Abstract. The review deals with chemical aspects of the problem of preparation of a novel class of advanced materials, viz., high-temperature superconducting cuprates of complex chemical composition and structure. Investigations into these types of superconductors not only made it possible to reveal the ‘composition–treatment–structure–property’ correlations, but also contributed significantly to the development of concepts of chemical interactions in complex oxide systems, high-temperature phase transformations, the nature of peritectic reactions, properties of cuprate melts and structural phase transitions. Particular attention is paid to the analysis of different experimental results obtained in the studies of features of physicochemical processes occurring in complex metal-oxide systems. The bibliography includes 292 references.

I. Introduction

Complex cuprates with a high transition temperature to the superconducting state were discovered more than 12 years ago and called high-temperature superconductors (HTSC).^{1–5} The discovery of HTSC has initiated fundamental investigations into their crystal structure and physicochemical properties as well as the search for possibilities of practical use of these phases.^{6–24}

From the chemical viewpoint, the history of superconductivity is a chain of discoveries of materials with more and more complicated structures and can be considered as specific ‘chemical evolution’ of these materials from simple to complex ones (Fig. 1). This dates back to 1911 when the Dutch physicist H Kamerlingh-Onnes first obtained liquid helium. This breakthrough has made it possible to systematically investigate the properties of materials at temperatures close to absolute zero. Kamerlingh-Onnes had established²⁵ that mercury metal known as a ‘bad metal’ completely loses electrical resistance at 4.2 K. In 1933, Meissner and Oxenfeld showed²⁶ that superconductors (SC) are simultaneously ideal diamagnetics, which means that they completely exclude the magnetic field lines from their own bulk.

Received 27 April 1999

Uspekhi Khimii 69 (1) 3–40 (2000); translated by A M Raevsky

Following the discovery of superconductivity, the common belief was that superconductors would find extensive practical applications. However, this is limited mainly because of a very low transition temperature to the superconducting state (the so-called critical temperature, T_c). In the mid-1980s, it has been possible to raise this temperature^{2, 12, 27, 28} to 23.2 K for Nb₃Ge intermetallic, despite the fact that commonly accepted theories of superconductivity (see, e.g.,²⁶) casted scepticism concerning the possibility of attainment of this high-temperature barrier.

In 1986, Bednorz and Müller²⁹ discovered that ceramics based on copper, lanthanum and barium oxides (La_{2–x}Ba_xCuO₄) can

Figure 1. Chronology of discoveries in the field of high-temperature superconductors.

undergo a transition to the superconducting state at 30 K. Mention should be made of studies by Lazarev, Kahan and Shaplygin³⁰ who synthesised complex cuprates of analogous composition in 1978 and of those by a group of researchers from France,³¹ carried out two years later. However, unfortunately, the electrical conductivity of these specimens was measured down to liquid nitrogen temperature (77 K) only, which precluded observation of the effect of superconductivity.

It should be emphasised that high-temperature superconductivity was first observed for an oxide ceramic, which usually possesses dielectric or semiconducting properties, rather than for conventional intermetallides, organic or polymeric structures.²⁶ This destroyed the psychological barrier to the synthesis of HTSC and allowed the synthesis of new generations of metal-oxide superconductors nearly simultaneously and over a short period. The brief history is as follows. In February 1987, using the idea of ‘chemical compression’ for structure modification, Wu *et al.*³² prepared a superconducting ceramic based on barium, yttrium and copper oxides ($\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$) with a critical temperature of 93 K, which is higher than the liquid nitrogen boiling temperature. In January 1988, Maeda *et al.*³³ synthesised a series of compounds with composition $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$. Among them, the phase with $n = 3$ had a T_c of 108 K. A month later, Sheng and Hermann³⁴ prepared a superconductor $\text{Tl}_2\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$ with $T_c = 125$ K. Finally, in 1993, Antipov, Putilin *et al.*^{35, 36} discovered a series of mercury-containing superconductors with composition $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+\delta}$ ($n = 1-6$). Currently, the $\text{Hg}1223$ -phase of this family has the highest T_c (135 K). It should be noted that at an external pressure of 350×10^3 atm the transition temperature increases to 164 K,^{12, 36} which is only 19 K lower than the lowest temperature ever reached under natural conditions on the Earth. These are the main stages of ‘chemical evolution’ of superconductors from mercury metal (4.2 K) to mercury-containing HTSC (164 K).

Currently, about 50 individual layered superconducting cuprates are known¹⁴ (Table 1). Sometimes, sensational information on the preparation of novel ‘copper-free’ superconductors with T_c above room temperature is reported. ‘Copper-free’ superconductors have been known for some time; however, no high transition temperatures to the superconducting state have yet been observed for these compounds (the highest T_c values for copper-free superconductors were reported for $\text{Ba}_{1-x}\text{K}_x\text{BiO}_3$ and fullerene-based intercalation phase Cs_3C_{60} ³⁷ (see Table 1).

A line of investigations associated with attempts to synthesise ‘ecologically safe’ HTSC free from heavy metals (Hg, Pb, Ba) deserves special mention. Oxycarbonate phases of Ca prepared under high pressure³⁸ can serve as an example of these HTSC.

Thus, most HTSC are oxide phases with very complicated chemical composition. These compounds are extremely sensitive to the conditions for synthesis, heat treatment and operating conditions; they are often called ‘chemical’ superconductors.¹⁴ Numerous studies were devoted to structural,^{12, 17, 18} physical,¹⁹ synthetic^{2-11, 13, 14, 20-22} and technological aspects^{15, 16, 23, 24} of preparation of HTSC materials; however, only very few of them consider all these problems simultaneously. It should be noted that studies of the processes accompanying preparation of HTSC-materials by different methods not only allow the solution of a practically important problem of revealing the ‘composition–treatment–structure–properties’ correlations, but also favours the progress of general chemical ideas of the nature of complex oxide systems, *e.g.*, of the interaction between their components, the effect of mutual rare-earth (RE) element substitution, high-temperature phase relations, the nature of peritectic reactions, the structure and properties of the cuprate melts, oxygen and cation nonstoichiometry of solid phases and structural phase transitions. In this regard, the principles of the synthesis of metal-oxide superconductors are of considerable interest to chemical sciences. This review deals with a systematic consideration of fundamental physicochemical problems related to the preparation of HTSC-materials as well as with analysis of

different experimental results obtained by researchers all over the world.

II. Characteristic features of high-temperature superconductors

1. The crystal structure

An analysis of the available data on the structure and composition of HTSC allows some generalisations to be made.^{14, 36} First, almost all HTSC are complex layered copper-containing oxides whose structure contains oxygen-deficient perovskite-like blocks (Fig. 2). The $(\text{Sr}, \text{Ca})\text{CuO}_2$ phase built of alternating blocks comprising alkaline-earth metal ions sandwiched with planar CuO_2 layers³⁸ is considered as a prototype of the oxide HTSC. It is the CuO_2 layers that are currently considered to be responsible for superconductivity in cuprates. In these layers, the copper atoms form a square network, whereas the oxygen atoms are placed on the lines connecting the copper sites. The electrons

Figure 2. Crystal structures of HTSC YBa₂Cu₃O₇ (a), Bi₂Sr₂CaCu₂O₈ (b), HgBa₂Ca₂Cu₃O_z (c). Dielectric (1) and oxygen-deficient (3) perovskite-like blocks containing superconducting CuO₂ planes (2) are shown.

of copper and oxygen atoms that form Cu–O bonds in such a layer ($3d_{x^2-y^2}$ and $2p_{xy}$ electrons, respectively) are delocalised, which means that they belong not to one but to all of the atoms in the layer. Therefore compounds comprising CuO₂ layers in their structure can possess a metallic-type conductivity. At temperatures below the critical temperature, superconductivity arises

Figure 3. Generalised physical phase diagram of a high-temperature superconductor depending on the relative concentration of charge carriers in the superconducting planes. Mark 1 on the abscissa axis corresponds to the state characterised by the maximum transition temperature to the superconducting state.

upon doping of the CuO₂ layers with an optimum amount of charge carriers (Fig. 3); this occurs upon ordering of oxygen atoms and vacancies after the high-temperature superconducting phase has achieved a certain oxygen stoichiometry, upon hetero-valent doping, upon applying an external pressure, *etc.*^{12, 16, 19}

It was experimentally established that manifestation of superconductivity requires that the formal oxidation state of copper in the CuO₂ layers with collective electrons be somewhat different from +2 and lie within the range from +2.05 to +2.25 for hole superconductors (123-, Bi- and Tl-families) or from +1.8 to +1.9 for electron superconductors^{2, 12} (phases of the Nd₂CuO₄ type). The Cu–O bond length in the layer is yet another important parameter determining the superconducting properties; this must be within the limits 0.190–0.197 nm provided that the distance between the nearest copper atoms lies in the range 0.380–0.394 nm. The copper atoms can also be bonded to the oxygen atoms in neighbouring layers; however, these bonds should be much longer and exceed 0.22 nm. In other words, the structure of superconducting cuprates contains inequivalent Cu–O bonds, *viz.*, strong in-plane bonds in each CuO₂ layer and much weaker bonds directed perpendicular to these layers. As a consequence, such superconductors have a layered structure, whereas the framework-type complex copper oxides (perovskites CuBO₃ with equivalent Cu–O bonds) possess no superconducting properties.

Electrical neutrality of crystals requires the presence of other charge-compensating layers or the presence of dielectric layers between superconducting CuO₂ planes. These interlayers consist of readily polarisable ions (*e.g.*, Ca²⁺, Sr²⁺ and Ba²⁺ ions) which, along with the holes in the CuO₂ layer, can form the Cooper pairs upon transition to the superconducting state.² Most of the known superconductors are built of alternating CuO₂ and BaO, SrO, TlO⁺, BiO⁺, Ca²⁺, Y³⁺, *etc.* layers. Changes in the number of CuO₂ layers in the structure give rise to homologous series of compounds with a similar structure (see Fig. 2). In this case, the crystal structure will be stable if each constituent layer is commensurate with the layers lying above and below a given layer.

This analysis of the genesis of the structure of different HTSC families is not only useful for finding a general approach to the description of the phenomenon of high-temperature superconductivity, but also favours a targeted search for and chemical design of novel superconductors.

2. Physical properties

In most cases, the practical applications of superconductors are associated with their capability to resist in the superconducting state the destructive action of a current density of $\sim 10^5$ A cm⁻² in magnetic fields from 2 to 10 T, while the first (ceramic) specimens of superconducting cuprates were characterised by more than modest critical current density^{8, 10} of ~ 1 –100 A cm⁻² (Fig. 4).

Currently, synthesis of superconducting phases with the desired crystal structure and T_c above the liquid nitrogen temperature can be accomplished without difficulty. However, the attainment of high values for other important parameters, *e.g.*, the critical current density J_c and its stability in an external magnetic field, faces great difficulties for a number of reasons. For instance, evolution from metallic to ceramic superconductors results in an increase in T_c and, at the same time, in a dramatic decrease in the coherence lengths of oxide superconductors¹⁹ compared to those of low-temperature intermetallide superconductors (0.2 nm and ~ 2 nm, respectively). The fundamental physical parameters of high-temperature superconducting YBa₂Cu₃O_z phase are listed in Table 2 as examples. As a consequence, the grain boundary thickness in polycrystalline metallic superconductors is commensurate with the coherence length, which favours the appearance of efficient pinning centres and an increase in the critical current. On the contrary, the superconduction current in oxide superconductors is to a great extent limited by processes occurring at grain boundaries; this is

Figure 4. Dependence of the stability of the critical current density on the external magnetic field at 77 K for different classes of HTSC materials; (1) sintered ceramics; (2) Bi2212 tapes; (3) single crystals; bulk melt-solidified ceramics: (4) Y123; (5) Nd123; (6) Y123 doped with ^{235}U and irradiated with slow neutrons and (7) thin films.

the reason why the demands imposed on the state of the intercrystallite boundary are so severe.^{9–11} The situation is complicated by the fact that, because of the specific layered structure, almost all high-temperature superconducting phases possess a very high crystallographic anisotropy of physical properties, which requires texturing of the polycrystalline material.¹¹

Additionally, HTSC are type II superconductors. In an external magnetic field, they can exist in the mixed state where the magnetic flux partly penetrates the superconductor in the form of the so-called Abrikosov fluxoids.¹⁹ As a rule, the vortex lattice thus formed becomes more stable if extra pinning centres are generated. It is assumed that each pinning centre is a distortion of the superconductor structure (a structural defect), the size of which is comparable with the coherence length.^{11, 19} Generation of efficient pinning centres in high-temperature superconducting

materials is necessary since the practical use of HTSC in the heavy-current devices requires not only high critical current densities, but also enhanced current stability in external magnetic fields.

3. Chemical behaviour

The preparation of modern high-temperature superconducting materials encounters considerable difficulties due to the complexity of their chemical composition and structure (and, as a consequence, to the thermal and chemical instability).²⁷ The fact that solid-phase (ceramic) synthesis of superconducting cuprates is simple and rapid, as well as giving a first preparation of defect-free (according to visual inspection) as-grown small single crystals only gave the deceptive impression that most problems had been left behind. However, conventional methods of solid-phase synthesis of HTSC appeared to be inefficient for the preparation of materials with the desired properties. Because of this, the development of melt solidification methods^{6–11} has begun. These methods are based on melt crystallisation under controlled conditions, which allows a complex treatment of the real structure of the material. It should be noted that almost all HTSC are characterised by incongruent melting and their melts are multi-component heterogeneous (containing both gaseous and solid phase along with the melt) open systems (participating in oxygen exchange with environmental gases), shifted apart from thermodynamic equilibria.

This can be exemplified in the family of high-temperature superconductors, *viz.*, $\text{RBa}_2\text{Cu}_3\text{O}_x$ phases (R123-phases, R is a RE element) studied in most detail. These complex cuprates are composed of such chemically different components as stoichiometric (with respect to oxygen) high-melting oxides of alkaline-earth and RE elements (BaO and R_2O_3) and a low-melting 'acidic' oxide of a transition metal (copper) in different oxidation states. As a result, the problem arises of oxygen nonstoichiometry, which requires consideration of the phase diagrams for quaternary $\text{R}_2\text{O}_3\text{--BaO--CuO}_n\text{--O}_2$ systems with complicated 'pO₂–temperature–composition' relations (especially in the region where the solid and liquid phases coexist) instead of conventional isothermal $\text{R}_2\text{O}_3\text{--BaO--CuO}$ phase diagrams. In addition, RE-element-for-barium substitution solid solutions can be formed because of rather large ionic radii of 'light' RE elements (La, Pr, Nd, Sm, Eu, Gd); their equilibrium composition in the supersolidus region is determined by the composition of the melt equilibrated with the solid solution.⁸ This complicates further the general pattern of phase relations and makes optimisation of the processes of preparation of high-temperature superconducting materials more difficult.

