219** was synthesised by Serebryakov and coworkers.^{112, 113} The key step of this scheme involved 1,4-*cis*-hydrogenation of conjugated dienes proposed by Frankel *et al.*⁵⁹

(a) KOH , 18-C-6, PhH ; (b) H_2 , $\text{Cr}(\text{CO})_6$, C_6H_{14} ; (c) KOH , HCl .

Condensation of propanal with triethyl 3-methyl-4-phosphonocrotonate under conditions of phase transfer catalysis afforded a mixture of esters (2*E*,4*E*)- and (2*Z*,4*E*)-**220**. Hydrogenation of this mixture over $\text{Cr}(\text{CO})_6$ gave rise to ester (3*Z*)-**221** with 99% purity. Saponification of the ester **221** under mild conditions produced the acid **219** in 11.4% total yield.

* * *

In conclusion, note that the synthesis of insect pheromones is a good 'proving ground' for new methods of organic chemistry. All the aforesaid refer in full measure both to stereoselective procedures for the construction of (*Z*)-trisubstituted $\text{C}=\text{C}$ bonds and to procedures for the construction of chiral synthons required for the preparation of pheromones of the group under consideration.

Abstract. The review is devoted to industrially important syntheses based on diacetylene, a side product from electrocracking, oxidative pyrolysis of methane and plasmochemical synthesis of acetylene. Reactions of diacetylene and its derivatives with mono- and dinucleophilic reagents occurring in the chemisorption of diacetylene from industrial gases and resulting in stable reactive compounds which can be used as valuable intermediates for organic synthesis and pharmaceutical industry are described. Some specific features of diacetylene reactions in superbasic media are discussed. The bibliography includes 266 references.

I. Introduction

Preparation of chemical products on the basis of acetylene is one of the most promising trends in basic industrial organic synthesis. The interest in acetylene-related raw materials, which subsided considerably in 1955–1975, has now rekindled.¹ The reorientation towards coal and gas as valuable raw materials of the future and the development of new technologies for acetylene production from coal, *e.g.* using plasmochemical reactions, played a crucial role in the revision of the place of acetylene in organic synthesis.² The use of acetylene and its derivatives in small-tonnage production of sophisticated and expensive organic compounds holds especially great promise.^{1,2}

The classical studies by A E Favorsky and W Reppe have formed the basis for modern technologies of the chemistry of acetylene, *viz.*, vinylation, ethynylation and carbonylation reactions. A vast body of accumulated data on reactions of acetylene is documented in numerous monographs and reviews.^{1–40} On the other hand, some technological aspects of the chemistry of acetylene were obviously underestimated. This is particularly true of diacetylene (butadiyne) formed in the manufacture of

acetylene. As regards the potential utility of side products derived from acetylene and accompanying compounds (methylacetylene, allene, diacetylene, higher alkynes, phenylacetylene, *etc.*), diacetylene occupies the second place after the methylacetylene–allene fraction.

A significant contribution to the chemistry of diacetylene and its commercial application was made by Russian scientists belonging to the M F Shostakovskii^{3, 8, 11–32, 34} and A A Petrov^{36–40} scientific schools. The aim of the present review is to analyse and systematise the published data devoted to industrial syntheses based on diacetylene and to evaluate the prospects for the development of this branch of chemistry.

II. The problem of diacetylene utilisation

Despite the fact that many compounds of the diacetylene series (1,3-diynes) had been known since the XIX century, the development of the chemistry of these compounds began only after 1950³ when they were discovered in nature^{4,5} as well as among the products of electrocracking and oxidative pyrolysis of methane.⁶

Under industrial conditions, these two reactions yield, in addition to acetylene, some of its homologues and derivatives among which diacetylene constituting 5% of the whole manufacture of acetylene presents the greatest practical interest.¹

Utilisation of the accompanying diacetylene presents a serious problem for chemical technology. All industrial methods used for the isolation of acetylene are based on the sorption–desorption principle. Higher alkynes and diacetylene are extracted with the help of selective solvents, *e.g.*, anhydrous ammonia, cooled methanol, *N*-methylpyrrolidone, DMF.^{3,6}

The first solution to this problem was proposed and implemented at the oldest petrochemical plant ‘Chemische Werke Huls A.G.’⁴¹ Preparation of 1-methoxybut-1-en-3-yne as a 50% solution in methanol from accompanying diacetylene has been described.⁴² However, this method is not industrially acceptable because of extremely high diacetylene concentrations in the reactor. Labour protection laws currently in force in the Russian Federation prohibit the use of industrial technologies based on the use of material (gas or liquid) flows containing more than 10% of diacetylene.⁶ Therefore, problems of diacetylene extraction from gases produced by pyrolysis of hydrocarbon raw materials have

I A Maretina, B A Trofimov Irkutsk Institute of Chemistry, Siberian Branch of the Russian Academy of Sciences, ul. Favorskogo 1, 664033 Irkutsk, Russian Federation. Fax (7-395) 239 60 46. Tel. (7-395) 246 14 11. E-mail: admin@irioc.irk.ru (B A Trofimov)

Received 29 November 1999

Uspekhi Khimii 69 (7) 642–660 (2000); translated by R L Birnova

received recently considerable attention, especially with regard to the safety of acetylene extraction due to the ability of diacetylene to undergo polymerisation and decomposition with explosion.

It should be noted in this connection that operations with diacetylene in manufacturing plants and in the laboratory belong to the category of particularly hazardous ones. It is therefore expedient to give due consideration to the vast experience accumulated in this area. The formation of a liquid phase in gas flows containing diacetylene is impermissible. The schemes of chemical conversion of diacetylene into practically valuable compounds should employ exclusively alkaline media, because the polymers formed under these conditions as side products are not hazardous. Manipulations with condensates or products prepared based on industrial diacetylene-containing gases differ substantially from those with pure diacetylene, since the polymerisation processes are more pronounced owing to the presence of higher 1,3-diynes. It is therefore preferable to prepare compounds which can easily be removed by distillation. It is rather difficult to isolate high-boiling products from such mixtures by conventional methods.

The technologies implemented in Russia were developed with due regard for safety for two main types of the processes, *viz.*, those in which liquid ammonia^{36,43,44} and *N*-methylpyrrolidone³⁷ were used as selective solvents. A possible approach to diacetylene utilisation is based on its ability to react with alcohols.^{36,37,41,42} The products of this reaction can be used in the synthesis of some aromatic and heterocyclic compounds (*e.g.*, monomers, dyes and drugs) as well in the production of plasticisers, herbicides, rubber vulcanisation accelerants, intermediates for electronic industry, broad-spectrum metal corrosion inhibitors, *etc.*^{36,37} Other conversions of diacetylene can be used in the synthesis of otherwise inaccessible heterocyclic compounds.^{38–40,45–47} All this makes diacetylene and its heterofunctional derivatives promising candidates for building blocks in the targeted synthesis of heterocyclic compounds.^{11–17,38–40,47}

Diacetylene most easily enters into reactions of nucleophilic addition with amines, alcohols and thiols, and high reactivities of the adducts make them promising reagents for practical purposes. In reactions with nucleophilic reagents, diacetylene behaves as a typical alkyne activated by an acceptor group,⁴⁷ *i.e.*, in this case the addition occurs at the terminal carbon atom of the acetylene bond, eventually resulting in the formation of 1-heteroalk-1-en-3-yne.

III. Reactions with amines

The addition of primary amines to diacetylene occurs readily at 30–40 °C in the absence of a catalyst. Usually, monoadducts of the type **1** cannot be isolated,⁴⁸ 1-*tert*-butylaminobut-1-en-3-yne (**1f**) being the only exception.⁴⁹ *N*-Alkyl(β -aminovinyl methyl)-ketimines or their tautomers, *e.g.*, *N*-alkyl-3-alkylaminocrotonal-dimines **2**, are the reaction products, which are formed in good yields.

R = Me (**a**), Et (**b**), Prⁿ (**c**), Prⁱ (**d**), Buⁿ (**e**), Bu^t (**f**).

According to the published data,^{48,49} the adducts **2** have *s*-Z-conformation which is stabilised by an intramolecular hydrogen bond. The reaction of diacetylene with secondary amines gives 1-dialkylaminobut-1-en-3-yne (**3**).^{3,47}

R = Me (**a**), Et (**b**), Prⁿ (**c**), Buⁿ (**d**); R₂N = N(CH₂)₂O (**e**).

The stereochemistry of the reaction of diacetylene with diethylamine in various solvents and at different temperatures resulting in the formation of the *Z*- and *E*-isomers **3b** has been studied.⁵⁰ The *E*:*Z* ratio increases with temperature. The *Z*-isomer prevails in acetonitrile, diethylamine and THF at 0–20 °C, whereas the *E*-isomer is predominantly formed in ethanol at 20 °C. The *Z* → *E* transition is observed only in the photolysis.

The kinetics of addition of secondary amines to diacetylene in dioxane at 20–80 °C corresponds to that of second-order reactions.⁵¹ The formation of compounds **3b,d** was monitored by UV-spectroscopy. The low values of activation entropy ($\Delta S^\ddagger = -55$ e.u.) and enthalpy ($\Delta H^\ddagger = 33.4$ kJ mol⁻¹) for the amine **3b** prompted a conclusion⁴⁷ that the addition occurs *via* intermediate products with considerable charge separation (bipolar ions). The final products result from intramolecular (*E*-isomers) or intermolecular (*Z*-isomers) proton transfer. The charge separation in the transition state favours both specific orientation of the amine and dioxane molecules and low values of activation entropy and enthalpy.⁴⁷

1-Dialkylaminobut-1-en-3-yne **3** with primary alkyl substituents react with primary amines to give potentially tautomeric aminocrotonal-dimines **4** due to the exchange of the amino groups. Reactions of compounds **3** with arylamines yield *C*-(2-dialkylaminovinyl)-*C*-methyl-*N*-(aryl)azomethines **5**.^{40,48} Depending on conditions, the hydration of amines **3** gives either 4-dialkylaminobut-3-en-2-ones **6**,^{3,46,52,53} or 3-dialkylaminobut-2-enals **7** (Scheme 1).⁴⁶

R¹ = Me (**a**), Et (**b**), Prⁿ (**c**), Buⁿ (**d**).

The addition of alcohols to enamino ketones **6** which is catalysed by bases gives the vinyllogues of aminoacetals **8**⁴⁰ which easily react with CH-acids, *e.g.*, malonodinitrile, to give the diene **9** (see Scheme 1).⁴⁰ Stepwise *C*-alkylation and hydrogenation of the amines **3** results in *N*-monosubstituted 1-aminoalkanes which represent valuable building blocks for the introduction of the 4-aminobutyl group.⁵⁴

The reaction of diacetylene with an excess of diethylamine in dilute aqueous solutions of acetonitrile, ethanol or THF results in the diadduct, *viz.*, 1,3-bis(diethylamino)buta-1,3-diene (**10**); upon subsequent concentration of the reaction mixture, the latter is hydrated by a residual amount of water to be converted first into the hemiaminal **11** and then into the aldehyde **7b** following splitting-off of diethylamine.⁵⁵

The reaction of the monoadduct **3b** with diethylamine is accompanied by the appearance of a band at 325 nm in the UV spectrum of the reaction mixture; its intensity increases with a simultaneous decrease in the intensity of the band at 275 nm corresponding to the original amine **3b**. After completion of the reaction, the UV spectrum contains only the former band corresponding to the product **10**.⁵⁵

The absorption band of the original enyne **3b** in the IR spectrum is shifted towards the low-frequency region; its intensity decreases simultaneously with the appearance of a band around 1580 cm^{-1} , which corresponds to the product **10** having Z-configuration.⁵⁵ The intensity of this band increases as the reaction proceeds further. The first diethylamine molecule adds to diacetylene in acetonitrile much faster than the second one.

Thus, the first step of the conversion of diacetylene into the bisadduct **10** is the rate-limiting step. The enhancing effect of the solvent is attributed to incomplete removal of water and hence to electrophilic catalysis by water molecules which attack the terminal atom of the ethynyl group:

This transition state is in accord with the observed regioselectivity of the reaction and Z-configuration of the diene formed as well as with the high negative entropy and low activation energy of the reaction. The proton transfer and the addition of the nucleophile are synchronous processes and are accompanied by the migration of the positive charge to the α -carbon atom as might be expected. Otherwise, the allene **12** would be formed.⁵⁵

In aqueous solutions, the role of a nucleophile is played by water, which leads to the formation of the enamino ketone **6b**. The calculated rate constants for this reaction in aqueous THF are much lower than the rates of addition of the second diethylamine molecule to the amine **3b**, the enthalpy of activation is also lower. This attests to a concerted process and the involvement of the nucleophile in the limiting stage of both reactions, since water is a much weaker nucleophile than diethylamine.⁵⁵

1,2-Diaminoethane reacts with diacetylene to give a mixture of tautomers of 5-methyl-2,3-dihydro-1,4-diazepine (**13**).⁵⁶

It was expected that the reaction of diacetylene and its homologues with 1,3-diaminopropane would give 1,2,3,4-tetrahydro-1,5-diazocine.⁵⁷ However, the reaction product represents a mixture of Δ^1 -tetrahydropyrimidine (**14**), 2-methyl- Δ^1 -tetrahydropyrimidine (**15**), 2-methyl- (**16**) and 2,2-dimethylhexahydropyrimidines (**17**).

This can be rationalised as the addition of two diamine molecules to one diyne molecule, resulting in the diadducts **A** and **B** which undergo further cyclisation and fragmentation in two directions (Scheme 2).

Scheme 2

These results are similar to those obtained for the reaction of acetylacetone with 1,3-diaminopropane⁵⁷ and formally correspond to the scission of β -diketone derivatives.

As noted above, reactions of diacetylene with solutions of primary and secondary amines in aqueous ethanol produce enamino ketones **6**. It was found, however, that the physical constants of enamino ketones **6** thus prepared do not coincide with those prepared by amination of alkoxy ketones.⁵⁸ Later, this discrepancy was explained⁵⁹ by the formation of enamino aldehydes **7** along with enamino ketones **6** in reactions of diacetylene with solutions of amines in aqueous ethanol. Depending on the size of the alkyl substituents at the nitrogen atom and the concentration of the aqueous solution of alkali (3%–5%), the content of the aldehyde in the reaction mixture changes and may exceed 40% with respect to the ketone.⁵⁹ Thus if 3-dimethylaminobut-2-enal (**7a**) is formed only in trace amounts, the yields of the products **7b** and **7d** amount to 35% and 43%, respectively.⁵⁹

It is believed⁴⁶ that the formation of enamino ketones **6** from amines **3** can also occur *via* aldehydes **7**. With an increase in temperature, the ketone:aldehyde ratio increases.⁴⁶ Thermal isomerisation occurs quantitatively, probably, *via* the oxetene cycle. The aldehyde **7b** is fully isomerised into the ketone **6b** in 4 h at 150°C .

The addition of water to amines **3a,b** occurs easily in the presence of catalytic amounts of an alkali exclusively at position 3 and results in alkyl 2-dimethylaminovinyl ketones **18**.⁶⁰

R = Me (a), Et (b).

These conversions were used to develop a procedure for chemisorption of diacetylene by aqueous solutions of primary and secondary amines aimed at separation of diacetylene in the manufacture of acetylene by oxidative pyrolysis of methane.⁵⁹ This approach has been approved at the Yerevan Industrial Corporation 'Nairite' with both a real abgas[†] and a diacetylene-enriched condensate. Their compositions are shown in Table 1.⁵⁹ The presence of methane, nitrogen, ethylene and some other components in the abgas can be explained by the fact that diacetylene-containing gases are diluted with a cracking gas from which acetylene had previously been removed by absorption down to concentrations of $\text{HC}\equiv\text{C}-\text{C}\equiv\text{CH}$ (< 10 vol.%) which ensure their safety upon transportation.⁵⁹ Chemisorption of diacetylene is performed by a 25% aqueous solution of dimethylamine. The number of absorption plates and the design of the absorption apparatus ensure the absorption of 92%–94% of diacetylene at its average concentration of 6%–7%. The addition of dimethylamine to diacetylene occurs at 25–30 °C. Since this reaction is exothermic, the temperature of the reaction mass increases slowly to 50 °C.[‡] The amine **3a** formed in the first step was isolated from the reaction mixture in its individual state and characterised.⁵⁹

Table 1. The composition of abgases and their condensates.

Component	Content (vol.%)	
	in abgas	in condensate
Hydrogen	35–40	—
Methane	20–25	—
Nitrogen	7.0–11.0	—
Diacetylene	6.0–8.0	36–52
Ethylene	1.0–2.0	—
Methylacetylene	1.0–1.5	5.5–7.5
Benzene	1.0–1.5	5.0–7.0
Allene	0.5–1.0	3.5–5.5
Vinylacetylene	0.5–1.8	4.0–4.5

Then, the reaction mass is loaded into a reactor where the triple bond is hydrated at 60–65 °C. The ketones **6** formed are rather stable and convenient C₄-synthons for the synthesis of heterocyclic compounds.^{38–40}

1-Dialkylaminobut-3-yn-2-ones (**19**), which are promising reagents for the synthesis of heterocyclic compounds, are easily prepared by bromination and dehydrobromination of enaminone ketones **6**.^{62–67}

R = Me (a), Et (b), Prⁿ (c).

[†] Abgas is a technical term, which designates an absorption gas.

[‡] Among a vast array of products present in diacetylene as admixtures, vinylacetylene ranks second in reactivity after diacetylene. However, even this compound reacts with aqueous solutions of secondary amines at a detectable rate only at 100 °C in an autoclave.⁶¹

The structures and reactivities of enamino ketones **6**, **18** and ynamino ketones **19** were described in numerous publications.^{38, 39, 52, 62} The effects of substituents on the distribution of electron density in the molecules of en- and ynaminocarbonyl compounds were studied by ¹³C-NMR spectroscopy. These studies were aimed at the determination of spin-spin coupling constants (J_{CC}) ¹³C–¹³C at the double and triple bonds.⁶² The J_{CC} values were found to be significantly smaller than those calculated according to the additive scheme. This is due to delocalisation of the multiple bonds by direct polar conjugation, through the double (triple) bond involving the lone pair on the nitrogen atom and the π -system of the carbonyl fragment.

The contribution of the bipolar resonance form was estimated to be ~ 30% for enamino ketones **6** and exceeded 50% for ynamino ketones **19**.⁶² Comparison of chemical shifts in the ¹³C NMR spectra of carbon atoms at the triple bond of substituted ynamines with the corresponding values for the C atoms at the double bond of enamines led to a conclusion about cross-polarisation of the orthogonal π -system of the triple bond in ynamines containing acceptor groups.⁶²

This effect is manifested in the abnormally low shielding exerted by the dialkylamino group on the carbon atom of the multiple bond nearest to the nitrogen atom. Data on the structures of ynamino carbonyl compounds suggest that the conjugation of the donor and acceptor groups through the multiple bond (the so-called 'push-pull effect') strongly influences the distribution of electron density in the molecules and, as a consequence, their reactivities. As a result, these compounds acquire specific properties which differ radically from those of both ynamines and ketones containing a triple bond.⁴⁰

The behaviour of ynamino ketones **19** in cyclisation reactions differs from that of enamino ketones **6** and **18**.^{38, 39, 52} Whereas enamino carbonyl compounds typically 'deliver' three-carbon fragments in cyclisation,⁴⁰ ynamino ketones mostly react like simple ynamines, *i.e.*, with a twofold attack by bifunctional reagents on the carbon atoms of the triple bond (1,1-attack).⁵²

19, **22**: R = Me (a), Et (b), Prⁿ (c); **20**: X = NH (a), O (b), S (c);

21: Y = O (a), S (b).

Thus the reaction of ynamino ketones **19** with ethylenediamine, ethanolamine and 2-mercaptoethanol is accompanied by the elimination of the dialkylamino group and the formation of

1-(4,5-dihydroimidazol-2-yl)prop-1-en-2-ol (**20a**), 1-(4,5-dihydro-oxazol-2-yl)prop-1-en-2-ol (**20b**) and 1-(4,5-dihydrothiazol-2-yl)prop-1-en-2-ol (**20c**), respectively, containing a fully enolised carbonyl fragment.^{68,69} The use of derivatives **20** as the X_{α} -inhibition factor⁷⁰ and anticonvulsants, *e.g.*, in the treatment of industrial electronic shock traumas, was described.⁷¹

The ynamino ketones **19** react with aromatic α,β -bifunctional reagents, *e.g.*, 2-aminophenol and 2-aminobenzenethiol, like ordinary ynamines^{72–76} to produce 1-(benzooxazol-2-yl)propan-2-one (**21a**) and 1-(benzothiazol-2-yl)propan-2-one (**21b**), respectively.^{77,78} Benzothiazole **21b** has been used in the synthesis of compounds for modulation of information signals⁷⁹ and pharmaceutical preparations against acidophilia, bronchial asthma, allergies,⁸⁰ diabetes and nephropathies.⁸¹ Benzothiazoles of the type **21b** manifest herbicidal activities⁸² and are used in the production of liquid-crystal compositions.⁸³

The cyclisation of ynamino ketones **19** with *o*-phenylenediamine results in 2-dialkylamino-4-methyl-3*H*-1,5-benzodiazepines **22**⁶⁹ in up to 83% yields.

Photosensitive materials based on benzodiazepines **22** were patented.⁸⁴ Compounds of this class are used in the therapy of cholecystitis, gastritis⁸⁵ and meningitis⁸⁶ as well as squalene synthase inhibitors,⁸⁷ atypical neuroleptics⁸⁸ and fungicides against *Penicillium notatum*.⁸⁹ Thus, benzodiazepines of the type **22**, which have a wide range of practical applications, can also be synthesised from ynamino ketones.

The reaction of diacetylene with primary amines in the presence of copper(I) salts occurs as 1,4-addition and results in the formation of pyrrole or 1-alkylpyrroles.³ This reaction is carried out at 140–160 °C both in the absence of the solvent and in methanol, ethanol or DMF. In the latter case, the resulting pyrroles have a high degree of purity and are formed in higher yields. The reaction of ammonia and primary alkyl- and arylamines with disubstituted symmetrical 1,3-diynes in the presence of copper(I) chloride affords 1,2,5-trisubstituted pyrroles **23**.³

$R^1 = \text{H, Me, Et, Ph}; R^2 = \text{H, Me, Et, Bu}^n, \text{Ph}.$

According to Shostakovsky and Bogdanova,³ the role of a catalyst in this reaction consists in the formation of a non-polar π -complex with one of the triple bonds where the electron density is evenly distributed between both carbon atoms, which facilitates the interaction of the nucleophilic nitrogen with the fourth carbon atom of the conjugated diyne system. The smooth course of this reaction made it possible to develop a general scheme for the synthesis of substituted pyrroles.³ The practical significance of this class of compounds is documented in numerous monographs and reviews.^{13–16, 21, 29, 90–94} In the absence of a catalyst, the reaction of diphenylbutadiyne with benzylamine affords 2,3,6-triphenylpyridine (**24**) in 50% to 70% yield.⁹⁵

The specific feature of this reaction is that in the absence of a catalyst only pyridine **24** is formed; however, in the presence of Cu_2Cl_2 it proceeds simultaneously in two directions. This phe-

nomenon is interpreted by the ability of copper(I) chloride to coordinate both at the nitrogen atom and at the triple bond.⁹⁵

IV. Reactions with alcohols

The synthesis of 1-alkoxybut-1-en-3-yne **25** by the reaction of diacetylene with alcohols in the presence of a catalyst was described;³ however, the physical constants obtained by different authors differ.⁹⁶ This may be due to the difference in the ratios of *E*- and *Z*-isomers in the specimens prepared under different conditions or due to their contamination with products of further transformations of the ethers **25**.

$R = \text{Me (a), Et (b), Pr}^n \text{ (c), Bu}^n \text{ (d), n-C}_5\text{H}_{11} \text{ (e).}$

The addition of methanol, ethanol, propan-1-ol, butan-1-ol, 2-methylpropan-2-ol, pentan-1-ol and hexan-1-ol to diacetylene has been studied under identical conditions at the alcohol: diacetylene ratio of 3:1 in the presence of catalytic amounts of KOH.⁹⁶ The content of *E*- and *Z*-isomers was determined on the basis of ^1H NMR spectroscopy and GLC data.

The ethers **25a,b** appeared to be pure *Z*-isomers; their homologues **25c,d** contained approximately equal amounts of the *E*-isomer (12.8%–13.3%), whereas compounds **25e,f** represented equimolar mixtures of *E*- and *Z*-isomers.⁹⁶ It is probable that the rule of *trans*-nucleophilic addition is observed only for lower alcohols. However, if the reaction mixture contains compounds capable of forming complexes with diacetylene, the above rule may not be observed as is the case even with the reaction of diacetylene with methanol, which gives up to 15% of the *E*-isomer with dioxane as a solvent.⁹⁶

Kinetic studies of reactions of diacetylene with lower aliphatic alcohols in the presence of KOH were carried out using UV spectroscopy and GLC.^{97,98} The reaction of diacetylene with methanol (5 moles/mole of $HC\equiv C-C\equiv CH$) in the presence of KOH (0.22 moles/mole $HC\equiv C-C\equiv CH$) is described by an equation for a pseudo-unimolecular reaction with the activation enthalpy, $\Delta H^\ddagger$, of 87.8 kJ mol^{–1} and the activation entropy, $\Delta S^\ddagger$, of –19 e.u. The experimental results suggest⁴⁷ that the addition of the alkoxide ion to the terminal carbon atom of diacetylene followed by rapid protonation of the carbanionic intermediate **26** formed is the rate-limiting step of this reaction. *sp*²-Hybridisation of the carbon atom orbitals at the double bond and spatial hindrances created by bulky alkoxy and ethynyl groups direct the attack of the proton donor to the *trans*-position relative to the alkoxide ion.

UV spectroscopy and GLC were used to study⁹⁸ the kinetics of the reaction of diacetylene with methanol and ethanol under conditions close to the industrial ones,³⁷ in the presence of potassium hydroxide and sodium hydroxide at 50–73 °C and at a 1,3-diyne concentration of 2.5 mass %–10 mass %. Such a narrow temperature range can be explained by the fact that at lower temperatures diacetylene is predominantly polymerised due to the slow rate of the main reaction. At temperatures above 73 °C, this reaction proceeds further.⁹⁸ Since the rate of formation of the ether **25b** is proportional to the concentration of diacetylene in the solution, the reaction should be carried out at the maximally permissible (up to 10 mass %) concentration of $HC\equiv C-C\equiv CH$. The dependence of the rate constant for the formation of the ether **25b** on KOH concentration is more complex. With an increase in KOH concentration from 1% to 5%, the rate constant increases abruptly. Within the concentra-

tion range of KOH from 5 mass % to 15 mass %, the reaction rate is not changed ($k_{\text{aver}} = 2.7\text{--}2.8 \text{ l mol}^{-1} \text{ s}^{-1}$, 60°C), but this drops drastically after further increase in the catalyst concentration.⁹⁸ This is ascribed to the simultaneous effect of several factors. At low concentrations of the catalyst, the increase in the reaction rate is mainly due to an increase in the concentration of the alkoxide ions responsible for this reaction. At 5 mass %–15 mass % of KOH, the concentration of alkoxide ions increases to such an extent that its fluctuations within the indicated range do not influence the reaction rate. At KOH concentrations above 15 mass %, the rate of side reactions increases drastically. From these data, it was concluded that the optimum concentration of KOH is 5 mass %.⁹⁸

When diacetylene was passed through a solution of monoethanolamine in benzene at 0°C , a crystalline product was formed which represents 2-[2-(2-hydroxyethyl)iminopropyl]oxazolidine (**27**) as can be judged from the ^1H and ^{13}C NMR spectral data.

This adduct of diacetylene with ethanolamine is used for stabilisation of biologically active substances in grass fodders.⁹⁹

The binding of 1,2- and 1,3-diols to diacetylene was studied in the presence of catalytic amounts of alkali and resulted in a mixture of cyclic acetals of but-3-ynal, buta-2,3-dienal (**28**) and but-2-ynal (**29**); their ratio changed depending on experimental conditions.¹⁰⁰

$n = 0$: $\text{R}^1 = \text{R}^2 = \text{H}$; $n = 1$: $\text{R}^1 = \text{R}^2 = \text{H, Me}$, $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$.

Bifunctional derivatives of the aromatic series, such as *o*-, *m*- and *p*-aminophenols, add to diacetylene in the presence of alkalis

like ordinary alcohols, *i.e.*, through the hydroxy group, to give 1-aryloxybut-1-en-3-yne (**30**).¹⁰¹

Alcohols (glycols, amino alcohols) and phenols add to diacetylene under much milder conditions than to acetylene and vinylacetylene.^{37,98} The vinylation of lower alcohols with acetylene requires the use of superbasic media^{19,20,23,28,102} or heating up to $120\text{--}140^\circ\text{C}$, and their addition to vinylacetylene occurs at temperatures around 100°C , while the optimum temperature for the reaction of diacetylene with methanol in the presence of KOH (5 mass %) is as low as $72\text{--}73^\circ\text{C}$.^{37,98} This circumstance is extremely important because the substantial difference between the rates of the reaction of methylacetylene, vinylacetylene and diacetylene with lower aliphatic alcohols allows selective chemisorption of diacetylene from gas mixtures produced by acetylene-manufacturing plants^{36,37} which contain these particular hydrocarbons. Moreover, extraction of diacetylene from industrial gases allows implementation of technologies for industrial syntheses of isopropenylmethyl ether, acetone and acetylacetone based on the accompanying methylacetylene–allene fraction.¹

Numerous transformations of the ether **25a** have been described under conditions of alkaline and acid catalysis (Scheme 3).¹⁰³ Thus the addition of the second methanol molecule to the ether **25a** in the presence of an alkali results in 1,1-dimethoxybut-3-yne (**31a**). Its analogue, *viz.*, 1-methoxy-1-phenethoxybut-2-yne, is used in perfumery.¹⁰⁴

1,1-Dimethoxybutan-3-one (**32a**) is formed in 80% yield as a result of hydration of the triple bond of acetal **31a** under conditions of acid and mercury salt catalysis (H_2SO_4 , HgSO_4) in boiling aqueous methanol (see Scheme 3). The addition of an alcohol and water to the ether **25a** in the presence of an acid catalyst also results in the acetal **32a** in 85% yield.

1,1,3,3-Tetramethoxybutane (**33a**) and a small amount of 1,1,3-trimethoxybut-2-ene (**34a**) are formed under identical conditions but in the presence of dry methanol (3 equiv.). Upon mild hydrolysis at room temperature, this mixture is converted into the acetal **32a**; its complete hydrolysis yields 1,3,5-triacetylbenzene, which was first observed by Claisen.¹⁰⁵

Thus, the acetals **32a,b** appear to be the most convenient and stable intermediates prepared from diacetylene.¹⁰⁶

Thermal or catalytic elimination of methanol from the acetal **32a** gives 4-methoxybut-3-en-2-one (**35a**);¹⁰⁶ a mixture of compounds **32a** and **35a** (7 : 3) is formed in the presence of catalytic amounts of acids or alkalis. Its homologue **32b** ($\text{R} = \text{Et}$) yielded

$\text{R} = \text{Me (a), Et (b)}$.

Scheme 3

an equilibrium mixture of **32b** and **35b** in a 7.5:2.5 ratio upon storage under conditions close to those employed in industry.⁹⁸

The structure of the ketone **35a** was studied in detail using UV, IR and NMR spectroscopy.¹⁰⁷ Analysis of thermochemical and ¹H NMR spectral data revealed¹⁰⁸ that this compound has *E*-configuration.¹⁰⁸

A kinetic analysis of acid-catalysed hydrolysis of the ethers **25a,b** by polarography^{109,110} provided support for the initial rapid hydration of the triple bond with subsequent slow protonation of ketones **35a,b**, which are further decomposed to 3-oxobutanal (**36**); the latter undergoes self-cyclisation into 1,3,5-triacetylbenzene (**37**). In water, the rate of this reaction is an order higher than in 25% aqueous DMF.

R = Me (a), Et (b).

Evidence for primary hydration of the ethers **25a,b** was also obtained in kinetic studies of formation of 1,1-dialkyloxybutan-3-ones by GLC.^{111–113}

The reaction of 1-methoxypent-1-en-3-yne (**38a**), 1-methoxyhex-1-en-3-yne (**38b**) and 1-methoxyhept-1-en-3-yne (**38c**) with methanol and water under conditions of acid catalysis gave 1,1-dimethoxyalkan-3-ones **39a–c**, respectively.¹¹⁴

R = Me (a), Et (b), Prⁿ (c).

Derivatives of the aldehyde **36** containing functional groups in the methylene group have been synthesised. The synthesis of 2-bromo-3-oxobutanal (**40**) by direct bromination of the acetal **32** was described.¹¹⁵ However, reproduction of the experiments and structural analysis of the reaction products by GLC revealed the formation of three compounds, which suggests that bromination of the original acetal occurs in all the three possible directions.¹¹⁵ The bromosubstituted ketone **40** was synthesised in ~60% yield by bromination of enamino ketones **6a,b** in an aqueous medium. This reaction is accompanied by hydrolysis of 4-dialkylamino-3,4-dibromobutan-2-one **41** formed with elimination of the secondary amine and dehydrohalogenation.¹¹⁵

R = Me (**6a**, **41a**), Et (**6b**, **41b**); R₂N = (CH₂)₄N (**6e**, **41c**), (CH₂)₅N (**6f**, **41d**).

Intensive development of the chemistry of β -functionalised vinyl ketones has begun following synthesis of β -chlorovinyl methyl ketone by addition of acetyl chloride to acetylene.¹¹⁶ The synthetic potentialities of β -chlorovinyl ketones have been reviewed.^{116–118} The transfer of the acetylvinyl residue was named by A N Nesmeyanov and N K Kochetkov as 'ketovinylation'.¹¹⁹ The synthetic potential of this reaction was further expanded owing to the involvement of other β -substituted vinyl ketones RCOCH=CHY (Y = OR, NR₂, SR, NO₂, N₃,

SO₂R);¹²⁰ the activities and the selectivities of their reaction centres C(1) and C(3) can be altered by using different solvents.¹²¹

A pilot plant for the synthesis of the acetal **32b** based on dilute diacetylene-containing industrial gases accompanying manufacture of acetylene by electrocracking of methane (see Scheme 3) was installed at the Scientific-and-Industrial Association 'Azot' (Saratov) in 1974. The ether **25b** was obtained as a by-product.^{37,122} This version of diacetylene utilisation was implemented on an industrial scale with DMF and *N*-methylpyrrolidone as selective solvents. A pilot-plant unit for isolation of diacetylene formed as a side product in the manufacture of acetylene by oxidative pyrolysis of methane and preabsorption with ammonium was installed at the Scientific-and-Industrial Association 'Azot' (Novomoskovsk) in 1980.^{36,43,44,123–127} The technological process^{36,123} involved isolation of diacetylene from the bottoms of an ammonium preabsorption unit followed by the synthesis of the ether **25a**. Its hydration and methoxylation in the presence of catalytic amounts of H₂SO₄ yield the acetal **32a**, which is further used in the synthesis of 4-methylpyrimidine-2-thiol (**42**) by the reaction with thiourea in the presence of HCl and its oxidation product, viz., bis(4-methylpyrimidin-2-yl) disulfide (**43**).^{36,123}

The pyrimidinethiol and disulfide thus prepared accelerate the vulcanisation of rubbers having a unique spectrum of action.^{127,128} Their addition to rubber mixtures increases the resistance of the compositions to prevulcanisation by 150%. The disulfide **43** is a novel accelerant having a retarded initial period of action. The use of such accelerants prevents early cross-linking in processing of rubbers.^{128–130} Pyrimidinethiol **42** was used in the preparation of antitumour drugs¹³¹ and novel nematocides.¹³² It is also used as a lustre-enhancing coating in the production of electrolytic copper foils.^{36,133} The addition of small (0.003–0.03 g litre⁻¹) concentrations of this compound to electrolytes for the production of copper foil increases its yield by 60% and improves its physico-mechanical properties. The use of pyrimidinethiol **42** in the production of photographic materials for thermal development is widely known.¹³⁴

Thus, the interest in the practical use of diacetylene is determined by industrial demands, on the one hand, and by broad potentialities of the syntheses on the basis of 1,3-bifunctional compounds, on the other hand. The latter are the nearest derivatives of diacetylene and offer promising approaches to the synthesis of various classes of organic compounds. The list of products which can be prepared from diacetylene is given below.

Compound	Price per kg /USD ^a
1,1-Dimethoxybutan-3-one	201.75
(<i>E</i>)-4-Methoxybut-3-en-2-one	1716
1,3,3-Trimethoxybutane	1600
4-Diethylaminobutan-2-one	1290
Thiophene	236
5-Methylisoxazole	660
3-Methylpyrazole	2566
4-Methylpyrimidine	5200

V. Reactions with sulfur-containing nucleophiles

1. Reactions with hydrogen sulfide and sulfide ions

Systematic studies of reactions of acetylene and its derivatives with hydrogen sulfide and sulfide ions^{12, 17, 20, 23, 26–32, 136–138} have been extended to diacetylene.¹²

The reaction of diacetylene with hydrated sodium sulfide occurs through the formation of the ethynylvinylthiolate anion (**44**) and results in both di(2-ethynylvinyl) sulfide (**45**) and thiophene (**46**),^{12, 136–138} which is the product of cyclisation of the anion **44** or the corresponding thiol.

Earlier, an attempt was made¹³⁹ to synthesise thiophene from diacetylene by reaction of hydrated sodium sulfide with diacetylene in aqueous ethanol at pH 8–10; however, in this case the yield of the target product did not exceed 20%. When this reaction was carried out in a superbasic medium (KOH–DMSO), thiophene was obtained in high yields (up to 94%) and with high selectivity.^{12, 136} The sulfide **45** is not formed under these conditions. If the reaction is carried out in dimethyl sulfoxide, the addition of an alkali is unnecessary, since it is liberated in this reaction, but the yield of thiophene does not exceed 55%. The effect of reaction conditions on the yield of thiophene is demonstrated in Table 2.

Table 2. The effect of conditions of the reaction of diacetylene with sodium sulfide on the yield of thiophene (solvent, DMSO).

T /°C	Time /min	Concentration of reagents/mol		Yield of thiophene (%)
		C ₄ H ₂	Na ₂ S·9H ₂ O	
20	90	0.054	0.108	44.1
55	75	0.038 ^a	0.083	93.9
70	90	0.120	0.061	54.9
100	75	0.072	0.14	40.0

^a In the presence of 0.08 mol of KOH.

It should be emphasised that the addition of alkali is only necessary to trigger the synthesis, since the alkali liberated accelerates further the reaction. High selectivity of this reaction is worthy of note, *viz.*, the purity of raw thiophene distilled from the reaction mixture without additional purification reaches 99.9%.

Since this reaction represents nucleophilic addition of the sulfide ion to diacetylene with subsequent cyclisation of the intermediate product,¹⁴⁰ its rate should be higher in the solvents which do not suppress the activity of anions owing to their solvation. By virtue of their high dielectric permittivity, aprotic dipolar solvents (*e.g.*, DMSO, hexamethylphosphoric triamide) enhance electrolytic dissociation of sodium sulfide and sharply increase the concentration of the weakly solvated sulfide ion.¹⁴⁰ *N*-Methylpyrrolidone was also used as a solvent, and the reaction was carried out under identical conditions (55 °C, equimolar amounts of KOH and sodium sulfide). At 70 °C, the reaction of diacetylene with sodium sulfide carried out in an aqueous medium in the presence of an alkali gives thiophene in 52.5% yield.¹²

The conditions of the reaction of diacetylene with the sulfide ion giving exclusively the sulfide **45** (yields up to 89.5%) have been found.¹⁴⁰ In this reaction, liquid ammonia is used as a solvent and

sulfide ions are generated from ammonium sulfide formed *in situ* from ammonia and hydrogen sulfide:

The product **45** has *Z,Z*-configuration, which points to high *trans*-stereoselectivity of this reaction.¹⁴⁰

Among reactions of diacetylene with sulfur-containing compounds, synthesis of thiophene undoubtedly presents the greatest interest from the practical point of view. This stimulated the development of a procedure for continuous synthesis of thiophene from diacetylene and sodium sulfide in aqueous-alkaline media¹² with continuous removal of thiophene and replenishment of the reaction mixture with the starting reagents. Circulation of diacetylene lasted for 6 h at 70 °C; the yield of thiophene of 99% purity exceeded 70%. The results were reproducible. An increase in temperature caused a dramatic decrease in the yield of thiophene.

It should be noted that polymers formed from diacetylene in these media are not explosive. However, the synthesis performed in DMSO is more efficient, since it results in thiophene of high purity (99.9%) and in 94% yield.¹³⁶ The obvious advantages of this method include its simplicity, one-step procedure and wastelessness as well as high yields and high purity of the final product. Presumably, diacetylene present in waste gases from acetylene-manufacturing plants can also be used in large-scale productions, since the activities of the accompanying products (*e.g.*, methylacetylene, vinylacetylene) in the reaction with sulfide ions is much lower.¹²

2. Reactions with thiols

The addition of thiols to diacetylenes has been carried out under diverse conditions.³ In the presence of catalytic amounts of an alkali, thiols are easily added to one of the triple bonds of diacetylene to form 1-organylthio-1-en-3-yne **47**.³

This reaction is neither accelerated by free-radical initiators nor is decelerated by antioxidants, which suggests its heterolytic mechanism.³ Like many other ionic reactions of nucleophilic reagents with alkynes, it occurs as *trans*-addition and results in the *Z*-isomers **47**. However, this reaction is complicated by the addition of thiol to the sulfide **47** and the formation of 1,4-bis(organylthio)buta-1,3-dienes **48**, which significantly diminishes the yield of the primary adduct **47**.

R = Alk, Ar, Het.

The *in situ* generation of the thiolate anion from *S*-alkylisothiuronium salts¹⁴¹ or thioacetates¹⁴² under the action of alkalis prevents competitive free-radical addition of the free thiol thus reacting to sulfides **47** in high yields. The reaction of diacetylene with thioacetates is carried out in the presence of KOH (1.2 moles per mole of the starting acetate) with methanol as a solvent. This reaction gives sulfides **47** in up to 80% yields.^{141, 142}

R = Et (**a**), Prⁿ (**b**), Prⁱ (**c**), Buⁿ (**d**).

The IR spectra of sulfides **47a–d** contain characteristic absorption bands at 3290 (≡CH), 2100 (C≡C) and 1560 cm^{–1} (C=C–S). In ¹H NMR spectra, the spin-spin coupling constant of vicinal protons (*J*_{HH}) is 10 Hz, *i.e.*, it is characteristic of the *cis*-arrangement of vinylic protons.