Thus, the main problems are (i) the formation of nonstoichiometric (with respect to both oxygen and cations) solid solutions with a preset composition, the degree of chemical homogeneity (*i.e.*, with a particular macroscopic and microscopic distribution of the solution components) and (ii) targeted formation of a real structure of high-temperature superconducting material which provides the desired set of 'structurally sensitive' properties. Accompanying (and sometimes no less important) problems are the investigation of the stability of this type of solid solution including the study of metastable states of high-temperature superconducting phases and their low-temperature decomposition,^{7, 8} the study of equilibrium phase diagrams of high-temperature superconducting systems,^{8–11} the effects of their prehistory and topochemical memory,^{39, 40} chemical degradation of HTSC,^{2, 22} procedures for the preparation of superconducting composites,^{2, 6, 13, 15, 16, 23, 24} *etc.*

III. Phase diagrams of high-temperature superconductors

Phase diagrams reflect the phase states and phase relations depending on the temperature, pressure and the concentrations of the components in the systems. Therefore, it is reasonable to begin the analysis of efficient methods for the synthesis of metal-

oxide superconductors with the most comprehensively and reliably studied $R-Ba-Cu-O$ systems in order to demonstrate general principles of the use of phase diagrams for the preparation of high-temperature superconducting materials. Investigations into the phase diagrams of a promising and technologically important $Nd-Ba-Cu-O$ system,^{7,8,16} which exhibits the salient features of the phase diagrams of cuprate superconductors in the supersolidus region seem to be the most interesting.

1. Subsolidus phase relations

a. Geometrical factors and phase stability

Most superconducting compounds are thermodynamically stable only in narrow ranges of temperature and partial pressure of oxygen; many of them are metastable under storage and operating conditions. Therefore, one can hardly find high-temperature superconductors (especially, among the last-generation materials) free from dopants stabilising their structure. As a rule, superconducting complex oxides are solid solutions with fairly wide homogeneity regions and comprise several elements with close crystallochemical characteristics. Internal structural strain is naturally relieved due to the difference in the ionic radii of the constituent elements.^{2,17,18,36} ‘Chemical’ deformation of the crystal structure of superconductors due to doping, as well as that caused by external pressure, can lead to essential changes in the superconductivity parameters due to changes in the distances between the superconducting planes and dielectric blocks and/or to the charge redistribution between them.^{41–45} Because of this, the consideration of geometrical factors seems to be of great importance. The following types of substitution affecting the properties of high-temperature superconducting phases and the phase relations in high-temperature superconducting systems can be distinguished, (i) variation of RE elements (R) in $R-Ba-Cu-O$ systems; (ii) Bi/Pb substitution in bismuth-containing HTSC; (iii) Hg/Pb, Hg/Re and Ba/Sr substitutions in mercury-containing HTSC;^{36,46,47} (iv) substitutions of alkaline-earth cations in binary and ternary cuprates; and (v) fluorination of $RBa_2Cu_3O_{z-j}F_j$ phases.⁴⁸

The simplest method for assessing the stability of oxide superconductors is based on the well-known Goldschmidt criterion for tolerance, according to which a perovskite-like structure $ACuO_3$ is stable² if $0.8 < t < 1$, where

$$t = \frac{r_A + r_O}{\sqrt{2}(r_{Cu} + r_O)}$$

and r are the ionic radii of the elements constituting the crystal lattice. The use of different REE is the most prominent example and important method of chemical modification of HTSC, since the radii of R^{3+} cations with close chemical properties monotonically decrease due to the effect of lanthanide contraction. Along with the differences in the magnetic moments of R^{3+} ions, energies of their stabilisation by the ligand crystal field and possible oxidation states (+4, +3 or +2), the above-mentioned geometrical factor provides an additional degree of freedom in the synthesis of superconducting phases.

Currently, almost all RE analogues of $YBa_2Cu_3O_z$ have been synthesised by isomorphous substitution of yttrium.^{7,12,18,22} As has been mentioned above, the unit cell of the $RBa_2Cu_3O_z$ phase can be represented as three perovskite-like blocks containing barium or yttrium ions at the centre (see Fig. 2). Phases of the $RBa_2Cu_3O_z$ type are characterised by two oppositely directed effects,⁴⁹ viz., by structure stabilisation towards simple oxides due to the coordination of barium ions and the formation of BaO_{10} polyhedra and by structure destabilisation owing to the formation of RO_8 , CuO_4 and CuO_5 polyhedra. Small ionic radii (R^{3+}) of ‘heavy’ REE and yttrium result in the ‘repulsion’ of oxygen ions in a smaller polyhedron (RO_8) and generation of steric hindrances. Almost no structure destabilisation effect is observed for ‘light’ REE with the largest ionic radii ($Nd-Gd$) in the case of

isomorphous isovalent replacement of the yttrium ion by its RE analogues.

The oxygen content, which affects both the concentration of the charge (hole) carriers in superconducting CuO_2 planes and the average $Cu-O$ bond length, is the second factor influencing the stability of high-temperature superconducting phases with the $YBa_2Cu_3O_z$ structure. It is noteworthy that the estimates of both the lower and upper limits of thermal stability of the phases under consideration^{50,51} suggest that tetragonal non-superconducting modifications ($RBa_2Cu_3O_6$) are more stable than the orthorhombic superconducting phases characterised by higher content of oxygen ($RBa_2Cu_3O_7$) and ‘holes’. The decrease in the thermal stability of solid solutions with partial substitution of REE cations for barium cations in the structure, in which the average oxidation state of copper increases in parallel to the increase in the degree of heterovalent substitution, is an additional confirmation of this hypothesis.

The two above-mentioned structure destabilisation factors should also be taken into account when analysing the ‘geometrical’ stability of bismuth-containing superconducting cuprates (see Fig. 2b).⁵² In these systems, almost all the most important phases are non-stoichiometric compounds with respect to all of the components. According to the data reported,^{53–55} the superconducting phase of the $Bi_2Sr_2CaCu_2O_z$ type (2212-phase) is Bi-excessive and (Ca + Sr)-deficient and the ‘ideal’ 2:2:1:2 composition seems not to be a single phase. The reasons for the existence of such a wide homogeneity region can be⁵³ (i) isomorphous substitution of calcium ions for strontium ions⁵⁶ and, to a lesser extent, partial hetero-valent substitution of strontium and calcium ions for bismuth ions; (ii) the formation of intergrowth structures with higher and lower homologues containing different amounts of calcium and copper and (iii) exchange between the crystallographic positions of bismuth and copper atoms due to the packing faults of the layered structure. Compared to $RBa_2Cu_3O_z$ phases in which the dielectric ‘barium’ block exhibits a fairly high ‘geometrical’ stability, the dielectric Bi_2O_2 blocks can additionally contribute to the structure destabilisation.

A formula was proposed⁵² for assessing the relative stabilisation of bismuth-containing HTSC with extra oxygen and with lead ions which replace bismuth ions in the structure

$$\frac{t}{t_0} = 1 + \left(\frac{\alpha}{y_0} + \frac{2\gamma}{nz_0} \right) \delta + \left(\frac{\beta}{y_0} + \frac{\gamma}{nz_0} \right) x.$$

Here t is the parameter of the criterion for ‘geometrical’ stability of a bismuth-containing high-temperature superconducting phase doped with lead and containing extra oxygen, t_0 is the analogous parameter for a ‘pure’ bismuth-containing high-temperature superconducting phase, α , β and γ are constants, n is the number of superconducting CuO_2 planes, δ is the amount of extra oxygen and x is the degree of lead-for-bismuth substitution.

It was assumed⁵² that the length of the ‘in-plane’ Bi–O bond is determined by the relationship

$$y = y_0 + \alpha\delta + \beta x,$$

whereas the $Cu-O(2)$ bond length is determined by the relationship

$$z = z_0 - \gamma h,$$

where h is the concentration of ‘holes’. According to calculations, the highest stabilisation of superconducting structure (especially at large n , i.e., for higher members of the homologous series) can be achieved, as in the case of 123-phases, if the internal structural strain is relieved by doping the oxide matrix with cations with large ionic radii (in this case, by doping with lead ions in the Bi_2O_2 block).

The virtually planar structure of the CuO_2 layers^{35,36} is a possible reason for the record transition temperatures to the

superconducting state for mercury-containing HTSC. Therefore the geometrical factors can directly affect fundamental superconducting characteristics of a system. Schematically, the structure of $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+\delta}$ phases can be represented as $(\text{HgO}_\delta)(\text{BaO})(\text{CuO}_2) \cdot [(\text{Ca})(\text{CuO}_2)]_{n-1}(\text{BaO})(\text{HgO}_\delta)$ layers stacked along the c axis of the unit cell.³⁶ These compounds have primitive tetragonal unit cells in which the parameter c increases as the thickness n of the perovskite fragment $c(\text{\AA}) = 9.5 + 3.2(n-1)$ increases.

The coordination of the copper atoms in CuO_2 layers varies from octahedral in the Hg1201-structure to tetragonal-pyramidal in the Hg1212-phase and to the square and tetragonal-pyramidal in the Hg1223-phase as the thickness of the perovskite fragment increases. The octahedra and tetragonal pyramids are appreciably elongated along the c axis due to Jahn–Teller distortion. Long Cu–O bonds between the copper atom and the axial oxygen atom and, correspondingly, a very weak interaction between these atoms in the coordination polyhedra of copper are the salient features of the structure of mercury-containing HTSC. On the other hand, a successive increase in the thickness of perovskite fragments owing to the incorporation of additional CaCuO_2 blocks results in compression of interatomic planar Cu–O distances in the structures of higher homologues. This can be interpreted as anisotropic ‘chemical’ compression and results in the distortion of the CuO_2 layers with an increase in n and in corrugation of their planarity. As a consequence, the highest homologues are characterised by lower transition temperatures to the superconducting state. This effect of anisotropic chemical pressure is several times stronger than that caused by external isotropic pressure.⁵⁷ Therefore, it can be suggested that the use of non-traditional methods of chemical synthesis (*e.g.*, layer-by-layer epitaxial deposition of thin films on the substrates with specially chosen parameters) rather than conventional isovalent cation substitution resulting in isotropic compression of the structure will be the most promising way for structure modification to achieve higher T_c . The use of these substrates can result in anisotropic deformation of the crystal lattice of a high-temperature superconducting phase.⁵⁸

A limited set of cations which constitute high-temperature superconducting phases along with copper and oxygen atoms is a factor that restricts the search for new superconducting materials. As has been mentioned above, this is associated with the necessity of meeting the conditions of commensurability of interatomic distances and electrical neutrality. The possibility of varying the composition of the anionic sublattice appreciably extends the area of search; this has been exemplified successfully with F^- anions, the crystalchemical characteristics of which are close to those of O^{2-} ions.⁴⁸ Incorporation of fluorine into the structure of the non-superconducting oxide $\text{YBa}_2\text{Cu}_3\text{O}_6$ results in its oxidation with the formation of the $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ phase with $T_c = 94$ K. In this case, several copper atoms in the structure have an octahedral environment consisting of four fluorine atoms and two axial oxygen atoms. In such a structure, the symmetry of the high-temperature superconducting phase remains tetragonal after oxidation because of the absence of ordering of the anions and oxygen vacancies in the CuO_2 plane of the dielectric (‘barium’) perovskite-like block. An increase in the coordination number of copper atoms is accompanied by strong Jahn–Teller distortion of the $\text{Cu}(\text{O},\text{F})_6$ octahedra, which is responsible for the appreciably larger parameter c of the fluorinated phase compared with that of its oxide analogue (12.8–13.2 vs. 11.8 Å, respectively).

Geometrical factors also affect the stability of the most important non-superconducting phases in the systems under consideration, in particular, that of binary and ternary cuprates containing RE and alkaline-earth elements.^{59–64} For instance, the formation of ‘blue’ phases of the $\text{Y}_2\text{Cu}_2\text{O}_5$ type (the 202-phase) is characteristic of REE of the yttrium group, whereas ‘light’ REE with large ionic radii form phases of the La_2CuO_4 type (the 201-phase).⁵⁹ ‘Green’ R_2BaCuO_5 phases with the framework structure, obtained for almost all REE, are stable in air up to

1250 °C.^{8,17,59,61} ‘Light’ REE with large ionic radii form the ‘422-phases’ with composition $\text{R}_{4-2x}\text{Ba}_{2+2x}\text{Cu}_{2-x}\text{O}_{10-2x}$ ($\text{R} = \text{La}, \text{Nd}$),^{59,61} which is associated with the formation of brown solid solutions rather than green substances at $0.15 \leq x \leq 0.25$ for $\text{R} = \text{La}$ and at $0 \leq x \leq 0.1$ for $\text{R} = \text{Nd}$, the latter being characteristic of the Y_2BaCuO_5 phase.

The changes in the ionic radii of alkaline-earth elements (Ba, Sr, Ca), whose binary cuprates play a special role in high-temperature superconducting systems, also result in essential changes in the phase diagrams.^{60,61,63} It is suggested that two cuprates with Ba : Cu ratios of 2 : 3 and 3 : 5 exist in the Cu-rich region of the phase diagram of the BaO–CuO system (see S.1).[†] Like BaCuO_2 , these cuprates can formally be considered as compounds belonging to the BaO–CuO–‘ Cu_2O_3 ’ system since they have a rather wide oxygen homogeneity region (see S.2). An increase in the temperature and a decrease in the p_{O_2} results in decomposition of $\text{Ba}_2\text{Cu}_3\text{O}_5$ and $\text{Ba}_3\text{Cu}_5\text{O}_8$ with the liberation of CuO and the formation of BaCuO_2 , which is stable in air up to ~ 1015 °C (at this temperature, the compound melts with the evolution of oxygen).

Barium cuprate Ba_2CuO_3 , which is thermally stable at high p_{O_2} , is found in the Ba-rich region of the phase diagram of the BaO–CuO system. Cuprite BaCu_2O_2 containing monovalent copper is the only phase stable at reduced partial pressure of oxygen and/or at high temperatures. The phase relations in the Ca–Cu–O system exhibit some specific features as compared with Sr–Cu–O and Ba–Cu–O systems, which is probably due to the impossibility of calcium ion, which has the smallest ionic radius among alkaline-earth metal cations, to stabilise Cu^I and Cu^{III} .^{22,23,61} No stoichiometric quaternary compounds were found in the Sr–Ca–Cu–O system, whereas the stability of solid solutions of mixed strontium and calcium cuprates is determined by the temperature and partial pressure of oxygen, as in the case of the Ba–Cu–O system. At high p_{O_2} and moderate temperatures, the cuprate $\text{Sr}_{14-x}\text{Ca}_x\text{Cu}_{24}\text{O}_{41+\delta}$ is stable. An increase in temperature and/or a decrease in p_{O_2} results in sequential formation of the cuprate phases $\text{Sr}_{1-x}\text{Ca}_x\text{CuO}_2$ (1 : 1) and $\text{Sr}_{2-x}\text{Ca}_x\text{CuO}_3$ (2 : 1) and the cuprite $\text{Sr}_{1-x}\text{Ca}_x\text{Cu}_2\text{O}_{2+\delta}$ (1 : 2).