The use of liquid ammonia or of aqueous ammonia for nucleophilic thiolation of 1,3-diynes opens up new prospects for

the synthesis of unsaturated sulfides and practical utilisation of diacetylene in those technological processes where liquid ammonia is used as a selective solvent.³⁶

The reaction of diacetylene with thiols was studied¹⁴³ both in liquid ammonia and in aqueous ammonia at concentrations of ammonia varying from 25% to 70% within the temperature range of -33 to $+20$ °C. The aim of these studies was to reach the maximum use of the high solubilising capacity of ammonia with respect to diacetylene, which is determined by its moderate dielectric permittivity and polarity as well as by its relatively high basicity and ability to form hydrogen bonds and ammonium salts with thiols, which exist in ammoniacal solutions as contact ionic pairs and free ions. These factors altogether enhance the reactivity of thiolate ions, which are weakly solvated by ammonia. In fact, the reaction of diacetylene with thiols in liquid ammonia occurs under mild conditions (-33 °C) and is completed immediately after mixing of the reactants. Irrespective of the diacetylene: thiol molar ratio (1.0:0.5, 1:1, 1.0:1.2, 1:2), the selectivity of the reaction is not changed and the reaction results exclusively in sulfides **47** in 84% to 98% yields. This suggests that the secondary reaction leading to disulfides **48** is completely excluded in this case.¹⁴³

R = Et (**a**), Buⁿ (**d**), n-C₆H₁₃ (**e**), (CH₂)₂OH (**f**), CH₂CH(OH)CH₂OH (**g**), CH₂Si(OMe)₃ (**h**), (CH₂)₂Si(OMe)₃ (**i**), CH₂Si(OEt)₃ (**j**).

In this reaction, ammonia activates both the thiolate ion and diacetylene due to the formation of hydrogen bonds. The violation of the stereospecificity of the addition of thiols to diacetylene in liquid ammonia is attributed to the formation of diacetylene–ammonium complexes.¹⁴³ The adducts **47a,d–j** represent mixtures of *E*- and *Z*-isomers; the spin-spin coupling constants for the protons of *E*- and *Z*-ethylene fragments in the ¹H NMR spectra have characteristic values (15 and 10 Hz, respectively). The proportion of the *Z*-isomer increases with an increase in the bulk of the radical R, reaching a maximum (30%) in the case of compounds **47h–j**, *i.e.*, at the highest branching in the immediate vicinity of the sulfur atom. This suggests a significant contribution of spatial effects to the stereochemistry of this reaction, which seems to be predominantly kinetic, for the ratio of *E*- and *Z*-isomers is not changed after thermal treatment of the reaction products.

High reactivity of diacetylene with respect to thiols in liquid ammonia¹⁴³ permits, in principle, its quantitative isolation from gas mixtures in the form of sulfides **47**. Mild conditions of this reaction allow the involvement of thiols containing various functional groups.

3. The reaction with dithiocarbamate ions

Reactions of diacetylene with carbon disulfide and secondary amines or its direct reaction with ammonium dithiocarbamate in protic or aprotic solvents represent an efficient utilisation of diacetylene as a valuable product.¹⁴⁴ This reaction proceeds very easily in the absence of a catalyst when gaseous diacetylene is passed through a solution of a mixture of a secondary amine and carbon disulfide in MeOH, EtOH, Et₃N, THF, DMSO, acetone, benzene or ether or through a solution of dithiocarbamate at 20–50 °C and results in *s*-(*Z*)-(but-1-en-3-ynyl) *N,N*-dialkyldithiocarbamates **49** and 1,4-bis-(*N,N*-dialkylthiocarbamoylthio)-buta-1,3-dienes **50** in up to 94% yields.

49: R¹ = R² = Et (**a**), Prⁿ (**b**); R¹–R² = (CH₂)₅ (**c**), (CH₂)₂O(CH₂)₂ (**d**); R¹ = R² = H (**e**), R¹ = H, R² = Me (**f**);

50: R¹ = R² = R³ = R⁴ = Et (**a**); R¹ = R² = Et, R³–R⁴ = (CH₂)₅ (**b**).

Mild conditions of this reaction are determined by high nucleophilicities of dithiocarbamate ions. The reaction products are *Z*-isomers.¹⁴⁴ However, the reaction of diacetylene with ammonium *N,N*-diethyldithiocarbamate is not stopped at the addition of one mole of dithiocarbamic acid and is complicated by further conversions resulting in the formation of bis(dithiocarbamate) **50**. Dithiocarbamates are used as nematocides and flotation agents^{145, 146} as well as in the production of photo-sensitive materials. The information about the use of alkynes in the synthesis of such esters is scarce.¹⁴⁷

VI. Reactions with ketoximes and amidoximes

It might be expected that the extension of the reaction of ketoximes with alkynes, which results in pyrroles (the Trofimov reaction),^{13, 15, 16, 22, 29, 90, 93} to diacetylene¹³ would open a route to the synthesis of ethynylpyrroles of the type **51** which could be regarded as promising monomers and reagents in fine organic synthesis. However, the route resulting in *O*-adducts, *e.g.*, *O*-(but-1-en-3-ynyl)ketoximes **52**, proved to be preferable due to the high reactivity of triple bonds of diacetylene with respect to nucleophilic reagents.^{13, 148, 149}

R¹ = Me, R² = H (**a**); R¹–R² = (CH₂)₄ (**b**).

In aqueous DMSO, diacetylene exothermally adds to ketoximes in the presence of catalytic amounts of alkalis resulting in vinylketoximes **52**.^{148, 149} It was of interest to find out whether more drastic conditions, which are normally used in the synthesis of pyrroles from ketoximes and acetylene, would result in cyclisation of vinylketoximes **52** through a [3,3]-sigmatropic shift characteristic of simple *O*-vinylketoximes.¹³ However, under different reaction conditions diacetylene reacted with ketoximes to give either vinylketoximes **52** or black-coloured insoluble polymers formed upon more profound transformations of diacetylene itself and its adducts.¹³ Ethynylpyrroles **51** were not found. The best yields of the adducts **52** (36%–41%) were obtained in the presence of ~10%–30% of water in DMSO and at a concentration of KOH 1%–2%. A decrease in the reagent's concentration increased the yield of the adduct, since polymerisation is inhibited under these conditions. An increase in the alkali concentration has a negative effect on the reaction yields. In neither case were bisadducts formed. The reaction of ketoximes with diacetylene is stereospecific and occurs as *trans*-addition. According to the ¹H NMR spectroscopic data, the adducts formed have *Z*-configuration (*J*_{HH} = 6.5–6.7 Hz), which corresponds to the nucleophilic addition to the triple bond with concerted attachment of a

proton from the reaction medium. Vinylketoximes **52** are rather unstable mobile fluids, these do not withstand heating up to 70–90 °C, being rapidly and quantitatively converted into a black insoluble powder even in solution. Thermolysis products largely contained polymers formed with involvement of the triple bonds. Pyrroles were not detected, either.

The reaction of diacetylene with amidoximes in the presence of KOH in aqueous DMSO gives *O*-adducts **53**. Their rearrangement into the corresponding ethynylimidazoles was not observed.¹⁵⁰

R = Me, Ph.

VII. Reactions with hydrazines and semicarbazide

In the syntheses of heterocyclic systems, 1,3- and 1,4-dicarbonyl compounds are widely used.¹⁵¹ The role of such C₃- and C₄-synthons can be played by 1,3-diyne.^{12, 13, 16, 17, 38–40}

Three independent groups of investigators reported simultaneously on the synthesis of pyrazole derivatives by addition of hydrazines to diacetylene and its mono- and disubstituted homologues.^{38, 39, 49, 56, 152–155} Apparently, hydrazine reacts with diacetylene as a primary amine to give an intermediate **54**; further intramolecular attack of the second amino group at the C(3) atom results in the formation of the pyrazole ring **55**.⁴⁸

Z-Configuration of the adduct favours the cyclisation. The condensation of methyl diacetylene with hydrazine hydrate gives 3,5-dimethylpyrazole together with 3(5)-ethylpyrazole,¹⁵⁵ which confirms the feasibility of another type of attack at the conjugated diyne system. In anhydrous media, the reactions of diacetylene with monosubstituted hydrazines result in 1,3-dialkylpyrazoles **56**, whereas 1,5-dialkylpyrazoles **57** are formed in the presence of water. The reaction of diacetylene with methylhydrazine in an ethanolic solution gives a mixture of pyrazoles **56a** and **57a** (4 : 1), which corresponds to the predominant attack of hydrazine at the carbon atom bearing the hydrogen atom.¹⁵⁶

R = Me (a), Et (b).

Pyrazole **55** has become accessible due to the reaction of diacetylene with hydrazine.^{152, 154, 155} Direct synthesis of pyrazoles seems to be one of possible clues to the practical solution of the problem of diacetylene utilisation;¹⁵⁵ the resulting pyrazoles with various substituents are used as starting compounds in the synthesis of *C*- and *N*-vinylpyrazoles.¹⁵⁵

Syntheses of vinylpyrazoles and their homo- and copolymerisation acquired further development.^{157–159} Syntheses of biological additives to polymeric materials based on pyrazoles

prepared from diacetylene were also described.^{157, 158} The synthesis of *C*-vinylpyrazoles from pyrazole **55** was carried out.¹⁵⁹ Vinyl derivatives of some azoles, including pyrazole, were used in various branches of industry, such as production of plastics and synthetic fibres, radio engineering and medicine.¹⁵⁹ Some novel herbicides,^{160–162} pesticides,^{163, 164} antidiabetic drugs,¹⁶⁵ immunostimulators¹⁶⁶ and perfume compositions¹⁶⁷ prepared from pyrazoles **55–57** have been covered by patents. Synthesis of polychelating agents of the pyrazole series designed for solidification of epoxide resins was described.¹⁵⁷ The possibilities of extractive isolation of noble metals (Pd, Au, Ag) with pyrazole **55** hydrochlorides,^{168, 169} of preparation of complex-forming ion-exchange resins,^{170, 171} absorbents for concentration of platinum metals,¹⁷² nitration catalysts¹⁷³ and disproportionation catalysts in the synthesis of monoalkyl- and monoaryl-halogenosilanes¹⁷⁴ were demonstrated.

The reaction of diacetylene with semicarbazide, which manifests much weaker basic properties than hydrazines, yields a mixture of 3- and 5-alkylpyrazolecarboxamides (**58**, **59**).¹⁷⁵ The amides **58**, which are irreversibly isomerised into the adducts **59** under these conditions, are the main reaction products.¹⁷⁵ Other 1,3-diyne produce exclusively amides of the type **59**.¹⁷⁵

R = H (a), Me (b), Et (c), Prⁿ (d).

The presence of a pyrazole ring was confirmed¹⁷⁵ by acid hydrolysis of the adducts **59**, which was accompanied by decarboxylation and formation of pyrazoles **60**. Synthesis of 1-guanyl-3-methylpyrazole (yield 86%) from pyrazole **55** was described.¹⁷⁶ Pyrazole-1-carboxylic acid derivatives are used as pesticides¹⁷⁷ and insecticides.¹⁷⁸

Functionalised pyridines were prepared based on diacetylene and compounds containing a weakly nucleophilic nitrogen atom and an active CH-component (*e.g.*, acetylacetoneimine and ethyl β-aminocrotonate).^{176–178} The reaction products are 3-acetyl-2,4-dimethylpyridine (**61**) and ethyl 2,4-dimethylnicotinate (**62**), respectively.

R = Me (**61**), OEt (**62**).

Since the nucleophilicity of the nitrogen atom in the starting enamino ester and the enamino ketone is lowered, the reaction with diacetylene occurs in the presence of metallic sodium.

The formation of one of two possible isomers in both reactions was confirmed by ¹H NMR and IR spectroscopy as well as by chromatography. Moreover, pyridine **62** was obtained independently by oxidation of ethyl 2,4-dimethyl-1,4-dihydropyridine-3-carboxylate synthesised from crotonaldehyde and ethyl β-aminocrotonate.¹⁷⁸ The IR spectra of compounds **61** and **62** contain bands corresponding to stretching vibrations of the pyridine ring (1560, 1580 cm^{−1}), ester (1076 cm^{−1}) and carbonyl (1721 cm^{−1}) groups.^{176, 178} The protons of the pyridine ring in the ¹H NMR spectrum of compound **62** resonate as two doublets in the low-field region at δ 8.24 and 6.84 (*J* = 5.2 Hz). The former belongs to the proton at the C(6) atom, which is especially strongly

desielded by the nitrogen atom of the pyridine ring, while the latter corresponds to the proton at the C(5) atom.

Pyridines prepared from diacetylene are candidates for the synthesis of nicotinic acid. However, the above-described reaction is inefficient because of low yields of the target products. A promising procedure for large-scale synthesis of nicotinic acid was developed^{37, 130} on the basis of 4-aminobut-3-en-2-one (**63**) obtained by transamination of the ether **25b**.⁵⁸ Aminobutenone **63** cyclises spontaneously into 5-acetyl-2-methylpyridine (**64**),¹⁷⁹ which is further oxidised to pyridine-2,5-dicarboxylic (isocinchomeric) acid (**65**), which in turn is decarboxylated into nicotinic acid (**66**) at 200 °C.³⁷

VIII. Reactions with guanidine

The reaction of diacetylene and monosubstituted 1,3-diynes with guanidine in the presence of equimolar amounts of metallic sodium yields 4-alkyl-2-aminopyrimidines **67**.^{180, 181}

$\text{R} = \text{H}$ (**a**), Me (**b**), Et (**c**), Pr^n (**d**).

The structure of cyclisation products was established by a comparison of physical constants of isolated compounds and their picrates with those of known compounds obtained by independent synthesis.^{180, 181}

Amines of the pyrimidine series are widely used in large-scale organic synthesis, particularly, in the pharmaceutical industry.¹⁸² Some of them are intermediates in the synthesis of sulfonylamide drugs, e.g. sulfamerazine 2-(*p*-aminophenylsulfonylamido)-4-methylpyrimidine (**68**),¹⁸² which can be prepared in high yields from the acetal **32a** or the ether **25a**.¹³⁰

Sulfamerazine (**68**) is less toxic and more easily accessible (one-step procedure, high yields) than the well-known drug sulfodimezine [2-(*p*-aminophenylsulfonylamido)-4,6-dimethylpyrimidine] prepared from 2-amino-4,6-dimethylpyrimidine by a six-step procedure. Sulfamerazine is manufactured by the pharmaceutical company 'Polfa' and is used in the treatment of streptococcal and pneumococcal infections. Some derivatives of the pyrimidine **67a**, which include protein tyrosine kinase inhibitors,¹⁸³ vitronectin receptor antagonists,¹⁸⁴ potent psychotropic drugs,¹⁸⁵ novel fungicides¹⁸⁶ and perfume compositions,^{187, 188} were patented.

IX. 1-Dialkylaminobut-1-en-3-yne as building blocks for the synthesis of heterocyclic compounds

Some cyclisation reactions occur exclusively with the amines **3**. Their reaction with 1,2-ethanedithiol and 1,3-propanedithiol result in 5-dialkylamino-7-methyl-5*H*-2,3-dihydro-1,4-dithiopynes **69a-c** and 2-dialkylamino-4-methyl-2,6,7,8-tetrahydro-1,5-dithiocines **70a-c**, respectively.^{189, 190}

$\text{R} = \text{Me}$ (**3a**, **69a**, **70a**), Et (**3b**, **69b**, **70b**); $\text{R}_2\text{N} = \text{N}(\text{CH}_2)_2\text{O}$ (**3e**, **69c**, **70c**); $n = 2$ (**69a-c**), 3 (**70a-c**).

The condensation of 2-aminobenzenethiol with the amines **3a,b,e** is performed at room temperature in the absence of a catalyst and gives 2-dialkylamino-4-methyl-2,5-dihydro-1,5-benzothiazepines **71a-c** in up to 90% yields.^{190, 191}

$\text{R} = \text{Me}$ (**3a**, **71a**), Et (**3b**, **71b**); $\text{R}_2\text{N} = \text{N}(\text{CH}_2)_2\text{O}$ (**3e**, **71c**).

High yields of the reaction products and the absence of routes to their direct synthesis from diacetylene makes this method for the preparation of thiazepines promising.

1,4-Dithiopyne derivatives are biologically active and can be used as tranquillisers.^{192, 193} 1,5-Benzothiazepines manifest antiarrhythmic activity¹⁹⁴ and are used as regulators of the cardiovascular function.^{195, 196} Compounds **72** are tranquillisers,¹⁹⁷ and 1,5-benzothiazepines **73** possess antifungal activity.¹⁹⁸

The salient advantage of 1-dialkylaminobut-1-en-3-yne over diacetylene and its other derivatives as building blocks becomes especially obvious in the synthesis of isoxazoles. The latter cannot be obtained by the reaction of diacetylene with hydroxylamine hydrochloride.⁴⁷ 1-Alkoxy- and 1-alkylthiobutenynes give a mixture of 3- and 5-methylisoxazoles.^{37, 38, 47} On the other hand, 1-dialkylaminobut-1-en-3-yne **3** give exclusively 5-methylisoxazole (**74**) in reaction with hydroxylamine (Scheme 4).^{37, 47} The latter yields cyanoacetone (**75**) upon alkaline treatment.¹⁹⁹ Cyanoacetone reacts with phenylhydrazine to give the cyclisation product, viz., 5-amino-3-methyl-1-phenylpyrazole (**76**).³⁷ The latter is subjected to Wilsmeier-Haack formylation to give 5-amino-3-methyl-1-phenylpyrazole-4-carbaldehyde (**77**),²⁰⁰ which is used in the construction of fused pyrazolopyridines **78** and **79** and pyrazolopyrimidines **80** (see Scheme 4).^{201, 202}

Novel long-acting sulfonylamide drugs of the type **81** can be prepared from the isoxazole **74**.²⁰² Aminopyrazole **76** is used in the synthesis of pharmacologically active compounds (e.g., antidepressants, anticonvulsants, analgesics, etc.),²⁰³ biologically active reagents, some key synthons,²⁰⁴ diazo dyes for colour offset,²⁰⁵ heterocyclic anionic monoazo dyes²⁰⁶ and compositions for colour photography.²⁰⁷⁻²⁰⁹

$R^2 = R^3 = \text{Me, Et.}$

X. Reactions with carbonyl compounds

General methods for the synthesis of diacetylene alcohols and glycols include the reaction of sodium derivatives of 1,3-diynes with carbonyl compounds in liquid ammonia, condensation of mono- and bis(bromomagnesium) derivatives of 1,3-diynes with aldehydes and ketones in THF, the Favorsky condensation of 1,3-diynes with carbonyl compounds in the presence of KOH powder in ether or THF, oxidative condensation of α -acetylenic alcohols in the presence of copper salts and the Hodkevich–Kadyo condensation of monoacetylenic alcohols.³

This review provides a detailed description of reactions of diacetylene with carbonyl compounds which are applicable to industrial diacetylene and result in the formation of valuable products. Since some technological schemes used in acetylene production include selective extraction of diacetylene with liquid ammonia,³⁶ its extraction with ammoniacal and aqueous ammoniacal solutions also seems to be efficient. A one-step procedure was developed for the synthesis of bis-tertiary diacetylenic glycols by the reaction of diacetylene with ketones in the presence of a catalytic system (ammonia–water–alkali).²¹⁰ The use of a small excess of the ketone allows preparation of glycols **82** in nearly quantitative yields without the formation of the diacetylenic alcohols **83**.

82, 83: $R^1 = R^2 = \text{Me}$ (**a**); $R^1 = \text{Me}$, $R^2 = \text{Et}$ (**b**); $R^1-R^2 = (\text{CH}_2)_5$ (**c**); $R^1 = \text{Me}$, $R^2 = \text{Bu}^n$ (**d**); $R^1 = \text{Me}$, $R^2 = n\text{-C}_6\text{H}_{13}$ (**e**).

A simple and efficient one-pot synthesis of tertiary alkylthioenynol alcohols **84** from diacetylene, ketones and thiols in liquid ammonia has been developed.^{211–214}

Diacetylenic alcohols 83	R^3 in the thiol $R^3\text{SH}$	Thioalcohol 84
83a ($R^1 = R^2 = \text{Me}$)	Et	84a
	Pr^n	84b
	Bu^n	84c
83b ($R^1 = \text{Me}$, $R^2 = \text{Et}$)	Et	84d
83c ($R^1-R^2 = (\text{CH}_2)_5$)	Et	84e
83f ($R^1-R^2 = (\text{CH}_2)_4$)	Et	84f

The alcohols **84a–f** are characterised by a broad spectrum of biological activities and exhibit interest as monomers and intermediates for fine organic synthesis and for the pharmaceutical industry.²¹⁵

Condensation of diacetylene with ketones in the presence of catalytic amounts of an alkali (0.01–0.1 moles per mole of $\text{HC}\equiv\text{C}-\text{C}\equiv\text{CH}$) in liquid ammonia with subsequent addition of a thiol was studied with the aim of developing a reliable procedure for the synthesis of alkylthioenynol alcohols **84** and glycols **85**.²¹³ This reaction is carried out with a 6%–10% diacetylene solution in liquid NH_3 at the temperature of liquid ammonia and at the diacetylene:ketone:thiol molar ratio of 1.0:0.5:1.2. Alkali metal cations catalyse the condensation of diacetylene with ketones and simultaneously accelerate the reaction of diacetylenic alcohols **82** with thiols resulting in compounds **84** (yields 83%–96%).²¹³ An excess of diacetylene (relative to the ketone) directs the reaction towards the formation of diacetylenic alcohols. Alkylthioenynol glycols **85** are formed in 89% to 95% yields at the diacetylene:ketone:thiol molar ratio of 1.0:2.0:1.3.^{213, 216}

$R^1 = \text{Me}$; $R^2 = \text{Me, Et}$; $R^1-R^2 = (\text{CH}_2)_4$;

$R^3 = \text{Et, Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i$.

The sulfides **84** can also be synthesised by the condensation of enynyl sulfides **47** with acetone under conditions of the Favorsky reaction.²¹⁷ Since the presence of the hydroxy functional group often excludes the possibility of selective attack at other reaction centres, Volkova *et al.*²¹¹ have converted alcohols **84a,b** into ethers (**86b**), esters (**87a,b**), β -cyanoethyl (**88a,b**), trimethylsilyl (**89a,b**) and glycidyl (**90a,b**) derivatives and acetals (**91a**) (Scheme 5).

Scheme 5

$\text{ZR} = \text{C}\equiv\text{C}-\text{CH}=\text{CH}-\text{SR}$, where $R = \text{Et}$ (**a**), Pr^n (**b**).

The functionalisation of the thioethers **47a–c** was described.¹⁴² These sulfides, contrary to the published data,³ enter into the Mannich reaction with secondary amines on heating in dioxane in the presence of copper(I) chloride to give 1-alkylthio-5-dialkylaminopent-1-en-3-yne **92a–c**.

The reaction of 2-methyl-6-phenylhexa-3,5-diyn-2-ol with alcohols and ketones²¹⁸ was used to obtain the corresponding ethynylvinyl ethers and dioxolanes which contain an enyne fragment in the side chain and manifest pharmacological activities.²¹⁹

An unusual reaction of tertiary alkylthioenynol alcohols **84** with CO₂ was carried out under a pressure of 70–73 atm at 70–75 °C in the presence of catalytic amounts of copper(I) salts and triethylamine without solvents.^{220, 221} The products of this reaction are 5-(3-alkylthioprop-2-enylidene)-4,4-dimethyl-1,3-dioxolan-2-ones **93a,b**.²²⁰

R = Buⁿ (**84c**, **93a**), Me (**84g**, **93b**); X = Cl, OAc.

Stable 1,2-bis(1,3-dioxolan-2-on-5-ylidene)ethanes **94a–d** are formed from diacetylenic glycols **82a–d** in more than 90% yields under analogous conditions.²²¹

X = Cl, OAc.

R ¹	R ²	Glycol 82	Product 94
Me	Me	82a	94a
Me	Et	82b	94b
Pr ⁿ	Pr ⁿ	82f	94c
(CH ₂) ₄		82g	94d

The reaction of the tertiary diacetylenic alcohol **83a** or the bis-tertiary diacetylenic glycol **82a** with hydrogen sulfide²²² in the presence of alkaline catalysts result in dihydrofuranthione **95**.

Condensation of diacetylene with carbonyl compounds was carried out under conditions close to the industrial ones.^{223–225} 2,7-Dimethylocta-3,5-diyne-2,7-diol (**82a**) was obtained in 72% yield (acetone, 25% aqueous NH₃, 0.01–0.04 mole of KOH or NaOH per mole of acetone, 10-fold excess of diacetylene).²²⁴ A decrease in the catalyst's concentration to 0.01 mole decreases the yield of glycol to 11% and simultaneously increases the yield of 2-methylhexa-3,5-diyn-2-ol (**83a**) from 9% to 61%. An increase in the ammonia concentration in the reaction mixture directs the reaction exclusively towards the formation of glycol **82a**; its yield reaches 94%. Butylmethyl- and hexylmethyl ketones react with diacetylene in the presence of an alkali (0.3 mole per mole of ketone) to form diacetylenic alcohols **83** (yields ~ 60%).²²⁴ It was

shown that the anion-exchange resin AB-17-8P(OH) catalyses the condensation of diacetylene with carbonyl compounds.²²⁶ Tetramethylammonium hydroxide also catalyses the reaction of diacetylene with formaldehyde.²²⁷ The reaction with formaldehyde occurs smoothly at 20–40 °C and yields, in addition to hexa-2,4-diyne-1,6-diol (**96**), 1,3-dioxolanes **97** and **98** which are the products of subsequent reaction of formaldehyde with the diol **96** and 2,4-pentadiynol.²²⁷

Alkylation of alcohols **83a–d** (dialkyl sulfate, 5–15 °C, 2 h) was used to prepare ethers of tertiary diacetylenic alcohols **99** in up to 80% yields.²²⁸

R ¹	R ²	R ³	Alcohol 83	Ether 99
Me	Me	Me	83a	99a
Me	Me	Bu ⁿ	83a	99b
Me	n-C ₆ H ₁₃	Me	83e	99c
Me	Bu ⁿ	Et	83d	99d

β-Diketones and acetylenic ketones were synthesised from ethers **99**.²²⁹ In the presence of HgSO₄ (1 h, 65–70 °C), the hydration of the terminal triple bond of the ethers **99** gives ketones **100** in up to 93% yields.²²⁹ β-Diketones **101** are formed with an increase in temperature to 80 °C and with larger amounts of HgSO₄ in 8–10 h as a result of total hydration of both triple bonds (yields 60%–80%).²²⁹

A number of papers are devoted^{230–237} to the synthesis of potentially physiologically active compounds based on acetylenic and diacetylenic alcohols and glycols as well as to the analysis of biological activities of reaction products and their applications in agriculture.

It was shown that diacetylene and diynes containing terminal triple bonds add to the carbonyl group of 1,2,3-trimethylpiperidin-4-one under conditions of the Favorsky reaction to yield a mixture of isomeric alcohols and glycols containing predominantly epimers **102**, the products of axial addition of diynes to the C=O bond.^{230–237}

A correlation was found between the biological activity and chirality of asymmetrical diacetylenic glycols.²³⁰ Acpinol, which represents a product of exhaustive hydrochlorination of a mixture of isomers of the glycol **102**, was recommended for use in agriculture.^{236–240} A method of manufacture of acpinol employs diacetylene present in the abgases from acetylene-manufacturing

plants. The purity of the product depends on the composition of the abgas.²³⁰

The cyclohydration of alkoxyvinylacetylenic alcohols **103–105** obtained from ethoxybutenyne (**25b**) and butoxybutenyne (**25d**)^{241, 242} under conditions of the Kucherov reaction or in dilute H₂SO₄ at room temperature results in dihydropyran-4-ones **106–108**.^{243, 244}

R¹ = R² = Me (**103**, **106**); R¹–R² = (CH₂)₅ (**104**, **107**);
R¹–R² = (CH₂)₂NMe(CH₂)₂ (**105**, **108**); R³ = Et (**b**), Buⁿ (**d**).

The synthesis of 2-alkyl-2,3-dihydro-γ-pyrones **109** from the ether **25a** and aldehydes was described.²⁴⁵ Condensation of lithium methoxybutenyne with various aldehydes (from MeCHO to iso-C₅H₁₁CHO) in THF at –78 °C yields secondary alcohols which undergo hydration at the triple bond with subsequent cyclodehydration to give dihydropyrones **109a–e**.²⁴⁵

R = Me (**a**), Et (**b**), Prⁿ (**c**), Prⁱ (**d**), iso-C₅H₁₁ (**e**).

The yield of the reaction products increases with an increase in the length of the alkyl radical. Thus pyrones **109a** and **109e** are formed in 40% and 80% yields, respectively. The reaction of the lithium derivative of the ether **25a** with lactones affords spiroketals **111**.²⁴⁶

For example, the hydroxy ketone **110** was obtained from δ-valerolactone in THF at –78 °C in 98% yield. Its conversion into the spiroketal **111** can be carried out in two ways,²⁴⁶ viz., by direct conversion under the action of 30% HClO₄ in CH₂Cl₂ (yield 58%) or *via* an intermediate trimethoxy ketone **112** (yield 86%). These dihydropyrones are used as fungicides.²⁴⁷

A general method for the synthesis of functionalised spiroketals from lactones and (Z)-lithium derivatives of the ether **25a** was proposed.²⁴⁸

Some novel antiinflammatory drugs and a pharmaceutically stable inhibitor of LTA₄-hydrolase based on the *E*-isomer of the ether **25a** were patented.²⁴⁹ These compounds are used as constituents of composite fuels for stabilisation of combustible mixtures.²⁵⁰

Ethynylation with diacetylene was used in the synthesis of additives to perfume compositions, *e.g.*, 2,6,11,15-tetramethylhexadecane-6,11-diol²⁵¹ or 6,11-dihydroxycroctane and croctane.²⁵² A commercial synthesis of squalane by ethynylation of geranylacetone with a diacetylene–*N*-methylpyrrolidone complex (1:1) in the presence of KOH with subsequent reduction over Raney nickel was described.²⁵³

The alkoxy- and alkylthioenynes alcohols prepared from diacetylene can be used in the synthesis of various polyfunctional unsaturated compounds.²⁵⁴

Hydrolytic scission of vinyl ethers **103a,b** by dilute acids results in acetylenic hydroxy aldehydes **113**, which are readily isomerised into oxoaldehydes **114** in up to 75% yields.²⁵⁴ The reaction of vinyl ethers **103a,b** with ethyl vinyl ether was used to obtain acetals **115** (yield 80%). The oxidation of vinyl ethers **103a,b** with chromic acid in acetone gives a mixture of aldehydes **113** and **114** in a total yield of 61% and the oxo acid **116** in 10% yield.

R = Me (**a**), Et (**b**).

Reactions of tertiary alcohols **103a–d** with acetone, acrylonitrile, acetic anhydride, epichlorohydrin and glycols (Scheme 6) were studied.²⁵⁵

R¹ = Me (**a**), Et (**b**), Prⁿ (**c**), Buⁿ (**d**);
R², R³ = H, Me; *n* = 0 (**122**), 1 (**123**).

The reactions of the vinyl ether **103a,d** with acetone result in 5-(3-alkoxyallylidene)-2,2,4,4-tetramethyl-1,3-dioxolanes **117a,d**.²⁵⁵ Cyanoethylation of these ethers with acrylonitrile occurs in the presence of an 40% aqueous solution of KOH or MeONa in *tert*-butyl alcohol and results in 1-alkoxy-5-(2-cyanoethoxy)-5-methylhex-1-en-3-yne **118a,d** in up to 50% yields. Acetylation of the alcohols **103a,d** with acetic anhydride in pyridine at 70–90 °C results in 5-acetoxy-1-alkoxy-5-methylhex-1-en-3-yne (**119a,d**) in 21% to 49% yields.²⁵⁵ During distillation, acetates undergo deacetylation and dehydration to give the enynal **120**.²⁵⁵ The reaction of epichlorohydrin with ethers **103a–c** in an alkaline medium afforded glycidyl ethers **121a–c** in 60%–65% yields (see Scheme 6).²⁵⁶ The resulting products are candidates for epoxy-containing monomers.²¹⁵

The reaction of bisprimary and primary-secondary α - and β -glycols with ethers **103a,b,d** in the presence of the Newland catalyst ($\text{HgO} - \text{BF}_3$) results in 2-(4-methyl-2-oxopent-3-enyl)-1,3-dioxolanes **122** in up to 64% yields (see Scheme 6).²⁵⁷ Presumably, this reaction begins with isomerisation of the alkoxy-enyne alcohol into an unstable alkoxydivinyl ketone. The latter adds a glycol molecule to give an asymmetrical hydroxy acetal, which easily loses the alcohol molecule and cyclises into 1,3-dioxolanes **122** or 1,3-dioxanes **123**.²⁵⁷ Moderate neuroactivity of 1,3-dioxolanes and 1,3-dioxanes prepared on the basis of alkoxy-enyne tertiary alcohols was established.²⁵⁸

It is worth noting that the most reactive compounds of this series manifest both general depressant activity and a stimulating effect on the central adreno- and dopaminergic systems of the brain, which makes them similar to antidepressants.²⁵⁸

Base-catalysed thermolysis (the retro-Favorsky reaction) of 8-methoxyoct-7-ene-3,5-diyn-2-ol (**124**) was studied.²⁵⁹ In organic media, this is accompanied by different reactions the direction of which depends on the nature of the solvent.²⁵⁹ In benzene or THF, the thermolysis at the boiling temperature of the reaction mixture results in the formation of 1-methoxyhex-1-ene-3,5-diyne (**125**) in 85% yield.²⁵⁹

The formation of 2,2,4,4-tetramethyl-5-(5-methoxypent-4-en-2-ynylidene)-1,3-dioxolane (**126**) isolated from the reaction mixture as a side product can be attributed to the reaction of the original alcohol with acetone in the presence of KOH. In air, the product **126** is oxidised to 2,2,4,4-tetramethyl-5-(3-formylpropynylidene)-1,3-dioxolane (**127**).²⁵⁹

Vinyl ethers **103** react with nitrogen bases (hydrazine, methylhydrazine, hydroxylamine) in acid and alkaline media with the formation of heterocyclic compounds of the pyrazole and isoxazole series.²⁶⁰

Some natural thiophene derivatives (*e.g.*, 7-thienylheptatrienal) were synthesised from (*E*)-methoxybutenyne and thiophene-2-carbaldehyde.²⁶¹

XI. Conclusion

The data accumulated thus far demonstrate the possibility of utilisation of diacetylene in industrial syntheses of valuable products, reagents, starting compounds for pharmaceutical industry, materials for new technologies, *etc.*

The processes aimed at acetylene production based on pyrolysis of hydrocarbon raw materials will long be used as a source for large-tonnage synthesis of diacetylene the utilisation of which is still a challenge for chemists and also common sense, since combustion of hydrocarbon gases is most senseless in this case. As D I Mendelev used to say, 'one can fire a furnace with banknotes'.²⁶²

It has now become quite clear that diacetylene can be used for small-capacity, profitable manufacture of thiophene, vitamins A and PP, geraniol and phytol derivatives, pyrazoles, pyrimidines and pyridines. Studies of diacetylene polymerisation reactions present special interest. The first example of polyacetylene synthesis from a diacetylenic monomer has been described recently.²⁶³

The diacetylene present in industrial gases enters into reactions of nucleophilic addition selectively. In this review, it is these transformations which encompass only some of possible applications of diacetylene and its derivatives that are analysed in detail. Thus copolymers of diacetylenic glycols and their derivatives are used as a basis in the preparation of stereoregulatory membranes mimicking cell liposomes¹⁴ and thermochromic polymeric layers^{264,265} for laser image recording and observations over conformational transitions in polymers at ambient temperatures.

The role of compounds produced from diacetylene will be increasing with the development of new technologies. The synthesis of reagents based on diacetylene can be the first step towards its commercial utilisation. This, in turn, will give an impetus to the development of new procedures for the synthesis of a vast variety of useful compounds from inexpensive industrial raw materials using reactions discussed in the present review.²⁶⁶

Abstract. Data on the synthesis of a new class of fluorocarbon compound, fluorofullerenes, by reactions of C₆₀, C₇₀, their mixtures and higher fullerenes with molecular fluorine are surveyed. The physicochemical and thermodynamic properties are presented for pure C₆₀F₄₈, which is the only compound formed selectively in direct fluorination of C₆₀, and for fluorofullerene mixtures. The bibliography includes 70 references.

I. Introduction

Very few naturally occurring compounds of fluorine exist, these are primarily mineral inorganic compounds. The unique properties inherent in fluorine and its compounds^{1,2} have served as the basis for the development of new modern technologies and a large number of fluorine-containing materials both in organic and inorganic chemistry.^{3,4}

The interest in the reaction of molecular fluorine with the new form of carbon, *viz.*, fullerenes, is undoubtedly due to the widely known useful properties of the products of direct fluorination[‡] of graphite, such as high thermal stability (up to 400 °C) of graphite fluorides (CF)_n and (C₂F)_n, the possibility of using fluorine-intercalated graphites C_xF with high degrees of fluorination as cathodic materials for lithium batteries, as well as the good antifriction properties of these compounds.^{5,6}

On the one hand, the polyhedral clusters of carbon, fullerenes, can be regarded as inorganic compounds, as this is an allotropic modification of carbon. On the other hand, fullerenes can be placed among organic compounds, as their behaviour in chemical transformations is similar to that of unsaturated hydrocarbons. Formally, C₆₀ and C₇₀ fullerenes have 30 and 35 double bonds, respectively.

Owing to delocalisation of the π -electron density, fullerenes undergo both addition to the double bonds and electrophilic addition with the intermediate formation of charge transfer complexes and, eventually, various derivatives. The C₆₀ fullerene can add up to 24 chlorine or bromine atoms or methyl groups. As

the size of the functional groups being added decreases, their number increases; for example, hydrogenation of C₆₀ can result in C₆₀H₃₆.

What is the maximum number of addends in the case of fluorine? On the one hand, the van der Waals radius of fluorine (1.35 Å) is greater than that of hydrogen (1.2 Å), and on the other hand, fluorine forms stronger bonds with carbon. The authors of theoretical work^{7–9} published before experiments on hydrogenation and halogenation of fullerenes were carried out had predicted that the completely fluorinated fullerene C₆₀F₆₀ would be stable. However, in this case, the steric interaction of the adjacent fluorine atoms would result in elongation of the carbon–carbon bonds in the fullerene framework to 1.67 Å,¹⁰ as well as in a decrease in the C–F bond energy by 15% in comparison with that of the C–F bond in CF₄.¹¹ The authors of yet another theoretical work¹² noted that the formation of the C₆₀F₆₀ molecule is possible provided that steric strain is relieved by distortion of the carbon framework with retention of the icosahedral symmetry. It was anticipated that, owing to its unique spherical symmetry, perfluorofullerene would possess good lubricating properties, similarly to graphite fluorides. It did not take the experimenters too long to answer these questions, and as early as in 1991, the first study was published¹³ dealing with the synthesis of highly fluorinated fullerene by the reaction of C₆₀ with molecular fluorine. It was shown that addition of 36 (as in the reaction with hydrogen) or more fluorine atoms can occur. Thus, a new line of research, *i.e.*, studies on the fluorination of fullerenes, appeared in fluorine chemistry.

This review is aimed at generalisation of the literature data available since 1991 and the own author's results concerning fluorination of fullerenes with molecular fluorine. We intentionally limit ourselves to direct fluorination reactions. First, the reaction of F₂ with fullerenes drew the highest attention of researchers in 1991–96; these were the peak years in the activity of scientific groups in the USA, Great Britain, France and Japan, who were experienced in direct fluorination and possessed the corresponding experimental equipment. Second, direct fluorination reactions are well-developed technological processes that have been implemented in large-tonnage manufacture of various fluorine-containing products. If areas of fluorofullerene application demanding their production on a relatively large scale are

[‡] The term 'direct fluorination' designates the reaction involving molecular fluorine, as it is generally accepted in the literature (see *e.g.* Ref. 4).

found, it is the reactions with molecular fluorine that can prove to be the most efficient and economically sound.

We leave the studies on the alternative methods for fullerene fluorination, including the reactions with fluorides of transition metals, noble gases, *etc.*, outside the scope of this review; these studies have been covered in recent reviews.^{14,15} The authors of almost all pioneering publications of the early 1990s used samples obtained by direct fluorination of C₆₀ or C₆₀/C₇₀ mixtures to study the physical and chemical properties of fluorofullerenes. On the other hand, despite the abundance of original works published in this period, neither detailed analysis of the results obtained nor coordination of the data obtained by different authors regarding the composition and properties of fluorination products have been carried out to date.

II. Synthesis of fluorofullerenes

1. Direct fluorination of C₆₀ and C₆₀/C₇₀

The first synthetic study¹³ on fullerene fluorination was carried out soon after the development of the procedure for their synthesis in macroscopic quantities. Selig *et al.*¹³ studied the fluorination of fullerenes using a Sartorius magnetic balance, which allowed them to detect the changes in the sample weight to within 0.1 mg. The samples were kept in a fluorine atmosphere for at least 20 h to attain a constant weight. The largest weight gain occurred within the first several minutes, after which the absorption of fluorine markedly retarded. The electron impact (EI) mass spectrum (70 eV) of the yellowish-brown reaction product with the composition F : C₆₀ = 38 (the composition was determined by measurement of the weight gain and by titrimetry) contained peaks corresponding to the C₆₀F_{30–44} molecules, the most intense peak being due to the C₆₀F₃₆ molecule. It should be noted that Selig *et al.*,¹³ who used an IR cell for the fluorination, observed accumulation of CF₄ during the reaction ($\nu_{C-F} = 1283 \text{ cm}^{-1}$). It was shown¹⁶ that fluorination of fullerenes with molecular fluorine is accompanied by side reactions to give perfluoroalkanes C_nF_{2n+2} ($n = 1-4$). The mass spectrum of a gas phase sample taken directly from the reactor zone during the experiment (Fig. 1) showed, in addition to the F₂⁺ ions, the presence of C_nF_k⁺ ions ($n = 1-4, k = 1-9$).