Perhaps the most spectacular example of changes in the phase relations caused by geometrical factors is represented by R–Ba–Cu–O systems. There are three main types of quaternary isothermal cuts of the subsolidus phase diagrams of these systems.⁶² The simplest type (Fig. 5a) is characterised by the presence of a ‘point’ $\text{RBa}_2\text{Cu}_3\text{O}_z$ phase formed by ‘heavy’ REE of the yttrium subgroup with the smallest ionic radii (Y, Dy, Ho, Er, Tm, Yb, and Lu), though the phase relations for Yb and Lu can have some peculiarities due to relative instability of the 123-phases.⁶³ Solid solutions of the $\text{R}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ type (Fig. 5b) are formed in systems with ‘light’ REE with large ionic radii (La, Nd, Sm, Eu, and Gd). In these systems, the variation of the composition of non-superconducting (secondary) phases, which play a significant role in the processes of peritectic melting and crystallisation, and of the equilibrium tie-triangles depends on the ionic radii and nature of the REE. The third type of phase relations (Fig. 5c), which differs from the two preceding cases in the absence of the phase of the 211/422-type,^{61–63} is characteristic of the Pr–Ba–Cu–O system. In the Pr- and Ba-rich region, the Pr_{123}ss phase is in equilibrium with the $\text{Pr}(\text{IV})$ -containing phase of the PrBaO_3 type. No compounds with the 1 : 2 : 3 stoichiometric composition are formed in systems containing Ce and Tb for which the most characteristic oxidation state is +4.⁶¹

Systems $\text{Bi}(\text{Pb})\text{–Sr–Ca–Cu–O}$, $\text{Tl–Ba}(\text{Sr})\text{–Ca–Cu–O}$ and $\text{Hg}(\text{Re},\text{Pb})\text{–Ba}(\text{Sr})\text{–Ca–Cu–O}$ are quinary or even septenary, therefore their phase diagrams are extremely com-

[†] The letter S denotes Supplement which contains notes added in proof (the results reported when preparation of the manuscript was completed as well as the results obtained in recent studies and accepted for publication elsewhere).

The volatility of metal-containing components further complicates the problem of stabilisation of these structurally complex superconducting phases. If the doping of phases in the Bi—Sr—Ca—Cu—O system with lead oxides can be considered mostly as a convenient procedure for enhancing the formation dynamics of higher homologues of metal-oxide SC,^{53, 69} the search for possibilities of stabilisation of the structure of mercury-containing HTSC (*e.g.*, by doping with rhenium,^{36, 68} lead and/or strontium^{46, 47, 65} compounds) is of prime importance.

In early studies, metastability of superconducting phases was often considered as the condition for the existence of high-temperature superconductivity;^{1,2} however, the results of modern investigations do not confirm this assumption. Nevertheless, the problem of chemical metastability of high-temperature superconducting phases still remains topical, since this can have both negative and positive consequences from the practical viewpoint. Generally, this is associated with the analysis of the evolution of states of a supersaturated (with respect to one or several components) solid solution under given conditions.

Figure 6. Types of phase diagrams of the Bi–Sr–Ca–Cu–O system (at $p_{\text{O}_2} = 0.21$ atm); (a) polythermal section along $\text{Bi}_2\text{Sr}_2\text{CuO}_6$ – $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$; phase relations in a quasi-quaternary system Bi_2O_3 – CaO – SrO – CuO at 850 (b) and 910 °C (c).

Phase relations in systems containing 'light' REE (La, Pr, Nd, Sm, Eu and Gd) are very complicated because of the formation of solid solutions of the $\text{LR}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ type; difficulties in synthesising several phases of the stoichiometric 123-composi-

Figure 7. tion containing REE (La, Nd and Sm) have also been reported.^{7, 8, 70–79} It was shown that the homogeneity region of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution becomes narrower near the composition $\text{NdBa}_2\text{Cu}_3\text{O}_z$ as the temperature decreases⁷⁵ and near the composition $\text{Nd}_2\text{BaCu}_3\text{O}_z$.^{63, 76, 78–81} In any case, the system becomes thermodynamically unstable as regards solid-phase decomposition in the region of subsolidus equilibria⁸² (see S.3).

This problem is of interest first of all owing to pronounced variation of the superconductivity parameters of the metastable $\text{R}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution depending on its state. Of great importance is also the degree of homogeneity of this solid solution, which depends on the preparation conditions and subsequent heat treatment. For instance, an increase in the parameter x of a solid solution homogeneous at the unit cell level can result in disordering of the oxygen sublattice in the basal plane due to the presence of additional amounts of REE^{7, 8, 76, 83–90} and in a reduction of the T_c value. If a solid solution decomposes with the formation of a heterogeneous mixture of particles of different compositions upon heat treatment, a mechanical mixture of phases with individual characteristics will be detected. A nanocomposite in which chemical inhomogeneity exists at a level comparable with the size of tens of unit cells can exhibit a fairly high T_c and nonlinear field dependence of superconducting properties (see Fig. 4).

It was reported that macroscopic phase segregation can occur in an atmosphere of elevated partial pressure of oxygen as a result of decomposition of supersaturated solid solution with the formation of barium cuprate.⁷⁶ The specific behaviour of single crystals on heat treatment⁸ is most probably due to a fundamentally different mechanism, which manifests itself, in particular, in the formation of a quasi-periodic tweed structure and in quasi-periodic spatial modulations of the ratio of concentrations of the elements constituting the single crystal (the so-called ‘compositional waves’). For instance, the Ba:Nd ratio in $\text{NdBa}_2\text{Cu}_3\text{O}_z$ varies from 2.0 to 0.7 (Fig. 8). Spinodal decomposition of the

$\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution, *i.e.*, its instability towards small fluctuations of x , resulting in phase demixing and eventually in the formation of coherent domains with appreciably different chemical composition, was suggested to be a possible reason for these changes.⁸ Reduction of temperature enhances the driving force of decomposition; however, its rate can be low because of extremely slow diffusion of components (the maximum rate of the process was experimentally observed at ~ 500 $^{\circ}\text{C}$, see also S.3). The possibility for spinodal decomposi-

Figure 8. Quasi-periodic nanoscale fluctuations of the composition of $\text{NdBa}_2\text{Cu}_3\text{O}_z$ single crystals after low-temperature treatment at $p_{\text{O}_2} = 1$ atm. The composition of crystal matrix without nanoscale fluctuations (1, open circles) and with nanoscale fluctuations (2, filled circles); (3) variations of composition that should be observed upon the formation of interphase boundaries between the particles of decomposition products and the crystal matrix into which they are incorporated.

tion to occur was inferred from the experimental results obtained for the specimens prepared by zone melting⁹¹ and large-grain ceramics;^{70,92} it was also postulated (based on the data on the equilibrium phase diagrams⁸⁰) for a model of a regular-type solution with a high positive energy of interaction between the components ($\sim 40 \text{ kJ mol}^{-1}$).

Structurally, the segregation of a $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution can be represented as a local change in the occupation of the barium sites in the $\text{NdBa}_2\text{Cu}_3\text{O}_z$ structure, which results in the ordering of Nd^{3+} and Ba^{2+} ions in the BaO layer. The macroscopic picture of this phenomenon can be considered using the results of studies of the structure and properties of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution with a different degree of substitution (x).^{76,78,89,90} This substitution has two salient features. First, it is hetero-valent ($\text{Nd}^{3+} \rightarrow \text{Ba}^{2+}$, the 'hole' redistribution in the structure); second, this leads to the substitution of a smaller neodymium ion for larger barium ion (the ionic radii are 1.11 and 1.35 Å, respectively; internal 'chemical pressure').

The entropy of mixing of an ideal solution based on the $\text{NdBa}_2\text{Cu}_3\text{O}_z$ phase and a hypothetical compound $\text{NdNd}_2\text{Cu}_3\text{O}_z$ should be maximum for the composition $\text{NdBaNdCu}_3\text{O}_z$ (the Nd213-phase) (Fig. 9). Therefore, from the viewpoint of the entropy factor, the formation of a continuous series of $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solutions with statistical distribution of Nd^{3+} and Ba^{2+} ions at the barium positions is the most favourable up to $x = 1$. However, the thermal stability of such a solid solution decreases as the degree of substitution x increases, *i.e.*, compression of the structure can result in a decrease in the formation energy of the crystal lattice due to the internal steric strain.^{76–81} The formation of the solutions with $x > 1$ is unfavourable both from the viewpoint of energy factors and because of the decrease in the contribution of the entropy of mixing.

Such an approach makes it possible to consider the solutions with $x = 1$ as a 'boundary' between real and hypothetical solid solutions. If the contributions of the entropy and energy factors are close, a distortion (puckering) of planar fragments of the structure can occur at $x \approx 1$, resulting in a new type of atomic ordering and in a reduction of the symmetry of the structure.^{78,89,90} Despite the fact that such a structural transition results in a decrease in the entropy of the system, a gain in the free energy owing to the increased energy of the lattice formation can be obtained in the case of partial relief of internal strain caused by the 'chemical pressure'. Therefore, different types of cation ordering can be observed within the homogeneity region of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solutions, which is also accompanied by changes in the oxygen sublattice.

The results of investigations of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution ($0 \leq x \leq 0.9$) by X-ray diffraction (XRD) and Raman

Figure 9. The effect of chemical pressure on the change in the structure of $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution.

Figure 10. Results of investigations of $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solutions by X-ray diffraction (a) and Raman spectroscopy (b); (a): unit cell parameters: (1 and 4) a ; (2 and 5) b ; (3 and 6) $c/3$; (1–3) quenching; (4–6) oxidation; (b): (1 and 2) the Raman shift; (3 and 4) broadening of an apical oxygen vibration mode (β); (1 and 3) oxidation; (2 and 4) quenching.

spectroscopy (RS) are shown in Fig. 10.^{89,90} The range of variation of x may conventionally be divided into three intervals, *viz.*, $0 \leq x \leq 0.3$, $0.3 \leq x \leq 0.6$ and $0.6 \leq x \leq 0.9$.⁷⁶ The specimens for which the degree of substitution x varies within the first interval have tetragonal or orthorhombic crystal lattices; the unit cell parameters a and $c/3$ ($a < c/3$) regularly decrease due to replacement of the Nd^{3+} ions of a smaller radius for the Ba^{2+} ions. The unit cell of the tetragonal phase ($a = c/3$) of the solid solution with x values within the second interval is characterised by an 'isotropic' compression of the unit cell, which occurs as x increases. An orthorhombic distortion of the unit cell is observed for compositions within the third interval. This distortion is retained even in the high-temperature region.^{81,89}

It was established in structural studies^{76,78,89,90} that the 123- and 213-phases[‡] are characterised by different types of ordering of the Nd^{3+} and Ba^{2+} cations, namely, 'vertical' ordering with the formation of uniform cation layers (Fig. 11) occurs in the former, whereas 'horizontal' superstructural ordering of barium ions and neodymium ions which replace the barium ions occurs in the latter. The appearance of a structure consisting of alternating chains of barium ions and those of neodymium ions that occupy the barium positions predetermines the ordering of oxygen ions. One of the oxygen positions along the shortest axis (b) in the high-temperature orthorhombic modification of the 213-phase is only partly occupied. Ordered rows of CuO_5 pyramids could be formed

[‡] In the phase diagram, they are terminating points of the existence region of solid solutions.

Figure 11. Different types of cation ordering in the structure of $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution; (a) vertical Nd/Ba ordering; (b) cation and anion disordering and (c) in-plane Nd/Ba ordering. The solid solution with composition $x = 0$ and $z = 7$ is denoted as '123', that of composition $x = 0.5$ is denoted as '336' and that of composition $x = 1$ and $z > 7$ is denoted as '213'; symbol O* corresponds to the position with variable occupation by oxygen atoms.

in the 'former' [BaO] block in the ideal (most oxidised) structure; however, a more complicated superstructural ordering in the real low-temperature orthorhombic modification of the 213-phase is observed. The temperature dependence of the oxygen content has an apparent sigmoid shape, which probably reflects this structural transition (at 700–720 °C in air⁸⁹) (see S.4).

The solid solution of intermediate compositions ($0.3 < x < 0.6$, the 336-phase) is tetragonal. Unlike the 123-phase, the 'vertical ordering' in this phase is distorted and a fraction of additional neodymium ions occupies the barium positions. At the same time, 'horizontal' ordering of cations in the barium positions does not occur yet in the 336-phase, which differentiates this phase from the 213-phase and results in disordering of the cationic sublattice.^{84–90} A maximum on the curve of the dependence of apical oxygen mode broadening in the Raman spectra on the composition of solid solution (see Fig. 10) corresponds to disordering of the oxygen sublattice.⁹⁰ It should be noted that analogous structural transformations result in changes in the hole distribution,^{84,87} which also pertains in greater degree of substitution in solid solutions. In this case the hole concentration in the superconducting CuO_2 planes decreases (the average, 'collective' charge of the plane decreases), whereas the average oxidation state of the copper atoms in the CuO_y plane of the dielectric (Nd,Ba)O block increases (see S.5).

Phase 'separation' of HTSC is a common phenomenon, which should be taken into account when analysing the phase relations in all the systems in question. For instance, it was postulated⁹³ that nonuniformity of oxygen distribution in the Y123-phase at a microscopic level is due to the spinodal decomposition. Low-temperature annealing of a single-phase solid solution $(\text{Bi,Pb})_2\text{Sr}_2\text{CaCu}_2\text{O}_z$ in the preparation of a bismuth-containing 2212-phase enriched with lead⁹⁴ resulted in its solid-phase decomposition with the formation of a lamellar nanostructure with alternating domains enriched with and depleted of lead. This decomposition should be extremely slow because of the low rate of cation diffusion, the necessity of overcoming the energy barriers associated with the formation of a solid-solid interface and elastic deformation of the matrix for phases with different molar volumes and crystal structure.^{8,75,82} In accordance with the Ostwald rule, the degree of supersaturation of a solid solution can be partially reduced in several intermediate steps, where a coherent or semi-coherent interface is formed in the matrix of the initial phase rather than requiring that the energy barrier to hetero-phase nucleation of a new phase is to be overcome. Differences in the lattice parameters of solid solutions of different compositions give rise to local structural strain.⁷⁵

Obviously, this problem requires studies of the initial stages of phase decomposition ('ageing' of the supersaturated solid solution) and construction of the so-called TTT (Time–Temperature–Transformation) diagrams for different initial states of solid solutions (ceramics, single crystals, films) as in the case of many alloys used in metallurgy.⁸² Mention may be made that solid-phase decomposition of HTSC can significantly improve certain practically important characteristics; in particular, this can be used for targeted formation of microscopic structural defects capable of acting as efficient pinning centres.^{7,8,94}

2. Phase relations in the supersolidus region

a. The use of the Gibbs phase rule

Experimental studies of phase relations in the supersolidus region and the development of realistic models of phase diagrams which fulfil the Gibbs phase rule are necessary for devising efficient methods for the preparation of high-temperature superconducting materials.^{8,9,53,61,64,74,75,95}

Experimental data on complex cuprate systems which would allow reliable calculation of the phase diagrams are extremely insufficient. Often, experimental phase diagrams (especially in the supersolidus region) are reported as being 'schematic' or 'tentative' ones, since they do not often fulfil the Gibbs phase rule. Nevertheless, several basic and doubtlessly reproducible characteristics (*e.g.*, melting temperatures and eutectic compositions) that are of great importance can be distinguished.^{61,95} The Y–Ba–Cu–O, Nd–Ba–Cu–O and Bi–Sr–Ca–Cu–O systems are a few examples of comprehensively studied high-temperature superconducting systems for which three-dimensional^{78,81,96,97} or multidimensional⁶⁴ models have been proposed for the description of phase relations.

Numerous experimental studies^{96–108} and reviews^{13,21,22,63,100–102} have been devoted to the investigation and description of the phase diagram of parent Y–Ba–Cu–O system containing the high-temperature superconducting Y123-phase characterised by a very narrow cation homogeneity region. In particular, ~ 11 invariant reactions involving the melt (L) were found in the phase diagram of this system in the supersolidus region,⁹⁶ *e.g.*,

(a ternary eutectic at 890 °C with the liquid phase composition Y : Ba : Cu $\approx$ 1.0 : 32.5 : 66.5),

(a binary eutectic at 910–920 °C, ~ 69 mol. % – 71 mol. % of CuO),

(near 940 °C with the liquid phase composition Y : Ba : Cu $\approx$ 2.0 : 23.0 : 75.0),

(at ~ 1015 °C) and the peritectic decomposition reaction at 1000–1015 °C

However, it should be noted that the peritectic decomposition temperature (T_p) of the Y123-phase appreciably decreases at low partial pressure of oxygen^{8,13,100,107} and increases at high pressure of oxygen (1–3000 atm), the phase relations in the system being changed in the latter case.¹⁰⁸ In both cases, the mechanism of decomposition of the 123-phase is also changed. Therefore, the simplified consideration of reaction (1) is incorrect. The peritectic decomposition reaction should be written as

where S and O₂ denote the melt, ‘secondary’ solid phases and the gaseous phase (oxygen), respectively.

Therefore, the Y₂O₃–BaO–CuO–O₂ system should be considered as a quaternary system for which four phases (two solid phases, one liquid and one gaseous phase) are in equilibrium at the peritectic decomposition point of YBa₂Cu₃O_z. Obviously, such an approach makes it possible to fix the partial pressure of oxygen in the gas phase ($p_{\text{O}_2} = \text{const}$). An assumption can be made which is useful in studying many high-temperature superconducting systems that the gas phase consists of the only component (oxygen) and, therefore, the total pressure $p_{\text{tot}} = p_{\text{O}_2}$. This is incorrect in the case of thallium- and mercury-containing HTSC (see above). Hence, the transformation (2) can be conditionally considered monovariant at $p_{\text{tot}} = p_{\text{O}_2} = \text{const}$. In fact, a particular temperature of ‘melting’ (decomposition) of the 123-phase at fixed partial pressure of oxygen in the gas phase is observed, since it is necessary to introduce an additional condition (the cation stoichiometry), which imposes restrictions on the composition of the solid phase which undergoes decomposition.

This assumption is also valid if the decomposition of a solid solution follows the scheme^{76–81}

A substitution solid solution virtually degenerates into the stoichiometric 123-phase ($x \rightarrow 0$) at temperatures near peritectic melting. If both the cation composition (x) of the phase that undergoes decomposition and the partial pressure of oxygen are fixed, the experimentally determined peritectic decomposition temperature should have a unique value.

Interpretation of phase equilibria in R–Ba–Cu–O (R = Nd, Sm) systems would be incomplete without considering the recently reported data⁸¹ which suggest the existence of a five-phase equilibrium in the Nd-rich corner of the phase diagram.

Obviously, this equilibrium is invariant at fixed p_{O_2} (see S.6).

Investigation of bismuth-containing high-temperature superconducting systems also confirms the necessity of considering all restrictions imposed on the system and thus reduce the number of degrees of freedom. As in the case of Nd_{1+x}Ba_{2-x}Cu₃O_z system, the composition of phases that can be in equilibrium with the high-temperature superconducting phase at the point of peritectic decomposition, as well as the corresponding decomposition temperatures differ depending on the stoichiometric ratios of the cations constituting the high-temperature superconducting phase and on the p_{O_2} value in the gas phase. Consequently, the peritectic decomposition products of the Bi2212-phase (Bi_{2+δ}Sr_{2-x}.Ca_{1+x}Cu₂O_z) usually include different bismuthates [CF = Bi₂(Sr,Ca)_{3+n}O_{6+n}], alkaline-earth cuprates [AEC = (Sr,Ca)_nCu_mO_z] and a melt. Melting and crystallisation of

bismuth-containing composites are strongly affected by silver metal used as the sheath of ‘long-length’ tapes; the solubility of silver metal in the melt can reach up to 4 at. %–5 at. %.^{23,53,54,64} Therefore, the process of peritectic decomposition in this system can be represented as a six-phase equilibrium.

Practically, it is important that the partial pressure of oxygen changes not only the composition, but also the composition-dependent morphology of particles of the AEC and CF phases which coexist with the melt^{23,54} and, hence, the resulting microstructure of high-temperature superconducting tapes. It is obvious that a simplified analysis of the process (5), *e.g.*, without considering the effect of gaseous atmosphere (O₂) or silver, can lead to failures in developing new procedures for the preparation of bismuth-containing HTSC.

b. The surface of the liquidus

A realistic model of a phase diagram of a system in the super-solidus region is constructed on the basis of determination of melt composition and using the results of an analysis of the composition of the equilibrium solid phases. The solubility of REE oxides in cuprate melts was studied by differential thermal analysis (DTA), the dissolution-extraction method, quenching experiments, the ‘last droplet’ method, high-temperature microscopy and liquid-phase epitaxy (LPE) and single-crystal growth experiments.^{78–81,109–116} Unfortunately, in some instances the complexity of peritectic reactions, slow dynamics of establishing a true equilibrium with the gas atmosphere, supercooling of the melt, corrosion of crucibles used and contamination of the melt with impurities can make the results of DTA studies incorrect. The use of a direct melt sampling procedure during the quasi-equilibrium heating and cooling of melt in a temperature-controlled chamber made it possible to appreciably increase statistical representativeness and reliability of the results.^{109,111,113,114}

Generally, the solubility of REE oxides in a melt increases with an increase in temperature and partial pressure of oxygen, as well as in the case of REE with large ionic radii and at high copper oxide content.^{109,114} Tendencies of changes in the slope of the liquidus near T_p observed on going to REE with large ionic radii and on increasing p_{O_2} are similar. Practically, of most interest are the solubility of REE oxides and changes in the slopes of the liquidus near T_p , which make possible the prediction of the features of crystallisation in the systems under consideration. For instance, the content of yttrium in the melt at the peritectic decomposition temperature of the Y123-phase increases from 0.4 at. % at $p_{\text{O}_2} = 0.01$ atm (at 985 °C) to 0.6 at. % at $p_{\text{O}_2} = 0.21$ atm (at 1005 °C) and to 0.7 at. % in pure oxygen (at 1030 °C), whereas the neodymium content at $T_p = 1086$ °C (at 0.21 atm O₂) is several times higher (3 at. %). The content of neodymium in melts with high concentration of copper oxide can differ from that of yttrium by an order of magnitude (~ 7 at. % Nd at 1065 °C in air for the melt with a Cu : Ba ratio of 6 : 1).¹⁰⁹

Analysis of the solubility curves makes it possible to evaluate several important parameters, *viz.*, the dissolution enthalpy of the solid phase (it is determined from the slope of the liquidus),^{109,113–115} the peritectic decomposition temperature of the solid phase (it is determined from the bending of the solubility curve, since the dissolution enthalpies of 123- and 211-phases are different),^{113,114} the Gibbs standard energy of a peritectic reaction (when determining the solubility limits at different p_{O_2}).¹¹¹

The dependences of solubility of REE oxides on the ‘geometrical’ stability of R123-phases, which is determined by the ionic radius of REE, are shown in Fig. 12.^{8,63,81,113,114} As can be seen, the thermal stability of phases, characterised by the peritectic decomposition temperature, and the thermodynamic stability associated with the dissolution enthalpy of the solid phase in a melt increase as the ionic radius of REE increases. The same reason is also responsible for an increase in the ability of the melt to exist in the supersaturated state, since the smaller the slope of

Figure 12. Dependences of thermal (T_p) and thermodynamic (ΔH) stability of $\text{RBa}_2\text{Cu}_3\text{O}_2$ -phases on the ‘geometrical’ stability of their crystal lattices (t) (at $p_{\text{O}_2} = 0.21$ atm); T_p is the peritectic temperature; ΔH is the dissolution enthalpy of R123 in the $\text{BaO} : \text{CuO} = 3 : 5$ melt; ε is the slope of the liquidus near T_p , which characterises the tendency to supersaturation; t is the Goldschmidt tolerance factor which reflects the ‘geometrical’ stability of the lattice.

the liquidus near the peritectic decomposition temperature, the higher the supersaturation at a given supercooling of the melt and the larger the amount of the substance that can be solidified. As has been mentioned above, these changes are explained by stabilisation of a defect perovskite-like lattice of 123-phases upon introduction of REE ions with large ionic radii (except for praseodymium, which drops out of the common dependence).

Establishment of the composition of the solid phase that is in equilibrium with a given melt is the key problem in the analysis of the liquid phase composition. Obviously — and this is of prime importance — knowledge of the liquid phase composition permits control of the structure and properties of the solid solution that directly depend on its composition. Actually, according to the Gibbs phase rule, the number of degrees of freedom for the ' $\text{R}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z + \text{L} + \text{O}_2$ ' equilibrium is $4 - 3 + 2 = 3$. Therefore, at a fixed temperature and partial pressure of oxygen, the solid phase composition is unambiguously determined by the melt composition. The dependences, which in combination with the equilibrium phase diagram can be used for predicting the composition of a solid solution with the maximum substitution degree, which can be crystallised from a melt of prescribed composition at a fixed temperature and partial pressure of oxygen, are shown in Fig. 13.⁷⁸⁻⁸¹

Distribution of the neodymium oxide between the solid solution and the melt is the most sensitive parameter of the equilibrium under consideration.^{80,81} The maximum on the curve of the content of neodymium oxide in the melt (see Fig. 13) is due to the influence of two oppositely directed factors, *viz.*, an increase in the neodymium content in the melt on an increase in the temperature and simultaneous decrease in the solubility limit of neodymium on the shift of the melt composition towards the BaO-rich region where a more thermally stable, less-substituted solid solution turns to equilibrium. In fact, the curve under consideration is a projection of the spatial trajectory of the point of ternary equilibrium 'Nd123ss-201-L' on the 'temperature-composition' plane. The equilibrium melt compositions of the solid solution depleted of and enriched with neodymium are strongly different and are shifted towards the region of Cu-rich compositions (Cu:Ba = 7:6 $\approx$ 5:3 for the 123-phase and Cu:Ba = 16:3 for the 213-phase). Quantitative analysis of the effects of the liquidus curvature near the '123-phase-melt' equilibrium showed that the substitution $x \approx 0$ is achieved in the

Figure 13. Temperature dependences of the Cu:Ba ratio (1), NdO_{1.5} content (2) in melt L and the (1 + x) parameter (3) of the solid phase of the Nd_{1+x}Ba_{2-x}Cu₃O_z solution coexisting in two-phase ‘Nd_{1+x}Ba_{2-x}Cu₃O_z + L’ equilibrium (at pO₂ = 0.21 atm). Numbers on curve (3) are the values of the parameter x.

case of crystallisation from melts enriched with barium oxide and on lowering the crystallisation temperature.⁷⁹

c. Characteristic features of polythermal sections

Technologically, the quasi-binary system ' $\text{Ba}_3\text{Cu}_5\text{O}_8$ '– $\text{Nd}_4\text{Ba}_2\text{Cu}_2\text{O}_{10}$ (Fig. 14*a*) is the most important since the compo-

Figure 14. Most practically important quasi-binary polythermal sections of the Nd–Ba–Cu–O system (at $p_{O_2} = 0.21$ atm).

sitional point of the 123-phase belongs to this section. This can significantly simplify the consideration of transformations in this system. Investigations into phase relations in the vicinity of the 123-phase showed that the region of two-phase 'Nd123-phase-liquid' equilibrium in air lies in the temperature range 970–1090 °C (at $p_{O_2} = 0.21$ atm).^{110–113}

The region of solid solutions based on the 123-phase belongs to another important $BaCuO_2$ –'Nd₂CuO₄–CuO' quasi-binary section (Fig. 14b).^{63, 76, 78} Invariant transformations involving the liquid phase ($MS_1 \sim 1000$ °C, $M'S_2$, 990 °C) characterise the highest probability of synthesising the solutions with the minimum (S_1) and maximum (S_2) substitution degrees. However, if the reaction with the 213-phase is fairly well studied,^{78, 81} it is difficult to carry out quantitative studies of equilibria with the 123-phase because of the very large slope of the solidus in the vicinity of the (S_1) point.^{75, 79} It should be noted that the appearance of a liquid in this section with the increase in the temperature near the 123-phase is explained by the melt field propagation towards the $BaCuO_2$ phase. According to the reported data,^{78–81} the increase in temperature shifts the composition of the melt which is in equilibrium with 123- and 422-phases away from the point corresponding to barium cuprate because of the extension of the two-phase '422 + L' field. The maximum peritectic decomposition temperature of the 123-phase (S , ~ 1085 °C) is achieved for those compositions that somewhat deviate from the ideal 123-phase (partial substitution of Nd for Ba). This fact is mistakenly ignored in some communications.

The composition of a solid solution with the maximum peritectic decomposition temperature T_p returns almost completely to the 123-composition only after appreciable reduction of the partial pressure of oxygen.⁷⁵ For instance, the composition of the solid solution with the maximum T_p is characterised by $x \approx 0.1$ in oxygen, $x = 0.05$ in air and $x \approx 0.0$ at $p_{O_2} = 10^{-3}$ atm. No solid solution based on the 123-phase is present in the system above the maximum temperature of peritectic decomposition (the '422 + L' field). Below this temperature, the solid solution region is 'gripped' from both sides by the '422 + Nd123ss + L' three-phase field. At 1060 °C, the '422–Nd123ss–L' tie-triangle becomes geometrically impossible for compositions with $x > 0.6$ ⁸¹ and a decrease in temperature leads to establishment of equilibrium between the most neodymium-rich solid solution, neodymium cuprate and the melt. The slope of the solidus changes correspondingly.⁸⁰ As has been mentioned above, below 990 °C the solid solution is in equilibrium with other two solid phases (CuO and Nd_2CuO_4).

Thus, this type of systems is characterised by the following qualitative features.

1. The region of the solid solutions based on high-temperature superconducting phases can be rather extended. The problems of determining the composition of solutions with the lowest substitution degree and of the existence of solutions with Ba^{2+} substitution for R^{3+} in R – Ba – Cu – O systems (see Refs 7, 63, 76, 117) are poorly studied.

2. The decomposition temperature of a solid solution can vary over a wide range depending on its composition. This is probably associated with the complicated character of the cation ordering within the homogeneity region. The shape of the solidus near the maximum T_p (a sharp or flattened maximum) can provide information on the type of the solid solution, daltonide or berthollide that is formed.