In 1991, a paper by Holloway *et al.*¹⁷ was published. Direct fluorination of C₆₀ fullerene at 70 °C was monitored for several days. Three to four days after the beginning of fluorination, the black C₆₀ powder underwent an abrupt colour change to dark-brown; this colour remained apparently unchanged for another three to four days and then abruptly changed to light-brown. Subsequent fluorination resulted in gradual decolourising of the sample to white eventually. The stepwise change in the colour of the powder during the reaction was considered as evidence for consecutive addition of fluorine atoms to the fullerene molecule. It was assumed that the two intermediates (dark- and light-brown) were stable, partially fluorinated fullerene derivatives, C₆₀F₆ and

C₆₀F₄₂, while the white powder was C₆₀F₆₀. The formation of C₆₀F₆₀ was proven by NMR spectroscopy [the ¹⁹F NMR spectrum contained one intense band with a chemical shift (δ) of -150.5 ppm]. On the other hand, analysis of the mass spectra of the white powder showed peaks corresponding to species with compositions ranging from C₆₀F₆ to C₆₀F₄₂; however, species with higher fluorine contents (> 42) were not found.

Tuinman *et al.*¹⁸ performed the fluorination of fullerenes in various temperature and time modes using reaction vessels made of different materials (Pyrex, quartz, steel). For example, the following procedure was described: through a tube with an inserted capillary containing the fullerene, helium was first passed at 160 °C at a flow rate of 50 ml min⁻¹ for two hours in order to remove traces of moisture and then fluorine was passed at a flow rate of 1 ml min⁻¹ together with helium. When the temperature was increased, no visible changes in the sample occurred until helium feeding to the reactor was stopped (at 210 °C); as this was done, the volume of the powder increased and its colour changed from black to yellow. Then the temperature was increased to 275 °C and fluorine was passed for additional 4 h (the temperature was not further increased because of the vigorous reaction of fluorine with quartz). According to mass spectroscopic data, the main products, *viz.*, white powders, were mixtures of fluorofullerenes C₆₀F_{38–46} (Fig. 2); however, no perfluorinated fullerene C₆₀F₆₀ was detected, the maximum degree of fluorination being 48 (the C₆₀F₄₈ molecule). It was noted that molecules containing more than 48 fluorine atoms were not formed upon longer treatment of fullerenes with fluorine.

Figure 2. Electron impact mass spectra (70 eV) of a sample synthesised by Tuinman *et al.*¹⁸

Kniaz *et al.*¹⁹ monitored the course of C₆₀ fluorination using a Sartorius balance. The most intense peak in the mass spectrum of the air-stable yellowish-white reaction product corresponded to the C₆₀F₄₀ molecule. In addition, a 10⁻⁵ times less intense peak corresponding to the C₆₀F₆₀ molecule was observed. In order to improve the quality, the resulting product was sublimed at 300 °C; this gave a yellow sublimate and a white non-volatile residue which included black grains of amorphous carbon. Unlike the spectra of the starting sample, the mass spectra of the sublimate and the residue did not display peaks corresponding to the highly fluorinated C₆₀F_x molecules ($x > 48$). The absence of these peaks was explained by the liberation of molecular fluorine from C₆₀F_x ($x > 48$) during sublimation.

Okino *et al.*^{20–23} determined the composition of fluorofullerenes by X-ray photoelectron spectroscopy (XPS) in thin films obtained by deposition of C₆₀ on nickel plates which were then treated with fluorine under the same conditions as the C₆₀ powders (Table 1). The XPS data are in good agreement with mass spectroscopic data. For example, a sample with the composition F : C₆₀ = 45 (XPS data) contained C₆₀F₄₄ and C₆₀F₄₆ as the major components. It should be noted that the X-ray photoelectron spectra of the samples with low fluorine content (F : C₆₀ < 20) contained peaks belonging to the C₆₀ fullerene and C₆₀F_x fluorofullerene ($x \approx 40$) phases. It was assumed that even short-term fluorination converts a fraction of fullerene molecules to derivatives with high fluorine content, whereas the data of chemical analysis and XPS of the C₆₀F_x samples, where $x < 20$,

showed only the presence of unreacted C₆₀ together with highly fluorinated molecules.

Hamwi *et al.*^{24,25} fluorinated C₆₀ using a setup made of Monel and steel. A fullerene powder was placed in an aluminium boat; the reaction was carried out at 20–300 °C, either under static conditions ($p = 1–5$ atm) or in a stream of fluorine (the flow rate was 2 ml min^{−1}) for 10–336 h. Thermogravimetric analysis showed that fluorofullerenes started to decompose at 180 °C. For this reason, the reaction at temperatures above 180 °C was stopped at the instant when the product weight started to decrease. This resulted in a series of differently coloured powders (from black to pale yellow). The maximum weight gain recorded for one of the samples corresponded to the stoichiometry F:C₆₀ = 58.5. On the other hand, without mass spectroscopic analysis, it is difficult to make reliable conclusions on the actual presence of molecules with such a high fluorine content.

Short-term reactions of the same compounds gave fluorofullerenes with low fluorine stoichiometric factors (*e.g.*, C₆₀F₉), as determined from weight gain. According to IR spectroscopic and X-ray diffraction data, these samples contained only the non-fluorinated fullerene, while the ¹⁹F NMR spectrum exhibited one broad peak, which proved the presence of fluorine in the products.²⁵

It was found^{24,25} that C₆₀/C₇₀ fullerene mixtures are more reactive than C₆₀ fullerene. For example, the reaction of C₆₀/C₇₀ with fluorine at room temperature for 4 h resulted in an increase in the sample weight; however, the weight of pure C₆₀ samples did not change upon longer treatment (48 h) under the same conditions. Fluorination of C₆₀/C₇₀ at 300 °C for 4 h afforded a pale

yellow product with the ratio F:C₆₀ = 44, whereas for pure C₆₀, it took 8 h to attain the same degree of fluorination.

Bagryantsev *et al.*¹⁶ fluorinated a C₆₀/C₇₀ fullerene mixture and found that if the reaction temperature is raised from 70 to 315 °C, the content of fluorofullerenes with higher degrees of fluorination gradually increases. The C₆₀F_x ($x = 38, 40$) and C₆₀F₄₈ fluorofullerenes were the main components among the products obtained at 70 and 315 °C, respectively. The trend towards higher degrees of fluorination at elevated temperatures was also observed in the case of C₆₀ fullerene (Table 2). For example, the C₆₀F₄₆ fluorofullerene with a small admixture of C₆₀F₄₄ and C₆₀F₄₈ was the main reaction product at 275 °C. Fluorination of C₆₀ at 315 °C under dynamic conditions resulted in a mixture of fluorofullerenes, in which C₆₀F₄₈ was the major product, C₆₀F₄₆ was a minor product, whereas the content of C₆₀F₄₄ was insignificant. Figure 3 shows a diagram demonstrating the effect of fluorination time of C₆₀ at 315 °C on the C₆₀F₄₈ content in the resulting samples. Repeated fluorination increased the C₆₀F₄₈:C₆₀F₄₆ ratio but also resulted in an appreciable loss of the original fluorofullerene due to thermal destruction (partial burning and sublimation); according to mass spectroscopic data, the content of the main product (C₆₀F₄₈) was as high as 95%. Fluorination at higher temperatures (up to 355 °C) for 2–3 h resulted in ~90% of C₆₀F₄₈; the reaction yield was > 80% in most cases. This procedure was beneficial regarding the reaction time and the consumption of reactants.

A study of the effect of the method of feeding fluorine to the reactor showed that the reaction under dynamic conditions in the absence of flashes mostly gave two components, *viz.*, C₆₀F₄₈ and

^a The reaction yield (ω) was calculated using the formula: $\omega = (m_{\text{exp}}/m_{\text{theor}}) \times 100\%$, where m_{exp} and m_{theor} are the C₆₀F₄₈ masses; ^b the calculation is based on the weight gain; ^c the measurement accuracy is ±0.02; ^d F₂ diluted with 90 vol.% Ar was used; ^e the fluorination of fluorofullerenes C₆₀F_x was carried out successively in quasi-static, static and dynamic modes.

Figure 3. Effect of time (t) of C_{60} fluorination with molecular fluorine at $315\text{ }^{\circ}\text{C}$ on the $C_{60}F_{48}$ content (ω) in the samples synthesised.

$C_{60}F_{46}$. The product obtained under quasi-static conditions (Fig. 4) contained $C_{60}F_x$ fluorofullerenes, where $x = 40\text{--}48$, and an admixture of the $C_{60}F_{44}O$ and $C_{60}F_{46}O$ oxyfluorides (empirical formula $C_{60}F_{45.45}O_{0.05}$). It is evident from Fig. 4 that the absorption of fluorine at low temperatures (up to $110\text{ }^{\circ}\text{C}$) virtually does not occur (section I). In section II, starting from $110\text{ }^{\circ}\text{C}$, noticeable fluorine absorption at a specified, constant rate of heating was observed. The rate of fluorine absorption in the temperature range from 160 to $311\text{ }^{\circ}\text{C}$ (section III) was almost constant. When the temperature was maintained constant (section IV, $315\text{ }^{\circ}\text{C}$), noticeable fluorine absorption ceased.

Figure 4. Changes in the temperature and in the fluorine amount absorbed (W) during the fluorination of C_{60} under quasi-static conditions.

Matsuo *et al.*²⁶ fluorinated C_{60} using various methods: with molecular fluorine, with a mixture of fluorine and hydrogen fluoride, with molecular fluorine under UV irradiation, and by passing a stream of fluorine through a $CFCl_3$ solution of fullerene (Table 3). The last-mentioned technique, which is the only reported example of liquid-phase fluorination where a low degree of fluorination is attained, might be a promising method for the

synthesis of fluorofullerenes with low fluorine contents. However, the methods which were used to analyse the products do not allow unambiguous conclusions to be made about the actual molecular composition of the fluorides, in particular, about the formation of products with low fluorine content. In general, the molecular formulae established for the fluorofullerenes were in agreement with the data reported by other investigators. For example, the largest degree of fluorination was attained when UV irradiation was used (see also the data in Ref. 27).

Chilingarov *et al.*²⁸ studied C_{60} fluorination under conditions of a mass spectroscopic experiment where molecular fluorine was fed from a cylinder into an effusion cell. The temperature ($500\text{--}800\text{ K}$) and the reaction time, as well as the fluorine pressure ($10^{-4}\text{--}10^{-5}\text{ atm}$) were varied. In the F_2 (gas)– C_{60} (solid) system, only molecules with an even number of fluorine atoms, $C_{60}F_{2n}$ ($2 < 2n < 44$), were formed. The composition of the gas phase was largely temperature-dependent: an increase in temperature shifted the distribution of ions in the mass spectrum towards smaller masses. For example, the following major products were obtained: $C_{60}F_{38}$ at 510 K , $C_{60}F_8$ at 760 K , and $C_{60}F_2$ and $C_{60}F_4$ at 800 K . Longer reaction times at 745 and 800 K increased the content of $C_{60}F_{18}$ and $C_{60}F_{22}\text{--}C_{60}F_{46}$, respectively. A search for conditions for selective synthesis of a certain fluorofullerene in the gas phase was performed. For example, the maximum yield of $C_{60}F_{18}$ (50%) was attained if the reaction was carried out for 20 h at 720 K and at a fluorine pressure of $2 \times 10^{-4}\text{ atm}$ in the presence of NiF_2 . In the presence of MnF_2 (10 h , 615 K , $p_{F_2} = 2 \times 10^{-4}\text{ atm}$), up to 90% of $C_{60}F_{36}$ was formed. No study of solid-phase fluorination products, which could be obtained, *e.g.*, by condensation from the gas phase, was carried out.²⁸ Therefore, it is impossible to estimate the applicability of the above approach for the selective synthesis of macroscopic quantities of fluorofullerenes.

Thus, the studies on direct fluorination of fullerenes described in this Section showed that

(1) the reaction with molecular fluorine occurs readily and the products of fullerene fluorination can form even at room temperature;

(2) as a rule, mixtures of fluorofullerenes $C_{60}F_n$ with a wide range of compositions are formed ($9 \leq n \leq 54$, see Ref. 25); the samples with fluorine content $n < 36$ are mixtures of highly fluorinated products ($36 \leq n \leq 48$) and unreacted C_{60} (the higher the content of the latter in the mixture, the smaller the stoichiometric coefficient for the fluorine atom);

(3) fluorofullerene molecules from $C_{60}F_2$ (see Ref. 28) to $C_{60}F_{102}$ were detected in the gas phase.²⁷

The studies were carried out in the temperature range of $20\text{--}300\text{ }^{\circ}\text{C}$ (on increasing the temperature above $300\text{ }^{\circ}\text{C}$, either no noticeable weight gain in the sample occurred or fluorine reacted vigorously with the reactor material); $C_{60}F_{44}$ and $C_{60}F_{46}$ were the main fluorination products at $275\text{--}300\text{ }^{\circ}\text{C}$.¹⁶

2. Fluorination of fullerene bromo and chloro derivatives

In order to obtain fullerene derivatives with low fluorine content, an attempt was made to fluorinate bromo and chloro fullerene derivatives such as $C_{60}Br_{24}$, $C_{60}Br_8$, $C_{60}Br_6$ and $C_{60}Cl_{24}$ with

Table 3. Conditions of the synthesis of fluorofullerenes from C_{60} and their characteristics.²⁶

molecular fluorine.²⁹ The idea was to perform the reaction in two stages: in the first step, fluorine had to add to the carbon atoms unoccupied by bromine or chlorine, while in the second stage, due to the lower strength of the C–Cl and C–Br bonds with respect to the C–F bond, abstraction of Br₂ and Cl₂ on heating was expected giving rise to fluorofullerenes with a low fluorine content. However, the reaction of C₆₀Br₂₄ with molecular fluorine resulted in complete displacement of bromine even without additional heating to give fluorofullerenes with variable composition up to C₆₀F₄₄ with predominant formation of C₆₀F₃₆. Fluorination of C₆₀Br₈ gave C₆₀F₃₆; the resulting product contained mostly C₆₀F₁₈ as well as mono- and dioxides of fluorofullerenes. As in the reaction of C₆₀ fullerene with gaseous fluorine, fluorine compounds with an even number of fluorine atoms in the molecule were formed.

3. Synthesis of pure fluorofullerenes by direct fluorination

The use of the reaction of C₆₀ with molecular fluorine for the synthesis of fluorofullerenes with a particular number of fluorine atoms was first reported by Gakh *et al.*³⁰ Fluorination was carried out in two stages. A stream of molecular fluorine ($v = 1.3 \text{ ml min}^{-1}$) was passed over a mixture of C₆₀ with NaF at 250 °C for 20 h, then the product was extracted with CFCl₃ and dried; a new portion of NaF was added, and the mixture was again treated with a stream of F₂ (275 °C, 30 h). After extraction and drying, the composition of the sample was determined by mass spectroscopic analysis using field desorption for ionisation. The intensity of the ion corresponding to the C₆₀F₄₈ molecule was 69% of the overall intensity of the ions corresponding to the C₆₀F_{2n} molecules ($2n \leq 48$). A study of the ¹⁹F NMR spectrum of a sample with a sufficiently high content of C₆₀F₄₈ allowed the researchers to suggest the molecular structure of C₆₀F₄₈ (see Section III.5).

Considerable progress^{16,31,32} in the synthesis of pure C₆₀F₄₈ (with > 95% of C₆₀F₄₈ in the samples) was attained in studies of the dependence of the composition of the products of C₆₀ fluorination with molecular fluorine on the temperature (70–355 °C) and on the reaction conditions. At each intermediate step before the next increase in the temperature, the molecular composition was determined by high-temperature mass spectroscopy with electron impact ionisation and evaporation of samples from the effusion cell. The fluorination products had the form of white powders stable in air for at least three years. The molecular structure of the C₆₀F₄₈ fluorofullerene obtained by this method was identical to that reported by Gakh *et al.*³⁰

4. Fluorination of C₇₀ and higher fullerenes

The fluorination of C₆₀/C₇₀ mixtures resulted in a series of products C₇₀F_n, where $n = 48$ (see Ref. 24) and 54 (see Ref. 18) for the components with the maximum degree of fluorination. The reaction of pure C₇₀ with fluorine resulted in mixtures of fluorides containing mainly C₇₀F₄₀ (see Ref. 13), C₇₀F₃₈ (see Ref. 16) and C₇₀F₅₄ (see Ref. 31). In these mixtures, C₇₀F₄₆ (see Ref. 13), C₇₀F₄₈ (see Ref. 16) and C₇₀F₅₆ (see Ref. 31), respectively, had the maximum degrees of fluorination. Experiments carried out successively at 250, 280 and 350 °C showed an increase in the degree of fluorination with increase in temperature. However, even at 350 °C, the fluorination product was a mixture of compounds from C₇₀F₃₈ to C₇₀F₅₆ (Fig. 5).¹⁶

The only reference to the fluorination of higher fullerenes with molecular fluorine can be found in the paper by Bagryantsev *et al.*³¹ The mass spectrum of the product of fluorination of a fullerene mixture containing small amounts of C₇₆ and C₈₄ showed the presence of C₇₆F₅₄ and C₈₄F_n ($n = 56–62$). The reaction was carried out under the same conditions as the fluorination of C₇₀ to give C₇₀F₅₆.³¹

Thus, the maximum number of fluorine atoms that can be added to C₆₀ and C₇₀ (48 and 56, respectively) corresponds to 80%

Figure 5. Electron impact mass spectrum of a C₇₀F_n sample ($n = 38–56$) synthesised at 350 °C. The maximum degree of fluorination corresponds to C₇₀F₅₆ (1904 amu) and the most intense peak corresponds to 1828 amu, i.e., C₇₀F₅₂.

occupation of the reaction sites in fullerene molecules. More extensive fluorination on treatment of fullerenes with molecular fluorine at temperatures of up to 350 °C is probably hampered by the inaccessibility of the remaining double C=C bonds because of steric hindrance caused by the size of the fluorine atoms and the rigidity of the spherical carbon skeleton. Pure fluorides of the C₇₀ fullerene will probably be hardly accessible due to the lower symmetry of C₇₀ in comparison with C₆₀. In the case of heavy fullerenes, the prospects for the synthesis of pure compounds are also complicated by the existence of geometrical isomers.

III. Methods of study and physical properties of fluorofullerenes

1. IR spectroscopy

The IR spectroscopic data for fluorofullerenes are reported in many papers. As the compositions of fluorofullerene samples are known, one can follow a correlation between the vibration frequency of the C–F bonds and the fluorine content in the samples. For example, the broad unresolved band at 1148–1165 cm^{−1} typical of fluorofullerene mixtures C₆₀F_x ($36 \leq x \leq 48$)^{13,19} shifts towards 1170–1176 cm^{−1} for the pure C₆₀F₄₈ fluorofullerene.¹⁶ A similar shift of bands with increase in the fluorine content was also observed in the case of fluorinated graphite: 1110–1120 cm^{−1} for fluorine-intercalated graphite with the composition C₂F (see Ref. 26) and 1220 cm^{−1} for graphite fluorides (CF)_n, (C₂F)_n.^{33,34}

The main distinction of the IR spectra of pure C₆₀F₄₈ from those of fluorofullerene mixtures is that fine structure in the region of C–F vibrations and a group of intense bands in the region of 600–800 cm^{−1} are displayed (see Refs 26, 32). One can see in Fig. 6 that the most intense peaks at 650 and 723 cm^{−1} are characteristic only of the C₆₀F₄₈ fluorofullerene but are absent from the IR spectrum of a C₆₀F₄₆ sample. Evidently, the bands in this spectrum region can serve as ‘fingerprints’ of pure C₆₀F₄₈. The IR spectra for certain C₆₀F₄₈ isomers were calculated in a theoretical study,³⁵ but no detailed assignment of the normal vibration modes has been carried out to date.

IR spectroscopic data for some C₆₀F_x fluorofullerene samples are presented in Table 4.

Figure 6. IR spectra of fluorofullerene samples: $C_{60}F_{46}$ (1) and $C_{60}F_{48}$ (2).³²

Table 4. IR spectroscopic data for some samples of $C_{60}F_x$ fluorofullerenes.

x	Vibration frequencies / cm^{-1}	Ref.

2. Electronic structure and electrochemical properties

The electronic structure of fluorinated fullerenes differs from the electronic structure of the original fullerenes. The high electronegativity of fluorine decreases both the LUMO and the HOMO energies, thus the electron affinity and the first ionisation potential of $C_{60}F_x$ and $C_{70}F_x$ increase in comparison with those of C_{60} and C_{70} . Obviously, the changes in the electronic potentials occurring due to transformation of fullerenes to fluoro derivatives affect their electrochemical and photoelectrochemical behaviour. Data on the electronic structures of the $C_{60}F_{48}$ and C_{60} molecules obtained by XPS, from the near fine structure and from the near-edge X-ray absorption fine structure spectra (NEXAFS) are presented in Fig. 7.

It was found³⁶ that the work functions for $C_{60}F_x$ are 5.6, 5.2 and 5.4 eV for $x = 30, 36$ and 48, respectively. This is considerably higher than the work functions for organic compounds (usually, 4.1–5.0 eV) and for C_{60} fullerene (4.7 eV³⁹), which points to strong electron-withdrawing properties of fluorofullerenes.

The addition of fluorine to fullerene shifts the bands in the absorption spectra from 1.8 eV for C_{60} fullerene to 6.4 eV for $C_{60}F_x$ ($42 \leq x \leq 48$).⁴⁰

Many researchers have studied fluorofullerenes by XPS,^{25,26,41–43} but the data of different authors are in poor agreement due to the use of different types of X-ray radiation, different calibrations of the instruments and different substrate materials. In certain cases, surface charging and a shift of the absolute energy scale were observed, which complicated considerably the interpretation of the spectra and made it difficult to obtain reliable data on the composition of the fluorofullerene samples and on the chemical shifts. According to some data of

Figure 7. Energy diagram for the C_{60} and $C_{60}F_{48}$ molecules in the gas and solid phases³⁶ (the HOMO value was changed in accordance with the data in Refs 37 and 38).

multicomponent photoelectron C_{1s} spectra,^{22,25,41,42} destruction processes take place on a sample surface exposed to hard X-radiation, which is accompanied by a flow of high-energy electrons. In addition, it was found²⁶ that the relative intensity of peaks in the photoelectron spectra depended on the duration of the exposure of samples to X-radiation. This was explained by the destructive effect of the electron flux. For example, according to the data reported by Matsuo *et al.*²⁶ the $C_{60} : F$ ratio was 42 after irradiation of a fluorofullerene sample for 33 s, while an increase in the irradiation time to 750 s decreased the content of fluorine to $C_{60} : F = 38$.

The use of electron-free synchrotron radiation (40–500 eV) made it possible to prevent the destruction of the fluorofullerene surface layer and to eliminate the charge accumulation on the sample surface. The photoelectron spectra obtained under these conditions⁴³ displayed peaks at 287.2 and 284.9 eV, which were interpreted as the energies of the $1s$ electrons of the carbon atoms (E_b) involved in the formation of the C–F and C–C bonds, respectively (Fig. 8a). Similar two-component C_{1s} spectra were also obtained in other studies.^{26,36,45,46} The two lines in the F_{1s}

Figure 8. X-Ray photoelectron spectra of $C_{60}F_{48}$: (a) spectrum of carbon $1s$ electrons; (b) spectrum of fluorine $1s$ electrons excited by X-ray radiation of $AlK\alpha_{1,2}$ with Teflon as the standard.⁴⁴

photoelectron spectrum of $C_{60}F_{48}$ fluorofullerene (Fig. 8b) at 685.9 and 689.5 eV represent two states of fluorine, namely, those in fluorofullerene and in Teflon, respectively.

In certain studies, the XPS method was used to determine the compositions of the samples obtained (see Tables 1, 2). However, the accuracy of these estimates is insufficient, ± 2 fluorine atoms per fullerene molecule.

It is well known that, depending on the fluorine content in fluorine-intercalated graphite C_xF , the nature of the C–F bond changes from ionic to partially ionic (or partially covalent).⁵ The F_{1s} photoelectron spectra of C_xF compounds with low fluorine content display one peak at 684.5 eV; this corroborates the existence of only one type of fluorine atoms in the compound, which are in the same electronic state as those in metal fluorides (for instance, the peak at 685.6 eV represents LiF^{22}). It is believed⁵ that intercalated fluorine atoms distributed between carbon layers undergo ionisation and interact with the $C_x^{\delta+}$ polycation.

The increase in x in C_xF to 10 is accompanied by some delocalisation of the electron density, hence the C–F bond cannot be considered as purely ionic. The F_{1s} spectrum displays a peak at 685.7–685.8 eV. Subsequent increase in the fluorine content in C_xF produces a second peak in the C_{1s} spectrum, which is explained by a covalent contribution to the energy of the fluorine–carbon bond. Thus, the C_xF compounds with the composition $2 \leq x \leq 4$ contain fluorine–carbon bonds of two types: ionic and partially ionic (or partially covalent). The observed chemical shifts in the photoelectron spectra are listed in Table 5.

Matsuo *et al.*²⁶ compared the photoelectron spectra of fluorofullerene, fluorine-intercalated graphite C_2F and graphite fluorides $(C_2F)_n$ and $(CF)_n$ (Fig. 9). It is important that the high-energy peak for $C_{60}F_{43}$ fluorofullerene (291.1 eV) is located approximately between the corresponding peaks of C_2F and graphite fluorides, whence the authors conclude that the degree of covalency of the C–F bond in fluorofullerene is intermediate between those of the C–F bonds in C_2F intercalates and in graphite fluorides.

The differences between the electron binding energies (ΔE_b) in carbon atoms with different chemical environments were compared;²⁶ the difference is manifested in the C_{1s} photoelectron spectra as two peaks. It was concluded that the greater ΔE_b , the

Figure 9. X-Ray photoelectron spectra of carbon $1s$ electrons in fluorine-intercalated graphite C_2F (1), $C_{60}F_{43}$ fluorofullerene (2) and graphite fluorides $(C_2F)_n$ (3) and $(CF)_n$ (4).²⁶

more ionic and less covalent the C–F bond. For example, ΔE_b for $C_{60}F_{33}$ and $C_{60}F_{31}$ samples is smaller than that for fluorine-intercalated graphite C_2F and larger than that for graphite fluoride $(C_2F)_n$, which suggests that the C–F bond in fluorofullerene has an intermediate character between covalent and semi-ionic. Comparison of the ΔE_b values in the C_{1s} spectra in $C_{60}F_{48}$ fullerene (1.8 eV) and in the spectra of fluorine-intercalated graphite (2.6 eV) and graphite fluorides (1.9 eV) showed that the C–F bond in $C_{60}F_{48}$ is covalent. The average ΔE_b values were 2.2–2.4 eV (see Table 5).

The electrochemical behaviour of fluorofullerenes was first studied by cyclic voltammetry. Holloway *et al.*¹⁷ studied the electrochemical reduction of $C_{60}F_{48}$ in a CH_2Cl_2 solution and detected the reaction products using a mass spectrometer. It was shown that the reduction of $C_{60}F_{48}$ occurs reversibly and that the reduction potential of $C_{60}F_{48}$ is 1.38 V higher than that of C_{60} . This agrees completely with the fact that the electron affinity of fluorinated fullerenes is about 1.5 eV higher than that of fullerenes. Based on the mass spectra obtained using the electro-spray method, it was concluded⁴⁷ that the electrochemical reduction mechanism includes a series of consecutive reactions of electron transfer and abstraction of fluorine atoms.

A study of the electrochemical properties of fluorofullerenes in solid electrolytes based on polyphosphazene derivatives doped with Li^+ was carried out.⁴⁸ The cathodic mixture contained a fluorofullerene, graphite and the electrolyte in the mass ratio

^a The sample composition is given in accordance with original work.

1 : 1 : 2. The voltammograms of $C_{60}F_x$ and $C_{70}F_x$ fluorofullerenes in solid-phase lithium batteries showed peaks at potentials of 3.1 and 3.4 V relative to the $E(\text{Li}^+/\text{Li})$ potential, which corresponded to irreversible reduction of $C_{60}F_x$ and $C_{70}F_x$. After two voltammetric cycles, XPS showed a decrease in the relative intensity of the signal at 289 eV in the C_{1s} spectrum for the carbon atoms involved in the C–F bonds and the appearance of a new signal at 685 eV in the F_{1s} spectrum. This is evidence for irreversible reduction of C–F bonds during the experiment and the formation of LiF. Similar experiments with fluorinated graphite $(\text{CF})_n$ showed that its reduction potential is 0.5 V more negative than that of fluorofullerene. This implies that the C–F bond in the $C_{60}F_x$ molecule is reduced more readily than the C–F bond in $(\text{CF})_n$. It was assumed that reduction of fluorofullerenes under galvanostatic conditions is homogeneous, unlike the heterogeneous reduction of graphite fluoride $(\text{CF})_n$.

The electrochemical behavior of fluorofullerenes the synthesis of which is described in Section II and Table 3 was studied as a function of the elementary composition (from $C_{60}F_{15}$ to $C_{60}F_{47}$).⁴⁹ It was shown that the reduction potentials of fluorofullerenes approach the reduction potential of C_{60} fullerene as the fluorine content decreases.

3. Crystal structure

The structure of C_{60} fullerene at room temperature is described by a face-centred cubic (FCC) lattice with the parameter $a = 14.17 \text{ \AA}$; the distance between the neighbouring C_{60} molecules is $10.02 \text{ \AA}$, and the density is 1.72 g cm^{-3} (which corresponds to $1.44 \times 10^{21} \text{ molecules cm}^{-3}$).¹⁰

Data of numerous X-ray diffraction studies (see, *e.g.*, Refs 19, 20, 50–53) indicate that at room temperature, the products of fullerene fluorination have the same FCC lattice (Table 6) as the matrix compound C_{60} but with an increased spacing. The increase in the distance between two neighbouring molecules following fluorination manifests itself as a shift of diffraction lines to smaller reflection angles: the first maximum is at $2\theta = 9^\circ$,¹³ which is much smaller than for crystalline C_{60} . Some papers reported the absence of crystallinity, especially for samples obtained at rather low temperatures.^{20, 24, 25} The diffraction pattern usually contained two diffuse peaks indicating the absence of long-range order, characteristic of crystals.

Figure 10. X-Ray diffraction patterns of samples with increasing contents of $C_{60}F_{48}$ (1–3), $C_{60}F_{46}$ fluorofullerene (4) and C_{60} fullerene (5).⁴⁶

The a parameters for fluorofullerene samples obtained by different research groups and described by a FCC lattice range from 16.98 (see Ref. 20) to $17.6 \text{ \AA}$,²⁴ which approximately corresponds to an increase in the molecular volume by a factor of 1.8 relative to that of C_{60} .⁵⁰

Due to the replacement of the short double bonds by longer single bonds, the radius of the carbon cage in a fluorofullerene molecule increases by 1% (from 3.53 to $3.56 \text{ \AA}$)⁴⁷ with respect to that of C_{60} , or by 10% according to other data.²¹ Representing a fluorofullerene molecule by two concentric spheres which correspond to the positions of the carbon and fluorine atoms (the C–F bond length is $1.36 \text{ \AA}$) and considering that fluorination results in an increase in the radius of the carbon cage by 10%, Okino *et al.*²¹ calculated the X-ray spectra for $C_{60}F_{45}$ and $C_{70}F_{32}$ samples.

Kniaz *et al.*^{19, 51} studied a sublimed fluorofullerene powder; the most intense peak in its mass spectrum was that of $C_{60}F_{40}$. It was shown that it contained 60% of a FCC phase and 40% of a hexagonal phase (see Table 6) and had a higher degree of crystallinity than unsublimed fluorofullerene.

Table 6. Lattice parameters, the number of molecules in a unit cell and the density of fluorofullerenes at room temperature.

Compound	Lattice type	Lattice parameters / $\text{\AA}$		z	$V_{\text{cell}}/z / \text{\AA}^3$	$d_{\text{calc}}^a / \text{g cm}^{-3}$	Ref.

$C_{60}F_{40}$ (see ^d)	BCT-40%	11.85	19.28	2	1354	—	19, 51
	FCC-60%	16.677		4	1160	—	19, 51
$C_{60}F_{46}$ (see ^d)	FCC	17.158(3)		4	1263	2.096	46
$C_{60}F_{48}$ (see ^d)	BCT	11.852(8)	17.91(1)	2	1258	2.155	46
	FCT	16.75	17.9	4	1256	2.096	46
$C_{60}F_{48}$ (see ^d)	BCT	11.859(3)	17.83(2)	2	1254	2.162	52
$C_{60}F_{46}$ (see ^d)	FCC	17.24(1)		4	1281	2.116	52
$C_{60}F_{48}$ (see ^d)	orthorhombic	12.06(3) ^e	12.21(4)	1	1398	1.939	53

Note. The following designations are used: FCC is face-centred cubic lattice, BCT is body-centred tetragonal lattice, and FCT is face-centred tetragonal lattice; ^a $d_{\text{calc}} = M/(VN_A)$, where M is molecular mass, V is the cell volume, N_A is the Avogadro number; ^b composition was determined by photoelectron X-ray spectroscopy; ^c composition was determined from the weight gain; ^d composition corresponds to the most intense peak in the mass spectrum; ^e lattice parameter b is equal to $37.97(8) \text{ \AA}$.

It was found⁴⁶ that at room temperature, $C_{60}F_{48}$ has a body-centred tetragonal cell with the parameters $a = 11.852(8)$ and $c = 17.91(1)$ Å. It was assumed previously⁵³ that the $C_{60}F_{48}$ structure can be described by an orthorhombic cell (see Table 6). Comparison of X-ray diffraction data for fluorofullerene samples with different molecular compositions (Fig. 10) shows that, where a mixture of fluorofullerenes with averaged composition is concerned, the crystal structure corresponds to an FCC lattice similar to that of C_{60} , whereas the $C_{60}F_{48}$ fullerene has a body-centred tetragonal lattice.

4. NMR spectroscopy

^{19}F NMR of solutions. The NMR method was first employed to study the products of fullerene fluorination back in 1991.¹⁷ The ^{19}F NMR spectra of solutions of fluorofullerenes in acetone or tetrahydrofuran exhibit singlet peaks with chemical shifts of -150.5 and -152.7 ppm. It was suggested¹⁷ that either one or both peaks were due to the $C_{60}F_{60}$ molecule in which all fluorine atoms are equivalent. However, the mass spectra of these samples did not show the presence of $C_{60}F_{60}$.

Some ^{19}F NMR spectra had a signal at -188 ppm, due to the hydrogen fluoride resulting from the reactions of fluorides with the residual water in acetone.¹⁷ It has been found⁵⁴ that the integral intensity of the ^{19}F NMR signal of the fluoride ion in THF depends on the amount of water in THF.

Kniaz *et al.*¹⁹ have employed the ^{19}F NMR method to study acetone solutions of the product of fluorination of C_{60} , the product of its sublimation at 300 °C and the non-volatile residue after sublimation. The ^{19}F NMR spectra thus obtained were identical to those reported in the study cited above.¹⁷ Analysis of the initial fluorofullerene by mass spectroscopy showed that the intensity of the peak due to the $C_{60}F_{60}$ molecule was 10^5 times lower than that of the most intense peak, which corresponded to the $C_{60}F_{40}$ molecule. After sublimation, the mass spectra of neither the sublimate nor the residue exhibited signals for $C_{60}F_n$, where $n \geq 50$. The researchers explained this outcome by assuming that less stable, higher fluorofullerenes were destroyed during sublimation to give F_2 or CF_4 . It was found that the NMR signal intensity passes through a maximum (corresponding to the composition $C_{60}F_{36}$) as fullerene gets saturated with fluorine. Hence, the signal at -149 ppm could belong to yet another highly symmetrical molecule, $C_{60}F_{36}$.

The ^{19}F NMR spectrum of a THF solution of fluorofullerene (prepared¹⁷ by direct fluorination of C_{60}) studied by Boltalina *et al.*⁵⁵ looked like those reported previously.^{17, 19, 54} Unlike earlier studies, in this study, the solution was analysed by mass spectroscopy. The spectra contained intense peaks in the region of small masses (which were not identified) but no signals corresponding to fluorofullerenes. This outcome may be due to the chemical interaction of fluorofullerene with the solvent; this would account for the fact that the data obtained by NMR spectroscopy for solutions of fluorofullerenes in THF or acetone do not agree with the data obtained by other methods which do not require dissolution of samples.

The line occurring at ~ -150 ppm in the ^{19}F NMR spectrum of a THF or acetone solution of fluorofullerenes can apparently be attributed to the product of decomposition of fluorofullerenes accompanied not only by the loss of fluorine but also by destruction of the carbon skeleton. The composition of the products of reactions between THF or acetone and fluorofullerenes $C_{60}F_x$ has not yet been identified. To eliminate the influence of solvents, NMR studies of solid samples should be carried out.

^{19}F NMR of solid samples. Static ^{19}F NMR spectra of solid $C_{60}F_n$ fluorofullerenes have been reported.^{24, 25} The spectra consist of one broad line with $\delta -153$ ppm and the half-width $\Delta\nu_{1/2} = 60-120$ ppm (Fig. 11). The δ values observed in the NMR spectra of a black sample (the mass spectrum of which exhibited ions corresponding to C_{60} , C_{70} and low-fluorine fluorofullerenes) and of a pale-yellow sample consisting mainly of fluorofullerenes were identical. The NMR spectra differed only in

Figure 11. ^{19}F NMR spectrum (relative to CF_3CO_2H) of solid samples of $C_{60}F_n$ fluorofullerenes at 20 (1) and 300 °C (2).^{35, 36}

the $\Delta\nu_{1/2}$ value, which was 115 ppm for the pale-yellow sample and 140 ppm for the black one. Fluorination of C_{60} with molecular fluorine for two weeks at room temperature gave a light-brown fluorofullerene, which was then sublimed at 150 °C. The ^{19}F NMR spectrum of this sample exhibited a narrow peak at -155 ppm with $\Delta\nu_{1/2} = 8$ ppm. It was suggested²⁵ that this peak width corresponded to highly symmetrical molecules such as $C_{60}F_{60}$ or $C_{60}F_{36}$. The spectra of some fluorofullerene samples sublimed at 110 °C and 150 °C had an additional signal with $\delta = -133$ ppm; this was attributed to the presence of oxyfluorides $C_{60}F_{60-2y}O_y$. Unfortunately, the researchers did not investigate the composition of the samples; therefore, the reliability of the conclusions drawn cannot be judged.

^{13}C NMR. A solid sample having $C_{60}F_{46}$ as the major component (according to the data of mass spectroscopy) was studied by ^{13}C NMR.⁴¹ The technique of $^{13}C-^{19}F$ polarisation exchange showed that the sample was a mixture of compounds differing from one another in molecular motion parameters. For one of the components characterised by fast molecular re-orientations (similar to those observed in plastic crystals), the ratio of the $sp^2:sp^3$ resonance lines was found to be $14:46$, *i.e.* it complied with the stoichiometry $C_{60}F_{46}$, determined from the mass spectroscopy data. The resonance lines of the sp^2 -hybridised carbon atoms occurred in the region of $140.0-142.5$ ppm, while those of sp^3 carbon were manifested at $86-90$ ppm. However, in addition to the lines assigned to $C_{60}F_{46}$, the ^{13}C NMR spectrum exhibited a broad band at 118 ppm having $\Delta\nu_{1/2} = 40$ ppm and an intensity of $20 \pm 10\%$ of the total peak intensity. The dynamics of cross-polarisation of this line indicated that the other component of the sample comprises molecules immobile in the solid phase.

5. Molecular structure of $C_{60}F_{48}$

Experimental data on the structure of $C_{60}F_{48}$ were first obtained by Gakh *et al.*³⁰ Mass-spectroscopic analysis of the specimen they studied (the procedure of the synthesis is described in Section II.3) showed that the intensity of the ion derived from the $C_{60}F_{48}$ molecule amounted to 69% of the total intensity of ions derived from $C_{60}F_{2n}$ ($2n \leq 48$). The ^{19}F NMR spectrum of a solution of this sample in the $CFCl_3-CDCl_3$ mixture exhibited eight main lines with equal intensities (Fig. 12). It was found³⁰ that this spectrum can be attributed to 14 isomers of $C_{60}F_{48}$ including optical isomers which contain eight groups of equivalent fluorine atoms. Using ^{19}F (COSY) homonuclear correlation spectroscopy, a two-dimensional spectrum of $C_{60}F_{48}$ was recorded,³⁰ in which the cross-peaks were due to the spin-spin scalar interactions of the fluorine nuclei in the system. Based on this spectrum, the molecular structure of the fluorofullerene shown in Fig. 13a was proposed. The use of homonuclear two-dimensional $^{19}F-^{19}F$ COSY spectroscopy for $C_{60}F_{48}$ ³¹ revealed additional cross-peaks, which were consistent with the proposed structure.³⁰ Note that Boltalina *et al.*³¹ fluorinated a fullerene extract ($C_{60}:C_{70} = 3:1$) and, according to mass spectrometry, the fluorination product contained up to 30% of $C_{70}F_x$ ($x = 44-56$) and traces of fluorinated higher fullerenes ($C_{76}F_y$ and $C_{84}F_z$). However, these impurities barely influenced the NMR spectral pattern.

Figure 12. ^{19}F NMR spectrum of a solution of $\text{C}_{60}\text{F}_{48}$ in the $\text{CFCl}_3\text{--CDCl}_3$ system.³⁰

Figure 13. Schlegel diagrams for optical isomers of the $\text{C}_{60}\text{F}_{48}$ molecule with D_3 symmetry (a)³⁰ and with S_6 symmetry (b).^{35,36} The atoms equivalent in symmetry are denoted by the same characters, (a–f) for F atoms and A and B for C atoms.

Semi-empirical quantum-mechanical calculations for the relative stability of nine isomers of $\text{C}_{60}\text{F}_{48}$, namely, five chiral pairs with D_3 symmetry and four meso forms with S_6 symmetry, have shown³⁵ that two of these isomers, namely, those presented in Fig. 13, are more stable than any other isomer by at least 175 kJ mol^{-1} . In addition, the difference between the energies of formation of these isomers is negligibly small and amounts to 2 kJ mol^{-1} . In view of the size of the molecular system in question and the degree of uncertainty inherent in semi-empirical methods, these isomers can be regarded isoenergetic. The double bonds in them are located only at the edges shared by pentagons and hexagons in the carbon cage (see Fig. 13). The presence of a double bond at an edge shared by two hexagons increases the energy of formation of $\text{C}_{60}\text{F}_{48}$ by 174.7 kJ mol^{-1} . Conjugation of double bonds is a destabilising factor, which increases the $\Delta_f H$ value by 500 kJ mol^{-1} with respect to that of the most stable isomer.