3. As a rule, the reduction of p_{O_2} results in a change in the shape of the homogeneity region of the solid solution. In particular, the decomposition temperature of the solid solution and the slope of the solidus are changed and a narrowing or (more rarely) broadening of the homogeneity region is observed.

4. The compositions of equilibrium phases in the supersolidus region are different, which depends on the composition of the solid solution based on the high-temperature superconductor. Particular emphasis should be placed on quantitative determination of the equilibrium tie-lines in the 'solid solution–melt' two-

phase region. Each tie-line is unique; therefore, the choice of a particular compositional point on the phase diagram (all other conditions being constant) determines not only the possible type and weight ratio of the coexisting phases, as in the case of the Y – Ba – Cu – O system, but also the chemical compositions of these phases and, hence, the physical properties of the crystallising solid solution. Determination of the actual chemical compositions of the coexisting phases is also necessary to avoid the errors when constructing the phase diagrams.

5. As a rule, polythermal quasi-binary sections of high-temperature superconducting systems are characterised by certain temperatures of invariant transformation (in this case, at about 1000 °C, see Fig. 14). Below this temperature, liquid phases disappear and the equilibrium between solid phases is established.

6. The narrowing of the homogeneity region can occur below the above-mentioned temperatures. In other words, solid solutions with the highest (lowest) substitution degrees appear to be less stable at both higher and lower temperatures. Analysis of this temperature region is closely related to studies on the decomposition dynamics of supersaturated solid solutions, the formation of a particular nanostructure and to changes in physical characteristics of the system.

3. Melt crystallisation mechanisms

a. Single-crystal growth

Peritectic decomposition is a salient feature of all oxide superconductors, which is due to their multicomponent composition and structural complexity. Crystallisation involves two different phases (the crystal and the mother liquid/melt) separated by a mesophase layer, which is a thin layer of the melt immediately adjacent to the solid phase.⁸ The components are transferred from one phase (the 'mother' or nutrient phase) to the other phase (crystal) as this interface moves. In turn, the rate of the process can be limited by the kinetics of deposition of the substance on the crystal face, diffusion of the substance from the surrounding phase as well as by dissipation of the latent heat of crystallisation.

Crystallisation cannot proceed in the absence of the driving force (supersaturation, supercooling or metastability of homogeneous 'mother' phase). In the case of crystallisation from the solution or melt, the driving force is often represented as the relative supersaturation of the melt

$$\sigma = \frac{c_1 - c}{c_1},$$

where c_1 is the equilibrium (under given conditions) concentration in the melt of the component transferred to the solid phase and c is its running value. The region of supersaturated solution is divided into the region of metastability and the labile region. The interface between these regions corresponds to maximum supersaturation in the system that can be achieved until spontaneous crystallisation begins.⁸ For the Y123-phase, this region is rather narrow (0.8 °C in air with respect to supercooling).¹¹⁸

Investigations of the primary crystallisation field (PCF) are important when considering single-crystal growth. Unfortunately, the PCF boundaries have not been reliably determined yet even for the Y123-phase, though it is obvious that the PCF does not include the melt of the 1:2:3 stoichiometric composition. In different studies, the ratios of barium and copper oxides ($Ba:Cu$) for PCF were estimated at 17:83–44:56, 24:76–46:54, 18:82–46:54 and 24:76–42:58, whereas the yttrium content (at. % Y) varied in the range 3.0–5.0, 1.0–2.0, 2.0–4.0 and 0.5–3.5, respectively.¹³ Crystallisation of the $Nd_{1+x}Ba_{2-x}Cu_3O_z$ solid solution with $x > 0.7$ from the $Ba:Cu = 3:12$ melt has been reported.¹⁰⁹ The composition of the solid solution changed during isothermal annealing. Artifacts in the determination of the PCF (especially using thermal analysis) often arise because of the absence of local equilibrium with the gas phase; therefore, data on PCF should be interpreted carefully. In some instances, the results of determination of the position of the

liquidus surface should be used instead. The most important problem is the search for chemical additives that extend the PCF and allow the single-crystal growth over wider temperature and concentration ranges. Most often, BaF_2 , Bi_2O_3 , B_2O_3 , Ag and BaCl_2 are used as such additives.^{13, 119–121}

If a crystal face contacts the metastable ‘mother’ phase, it can grow. Several main growth mechanisms exist under conditions of fast diffusion of the components of the crystallising substance and the absence of problems with dissipation of the heat of crystallisation.⁸ Depending on the driving force of crystallisation, continuous growth (face deposition), ‘island’ growth due to two-dimensional nucleation and spiral growth along the screw dislocations can be observed.

The last-named mechanism is the most probable for ordinary solution/melt supersaturations; the first two mechanisms are observed very rarely because of the high activation energy of the processes.⁸ The ‘Terrace-Ledge-Kink’ (TLK) growth of the crystal due to the ‘sliding’ of the crystallising layers of the moving terraces over the surface is also characteristic of high-temperature superconducting materials,⁸ whereas renucleation on the defects of the ‘two-dimensional angle’ type (the so-called ‘Twin-Plane-Re-entrant-Edge’ or TPRE growth) occurs much more rarely and was detected in high-temperature superconducting systems only recently (Fig. 15).⁸¹ In real systems, the common events are (i) crystal face formation as a result of complex interaction of several crystallisation centres, (ii) combination of several growth mechanisms, (iii) growth due to the formation of macroscopic spirals and

terraces, *etc.* Currently, the morphology of growth of the spirals of R123-phases and its dependence on the crystallographic indices of the crystal face,^{122, 123} the degree of supersaturation, temperature and the nature of REE are well studied.^{124–126}

b. Evolution of a polycrystalline system

The behaviour of the peritectic melt[§] obeys general regularities of crystallisation of an individual crystallite from the homogeneous melt. At the same time, analysis of this system is rather complicated and should be performed with consideration of the interactions between the melt and both the properitectic and gas phases that coexist at the peritectic decomposition point of HTSC. Additionally, the fact that crystallisation of a peritectic melt results usually in the formation of a polycrystalline product should be taken into account.

When polycrystalline HTSC are prepared using melt crystallisation techniques, their microstructure is formed under non-equilibrium dynamic conditions. Hence the problem arises of the search for methods of reproducible preparation of materials comprising well-shaped crystallites with an optimum size and optimum mutual orientation and sufficiently strong intercrystallite contacts. From this point of view, the most interesting is to analyse the regularities of the formation and evolution of an ensemble of crystallites at both small and large deviations of the system from the equilibrium state. Three types of crystallisation models of REE-containing cuprates are known, in which the interaction in the 211-phase–melt subsystem is considered. These are phenomenological models of the interaction between the particles of secondary phases and the melt, computer models of this interaction and mathematical models of propagation of the crystallisation front of the high-temperature superconducting phase and changes in its morphology. The models of REE-containing melt crystallisation with inclusion of interactions in the ‘gas phase–melt’ subsystem are much less developed.

Superconducting phases are mainly formed owing to dissolution in the melt of ‘secondary’ phase particles, followed by homogeneous formation of the high-temperature superconducting phase in the melt.^{8–11, 127–130} In the vicinity of the surface of the particles of the 211-phase, the melt is enriched with yttrium and the crystallites of the $\text{YBa}_2\text{Cu}_3\text{O}_x$ phase are formed near the surface of these particles rather than at the ‘211-phase–melt’ interface. Crystallisation is accompanied not only by ‘pushing’ large particles of the 211-phase by the growing faces of crystallites of the 123-phase, but also by their trapping by the bulk of the growing crystallites. The formation of crystallites of the $\text{YBa}_2\text{Cu}_3\text{O}_x$ -phase is preceded by an induction period, after which crystallisation proceeds in the bulk at an abnormally high rate. Different melt crystallisation models are presented in Table 3.

Mention should be made of considerable interest in the computer simulation of crystallisation processes. Different computer models and simulation concepts are used (*e.g.*, ‘cellular automata’ and diffusion-in-melt models and the phase field concept for multiphase systems, see S.7). It can be assumed that solidification of a peritectic melt can proceed in different ways depending on the parameters of the initial state of the melt, which results in the appearance of three different crystallisation regions characterised by particular final microstructure of polycrystalline materials.^{127, 128} The provision of stable crystallisation of the superconducting phase owing to stabilisation of the nucleation process is the most important condition for the preparation of high-temperature superconducting materials with high output characteristics.

The experimental proof of this statement was obtained in studies of the doping of melts with REE oxides.^{128, 129} The melt

Figure 15. The mechanism of crystal growth in high-temperature superconducting systems (the $\text{Nd}_{1.85}\text{Ba}_{1.15}\text{Cu}_3\text{O}_x$ -phase) by renucleation on defects of the ‘dihedral angle’ type (the so-called ‘Twin-Plane-Re-entrant-Edge’ or TPRE growth);⁸¹

(a) general view of the growing crystal face: twins are crossed by microscopic cracks arisen after thermal shock on detaching the crystal from the melt surface; the crystallisation front of the ‘tail’ of growth spirals that form a visually observed macroscopic spiral moving along the twinning direction at a higher velocity; (b) the structure of twins according to atomic force microscopy data; the twin boundaries are indicated by arrows.

§ Hereafter a ‘peritectic melt’ is meant a system consisting of a liquid and a solid (high-temperature, properitectic) formed upon peritectic decomposition of the HTSC.

Table 3. Crystallisation mechanisms of peritectic melts.

Model	Morphology of particles of a 211-phase	Proposed scheme of the interaction	Result of interaction	Ref.
Heterogeneous nucleation	any			6
Dissolution in melt and homogeneous nucleation	isotropic (spheres)			6, 8
Edge effects, entrapment of particles of the 211-phase by the crystallisation front	highly disperse particles			9, 11
Formation of 'gaps' and displacement of the melt to grain boundaries on trapping the particles of the 211-phase	large particles			9, 11
'Pushing-and-trapping' of particles of the 211-phase by the crystallisation front ^a	—			8
Dispersion of particles of the 211-phase by the moving crystallisation front	anisotropic particles (needles)			9, 11

^a The mechanism is determined by particle size, the energy of surface interaction and by the crystallisation rate.

analysed contained $\sim 80\%$ of Cu(I), which was confirmed by the results of quenching experiments and chemical analysis,^{55, 129} by BaCu_2O_2 observation using X-ray phase analysis^{13, 129, 131} and by *in situ* measurements of the EXAFS spectra of the melt.^{132, 133} Cooling of the melt results in the recovery of the initial oxygen content, which occurs more easily with an increase in the partial pressure of oxygen in the gas phase.

In principle, the transformation $\text{Cu(I)} \rightarrow \text{Cu(II)}$ provides a possibility for crystallisation of a non-superconducting phase of barium cuprate BaCuO_2 to occur. This is favoured by the presence in the melt of the components necessary for the crystallisation of BaCuO_2 and by the fact that the temperature of its crystallisation in air⁹⁶ and the crystallisation temperature of the $\text{YBa}_2\text{Cu}_3\text{O}_x$ -phase are close. In other words, a 'bifurcation'-like situation occurs in the 211-phase–melt system, which can be followed by crystallisation of either yttrium–barium cuprate $\text{YBa}_2\text{Cu}_3\text{O}_x$ or barium cuprate BaCuO_2 .^{127–129} It is this phenomenon that is

observed experimentally. In these cases, the direction of crystallisation depends on many factors (which are often ignored) such as the oxidation rate of the melt during its cooling, the rate of dissolution of the Y_2BaCuO_5 -phase in the melt, the partial pressure of oxygen in the system, the gradients of both the temperature and oxygen pressure at the gas phase–melt interface and, finally, the prehistory of the sample and its size. Because of this, small deviations from the empirically established conditions for the synthesis of the $\text{YBa}_2\text{Cu}_3\text{O}_x$ phase immediately result in undesirable formation of non-superconducting cuprate phases even in high-density specimens and in dramatic deterioration of properties of the high-temperature superconducting material prepared.

Crystallisation of the 123-phase can probably be the major process in the system if nucleation begins at a temperature which is higher than the crystallisation temperature of BaCuO_2 . Superconducting layered yttrium–barium cuprate is the only phase

whose specific crystal structure can be selectively affected by the doping of the melt with REE ions. This makes it possible to experimentally distinguish between the melting temperatures of binary non-superconducting and ternary superconducting cuprates, thus performing targeted crystallisation of the high-temperature superconducting phase from a multicomponent melt.^{128, 129, 134, 135}

The general pattern of the process can be changed dramatically upon a decrease in the partial pressure of oxygen in the gas phase. Oxidation becomes the limiting stage of crystallisation in an oxygen-deficient atmosphere.^{129, 135} Copper (Cu^{2+}) ions formed upon melt oxidation are bound by the excess R^{3+} and Ba^{2+} ions to form the $(\text{R}, \text{Y})\text{Ba}_2\text{Cu}_3\text{O}_z$ -phase; however, no rapid crystallisation of the nonequilibrium product (binary barium cuprate) is observed. Thus it can be assumed⁵⁵ that the formation of the phase and microstructure of the material are strongly affected by three main factors. These are (i) the total flux of yttrium (REE) ions j_Y from the surface of the 'green-phase' particles to the melt, which is mainly determined by dispersity of the particles and by the surface energy of the interface; (ii) the oxygen flux j_O to the crystallising melt, which depends on both the partial pressure of oxygen in the gas phase and geometric characteristics of the specimen and (iii) the heat flux j_Q evolved from the specimen during its cooling, which is determined by the heat treatment regime.

Thus, the optimum procedure for preparation of high-quality high-temperature superconducting materials should take into account simultaneous and mutually dependent changes in these most important parameters of the process.

4. Oxygen nonstoichiometry of high-temperature superconducting phases

The oxidation stage is of particular importance when preparing, e.g., the $\text{RBa}_2\text{Cu}_3\text{O}_z$ superconductors with a wide oxygen homogeneity region ($z = 0-1$).^{1, 2, 8, 13, 17, 22, 50, 100, 108} For bismuth-, thallium- and mercury-containing high-temperature superconducting phases, the homogeneity region is much narrower.^{17, 56, 67, 69, 101} On the contrary, several high-temperature superconducting materials [e.g., the 'electron'-type (Nd , Ce) CuO_{4+y} HTSC] require annealing in a reductive atmosphere.² In all cases, there are strong reasons for detailed investigation of the oxygen nonstoichiometry of HTSC. Here, it is well to bear in mind the following.