Since the shape of fluorofullerene molecules is nearly spherical, it would be natural to expect molecular mobility in the crystalline phase similar to that observed for C_{60} fullerene.¹⁰ Figure 14 presents the variation of the static ^{19}F NMR spectra of fluorofullerenes vs. temperature. These data (Fig. 14a) indicate that, as the temperature decreases to 320 K and below, the velocity of re-orientation of the $\text{C}_{60}\text{F}_{48}$ molecules in the fluorofullerene crystal lattice smoothly decreases, and at temperatures below 260 K, the rotational re-orientation of molecules stops on the NMR time scale, the spectrum exhibiting one broad line with $\Delta\nu_{1/2} = 40\,000\text{ Hz}$. At temperatures above 320 K, the $\text{C}_{60}\text{F}_{48}$ molecules rotate isotropically, the velocity of rotation being sufficient for observing the fine structure in the signals of the two groups of fluorine atoms in fluorofullerene molecules.⁵⁶

Figure 14. Variation of the static ^{19}F NMR spectrum of crystalline $\text{C}_{60}\text{F}_{48}$ (a) and $\text{C}_{60}\text{F}_{46}$ (b) fluorofullerenes as a function of temperature /K: (1) 200, (2) 260, (3) 300, (4) 340.

The high-resolution ^{19}F NMR spectrum of a polycrystalline sample of $\text{C}_{60}\text{F}_{48}$ consists of eight lines with equal intensities, which correspond to eight groups of magnetically non-equivalent fluorine atoms in the $\text{C}_{60}\text{F}_{48}$ molecule. It should be noted that the chemical shifts of these lines⁵⁶ virtually coincide with the chemical shifts observed in the ^{19}F NMR spectrum recorded for a solution of $\text{C}_{60}\text{F}_{48}$ in CDCl_3 .³⁰ Thus, the crystal lattice does not exert significant influence, compared to the influence of the solvent, on the ^{19}F chemical shifts of $\text{C}_{60}\text{F}_{48}$. The four groups of low-intensity lines ($< 10\%$ of the total intensity of peaks) observed in the spectra of both solutions and solid samples can apparently be assigned to $\text{C}_{60}\text{F}_{2n}$ impurities ($2n < 48$) or to other $\text{C}_{60}\text{F}_{48}$ isomers.

The high-resolution ^{13}C NMR spectra of a $\text{C}_{60}\text{F}_{48}$ sample exhibit two equally intense lines in the region of signals corresponding to sp^2 carbon atoms, pointing to the presence in the $\text{C}_{60}\text{F}_{48}$ molecule of two magnetically non-equivalent groups of carbon atoms not attached to fluorine atoms.⁵⁶ In accordance with the ^{19}F NMR spectrum, the region of signals of the sp^3

Figure 15. ^{13}C NMR $\{^1\text{H}, ^{19}\text{F}\}$ spectrum of a solution of $\text{C}_{60}\text{F}_{48}$ in CDCl_3 (recorded by Prof. T Ono, Japan).

carbon nuclei should contain eight peaks corresponding to eight magnetically nonequivalent groups of carbon atoms attached to fluorine atoms. However, the spectral pattern was fairly complex because each of the eight expected lines was split due to the scalar ^{13}C – ^{19}F spin–spin interaction. The complex multiplet was resolved by using equipment for C–F decoupling (Fig. 15). It is worth noting that ^{13}C NMR data obtained by other investigators⁴¹ only pointed out the presence of non-resolved broad bands in the regions of sp^2 and sp^3 carbon signals.

Thus, the compound $\text{C}_{60}\text{F}_{48}$ has been studied comprehensively by NMR spectroscopy; it was found that the isomeric purity of this compound prepared by direct fluorination of C_{60} reaches 90%, which is a startling result if one recalls that tens of thousands geometrical isomers of $\text{C}_{60}\text{F}_{48}$ can theoretically exist. To elucidate the molecular structure more precisely (to choose between the most probable structures, D_3 and S_6), experimental and theoretical data of IR and Raman spectroscopy and crystallography should be resorted to. Additional experiments are needed including the synthesis of $\text{C}_{60}\text{F}_{48}$ with an endohedral ^3He atom and subsequent analysis of the chemical shifts in the ^3He NMR spectra.

IV. Chemical properties of fluorofullerenes

Fluorocarbon polymers such as Teflon are known to be exceptionally chemically inert, being able to react slowly only with liquid sodium metal. This is due to the great strength of the C–F bond (460 – 540 kJ mol^{-1}), the non-polar character of this bond and the rigidity of carbon chains covered by a shell of fluorine atoms. A similar type of behaviour could have been expected of fluorofullerenes. However, fluorofullerenes were found to exhibit oxidative properties. A typical feature of fluorinated fullerene derivatives is high reactivity. Strong repulsion of fluorine atoms from one another is supposed to be the driving force of reactions. The C–F bond length in fluorofullerenes is 1.49 Å;²³ for comparison, this bond length in aliphatic fluorocarbons is 1.38 Å.⁴ Correspondingly, the energy of the C–F bond in fluorofullerenes is 150 – 250 kJ mol^{-1} lower than that in aliphatic fluorocarbons. According to both kinetic and thermodynamic factors, fluorofullerenes have lost the inertness of the C–F bond, typical of fluorocarbons; fluorine can be transferred to electron-saturated compounds and electrons can be captured from some reagents such as benzene.

The chemical properties of fluorofullerenes have been poorly studied yet. This is due to several reasons, namely, inaccessibility of macroscopic quantities of the compounds and the difficulty of the analysis of the reaction products (*i.e.* the formation of mixtures of compounds with closely similar properties).

It has been reported⁵⁷ that highly fluorinated fluorofullerenes enter into a number of oxidative reactions (with sodium iodide or isopropanol) and into fluorination reactions (with aromatic compounds in the presence of Lewis acids). Mixing a solution of a

$\text{C}_{60}\text{F}_{44}$ – $\text{C}_{60}\text{F}_{46}$ fluorofullerene mixture with 0.1 M NaI in acetone results in immediate evolution of iodine; after keeping the mixture for several hours at room temperature, a black precipitate is formed. Analysis of the reaction solution by mass spectroscopy shows the presence of fluorofullerenes with a fluorine content lower than that in the initial sample.

It was shown that fluorofullerenes react with bromides in a similar way. In the reaction with tetrabutylammonium bromide in chloroform, immediate evolution of bromine was observed.

The reaction with isopropanol proceeding on prolonged heating (85°C) afforded 1.6 moles of acetone per mole of fluorofullerene.

The reaction of fluorofullerenes with benzene in the presence of $\text{BF}_3 \cdot \text{Et}_2\text{O}$ was studied. Mass-spectroscopic analysis of the reaction mixture, the colour of which slowly changed from yellow to brown, indicated the formation of fluorobenzene and the presence of fluorofullerenes with lower mass numbers. It was noted that degradation of fluorofullerenes C_{60}F_x is accelerated as x increases. Some reactions result in the formation of a black resin.

It should be noted that even pyridine, which is well known to be inert towards electrophilic substitution, does react slowly with higher fluorofullerenes at elevated temperatures giving rise to 2-fluoropyridine (the yield reaches 10%).

Unfortunately, it cannot be understood from the results obtained what is the mechanism of these reactions, whether it is ionic (fluorine transfer) or radical (electron transfer). On the one hand, the predominant formation of biphenyl in the reaction of fluorofullerene with phenyllithium supports the radical mechanism, while, on the other hand, fluorination of pyridine is a typical ionic process (by analogy with the well known reactions of pyridine with other electrophilic fluorinating agents).

In one of the first publications dealing with fullerene fluorination,⁵⁸ it was noted that fluorination products tend to enter into a nucleophilic substitution reaction, namely, the OH^- anion reacts with a double bond in fluorofullerene, then HF is eliminated and fluorofullerene oxide is produced.

As noted above, detailed investigation of the chemical properties of fluorofullerenes is possible only provided that individual compounds are available and their molecular structures and the degrees of purity are known. In the last two years, certain progress has been attained along this line. In particular, the isolation of pure $\text{C}_{60}\text{F}_{18}$ and of its oxo derivative $\text{C}_{60}\text{F}_{18}\text{O}$ are worthy of note.^{59,60} An example of chemical transformation of individual fluorofullerenes is the reaction of $\text{C}_{60}\text{F}_{18}$ with benzene in the presence of FeCl_3 , known as the Friedel–Crafts reaction, which resulted in the synthesis of $\text{C}_{60}\text{F}_{15}\text{Ph}_3$, called ‘triumphene’.⁶¹

V. Thermodynamic studies of the fluorofullerene $\text{C}_{60}\text{F}_{48}$

The thermodynamic properties of $\text{C}_{60}\text{F}_{48}$ known to date are summarised in Table 7.

The low-temperature heat capacity of $\text{C}_{60}\text{F}_{48}$ in the temperature range from 8 to 356 K was measured by adiabatic calorimetry.^{62,65} These data were used to calculate the numerical values of

Table 7. Thermodynamic characteristics of C₆₀F₄₈.

Characteristic	Value	Ref.
$C_{p,m}(298.15) / \text{J K}^{-1} \text{mol}^{-1}$	1365.2 ± 2.7	62
$H_m^\circ(298.15) - H_m^\circ(0) / \text{kJ mol}^{-1}$	192.48 ± 0.83	62
$S_m^\circ(298.15) - S_m^\circ(0) / \text{J K}^{-1} \text{mol}^{-1}$	1137.2 ± 5.7	62
$G_m^\circ(298.15) - H_m^\circ(0) / \text{kJ mol}^{-1}$	146.6 ± 2.9	62
$\Delta_f S_m^\circ(298.15) / \text{J K}^{-1} \text{mol}^{-1}$	-4071.6 ± 5.8	62
$\Delta_s H_m^\circ(476) / \text{kJ mol}^{-1}$	109 ± 7	63
$\Delta_f H_m^\circ(\text{cryst.}) / \text{kJ mol}^{-1}$	-7563 ± 166	64
$\Delta_f H_m^\circ(\text{gas}) / \text{kJ mol}^{-1}$	-7454 ± 166	64

the thermodynamic functions $H^\circ(T) - H^\circ(0)$, $S^\circ(T) - S^\circ(0)$ and $G^\circ(T) - H^\circ(0)$. The curve for the variation of the specific heat capacity of C₆₀F₄₈ as a function of temperature, presented in Fig. 16 displays a phase transition in the temperature range of 315–345 K ($T_{tr} = 329.6 \pm 0.4$ K and $\Delta_{tr}H = 7.0 \pm 0.7$ kJ mol⁻¹). According to NMR and X-ray diffraction data, this transition is due to the transformation of the ordered body-centred tetragonal phase into a face-centred cubic plastic phase.

**Figure 16.** Specific heat capacity of C₆₀F₄₈ vs. temperature.⁵⁶

The partial pressures of C₆₀F₄₈ have been measured in the temperature range of 395–557 K by high-temperature mass spectroscopy using PbI₂ and C₆₀F₃₆ as internal standards.⁶³ The researchers suggested calculating the partial pressures (in Pa) using the equation

$$\ln[p(\text{C}_{60}\text{F}_{48})] = -\frac{13\,146}{T} + 24.34.$$

The enthalpy of sublimation of C₆₀F₄₈ (see Table 7) calculated using the second law of thermodynamics is lower by 66 kJ mol⁻¹ than the enthalpy of sublimation of C₆₀ (175 ± 3 kJ mol⁻¹), which is due to the smaller energy of intermolecular interactions in the fluorofullerene.

The energy of combustion of C₆₀F₄₈ for burning in a rotating bomb calorimeter ($-24\,638 \pm 163$ kJ mol⁻¹) and the standard molar enthalpy of formation of C₆₀F₄₈ in the crystalline state have been determined⁶⁴ (see Table 7).

In 1992, the $\Delta_f H_m^\circ(\text{gas})$ values for C₆₀F₄₈ were estimated by semi-empirical MNDO and AM1 methods.⁶⁶ The values found for C₆₀F₄₈ isomers formed upon the addition of fluorine atoms to C₆₀ with and without rupture of the C–C bonds in the carbon cage were -7395 and -5508 kJ mol⁻¹, respectively. The former value is close to the enthalpy of formation found experimentally; however, in view of the molecular structure of fluorofullerene C₆₀F₄₈ now established (see Section IV), which rules out the presence of =CF₂ groups in the molecule, this appears to be an accidental coincidence.

The energy of the C–F bond in C₆₀F₄₈ calculated from experimental data⁶⁴ proved to be 36% lower than that in CF₄ (Fig. 17). The reason is elongation of the C–F bonds in C₆₀F₄₈ with respect to those in tetrafluoromethane, difluoroethane or difluorofullerene due to steric factors.

**Figure 17.** Energy of the C–F bond in some fluorocarbons.

VI. Conclusion

In conclusion, we would like to mention some lines of investigation into direct fluorination of fullerenes which appeared recently and are, in our opinion, the most interesting and promising. In the near future, the search for the routes of the selective synthesis of fluorofullerenes, especially those with low fluorine contents (less than 36 fluorine atoms per fullerene molecule) would be continued. As shown above, no convincing evidence supporting the assumption that low-fluorine compounds can form in substantial amounts in the reaction of F₂ with fullerene can be found in the literature. Indirect data indicate that these compounds could be prepared by liquid-phase fluorination; however, exhaustive spectroscopic investigation of the reaction products is still to be performed.

Recent studies of Chilingarov *et al.*^{28,67} in which fullerene mixed with transition metal difluorides is treated with molecular fluorine at elevated temperatures deserve attention. The use of transition metal difluorides as catalysts restricts substantially both the number of the products formed and the degree of saturation of fullerene molecules with fluorine. Nevertheless, it is still unclear whether this method would prove more efficient than the known solid-phase reactions involving trifluorides of metals of the first transition row.

Development of methods for purification and separation of fluorination products would remain among the most topical tasks. Attempts of using various methods for the separation of fluorofullerene mixtures resulting from direct fluorination have been reported in the literature. In particular, a technique used fairly often for this purpose is sublimation. However, these attempts have not yet been a success because the properties of compounds with close contents of fluorine (36 to 48 fluorine atoms per fullerene molecule) are close. Nevertheless, a series of recent publications dealing with chromatographic separation of several fluorofullerenes, their oxidised forms and even fluorofullerene isomers prepared by reactions with metal fluorides demonstrated high efficiency of this method as applied to the given class of compound.^{68,69} The most impressive example is isolation of > 40 individual compounds from a C₇₀F_x sample prepared by the reaction of C₇₀ with MnF₃. Among these 40 compounds, seven isomers of C₇₀F₃₆ alone were present.⁷⁰

The formation of carbon filaments upon decomposition of hydrocarbons catalysed by iron subgroup metals and their alloys

V V Chesnokov, R A Buyanov

Contents

I. Introduction	623
II. The carbide cycle mechanism of carbon formation	623
III. Regularities in the formation of carbon of different morphological types on iron subgroup metals	626
IV. Conclusion	636

Abstract. The structure of filamentous carbon formed upon catalytic decomposition of hydrocarbons on iron subgroup metals and their alloys is considered. The regularities of the deposition of carbon on these metals are generalised. The carbide cycle mechanism of carbon formation is considered in detail. The growth models of some morphological modifications of filamentous carbon are discussed. The bibliography includes 151 references.

I. Introduction

Deactivation of catalysts may be determined by a number of factors,¹ one of which is carbonisation (coking) of catalysts in the processing of hydrocarbons. The development of an efficient method for combating this phenomenon would allow substantial extension of the lifetime of catalysts; therefore, the interest of investigators in the mechanisms of catalytic formation of carbon has not decreased for many decades. This interest is also due to the fact that in a number of cases, the carbonised mineral phases (metals, oxides, and others) and carbon itself can be regarded as carbon-mineral and carbon composite materials possessing special properties.

The formation of filamentous carbon upon decomposition of hydrocarbons on iron subgroup metals and their alloys is one of the most exotic (from the viewpoint of its mechanism) and practically important processes. The properties of carbon graphite deposits on catalysts are mainly determined by their morphological and crystallographic features. The main task in the development of technologies for the preparation of a broad spectrum of such composites should be the elaboration of a scientifically substantiated procedure of process control. To the end, it is necessary to know the mechanisms underlying all its stages.

II. The carbide cycle mechanism of carbon formation

1. Decomposition of hydrocarbons on metallic iron

Various suggestions on the possible role of carbides as intermediates in the formation of carbon deposits were put forward in early

studies generalised by Storch *et al.*² in their monograph nearly five decades ago. It has been noted, in particular, that the hypothesis according to which carbides are intermediates in the formation of free carbon is attractive but stands in need of evidence.

Kagan *et al.*³ considered carbonisation of an iron catalyst to be the result of two independent reactions

However, a later study proved⁴ that the important parts of the process of carbon formation in the decomposition of hydrocarbons on iron are the steps of carbide formation and decomposition.

The proposed carbide mechanism of carbon formation could be confirmed by the establishment of a common limiting step and a common intermediate in the formation of a carbide and carbon. To this end, the activation energies of carbon and iron carbide formation^{5,6} were measured in the experiments on carbonisation of iron in the butadiene decomposition. The formation of the carbide in the temperature range 573–723 K is virtually unaccompanied by its decomposition and liberation of carbon. The formation of iron carbide Fe_3C is a topochemical reaction, *i.e.*, it occurs through formation and growth of nuclei of the carbide phase. An integral kinetic curve of the reaction is S-shaped; therefore, an approximate formula⁷ is used to determine the specific rate of carbidisation

$$W = 2 \frac{W_{\max}}{\pi S},$$

where $W_{\max}$ is the maximum observed rate of carbidisation, S is the specific surface of a sample. The activation energy was determined from the $W_{\max}$ values at different temperatures.

In the range of temperatures 808–874 K, the activation energy of carbide decomposition (197 kJ mol^{-1}) is substantially higher than that of its formation (88 kJ mol^{-1}). For this reason, the ratio between the rates of these reactions changes with temperature. Above 1023 K, the rate of iron carbide decomposition exceeds the rate of its formation, and the carbide phase is not formed. Investigations into the kinetics of carbon formation on iron showed that the activation energy of carbon formation at 1023–1027 K amounts to 96 kJ mol^{-1} and becomes close to that of carbide formation. Obviously, the common limiting step of both reactions is the formation of an intermediate, surface carbide-like compound of the type $[\text{Fe}-\text{C}]$. This makes it possible to represent the mechanism of formation of carbon deposits on iron with the following scheme:

In our studies, this mechanism has been called the carbide cycle mechanism.^{4–6,8–17} The reactions proceed in an open flow system from which the gaseous decomposition products are removed; therefore, the thermodynamic restrictions here are of minor significance.

The carbide cycle mechanism includes two basic steps:⁵ the ‘chemical’ step in which the catalytic decomposition of hydrocarbons occurs on the surface of a metal particle with the formation of carbon atoms whose concentration increases to definite limiting values, and the ‘physical’ step in which the crystallisation centres (nuclei) of the graphite phase are formed on definite faces of a metal particle. In this step, migration (diffusion in the bulk of the metal particle) of carbon atoms towards these centres and growth of a definite variety of graphite particles, predominantly in the form of filaments begin.

Despite the fact that the formation of carbon comprises two steps, the mechanism, on the whole, was called the mechanism of the carbide cycle since the carbon atoms involved in the graphite formation ‘originate’ from intermediate carbide compounds.

The character of carbon deposits is determined by the properties of metal catalyst particles, the nature of a hydrocarbon, as well as by the distinctive features of crystallisation centres and mass-transfer of carbon atoms.

The mechanism of the carbide cycle considered above in the example of the model system $\text{Fe} + \text{C}_4\text{H}_6$ can also be extended to the decomposition of other hydrocarbons. Naturally, the activation energies of formation of carbon deposits from different hydrocarbons differ substantially: *e.g.*, for methane, butane, propylene, isobutylene and butadiene they are ^{6,18} 209, 184, 146, 138 and 96 kJ mol^{-1} , respectively. The relationship between the activation energies (E_a) and enthalpies (ΔH) of the iron carbide formation from different hydrocarbons (Fig. 1) is described by the Brönsted–Polanyi equation.

Figure 1. Dependence of the activation energy of carbon formation on the enthalpy of iron carbide formation in the decomposition of various hydrocarbons.

The formation of carbon from aromatic hydrocarbons can also occur by the carbide cycle mechanism. This was demonstrated in the example of benzene decomposition on metallic iron.¹⁹ At temperatures above 773 K, the catalyst in the steady state is in the form of metal, whereas below this temperature the metallic iron passes to the carbide. The formation of carbon from benzene on metallic iron in the temperature range 773–998 K can be described by the scheme

At temperatures above ~ 898 K, the limiting step is the dissociative adsorption of benzene accompanied by the formation of C_6H_5 or C_6H_4 species,^{20–22} while below this temperature the reaction is limited by the scission of the benzene ring with the formation of intermediate carbide-like compounds.

2. The role of topochemical processes in the mass-transfer of carbon in the carbide cycle mechanism

Studies of the carbon phase formation on metallic iron suggest the elucidation of not only the mechanism of decomposition of hydrocarbons with liberation of carbon atoms, but also of the mode of generation and formation of a new phase from these atoms. The theory of solid-phase reactions²³ and the theory of crystallisation²⁴ are based on the assumption that the initial formation of nuclei of a new phase is often the limiting step of these processes. Under the conditions of topochemical process, the nuclei are formed on the active centres the role of which can be played by surface defects, associates, clusters, sites of the exit of dislocations onto the surface of crystals, *etc.*

In the decomposition of hydrocarbons accompanied by the formation of intermediate carbide-like compounds, carbon atoms are liberated which diffuse into the bulk of the metal and form there a solid solution.¹³ The question arises of how the nuclei of the new phase (graphite) are formed and how does the transport of carbon to these nuclei occur.

In accordance with the carbide cycle mechanism,^{4–6,10–18,25} the subsurface layer of the metal becomes supersaturated (by over two orders of magnitude) with the carbon liberated in the decomposition of intermediate carbide compounds. Indeed, the decomposition of intermediate carbide compounds forms a mixture of carbon and the metal in which the C:Fe ratio appears to correspond to the composition Fe_3C (~ 6 mass % – 7 mass % of carbon), whereas the saturated solution of carbon in iron contains not more than 0.025 mass % of carbon.²⁶ The concentration of carbon is averaged over the bulk of the metal, and this results in the appearance of a graphite nucleus at one of the sites of the metal particle surface. The growth of the graphite phase occurs by virtue of excess carbon in the supersaturated solution. High gradients of carbon concentration appear between the surface site where decomposition of hydrocarbons takes place and the site where the graphite phase is formed. The presence of such a gradient ensures the diffusive transport of carbon atoms through the bulk of a metal particle.

The appearance of a concentration gradient in a solution of carbon in the metal is explained by the specific features of carbon formation through the carbide cycle mechanism and by the difficulties of graphite nuclei formation.

The above considerations make it possible to present a general scheme of all the steps of the graphite phase formation. The activation energies of deposition of carbon formed upon decomposition of acetylene on α -iron (E_c) and diffusion of carbon through the α -iron phase (E_d) are close,²⁷ their values are within the range 67–80 kJ mol^{-1} . This is only possible provided the activation energy of decomposition of hydrocarbons by the carbide cycle mechanism (E') is smaller than E_d . In this case, the growth of the carbon phase is limited by the step of diffusive transfer of carbon, which predetermines the apparent equality $E_c \simeq E_d$. However, the activation energy of the decomposition of a number of more stable hydrocarbons by the carbide cycle mechanism may be rather high and $E' > E_d$; in this case it is not the carbon diffusion but rather the formation of intermediate compound $[\text{Fe}-\text{C}]$, *i.e.*, decomposition of hydrocarbons, that becomes the limiting step. Then the values of E' and E_c coincide. Thus, the diffusion of carbon in the metal from the site of its liberation towards the nucleus or the graphite phase on which it condenses is an important step in the catalytic process of carbon deposition on metals.¹³ Deposition of carbon on iron subgroup metals occurs at increased temperatures when carbides of these metals are not formed (for Fe, Ni and Co, these temperatures amount to 1023, 673 and 573 K, respectively).

Relevant experiments have shown²⁸ that the formation of graphite nuclei is a more energy-consuming process than the carbide phase formation. This may be explained by the fact that

carbon is formed by the carbide cycle mechanisms through an intermediate surface carbide compound which is transformed into carbide after saturation with carbon from its solid solution in the metal.¹³ Under definite conditions, the deposition of carbon can begin with the formation of a thermodynamically unstable metastable carbide phase.²⁹⁻³² The carbide formation accompanied by the liberation of elementary carbon was observed, in particular, in CO disproportionation on iron.⁷ In this case, the accumulation of carbon in the carbide phase may be regarded as only an intermediate step in the formation of graphite nuclei. Owing to this step, the concentration of carbon in the metal bulk may be considerably higher than merely in the saturated solution of carbon in the metal.

3. The formation of carbon on iron carbide

As noted above, under definite conditions a metal catalyst undergoes some changes under the action of the reaction medium and can exist in the form of a metastable carbide in the steady state. For this reason, irrespective of whether the metal or the carbide is the active origin of the process of carbon formation, one can say that carbon will be formed by the carbide cycle mechanism.

Accumulation of carbide-like compounds leads first to the appearance of the Fe_3C phase nuclei and then to the complete phase transformation of the metal into the carbide. The carbide mechanism of the formation of carbon deposits on Fe_3C is preserved in any case; however, the features of its implementation are determined by the chemical nature of the active phase.

The chemical nature of the active phase is primarily manifested in the step of decomposition of an intermediate carbide-like compound. The limiting step of the formation of carbon deposits on the metal is the formation of a carbide-like compound, whereas its decomposition and aggregation of the liberated carbon atoms occur rather quickly. The limiting step of carbon formation on the carbide is the liberation of carbon atoms from the carbide, the carbide passing to a transient state with a disturbed stoichiometry. The disturbed stoichiometry of the surface carbide is recovered upon hydrocarbon decomposition. As the bulk of a catalyst contains a considerable amount of carbon, the diffusive transfer of carbon atoms through the carbide bulk virtually does not take place, while their surface migration is negligible. In this case, the carbon phase is formed as islets or a continuous film shielding the catalyst's surface.

The rate of carbide decomposition increases with temperature. Direct measurements of the initial rate of Fe_3C decomposition were performed using a high-temperature X-ray chamber.^{6, 12}

It was established that $\alpha\text{-Fe}_2\text{O}_3$ undergoes various transformations under the action of the reaction medium (buta-1,3-diene diluted with helium at the molar ratio 1 : 10)

which occur over 10 min; after this the composition of the catalyst corresponds to iron carbide and remains unchanged with time. The contents of α -Fe and Fe_3C in a sample were estimated from the heights of the corresponding peaks (110) and (210) on the diffractograms. In an inert medium, iron carbide decomposes into carbon and a solid solution of carbon in α -Fe (ferrite). The initial rate of Fe_3C decomposition coincided with the rate of carbon formation in the presence of the carbide phase.⁶ This fact confirms that the formation of carbon deposits is limited by the step of carbon liberation from iron carbide. As a result, iron carbide is depleted in carbon to give a non-stoichiometric carbide with which a hydrocarbon interacts. The carbon atoms formed during decomposition of hydrocarbon by the carbide mechanism are again involved in finishing the 'build-up' of the carbide. X-Ray structural studies showed that the interplanar distances in the carbide correspond to the standard values. Consequently, in the course of reaction the system contains stoichiometric carbide Fe_3C , while the slow step is the liberation of carbon from it.

A detailed scheme of the catalytic process of formation of carbon deposits by the carbide cycle mechanism has the following form:

where $[\text{Fe}-\text{C}]$ is the carbide-like intermediate compound, $[\text{Fe}_3\text{C}_{1-x}]_n$ is the intermediate surface carbide with disturbed stoichiometry, $nx = 1$.

Depending on the conditions, either the carbide phase or the metal phase can be stable; although, naturally, only one phase exists in the steady state. The reaction route 1 corresponds to the formation of carbon from hydrocarbons on a metal without formation of the carbide phase. Reaction 2 describes the phase chemical transformations occurring under the action of the reaction medium. Reaction 3 is related to the liberation of carbon and the subsurface non-stoichiometric carbide which can be saturated with carbon under the action of gaseous hydrocarbons.

4. Specific features of the carbide cycle mechanism in the formation of carbon on nickel

The above-cited scheme of the carbide cycle describes the processes occurring on nickel, cobalt and a number of other metals. Naturally, individual features of each metal catalyst are manifested in individual steps of the formation of carbon deposits, though this takes place within the limits of the regularities described.

Let us consider, for example, the features of formation of carbon deposits from butadiene on nickel.^{6, 15}

Using a high-temperature X-ray chamber, it was shown that in the hydrocarbon medium, nickel carbide is formed at temperatures below 623 K. In this case, deposition of carbon proceeds very slowly and does not change the kinetics of carbide formation, which was therefore studied in the temperature range 548–623 K, while the kinetics of carbon formation was studied at 773–923 K. The former reaction is of first order with respect to butadiene and is characterised by an activation energy of 96 kJ mol⁻¹, while the latter is zero order and has an activation energy of 134 kJ mol⁻¹.

These distinctions indicate that the reactions of carbide formation and carbon depositions on nickel have different limit-

Table 1. Coefficients of carbon diffusion through iron subgroup metals and their temperature dependences.

	2.5×10^{-10}	42		

^a Activation energy E_a is expressed in kJ mol^{-1} .

ing steps. The value of E_a for the second reaction is 134 kJ mol^{-1} , which corresponds to the activation energy of carbon diffusion through this metal.^{27, 33–39} Consequently, it may be presumed that the limiting step of carbon formation on metallic nickel is its diffusion through nickel to the nuclei and the graphite phase which is being formed. Thus, the limiting steps of the processes of formation of carbon deposits on iron and nickel are different. This is explained by the fact that the coefficient of carbon diffusion in α -Fe is nearly three orders of magnitude larger than that in nickel (Table 1).^{40–44}

At temperatures below 623 K, the formation of Ni_3C carbide occurs considerably faster than its decomposition; in this temperature range, carbon is formed on nickel carbide.

Substitution of benzene or hexane for butadiene does not affect the rate of carbon formation. This may indicate that the formation of carbon from the above-mentioned hydrocarbons on nickel is limited by the same step, *i.e.*, the diffusion of carbon atoms through the bulk of the metal.

5. Regularities of carbon formation from methane on nickel

The results of studies of the nature of the active phase of Ni/SiO_2 catalysts in the reforming of methane by carbon dioxide confirmed the important role of the surface layers of nickel carbide in both implementation of the major transformation and formation of carbon.⁴⁵ The reaction proceeds on the surface layer which is formed in the beginning of the process and which is close in its composition to nickel carbide. The adsorbed forms of carbon resulting from the activation of methane on the nickel surface are in equilibrium with methane in the gas phase. They can be irreversibly transformed to CO by reacting with adsorbed oxygen (in different forms), which results from the activation of carbon dioxide. A portion of carbon in the amount equivalent to its content in the subsurface carbide layer is rapidly dissolved in the bulk of nickel. This carbon diffuses into the bulk of the metal and is involved in the formation of carbon deposits.

Owing to high thermodynamic stability of methane, its behaviour in the process of nickel carbonisation is different from that of other hydrocarbons.

Chemisorption and subsequent decomposition of methane on the surface of nickel single crystals were studied by high-resolution spectroscopy of characteristic electron energy losses and by Auger spectroscopy.^{46–55} It was established that at lower temperatures, methane is chemisorbed in the dissociative mode with formation of the methyl radical and a hydrogen atom. On temperature increase from 373 to 600 K, the radical $\text{CH}_3^\cdot$ undergoes stepwise dehydrogenation

Schouten *et al.*⁵⁶ carried out experiments at 600 K and have proposed a similar scheme of the formation of surface nickel carbide:

Kinetic studies of methane decomposition were performed at 723–823 K in a catalytic reactor with a microbalance.^{57–59} Analysis of the results obtained was based on the model of Grabke^{60, 61} according to which the decomposition of methane on α -Fe and γ -Fe surfaces occurs as a result of successive splitting of hydrogen atoms, while the limiting step is the decomposition of the methyl radical. On the other hand, Alstrup and Tavares^{57, 59} showed that the limiting step could be both dissociative adsorption of methane and dehydrogenation of adsorbed methyl groups, whereas Snoeck *et al.*⁶² state that this process is limited by the step of detachment of the first hydrogen atom from the methane molecule adsorbed on the nickel surface.

Our kinetic studies of methane decomposition on aluminium–nickel catalysts⁶³ showed that the activation energy of carbon formation on nickel decreases as the temperature increases. In the temperature range 798–873 K, the activation energy is 75 kJ mol^{-1} , which is close to the literature data [*cf.*

88 kJ mol^{-1} (Ref. 58), 90 kJ mol^{-1} (Ref. 59), 96 kJ mol^{-1} (Ref. 64) and 97 kJ mol^{-1} (Ref. 65)]. Apparently, the limiting step is dehydrogenation of the adsorbed methyl radical with formation of surface nickel carbide, which is confirmed by the study of the kinetics of nickel carbide formation from methane on the (110) face of a nickel single crystal.⁵⁶ The activation energy of the surface nickel carbide formation is $87 \pm 12 \text{ kJ mol}^{-1}$ (see Ref. 56).

In the temperature range 923–1023 K, the activation energy of carbon formation from methane decreases to 26 kJ mol^{-1} . Similar values of the activation energy of carbon formation from methane (0 – 40 kJ mol^{-1}) were obtained for the nickel-containing catalysts,^{66, 67} as well as for the (111) and (100) faces of nickel.^{50, 51, 68} The value 26 kJ mol^{-1} coincides with the experimental E_a , which characterises the dissociative adsorption of methane on the face (100) of the nickel surface with formation of the methyl radical and a hydrogen atom.⁶⁸ This makes it possible to conclude that the limiting step of methane decomposition on nickel catalysts at 923–1023 K is the dissociative adsorption of methane with formation of a hydrogen atom and methyl radical.

III. Regularities in the formation of carbon of different morphological types on iron subgroup metals

1. Varieties of carbon deposits

Carbon formed on the iron subgroup metals or their alloys with other metals is produced in the form of deposits possessing various crystallographic characteristics, which depend on the specific features of catalysts and conditions of the process. Using these dependences, one can purposefully control the technologies of preparation of carbon deposits of various morphologies.⁶⁹ Carbon can be deposited as filaments of different configuration, nanotubes, plates and other forms.

The most interesting varieties are characteristic of the forms of filaments. Figure 2 shows three basal structures of carbon filaments.

Figure 2. The structures of graphite filaments with different positions of basal planes;

(a) coaxial-cylindrical; (b) coaxial-conical; (c) flat-parallel (in the form of stacks of plates of graphite planes).

Carbon nanotubes have first been revealed as a concomitant product in the preparation of fullerenes by vaporisation of graphite in an electric arc.⁷⁰ It was shown later that nanotubes could also be obtained by catalytic methods.^{71–73} Nanotubes differ from carbon filaments primarily in their smaller sizes. Carbon nanotubes consist of 1–50 cylindrical graphite-like layers coaxially inserted into each other;^{70, 74, 75} the diameters of cylindrical cavities are 0.7–6 nm, whereas the lengths of the tubes reach several micrometers. In a chemical respect, the nanotubes obtained by graphite vaporisation differ from the known forms of carbon in their increased resistance to oxidation.⁷⁶

2. Regularities of the formation of filamentous carbon

The growth of carbon filaments is catalysed by finely dispersed metal particles. The limits of sizes were established outside which the metal particles are coated with carbon and lose their abilities

to perform catalytic functions.^{77–80} The lower limit is ~ 30 Å, while the upper limit depends on the coefficient of carbon diffusion in the bulk of the metal particle. For nickel and cobalt, these are ~ 1000 – 1500 Å. The carbon diffusion coefficient in iron is 2–3 orders of magnitude larger than that in nickel and cobalt; therefore, the upper limiting size of iron particles is at least one order of magnitude larger.⁷⁹

The growth of carbon filaments on finely dispersed particles of the iron subgroup metals and their alloys with some other metals is a physical step of the carbide cycle mechanism.^{5, 6, 9–18, 77–79} This process is to some extent unique and is of great interest for fundamental science.

The growth of carbon filaments was directly observed in the gas chamber of an electron microscope.^{33, 35} The following regularities were revealed:

(1) a particle of a catalyst is present at the growing ends of each filament;

(2) the diameter of filaments is controlled by the size of the catalytic particle at the growing end, which is fragmented in most cases, and this initiates growth of finer filaments;

(3) the diameters of filaments range from 100 to 1500 Å, while their lengths can reach 8×10^4 Å;

(4) the grown filaments have various forms (loops, helices, interwoven mass);

(5) the dependence of the rate of filament growth on time is S-shaped;

(6) the time for the carbon filament formation depends on the reaction temperature: at 923 K, the growth of some filaments lasts for 10 min, while at 1243 K their growth stops after 30 s.

The catalytic particle at the end of the filament is pear-shaped.^{33, 35} An electron-transparent channel often passes along the entire filament length to its top. Reasonably, the filament has an external layer which is more resistant to oxidation than the internal one. The thickness of the external layer makes up $\sim 10\%$ of the outer diameter.

In order to understand the regularities of formation of carbon filaments, it is necessary to answer at least the following questions.

(1) Why carbon atoms are formed predominantly on one crystal face of a metal particle and crystallise into graphite structures on other faces?

(2) What are the driving forces for the migration of carbon atoms to the sites of graphite phase formation and what are the peculiarities of the mass-transfer of carbon atoms?

(3) What are the conditions for the appearance of the graphite phase crystallisation centres and specific features of these centres?

(4) How do the crystallographic and crystallochemical features of metal particles influence the properties of graphite structures formed on them?

(5) What possibilities exist for the targeted formation of graphitic phases of different morphological types?

There are two explanations of the reasons for the transfer of carbon atoms from the front part of catalytic particles where they are formed to the rear side where the filament grows. Some investigators presume that this transfer occurs owing to the diffusion of carbon atoms over the surface of the catalytic particle.⁸¹ However, the more popular is another viewpoint according to which the growth of filamentous carbon occurs as a result of diffusion of carbon atoms in the bulk of the metal particle.^{33–35, 39, 82–91}

The mechanism of filamentous carbon growth proposed by Baker *et al.*^{33, 35} is presented schematically in Fig. 3. After formation of small metal particles on a support (Fig. 3a), deposition of amorphous carbon takes place at the site of particle contact with the support (Fig. 3b). The formation of amorphous carbon is explained by the gas-phase polymerisation of acetylene. At the same time, acetylene is decomposed on a metal particle surface, and the carbon atoms are dissolved in the bulk of the metal. Decomposition of acetylene and solubilisation of carbon are accompanied by heat release, and this creates temperature gradient along the particle. Owing to this gradient, carbon moves

Figure 3. Schematic representation of the mechanism of the filamentous carbon growth from acetylene on a metal (see the text for comments).

to a colder part of the particle in contact with the support. The deposited carbon raises the metal particle and removes it from the support. The initial filament growth causes curvature of the metal particle which becomes pear-shaped, and this in turn leads to the formation of a channel (Fig. 3c). The increase in the filament growth rate is explained by the insulation of the particle from the support and the corresponding increase in the temperature gradient. The excess carbon formed on the outer surface of the particle migrates from this surface and builds the external wall of the filament. It is presumed that the external wall of the filament has a different structure from that of its core. The filament growth stops when the 'hot' side of the particle is covered by carbon (Fig. 3d).

In the authors' opinion,³⁵ their hypothesis is confirmed by the fact that the activation energies of the growth of carbon filaments on α -Fe, Co, Cr and Ni are close to the activation energies of carbon diffusion in the bulk of the corresponding metal. However, the values of the growth rates of carbon filaments on different metals^{33, 35} are contradictory. If the formation of filaments is governed only by the diffusion of carbon atoms in the corresponding metal, then under the same experimental conditions (1010 K, acetylene as the carbon source, catalytic particles of the same sizes), the growth rates should be proportional to the diffusion coefficient of carbon atoms in the corresponding metal. As noted above, the coefficient of carbon diffusion in metallic iron is 2–3 orders of magnitude larger than that in cobalt or nickel. Consequently, the rate of growth of carbon filaments on iron should be proportionally higher. However, in practice it proved to be lower on iron than on nickel or cobalt.^{33, 35} In this context, it is reasonable to suggest that the limiting step on iron is the interaction of acetylene with the surface of the metal.

The driving force of diffusion was presumed^{33, 35} to be the temperature gradient arising between the sites where the decomposition of hydrocarbons occurs and the sites where the graphite phase grows. The higher the metal temperature the larger the solubility of carbon in it; for this reason, concentration gradient also appears.

The concept according to which the growth of filamentous carbon is brought about by carbon diffusion in a crystal has been accepted by most investigators, whereas the appearance of mass gradient determined by the temperature gradient has become the subject of lively discussion.^{81, 82, 84–87, 92} The arguments of the opponents were based on the fact that the hydrocarbons, the decomposition of which is an endothermic process (*e.g.*, methane), also provide the growth of carbon filaments. The suggestion according to which the deposition of carbon is explained by the presence of admixtures of other hydrocarbons in methane was disproved by the fact that with high-purity methane (99.99 vol.%) the degree of its decomposition reached 30%.⁸⁷

In order to assess the magnitude of the temperature gradient, Tibbetts *et al.*⁹³ have simulated the process of the growth of the carbon filaments from acetylene on γ -Fe. To simplify calculations, they suggested that the filament has no hollow channel and its

diameter is equal to the diameter of the metal crystal initiating the filament growth. The thermal balance of the growing filament end was calculated on the assumption that all the heat released in the decomposition of hydrocarbons is absorbed by the metal particle. Calculations showed that the temperature gradient is smaller than 2×10^{-3} K, and such a small magnitude cannot ensure the really observed growth rates of carbon filaments. Nonetheless, unsuccessful attempts were undertaken to prove a substantial influence of the temperature gradient.^{94–96}

An alternative explanation of the nature of the driving force of diffusion is based on the appearance of concentration gradient. In the model proposed by Rostrup-Nielsen and Trimm,⁹⁷ it was suggested that the solubility of carbon at the hydrocarbon–metal boundary is higher than that at the metal–graphite boundary. However, the data on solubility used in this model and based on the results reported by Wada *et al.*⁸⁸ are questionable.

The hypothesis of concentration gradient was also supported by the authors of a series of studies,^{98–100} who investigated the growth of filamentous carbon upon disproportionation of CO on Co/Fe alloys. It was presumed that the activity of carbon at the gas–metal interface is determined by the carbon activity in the gas phase. The activity of carbon at the metal–filament interface was assumed to be equal to the activity of graphite. On the basis of this simple assumption, a kinetic equation was deduced according to which the rate of carbon deposition depends linearly on the carbon activity in the gas phase. However, the explanation of the reasons for the appearance of the concentration gradient^{97–100} appears to be supported with insufficient argumentation.