1. The oxygen content is correlated with the concentration of charge carriers, whose optimum value provides the maximum T_c value (a T_c 'dome'). 'Underdoped' ('underoxidised') or 'overdoped' ('overoxidised') phases can have a much lower T_c (Fig. 16). In the general case, it is the concentration of the charge carriers localised on particular elements of the structure that determines the physical phase diagram of HTSC (see Fig. 3).¹⁶

2. Changes in the oxygen content can result in significant changes in the phase stability and in structural phase transitions. For instance, ferroelastic $\text{RBa}_2\text{Cu}_3\text{O}_z$ -phases undergo an 'order-disorder' second order phase transition which is accompanied by a tetragonal-to-orthorhombic distortion of the crystal lattice and simultaneous formation of extended twins.^{8, 22, 93, 126} The changes in thermodynamic characteristics of high-temperature superconducting phases with different oxygen content can result in the appearance of the low-temperature stability threshold,^{50, 51, 75, 106} phase separation in such solid solutions and in nonuniform oxygen distribution over the superconducting matrix.^{8, 93}

3. Investigations of oxygen diffusion in high-temperature superconducting phases is not only of practical, but also of theoretical importance since the diffusion coefficient is a 'structurally sensitive' quantity, which depends on the concentration of oxygen vacancies (and, hence, on specific features of the equilibrium p_{O_2} - T - z -diagram), their ordering (the crystal lattice symmetry of the high-temperature superconducting phase and second order phase transitions, effects of various types of

Figure 16. Dependence of the transition temperature to the superconducting state on the 'hole' concentration (a), oxygen nonstoichiometry (b) and unit cell parameters which are determined by the oxygen content (c) for the most abundant types of HTSC; (a): $\text{YBa}_2\text{Cu}_3\text{O}_z$ -phases (1) and $(\text{La}, \text{Sr})_2\text{CuO}_{4+y}$ (2); (b): $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+z}$ (1) and $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+z}$ (2); (c): the $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+z}$ homologous phases, Hg1223 (1), Hg1212 (2), Hg1234 (3), Hg1245 (4) and Hg1201 (5).

substitution in the structure), the energy parameters of different oxygen sites (the activation energy and the probability of exchange between the oxygen positions, etc.). A rather high anisotropy of the diffusion coefficients along the main crystallographic directions can indicate a layered structure of the HTSC (two-dimensional diffusion in CuO_y planes in which the vacancies are concentrated, etc.). Relatively large absolute values of the diffusion coefficients of high-temperature superconducting phases compared to those of other systems¹³⁶⁻¹³⁹ indicate that they are highly defective. Studies of the diffusion mechanism give useful information on the different types of the oxygen bonding in the structure.¹⁴⁰ Finally, parameters of the oxygen diffusion can essentially depend on the size of grains of the high-temperature superconducting phase, the quality of their surfaces, specific features of the interface between the superconducting and gas phases, the presence of internal microscopic strain, etc. Thus, analysis of these dependences makes it possible to obtain information on the real structure of high-temperature superconducting materials. The results of the diffusion studies can be used for determination of thermodynamic properties of high-temperature superconducting phases.

a. Phase diagrams of $\text{RBa}_2\text{Cu}_3\text{O}_z$ - O_2 systems and the oxygen ordering processes

The problem of oxygen nonstoichiometry in $\text{RBa}_2\text{Cu}_3\text{O}_z$ - O_2 systems and related phenomena are extremely complicated.^{13, 100, 141-148} Different types of diagrams used to represent the oxygen nonstoichiometry in high-temperature superconducting phases of the Y-Ba-Cu-O system are shown in Fig. 17.

The p_{O_2} - T - x - z -diagram presented in Fig. 18 illustrates the effect of cation ordering on the 'behaviour' of the oxygen sublattice in the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution.⁸⁹

Obviously, the temperature, total pressure and partial pressure of oxygen in the system affect significantly the oxygen content in the HTSC-phase, peculiarities of oxygen ordering and symmetry of the crystal lattice of this phase, the stability of various homologues of the high-temperature superconductors (123-, 247-

Figure 17. Types of representation of the diagrams of equilibrium oxygen content in $\text{YBa}_2\text{Cu}_3\text{O}_z-\text{O}_2$ systems; (a): $p_{\text{O}_2}-T-z$ -diagram; T/K : (1) 573; (2) 623; (3) 673; (4) 723; (5) 773; (6) 823; (7) 873; (8) 923; (9) 973; (10) 1073; and (11) 1173; (b) phase relations at a high pressure of oxygen, the z value varies from 6.40 to 6.85; (c) calculated low-temperature diagram of oxygen content in the Y123-phase and different types of ordering of the oxygen sublattice.

or 124-phases) and that of the high-temperature superconducting phase against peritectic and/or solid-phase decomposition.

The highest T_c values are achieved at the optimum oxygen content in the high-temperature superconducting phase.¹⁴⁸ The $(T_c)_{\text{max}}$ values for $\text{YBa}_2\text{Cu}_3\text{O}_z$ are 93.5 K at $z = 6.94$ and 87 K at

$z = 7.0$ and 6.85. ‘Heavy’ REE of the yttrium subgroup with smaller ionic radii form 123-phases for which $(T_c)_{\text{max}} < 90$ K, which means that the maximum value is shifted towards lower oxygen content. For instance, $(T_c)_{\text{max}} = 87$ K at $z = 6.90$ for $\text{YbBa}_2\text{Cu}_3\text{O}_z$. On the contrary, HTSC containing ‘light’ REE are characterised by higher $(T_c)_{\text{max}}$ values at higher oxygen content. Probably, the $(T_c)_{\text{max}}$ values of $\text{NdBa}_2\text{Cu}_3\text{O}_z$ with $z = 7$ and its analogue $\text{LaBa}_2\text{Cu}_3\text{O}_z$ with $z > 7.0$ reach 96 K^{7,8,43,86} and 98–100 K,⁸⁶ respectively. High oxidation degrees of these phases are achieved by heat treatment at low temperatures (350 °C) and high pressure of oxygen (100–900 atm).^{7,8,92} The effect of ionic radii of REE on T_c of the 123-phases is explained^{17,42,43} using the model of charge redistribution between the superconducting CuO_2 planes and dielectric CuO_y blocks in the structure under conditions of internal chemical pressure (followed by compression or expansion of the structure) which results from changes in the geometrical size of cations occupying the sites of REE ions. Analogous dependences are also known for other cuprate superconductors and the optimum oxygen content is different for different HTSC homologues (see Fig. 16c).

The formation of twins owing to relaxation of internal strain which appears upon orthorhombic distortion of a tetragonal unit cell in the course of oxygen diffusion into the grains of superconductor is clear evidence of the ordering of oxygen atoms in the unsubstituted 123-phases. The distance $\Delta\lambda$ between the twin boundaries in the twin ensemble varies in accordance with the formula:¹⁴⁹

$$\Delta\lambda = \left(\frac{128\pi\gamma G}{ES} \right)^{0.5},$$

where γ is the specific energy of the twin boundary, G is the size of twinned grain, E is the elastic modulus of the material and S is the coefficient of orthorhombicity.

Thus, one can expect that the largest twins will be formed in single crystals and that the size of these defects will to a great extent depend on the elasticity and ‘degree of orthorhombicity’ of the material used. Twinning results in microscopic cracking of melt-solidified ceramics. Perfect specimens can be obtained using both the single-crystal detwinning and twin-free crystal growth methods.^{150,151}

b. Diffusion of cations and anions

Oxygen diffusion in high-temperature superconducting phases has been studied using different methods such as dynamic¹⁵² and isothermal¹⁵³ thermogravimetry, electrochemical potentiometry,¹⁴³ $\text{O}^{18}/\text{O}^{17}$ tracer diffusion method,^{154–156} determination of internal friction coefficients,¹⁵⁵ *in situ* measurements of electrical resistivity,¹⁵⁷ direct observations of the twinning front propagation in single crystals,^{158,159} method of isotope exchange with the gas phase^{160,161} and computer simulation using the cellular automata method.¹⁴⁷ The diversity of methods used and factors affecting the oxygen diffusion explains a great scatter (several orders of magnitude) of results obtained by different groups of researchers. Nevertheless, mention may be made of several important regularities.

1. One must discriminate between the coefficients of self-diffusion D_{self} and the coefficients of chemical diffusion of oxygen D_{chem} in high-temperature superconducting phases related by a simple formula¹⁵⁷

$$D_{\text{chem}} = D_{\text{self}}\Phi,$$

where Φ is the so-called thermodynamic factor. Usually, the Φ value is nearly constant if the oxygen content z in the R123-phases lies in the range from 6 to 6.8; however, it increases rapidly as z approaches the value corresponding to the most oxidised state ($z = 7$). As a rule, the D_{chem} value is 4–5 orders of magnitude higher than that of D_{self} .

2. For polycrystalline materials based on the Y123-phase, the D_{chem} and D_{self} values vary in the ranges 10^{-5} – 10^{-11} and 10^{-9} – 10^{-13} $\text{cm}^2 \text{ s}^{-1}$, respectively. The activation energies of

Figure 18. Section of the $p_{\text{O}_2}-T-x-z$ -diagram of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z-\text{O}_2$ system at $p_{\text{O}_2} = 0.21$ atm, which illustrates the effect of the character of cation ordering on the equilibrium oxygen content in this solid solution.

self-diffusion in the R123-phases decrease as the ionic radii of REE increase.¹⁴³

3. For single crystals, the coefficient of self-diffusion of oxygen along the c axis at 400 °C ($D_c = 10^{-16} - 10^{-17} \text{ cm}^2 \text{ s}^{-1}$) is six orders of magnitude lower than for polycrystalline samples (D_{poly}), whereas the rate of diffusion along the b axis at 300 °C in detwinned crystals ($D_b = 2 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$) is at least two orders of magnitude higher than that of diffusion along the a axis ($D_a = 5 \times 10^{-14} \text{ cm}^2 \text{ s}^{-1}$).¹⁵⁴ Thus, self-diffusion in single crystals is highly anisotropic and proceeds almost completely in the ab plane [$D_{ab} = D_{\text{poly}} = (10^4 - 10^6)D_c$, $D_b = 100D_a$, $D_b = 10D_{ab}$]. At the same time, the coefficient of chemical diffusion for these types of single crystals lies in the range $10^{-8} - 10^{-7} \text{ cm}^2 \text{ s}^{-1}$.

4. Second order phase transitions, occurring on ordering or disordering of the oxygen sublattice, must result in jumpwise changes in the diffusion coefficients. This is confirmed by the results obtained in the studies of diffusion coefficients of $\text{RBa}_2\text{Cu}_3\text{O}_z$ ($R = \text{Y}$ and Nd) phases over a wide range of temperature and partial pressure of oxygen.¹⁴³ According to the reported data, the rate of oxygen diffusion in the orthorhombic phase is higher than that in the tetragonal phase despite the fact that the number of available oxygen vacancies in the latter is larger than in the former. Probably, this indicates changes in the elementary mechanism of the process.

The role of mobility of the cationic sublattice is at least as important as, and in some instances even more important than, that of oxygen diffusion; however, it has been much less studied.¹³⁶⁻¹⁴⁰ Migration of cations in single crystals of oxide superconductors follows ordinary diffusion mechanisms (vacancy-type, interstitial, dissociative, along dislocations and point defects); in polycrystalline HTSC, diffusion along the grain and pore surface, twin boundaries, *etc.*, is additionally observed.¹⁴⁰

Self-diffusion of Cu^{2+} in the $\text{YBa}_2\text{Cu}_3\text{O}_z$ phase was studied by the tracer diffusion method.¹³⁷⁻¹³⁹ The activation energy of this highly anisotropic process lies in the range 165–255 kJ mol^{-1} and the diffusion coefficient at 780–900 °C lies within the limits $\sim 5 \times 10^{-12} - 10^{-13} \text{ cm}^2 \text{ s}^{-1}$. The value of the diffusion coefficient of copper at 600 °C found by extrapolation is estimated at $\sim 6 - 9 \times 10^{-14} \text{ cm}^2 \text{ s}^{-1}$. The bulkier Ba^{2+} ion has a lower coefficient of self-diffusion in the same temperature range ($\sim 10^{-14} - 5 \times 10^{-15} \text{ cm}^2 \text{ s}^{-1}$).¹³⁷⁻¹³⁹ The coefficient of self-diffusion of Y^{3+} ion in the Y123-phase varies from 10^{-14} to

$10^{-16} \text{ cm}^2 \text{ s}^{-1}$ in the temperature interval 780–980 °C (the activation energy is 280 kJ mol^{-1}).¹³⁷⁻¹³⁹

Therefore, self-diffusion of oxygen in high-temperature superconducting phases proceeds at a rate which is 1–3 orders of magnitude higher than that of self-diffusion of cations, especially in those regions where low-temperature oxidation of superconductors occurs. This is first of all due to the differences in the atomic weights of the elements, the charge of their ions and structural features of high-temperature superconducting phases containing oxygen-deficient perovskite-like blocks. Taking into account different values of diffusion coefficients, the cationic framework can be considered virtually immobile when studying various low-temperature processes with participation of high-temperature superconducting phases (see also Section III.1.b and S.3).

The final stage of preparation of HTSC can be optimised using the data on the equilibrium oxygen content and the parameters of its diffusion in high-temperature superconducting phases (see above). In combination with specific features of phase relations described above, this opens additional opportunities of targeted design of high-temperature superconducting materials.

IV. Development of advanced methods for the synthesis of high-temperature superconducting materials

Preparation of high-temperature superconducting materials with desired characteristics is the most important problem that became topical immediately after the discovery of this class of complex cuprates. However, only a few types of high-temperature superconducting materials such as highly homogeneous powders (used as intermediate products for the preparation of ceramics, coatings, silver-sheathed tapes), thin films and hetero-structures, large-grain ceramics and long-length composites can be used in such areas as power engineering, electronics and medicine. A general view of the main classes of materials based on HTSC-phases is shown in Figs 19–21 (see S.8–S.10)

1. Chemical homogenisation and preparation of high-quality powders

Early studies of high-temperature superconducting materials were carried out using the so-called ceramic method, which includes thorough mechanical mixing of oxides (in some instances,

Figure 19. Single crystals of HTSC;

(a), general view of needle-shaped $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ ‘stalactic’ crystals grown under isothermal conditions by the ‘pellet-in-pellet’ method with addition of a small amount of BaF_2 (see S.8); (b) the largest (by the date of publication of this review) ‘pyramidal’ $\text{NdBa}_2\text{Cu}_3\text{O}_z$ HTSC-crystal grown by the modified Czochralski method and a polished experimental substrate for thin film deposition, obtained by sawing a ‘bulk’ $\text{YBa}_2\text{Cu}_3\text{O}_z$ crystal grown by using this method (published by courtesy of Professor Y Shiohara, SRL, ISTECH, Japan);¹¹⁴ (c) general view of plate-like mercury-containing HTSC-crystals obtained by ampoule synthesis using the contact pair method (the only Hg-based crystals with peak effect known to date, see S.9); a pronounced peak effect observed on the ‘critical current vs. external magnetic field’ dependence is assumed to be due to double (Hg/Pb and Ba/Sr) substitution (published by courtesy of S R Lee, M V Lomonosov Moscow State University, Russian Federation).

Figure 21. A cross section of $\text{HoBa}_2\text{Cu}_3\text{O}_7/(\text{La}, \text{Pr}, \text{Ca})\text{MnO}_3$ epitaxial film grown on the LaAlO_3 substrate (the 001 orientation) in the region of the HTSC–manganite interface according to high-resolution transmission electron microscopy data (see S.10). The smooth atomic layers at the interface indicate chemical compatibility of HTSC cuprate and manganite with giant magnetoresistance effect (published by courtesy of Professor A R Kaul, M V Lomonosov Moscow State University, Russian Federation).

alkaline-earth metal oxides and carbonates) and repeated 'calcination–grinding' (heat-and-heat) cycles needed for the solid-phase reaction between the reagents to proceed.^{2–5, 14}

This conventional method for the preparation of many types of structural and functional ceramics has essential drawbacks, the most important of which consists in long-term heat treatment because of rather large grain size and mixing inhomogeneity of the reagents (see S.11). Often, the growth of crystallites is uncontrollable, which results in both chemical and granulometric inhomogeneity. In combination with anisotropy of crystallites constituting the HTSC, this results in irreproducibility of their electrical and magnetic properties. Almost all oxide superconductors known to date are complex multicomponent chemical compounds. Distinctions in properties of the elements constituting high-temperature superconducting phases due to their different positions in the Periodic Table preclude development of a unified procedure for the preparation of HTSC by the ceramic method.