Based on the carbide cycle mechanism, a model of the filamentous carbon growth was constructed which does not contradict most experimental results.^{5,6,15} We believe that the mass-transfer of carbon atoms occurs owing to their diffusion in the bulk of metal particles from the formation site to the crystallisation centres. Depending on the ratios of the rates of formation and diffusion of carbon atoms, the limiting steps of the process may be different. Let us consider the growth of carbon filaments under the conditions where the limiting step is the diffusion of carbon atoms in the metal particle.

In a saturated solution, the solid and dissolved phases possessing equal chemical potentials are in equilibrium. In our case, however, carbon on the front and rear sides of the metal particle is in different states which are characterised by different chemical potentials. The pool of carbon on the front side of the particle is continually replenished due to the decomposition of hydrocarbons. On the rear side, carbon is formed as the graphite phase. The concentrations of saturation (solubility) of carbon at these sites are substantially different; therefore, a concentration gradient arises, which ensures continuous dissolution of carbon on the front side and its diffusive mass-transfer to the rear side of the metal particle. This gradient is rather high. The concentration of carbon atoms on the front side of the nickel particle formed by decomposition of intermediate carbide-like compounds is close to the concentration of carbon in Ni_3C carbide, *i.e.*, it reaches 25 at. %. This value is confirmed by the calculation of the linear rate of carbon filament growth.¹⁵

The linear rate of the carbon filament growth (V) is determined by the amount of carbon Q which has diffused through an area section unit of a metal particle in unit time.

$$Q = \frac{D(c_1 - c_2)}{L} \text{ and } V = \frac{D(c_1 - c_2)}{Ld},$$

where D is the coefficient of carbon diffusion in the metal, c_1 is the carbon concentration in the surface carbide-like compound, c_2 is the carbon concentration in the saturated solution of carbon in nickel on the rear side of the metal particle, L is the diameter of the metal particle at the end of the filament, d is the density of graphite.

These formulae were used to calculate the rates of the growth of carbon filaments 600 Å in diameter on metallic nickel at 873 K.

Decomposition of an intermediate carbide-like compound of the Ni_3C type gives the concentration $c_1 = 0.514 \text{ g cm}^{-3}$; the values of $c_2 = 3.8 \times 10^{-3} \text{ g cm}^{-3}$, $D = 3.89 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, $d = 2 \text{ g cm}^{-3}$ were taken from the monograph of Buyanov.⁵ The growth rate of carbon filaments found (1650 Å s^{-1}) is close to the values measured experimentally^{33,34} ($800–1600 \text{ Å s}^{-1}$).

An analogous explanation of the reasons for the diffusion of carbon atoms in the metal particle is given in Refs 101–107.

At present, the concept of the formation of carbon filaments by carbide cycle mechanisms is commonly accepted for the iron subgroup metals and their alloys.¹⁰⁸

3. The effect of the orientation of faces of metal single crystals on the growth of carbon filaments

Detailed crystallographic studies of the role of the orientation of catalytic particles in the preparation of filamentous carbon were carried out by Audier *et al.*^{98–100,109–115} using mainly the disproportionation reaction of CO on Fe–Co and Fe–Ni alloys. It turned out that on all alloys with the body-centred cubic (BCC) structure, the carbon filaments are formed; the metal particles which initiate their growth are oriented in such a manner that the direction [100] of single crystals is parallel to the filament axis. The (100) face of the crystal is free from carbon. The alloys with the face-centred cubic (FCC) structure also catalysed the growth of filaments; however, they had a different orientation relative to the carbon filament. The direction [110] of crystals was always parallel to the filament axis.

Electron microscopy studies of the metal particle–filamentous carbon interface showed^{98–100,109–116} that the liberation of carbon and generation of graphite layers occur on the vicinal faces of the catalyst particle. Near the metal–carbon interface, the graphite planes are arranged essentially parallel to the metal surface. The experiments were performed under the following conditions: the gas phase was compressed (75% CO and 25% CO_2), the pressure was 10^5 Pa and the temperature range was 723–923 K.

However, an investigation of the structure and texture of the filamentous carbon obtained from benzene on iron and from buta-1,3-diene on nickel showed⁷⁷ that the particles of metallic iron are oriented differently relative to the filament axis. The iron particles which initiated the growth of filaments were single crystals in which it was the direction [110] that was parallel to the filament axis. Analogous results were obtained later by Rodríguez *et al.*¹¹⁷ In crystals of metallic nickel the direction [100] was parallel to the filament axis, while the planes (100) and (110) were free from carbon. Similar orientation and disposition of faces were established by Yang and Chen.⁹⁴ Such an orientation of metal crystals and the presence of low-index faces in them are not occasional. Different faces possess different activities in the decomposition of hydrocarbons; the diffusion rate of carbon atoms through single crystals of metals can also be anisotropic.⁷⁷

Thus, different faces and sites of the surface of metal crystals where the mechanism of the carbide cycle of decomposition of hydrocarbons is valid are not equivalent and they exhibit different properties in the general process of formation of carbon deposits. The distinction between the adsorption and catalytic properties of different faces and surface sites is confirmed by numerous data. For example, in the studies of methane decomposition on nickel in the temperature range 300–773 K it was found^{56,118,119} that this reaction proceeded only on the faces (100) and (110) [but not on the (111) face]. At temperatures up to 673 K, surface carbide structures are formed on the surface of these faces and diffusion of the carbon formed in the bulk of nickel crystal becomes noticeable above 573 K. No chemisorption of methane or formation of carbon on the (111) face could be detected.

Decomposition of ethylene on the nickel faces (111), (110) and $5(111) \times (110)$ is yet another example.¹²⁰ On the stepped faces $5(111) \times (110)$, the cleavage of bonds occurs in the lower temperature range than on the smooth faces (111) and (110).

Presumably,^{77–79} the generation of the graphite phase is easier on the face (111) than on the faces (100) and (110) because of high degree of its geometric correspondence to the structure of the basal graphite plane. This conclusion is in good agreement with the results reported by Eizenberg and Blakely¹²¹ who studied the isolation of carbon from a supersaturated Ni–C solution on the faces (111), (311), (110), (210) and (110) and the vicinal high-index surfaces of nickel. In the course of the monolayer filling, the vicinal surfaces of nickel are spontaneously restructured (faceted) into stepped faces formed by the terraces (111) and the monoatomic steps (110) or (310) depending on the index of the initial face.

4. Steps of the growth of carbon filaments from methane on nickel-containing catalysts

Four individual sites (stages) which differ in the features of the carbon filament growth can be distinguished on the kinetic curves describing the decomposition of methane on the catalyst containing 85 mass % of Ni/Al₂O₃¹²² at 823 K. Analogous stages were observed in the formation of carbon from acetylene.²⁷

Crystals of nickel of various shapes are formed after the reduction of an aluminium–nickel catalyst. In conformity with the carbide cycle mechanism, the carbon atoms liberated as a result of methane decomposition in the induction period of filament growth diffuse into the bulk of the metal and form there a supersaturated solution of carbon in nickel relative to the graphite phase. As soon as the critical level of supersaturation is reached and a crystalline graphite nucleus appears at some site, condensation of the carbon atoms from the supersaturated solution occurs on the nucleus formed. In this case, the concentration of dissolved carbon in the zone adjoining the graphite phase decreases to its level in the saturated solution. The (111) faces of nickel are the most favourable for the formation of graphite nuclei, since the symmetry and parameters of the flat networks (111) of nickel (Fig. 4a) and (002) of graphite coincide. The graphite filaments formed upon carbonisation of Ni/MgO or Ni/Al₂O₃ catalysts have a coaxial conical structure where the graphite (002) layers are inserted one into another as funnels (see Fig. 2b). The correspondence of the structures of the face surface of nickel particles and the graphite filament can serve as a virtually classical example. It was shown⁶³ that the frontal side of a nickel crystal is formed by the (100) and (110) faces, while the faces (111) form its rear part.

After the appearance of the graphite crystallisation centres, the growth of graphite filaments begins, which is accompanied by the reconstruction of metal particles. During this period, the rate of carbon formation comes to stationary level. The shape of the metal crystals depends substantially on the rate of liberation of carbon atoms, their mass-transfer and specific features of the graphite structure.¹²² The more intense the process the more labile is the structure of the metal particle.

Boellaard *et al.*¹⁰⁵ noted that the formation of carbon filaments with the coaxial-conical structure should result in slippage of the carbon layers relative each other. Due to irregular supply of carbon atoms to the back, rear side of a cone-like metal particle, the carbon layers lose the form of ideal cones, and the body of filaments acquires an imperfect graphite structure with numerous

defects, in particular with a considerable number of edge dislocations.

However, in our opinion, as the new graphite layers grow, the nickel particle should be lifted a little, while the (111) face of nickel and the basal graphite face should slide relative each other. Each new graphite plane slides to the central part of the carbon filament. Owing to high mobility of nickel atoms at the Ni–C interface, the surface metal atoms dislocate towards the filament axis, and this explains considerable transformation of the metal particle during the accelerated growth of the carbon layer observed on kinetic curves. In this case, the nickel particle (Fig. 4b) changes its shape (Fig. 4c). According to the crystallographic laws, the angle α between the faces (111) should be approximately equal to 71°. However, at 823 K the transfer of nickel atoms out to the ‘tail’ of the crystal occurs rather strongly, which decreases the angle α to 50–60°. It may be suggested that the relief of the above-mentioned faces is determined by the atomic steps which change the slope of the plane. The nickel particles which initiate the growth of filamentous carbon from methane on Ni/Al₂O₃, are well formed (see Fig. 4c). The face (100) is oriented towards the filament growth, while the faces (111) in the ‘tail’ part of the nickel crystal form a pyramid with its top facing the side opposite to the filament growth direction.⁶³

It is clear that after the induction period the appearance of new crystallisation centres at some sites of the metal surface becomes virtually impossible. As a result, the site where the graphite growth occurs becomes the back (rear) side of the particle, while all the other faces, which are not closed by graphite, begin to play the role of the front side on which methane is decomposed by the carbide cycle mechanism. At relatively low temperatures of 748–798 K, such a form of nickel crystal remains invariable for a long time, which ensures stable growth of filamentous carbon. This stage is associated with the steady-state period of the filamentous carbon growth.

The velocity of filamentous carbon growth from methane at 823 K was estimated on the basis of the rate of carbon formation. Rather simple calculations¹²² showed that the mean filament growth velocity is 6 Å s^{–1}, while the carbon concentration on the front side of the nickel particle is only 2–3 times higher than that in the saturated solution in nickel at 823 K. It should be remembered that these results refer to the decomposition of the most stable hydrocarbon, *viz.*, methane. Therefore, in this case the limiting step is the decomposition of CH₄ molecules rather than the diffusive transfer of carbon atoms in the bulk of nickel particles. If the growth of filaments is limited by the diffusion of carbon in the bulk of the metal, then, as it was shown above, the gradient of carbon concentration becomes extremely large. This gradient predetermines the magnitude of diffusive flux of carbon atoms in the metal particle and has a strong effect on the phase state of the metal.

Transition metals (Fe, Co, Ni) have small atomic radii. In particular, it is 1.24 Å for nickel, and for this reason, the carbon atom with a radius of 0.77 Å is too large to occupy the octahedral voids of the most dense FCC-packing of nickel. Thus, diffusion of carbon through the nickel particle results in distortion of the crystal lattice of the latter. In some cases, the catalytic particle can become highly labile owing to a high carbon concentration, intense motion of carbon atoms through the metal bulk and the release of heat upon their condensation in the form of graphite phase.

Centres of carbon crystallisation on the metal particle are formed if a high energy barrier, which is 170 kJ mol^{–1} for nickel¹²³ and 220–300 kJ mol^{–1} for iron, is overcome.¹⁷ This is possible owing to a considerable supersaturation of carbon solutions in the metal which is especially large in the early stages of hydrocarbon decomposition. Studies using a high-temperature X-ray chamber showed¹²⁴ that in the course of induction period the concentration of carbon atoms on nickel exceeds 2 at.%.

Based on a thermodynamic analysis, Parmon¹²⁵ concluded that owing to a strong supersaturation of iron or nickel with

Figure 4. Schematic representation of a mechanism of the generation and growth of carbon filaments on Ni–Cu and Ni catalysts (see the text for comments).

carbon, which can reach > 10 mass %, melting of the metal should begin at ~ 920 K. In our opinion, this relates primarily to the induction period of the filamentous carbon growth because after the formation of graphite nuclei the maintenance of such a high carbon concentration in the metal is hardly probable.

The formation of carbon filaments is often associated with the high mobility of metal–carbon particles. In this connection, one should mention the VLS (vapour–liquid–solid) mechanism proposed for the description of the growth of silicon filaments on drops of a liquid metal.¹²⁶

The problem of the possibility of melting of metal particles has not been totally solved yet, and the temperature boundary where the metal particles catalysing the growth of filamentous carbon or nanotubes can pass to the liquid state, has not been established yet. Some authors state^{127, 128} that the finely dispersed catalytic particles of iron are capable of melting even at temperatures below 1173 K. They believe that the particles of liquid iron are ‘responsible’ for the efficient growth of carbon filaments. However, according to other data (see, *e.g.*, Refs 129 and 130), the ‘liquefaction’ of iron particles occurs at ~ 1400 K.

Relevant calculations confirm that the growth of carbon filaments from methane is initiated by edged particles oriented in a definite manner relative to the filament axis; the growth of carbon filaments from alkenes, dienes and acetylene is initiated by the pear-shaped particles, the form of which is less expressed.

In the so-called ‘extrusion’ method, which is less common than the above-considered (classical) method for the formation of carbon filaments, the crystal initiating the carbon deposition remains in contact with the support. This process occurs in the growth of carbon filaments on Pt/Fe alloys³⁶ and on pure metals.^{35, 131, 132}

5. Specific features of the formation of carbon filaments on metallic iron

In a number of cases, deposits of carbon on iron catalysts have the form of filaments.⁷⁷ A general view of such filaments is shown in Fig. 2*a*. Figure 5 shows a micrograph of one such filament. As a rule, the carbon filament contains inclusions both at end of the filament and in its hollow channel, which, according to micro-

diffraction data, represent the metal phase. Reflexes on electronograms indicate that this phase has a body-centred cubic lattice of α -Fe. The characteristic feature is that the crystallites which are constituents of the filament structure are oriented in a definite manner relative to its axis. The crystallographic direction of α -Fe [110] is parallel to the axis. The metallic inclusion at the end of the filament has usually the drop-like form, which is narrowed in its lower part and is weakly edged. The inclusions have a block structure. This follows from the existence of boundaries between the blocks as seen on electron micrographs and from the periodic contrasting of the areas of overlap of individual blocks.

The carbon of the filament is graphitised, and this is clearly seen in micrographs obtained by the high-resolution electron microscopy method. The distance between the planes is 3.5 ± 0.2 Å, which is close to the interplanar distance d_{002} for graphite. Zaikovskii *et al.*⁷⁷ showed that the graphite layers are concentrically arranged around the filament axis and the inter-channel metal particle.

The distribution of carbon around the metal particle at the end of the filament is irregular. The smallest thickness of the carbon layer (only a few monolayers) is observed on the side of the metal particle where the decomposition of a hydrocarbon occurs. As the distance from the top of the metal particle increases, the thickness of the carbon layer increases. The orientation of graphite layers at different sites of the metal surface is also different. In contrast to the upper part of the metal particle, in its lower part the graphite layers form a certain angle with the surface and are in contact with the metal by their terminal sides (Fig. 2*a*).

In the hollow channel of the filament there are very thin (2–10 monolayers) partitions composed of carbon layers.

Note in conclusion that the mechanism of generation and growth of carbon filaments on α -Fe is extremely complex. When considering these processes, one should take into account the following characteristic features of carbonisation of metallic iron:

- (1) high diffusion coefficient of carbon in the bulk of the metal ensuring its rapid supply to different surface sites;
- (2) incomplete epitaxial correspondence between the parameters of α -Fe face (111) and the basal graphite plane (002), which impedes the formation of nuclei of the graphite phase.
- (3) the tendency of metallic iron to form carbides.

6. Regularities of the formation of carbon deposits in the ‘octopus’ form

On nickel–copper alloys, the formation of unusual morphological ‘octopus’ carbon was observed.^{63, 106, 133–135} One particle of nickel–copper alloy initiates the growth of several filaments in different directions (Fig. 4*a*).

In contrast to nickel, metallic copper has low activity in the processes of carbon formation. It was used as an additive to Ni/MgO and Ni/Al₂O₃, because it has the same face-centred lattice like nickel and forms alloys with nickel in a wide range of concentrations. After reduction by hydrogen of the catalyst containing 10 mass % of MgO, 12 mass % of Cu and 78 mass % of Ni, the X-ray patterns reveal the predominance of the lines of MgO and a nickel–copper alloy of cubic structure⁶³ with the unit cell parameter $a = 3.53$ Å; this parameter corresponds to an alloy of approximate composition Ni_{0.9}Cu_{0.1}. The mean size of the alloy particles found from the half-width of the line (311) is 210 Å.

Kinetic studies of the formation of carbon from methane on the catalysts Ni/MgO and Ni–Cu/MgO showed that the rate of this process decreases as the content of copper in the sample increases.⁶³ Addition of 12 mass % of copper decreases this rate 2–3-fold. As a result, the aggregation of carbon atoms proceeds in a more ordered manner, and one observes a rather clear-cut trend towards the formation of graphite on the (111) face of the nickel–copper alloy (see Fig. 4*a*). The lattice parameter of the alloy increases with the increase in the copper content, and the crystallographic correspondence of the (111) faces of the alloy and the faces (002) of graphite becomes more and more complete.

Figure 5. A micrograph obtained by the method of high-resolution electron microscopy (HREM) of a carbon filament formed on metallic iron from an atmosphere of benzene diluted with argon in the molar ratio C₆H₆:Ar = 1:15 at 923 K.⁷⁷

Electron microscopy analysis showed^{63, 79, 133} that carbonisation of the Ni–Cu/MgO catalyst upon decomposition of methane for 1 min at 873 K leads to the formation of carbon filaments, the ends of which contain metal particles. This metal particle usually has a well edged form, while its diameter exceeds the diameter of the carbon filament. The data from electronic microdiffraction (EMD) suggest that the (111) face of the FCC lattice of the metal is the most developed. It is perpendicular to the direction of the filament growth and is in contact with the (002) planes of graphite. The lateral (100) faces of the alloy are free, they have no contact with carbon and are the centres of methane decomposition. The form presented in Fig. 4a corresponds to the initial stage of the growth of filamentous carbon on particles of the Ni–Cu alloy.

Carbon can be formed simultaneously on two opposite faces (111) of the flattened alloy particle; this can give birth to two carbon filaments in the form of rings containing a metal particle inside. Sometimes, carbon is deposited simultaneously on three (111) faces of a nickel–copper alloy and the growth of filaments begins in three directions (Fig. 6). According to the data from EMD, the structure of such filaments is formed by the graphite layer (002), arranged perpendicularly to the filament growth direction.^{63, 79, 133}

Figure 6. A micrograph showing the filamentous carbon growth in three directions on the Ni–Cu alloy particles.⁶³

The sizes and shapes of faces which determine the equilibrium habits are known to be related to the surface energies of these faces. The difference in the habits of catalytically active particles in nickel and nickel–copper catalysts is explained by different degrees of proximity of the parameters of hexagonal lattices of the nickel and nickel–copper alloys to the parameter of the graphite lattice. The link of carbon with a particle of nickel–copper alloy over the face (111) is stronger; consequently, the surface energy in this case is lower than on the nickel particle, and the size of (111) face is increased.

After carbonisation with methane for 2 min at 873 K the particles lose their clearly expressed edging.⁶³

The increase in the carbonisation time to 5 min induces changes in the structure of metal particles. It becomes of micro-block-type, the size of the blocks being 50–200 Å. The defectiveness of the alloy surface deteriorates the ordering of the graphite layers formed and in some places the filament is separated into layers (Fig. 7). This favours the formation of bundles of filaments growing from one particle. Very often, thin branches appear from the major bundle or from the block-polycrystalline metal particle. At the ends of such branchings, there are also metal particles.^{63, 79}

Carbon deposits, formed on the Ni–Cu/MgO catalyst upon decomposition of CH₄ for 3 h at 875 K present a porous mass consisting of filaments intertwined in a complex manner. In

Figure 7. Morphology of the carbon formed from methane on the block particle of Ni–Cu alloy after a 5-min relaxation at 873 K.

addition to large filamentous formations, numerous thin filaments 50–100 Å in diameter are present. Taking this into account, it may be concluded that large particles of the alloy break into individual blocks which catalyse the growth of thin filaments.

Thus, one of the stages in the formation of carbon deposits is the diffusion of carbon atoms in the metal particle determined by different concentrations of these atoms near those faces where a hydrocarbon is decomposed and graphite is condensed. The directed diffusion of carbon atoms at elevated temperatures leads to the displacement of the matrix atoms (Cu and Ni). This effect is the stronger the higher the ability of components to form chemical bonds with carbon. Stratification and fragmentation of a single crystal of the initial alloy in the process of the carbon filament growth may be explained by bulk diffusion of atoms. Consequently, as the carbon accumulates, the morphological structure of the carbon mass begins to resemble a branched tree.⁶³

7. The reasons for deactivation of a catalytic particle in the growth of a carbon filament

The phenomenon of deactivation of catalysts in their carbonisation by hydrocarbons has been investigated.^{5, 136} Deactivation is caused by destruction and grinding of catalysts, removal of some components from them and by the mechanical capture of individual microparticles by the growing carbon filaments. This phenomenon was called carbon erosion.

Electron microscopy studies of carbon filaments which ceased to grow showed that the front side of nickel particles is covered by a carbon film. Treatment of such filaments with hydrogen or oxygen leads to the recovery of their activity and continuation of growth.²⁷

In our view, the cessation of the filamentous carbon growth is explained by the peculiarities of the process itself. As noted above, the diffusion of carbon atoms in the nickel particle is determined by the existence of a concentration gradient. The concentration of carbon on the faces (100) and (110) on the frontal side of the crystal is larger than its equilibrium concentration at the nickel–graphite interface. Supersaturation of carbon solution in the metal is the driving force of structural transformations on the surface of nickel. The larger the supersaturation the faster the deactivation.

Wesner *et al.*¹³⁷ considered surface autodiffusion of carbon atoms on the (100) face of a nickel single crystal which is induced by catalytic hydrogenation of CO with the formation of methane. On this face, sinusoidal grooves 1 μm deep were made at a distance of 7 μm. After the catalytic hydrogenation of CO for 6 h, the shape of the section profile changed substantially. Faceting of the groove was spreading from the ridge down to the

'valleys'. Taking this into account, it may be suggested that the nickel atoms dislocate from the 'valleys' in the direction of ridge peaks with simultaneous creation of cutting. The height of ridges increases with time. There are grounds to believe that in the process of carbon deposition reconstruction occurs of the surface of the front side of the metal particle, on which the steps corresponding to the (111) faces appear. Thus, conditions are created for the formation of new graphite nuclei on the front side of the nickel crystal. Therefore, the front side of the nickel crystal becomes coated with a thin carbon film with time despite the efflux of carbon atoms inside the crystal. This is the primary mechanism of deactivation of metal particles which catalyse the growth of carbon filaments.

One manifestation of the carbon erosion is the destruction of metal particles initiating the growth of carbon filaments with the formation of smaller and smaller fragments which can eventually be totally 'overgrown' with carbon and become isolated. A spectacular example may be the above-described growth of filamentous carbon on the Ni–Cu alloy particles in the Ni–Cu/MgO catalyst. The initially formed filaments 500–1000 Å in diameter are branched with time. This is due to the fact that the diffusion flux of carbon atoms in the bulk of alloy particles favours their fragmentation and crushing into subcrystals, a part of nickel being removed with carbon. As the initial particle is fragmented, a deposition of carbon begins not only on major filaments, but also on the surfaces of a contact between individual subcrystals. As a consequence, the initial particles undergo the ever-increasing splitting, while each new smaller particle becomes the centre of the growth of new filaments of a smaller diameter. Gradual extinction of the process of carbon deposition is explained by the fact that the metal particles of some minimal size prove to be covered by a graphite envelope and are switched off the process.

8. The effect of carbonisation temperature on the regularities of growth of carbon filaments in the decomposition of methane on nickel and nickel–copper catalysts

The increase in the reaction temperature influences the peculiarities of the filamentous carbon growth on both nickel and nickel–copper catalysts. Figure 8 shows the kinetic curves of carbon formation from methane at different temperatures on an Ni–Cu/MgO catalyst (analogous kinetic curves were also obtained for an Ni/MgO catalyst).¹²² The rate of carbon formation increases with temperature. However, at 973 K the higher rate is maintained only for a few minutes, after which it drops abruptly. Figure 9 shows an electron micrograph of a filamentous carbon obtained from methane at 1023 K on an Ni/Al₂O₃ catalyst. It is seen that the nickel particles appear to stretch along the filament length. As a result, the channel inside the carbon filament is filled with metallic nickel. Analogous morphology is also characteristic of the filamentous carbon obtained from

Figure 8. Kinetic curves of the carbon formation from methane on an Ni–Cu/MgO catalyst at 823 (1), 873 (2) and 973 K, respectively. *G* is the carbon increment.

Figure 9. A micrograph of the filamentous carbon formed from methane on an Ni/Al₂O₃ catalyst at 1023 K.

methane on an Ni–Cu/MgO catalyst at 973 K. A question arises: what is the reason for the internal cavity formation in the graphite filament and what forces 'drag' the metal particle along this cavity?

The second mechanism of deactivation of metal particles which catalyse the growth of carbon filaments consists in the following. The increase in temperature and the higher rate of the filamentous carbon growth lead to an increase in the viscous fluidity of the metal particle, which facilitates sliding of the graphite planes formed over the surface of the metal¹²² and intensifies the efflux of nickel atoms in the direction of the diffusion flow of carbon atoms, *i.e.*, into the 'tail' part of the metal particle. As a result, the particle is elongated, while the angle α (Fig. 10 *a*) decreases considerably; the catalytic particle is transformed (Fig. 10 *b*). In the limit, the particle is so elongated that it acquires the shape of a needle (Fig. 11). Since in this case, the (111) faces become virtually parallel, the graphite deposited on them does not push the nickel crystal ahead but rather brings about lateral compression, which makes it still more elongated. Because of a large length of the nickel needle, the accumulation of carbon and supersaturation of the tail part in it proceed slowly. After reaching the critical supersaturation of the tail part of the nickel crystal, rapid condensation of carbon atoms begins with the formation of graphite layers which create carbon partitions inside the filaments. This in turn leads to irregular forward movement of the metal needle by pulsation. This results in the periodic appearance of carbon partitions which are seen in Fig. 11.

However, the situation changes considerably if carbonisation is carried out at 973 K in an atmosphere of methane diluted with hydrogen in the molar ratio 1:1. The morphology of the filamentous carbon formed on both Ni/Al₂O₃ and Ni–Cu/MgO

Figure 11. A micrograph of the filamentous carbon formed from methane on the Ni–Cu/MgO catalyst at 973 K.

becomes different. A hollow channel appears inside the carbon filament. (Fig. 10 *c*).

We have already mentioned that as the intensity of the process increases, the probability of restructuring of the metal becomes higher until some faces disappear and the other faces develop. In this case, upon addition of hydrogen to methane, the methanation of carbon atoms on the front side becomes possible. In other words, the reaction takes place which is opposite to methane decomposition, the carbon concentration on the front side decreases and the entire process is slowed down. It is logical to suggest that in this labile system reconstruction of the structure shown in Fig. 10 *a* into the structure shown in Fig. 10 *b* occurs. On the rear, a less active face (100) is formed in the side outgrowth; this is surrounded by more active sites (111).^{111, 113} The carbon is predominantly deposited at the sites marked with the arrows in Fig. 10 *c*, and this determines the speed of the motion of the entire particle. Thus, the reason for the appearance, along the filament axis, of a hollow channel the diameter of which is commensurable with the size of the 'passive' face (100) on the rear side of the particle is the stretching of the catalytic particle. Baker and Harris²⁷ explained the formation of a hollow channel by the slower supply of carbon atoms because of the increase in its diffusion route. However, this is rather the consequence of the catalytic particle stretching. The graphite layers which arise slowly on this face are sealed off periodically, making partitions in the hollow of the channel. At a more rapid influx of carbon atoms, the hollow channel should have filled with carbon.

9. The effect of hydrogen on the formation of carbon filaments

The knowledge of general regularities and specific features of the carbide cycle mechanism allows prediction of the influence of hydrogen on the deposition of carbon. Hydrogen can hydrogenate metal (M) carbides with the formation of lower hydrocarbons, mainly, methane:

Owing to this property, hydrogen also affects the formation of carbon; in the case of nickel, this effect is stronger than in the case of cobalt or iron.

Upon dilution of buta-1,3-diene with argon alone, the carbonisation of nickel proceeds rapidly at the beginning of the reaction, but then the rate of carbon deposition drops abruptly (Fig. 12). Addition of hydrogen decreases the initial rate of carbon formation. The larger the partial pressure of hydrogen in the reaction mixture the stronger is this decrease. At a partial hydrogen pressure p_{H_2} of 17.5 kPa, the rate becomes constant and does not depend on the carbon content on the catalyst. At higher pressures, an induction period appears the duration of which increases with

Figure 12. Effect of hydrogen on carbonisation of nickel by buta-1,3-diene at 698 K. The partial pressure of hydrogen/kPa: (1) 26.2; (2) 17.5; (3) 8.8; (4) 3.5; (5) 0.

p_{H_2} . If a hydrocarbon is diluted with hydrogen 300 times, the induction period will become so long that carbon will not be formed over 2 h.¹³⁸

An electron microscopy study showed¹²³ that carbon deposits formed upon dilution of a hydrocarbon with argon or hydrogen to $p_{H_2} = 17.5$ kPa, present mostly a film which screens the nickel surface. At a higher hydrogen pressure, carbon is deposited in the form of filaments which do not block the surface.

When carbonisation occurs in the medium of a pure or argon-diluted hydrocarbon, favourable conditions are provided for the appearance of the graphite nuclei, since in this case the carbon atoms do not have enough time to escape from the place of hydrocarbon decomposition. During subsequent growth of the nuclei, these atoms form a regular layer blocking the nickel surface.

Upon partial or complete replacement of an inert diluent by hydrogen, hydrogenation of an intermediate carbide-like compound begins to occur in addition to the hydrocarbon decomposition. At the same time, hydrogenation of carbon with atomic hydrogen formed as a result of the dissociation of H_2 molecules on the nickel surface becomes possible. As the partial pressure of hydrogen is increased, the hydrogenation rate increases. This decelerates the formation of the carbon phase nuclei on the surface accessible to hydrogen and leads to the appearance of an induction period. The activation energy of the graphite nuclei formation is 170 kJ mol^{-1} during the deposition of the first 1%–2% of carbon on nickel.

In a hydrocarbon–hydrogen medium, such nuclei are formed on the surface to which the access of reagents is hampered since hydrogen hydrogenates both the carbon atoms formed and the graphite nuclei. Owing to diffusion, a portion of carbon atoms is transferred to the interblock boundaries of nickel microcrystallites where new graphite nuclei are formed on defects.

Deposition of carbon on the interblock boundaries of nickel crystallites favours their dispersion and increases the number of metal particles which are actively involved in the interaction with the reaction medium. After the induction period and with the accumulation of graphite nuclei, the activation energy of carbon formation decreases and becomes constant (140 kJ mol^{-1}) after deposition of 10% of carbon. The transfer of carbon to the graphite phase nuclei (diffusion of carbon atoms in the metal bulk) becomes the limiting step of carbonisation. The value 140 kJ mol^{-1} is close to the reference value of the activation energy of the diffusion of carbon atoms in nickel.

Fragmentation of polycrystalline nickel into particles coated with carbon on the side inaccessible to the gas medium creates prerequisites for the formation of filamentous carbon. In this case, the carbon constituting the growing filament is not hydrogenated because hydrogen is virtually incapable of penetrating to the surface of contact of the metal particle with the carbon filament

phase (on the rear side), though a constant influx of carbon atoms takes place. The frontal (active) part of the metal particle, which catalyses the carbon filament growth, is not screened by carbon for the above-mentioned reasons.

Thus, the addition of hydrogen prevents the deposition of carbon in the form of a film and creates favourable conditions for the formation of carbon filaments.

Nolan *et al.*¹³⁹ gave an interesting explanation of the reasons for the formation of carbon deposits of different morphological types. They believe that carbon is accumulated as open forms, *e.g.*, carbon filaments, in the presence of hydrogen. The edge faces of graphite with unsaturated bonds come out, onto the external surface of the filaments, and hydrogen saturates these bonds. In the absence of hydrogen, carbon should be deposited predominantly in such forms as nanotubes or carbon films which do not have any unsaturated bonds on the edge faces. Thus the major products of decomposition of pure CO on highly dispersed nickel particles are carbon films and nanotubes, whereas the hydrogen-diluted CO forms carbon filaments with the coaxial-conical disposition of the graphite planes in the filament body. It is stated that the slope of the graphite cones depends on the hydrogen concentration in the reaction medium. However, in our opinion, Nolan *et al.*¹³⁹ give too much attention to the compensation of the energy of the free valences of the edge faces due to the formation of C–H bonds. It is unclear why CO₂ cannot react with carbon atoms and compensate thereby the energy of free valences. Furthermore, it is not taken into account that the neighbouring graphite layers coming onto the external surface of filaments can interact with each other thus closing the free valences.¹⁴⁰ Coming back to the role of hydrogen, let us note that it influences primarily the rate of the filamentous carbon growth, and this, as was shown above, changes the morphology of filaments.

10. The formation of carbon filaments at temperatures above 1273 K

The fibres used for the preparation of carbon composite materials are known to be obtained from viscose, polyacrylonitrile, as well as from petroleum or coal pitch. However, these materials have a substantial disadvantage — they are costly. Therefore, the prospect of their replacement by filaments prepared by catalytic methods seems rather attractive. A method for the preparation of carbon fibres from the gas phase [vapour-grown carbon fibres (VGCF)] is being actively developed in the USA, Japan and China.^{141–145} To this end, use is made of iron-containing catalysts deposited on ceramic supports or of injection of a benzene solution of ferrocene into a reactor. The sources of carbon are benzene or methane diluted with hydrogen as well as the gaseous waste from the production of coke or from the converter production of steel (CO–CO₂–H₂). A useful effect is given by the addition of small amounts of sulfur-containing gases (*e.g.*, H₂S) to the gas flow of reagents. The reaction is carried out at temperatures 1273–1423 K. The process starts with the catalytic growth of primary fibres, then they become thicker due to the deposition of pyrocarbon. The fibres prepared by the VGCF method have the following characteristics: length, a few millimetres; diameter, 2–3 µm; density, ~ 2 g cm⁻³.

Structural studies showed that the use of iron particles at temperatures above 1173 K can yield long filaments uniform in size, which consist of densely packed cylindrical basal graphite planes and always have a hollow core.

Baird *et al.*⁸¹ have proposed a scheme of the growth of a tubular filamentous carbon which presumes diffusion of small carbon clusters over the surface of a metal particle. This model was further developed in a study of Oberlin *et al.*,¹⁴⁶ which is one of the most detailed investigations of the structure of filamentous carbon formed from a benzene–hydrogen mixture at 1373 K. The reaction products were tubular filaments of cylindrical shape with a hollow channel inside them. The diameter of the channel ranged from 20 to 500 Å and was not always constant along the filament length. In their cross-sections, the filaments had a 'dendritic'

structure: apparently, the graphite layers formed concentric rings. In the core of the filament, the graphite structure was more ordered than in the outer layers. Based on the results obtained, the authors have postulated a two-step mechanism of the filamentous carbon formation. In the first step, the filament core is formed which consists of long parallel carbon layers twisted around the hollow central channel. In the second stage, the filamentous carbon becomes thicker owing to pyrolytic depositions. The ends of filaments contain the catalyst's particles. The interplanar distances measured by the method of electron microdiffraction make it possible to presume that the catalytic particles are either iron carbide (Fe₃C) or α-Fe. However, no final conclusions have been made.

Tibbetts¹⁴⁷ attempted to establish the reason for the tubular structure of carbon filaments. As the basal face possesses lower specific surface energy than the edge faces, the free energy of the growing filament should be a minimum when the filament consists of curved basal planes forming cylinders. However, as the diameters of cylinders decrease, the degree of curvature of the planes increases and, naturally, the energy required for such curving also increases. Thermodynamic considerations indicate that the formation of a hollow core is more advantageous energetically than the deposition of carbon in the form of strongly deformed cylindrical planes of small diameter. The model proposed made it possible to predict accurately the minimum inner diameter of a carbon filament and to substantiate theoretically the tubular structure of the filamentous carbon.

Deactivation of catalysts at high temperatures is associated with the blockage of the surface of catalytic particles; however, there are different suggestions about the mechanism of this phenomenon. Some investigators believe^{93, 147, 148} that deactivation is due to the adsorption, on the frontal side of the metal particle, of highly condensed pyrolysis products, which are formed in the gas phase and are precursors of soot particles. The equation obtained on the basis of this hypothesis provides a satisfactory description of the histogram of the distribution of filaments with respect to their length which are formed upon methane decomposition on γ-Fe at 1320 K. According to Gadelle,¹²⁸ the catalyst is active in the liquid state, and even small changes in the surface composition induce its transition to a less active non-melting form which is easily blocked by carbon.

11. Growth of carbon filaments under the action of catalytic particles present inside the filament

It was shown that disproportionation of CO on the Fe/Ni and Fe/Co alloys yields the so-called bifilaments.¹⁰⁰ It was established^{111, 112} that the growth of bifilaments is catalysed by biconical microcrystals. In their structures, each of the bicones is analogous to a 'simple cone' which initiates the growth of classical filaments. It was established that the directions [100] of the alloy crystal with the body-centred cubic lattice and [110] of the alloy with the face-centred cubic lattice are parallel to the filament axis. In the alloys with the face-centred cubic lattice, the twinning of biconical crystals was often observed. No simple mechanism has yet been proposed for the explanation of the growth of these unusual filaments.

12. Regularities and the mechanism of the growth of helical carbon forms

Helical filaments or bifilaments first described by Baker *et al.*³⁷ were formed on an Fe/Sn alloy from acetylene at temperatures above 1073 K. One catalytic particle of the alloy initiates simultaneous growth of two filaments in the opposite directions. The two corkscrew-like filaments grow with approximately the same velocities, and in the course of the process, identical fragments are reproduced symmetrically in either filament.

Unusual helical forms of filamentous carbon were also observed in the carbonisation of an Ni–Cu/MgO catalyst which was carried out in the medium of buta-1,3-diene diluted with argon and hydrogen in the molar ratio C₄H₆:Ar:H₂ = 2:40:75

Figure 13. A micrograph of the mirror-symmetrical carbon filaments growing from one particle of an Ni–Cu alloy. Due to the increase in the carbon content on the Ni–Cu/MgO catalyst, its mass increased 28-fold (the same refers to Figs 14, 15).

at 723 K.¹⁴⁹ According to the X-ray diffraction data, after the reduction with hydrogen, the Ni–Cu alloy of cubic structure is predominant in the catalyst and the MgO phase is also present.

An electron micrograph of the mirror-symmetrical carbon filaments (Fig. 13) shows that the filaments are twisted into helices and originate from one metal particle. The thickness of these filaments ranges from 300 to 1000 Å, while their lengths reach 1 μm. Obtained by the HREM method, micrographs of metal particles on which carbon grows indicate (Fig. 14) that they possess a nearly symmetrical oval shape with the symmetry planes in the middle part and represent multiple twins. On the frontal side of the surface, in the middle of the oval metal particle there is a

Figure 14. A micrograph obtained by the HREM method of an oval particle of an Ni–Cu alloy. The arrows indicate the positions of the twinning boundaries.

Figure 15. A micrograph obtained by the HREM method of the Ni–Cu/MgO catalyst.

microparticle 10–15 Å thick and 30–50 Å wide with the structure of the hexagonal nickel. It is on these microparticles that the ‘chemical’ step of the carbide cycle mechanism is realised.

In the crystalline particles of the Ni–Cu alloy, there is a series of twinning planes (111) which are parallel to the mirror symmetry plane. The twinning planes separate the blocks of twins with the face-centred cubic structure. The interplanar distances in each block of twins are: $d_{111} = 2.03$ Å and $d_{002} = 1.7$ Å. In a micrograph obtained by the HREM method, one can easily notice that the twinning planes are grouped under a microphase particle on the frontal side of the crystal (Fig. 15), while they are rarely found in other places. In the catalysts on which the deposition of carbon reaches 2000%–5000%, the widths of twin blocks in a metal usually exceed 20 Å.

At the beginning of the reaction the frequency of the appearance of twins in the metal is much higher than that at its end. In a micrograph of the Ni–Cu/MgO catalyst subjected to carbonisation for 10 min (Fig. 16), one can see the carbonisation boundaries with a period of ~4 Å. This distance is sufficient for the placement of only three densely packed layers of atoms of the face-centred cubic lattice of a metal with the interplanar distance $d_{111} = 2.03$ Å.

The hexagonal nickel carbide Ni_3C (see Ref. 150) and metallic nickel¹⁵¹ have virtually the same crystal lattices (hexagonal close packing). Carbon atoms in carbide occupy 1/3 of the octahedral cavities in the packing of metal atoms.

According to the mechanism of formation of symmetrical carbon filaments proposed by Zaikovskii *et al.*¹⁴⁹, in the induction

Figure 16. A micrograph of the Ni–Cu/MgO catalyst containing 75 mass. % of carbon. In the middle part of the Ni–Cu alloy particle one can see the boundaries of twinning after each 4 Å. The sequence of densely packed layers corresponds to the alternation of the hexagonal and cubic structures of the alloy.

period of the filamentous carbon growth, decomposition of buta-1,3-diene yields a particle of Ni_3C carbide microphase metastable at 723 K, while the Ni—Cu alloy itself is supersaturated with carbon. When critical supersaturation is attained and at some site of the alloy surface a crystalline graphite nucleus is formed, then a rapid ‘discharge’ of carbon atoms onto it occurs. The graphite phase nuclei are preferentially formed on the (111) face of the Ni—Cu alloy since the symmetry and interatomic distances in flat networks (002) of graphite and (111) of the alloy oriented towards the graphite filaments coincide.

Owing to a strong supersaturation of the frontal zone of the metal particle with carbon, an intense diffusion flux of carbon to the places of its crystallisation in the form of graphite phase arises. Rapid diffusion of carbon atoms leads to an enhanced generation of defects in the metal. The metal, while remaining solid, passes to the viscous-fluid state. As a result, the particle of the Ni—Cu alloy acquires spherical shape which is the most advantageous from the energetic viewpoint. However, the diffusive fluxes of carbon atoms also induce dislocation of metal atoms, and the spherical particle is somewhat stretched (Fig. 17). There arises a regime of self-organisation of the symmetrical form of metal particles. As a result, the metal particles acquire an oval form with the symmetry plane in their centre part. In this case, each of the symmetrical halves is oriented in such a manner that the [111] directions of the alloy coincide with the directions of the growth of carbon filaments.