Publications concerning the development and application of the so-called chemical methods for the preparation of HTSC powder have been known since 1987.^{162–172} These methods allow improvement of the product homogeneity owing to the achievement of a nearly molecular level of component mixing in solution and its retention to a greater or lesser extent in subsequent stages of the synthesis. As a rule, the oxide powders thus obtained are

characterised by a rather large specific surface and, as a consequence, readily enter into solid-phase reactions and are active in sintering. Additionally, the efficiency of chemical methods of synthesis is also manifested in increased chemical homogeneity of ceramics.¹⁴

It is also appropriate to use chemical methods along with the most widely used melt solidification methods for the preparation of ceramics despite marked levelling of distinctions in the morphology of powders with different prehistory, because of complete or partial melting. The establishment of the nature of pinning centres requires materials with strictly specified content and distribution of impurities. The easiest way of doing this is to use chemical methods. Mention has been made^{9, 129, 173} of the possibility of controlling the size of crystallites of the secondary phases through the so-called effect of topochemical memory observed when varying the chemical prehistory of specimens.^{39, 40} Of particular importance is preparation of high-quality, highly disperse 'soft' powders for fabrication of long-length HTSC–metal composites (e.g., silver-sheathed tapes) by the 'powder-in-tube' method.^{16, 23, 54, 55} The size of internal cross sections of such composites varies from several to several tens micrometres. Therefore, 'coarse' and inhomogeneous powders (with broad distribution of the particle size) prepared by conventional ceramic method are unusable in this case.

The coprecipitation methods are widely used for the preparation of various types of ceramics. Therefore, it is not surprising that they were among the first chemical methods for the synthesis of HTSC powder.^{2, 29, 162} In some instances (in correctly designed experiments) it has been possible to prepare homogeneous disperse mixtures of salts with the predetermined cation ratio and to reproduce the results obtained. In an ideal case, the conditions under which precipitation of cations from a solution occurs simultaneously and at equal rates are optimum. Most of the methods used include precipitation of carbon-containing salts (oxalates and carbonates) the thermolysis of which is completed at 900–950 °C. Unfortunately, the presence of carbon-containing salts should be considered as a drawback of this type of method because of the possibility of the formation of oxycarbonate phases.^{36, 100, 136}

The citrate method^{2, 171} is the most widely used of the different versions of the sol-gel methods. Closely related to this method is the method of polymerised complexes, which has been successfully developed in a number of research laboratories worldwide.¹⁶³ In this case, the ability of α -hydroxy acids (e.g., citric acid) to form chelate complexes with metal ions is used. When heated to 100–140 °C, such complexes react with polyfunctional alcohols (e.g., ethylene glycol) to give low-molecular-weight oligomers (esterification). Subsequent heating to 180–200 °C results in their polymerisation and the formation of a viscous resin (gel) with uniformly distributed metal atoms. The gel can be decomposed to give the oxide powder. The sol-gel method is rather simple and inexpensive since almost no complex equipment is needed (the method requires no centrifuging, filtering, washing, drying, etc.) and readily available nitrates are most often used as initial substances. The viscosity of the gel obtained can be controlled by varying the component ratio and the duration and temperature of polymerisation. Therefore, the sol-gel method is used for the preparation of not only powders, but also thick films, fibres and planar ceramics.

Currently, the spray drying and spray pyrolysis techniques have received the widest acceptance among chemical methods for preparation of HTSC powders.^{162, 172} The latter method includes sonication of a mixture of salt solutions to obtain a mist with a droplet size of 0.5–0.8 μm , the transfer by a carrier gas into a hot chamber where instantaneous (complete or partial) decomposition of the droplets occurs. The oxide-salt product that is formed is collected on a filter at the outlet of the gas flow from the decomposition zone.

The molecular level of mixing of components (most often, nitrate solutions) and nearly instantaneous dehydration and

decomposition of microscopic spray droplets make it possible to prepare a homogeneous product. Repeated grinding and calcination characteristic of the ceramic technology and responsible for contamination of the product and uncontrollable grain growth are excluded in this case. However, the powders obtained can be contaminated with the material of the drying chamber (at high temperatures, in the presence of free acid). Additionally, the spray pyrolysis technique requires careful purification of large volumes of the carrier gas (oxygen) from CO_2 to avoid the formation of barium carbonate.

The method of rapid expansion of supercritical solutions (RESS)^{169, 170} at elevated temperature and pressure is based on the phenomenon of an anomalous increase in the solubility of inorganic compounds in water (or in other solvents such as ammonia, carbon dioxide, xenon, *etc.*) above its critical temperature (in autoclave). When such solutions are expanded in a chamber at a reduced pressure and temperature, the solubilities of the solutes decrease substantially and these are isolated as ultradisperse particles (often, as an X-ray amorphous phase or metastable crystalline modifications). Oxide materials can be best prepared using aqueous supercritical solutions.¹⁶⁹

The drawbacks of most chemical methods used for the synthesis of HTSC powders can be to a great extent compensated using cryochemical technology.^{162, 165–168} This method consists in the preparation of highly disperse and highly homogeneous salt (and the oxide) precursors by fast freezing of finely disperse salt solutions (preparation of cryogranulates) followed by removal of water by sublimation. Experimental conditions should exclude physicochemical processes resulting in deterioration of chemical and granulometric homogeneity of the product, *e.g.*, separation of sprayed microscopic drops into solvent-rich and solvent-depleted regions due to insufficiently high cooling rate, partial melting of cryogranulates and, hence, segregation of the components during the freeze-drying or on subsequent heat treatment of the freeze-dried product, *etc.*

Therefore, the highest homogeneity of the product is often achieved by (i) spraying the solution over a massive metal plate cooled by liquid nitrogen,¹⁶⁸ (ii) replacing (if possible) nitrate solutions by acetate^{168, 174} or nitrate–nitrite solutions and (iii) drying in a thin layer with slow heating to 125 °C in an argon stream^{14, 168} and decomposing the dried salt product in a furnace preheated to the desired temperature.

The use of highly disperse (tens of nanometres) and highly homogeneous precursors prepared by the cryochemical method makes it possible to accelerate substantially the phase formation and to prepare high-temperature superconducting phases that can hardly be synthesised by other methods. For instance, the Bi2223-phase was obtained¹⁶⁸ after annealing for 12–16 h only (*cf.* 200–300 h required when using the ceramic technology) at 750 °C and the Y124-phase was synthesised¹⁶⁸ after annealing in air at 815 °C (120 h). In the latter case, high-pressure stages (p_{O_2} up to 100 atm) usually required to synthesise this phase were excluded. Considerable achievements have been made in the preparation of different homologues of mercury-containing HTSC by the ampoule method using cryochemical technology and other methods of chemical homogenisation.¹⁷⁵

2. Thin film preparation

The known technologies of thin film preparation can formally be divided into physical and chemical ones.^{2, 24, 176} The former comprise the most widely used methods of pulse laser deposition and magnetron sputtering of films including the transfer of the material of the dense and chemically homogeneous target in the form of microscopic clusters knocked out by a high-energy beam from the target onto a substrate. These methods make it possible to prepare high-quality thin films with record physical characteristics and to carry out a layer-by-layer synthesis of novel types of structures (structural design) by ‘assembling’ the film literally at the atomic plane level.

However, expensive physical methods are almost inapplicable for the preparation of large specimens. This is achieved by using such chemical methods as liquid phase epitaxy (LPE)^{8, 112, 120} and chemical vapour deposition (CVD).²⁴ However, despite the advantages of precipitation from a solution in a melt by LPE, this has not acquired wide acceptance to date and has been developed by only a few research groups.¹²⁰ Among accepted methods for the preparation of thin high-temperature superconducting films, deposition on single-crystal substrates of thermally decomposed products of highly volatile organometallic precursors (Metal-Organic Chemical Vapor Deposition or MOCVD) is the most interesting.

Currently, the efforts of researchers from about 40 laboratories¹⁴ including those of the biggest electronic companies are focused on the development and improvement of CVD technology for the preparation of HTSC. This fact, as well as information on large-scale applications of the CVD method for the preparation of diverse epitaxial semiconducting films and oxide coatings suggest that this method can become one of the main methods for the preparation of high-temperature superconducting films in the future.

The MOCVD method^{2, 24} includes transfer of the metal constituents of films to the reactor as vapours of volatile organometallic compounds, mixing of the vapours with a gaseous oxidant and decomposition of the vapours in a hot-wall reactor or on a heated substrate followed by the formation of a HTSC film. Metal β -diketonates are most often used as volatile compounds (precursors). Novel volatile organometallic compounds^{2, 24, 177–179} made it possible to improve substantially film characteristics and to extend the potentialities of the MOCVD method.

The MOCVD method makes it possible to prepare thin HTSC films with characteristics that are at least as good as those of films prepared by physical methods. The obvious advantages of this method include first of all its versatility as regards the composition of the materials obtained, the possibility of single- and double-sided deposition of films with homogeneous composition and the same thickness on substrates with complex shapes and large surface areas (including continuous film deposition on a long-length metallic substrate, *e.g.*, a tape).¹⁷⁶ Unlike physical methods of sputtering, in which high performance of equipment is achieved due to the high energy of the particle beam of the sputtered substance and is connected with the risk of disturbing the morphology and stoichiometry of the film thus formed, the performance of the MOCVD method is achieved by increasing the vapour pressure of the volatile component and/or by increasing the flow rate of the carrier gas. Other advantages of the MOCVD method are the possibility of achieving higher deposition rates (up to several millimetres per hour) with retention of high quality of the film, the use of a flow-through setup operating at pressures of 10^{-3} –1 atm instead of high-vacuum equipment, its simplicity and low cost compared to those required when using physical methods and, finally, ‘flexibility’ of the process in the adjustment stage (primarily due to the smooth change in the vapour phase composition).

A common problem of all methods of thin film preparation including the MOCVD method is ‘symbiotic’ choice of substrates. The substrates should be highly chemically inert (to prevent contamination of high-temperature superconducting phase with alien components), cheap and readily available. Additionally, the substrate material must possess specific physical properties such as (i) rather small (< 2%) mismatch between the crystal lattice parameters and those of the deposited film to provide conditions for the epitaxial growth, (ii) close values of the thermal expansion coefficients (TEC) of the substrate and HTSC phase to avoid the formation of microscopic cracks in the film due to compression and, especially, tension caused by temperature variations; (iii) the absence of twinning-type phase transitions that can appreciably deteriorate the film morphology and (iv) low dielectric constant and dielectric loss tangent to provide the possibility of using the films in microelectronics and in microwave devices.

Unfortunately, almost none of the known substrates meets all the above-mentioned requirements (Fig. 22). Usually, SrTiO_3 , NdGaO_3 and LaAlO_3 are used as substrates.¹⁷⁹ Recently, large Y123 and Nd123 single crystals were used for homoepitaxy of the R123-phases of high-temperature superconducting films.¹⁸⁰ However, these single-crystal substrates are superconductors rather than dielectrics. Intrinsic in these substrates is the tetragonal-to-orthorhombic phase transition (*tetra-ortho*-transition) accompanied by the formation of a twin structure. Non-superconducting tetragonal solid solutions of the $\text{Pr}_{1-x}\text{Ba}_x\text{Cu}_3\text{O}_z$ type, in which no twinning occurs, seem to be more promising.⁸ Dielectric $\text{Nd}_{1.85}\text{Ba}_{1.15}\text{Cu}_3\text{O}_z$ single crystals are characterised by a high degree of orthorhombicity, the absence of *tetra-ortho*-transition, close TEC values, high lattice parameter matching with high-temperature superconducting films of the R123-phases and a narrow range of oxygen nonstoichiometry. For these reasons, they are also promising for use as substrates.^{80, 81, 181}

The second, chemical problem arising when using the MOCVO method is the control of the cation and anion stoichiometry of the films. The chemical vapour deposition is an incongruent process and depends on several factors such as the temperature, total pressure, partial pressures of oxygen, carbon dioxide and water (the oxidation products of the organic component of compounds used), their flow rates and distribution of the flows in the reactor and above the substrate, total composition and homogeneity of mixing of volatile components in the gas phase, *etc.* The most promising way of controlling the vapour composition is to carry out instantaneous evaporation of the mixture of volatile components from one source. This is achieved by using an aerosol obtained from the solution of organometallic compounds in organic solvent (*e.g.*, diglyme) or by pulse evaporation of microscopic portions of a mixture of organometallic compounds fed using a belt-conveyor feeder.²⁴

In the first case, the solvent vapour has a strong effect on the film deposition, namely, the thermal effect of solvent oxidation: a decrease in the partial pressure of oxygen and an increase in the partial pressure of carbon dioxide and water are observed. Using the results of thermodynamic analysis, it is possible to minimise the influence of these effects and to optimise the conditions for film deposition in the reactor with cold walls and induction heating of the substrate.^{2, 24, 179} At $p_{\text{CO}_2} < 10^{-5}$ atm and $T < 800$ °C, no barriers to the formation of the $\text{YBa}_2\text{Cu}_3\text{O}_{z-}$

phase are observed. Using an aerosol source, it is possible to attain high deposition rates and reproducibility of the composition and morphology of the R123- and Bi2212-films.¹⁷⁷

The second method consists in placing small droplets of an organic solution containing volatile metal complexes in a predetermined ratio on a fibre glass transport tape. The vapour formed on pulse heating of the tape in a vacuum chamber moves to the substrate. The amount of substances evaporated per pulse as well as the vapour composition can easily be varied from pulse to pulse. This method appeared to be very useful in the preparation of multilayered film structures of complex chemical composition.^{182, 183}

The third problem that arises only when using the MOCVD method consists in the necessity of a targeted search for highly volatile substances with reproducible volatility. The most serious problems are associated with barium transfer through the vapour phase. Because of coordinative unsaturation of Ba^{2+} ions and high ionicity of the barium–oxygen bond, barium complexes are oligomerised in both the solid and vapour phases. Stabilisation of barium dipivaloylmethanate is achieved by using the adduct of dipivaloylmethanate with phenanthroline, which saturates the coordination sphere of barium, thus resulting in nearly quantitative transition of this complex to the vapour phase.^{2, 24}

The fourth (technological) problem is associated with the necessity of designing the optimum film morphology. It was shown in the studies of the effect of various factors on the orientation of films that the introduction of an excess of bismuth and copper compounds in the course of growth of high-temperature superconducting Bi2212-films favours the formation of *c*-oriented films, whereas the introduction of an excess of an alkaline-earth metal results in *a*-oriented films.¹⁷⁷ This is associated with the fact that the presence of the excess of bismuth and copper results in the formation of an equilibrium liquid phase or, at least, in a shift of the compositional point towards the regions where a melt should be present. This increases the mobility of the film components and facilitates the formation of thermodynamically more favourable *c*-oriented films, whereas *a*-oriented films are formed under kinetically controlled conditions. This is confirmed by the LPE experiments.¹²⁰ Generally, the morphology (polycrystallinity, planarity, film orientation, the presence of microscopic inclusions of non-superconducting phases, microscopic cracks, *etc.*) depends on numerous process factors that should be optimised thoroughly.