Figure 17. The mechanism of the growth of a helical carbon filament obtained from buta-1,3-diene on the Ni—Cu crystals.

A particle of the hexagonal Ni_3C carbide microphase on the frontal side is a nucleus for the growth of a hexagonal structure piercing the catalytic particle of the Ni—Cu alloy. Under the reaction conditions, the catalytic particle consists of alternating layers of cubic and hexagonal Ni—Cu alloys. The passage of carbon atoms through the interlayer of the hexagonal metal may be represented as continuously alternating steps of formation and decomposition of the carbide. However, the saturation of hexagonal interlayers with carbon should decrease as they go farther and farther from the microphase of the hexagonal carbide. Consequently, in the course of reaction the layers of the hexagonal metal include most probably a non-stoichiometric carbide of variable composition.

During the reaction, the twinning planes are dislocated from the central zone of the Ni—Cu alloy to the crystal periphery. The driving forces of the dislocation of the interblock boundaries and, respectively, of restructuring is the diffusion of carbon atoms and the lesser stability of the alloy with the hexagonal structure than that of the alloy with the cubic structure.

Owing to an intense directed flux of carbon atoms from the central part of the crystal to its periphery (see Fig. 17), defects arise in the layers adjoining the twinning planes which induce restructuring of the layers. In other words, the plane of twinning begins to dislocate in the direction of the movement of carbon atoms to the site of carbon crystallisation into the graphite phase. Thus, the hexagonal planar inclusions representing a non-stoichiometric carbide of variable composition ‘disperse’ from the middle of the oval metal—carbon particles. The removal of these

interlayers from the central zone is probably compensated by their repeated regeneration by a microparticle on the surface of a large oval particle in such a way that the process is continuous.

Graphite filaments grow symmetrically and virtually over the entire surface of the Ni—Cu alloy particle. The route of the diffusion of carbon atoms from the place of their entry into the alloy particle through the nickel carbide microphase to different sites of the graphite phase growth is not the same (see Fig. 17). Because of this, the velocities of the graphite phase growth become also different and twisting of filaments occurs to the side opposite to the place where the carbide microparticle is situated.

IV. Conclusion

The above-discussed observations and conclusions are helpful in understanding the factors that influence the process of carbon filament formation and determine their properties. These properties include primarily the spatial order of the construction of the basal graphite planes in filaments, the diameters and lengths of filaments, the presence or absence of the inner hollow along the axis of filaments, their morphologies, the existence and degree of dispersion of other mineral components in the graphite structure of filaments, etc. Adsorption, catalytic, chemical, magnetic, mechanical and many other properties of filaments depend on these characteristics.

Note that the methods for controlling the synthesis of carbon materials are still in their infancy. For this reason, we will touch upon this issue only in brief and in most general terms.

The most substantial effect on the properties of filamentous carbon materials is the spatial distribution of the basal planes of graphite. The distribution of graphite layers in a filament determines such properties of the carbon material as its mechanical strength, adsorption capacity, chemisorption and catalytic characteristics, intercalation capacity and others.

As mentioned above, depending on the properties of the catalytic metal particle (head) and conditions of the implementation of the process, it is possible to synthesise graphite filaments of three major ‘basal’ structural types: with the coaxial-cylindrical, coaxial-conical and stack structures (see Fig. 2). The properties of metal particles which are of interest to us can be regulated by varying the method of their preparation and by adding other metals.

The diameter of a filament is determined by the size of the metal particle and differs little from it. The length of a filament depends on the time of its growth, which in turn is determined by the time during which the metal particle can efficiently play the role of the filament growth centre without undergoing deactivation or breaking into subcrystals.

The regime of the process has a substantial effect on properties of carbon materials not only directly, but also indirectly, through deactivation of metal catalyst particles. A decrease in the temperature of the process, dilution of a hydrocarbon with hydrogen, use of a less coke-producing hydrocarbon will make it possible to increase the yield of carbon formations per unit mass of a metal and to improve the graphite structure. However, in this case, naturally, the rate of carbon formation decreases.

This review was prepared with a financial support of the Russian Foundation for Basic Research (Projects Nos 99-03-32420, 00-03-32431) and the Grant for Leading Scientific Schools of Russian Federation (No. 00-15-97440).

Abstract. The published data on the synthesis, structure, properties and applications of dendrimers containing conjugated π -systems, transition metal complexes and organometallic compounds are surveyed and systematised. The bibliography includes 83 references.

I. Introduction

The chemistry of dendritic molecules, which is a fundamentally new branch of chemistry, began to develop explosively in the past few years. The beauty of these flower- or star-shaped structures is so amazing that it may spark the imagination of artists. However, apart from the great attractiveness of these experimental subjects the interest of investigators in this field of chemistry is mainly due to the potential applications of dendrimers, for example, in industry as novel catalysts and materials for molecular electronic devices and light energy conversion, in medicine and in other fields.

In contrast with polymers formed by spontaneous polymerisation, dendrimers, which are oligomeric compounds (in principle, they can be polymeric), are prepared by multistep synthesis. There are two different methodologies, *viz.*, the divergent and convergent approaches. In the divergent approach, dendrimers are constructed by the attachment of various fragments to a dendritic backbone (core). In this case, the molecule is built up layer-by-layer in the direction from the centre of the dendritic molecule to its periphery. The convergent methodology involves initial synthesis of dendrons, *i.e.*, the branches of a dendrimer, which are then coupled to the dendrimer core. This process resembles the assembly of individual sections on a common base.

More complex dendritic molecules built out of individual fragments are constructed using methods of organic, organometallic or coordination chemistry employed for the preparation of supramolecular structures.

Dendrimers have been described in numerous reviews;^{1–12} however, the number of new types of dendritic molecules continues to increase. In writing this review, we were guided by our own interests and thus confined ourselves to the consideration of those dendrimers which incorporate ethynyl and aromatic fragments synthesised in reactions catalysed by transition metal complexes and dendrimers containing transition metal complexes as their cores or at the periphery where the metal is linked to the ligand by a coordination bond or by a carbon–metal bond. In many cases, we followed the path of the authors of the original publications who have discussed zero-generation molecules as matrices for future dendritic systems of the first, second and higher generations. It should be noted that our subdivision into sections is arbitrary, since many dendrimers comprise both arylethynyl fragments (which is the object of our particular interest) and transition metal atoms, leaving silicon-containing and many other dendrimers beyond the scope of consideration. In our attempt at a maximally complete coverage of the available material, we kept on adding novel data, but soon realised that we had to stop, otherwise this review would have never been written, for the number of publications is increasing every day.

II. Hydrocarbon dendrimers containing conjugated π -systems

Cross-coupling reactions catalysed by palladium complexes are widely employed in the synthesis of dendrimers containing ethynyl or *p*-phenylene fragments. This type of dendrimer presents substantial practical interest because it ensures structural rigidity and conjugation between the fragments, which are essential for directed energy and electron transfer and for the preparation of photoreactive materials.^{13, 14} 1,3,5-Triethynylbenzene, which does not ensure conjugation between the substituents¹⁵ on the periphery, can nevertheless transfer photoexcitation energy^{13, 14} and represents a convenient core for the construction of such dendrimers. The photoreactive dendrimer **1**, the dendritic branches in which are linked together through ethynyl and *p*-phenylene bridges with a common focal point $\dagger$ of the dendrimer,¹⁶ *viz.*, the

$\dagger$ By the term ‘focal point’, the terminal point of the photoexcitation energy transfer in the molecule is understood in this case.

perylene fragment, may serve as an example. This dendrimer was synthesised by cross-coupling of a terminal acetylene with tribromobenzene according to the Sonogashira reaction.¹⁷ Studies of the photophysical properties of this dendrimer revealed that on irradiation with light with the wavelengths corresponding to the absorption maxima of peripheral triethynylbenzene groups, the radiation intensity of the perylene fragment in the dendrimer exceeds that of free ethynylperylene by more than two orders of magnitude under identical conditions. In this case, the efficiency

of the energy transfer from the periphery to the focal point of the dendrimer reaches 98%.¹⁶

Further investigations showed that the dendrimer of the next generation absorbs more light, but the efficiency of energy transfer to the focal point decreases.¹⁸

The dendrimers **2** containing 9-phenylcarbazole fragments linked through ethynyl bridges have been synthesised.¹⁹ Such dendrimers are designed for the preparation of organic photoconductors (*i.e.*, compounds with non-linear optical properties), photo- and electroluminescent materials.

A dendrimer containing 1,3,5-triethynylbenzene fragments was used as the monomer unit in the synthesis of a polyacetylenic polymer (Scheme 1).²⁰

A series of zero-generation dendrimers containing thiophene groups were prepared by trimerisation of acetylthiophene derivatives in the presence of SiCl_4 .²¹

These compounds can be used in the synthesis of dendrimers, organic polymers of higher generations, semiconductors and liquid-crystalline materials.

III. Conjugated dendrimers containing transition metal atoms

Conjugated systems, which contain several polydentate ligands coordinated to metal atoms within a single molecule, present substantial interest. Examples are provided by bi- (**3**, **4**) and trinuclear (**5**) complexes of ruthenium with a phenanthroline ligand synthesised by cross-coupling of a Ru–3-bromo-1,10-phenanthroline complex with 1,4-diethynylbenzene, 4,4'-diethynyl-1,1'-biphenyl and 1,3,5-triethynylbenzene, respectively.¹⁵

Measurements of the UV-spectra of the complexes thus prepared revealed that the main absorption bands of the bipyridine ligands do not change. Conjugation of the phenanthroline ligands in the binuclear complexes based on 1,4-diethynylbenzene (complex **3**) and 4,4'-diethynylbiphenyl (complex **4**) produced an additional low-energy absorption band. The absorption spectrum of the trinuclear complex **5** based on 1,3,5-triethynylbenzene more closely resembles that of the mononuclear complex, which points to the lack of conjugation between the substituents at positions 1, 3 and 5 of the central benzene ring.

Luminescence studies of the heteronuclear complexes **6–8** containing both Ru and Ni, Ru and Cu or Ru and Os cations, which have been prepared by cross-coupling of Ru–phenanthroline complexes and the bipyridine complexes of Ni, Cu and Os with 1,3,5-triethynylbenzene, established that such complexes can transfer photoexcitation energy.¹³

Thus the fragment **7** was used to build a more complex molecule **9**¹⁴ in which the Ni–bipyridine complex is the central part of the molecular architecture. It is of note that the syntheses of complex molecules on the basis of fragments **6–8** have been accomplished with 67% to 78% yields.

1,3,5-Triethynylbenzene was used as a basis for the synthesis of the tridentate phosphine ligand 1,3,5-($\text{Ph}_2\text{PC}\equiv\text{C}$) $_3\text{C}_6\text{H}_3$ (**10**). To this end, 1,3,5-triethynylbenzene was metallated with 3 equiv. of *n*-butyllithium and the lithium derivative formed was introduced into the reaction with chlorodiphenylphosphine.²² The

phosphine ligand **10** was first introduced into the reaction with the molybdenum or tungsten carbonyls $M(CO)_6$ ($M = Mo, W$) and

the complexes **11** formed were treated with cobalt carbonyl $Co_2(CO)_8$. These reactions afforded compound **12**.

The osmium complex **13** was obtained in a similar way. In the latter case, the phosphine ligand **10** was coordinated to three $Os_3(CO)_{11}$ clusters.

True organometallic compounds constitute an additional type of dendritic conjugated systems. The platinum complex **14** with triethynylmesitylene ligands prepared by cross-coupling of triiodomesitylene with trimethylsilylacetylene with subsequent desilylation is an example.²³

Triethynylmesitylene was introduced into the reaction with $Pt(Bu_3P)_2Cl_2$ in the presence of $CuCl$ and further converted into the complex **15** by a reaction with phenylacetylene. Substitution of

triethynylmesitylene for phenylacetylene yields first- and second-generation dendrimers.²³

The organoruthenium dendrimer **16** was synthesised following the convergent approach.²⁴ It was shown that the introduction of ruthenium atoms into a conjugated π -system significantly enhances both the non-linear optical properties of the original

compound and the two-photon absorption. These characteristics are also enhanced with the growth of the dendrimer.

IV. Dendrimers containing pincer-type ligands and their metal complexes

The presence of pincer-type ligands at the periphery of zero-generation dendrimers facilitates their metallation with the formation of metallacycles. Thus the complexes **17–19** containing pincer-type SCS ligands were used as building blocks in the synthesis of more complex dendrimers.^{25,26} For example, the pyridine group in compound **18** or the cyano group in compound

this case the pincer group is incorporated into the dendrimer structure as the connecting link.

19 is coordinated to palladium atoms to yield cationic complexes. The dendrimer **20** synthesised on the basis of the complexes **17** and **18** represents an organometallic compound the dendritic structure of which is formed by coordination bonds. It is noteworthy that in

The presence of SCS pincer-type ligands strongly restricts the application of non-palladium transition metal complexes, since only cyclopalladation is possible. Replacement of SCS by PCP

ligands made it possible to conduct cyclometallation with both Pd complexes and a variety of other transition metal compounds.

We made an attempt to synthesise zero-generation dendrimers on the basis of triethynylbenzene (**21**) and hexaethynylbenzene (**22**).^{27, 28}

Cyclopalladation of triethynylbenzene **21** was successful. The corresponding trinuclear palladium complex **23** was obtained in 90% yield. However, cyclopalladation of the ligand **22** designed for the synthesis of a hexanuclear complex failed, since this reaction gave a mixture of compounds. We attribute this failure to the high degree of conjugation within the molecule, which prevents the introduction of six electron-withdrawing substituents. Yet another trinuclear palladium complex **24** prepared by cyclopalladation of the ligand **21** is an efficient catalyst for the Heck reaction.²⁹

The applications of other transition metal complexes, *e.g.*, the Ni and Pt complexes **25** and **26** containing PCP pincer-type ligands, have been described.³⁰

M = Ni, Pt.

A method for the introduction of the pincer-type NCN and CN ligands, *e.g.*, 1-[3,5-(Me₂NCH₂)₂C₆H₃] and 1-(4-Me₂N-CH₂C₆H₄) units, at the periphery of organosilicon dendrimers of zero (G₀) and first (G₁) generations has been proposed.³¹ To this end, the corresponding bromo-substituted derivatives, *viz.*, 1-Br-3,5-(CH₂NMe₂)₂C₆H₃ or 1-Br-4-Me₂NCH₂C₆H₄, were lithiated and introduced into the reaction with an organosilicon dendrimer containing the chlorosilane groups Si(CH₂CH₂CH₂Cl)₃ at the periphery. This approach was used in the synthesis of the organosilicon dendrimers G₀-SiMe₂-C₆H₃(CH₂NMe₂)₂-1,3, G₀-SiMe₂-C₆H₄(CH₂NMe₂)₄, G₁-SiMe₂-C₆H₃(CH₂NMe₂)₂-1,3 and G₁-SiMe₂-C₆H₄(CH₂NMe₂)₄. The dendrimers synthesised and model compounds were metallated with Bu^tLi and further deuterated. Compound G₀-SiMe₂-C₆H₂(CH₂NMe₂)₂-1,3-Li-2 (**27**, X = Li) was converted into a platinum derivative under the action of 12 equiv. of PtCl₂(SEt)₂.

X = H, Li, D.

Catalytic activities of nickel complexes prepared on the basis of organosilicon dendrimers containing peripheral NCN pincer-type ligands were studied in the Kharasch-type addition of CCl₄ to alkenes.³² The kinetic data suggest that the catalytic activities of

zero- and first-generation dendrimers are lower than that of the monomeric catalyst (by 20% and 30%, respectively). However, complete separation of the catalyst from the reaction product by filtration through a membrane is an obvious advantage of dendrimers.³²

The dendrimer **28** containing cycloplatinated fragments with pincer groups was used as a sensor in the determination of SO₂.^{33,34} According to calculations, the molecule **28** is planar. In contrast with organosilicon dendrimers, this compound is poorly soluble in common organic solvents, which can be attributed to its structural peculiarities. Earlier studies have shown³³ that platinum and nickel complexes with NCN pincer ligands can reversibly bind SO₂; the resulting compound has the structure of a tetrahedral pyramid. The solubility of the complex formed is much higher than that of the starting compound. The dendrimer **28** (both in solution and in a solid state) reacts instantaneously with gaseous SO₂ to yield the corresponding addition products, which is accompanied by the appearance of an orange colour.

The formation of the adducts **29** was confirmed by ¹H NMR and UV spectroscopic data. The addition of SO₂ is reversible. The desorption of SO₂ occurs on heating of the adduct to 40 °C or *in vacuo*.

V. Dendrimers containing transition metal coordination complexes

1. Dendrimers containing coordination complexes with phosphine ligands

A search for novel catalytic systems stimulated the design of new ligands including those based on dendritic molecules with different electronic and spatial characteristics. It was anticipated that the use of dendritic ligands in combination with heterogenisation of a catalyst and biphasic systems would provide a clue to the problem of the catalyst's regeneration. Moreover, grafting of a catalyst on the surface of the dendrimer might enhance the regioselectivity by virtue of fixation of its conformation due to steric hindrances created by the dendrimer.³⁵ However, the experimental data available so far evidence that dendritic complexes manifest lower activities than their mononuclear analogues.³⁵ The reason for this may be related to steric hindrances and other problems due to larger sizes of dendrimers. Besides, the activity of a catalyst may be lost owing to the stabilisation of the complex by various functional groups present in the dendrimer.³⁵

Tertiary phosphines can form complexes with virtually all transition metals; many of those efficiently catalyse various reactions. It is not surprising therefore that the overwhelming majority of publications are devoted to the dendrimers containing phosphine complexes of transition metals. Thus the synthesis of ruthenium complexes with phosphine-containing dendritic ligands was described and their catalytic activity was investigated.³⁵ However, reactivities of these dendritic complexes appeared to be lower than that of the original mononuclear complexes RuH₂(PPh₃)₄. Unlike the latter, dendrimers did not react with chloroform and formed insoluble compounds with alkenes which could not be characterised; these compounds slowly reacted with CO to give the corresponding carbonyls. Preliminary studies showed that dendritic ruthenium complexes displayed high catalytic activities in the hydrogenation of ketones.³⁵

Synthesis of dendrimers containing bidentate phosphine ligands [–CH=NN(CH₂PPh₂)₂] at the periphery and the preparation of platinum, palladium and rhodium complexes based on them have been described.³⁶ Dendritic platinum and palladium complexes were methylated in the reaction with MeMgBr and carbonylated by treatment with CO.

Dendritic polyamines containing terminal diphenylalkylphosphine groups, which are ideal ligands for the complexation with transition metals in lower oxidation states, have been synthesised.^{37,38} The structure of one such compound (its right half is shown), *viz.*, a multinuclear gold(I) complex with a fourth-generation dendrimer containing 32 terminal diphenylphosphine groups (complex **30**), is given below.³⁷

X-Ray diffraction analysis of analogous gold(I) mono- and binuclear complexes revealed the presence of intermolecular NH...O hydrogen bonds in their crystal structures. It was suggested that similar intramolecular hydrogen bonds are also present in the Au complex with dendritic ligands. Such gold(I) multinuclear complexes represent a new class of metal-containing polymers with definite, probably spheric structures with dendritic molecules as the supporting matrices. These complexes can be used as catalysts and in medicine for biochemical diagnostics and as anti-inflammatory and anti-tumour drugs.³⁷

Dendritic molecules containing chiral ferrocenyl phosphine ligands present special interest. Zero- (compound **31**) and first-generation dendrimers containing up to eight chiral diphosphine ligands were synthesised on the basis of benzene-1,3,5-tricarbonyl chloride and adamantane-1,3,5,7-tetracarbonyl chloride³⁹ and a silylated ferrocenyldiphosphine derivative [C₅H₃(PPh₂)(CHMe.₂PCy₂)]Fe(C₅H₄SiMe₂CH₂CH₂CH₂Cl), where Cy is cyclohexyl.

Catalytic properties of rhodium complexes prepared by the reaction of $[\text{Rh}(\text{COD})_2]\text{BF}_4$ (COD is cycloocta-1,5-diene) with these dendritic ligands were studied in asymmetric hydrogenation of dimethyl itaconate. An enantiomer of dimethyl 2-methylbutane-1,4-diolate was obtained with *ee* 98%, which is only 1% lower than that achieved with a mononuclear complex.[‡] This

[‡] Mononuclear catalysts (ferrocene derivatives) are used in the commercial production of pesticides.⁴⁰

result is remarkable in that in this case the catalyst can be fully separated from the reaction products using membrane technology.

Dendrimers of the type **32** with peripheral diphenylphosphinomethyl ligands were synthesised from the organosilicon dendrimers $\text{G}_x-\text{CH}_2\text{CH}_2\text{SiMeCl}_2$ ($x = 0, 1$) by reacting them with $\text{Ph}_2\text{PCH}_2\text{Li} \cdot \text{TMEDA}$ (TMEDA is *N,N,N',N'*-tetramethylethylenediamine).⁴¹

The reaction of $[(\eta^3-\text{C}_3\text{H}_5)\text{PdCl}]_2$ with the dendrimer **32** afforded a palladium complex which was further used as a catalyst in the allylic alkylation of diethyl methylmalonate with sodium allyltrifluoroacetate in both a batch process and in continuous process using a membrane reactor. In the former case, the catalyst manifested an exceedingly high activity. The yield of the reaction product exceeded 80% after 30 min at a substrate : catalyst ratio of 2000 : 1 (see §). However, in a continuous membrane reactor at the same ratio of the reactants, the initially high catalytic activity was gradually almost extinguished following passage of 15 reactor volumes of the reaction mixture. The reaction mixture at the outlet from the reactor did not contain any catalyst. This loss of the catalytic activity was attributed to the decomposition of the palladium complex.

Synthesis of silica gel-grafted polyamidoamine dendrimers containing peripheral diphenylphosphinomethyl groups has been carried out.^{42,43} These dendrimers were used to prepare the corresponding rhodium complexes **33** which present interest as recyclisable catalysts in the reaction of alkene hydroformylation and can be used, in particular, in the production of drugs of the ibuprofen and naproxen type.⁴² Studies of the catalytic activities of such dendritic catalysts revealed that these activities increased with the increase in the length of the carbon chain between the amide and amine nitrogen atoms from two to six carbon atoms and did not change further. Such an increase in the catalytic activity seems to be due to the reduction of steric hindrances on the surface of the dendrimer.

Hydroformylation of styrene and vinyl acetate involving such catalysts occurred with virtually quantitative yields and high regioselectivity. The catalysts retained high catalytic activities over at least four cycles. However, slow wash-out[¶] of rhodium from the dendrimer immobilised on silica gel did occur.

§ With respect to 1 mol of the catalytically active groups.

¶ It is noteworthy that rhodium is not washed out from the catalyst with a pure solvent, but is washed out in the presence of CO or a $\text{CO}-\text{H}_2$ mixture, apparently, as a result of exchange of dendritic phosphine ligands in the rhodium complexes for CO.

2. Dendrimers based on metal complexes with polypyridine ligands

In the foregoing section we considered the methodology of synthesis of metal-containing dendrimers based on the formation of new carbon–carbon or carbon-heteroatom bonds. Coordination of polydentate organic ligands around metal atoms is an alternative route to the construction of metal-containing dendrimers.⁴⁴ This procedure was used, in particular, in the synthesis of the dendrimer **34** containing ruthenium cations coordinated by 2,3-bis(2-pyridyl)pyrazine.⁴⁴

In such dendrimers, transition metal coordination complexes function both as branching and linking blocks. These dendrimers are prepared using the ‘complex-as-a-metal–complex-as-a-ligand’ synthetic strategy in which a complex with free chelating groups (‘complex-as-a-ligand’) chelates a complex with labile ligands (‘complex-as-a-metal’). This approach allows stepwise monitoring over the dendrimer growth and involvement of building blocks containing various metals or ligands at each stage of the synthesis.

Dendrimers comprising complexes of different chemical nature can possess specific chemical properties, *e.g.*, provide gradients for electron transfer. Because of their remarkable photophysical and electrochemical properties, ruthenium(II) and osmium(II) complexes with polypyridine ligands represent ideal components for the synthesis of luminescent materials and other materials which can transform the light energy.⁴⁴

Numerous dendritic compounds were synthesised based on 2,3- and 2,5-bis(2-pyridyl)pyrazine (2,3- and 2,5-dpp) as the connecting ligands and 2,2'-bipyridine (bipy) as the terminal

ligand.⁴⁴ These complexes contain several chromophore groups and a large number of redox centres.

34

2,2':6',2''-Terpyridine (terpy) and its derivatives were used as ligands in the synthesis of metal-containing fragments of dendrimers. The synthesis of 1,3,5-tris(2,2':6',2''-terpyridin-4'-yl)benzene,

trinuclear⁴⁵ and hexanuclear (**35**)⁴⁶ ruthenium complexes prepared on its basis has been described.⁴⁵

The dendritic complex **36** containing 12 ruthenium atoms was obtained by a reaction of 12 equiv. of (terpy)RuCl₃ with a polyamide-based dendritic ligand.⁴⁷

The reaction of 1 equiv. of 1,3,5-tribromomethyl-2,4,6-trimethylbenzene with 3 equiv. of the ruthenium complex **37** was used to prepare the dendritic complex **38** containing six ruthenium atoms (Scheme 2).⁴⁸

A similar reaction of 1 equiv. of hexabromomethylbenzene with 6 equiv. of compound **39** gave the dendritic complex **40** containing 18 ruthenium atoms (Scheme 3).⁴⁹ Studies of electro-

chemical properties of compound **40** revealed that all ruthenium centres are independent and do not apparently interact with one another.

R = (CH₂)₃C[(CH₂)₃OBn].

Scheme 2

Scheme 3

The dendrimers **41** containing ruthenium atoms at the periphery and iron or cobalt atoms in the core were prepared on the basis of polypyridine ligands.⁵⁰

The central fragment of the dendrimer **41** was synthesised by complexation of a substituted bipyridine ligand to iron(II) or cobalt(II) ions.⁵⁰ The complex formed was introduced into reaction with a terpyridine ruthenium complex. Studies of electrochemical properties of the dendrimers revealed that a reversible redox process $\text{Ru(II)} \rightleftharpoons \text{Ru(III)}$ can occur at +0.81 V; however,

no apparent redox reaction involving iron or cobalt ions in the dendrimer core could be detected.⁵⁰

The incorporation of four bulky carborane groups at the periphery of the pentaerythritol-based ruthenium-containing dendrimer (complex **42**)⁵¹ resulted in restrictions of the conformational mobility, which was confirmed by magnetic non-equivalence of four methylene groups in the core and of two methyl groups at the periphery of the dendrimer. This had no effect on the electrochemical characteristics of the polypyridine ruthenium complexes of the type **42**.

The dendrimer **43** containing four ruthenium complexes with bipyridine ligands has been described.⁵² The NMR spectra of this dendrimer are extremely complex; therefore, its structure was established on the basis of UV spectroscopy, MALDI-TOF mass spectrometry and cyclic voltammetry.

Scheme 4

VI. Dendrimers containing complexes with metal – carbon σ -bonds

The convergent approach was used⁵³ in the synthesis of the dendrimers **44** with 3,5-dibenzoyloxybenzyl groups at the periphery (Scheme 4). 3,5-Dihydroxybenzyl alcohol (**45**) has been used as the monomer. It was noted⁵⁴ that the advantage of the convergent strategy is that it allows accurate monitoring of the number and localisation of functional groups in the final product. The intermediate products were isolated, purified and characterised after each step. Since all the intermediate and final products are easily soluble, the course of the reaction was monitored by NMR spectroscopy. Thus, any potential defects which might occur in the synthesis of dendrons could be detected prior to their attachment to the central fragment of the dendrimer.

The organoruthenium compounds of the type **46** were synthesised in a similar fashion.⁵⁴ The resulting metal-containing dendrimers were rather stable, which made it possible to synthesise larger dendritic structures containing Ru – C π - and σ -bonds.

This approach was used in the synthesis of third- and fourth-generation dendrimers containing up to 48 ruthenium atoms.⁵⁴ All the organoruthenium compounds thus prepared are readily soluble in common organic solvents.

A first-generation organosilicon dendrimer containing 12 peripheral organopalladium units was synthesised by oxidative coupling of the $[Pd_2(dba)_3 \cdot dba/TMEDA]$ complex (dba is dibenzylidenacetone) to a dendrimer containing iodoarene groups. Further reaction of the metal-containing dendrimer with MeLi and bipyridine⁵⁵ resulted in the dendrimer **47**.

The oxidative addition of benzyl bromide to the Pd-containing dendrimer **47** was studied. The stability of the newly formed

dendrimer containing organic derivatives of Pd(IV) and the main pathways of its decomposition were determined.

The synthesis of organoplatinum dendrimers of the type **48** has been described.⁵⁶ This involved the attachment of benzyl halides (RX) to $[PtMe_2(NN)]$ (where NN is the diimine ligand, *e.g.*, 2,2'-bipyridine). The reaction occurs with quantitative yields; however, the synthesis of larger dendrimers is complicated, since the solubility of the reaction products decreases as the size of the molecule increases. This reaction was followed by a colour change from orange-red (Pt^{II} complexes) to pale yellow (Pt^{IV} complexes). The increase in the chain length was repeated until NMR spectroscopy showed that the products contained structural defects. Larger organoplatinum dendrimers were obtained if the ligands were modified by introduction of *tert*-butyl groups, which increased the solubility of the dendrimers.⁵⁷ This synthesis employed a convergent strategy. The $[Pt^{IV}Me_4(\mu-SMe_2)_2]$ complex and 4,4'-bis(bromomethyl)-2,2'-bipyridine were used as the monomer units. The dendrimer **48** containing 14 platinum atoms was the last member of the series that has been synthesised. An attempt at preparing a dendrimer of the next generation containing 30 platinum atoms failed.

More recent studies⁵⁸ were aimed at investigating the possibility of synthesising multinuclear organopalladium compounds and bimetallic palladium–platinum dendrimers by the convergent approach. These studies showed that in this case the use of organopalladium compounds is limited because of the tendency of palladium(IV) complexes to undergo a reverse reaction, *viz.*, to the reductive elimination of alkyl halide.

VII. Dendrimers containing terminal ferrocenyl groups

The majority of iron-containing dendrimers reported so far contain iron in the form of ferrocenyl groups. This can be explained by the fact that the chemistry of ferrocenes is well-studied and its derivatives are rather stable compounds. The synthesis of such systems aimed at the construction of dendrimers which could undergo redox reactions involving electron interactions between the metal-containing fragments.⁵⁹ The electronic interaction between the transition metal atoms within one of such dendrimers (**49**) has been studied; its structure is shown below.

Polymers containing ferrocene derivatives are currently used for modification of electrodes and redox catalysts and biosensors.⁶⁰ The cation $[\text{FeCp}(\text{arene})]^+$ can be used as a starting material in the synthesis of dendrimers by the polyalkylation reaction. $[\text{FeCp}(\text{C}_6\text{Me}_6)]\text{PF}_6$ reacts with an excess of a base and ferrocenylalkyl halide $\text{I}(\text{CH}_2)_4\text{Fc}$ (Fc is $\text{C}_5\text{H}_5\text{FeC}_5\text{H}_4$) resulting in

selective hexasubstitution to give $\{\text{FeCp}[\text{C}_6(\text{CH}_2)_5\text{Fc}]_6\}\text{PF}_6$. According to cyclic voltammetry data, all the six ferrocenyl groups are electrochemically equivalent, being oxidised at the same potential. The positive charge in the central fragment of the molecule has no effect on the oxidation process.⁶⁰

The dendrimer containing peripheral ferrocenyl groups can form inclusion compounds with cyclodextrins (see, *e.g.*, compound **50**)⁶¹ localised at its periphery where they form a supramolecular structure of an even greater size.

The number of ferrocenyl groups incorporated into cyclodextrin molecules is limited by steric hindrances on the surface of the dendrimer. In the case of the dendrimer **50**, the reaction between the ferrocenyl groups and cyclodextrin is complete.

The synthesis of an unusual dendritic molecule **51**, which simultaneously incorporates Fe and Pt atoms (the platinum fragments in the centre and the ferrocenyl groups at the periphery), has been described.⁶²

In this case, the dendritic molecule was assembled from fragments containing one platinum atom and two ferrocenyl units, which were attached to the central fragment, *viz.*, hexakis(bromomethyl)benzene. This dendrimer was characterised by electrochemical and spectroscopic methods.

Dendrimers of the type **52** containing peripheral ferrocenyl groups linked to the central fragment through the amide groups have been used as sensors in the determination of inorganic anions (Cl^- , NO_3^- and HSO_4^- , see Ref. 63). Cyclic voltammograms of such dendrimers have the forms of simple reversible waves, which suggests that all of the ferrocenyl groups are equivalent in the oxidation process of Fe(II)/Fe(III) .⁶³ In this case, the 'sensitivity' of the dendrimers to the nature of the anion in the redox process increases on going from zero- (G_0) to the first-generation dendrimers (G_1), reaching a maximum for a second-generation dendrimer (G_2) preceding the third-generation dendrimer (G_3) where steric saturation of the surface with the ferrocenyl groups takes place. With an increase in the generation number, the ferrocenyl groups on the surface of the dendrimer become more closely spaced; this results in a decrease in the sizes of the cavities where the anions could penetrate.

An optimal dendrimer for smaller anions is that belonging to a generation in which the number of ferrocenyl groups precedes steric saturation of the surface, which ensures the most suitable bulk of the cavities.⁶³

VIII. Dendrimers containing transition metal π -complexes

One of the ways of modification of dendrimers containing arene groups at the periphery consists in the formation of π -arene complexes of transition metals. Thus, the synthesis of first- and second-generation organosilicon dendrimers (*e.g.*, the dendrimer **53**) containing aromatic rings with the Cr(CO)_3 groups linked has been described.⁶⁴

The starting organosilicon dendrimer was obtained by stepwise hydrosilylation and allylation. To this end, tetravinylsilane was introduced into the hydrosilylation reaction with methyl-dichlorosilane; the product formed was allylated with allylmagnesium bromide and repeatedly hydrosilylated with phenyldimethylsilane. The complexation involved only four out of eight benzene rings. The attempts to prepare a dendrimer with eight chromium atoms failed, since this required more drastic reaction conditions which resulted in the decomposition of the dendrimer.

Some first-generation organosilicon dendrimers containing peripheral alkyne groups further converted into the cluster π -complexes **54a** and **54b** by a reaction with $\text{Co}_2(\text{CO})_8$ have recently been synthesised.⁶⁵

The organometallic dendrimer **55** containing six peripheral rhenium atoms was synthesised from the 3,5-dihydroxybenzyl alcohol using the convergent approach.⁶⁶

However, an attempt at using this compound as a starting material for the synthesis of a dendritic oxo-rhenium complex by conversion of the carbonyl groups, which could be used as a catalyst in oxidation reactions, was unsuccessful.

IX. Dendrimers containing central metal-containing fragments

The syntheses of dendrimers containing chiral titanium complexes in the centre of the molecule have recently been reported.^{67,68} In these studies, (*R,R*)- $\alpha,\alpha',\alpha',\alpha'$ -tetraaryl-1,3-dioxolane-4,5-dimethanol (TADDOL) has been used as the core to which four dendrons prepared on the basis of 3,5-dihydroxybenzyl and/or octyl fragments were attached by the benzylation reaction.⁶⁷

The catalytic activity of titanium complexes of the type **56** was studied in addition of diethylzinc to benzaldehyde. A slight

decrease in the catalytic activity and stereoselectivity with the increase in the number of dendrimer generations from zero to third was observed. However, on going to the fourth-generation dendrimers the decrease in the catalytic activity was more pronounced, being nearly two-fold. These results leave hope that second- and third-generation dendrimers can have possible applications as catalysts in membrane reactors.

Analogously, dendrimers based on 1,3,5-triethynylbenzene with a central optically active 1,1'-bis(2-naphthol) fragment were prepared.⁶⁸

These dendrimers present special interest as chiral ligands and are used to recognise enantiomers. Catalytic activity of the titanium complex **57** was studied in the addition of diethylzinc to aldehydes, the enantiomeric excess attained being 89%–90%. Yet another possible application of these dendrimers is the construction of a fluorescent probe for optical determinations of enantiomeric compositions of chiral compounds.

A dendrimer containing phthalocyanine as the central fragment and its cobalt complex **58** have been described.⁶⁹ Studies of the electrochemical properties of the dendrimer **58** showed that the dendritic shell prevents intermolecular interactions of the phthalocyanine fragments and thus impedes the electron transfer to the centre of the molecule. In the oxidation of 2-mercaptoethanol with oxygen, the catalytic activity of the dendrimer was 20%

lower than that of the analogous non-dendritic phthalocyanine catalyst but its stability was higher in comparison with the latter.

A great number of papers are devoted to the synthesis of dendrimers containing metal-porphyrin complexes as the central fragments. Such compounds present interest as selective oxidation catalysts mimicking enzymes.⁷⁰ The dendritic shell enhances the regioselectivity of the catalyst thus increasing its similarity to enzymes. In addition, such compounds were used in model studies of electron transfer in biological objects⁷¹ and as fluorescent probes.⁷²

Yet another possible application of dendrimers is the use of their shells as protectors for the cores. The ruthenium(II) complex **59** coordinated to three dendritic bipyridyl ligands provides an example.⁷³ It was shown that the lifetime of this complex in the excited state exceeds that of its non-dendritic analogue, since the dendritic shell protects the central part of the dendritic molecule from contacts with a solvent and dissolved oxygen and thus prevents luminescence quenching.

The organoerbium dendrimers of the first (**60**) and second (**61**) generations⁷⁴ were synthesised in the reaction of $Er[N(SiMe_3)_2]_3$ with phenylethynyl dendrons.

The starting phenylethynyl dendrons of the first and second generations were synthesised by using the convergent approach developed earlier for phenylethynyl dendrons with peripheral 3,5-di-*tert*-butylphenyl groups.⁷⁵ According to the computer simulation data, phenylethynyl dendrons represent rigid planar molecules which apparently do not provide sufficient shielding of the central erbium atom despite their considerable sizes. For example, the dendrimers **60** and **61** synthesised are as sensitive to atmospheric oxygen and moisture as other compounds of the organo-lanthanide series.⁷⁴

Lanthanide derivatives are widely employed as lumino-phores.⁷⁶ However, the quantum yields of luminescence of lanthanide cations decrease as a result of cluster formation. In order to prevent luminescence quenching, lanthanide cations are encapsulated into a dendritic shell.^{76,77} To this end, lanthanide triace-

62

tates are introduced into a reaction with dendrons prepared on the basis of 3,5-dihydroxybenzyl fragments containing carboxy groups. The quantum yields of luminescence of the lanthanide complexes thus prepared (**62**) increased with the increase in the generation number for both solid samples and strongly diluted solutions of dendrimers in toluene. This effect can be attributed to the shielding of the lanthanide cations by dendritic ligands and the 'antenna effect', *i.e.*, the transfer of photoexcitation energy from the dendritic ligands to the lanthanide cations in the centre of the

dendrimers despite the fact that dendrons based on 3,5-dihydroxybenzyl halides are not conjugated molecules.

Synthesis of a series of dendrimers of the first, second and third generations the nuclei of which represent monovalent copper complexes with 1,4,7-triazacyclononane have been described.⁷⁸ The rate constants for the oxidation of the dendritic complexes **63** synthesised with gaseous oxygen at -78°C leading to the dendritic complexes **64** have been measured (Scheme 5). The oxidation rate constant for the second-generation dendrimer **63**

Scheme 5

($R = G_2$), $k_2 = 1.3 \times 10^{-2}$ litre mol $^{-1}$ s $^{-1}$, appeared to be two orders of magnitude lower than that of the first-generation dendrimer ($R = G_1$), $k_2 = 1.39$ litre mol $^{-1}$ s $^{-1}$. The third-generation dendrimer ($R = G_3$) was resistant to oxidation under identical conditions.

With an increase in temperature to -10 °C, the complexes **64** are decomposed as a result of intramolecular oxidation with the cleavage of the C–N bond. The half-life of the non-dendritic complex **64** ($R = G_0$) is 7 s, whereas those of the first- ($R = G_1$) and second-generation ($R = G_2$) dendrimers are 24 and 3075 s, respectively, which seems to be due to steric hindrances in the transition state of the decomposition reaction created by the dendritic substituents. This opens a way to the synthesis of thermally stable bimetallic complexes mimicking the effects of enzymes.

A method for encapsulation of noble metal microparticles in the core of polyamidoamine dendrimers (PAMAM) has been proposed.^{79–81} To obtain such materials, Pd(II) or Pt(II) cations were adsorbed by a polyamidoamine dendrimer containing hydroxy groups in the centre of the molecule with subsequent reduction with NaBH $_4$.⁷⁹ Such dendrimers contain microparticles of noble metals in their central fragment and are readily soluble in water, which makes it possible to conduct organic reactions (*e.g.*, hydrogenation of alkenes) involving these species in the aqueous phase.⁷⁹ The solubility of such catalysts in non-polar solvents can be increased through the use of surfactants, *e.g.*, fatty acids, which form salts with the surface amine groups of the dendrimer.⁸⁰ The use of perfluorinated carboxylic acids in biphasic systems containing perfluorinated solvents presents special interest, since this allows easy separation of the catalyst from the reaction product after the termination of the reaction.⁸¹

Metallodendrimers of the zero, first, second, third and fourth generations which contain Fe $_4$ S $_4$ (S $_4^{2-}$) as the dendrimer core and

can exist in two stable oxidation states, which can be used for storage of information, have been synthesised.⁸² The dendritic shell in compound **65** prevents possible electron transfer between closely arranged molecules, which would result in the loss of stored information.⁸² Voltammetric studies demonstrated that the electron transfer to the core of the molecule becomes more difficult with an increase in the number of the dendrimer generations.⁸²

The iridium complex with dendritic phosphine ligands **66** was used for reversible binding of fullerene C $_{60}$.⁸³ The complex **66** was

prepared by the reduction of Na_3IrCl_6 with carbon monoxide with subsequent attachment of dendritic phosphine ligands. On addition of fullerene to the bright yellow solution of the dendrimer **66**, the solution of the dendrimer–fullerene complex changes its colour to dark green.

III. P,N-Bidentate phosphorus-containing 4,5-dihydrooxazoles	665
IV. Other groups of chiral P,N-bidentate ligands	669
V. Conclusion	678

Abstract. Published data on the synthesis of rhodium and palladium complexes with optically active P,N-bidentate ligands and their applications in homogeneous asymmetric catalysis are summarised and discussed. The effect of the nature of the P,N-bidentate compounds on the structure of the metal complexes and on enantioselectivity in catalysis is examined. Allylic substitution, cross-coupling, hydroboration and hydrosilylation catalysed by Rh or Pd complexes with optically active P,N-bidentate ligands are considered. The prospects for the development of this field of chemistry are demonstrated. The bibliography includes 186 references.

I. Introduction

A fundamental problem studied at the border of chemical disciplines is the coordination behaviour of bi- and polyfunctional ligands. This problem includes competition of ligands for metal atoms, donor–acceptor interactions, isomerism of complexes, stereo- and regioselective synthesis of coordination compounds and specific complex formation in biologically important objects.¹ Of particular interest are phosphorus-containing compounds, which play an extremely important role in the development of views on coordination bonds, the geometry and the structure of complexes and on the mutual influence of inner-sphere ligands as well as in metal complex catalysis.^{2,3} Systems containing an electron-donating centre of a different nature, apart from the phosphorus centre, are being vigorously studied. P,N-Bidentate ligands are highly important. They simultaneously exhibit properties of both soft and hard bases and promote redistribution of functions in a catalytic cycle, formation of bimetallic structures and a specific arrangement of the metal coordination sphere. Thus P,N-bidentate ligands can provide *cis*- or *trans*-chelation, bridging binding in either the ‘head-to-tail’ or ‘head-to-head’ fashions (in particular, in structures with metal–metal bonds) and P-mono-dentate coordination. The particular type of coordination

depends, first of all, on the length of the bridge linking the donor atoms. Systems with two linking units are typical chelating agents; the bridging type of coordination is barely known for them, whereas three-unit species are capable of bridging coordination. Coordination of a P,N-system to a central atom gives rise to two moieties differing in kind, containing electron-donating centres with different steric and electronic characteristics. Being structurally asymmetric, P,N-bidentate ligands also possess clear-cut electronic asymmetry. In addition, both steric and electronic parameters of the electron-donating centres and the nature of the bridge linking them can be varied over wide limits. The features listed above are important in asymmetric catalysis in which very fine structural and electronic changes in the ligand nature can be significant. Therefore, it is quite natural that the greatest progress in the enantioselective catalysis of cross-coupling, allylation, hydroboration, hydrosilylation and other processes has been achieved by the use of metal complexes with P,N-bidentate chiral ligands.

Data on the role of optically active P,N-bidentate ligands in the coordination chemistry and catalysis are reported in several monographs and reviews.^{4–10} However, the information presented there concerns either a particular narrow group of compounds (for example, ferrocenyl systems⁸) or a particular catalytic reaction. The present review is the first attempt to summarise and describe systematically the role of chiral P,N-bidentate ligands in coordination chemistry and asymmetric catalysis. Attention is concentrated on the studies published over the last 15 years, most of all, in the 1990s, which were the years of vigorous development of the field of chemistry in question. This review deals only with P,N-bidentate systems with no additional electron-donating centres (*i.e.* devoid of O, S, Se and As or additional N or P atoms), only rhodium and palladium complexes being considered. Although examples of the use of W(0),¹¹ Au(I),^{12,13} Ir(I)¹⁴ and Pt(II)¹⁵ complexes in enantioselective catalysis do exist, the leading position of the two above-mentioned metals is beyond doubt.

We have classified the published data on the basis of the ligand structure. This approach appears expedient because it allows one to cover the achievements of both coordination chemistry and catalysis. Classification in terms of the types of organic reactions is more reasonable in considering the problems of enantioselective catalysis, whereas that accepted in coordination chemistry is based on the nature of the metal and the main initial metal complexes used. When these two aspects are discussed simultaneously, the nature of the P,N-bidentate ligand is a unifying point. Phosphorus-substituted ferrocenes and dihydrooxazoles are the subjects of separate Sections. This is due to the outstanding role of

these derivatives in asymmetric catalysis. Ligands of this type ensure high yields and high enantioselectivity of processes and provide the possibility of investigating some aspects of the catalysis mechanisms, for example, the role of the planar chirality of the ferrocenyl fragment. Phosphorus-substituted dihydrooxazoles represent a specific group of ligands developed for highly efficient allylation. The change in the steric and electronic parameters of the sp^2 -hybridised donor nitrogen atom incorporated in the five-membered ring influences the properties of the ligand and the catalytic activity of its metal complexes. The rather patchy group of other ligands is classified according to the nature of the electron-donating nitrogen centre; compounds with the phosphite donor centre are distinguished as a separate group. In addition, in arranging the information, we attempted, whenever possible, to group studies of the most productive scientific schools chronologically and to consider comprehensively the most important catalytic processes.

II. P,N-Bidentate phosphorus-substituted ferrocenes

1. Ligands with sp^3 -hybridised electron-donating nitrogen atoms. Aminoalkylferrocenylphosphines

In 1974, in the very beginning of the development of metal complex asymmetric catalysis, a publication appeared¹⁶ dealing with the synthesis of (S,R) -1-(1-dimethylaminoethyl)-2-diphenylphosphinoferrocene [(S,R)-**1**, (S,R)-PPFA][†] and (R,S) -1-(1-dimethylaminoethyl)-2-dimethylphosphinoferrocene [(R,S)-**2**, (R,S)-MPFA], which were the first representatives of chiral P,N-bidentate phosphorus-containing ligands.

The novel ligands were tested¹⁶ in enantioselective hydro-silylation of a series of prochiral ketones. The best result (yield 89%, *ee* 49%) was obtained in the reaction of acetophenone with diphenylsilane in the presence of $[\text{Rh}(\text{C}_6\text{H}_{10}\text{Cl})_2]_2 \cdot 4\text{L}$, where $\text{L} = (R,S)$ -MPFA [(R,S)-**2**].

Cat = $[\text{Rh}(\text{C}_6\text{H}_{10}\text{Cl})_2]_2 \cdot 4(R,S)\text{-MPFA}$.

The compound (R,S) -**2** was found to be markedly more efficient than the best mono- and bidentate phosphorus-containing ligands known at that time, namely, (R) - $\text{PhCH}_2(\text{Ph})(\text{Me})\text{P}^*$ and 2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane [($-$)-DIOP].¹⁶ It was also found that replacement of the dimethylamino group in the side chain of the ligand (R,S) -**2** by a hydrogen atom results in a sharp decrease in the stereoselectivity. These studies opened up a new line in the search for bidentate chiral ligands for metal complex catalysis. The researchers used simultaneously two fruitful concepts, namely, combination of two different electron-donating centres (phosphorus and nitrogen) and two types of chirality (central and planar) in the molecule of an optically active ligand. PPFA [(S,R)-**1**] has been modified, for example, by replacing the methyl substituents at the nitrogen atom by Et, Pr^i , Bu^i , etc.¹⁷ P,N-Bidentate ligands have been assayed in other asymmetric catalytic processes. Cross-coupling of (1-phenylethyl)magnesium chloride with vinyl bro-

mide catalysed by the complex $\text{PdCl}_2[(S,R)\text{-PPFA}]$ gave (S) -3-phenylbut-1-ene in 82% yield (*ee* 61%).^{17,18}

The enantiomer of the ligand (S,R) -**1**, namely, (R,S) -PPFA, also as a complex with PdCl_2 , ensures an even higher enantioselectivity in this type of reaction.¹⁹

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$ (*ee* 85%); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$ (*ee* 95%);

$\text{R}^1 = \text{R}^2 = \text{H}$ (*ee* 96%).

The bidentate ligand (S,R) -**1** is able to induce not only central but also planar chirality.²⁰

$\text{R} = \text{CH=CH}_2$, C(Me)=CH_2 , CH=CHBu ;

$\text{M} = \text{SnBu}_3$, MgCl , ZnCl , B(OH)_2 ; $\text{All} = \text{CH}_2=\text{CHCH}_2$.

For (S,R) -**1** and for its close analogue having two *tert*-butyl substituents at the phosphorus atom, a number of rhodium(I) cationic complexes, including $[(\text{NBD})\text{Rh}(\text{L})]^+\text{X}^-$ (NBD is norbornadiene, $\text{X}^- = \text{PF}_6^-$, ClO_4^-), $[(\text{COD})\text{Rh}(\text{L})]^+\text{Y}^-$ (COD is cyclooctadiene, $\text{Y}^- = \text{BF}_4^-$, BPh_4^-), have been prepared. The complexes have been thoroughly studied by ^1H NMR, ^{31}P NMR and IR spectroscopy and conductivity. The structure of the complex $\{(\text{NBD})\text{Rh}[(R,S)\text{-PPFA}]\}^+\text{PF}_6^-$ was established by X-ray diffraction analysis.²¹ The formation of a metal-containing chelate ring was demonstrated in all cases. The use of these complexes as catalysts of hydrogenation of *N*-acetyl- α -aminocinnamic acid ensures *ee* of up to 84%.^{21,22}

The further investigation into chiral phosphorus-containing ferrocenes has been mostly carried out by two research groups, namely, Weissensteiner's^{23–28} and Togni's^{29–39} groups. Thus Weissensteiner *et al.*^{23,24} synthesised epimeric ferrocenyl P,N-bidentate ligands, (R,R) -PTFA **3a** and (R,S) -PTFA **3b**.

In the model cross-coupling of (1-phenylethyl)magnesium chloride with vinyl bromide, the complex $\text{PdCl}_2[(R,R)\text{-PTFA}]$ provides an *ee* of 79% for a nearly quantitative chemical yield of 3-phenylbutene; in the presence of $\text{PdCl}_2[(R,S)\text{-PTFA}]$, the *ee* is only 4%. Thus, in this case, the process enantioselectivity is governed by the central chirality of the ligands **3a,b**. This outcome contrasts sharply with the results obtained in the catalysis by nickel complexes, which gave close values of the optical yield in the presence of (R,S) - and (R,R) -PPFA.¹⁷ The structure of the catalyst $\text{PdCl}_2[(R,R)\text{-PTFA}]$ was studied by ^1H , ^{13}C and ^{31}P NMR spectroscopy. According to X-ray diffraction data, the $\text{Pd}-\text{P}$ bond length [2.207(2) Å] is close to the average values observed in *cis*-palladium(II) dichloride complexes with aminophosphine ligands.²⁴ Subsequently, the palladium(II) complex $\{\text{Pd}(\eta^3\text{-C}_4\text{H}_7)[(R,R)\text{-PTFA}]\}^+\text{Tf}^-$ and the palladium(0) complex $\{\text{Pd}[(R,R)\text{-PTFA}]\}_2\text{L}$, where $\text{Tf} = \text{CF}_3\text{SO}_3$, L is maleic anhydride or dimethyl fumarate, have been studied in detail²⁵ using multi-nuclear NMR data (including the INDOR and EXSY techniques)

[†] Hereinafter, the first character denotes the configuration of the ferrocenyl core.

and X-ray diffraction analysis. It was concluded that PTFA, which is conformationally more rigid than PPFA, possesses also stronger chelating properties. An attempt²⁶ to use (*S,S*)-PTFA as a ligand in asymmetric hydroformylation of styrene proved unsuccessful: for rhodium(I)-based catalyst, *ee* was 0.5%, while in the case of platinum(II)-based catalyst, it is 7%–21%. This was explained²⁶ by the fact that the chelate angle formed by PTFA is rather small, especially in the case of complexation with platinum(II).

Enantiomeric ferrocenyl bidentate ligands **4a,b**, related in structure to PPFA and PTFA, have been prepared.^{27,28} Complexes of the ligand **4a** with PdCl₂ and the ligand **4b** with PdClMe, PdMe₂ and PdPh₂ were synthesised.

The structures of the ligands **4a,b** and complexes derived from them, which are promising in asymmetric catalysis, were studied by X-ray diffraction analysis and multinuclear NMR spectroscopy including low-temperature procedures. Broadening of the resonance signals of the diastereotopic methyl groups in the palladium complexes of **4a,b** suggests²⁸ that the energy barrier to the rupture of the Pd–N bond is low.

2. Ligands with *sp*²-hybridised electron-donating nitrogen atoms

a. Ferrocenylphosphinopyrazoles

Researches into ferrocene-based P,N-bidentate ligands have gained a new incentive due to the studies of Togni *et al.*^{29–39} Having started with minor structural changes, *i.e.* introduction of one or five methyl groups into the unsubstituted ring of (*S,R*)- or (*R,S*)-PPFA,²⁹ they used subsequently a fairly advantageous expedient, namely, they replaced the dimethylamino group by a pyrazole ring. This gave rise to a series of 1-diarylphosphino-2-[1-(pyrazol-1-yl)ethyl]ferrocenes **5a,b**²⁹ and **6a–g**.^{30–32}

The ligands **6a–t** were tested^{30,31} in the hydroboration–oxidation of styrene with catecholborane.

Cat = {[Rh(COD)₂]⁺BF₄[−]} (–**6a–t**).

In some cases, the reaction gives a substantial amount of an achiral primary alcohol but, in general, the enantioselectivity is high. The optical yield was found to be clearly dependent on the electronic properties of substituents at the donor centres — electron-withdrawing substituents in the pyrazole nucleus decrease the optical yield, whereas substituents in the phenyl groups at the phosphorus atom increase the optical yield [the *ee* values for the formation of (*R*)-1-phenylethanol in the presence of the ligands **6c, e, a, l, q** are 33%, 44%, 65%, 98% and 98.5%, respectively]. Rhodium(I) chloro carbonyl complexes **7a–t** were synthesised by reactions of **6a–t** with [Rh(CO)₂Cl]₂. They were characterised by the data of ¹H, ³¹P (¹J_{P–Rh} = 161–176 Hz) and ¹³C NMR and IR spectroscopy (*ν*_{CO} = 1980–2008 cm^{−1}) and mass spectrometry.³¹ X-ray diffraction analysis of the compounds **7n, o** was performed.³¹

An acceptable correlation has been found between the *ν*_{CO} and *ee* values for the complexes **7a–t**; the frequency of the carbonyl group vibrations is affected by changes in the σ-donor properties of the nitrogen centre and in the π-acceptor properties of the phosphorus centre. The cationic complexes [Rh(COD)(L)]⁺BF₄[−] have been prepared (L = **6b, c**) and also studied by multinuclear magnetic resonance and X-ray diffraction analysis. As in the complexes **7a–t**, in this case, too, a seven-membered chelate metallacycle is formed.

The ligands **6t–γ** have found application in a reaction significant from the synthetic standpoint, namely, allylic amination³² (the enantioselectivity reaches 99%).

The reaction mechanism, including allylic intermediates $[\text{Pd}(\eta^3\text{-PhC}_3\text{H}_3\text{Ph})(\text{L})]^+\text{PF}_6^-$, was studied in detail using X-ray diffraction analysis and 2D NMR. It was found that the attack of a nitrogen-containing nucleophile is directed at the carbon atom in the allylic ligand located in the *trans*-position relative to the phosphorus centre of the coordinated P,N-bidentate ligand. The activation barrier to the formation of the C–N bond in the *trans*-position relative to the phosphorus atom is 3 kcal mol⁻¹ lower than that for the *trans*-position to nitrogen.³² Calculation methods³³ and conformational analysis³⁴ [using ³¹P, ¹³C and ¹H (NOESY) data] of model allylic complexes have also been invoked to study the reaction mechanism and stereochemical features of the process.

The ligand **6u**, containing an adamantyl substituent in the pyrazole ring, proved to be the most efficient in allylic amination (*ee* 99%).^{32,35} By the addition of coordinating anions, F⁻, BH₄⁻ or OH⁻, in co-catalytic amounts, a virtually quantitative optical yield can be attained (>99.5%).³⁶

Similar derivatives of ruthenocene **8a,b**³⁷ and bimetallic systems **9a,b**, in which the pyrazole ring contains a second ferrocene fragment, have been synthesised.³⁸

The efficiencies of the ligands **6u** and **9a,b** in the catalysed allylic amination are comparable (*ee* >99.5%).³⁸ In catalytic hydroboration–oxidation, the ligand **8b** is somewhat inferior to the ferrocenyl analogue **5b** (the optical yields for 100% conversion of styrene are 87% and 94%, respectively).³⁷

Recently,³⁹ ligands **10a–d**, close analogues of the compounds **6a–γ**, have been proposed. In the presence of these ligands, asymmetric hydrosilylation–oxidation of norbornene has been carried out.

Compound 10	R ¹	R ²	Ar	Optical yield of hydroxy-norbornane (%)
a	Ph	Me	Ph	39
b	2,4,6-(MeO) ₃ C ₆ H ₂	H	Ph	82
c	2,4,6-Me ₃ C ₆ H ₂	H	Ph	91
d	2,4,6-Me ₃ C ₆ H ₂	H	3,5-(CF ₃) ₂ C ₆ H ₃	99

In the case of the ligands **10**, the optical yield increases on passing from **10a** to **10d**. It has been concluded³⁹ that optimisation of the ligand regarding steric factors should be done with allowance for its electronic asymmetry because the σ-basicity of the pyrazole fragment and the π-acidity of the phosphine fragment are important in hydroxylation–oxidation, as well as in hydroboration–oxidation.

b. Phosphinoferrocenyl-4,5-dihydrooxazoles

Phosphinodihydrooxazole ligands will be discussed in Section III. This Section is devoted to structures related to the ligands **6a–γ** but having a second chiral centre in the heterocyclic fragment. In particular, epimeric ligands of type **11a–c** have been synthesised.^{40–43} They are designated by the common abbreviation DPOF.

R = Prⁱ (a), Bu^t (b), Me (c).

The reaction of the compounds (S,S)- and (R,S)-**11b** with PdCl₂(MeCN)₂ gave complexes {PdCl₂[(S,S)-**11b**]} and {PdCl₂[(R,S)-**11b**]}; the latter was characterised by X-ray diffraction analysis.⁴⁰ These complexes were used as cross-coupling catalysts.

R = H, Ph; Cat = [Pd(All)Cl]₂L, L = (S,S)-**11a**, (S,S)-**11c**, (S,R)-**11a**.

The complex {PdCl₂[(S,S)-**11a**]} provides a higher enantioselectivity of this process than its epimer (*ee* 45% and 8%, respectively). The chemical yield is also substantially greater in the former case (74% and 23%, respectively). Thus, unlike the ligands (R,R)-PTFA **3a** or (R,S)-PTFA **3b**, in this case, the enantioselectivity is mainly due to planar chirality.

In the classical alkylation of malonates with allyl esters catalysed by [Pd(All)Cl]₂, the ligand (S,S)-**11b** ensures *ee* 90%; in the case of the ligand (S,S)-**11c**, the enantioselectivity is more than 99% (the chemical yield is nearly quantitative in both cases). In the presence of (R,S)-**11b**, *ee* is only 73%.^{42,43} In this reaction, the crucial role is also played by the stereochemistry of the ferrocenyl core of the ligand.

Cat = [Pd(All)Cl]₂L, L = (S,S)-**11b**, (S,S)-**11c**, (R,S)-**11b**.

The enantioselectivity of the reaction depends also on the steric requirements of the substrate. On passing from 1,3-diphenylprop-2-enyl acetate **12** to the methyl analogue **13**, the optical yield sharply drops (it is not more than 36%).

Cat = [Pd(All)Cl]₂L, L = (S,S)-**11b**.

Tetrasubstituted ferrocenyl ligands **14a,b**, constructed as combinations of two fragments of the ligands **11a** or **11b**, have also been synthesised.⁴⁴

The compound **14a** was converted into the palladium complex **15**; unfortunately, this complex was only scantily characterised by spectroscopic data (data on ¹H NMR and mass spectra were reported). Interestingly, the ligand prepared by replacement of the dihydrooxazole rings in the structure **14a** by the CH(Me)NMe₂ groups behaves as a P,P- rather than a P,N-bidentate ligand with respect to Pd(II) because the amino-group nitrogen atom is bound to palladium more weakly than the dihydrooxazole nitrogen.⁴⁴ In the Pd(II)-catalysed alkylation of the allyl acetate **12**, the ligands **14a,b** provide *ee* 96%–99%, the chemical yield being more than 90%; the epimer of compound **14a** with the opposite planar configuration displays the same enantioselectivity. Thus, in this case, unlike the ligands **11**, the planar chirality does not have a governing influence on the product configuration; this might be due to different reaction mechanisms.

Ligand (*S,S,S*)-DIPOF **16** has been studied^{14,45} in the asymmetric reduction of a series of prochiral aromatic and aliphatic ketones with diphenylsilane {with [Rh(COD)Cl]₂ as the pre-catalyst}.

The chemical yields in these reactions were 45%–100%, while the optical yields were 57%–91%. The best results were attained in the reduction of acetophenone to (*R*)-1-phenylethanol. In the presence of (*R,R,R*)-DIPOF, the reaction affords (*S*)-1-phenylethanol with *ee* 91%. The use of [Ir(COD)Cl]₂ as the pre-catalyst increases the optical yield to 96%.

In the hydrosilylation of acetophenone with diphenylsilane, the use of related dihydrooxazole systems, namely, arylideneaminoalkylferrocenylphosphines **17a–d** leads to commensurable results (*ee* 87%–90% for chemical yields of 86%–94%)⁴⁶ {with [Rh(NBD)Cl]₂ as the pre-catalyst}.

Ar = Ph (**a**), 3-CF₃C₆H₄ (**b**),
4-CF₃C₆H₄ (**c**), C₆F₅ (**d**)

The presence of the imino group in the ligand structure is of prime importance. Indeed, in the presence of the amine (*S,R*)-**18**, *ee* is 39%, while in the presence of (*S,R*)-PPFA [(*S,R*)-**1**], it is only 16%. However, the nature of the arylidene group barely influences the optical yield.

In conclusion, we would like to mention several other P,N-bidentate phosphorus-substituted ferrocenes which hold prospects as asymmetric catalysts. The first one is ligand **19**, for which cationic complex **20** has been obtained.⁴⁷ The P,N-bidentate manner of binding to palladium(II) in the complex **20** was established by ¹H, ³¹P and ¹³C NMR spectroscopy and X-ray diffraction analysis.

Phosphaferrocenes **21a–c**, representing a new class of ligands with planar chirality,⁴⁸ and analogous compounds **22**,⁴⁹ containing peripheral aza heterocycles have been synthesised.

A recent publication⁵⁰ describes the synthesis and resolution of diastereomers (*S,S*)-**23** and (*S,R*)-**23** with a chiral centre on the phosphorus atom.

A complex of the compound (*S,R*)-**23** with PdI₂ — [(1-MePhP-2-Me₂HN⁺CH₂C₅H₃)FeC₅H₅][PdI₃[−]] — has been prepared.⁵⁰ X-Ray diffraction analysis showed a P-monodentate binding to palladium of the ligand protonated at the nitrogen atom. The researchers suggested that the complex was formed upon opening of the chelate ring on treatment with the hydrogen iodide, resulting from decomposition of PdI₂, followed by the reaction of I₂ with traces of water. Hence, it was concluded that the six-membered metallacycle involving the ligand (*S,R*)-**23** is relatively unstable. However, this statement seems arguable because lots of metal complexes formed by related systems, for example, PPFA **1**, PTFA **3** or the ligands **4a,b** are known. The wrong choice of the initial palladium(II) compound appears to be a more probable reason.

Thus, the use of nitrogen-and-phosphorus-containing ferrocenes in asymmetric metal complex catalysis makes it possible to attain more than 90% optical yields in some important reactions such as cross-coupling, hydroboration–oxidation and hydrosilylation–oxidation of alkenes, hydrosilylation of ketones, and allylic substitution.

III. P,N-Bidentate phosphorus-containing 4,5-dihydrooxazoles

This group of ligands includes compounds containing an *sp*²-hybridised donor nitrogen atom.

In 1993, three research groups working independently, namely, Helmchen's group⁵¹ from the Institute of Organic Chemistry of Heidelberg University, Williams' group⁵² from the Technological University (Lawboro), and Pfaltz's⁵³ group from the Institute of Organic Chemistry of Basel University, reported almost simultaneously the synthesis and the use in enantiomeric catalysis of the first representatives of a new class of P,N-bidentate

ligands — phosphorus-containing 4,5-dihydrooxazoles. There is an opinion,⁵⁴ however, that Williams *et al.*⁵⁵ came out with the main concepts a year earlier. Subsequently, the effort of the three groups mentioned above resulted in the synthesis of a large series of phosphorus-substituted dihydrooxazoles such as **24**, **25** and **26a–t**.^{56–76}

When ligands of the type **26** are employed in the model alkylation of dimethyl malonate with the allyl acetate **12** [with [Pd(All)Cl]₂ as the pre-catalyst],^{51–53,56} optical and chemical yields reach 99%. The highest enantioselectivity is exhibited by the chiral substituted dihydrooxazoles **26b, c, e**. Other nucleophilic substitution reactions at the allylic carbon atom in the allyl acetates **27** were also performed with high enantioselectivity in the presence of these compounds. The results are summarised in Table 1.

It should be noted that, in the presence of the epimeric compounds **26m, n**, the corresponding derivatives are formed in the same optical yield (77%) and with the same (*S*) absolute configuration, *i.e.* the asymmetric induction is accomplished by the dihydrooxazole fragment.⁵⁶ The distance between the electron-donating centres is also significant — the ligand **24**, which forms a five-membered metal-containing chelate ring, provides a moderate selectivity (*ee* 73%).⁵¹

Several palladium-catalysed intramolecular alkylation reactions have also been successfully performed;⁶⁷ the best result was attained with the ligand **26e** (*ee* 80%–87%). Enantioselective allylic substitution is utilised to prepare natural products including optically active starting compounds for the synthesis of α - and

β -amino acids and their derivatives.^{58,66} A palladium(II) cationic complex was prepared from the compound **26b** and characterised by ¹H NMR spectroscopy (NOESY, ROESY) and X-ray diffraction analysis.

Resorting to low-temperature 2D NMR spectroscopy made it possible to propose a catalytic cycle for the alkylation of dimethyl malonate with the acetate **12** in the presence of the ligand **26b**.⁶⁸

Nu = CH(CO₂Me)₂.

The predominant (*S*)-enantiomer of the reaction product is formed *via* an attack by the nucleophile on the C(3) atom of the allylic fragment, located in the *trans*-position relative to the phosphorus centre, in the *exo*-**28**.

Detailed investigation of the reaction mechanism using model reactions permitted ligands of the type **26** to be employed in other asymmetric allylic substitution processes. Thus *ee* values of more than 99.9% are attained in some cases in the alkylation of nitromethane with the allyl carbonates RCH=CHCH(R)O.CO₂Me (R = Me, Et, Ph).⁶⁹ Among the ligands **26b, c, e, i, m, n, o** tested [with [Pd₂(dba)₃]·CHCl₃ as the pre-catalyst], the best results were obtained for **26b, c, i**.

In the case of cyclic substrates **29**, the best results were obtained for the ligands **26p, q**.⁷⁰ The epimeric compounds **26m, n** provide close enantioselectivities.

$n = 1$ (**a**), 2 (**b**), 3 (**c**), 4 (**d**); X = OAc, OCO₂Me, Br; R = Me, Et;
 $m = 1.5–3$; L = **26b, m, n, p, q**.

Phosphorus-containing cymantrenyldihydrooxazoles **30a–i** and **31a, b**⁷¹ ensure better asymmetric induction in some cases [with [Pd(All)Cl]₂ as the pre-catalysts].

In the reaction of the cyclic allyl acetates **29a, b, c** (X = OAc) with the anion derived from dimethyl malonate in the presence of the ligand **30d**, the optical yields are 96%, 93% and >99%, respectively. The configuration of the phosphorus centre is of fundamental importance in this case: in the presence of the epimeric ligand **30c**, the reaction with the compound **29b** results in *ee* of only 31%. Compounds achiral at phosphorus (including

Table 1. Enantioselectivity in allylic substitution in the compounds **27** in the presence of the ligands **26b,c,e**.

R = Prⁱ (**a**), Bu^t (**b**)

The ligand **30d** was also found to be highly effective in related reactions. Thus, when 3-chlorocyclopentene reacts with the sodium salt **32**, the reaction product **33** is formed in >94% yield and *ee* >98.5%.⁷²

R = Me (**a**), Et (**b**); L = **30d**.

A similar reaction with the *N*-substituted tetrahydropyridine acetate **34** results in a product yield of 84% and *ee* 98%.⁷³

L = **30d**.

Compound **35** is a valuable optically active initial compound for the preparation of aza sugars and (*R*)-nicotinic acid.

The use of phosphorus-containing dihydrooxazoles in the formation of the C–C bond according to the Heck reaction is equally effective. Thus the ligand **26c** ensures a fairly good enantioselectivity in the reactions with triflates.^{58, 74, 75}

Cat = [Pd(dba)₂] · 2L, L = **26c**.

In this reaction, phosphorus-substituted dihydrooxazoles are preferred over diphosphines including the known BINAP ligand [2,2'-bis(diphenylphosphino)-1,1'-dinaphthalene] because they do not induce undesirable side processes of double bond migration.⁷⁵

Complexes **37a–d**, prepared from the corresponding ligands and $\text{PdCl}_2(\text{MeCN})_2$ [followed by treatment with $\text{Ag}(\text{OTf})$ and water], have been employed for copolymerisation of styrene with CO.⁷⁶ This yielded poly(1-oxo-2-phenylpropane-1,3-diyl) with a molecular mass of $\sim 20\,000$.

In the presence of the achiral complex **37a**, an atactic polymer is formed, whereas catalysis by the optically active complexes **37b–d** results in a stereoregular isotactic polymer.

R = H (**a**), Bu^i (**b**), Ph (**c**), Bn (**d**).

Ligand **38** has been employed for copolymerisation of styrene and ethylene with CO in the presence of the complex $[\text{Pd}(\text{OAc})\text{LS}]^+ \text{TfO}^-$, where L = **38** and S is a solvent.⁷⁷

Other researchers working independently of the three leading groups mentioned above used successfully the ligands **26b,e** in allylic sulfonation,⁷⁸ while the ligand **26c** was used in the intramolecular Heck reaction.⁷⁹ The allylation mechanism was analysed theoretically by the extended Hückel method.⁸⁰

New phosphorus-containing oxazolines **39** and **40** have been synthesised. The ligand **39**⁸¹ ensures *ee* of 95%–99% in the allylic amination of the acetates **27d,h,i** with benzylamine or phthalimide.

R = Ph (**d**, 43%, *ee* 99%), 4- ClC_6H_4 (**h**), 4- BrC_6H_4 (**i**); L = **39**;

(a) BnNH_2 ; (b) HX, X =

The compound **40**, containing a carbohydrate fragment fused with a dihydrooxazole fragment, has been used as a ligand in the alkylation of dimethyl malonate with the allyl acetates **12** (*ee* 98%) and **13** (*ee* 69%) in the presence of $[\text{Pd}(\text{All})\text{Cl}]_2$.⁸² This resulted in the synthesis of phosphorus-containing dihydro-1,3-oxazine iso-

mers **41**. In the reaction with the allyl acetate **12** $\{[\text{Pd}(\text{All})\text{Cl}]_2$ as the pre-catalyst $\}$, *ee* depends on the ligand: it is 95% in the presence of *cis*-**41** and only 64% in the presence of *trans*-**41**.⁸³

On the basis of the compound **42**, neutral and cationic palladium(II) complexes have been prepared.⁸⁴ To the best of our knowledge, **42** is the only P,N-bidentate ligand of the dihydrooxazole type containing a phosphinite group. It would be of interest to study this compound in the asymmetric catalysis and to compare it with analogous phosphine systems.

Recently, a series of phosphorus-containing dihydrooxazoles **43a–n** have been synthesised. Unlike the ligands **26–42**, in this case, the diphenylphosphine fragment is not attached to the aromatic nucleus.^{85,86}

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Me}$ (**a**), Bn (**b**), Pr^i (**c**), Ph (**d**); $\text{R}^1 = (S)\text{-Me}$, $\text{R}^2 = \text{Pr}^i$ (**e**); $\text{R}^1 = (R)\text{-Me}$, $\text{R}^2 = \text{Pr}^i$ (**f**); $\text{R}^1 = (S)\text{-Ph}$; $\text{R}^2 = \text{Bn}$ (**g**), Pr^i (**h**), Ph (**i**), Bu^i (**j**); $\text{R}^1 = (R)\text{-Ph}$; $\text{R}^2 = \text{Bn}$ (**k**), Pr^i (**l**), Ph (**m**), Bu^i (**n**).

The alkylation with the allyl acetate **12** $\{[\text{Pd}(\text{All})\text{Cl}]_2$ as the pre-catalyst $\}$ in the presence of the ligands **43a–d** provides *ee* of 11%–90%, while this reaction in the presence of **43e–n** results in *ee* of 22%–98%. The best results were attained in the presence of the ligands **43c** and **43n**. The optical yield depends on the solvent; for example, with the ligand **43c** in CH_2Cl_2 , the *ee* is 90%, whereas that in MeCN is only 11%. Acetonitrile is the optimal solvent for ligands with two chiral centres such as **43e–n**. The researchers^{85,86} did not explain this fact. Apparently, the chiral centre of the dihydrooxazole ring in the compounds **43e–n** is responsible for the asymmetric induction because the diastereomers **43h** and **43l** provide *ee* of 90% and 93%, respectively, all other factors being the same.

A number of phosphorus-substituted dihydrooxazoles **44a–m**, differing in the nature of the substituent R in the 2-position, have been synthesised.⁸⁷

R = Me (**a**), Bu^i (**b**), CHPh_2 (**c**), CPh_3 (**d**), 1-adamantyl (**e**), 3,5- $\text{Bu}_2\text{C}_6\text{H}_3$ (**f**), ferrocenyl (**g**), CF_3 (**h**), Ph (**i**), 4- MeOC_6H_4 (**j**), 4- MeC_6H_4 (**k**), 4- $\text{NO}_2\text{C}_6\text{H}_4$ (**l**), C_6F_5 (**m**).

These ligands ensure *ee* of up to 94% in the alkylation of dimethyl malonate with the allyl acetate **12** in the presence of $[\text{Pd}(\text{All})\text{Cl}]_2$, the compound **44e** being the most effective. Electron-donating substituents in the dihydrooxazole ring were found to increase the optical yield. In general, the enantioselectivity attained with the ligands **44a–m** is somewhat lower than that observed with the ligands **26a–t**. This was attributed⁸⁷ to the fact that the relative strain and the tendency for opening of the five-membered chelate metallacycles formed by the ligands **44** are

greater than those in the case of **26**. Indeed, according to ^{31}P NMR spectroscopy, the reaction of $[\text{Pd}(\text{All})\text{Cl}]_2$ with the compound **44k** taken in a twofold excess relative to the palladium complex results in a complex containing two organophosphorus ligands in the palladium coordination sphere, while the reaction of the compound **26e** with the same Pd complex yields a metallacycle with only one phosphorus-containing ligand. In view of these data together with the results obtained using the ligand **24**, one can formulate a general rule: the phosphorus-substituted dihydrooxazoles forming five-membered chelate metallacycles are less effective than those forming six-membered rings. In this connection, compounds **45a–f** synthesised recently⁸⁸ are worthy of note.

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Pr}^i$ (**a**), Ph (**b**), Bu^t (**c**); $\text{R}^1 = \text{Pr}^i$; $\text{R}^2 = \text{H}$ (**d**);

$\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$ (**e**); $\text{R}^1 = \text{R}^2 = \text{Me}$ (**f**).

For example, in the alkylation of dimethyl malonate with cyclopent-2-enyl acetate (**46**), *ee* reaches 96%, the yield of the final product being 79%–99%.

$\text{L} = \text{45a–f}$.

The optical yield and the absolute configuration of the reaction product are controlled by the pyrrolidine fragment because in the presence of the ligand **45f**, *ee* is only 80%. The ligands **45a–f** should form complexes containing seven-membered metallacycles, which are moreover rather strained; nevertheless, they ensure a high level of asymmetric induction. Thus, the enantioselectivity in this reaction does not depend on the size of the metal ring.

In addition to the two, to some extent, related processes, *i.e.*, allylic substitution and Heck reaction, phosphorus-containing dihydrooxazole P,N-bidentate ligands have found application in the asymmetric version of catalytic hydrosilylation. Thus the ligands **26a–c,f,i,k,o,r–t** have been studied in the reduction of a series of prochiral aromatic and aliphatic ketones with diphenylsilane {with $[\text{Rh}(\text{COD})\text{Cl}]_2$ as the pre-catalyst}.^{89,90} In the hydrosilylation of acetophenone, the degree of conversion is 80%–99% and the optical yield is up to 86%. The highest enantioselectivity was found for the ligands **26b** (*ee* 82%) and **26r** (*ee* 86%); the latter ligand, which contains electron-withdrawing substituents at the phosphorus centre ensures also the highest catalytic activity.⁹⁰ It should be noted that in the presence of the ligand **26c**, which displayed very good properties in allylic alkylation, *ee* is only 40%. Too bulky substituents at the phosphorus centre do not enhance the enantioselectivity. Indeed, with the ligand **26o**, *ee* is only 17%. It is noteworthy that the replacement of the PAr^1Ar^2 fragment in the compounds **26** by SPh or SePh almost eliminates the asymmetric induction.

The use of the ligand **39** for the reduction of acetophenone with diphenylsilane {the catalytic system $[\text{Rh}(\text{COD})\text{Cl}]_2 \cdot 4\text{L}$ }⁹¹ proved especially successful (*ee* 94%). In the general case, the selectivity is inversely proportional to the size of the substituent at the 4-position of the dihydrooxazole fragment of the ligand. However, the asymmetric induction provided by the ligand **39** was found to be abnormally high, despite the fact that the two methyl substituents in the compound **39** create greater steric hindrance than one *tert*-butyl substituent in the compound **26c**. In the opinion of the investigators cited,⁹¹ interpretation of these effects requires further research into the mechanism of the rhodium-catalysed hydrosilylation and the structure of intermediates.

IV. Other groups of chiral P,N-bidentate ligands

The two classes of optically active P,N-bidentate ligands considered above mainly include particular series of compounds prepared specially to be investigated in catalytic reactions. The other compounds used as P,N-bidentate ligands are difficult to classify because they belong to different classes and types. We classified these compounds in terms of the structures of the nitrogen and phosphorus electron-donating centres; three groups of ligands were thus distinguished. Within each group, the data are mainly arranged according to the type of the catalytic reaction.

1. Ligands with sp^3 -hybridised electron-donating nitrogen atoms

Chiral P,N-bidentate ligands with sp^3 hybridised electron-donating nitrogen atoms became known earlier than other compounds (except for aminoalkylferrocenylphosphines). Back in 1977, syntheses of compound **47a** with two asymmetric centres, carbon and phosphorus, and the complex of the phosphine **47a** with PdCl_2 were reported.⁹² The formation of the metal chelate ring and the absolute configuration of the chiral centres in the complex were proved by X-ray diffraction analysis. Subsequently,⁹³ several more aminophosphines with benzene or naphthalene nuclei have been reported, for example, (*S*)-AMPHOS **48**, 1,2-DPNEA **49**, 1,8-DPNEA **50**, 2,1-DPNEA **51** and 2,3-DPNEA **52**.

Neutral or cationic Rh(I) complexes with ligands of the type **47b** and **48–51** were used as catalysts of hydrogenation of prochiral unsaturated acids. Thus hydrogenation of itaconic acid in the presence of 1,2-DPNEA **49** proceeds with an optical yield of up to 43%.⁹³

Other ligands, for example, the phosphorus-containing ephedrine derivative **53**, have also found application in the hydrogenation of prochiral unsaturated acids. The reduction of *N*-acetyl- α -aminocinnamic acid in the presence of $[\text{Rh}(\text{C}_8\text{H}_{14})\text{Cl}]_2$ and the ligand **53** gives the product in an optical yield reaching 77%.⁹⁴

Ligands **54**, **55a,b**, **56**, **57a,b**, **58** and **59a,b**^{95,96} have been used in the hydrogenation of *N*-acetyl- α -aminocinnamic and *N*-benzoyl- α -aminocinnamic acids in the presence of $[\text{Rh}(\text{C}_6\text{H}_8)\text{Cl}]_2$. The maximum optical yield (68%) was attained in the case of (*S*)-1-[2-(methyl-*tert*-butylphosphino)phenyl]ethylamine (**58**).⁹⁶

The cationic rhodium(I) complexes **60a,b** have been synthesised and characterised in detail by ¹H, ³¹P and ¹³C NMR and IR spectroscopy and conductometry.⁹⁷ The ligands present in these complexes contain rarely encountered carbamide donor centres. However, the reduction of Z-(α)-ethylacetaminocinnamic acid in the presence of the complex **60b** resulted in only a moderate enantioselectivity (*ee* 34%).

R = Bu^t (**a**), (CH₂)₃Si(OEt)₃ (**b**).

Yet another traditional field of application of chiral amino-phosphines with an *sp*³-hybridised nitrogen atom is cross-coupling. Both acyclic (**61a–g**, **62**) and heterocyclic (**63**, **64**) aminophosphines have been employed in these reactions.^{98,99}

Compound 61	R	Abbreviation
a	Me	(S)-ALAPHOS
b	Pr ⁱ	(S)-VALPHOS
c	Bu ⁱ	(S)-LEUPHOS
d	Bu ^t	(R)-t-LEUPHOS
e	Ph	(R)-PhGLYPHOS
f	Bn	(S)-PHEPHOS
g	cyclo-C ₆ H ₁₁	(R)-ChGLYPHOS

Cross-coupling of 1-phenylethylmagnesium chloride with vinyl bromide in the presence of complexes of PdCl₂ with the ligands **61a–g**, **62**, **63** and **64** proceeds with a moderate enantioselectivity [*ee* up to 55% for (S)-PHEPHOS **61f**]. The catalytic system NiCl₂·L was found to be more efficient; indeed, in the case of the ligand **61d**, the optical yield reaches 94%. It should be noted that movement of the chiral centre towards the phosphorus atom results in a decrease in the asymmetrising activity (*ee* 38% for **61a** and *ee* 25% for **62**).⁹⁹ For example, in the cross-coupling of 1-phenylethylmagnesium chloride with β-bromostyrene, the Ni complex (S)-AMPHOS **48** exhibits no catalytic effect, while PdCl₂·[(S)-AMPHOS] ensures a 95% chemical yield and a 40% optical yield.¹⁰⁰ Palladium(II) *cis*-dichloro compounds **65a,b** have been synthesised and characterised by X-ray diffraction data.¹⁰¹ These complexes and nickel complexes **66a,b** having a similar structure were tested in the cross-coupling of 1-phenylethylmagnesium chloride with vinyl bromide. In the presence of the palladium complexes **65a,b**, the optical yield was moderate (*ee* up to 45%). The use of the nickel complexes **66a,b** resulted in a higher enantioselectivity (for **66b**, *ee* 88%).

The synthesis of P,N-bidentate ligands **67a–k**, containing a pyrrolidine ring, has been described.^{102,103}

Compound 67	R ¹	R ²

j	H	Bn
k	H	Ph

The compounds **67b,c,g,h,i** were used to prepare the *cis*-diiodo metal chelates PdI₂·L, having a heteronorborene skeleton; diastereomeric palladium complexes with the ligands **67a–g** were separated by column chromatography. The structure of the complex compounds was convincingly proved by IR spectroscopy and ¹H, ¹³C and ³¹P NMR spectroscopy (including the use of solid-state techniques), FAB mass spectrometry and X-ray diffraction analysis. However, these products were not selective in cross-coupling, the *ee* values being not more than 10%. Meanwhile, in the case of NiCl₂·**67b**, the chemical yield is 98% and the optical yield is 75%.¹⁰³

P,N-Bidentate ligands **68** and **69**, containing a phosphinite group, have been described.¹⁰⁴

Palladium complexes formed by the ligands **68** and **69** proved to be inefficient in the cross-coupling of 1-phenylethylmagnesium bromide with vinyl bromide; the optical yield was only 6%–9% for a degree of conversion of 60%–74%.¹⁰⁴ This outcome was explained by insufficient rigidity of six- and seven-membered palladacycles and by lower basicity of the phosphinite group in comparison with the phosphine group. However, this interpretation is quite debatable. The palladium complexes were characterised only by ³¹P and ¹H NMR spectra. No data of long-wavelength IR spectroscopy which would provide information on the arrangement of the chloro ligands at the Pd atom based on the position of the ν_{Pd–Cl} band are available. No data on the molecular masses of the complexes can be found either. Therefore, it cannot be ruled out that the reaction of the ligand **69** with PdCl₂ gives a bi- or poly-nuclear compound [PdCl₂·L]_n, in which the P,N-bidentate ligands function as bridges linked according to the 'head-to-tail' pattern, rather than a chelate. As regards the basicity of the phosphorus centre in cross-coupling catalysts, the statistical data available to date do not permit an unambiguous conclusion about its role in the enantioselectivity. It is quite probable that in the case of aminophosphinites **68** and **69**, an appropriate catalytic system has not been chosen.

Several chiral aminophosphines have been tested in asymmetric hydrosilylation. For instance, the reduction of acetophenone with diphenylsilane with participation of (*S*)-AMPHOS **48** {[Rh(C₂H₄)₂Cl]₂ as the pre-catalyst} gave the corresponding alcohol with *ee* 33%, and in the case of reduction of *tert*-butyl methyl ketone, *ee* was 72%.¹⁰⁵ Subsequently,¹⁰⁶ this result was somewhat improved: catalysis by [Rh(COD)Cl]₂·10L, where L = (*S*)-AMPHOS **48**, gave α -phenylethyl alcohol in an optical yield of 51% and a chemical yield of 97%. Other pre-catalysts proved to be less efficient: for Pd(COD)Cl₂, *ee* reaches 50.5% but the degree of conversion is only 13%, while for Pt(COD)Cl₂ and [Ir(COD)Cl]₂, *ee* does not exceed 27%.

It should be noted that close analogues of (*S*)-AMPHOS **48** containing a di(*tert*-butyl)phosphine group in the benzene ring, instead of the diphenylphosphine group, are known,¹⁰⁷ namely, (*S*)- (**70a**) and (*R*)-DIBUTPHOS **70b**. According to X-ray diffraction analysis,¹⁰⁷ in the rhodium complex **71**, the ligand (*R*)-DIBUTPHOS **70b** forms a metal chelate.

However, the use of the ligands **70a,b** in the hydrosilylation of acetophenone with phenyldimethylsilane {with [Rh(C₂H₄)₂Cl]₂ as the pre-catalyst} gave a quite unexpected result: for a chemical yield of up to 92%, no enantioselectivity was observed at all.

The ligand (*S*)-PHEPHOS **61f** ensures an optical yield of 54% in the hydrosilylation of acetophenone with diphenylsilane {the [Rh(COD)Cl]₂·4L system}.¹⁰⁸ When cyclic imine **72** was subjected to hydrosilylation with diphenylsilane in the presence of the [Rh(COD)Cl]₂·2.8L system, where L = (*S*)-PHEPHOS **61f**, compound **73**, the enantiomer of the antidepressant pyrazidol, was obtained in 69% yield and *ee* 73%.¹⁰⁹

The behaviour of (*S*)-PHEPHOS **61f** and (*S*)-AMPHOS **48** in the reaction with [Rh(COD)Cl]₂ and [Rh(CO)₂Cl]₂ has been studied.¹¹⁰ The reaction products, binuclear Rh(I) complexes of the [Rh(L)Cl]₂ type and mononuclear complexes of the Rh(CO)Cl(L) type, were isolated and characterised by spectroscopy (IR, X-ray electron, ¹H NMR, ³¹P NMR and mass spectra).

To summarise the foregoing, it should be noted that rhodium and palladium derivatives of chiral aminophosphines with an *sp*³-hybridised peripheral nitrogen atom provide moderate enantioselectivity as catalysts of hydrogenation, cross-coupling and hydrosilylation. However, they are more effective in allylic substitution. Specifically, amino-substituted phosphinous amide **74**, in which the asymmetric phosphorus atom is incorporated in a heterocycle, ensured a chemical yield of 99% and an optical yield of 62% in the alkylation of dimethyl malonate with the acetate **12** {with [Pd(All)Cl]₂ as the pre-catalyst}.¹¹¹

The same model reaction was used to test a series of amino phosphinous amides **75a–j**, in which the phosphorus atom is achiral {[Pd(All)Cl]₂ as the pre-catalyst}.¹¹² In the presence of these ligands, *ee* is 76% for a chemical yield of 41%–82%. The best optical yield was attained with the ligand **75h**, having no substituents at the amide nitrogen atom.

Compound 75	R ¹	R ²
a	H	H
b	Me	Me
c	Bn	Bn
d	Pr ⁱ	Pr ⁱ
e	CH ₂ CH ₂ Pr ⁱ	CH ₂ CH ₂ Pr ⁱ
f	2-MeC ₆ H ₄ CH ₂	2-MeC ₆ H ₄ CH ₂
g	3-MeC ₆ H ₄ CH ₂	3-MeC ₆ H ₄ CH ₂
h	Bn	H
i	2-MeC ₆ H ₄ CH ₂	H
j	Bu ^t CH ₂	H

Ligands **76a,b**, **77**, **78a,b** and **79** with axial or central chirality of the peripheral nitrogen atom have been prepared.¹¹³

In the model allylic alkylation using [Pd(All)Cl]₂ as the pre-catalyst, the use of the ligands **76a,b** results in *ee* values of 93% and 96%, respectively. The chemical yields are 96%. An increase in the optical yield on passing from the compound **76a** to **76b**, was attributed¹¹³ to an increase in the size of the chelate metallacycle it forms. The ligands **77**, **78a,b** and **79** are much less enantioselective (*ee* up to 39%). In the presence of the ligands **80a–c**, in which the phosphorus center is further removed from the nitrogen centre, the asymmetric induction decreases with an increase in the distance between the donor centres.¹¹³

Compound 80	<i>n</i>	<i>m</i>
a	1	0
b	2	0
c	1	1

In the alkylation of dimethyl malonate with the acetate **12**, the ligands **80a–c** [with Pd(OAc)₂ as the pre-catalyst] ensure *ee* of 96%, 79% and 18%, respectively.¹¹⁴ The low optical yield observed in the last-mentioned case was explained by assuming monodentate coordination of the compound **80c** for the formation of the intermediate. The ligands **80a–c** were also employed in the cross-coupling of (1-phenylethyl)magnesium chloride with vinyl bromide. The best result (*ee* 46%) was observed for the ligand **80b**; in other cases, *ee* did not exceed 9%. Compounds **81a,b**, having a similar structure and containing additional chiral centres in the dihydroazepine ring, offer no advantages over the ligands **80a–c**.¹¹⁵

81a,b [R = Me (a), Et (b)]

In the same model allylic alkylation reaction {with [Pd(All)Cl]₂ as the pre-catalyst}, *ee* is 59% for the ligand **81a** and 37% for the ligand **81b**. A higher enantioselectivity (*ee* 68%) was achieved in the alkylation of dimethyl malonate with the sterically less shielded acetate **13** {the [Pd(All)Cl]₂ · **81a** catalytic system}.

When dinaphthalene derivatives **82a–h**, which also have a chiral axis, are employed in allylic alkylation [the acetate **12**, pre-catalyst Pd(dba)₂], the chemical yields are 77%–95% and the optical yields are 53%–73% (the ligand **82f** is the most effective).

Compound 82	R ¹	R ²
a	H	H
b	Me	Me
c	H	Et
d	H	Pr ⁱ
e	H	cyclo-C ₆ H ₁₁
f	Me	Pr ⁱ
g	Me	cyclo-C ₆ H ₁₁
h	cyclo-C ₆ H ₁₁	cyclo-C ₆ H ₁₁

The reaction of aminophosphine **82b** with PdCl₂(PhCN)₂ has been studied.¹¹⁶ According to the ¹H, ¹³C and ³¹P NMR spectra, the reaction gives an equilibrium mixture of three complexes, **83**, **84** and **85**, in a ratio of 10:85:5.

It was demonstrated by X-ray diffraction analysis that the complex **84**, which predominates in the mixture, is a chelate formed due to the P–C_σ binding. It was noted that this type of binding can play an essential role in the formation of intermediates in allylation processes.

Chiral N-*sp*³-hybridised aminophosphines, which have not yet found application in catalysis but, in our opinion, hold considerable promise, deserve special consideration. Most of these compounds contain asymmetric phosphorus and/or nitrogen atoms.

In particular, the reaction of compound **86** with PdCl₂(MeCN)₂ results in two epimers of the palladium chelate complexes, PdCl₂·[(S_N, S_C, S_P)-**86**] and PdCl₂·[(S_N, S_C, R_P)-**86**], which were separated by fractional crystallisation.¹¹⁷

Palladium and platinum *cis*-dichloro complexes **87a,b** with two chiral centres have also been described.¹¹⁸

Whereas the platinum complex **87a** exists as a single diastereomer (the asymmetric nitrogen atom has only one config-

87a,b [M = Pt (a), Pd (b)]

88

uration), the palladium analogue **87b** undergoes epimerisation with a half-transformation period of 30 min (according to ¹H NMR spectra and polarimetry). Unlike the complex **87b**, compound **88** contains a configurationally stable chiral nitrogen centre due to the stereochemical assistance of the neighbouring endocyclic carbon centre.¹¹⁹

The chiral nitrogen centre in the compound **89** also possesses configurational stability, as shown¹²⁰ by the data of ¹H (2D NOESY), ¹³C, ¹⁵N and ³¹P NMR, IR and mass spectra and X-ray diffraction analysis.

90a,b [R = Ph (a), 2-ClC₆H₄ (b)]

The complex exists as a single diastereomer both in solution and in the solid state but the palladacycle retains configurational mobility. The conformers differ little in energy, which detracts from the potential use of the compound **89** as a ligand in stereoselective catalysis.

Some aminophosphines with chiral centres at the phosphorus atom also appear interesting, for example, compounds **90a,b**, for which both neutral and cationic palladium(II) chelates have been obtained.^{121, 122}

The original bicyclic compound **91** contains five asymmetric carbon atoms in addition to the chiral phosphorus atom. This compound can bind to a metal as both a P-monodentate or a P,N-bidentate ligand (according to ³¹P, ¹³C and ¹H NMR spectroscopy).¹²³

(a) 0.5 equiv. [Rh(CO)₂Cl]₂; (b) 0.5 equiv. [Rh(COD)₂Cl]₂.

The complex PdBr(R)(L), where L = (*R*)-AMPHOS [(*R*)-**48**], R = Me, C ≡ CSiMe₃, has been synthesised.¹²⁴ Several ligands **92a–d** based on (*R*)-AMPHOS [(*R*)-**48**] have been prepared.¹²⁵

92a–d

L = CO (a), PPh₃ (b), P(OMe)₃ (c), P(OPh)₃ (d).

The complexes **92a–d** have found application so far only in the amination of 4-bromotoluene with piperidine catalysed by

palladium complexes; however, they are also of interest for asymmetric synthesis, especially in view of the possibility of changing the electronic properties of the phosphorus centre by changing the nature of the ligand L.¹²⁵

The dimethylhydrazone of the phosphorus-substituted (*R*)-camphor **93** reacts with $\text{PdCl}_2(\text{PhCN})_2$ to give initially six-membered chelate metallacycle **94** (according to the IR spectra, ^{31}P and ^1H NMR spectra and X-ray diffraction analysis).¹²⁶

On treatment of a solution of the complex **94** in CH_2Cl_2 with dry hydrogen chloride, the metal chelate rearranges giving rise to complex **95** with a coordinated sp^2 -hybridised nitrogen atom.

2. Ligands with sp^2 -hybridised electron-donating nitrogen atoms

The interest in ligands with sp^2 -hybridised donor nitrogen atoms arose somewhat later than that in compounds with sp^3 -hybridised nitrogen centres. In 1982, phosphines **96a,b** and their neutral palladium derivatives $\text{PdCl}_2(\text{L})$ were synthesised.¹²⁷ Later,¹²⁸ the cationic complexes $[\text{Pd}(\text{L})_2]^{2+}(\text{PF}_6^-)_2$ and $[\text{PdCl}(\text{L})]^{+}\text{X}^{-}$ ($\text{X} = \text{Cl}, \text{PF}_6$) were prepared.

Several other fairly interesting ligands and complexes based on them, for example, **97–99**, have been reported.^{129–131} X-ray diffraction analysis¹²⁹ showed that the $\text{Pd}-\text{Cl}(1)$ bond length in the complex **97** [2.394(2) Å] is markedly greater than the typical value, due to the strong *trans*-effect of the phosphorus centre with an unusual geometry.

The ligand **98** has a nine-atom bridge between phosphorus and nitrogen. It is thus able to form 12-membered macrometallacycles.¹³⁰ Nevertheless, the enantioselectivity (*ee* 86%) in the model alkylation of dimethyl malonate with the allyl acetate **12** {with $[\text{Pd}(\text{All})\text{Cl}]_2$ as the pre-catalyst} is quite comparable with the enantioselectivity attained when using catalysts with a standard size of the chelate ring.

Cationic complexes of the phosphinite **99**, $[\text{Rh}(\text{CO})_2(\text{PPh}_3)(\text{L})]^+\text{ClO}_4^-$ and $[\text{Rh}(\text{COD})(\text{L})]^+\text{ClO}_4^-$ (the latter was studied by X-ray diffraction analysis), have found use as catalysts of hydroformylation of a number of unsaturated substrates such as vinyl acetate, styrene, vinyl naphthalene and methyl acrylate.¹³¹ The optical yields were 12%, 6%, 78% and 92%, respectively for rather high degrees of conversion and regioselectivities. However, later it was shown¹³² that the last-mentioned value was erroneous.

The formation of complexes by phosphine **100** (PYDIPHOS) was thoroughly studied by spectral methods (IR spectroscopy, ^{31}P , ^1H and ^{13}C NMR spectroscopy) and mass spectrometry.^{133, 134}

Both rhodium (**101**) and palladium (**102**) metal complexes were described as chelates (the structure of the complex **102** was confirmed by X-ray diffraction analysis); however, the data obtained for the complex **101** do not rule out unambiguously an alternative highly symmetrical binuclear structure with bridging coordination of the P,N-bidentate ligands of the 'head-to-tail' type.¹³⁴ The enantioselectivity observed in catalytic reactions involving PYDIPHOS (**100**) is moderate. For hydroformylation of styrene in the presence of the complex **101**, the *ee* is 28%; ethoxycarbonylation in the presence of the complex **102** results in *ee* of 20%; in the model allylic alkylation {the $[\text{Pd}(\text{All})\text{Cl}]_2 \cdot 4\text{L}$ system}, *ee* is 9%.¹³⁵

Studies by Brown *et al.*^{136–141} deserve special attention. These researchers proposed effective ligands QUINAP **103** and PHENAP **104a,b**.

Cationic rhodium complexes **105a,b** with these ligands have found successful use as catalysts of hydroboration of vinylarenes with catecholborane.^{137, 138} The optical yields were 64%–95% and the chemical yields were 21%–71%. For example, in the hydroboration of styrene in the presence of the complexes **105a,b**, the *ee* values were 91% and 67%, respectively.¹³⁸

The complex **105a** has also been used as the catalyst for hydroboration–amination of vinylarenes;¹³⁹ the corresponding primary amines were obtained in optical yields of 77%–98% and in chemical yields of 50%–64%.

Allylic palladium complexes **106a–d** with the P,N-bidentate ligand **103** have been synthesised. Their structure was established based on the spectral data (IR spectroscopy and ³¹P, ¹³C and ¹H NMR spectroscopy and mass spectrometry).¹⁴⁰

Compound 106	R ¹	R ²	R ³
a	H	H	H
b	Ph	H	H
c	Ph	Ph	H
d	Ph	Ph	Ph

In the classical alkylation of dimethyl malonate with the allyl acetate **12** catalysed by the complex **106a**, the optical yield fluctuates from 67% to 98%, depending on the reaction conditions. For other allylic substrates, the optical yield varies from 47% to 67%. The replacement of dimethyl malonate by diethyl malonate decreases somewhat the enantioselectivity (*ee* 75%–78%). The use of the neutral complex PdCl₂·**103** instead of the cationic complex **106a** increases the optical yield (*ee* 79%).¹⁴⁰ A similar complex in which [Pd(All)(**104a**)]⁺ BF₄[−] is used instead of QUINAP **103** ensures a commensurable level of asymmetric induction in this reaction (*ee* 95%).¹⁴¹

Ligands **107a–d**¹⁴² used in hydroboration and compound **108**¹⁴³ containing an indole fragment have been prepared recently.

Compound 107	Configuration	Ar
a	<i>S</i>	3-MeC ₆ H ₄
b	<i>S</i>	3,5-Me ₂ C ₆ H ₃
c	<i>R</i>	2-biphenyl
d	<i>R</i>	2-furyl

Unfortunately, both the ligand **108** itself and its complex with PdCl₂ **109** are readily racemised. The corresponding cationic allylpalladium complex **110** is the only diastereomer.

The structures of **109** and **110** were studied¹⁴³ using spectral methods (IR and ³¹P, ¹H and ¹³C NMR spectroscopy and mass spectrometry). The complex **110** was studied by X-ray diffraction analysis. The metal atoms in both complexes were found to be coordinated to the isoquinoline nitrogen atom. The configurational stability of the allylic cationic complexes of Pd(II) of the type **110** gives hope for their successful use in asymmetric allylic substitution.¹⁴³

In addition to ligands with a pyridine or isoquinoline fragment, a large group of ligands with a peripheral imino group, iminophosphines, have been described. They were studied by Brunner *et al.*^{144, 145, 148–150} In particular, (*R*)-IMINPHOS **111** and (*R*)-AMINPHOS **112** (prepared by the reduction of **111** with NaBH₄) were compared in the hydrogenation of *N*-acetyl-α-aminocinnamic acid {[Rh(C₂H₄)₂Cl]₂ as the pre-catalyst} and hydrosilylation of acetophenone with diphenylsilane {[Rh(COD)Cl]₂ as the pre-catalyst}.¹⁴⁴

The ligand (*R*)-**111** was more enantioselective in hydrogenation than (*R*)-**112** (*ee* 17% and 14%, respectively). The *ee* value attained in hydrosilylation is 29% in the presence of (*R*)-IMINPHOS **111** and 53% for (*R*)-AMINPHOS **112**.¹⁴⁴ Note that the ferrocene arylideneaminophosphines **17a–d** and the aminophosphines (*S,R*)-**18** exhibit a diametrically opposite pattern of dependence (see Section II.2.b). Subsequently,¹⁴⁵ other imino- and amino-phosphines such as **113a,b**–**115a,b** and **116** have been studied in the hydrosilylation of acetophenone {[Rh(COD)Cl]₂ as the pre-catalyst}; however, they all proved to be middling asymmetric inducers because they ensured *ee* of not more than 20%. The best results were obtained with the ligands **113a** and **115a**.

R = H (**a**), Me (**b**).

A later publication¹⁴⁶ describes the synthesis of the (*S*)-enantiomer of IMINPHOS [(*S*)-**111**] and a large series of its palladium and platinum complexes such as PdCl(Me)(L), [Pd(η³-All)(L)]⁺ X[−] (η³-All = 2-RC₃H₄, 2-MeC₃Me₄, 2-RC₃H₂Me₂; X = Cl, O₃SCF₃), PdCl₂(L).¹⁴⁹ The chelating P,N-bidentate coordination of the ligand in these complexes was proved by ³¹P, ¹H and ¹³C NMR spectroscopy; neutral Pd(II) complexes were studied by X-ray diffraction analysis.

Close analogues of IMINPHOS **111**, compounds **117a,b**, are also known.¹⁴⁷ The enantioselectivity exhibited by these compounds in the alkylation of dimethyl malonate with the allyl acetate **12** catalysed by Pd complexes is also low (*ee* does not exceed 17%).

R = cyclo-C₆H₁₁ (**a**), 2-naphthyl (**b**).

Quite recently, a new large series of iminophosphines **118a–g** have been proposed;^{148–150} these products were used to prepare biologically active compound **119**, which belongs to the group of barbiturates.¹⁴⁹ In the reaction catalysed by palladium acetylacetonate in the presence of (*S*)-**118e**, the yield of the compound **119** was 89% (*ee* ~ 34%).

R¹ = C(Ph)(Me) (**a**), HC(Me)CH₂OH (**b**), HC(Et)CH₂OH (**c**), HC(Prⁱ)CH₂OH (**d**), HC(Bu^t)CH₂OH (**e**), HC(Ph)CH₂OH (**f**),

L = (*S*)-**118e**.

Although the optical yield attained is relatively low, this reaction opens up the way for accumulation of a valuable medicinal preparation, namely, the anesthetic methohexital **120**, which was prepared in the presence of the ligand (*S*)-**118e** in an optical yield of 80%.¹⁵⁰

L = (*S*)-**118e**.

Chiral aminoiminophosphines **121** and **122a,b** were found to be fairly effective in the alkylation of dimethyl malonate with the allyl acetate **12**.^{151–153}

121

(*S*)-**122a**, (*R*)-**122b**

When the reaction was carried out with the ligand **121** {[Pd(All)Cl]₂ as the pre-catalyst}, the chemical yield was 85% and the optical yield was 92%. In the allylic palladium intermediate, the ligand was found¹⁵¹ to be coordinated through the phosphorus atom and the imine nitrogen atom. The iminophosphines **122a,b** are also effective in this reaction {[Pd(All)Cl]₂·3L as the catalyst}: *ee* is 90%–92% for a nearly quantitative chemical yield.¹⁵² The ligand **121** was used in processes in which ketene silyl

acetals are used as nucleophiles.¹⁵³ The yields in these reactions reach 95% and *ee* is 93%.

R¹ = R² = R³ = R⁴ = Me; R¹–R² = (CH₂)₅; R³ = R⁴ = Me;

R¹ = R² = H, R³ = Me, R⁴ = Bu^tMe₂; R¹ = CO₂Me, R² = H,

R³ = R⁴ = Me; L = **121**.

Recently, a new series of phosphorus-substituted imines **123a–f**, containing substituents of different nature in the arylmethylidene fragment, have been prepared.¹⁵⁴ In the alkylation of dimethyl malonate with 3-pivaloyloxy-1,3-diphenylprop-1-ene {catalysed by [Pd(All)Cl]₂·4L}, the catalytic activity was found to be directly correlated with the enantioselectivity, on the one hand, and the electron-donating capacity of the substituent X on the other hand.

Compound 123	X	Yield (%)	<i>ee</i> (%)
a	CO ₂ Me	42	19
b	CF ₃	46	38
c	H	57	52
d	Me	76	74
e	OMe	88	85
f	NMe ₂	99	92

In the author's opinion,¹⁵⁴ this is due to the increase in the stability of the Pd(II) cationic complexes on passing from the ligand **123a** to **123f**.

It should be noted that ligands with *sp*²-hybridised donor nitrogen atoms have made a greater contribution to asymmetric catalysis than the ligands with *sp*³-hybridised nitrogen because, in addition to allylic alkylation, they are effective in hydroboration–oxidation and hydroboration–amination processes.

3. P,N-Bidentate derivatives of phosphorous acid

About 250 chiral P,N-bidentate ligands are currently used in the synthesis of coordination compounds and in asymmetric catalysis. The natures of the nitrogen centres in these compounds are quite diverse, while the phosphorus centres are usually acyclic phosphines (a PAr₂ fragment is encountered most often). (Phosphinites such as **42**, **68**, **69** and **99** and phosphinous amides **74** and **113–116** are the scanty exceptions.) The introduction of electron-donating or electron-withdrawing substituents into the corresponding positions of the benzene nucleus is almost the only method of controlling the inductive effect of phosphorus. However, there exists another, more effective method different in kind, namely, replacement of the carbon atoms in the first coordination sphere of phosphorus by heteroatoms (oxygen and/or nitrogen). This method allows fine adjustment of the chemical stability, the donor–acceptor properties and steric requirements of the ligand. A phosphorus centre of this type is present in P,N-bidentate ligands derived from phosphorous acid.

It is noteworthy that, starting from the early 1990s, the number of publications devoted to the use of chiral phosphites and phosphorous amides, especially P,P-bidentate ones, in the coordination chemistry and catalysis, has substantially increased.^{155, 156} The obvious advantages of these ligands have been outlined.¹⁵⁷

(i) They are readily available because most of them, including functionally substituted ones, can be prepared fairly easily (in one or two steps) and in a high yield from widely used optically active organic precursors, for example, amino alcohols or diols.

(ii) No P–C bonds, which would considerably hamper the oxidative destruction of the ligand, are present in the molecule.

(iii) Owing to the clear-cut π -acceptor properties inherent in phosphites,¹⁵⁸ they are more electrophilic ligands; coordinated phosphites are able to stabilise low oxidation states of complex-forming metals.

It should be noted that chiral phosphinophosphites are the best ligands for asymmetric hydroformylation.^{132,156} The introduction of an N-donor centre into the molecule of an ester or an amidoester of phosphorous acid extends the scope of application of chiral phosphites.

The first publication reporting the synthesis and complex formation of optically active aminoalkyl phosphites **124** and **125a,b** appeared in 1993.¹⁵⁹ The reaction of the compounds **124** and **125** with $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ afforded mono- and bi-nuclear Rh(I) chloro carbonyl complexes.^{159,160} The ligand **124** forms metal chelate **126**, while the ligand **125b** gives dimer **127b**. The reaction of $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ with the ligand **125a** gives rise to a mixture of monomer **128** and dimer **127a**; during storage of the solution, the latter product gradually rearranges to complex **128**. It should be noted that the complexes **127a,b** and **128** have been studied only in solution.

$n = m = 2$ (**a**); $n = 3, m = 1$ (**b**).

However, the use of the chiral P,N-bidentate derivatives of phosphorous acid **124** and **125a,b** in the hydrosilylation of acetophenone with diphenylsilane $\{[\text{Rh}(\text{CO})_2\text{Cl}]_2$ and $[\text{Rh}(\text{COD})\text{Cl}]_2$ as pre-catalysts $\}$ was not very effective (*ee* did not exceed 8%).¹⁵⁹

Ligand **129** was prepared¹⁶¹ by successive phosphorylation of diisopropyl tartrate and 4-aminomorpholine. It is coordinated as a P-monodentate ligand in the complex (acac)Rh(CO)L.

The complexes of phosphites **130–132** and phosphorous amide **133** with $\text{Pd}(\text{COD})\text{Cl}_2$ were studied by ^1H , ^{31}P and ^{13}C NMR, X-ray electron and IR spectroscopy and plasma desorption mass spectrometry.

It was shown that the compounds **130a–c**^{162–164} and **133**¹⁶⁵ form mononuclear chelates of the same type. According to X-ray diffraction data, the Pd–P distance in the palladium complex of the ligand **130a** (2.189 Å) is shorter than this bond in palladium dichloro complexes with P,N-bidentate ligands forming a six-membered metallacycle (2.205–2.241 Å).¹⁶² The bond shortening is due to the π -acceptor properties of the phosphite centre.

The resonance signals of phosphorus in the ^{31}P NMR spectra of Pd(II) *cis*-dichloro complexes with amino phosphites and amino phosphorous amides occur at a higher field than the signals of free ligands due to shielding of the phosphorus nucleus. However, in the case of similar aminophosphine complexes, the signals of the ^{31}P nuclei are located at a lower field than those for the free ligands.¹⁶⁶

Dioxazaphosphocane **131** forms a polynuclear compound of Pd(II), namely, *cis*- $[\text{PdCl}_2(\text{L})]_{20}$, in which the P,N-bidentate ligands function as bridges arranged in the 'head-to-tail' manner.¹⁶⁷ From the 1,3,2-dioxaphospholane derivative **132**, the dimeric complex **134** with bridging chloro ligands and an intramolecular palladium–nitrogen bond was synthesised.¹⁶⁸ This unusual pattern of complexation observed for the ligand **132** is due to the presence of the bulky substituent in the peripheral amino group of its molecule. As a consequence, the amino group becomes a very weak nucleophile, an analogue of Hünig bases.

Recently,¹⁶⁹ aminoalkyl phosphite **135** based on a unique amino alcohol, quincoridin, has been synthesised.

To the best of our knowledge, the compound **135** is the only known example of a P,N-bidentate ligand with a configurationally stable chiral nitrogen. This ligand was used to synthesise rhodium(I) chloro carbonyl chelate, $[\text{Rh}(\text{CO})\text{Cl}(\text{L})]$.

It should be noted that the increased (even in comparison with the most electron-withdrawing amino phosphites^{31,160}) π -acidity of the aminoalkyl phosphites **124**, **125a,b** and **135** influences the spectral characteristics of chloro carbonyl complexes of rhodium with these ligands. Thus the $^1J_{\text{P-Pb}}$ spin–spin coupling constants observed for these complexes are, on the average, ~ 100 Hz greater, while $\nu(\text{CO})$ values are greater by ~ 20 cm^{-1} .

Hydrophosphorane compounds are seldom used for the preparation of metal complexes with P,N-bidentate derivatives of phosphorous acid. Complex formation is accompanied by rupture of the P–H and P–N bonds and simultaneous formation of M–P and M–N bonds. The main studies dealing with the complexation of chiral hydrophosphoranes have been

surveyed in several publications.^{155, 170, 171} Therefore, here we shall consider only the tricyclic hydrophosphorane **136**, prepared not long ago.¹⁷² The reaction of this compound with $\text{Pd}(\text{COD})\text{Cl}_2$ gave the first stable palladated phosphorane **137** (in an almost quantitative yield).¹⁷³

After the proton has migrated from phosphorus to nitrogen, the compound **136** acts as a P-monodentate phosphorane ligand. When **136** is made to react with $\text{Pt}(\text{COD})\text{Cl}_2$, the phosphorane ring is opened at the apical P–N bond. In the complex $[\text{PtCl}_2(\text{L})]$, the ligand occurs in the ‘open’ form and is bound to the metal in the P,N-bidentate fashion.¹⁷⁴

The synthesis and coordination to metals of phosphite and phosphorous amide derivatives of alkaloids, quinine and codeine, have been the subject of a detailed review;¹⁷⁵ therefore, we do not discuss them here.

In 1997, diastereospecific synthesis of three amino-substituted phosphorous diamide ligands **138a–c** was reported.¹⁷⁶

In the classical allylic alkylation with the allyl acetate **12** {with $[\text{Pd}(\text{All})\text{Cl}]_2$ as the pre-catalyst}, the ligands **138a,b** ensured a degree of conversion of 100% and *ee* of 85%–87%, and the ligand **138c** provided 85% and 76%, respectively. Nearly identical results were attained in the related alkylation of dimethyl malonate with 3-methoxycarbonyloxy-1,3-diphenylprop-1-ene. Subsequently,¹⁷⁷ ligand **139** has been synthesised. The compounds **138a–c** and **139** (yields 70%–100%, *ee* 73%–94%) have found application as catalysts of allylic amination.

When diphenylallyl acetate is used as the substrate and benzylamine is employed as the nucleophile, the ligands **138a** and **138c** are the most effective (degree of conversion 95% and *ee* 93%). In the allylic amination of acetate **140** in the presence of the ligand **138a**, the yield is 93% and the optical yield is 89%.¹⁷⁸

L = **138a**.

It is worth noting that known bisphosphines, (+)-DIOP and (–)-BINAP, ensure *ee* < 5% in this reaction.¹⁷⁸

4,5-Dihydrooxazoles **141–143**, containing cyclic phosphite groups as substituents, are effective ligands for catalytic allylation.^{179, 180} Thus alkylation of dimethyl malonate with the allyl acetate **27** in the presence of the $[\text{Pd}(\text{All})\text{Cl}]_2 \cdot 2.5\text{L}$ catalytic system results in *ee* of 77%–92%.

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Bu}^t$ (**a**), Pr^i (**b**), Ph (**c**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bu}^t$ (**d**).

The best result was achieved in the presence of the ligand **142d**, the total yield of branched (**144a**) and linear (**144b**) reaction products being equal to 75%–92%.

Asymmetric induction is mainly accomplished due to the dihydrooxazole fragment. Thus for the ligand **141**, the *ee* is 83% and for the ligand **143**, it is 79%. In addition, the enantio- and regioselectivity of the process increase with an increase in the size and, especially, electronegativity of substituents at the phosphorus atom. The results of alkylation of dimethyl malonate with the acetates **27a,b** are listed in Table 2. It can be seen that both an increase in the size of substituents in the ligand and an increase in

Table 2. Enantio- and regioselectivity of the alkylation of dimethyl malonate with the acetates **27** $\{[\text{Pd}(\text{All})\text{Cl}]_2$ as the pre-catalyst}.

Compound 27	Ligand	<i>ee</i> (%)	The ratio 144a : 144b
a	23c	78	4 : 96
	145	84	47 : 53
	142a	90	76 : 24
	142a	96	95 : 5
b	142a	96	95 : 5

the steric requirements in the compound **27** results in higher enantioselectivity and regioselectivity of the reaction. It should be noted that the selectivity increases also on passing from the ligand **23c** to its analogue **145**, having perfluorophenyl groups attached to phosphorus.

Compound 146	Ar	R ¹	R ²
a	Ph	H	Ph
b	Ph	Ph	H
c	Ph	H	Pr ⁱ
d	Ph	Pr ⁱ	H
e	2-naphthyl	Pr ⁱ	H

Ligands **146a-e**, prepared using widespread chiral inducers, $\alpha,\alpha,\alpha',\alpha'$ -tetraaryl-1,2-dioxolano-4,5-dimethanols (TADDOL), were employed¹⁸¹ to prepare Rh(I) cationic complexes **147b,c** (the complex **147b** was characterised by X-ray diffraction analysis) and to carry out hydrosilylation of a series of aliphatic and aromatic ketones, including reduction of acetophenone with diphenylsilane {with [Rh(COD)Cl]₂ as the pre-catalyst}.

The best results were obtained with the ligand **146d**: the *ee* value in the reduction of acetophenone was 88% (chemical yield 91%) and in the reduction of *tert*-butyl methyl ketone, the *ee* reached 95%.

V. Conclusion

The data considered here demonstrate that the research into chiral P,N-bidentate ligands is developing rather vigorously. More than 270 compounds of this type are being used in asymmetric catalysis for allylic alkylation, cross-coupling, hydrosilylation of the C=O and C=C bonds, hydroboration-oxidation, hydroboration-amination and for the Heck reaction.

The use of rhodium and palladium complexes with optically active P,N-bidentate ligands in asymmetric catalysis is briefly summarised in Table 3. The table presents the results of the most thoroughly developed processes, namely, hydrosilylation, hydroboration-oxidation and allylic substitution. The enantioselective allylation was considered taking the model allylic alkylation of dimethyl malonate with the acetate **12** as an example. It follows from the data of Table 3 that phosphorus-substituted ferrocenes and dihydrooxazoles are the most effective in the hydrosilylation of the C=O bond; ferrocenylphosphinopyrazoles and QUINAP **103** are the best compounds for hydroboration-oxidation; and all the groups of chiral P,N-bidentate compounds proved efficient for

allylic substitution. It should also be noted that ferrocenylaminoalkylphosphines are effective stereoselective ligands for some cross-coupling reactions.

However, several topical problems in the chemistry of P,N-bidentate ligands are still to be solved.

(i) Among the problems of design and synthesis of these ligands, preparation of compounds with a chiral carbon atom at the phosphorus centre deserves attention in the first place because at present, predominant structures are those having asymmetric carbon atoms at the nitrogen centre and/or in the bridge linking phosphorus and nitrogen. It is also important to synthesise ligands with asymmetric donor atoms, especially, with configurationally stable chiral nitrogen atoms. Combination in a chiral ligand molecule of asymmetric atoms with different absolute configurations and chemical natures as well as combination of different types of chirality (for example, central and planar chirality, central and axial chirality, *etc.*) can provide effective transfer of chiral information from the metal complex to the substrate. For example, recently, phosphinodihydrooxazoles **148a,b** with a chirality axis were synthesised;^{182,183} allylic amination of the acetate **27** with substituted hydrazines¹⁸³ in the presence of these compounds results in *ee* of up to 99%, while the allylic alkylation of the allyl acetate **12**¹⁸² gives *ee* of up to 91%. It was shown¹⁸² that the binaphthalene cage is responsible for the increase in the stereoselectivity.

As noted above, an increase in the π -acidity of the phosphorus centre favours an increase in the chemical and optical yields in allylic substitution, hydroboration-oxidation and hydrosilylation of alkenes and hydrosilylation of ketones. The inductive effect of the phosphorus centre increases on passing from aminophosphines to amino phosphites or amino phosphorous amides. In these compounds, the inductive effect can be readily optimised.

In the development of new chiral P,N-bidentate ligands, optically active natural products can be used such as steroids, amino acids and alkaloids. No P,N-bidentate derivatives of phosphorous acid having a plane of chirality or a peripheral imino group are known to date. However, the synthesis of these compounds is quite practicable.

It should also be noted that the synthesis of phosphites and phosphorous amides involves phosphorylation of the corresponding proton-donating functional groups, which proceeds, as a rule, with high yields; therefore, one can expect that a new generation of P,N-bidentate ligands would contain a phosphite (or amino phosphite) centre, possess planar or axial chirality of the carbon framework, and the nitrogen-containing fragment would be represented by an oxazoline, oxazine, imine or pyrazoline group.

(ii) Regarding asymmetric catalysis, it is necessary to master those reactions in which optically active P,N-bidentate ligands have received little use, if any. This refers first of all to the addition of electrophilic reagents to alkenes (for example, hydrocyanation) and to hydroformylation and copolymerisation of alkenes or dienes in the presence of CO. Non-symmetrical phosphinophosphites,¹⁵⁶ *i.e.* systems with donor centres with different chemical natures, showed good results in these reactions. An example of using P,N-bidentate ligands in non-standard reactions is the aza Claisen rearrangement catalysed by the complexes PdCl₂L [L = (*S,S*)-**11b**, **26b,c,f**].¹⁸⁴

^a Followed by treatment with H₂O₂ and NaOH.

The use of phosphinodihydrooxazoles as ligands in cross-coupling, hydroboration and hydrosilylation of alkenes appears quite promising. It is necessary to study already known amino phosphites, amino phosphorous amides and phosphitodihydrooxazoles not only in allylic substitution reactions but also in all other catalytic processes in which ligands with electron-withdrawing P-donor centres can participate. These studies would substantially extend the scope of application of chiral P,N-bidentate ligands in enantioselective catalysis. Further perfection of well-developed processes is needed, first of all, in order to achieve quantitative enantioselectivity (for example,¹⁸⁵ it is known that certification of pharmaceutical preparations requires *ee* ≥ 99%). The enantioselectivity can be increased by introducing non-chiral additives.¹⁸⁵

(iii) Investigation into the mechanisms of catalytic reactions can provide the basis for recommendations on the reaction conditions and for targeted synthesis of optimal ligands. Despite the impressive progress in modern asymmetric catalysis, it largely relies on the rules obtained empirically. This is partly due to the necessity of taking into account too many factors influencing the outcome of a catalytic reaction such as the nature of the ligand and the metal, the ligand:metal and catalyst:substrate ratios, the temperature, the concentration, the nature of the solvent, the additives present, *etc.* and, to some extent, this is due to the absence of a detailed investigation of the mechanisms of catalytic reactions.

(iv) In the field of coordination chemistry, it appears topical to continue the studies on the regularities of complexation of the main groups of ligands. Unfortunately, isolation and reliable characterisation of complexes with transition metals is far from being performed for all the P,N-bidentate ligands effective in catalysis.

Thus, despite the considerable contribution of iminophosphine derivatives, such as the ligands **118a–g** or **123a–f**, to asymmetric catalysis, the coordination behaviour of these ligands has scarcely been studied. This also concerns several other effective stereoselective ligands, **138**, **139** and **141–145**. The complex formation of related compounds **124**, **125**, **129** and **130–135** has been extensively studied; however, no data on the use of these compounds in catalytic processes can be found. Evidently, catalytic experiment and the study of the structures of pre-catalysts and related metal complexes for each group of ligands should be combined with investigation of the coordination and catalysis mechanism.

It appears useful to synthesise a series of related complexes with different ligands (as has been done, for example, for chloro carbonyl rhodium derivatives of phosphinoferrrocenylpyrazoles **6a–t**³¹). Comparison of the characteristic features of coordination of these compounds to metals and their spectroscopic properties and estimation of the electronic effects of the electron-donating centres would permit more efficient prediction of catalytic experiments and elucidation of the corresponding correlations. This integrated approach has been realised to some extent for ferrocenylaminophosphines (including PPFA **1** and PTFA **3**), phosphinoferrrocenylpyrazoles and phosphinodihydrooxazoles. However, even for these compounds, further studies are needed because P,N-bidentate coordination and chelation cannot be postulated *a priori* even for well-known ligands (for example, in the ligand **80b**, P,C_σ- rather than P,N-binding predominates).

It is clear that the current state of asymmetric catalysis and the prospects for its development are determined by not only P,N-bidentate ligands. Considerable contribution is made by P,P-, P,O- and N,N-bidentate systems (see, for example, several studies^{4–10, 186}).

It can be stated with confidence that the use of P,N-bidentate compounds opens a new stage in the development of coordination chemistry and asymmetric catalysis.