The most topical problems associated with the development of the MOCVD technology and requiring practical solution are connected with deposition of $\text{RBA}_2\text{Cu}_3\text{O}_z$ -films on bicrystalline substrates (SrTiO_3 , sapphire) and fabrication of devices based on the Josephson effect (logistors, SQUID magnetometers, *etc.*), preparation of high-temperature superconducting films using substrates with a large surface area (up to 70 mm in diameter), *in situ* double-sided deposition of films and attainment of high superconduction characteristics of thin high-temperature superconducting films using conventional substrates (R-sapphire, Si) and high-quality CeO_2 buffer layer.¹⁸⁴

Recently, R123-films (R is the 'light' RE element), the effects of stabilisation of metastable phases (see S.11) and an increase in the critical currents in solid solutions have attracted the attention of researchers. Yet another topical problem is the preparation of thick films with high current-carrying ability deposited on flexible tapes made of nickel metal and its alloys (the so-called 'Rolling-Assistant Biaxially Textured Substrates' or RABiTS) preliminarily coated with a buffer layer.¹⁷⁶ The CVD method is certain to play a key role in solving this problem.

3. Large-grain ceramics and single crystals

a. Characteristic features of materials based on large-grain ceramics

Real structure. As a rule, the idea of designing any material is based on a concept of a real structure with several hierarchical levels.^{185, 186} The basic crystal structure determines the fundamen-

Figure 22. Properties of materials used as substrates for the deposition of high-temperature superconducting thin films.

tal properties of HTSC and is responsible for their structural organisation at the microscopic level. Individual crystallites, which are always imperfect and consist usually of smaller subcrystallites (mosaic blocks, coherent scattering domains) separated by extended defects, form an intermediate (mesoscopic) level. Ensembles of crystallites (grains, granules) and pores form the macroscopic level of structural organisation of HTSC. The current concepts on complicated structure of melt-processed specimens of superconducting ceramics are illustrated in Fig. 23.^{9, 11, 55, 187–191}

Ensembles of large pseudo-single-crystal domains (their size reaches 0.5–5 cm depending on the precipitation conditions) separated by large-angle boundaries are the main microstructural motifs of large-grain ceramics. Each domain is a stack of thin (5–50 μm) $\text{RBa}_2\text{Cu}_3\text{O}_x$ -plates or lamellae rather than a true single crystal. The lamellae are characterised by the aspect ratio of ~ 1000 . The plates are oriented parallel to one another and separated by low-angle boundaries, which makes them ‘transparent’ to the critical current. It should be noted that the real structure of melt-processed HTSC is characterised by the presence of various extended defects such as twin boundaries, ultradisperse inclusions of non-superconducting phases, different types of microscopic and macroscopic cracks, appeared due to low plasticity of the $\text{RBa}_2\text{Cu}_3\text{O}_x$ -phase, and increased concentration of dislocations. In principle, all levels of structural organisation of HTSC should be taken into account. However, only the composition, structure of boundaries and nature of various defects have been studied in detail,^{187–191} though such parameters as porosity and density of ceramics as well as the size of crystallites and pores should also be considered.

The real structure of melt-processed HTSC can be considered as a large-domain system with pronounced ‘collective’ superconducting properties resulting in very high integral superconductivity characteristics due to the specific crystallisation mechanism of the peritectic melt.^{9, 11} For instance, an increase in the total density of specimens as a result of melt solidification eliminates the percolation problems characteristic of the current flow in the specimens obtained by solid-phase synthesis. ‘Pseudo-single-crystalline domains’ are united to form macroscopic aggregates that (potentially) can carry heavy critical currents. Finally, a large number of structural defects (inclusions, dislocations, low-angle boundaries) favours the appearance of new pinning centres.⁶ Unfortunately, only the ‘lamellar’ level of the structure of melt-processed materials is formed spontaneously and is characterised by high superconducting parameters. The remaining hierarchical levels of the structure can be formed only by using special techniques.

Methods of generation of new pinning centres. Generation of efficient pinning centres of the magnetic flux, which make it possible to increase substantially the critical current density J_c inside the grains, is the most important stage of the preparation of materials with a high repulsion force. The methods of solving this problem can arbitrarily be divided into physical and chemical ones.

Currently, the highest J_c values have been obtained using samples of superconducting ceramics irradiated with high-energy particles. Irradiation of samples with neutrons or heavy ions to produce cluster-type radiation defects (tracks) of size 20–100 nm was found to be the most efficient.^{192, 193} In this case, the J_c value increases in proportion to the irradiation dose. However, this type of treatment encounters considerable technological difficulties. Additionally, it has such drawbacks as residual activity of materials and the possibility of radiation-induced degradation of samples if the radiation doses exceed an optimum.

More promising are chemical methods which make it possible to introduce non-superconducting highly disperse inclusions in the matrix of the 123-phase.^{194–203} Particles of the Y_2BaCuO_5 -phase, an intermediate crystallisation product, are most often used as inclusions.^{194–197} The results obtained in the studies of pinning^{6, 9, 11} suggest that changes in J_c depend on the content and

Figure 23. Macroscopic (10^{-3} – 10^{-2} m), mesoscopic (10^{-6} – 10^{-3} m) and microscopic (10^{-10} – 10^{-6} m) levels of real structure of large-grain ceramics.

dispersity of the Y_2BaCuO_5 -phase. It is noteworthy that particles of this phase are not the pinning centres themselves and that the major contribution is made by the 123-phase–211-phase interface and the interfacial defects. Introduction of zirconates, titanates, stannates, nickel metal, uranium-235 oxide (its radioactive decay leads to ‘internal’ irradiation of the superconducting matrix) also results in generation of new pinning centres (see Fig. 4).

Types of intercrystallite boundaries. Generation of efficient pinning centres plays an important role in the preparation of high-temperature superconducting materials characterised by high values of the transport critical currents. However, in this case the perfection of intercrystallite boundaries and their ‘transparency’ to the critical current are the most important points. As has been mentioned above, the oxide superconductors are characterised by abnormally low coherence lengths (ξ). Because of this, two types of links are formed between the crystallites, *viz.*, strong links (ordinary intergrain phase contacts similar to intercrystallite ‘necks’) and weak links which, in the general case, are the breaks of the phase continuity. The extension of weak links is comparable with ξ values. The reasons for the phase discontinuity can be the formation of both the domains with local changes in stoichiometry and amorphous domains on intercrystallite boundaries, or the appearance of microscopic cracks, as well as high crystallographic anisotropy of HTSC and spatial disordering of crystallites.^{204–206}

In accordance with the formation mechanism of the 123-phase, the ensemble of growing crystallites formed in the early stages of melt crystallisation consists of *c*-oriented nuclei with disordered orientations in the *ab* plane. Growth of particles of such

an ensemble and their coalescence result in the formation of large-angle boundaries that are parallel to the c axis and the tilt boundaries that are perpendicular to the c axis. The best transport characteristics will be obtained if the current will flow through both types of boundaries without a considerable loss. Based on these grounds, a 'brick wall' model of the transport current flow through high-temperature superconducting materials was proposed.²⁰⁷ According to this model, the tilt boundaries enabling the maximum surface area of intercrystallite contacts play an important role in the formation of high transport current.

However, the 'brick wall' model does not consider the current flow through large-angle boundaries along the ab plane. According to the 'railway switch' model,²⁰⁸ there are both large-angle intergrain boundaries and a rather large relative amount of intercrystallite links 'transparent' to the current flow, which favours low current loss. These links responsible for the current flow through intercrystallite boundaries and the current flow through the tilt boundaries necessary for obtaining the maximum surface area of intercrystallite contacts form a three-dimensional superconducting network. Such a mechanism is most characteristic of bismuth-containing HTSC. Probably, it can also be postulated for yttrium-containing polycrystalline superconductors.

Thus, the density of the critical current that flows through intercrystallite boundaries is mainly determined by mutual spatial orientation of their constituent crystallites. Nevertheless, it was assumed²⁰⁹ that in the general case the J_c values are only dependent on the surface area of the 'strongly linked' areas of intercrystallite boundary. Obviously, the probability for two oriented (textured) crystallites to be 'strongly linked' is much higher than for disordered grains. However, it was reported²⁰⁹ that high J_c values can also be retained in the latter (unfavourable) case. The results of recent studies^{176, 210} indicate the presence of high-angle-but-low-energy (HABLE) boundaries, thus confirming this conclusion. This means that probability factors come into play when considering the problem of a critical transport current in bulk specimens.^{9, 55, 128, 129}

b. Methods of preparation

Large-grain ceramics cannot be a chemically and structurally homogeneous material. It is a composite whose practically important superconducting properties are superior to those of

highly homogeneous specimens and single crystals. Therefore, the development of melt solidification processes revolutionised the production technology of high-temperature superconducting ceramics since it opened a new way to the practical use of superconducting ceramic materials.

Minimisation of the inclusion size of secondary phases. The modern classification of melt solidification procedures for preparation of HTSC and the most important details including the chemical type of the starting precursor, mechanical prehistory and the heat treatment regime are presented in Fig. 24. Some trends in the development of melt solidification methods can be traced, which made possible the preparation of materials with high superconducting characteristics. These are:⁷⁻¹¹

- (1) a step-by-step change in the regime of high-temperature treatment in order to increase the degree of nonequilibrium in all stages of the process;
- (2) the use of methods of synthesis resulting in more homogeneous and disperse starting oxide powders;
- (3) the use of precursors in different initial states and the introduction of various additives.

The first trend is associated mainly with attempts to shorten the duration of treatment of samples at maximum temperatures. This made it possible to prevent the rapid growth of particles of secondary phases at temperatures above the peritectic temperature, which was probably a reason for passing from the classical 'Melt-Textured-Growth' (MTG) method to its modified version, viz., 'Liquid Phase Processing' (LPP).

The 'Quenched-Melt-Growth' (QMG) method involves a chemically induced increase in the degree of nonequilibrium of the system. In this case, the 211-phase is formed in the region of thermodynamic stability as a result of a fast 'downward' interaction of Y_2O_3 with the melt rather than due to relatively slow 'upward' decomposition of $YBa_2Cu_3O_7$. Experiments on super-fast cooling of droplets of a high-temperature $Y_2O_3 + L$ melt in an evacuated vertical metallic tube²¹¹ are probably one of the most successful implementations of this method.

The QMG method has an important alternative, the doping of melts with, e.g., platinum²¹² (the 'Platinum-Doped-Melt-Growth' or PDMG technique) and cerium dioxide.²¹³ In this case, the formation and decomposition of not-too-stable Pt-containing complex oxides ($Ba_4CuPt_2O_9$, $R_2Ba_2CuPt_2O_8$, $R_2Ba_3Cu_2PtO_{10}$, etc.) not only affects the nucleation processes,

Figure 24. Melt solidification methods of preparation of large-grain ceramics.

but also retards the growth of individual faces of crystallites of the 211-phase. This results in a change in their shapes and sizes and prevents coalescence of the crystallites into larger aggregates.²¹³

Several methods such as the 'Melt-Powder-Melt-Growth' (MPMG) and 'Powder-Melt-Process' (PMP) involve additional grinding of both the starting reagents and intermediate products in order to increase their dispersity and homogeneity of mixing.^{6, 214} A successful attempt has been performed at using a highly homogeneous mixture of barium cuprate and copper oxide with yttrium oxide, which simulates the phase composition of the specimens prepared by the QMG method (the so-called 'Solid-Liquid-Melt-Growth', or SLMG method).¹⁹⁷ Yet another, basically new modification of this method is the directional recrystallisation of amorphised quenched melt at temperatures $\sim 100^\circ\text{C}$ below the peritectic decomposition temperature of the 123-phase (the so-called 'Quench-and-Directional-Recrystallisation' or QDR method). This allows a rather fast (over 3–5 min) formation of the 123-phase and ultradisperse 'green' phase and preparation of highly textured superconducting ceramics using conventional zone melting technique with reduced hot zone temperature.²¹⁵

A positive effect of the above-mentioned innovations becomes more understandable when considering numerous experimental data indicating that the particle size of the 211-phase depends on prehistory of the system, despite the extreme conditions for the synthesis.^{9, 173, 216, 217} This is probably due to the possibility of intermediate formation of a superheated metastable (congruent) melt of the 123-phase. Numerous structural defects (grain boundaries mostly) accumulated mainly in the fine crystalline material facilitate strongly the decomposition of the congruent melt into a melt and the 211-phase. However, the excess 'green' phase can inhibit the growth of faces of the 123-phase on sintering, thus resulting in a more fine-grained structure.²¹⁷ The addition of Pt or CeO_2 changes the surface energy at the 211-phase–melt interface and results in the formation of the 211-phase with another morphology (needle-shaped particles). In accordance with the mechanism considered above, this facilitates dispersion of anisotropic particles of the 211-phase by the moving crystallisation front and, finally, the formation of more finely disperse inclusions of the 211-phase in the 123-phase matrix (see Table 3). The possibility of controlling the composition of composites by extracting the excess of BaCuO_2 from stoichiometric specimens of the $\text{YBa}_2\text{Cu}_3\text{O}_x$ -phase using porous Y_2BaCuO_5 -substrates (the so-called 'Liquid-Phase-Removal-Process' or LPRP method) was also reported.²⁰⁰

Thus, the analysis of the published data^{9, 11, 55} shows that an increase in the dispersity and uniformity of distribution of the particles of secondary phases is simultaneously one of the major lines of modification of the 'melt solidification processes' and a criterion for evolution of these methods. The 211-phase has a complex effect on the microstructural and functional characteristics of specimens. This phase is responsible for completeness of crystallisation, strength of materials, morphology of the superconductor grains and the appearance of new pinning centres. Eventually, controllable modification and variation of the above-mentioned processes and parameters results in an essential improvement of functional characteristics of the materials obtained.

The role of gas atmosphere. As has been mentioned above, gas exchange with the environment plays an essential role in the preparation of high-temperature superconducting materials. By varying the partial pressure of oxygen it is possible to solve several important problems. First is the problem of reduction of the crystallisation temperature and provision of compatibility of the melt with low-melting substrates. The second problem is associated with modification of procedures for creation of supersaturation by smooth variation of the partial pressure of oxygen, which can favour both controllability of the process and a decrease in the amount of impurities in the final product. Third, prevention of bubbling and deformation of melt-processed material. Finally, the

fourth problem is the control of both the width of the homogeneity region and the cation ordering in the solid solutions based on the 123-phase.

The effect of partial pressure of oxygen on the processes of preparation of high-temperature superconducting materials has been little studied.^{13, 218–222} A decrease in the temperature of peritectic melting of the 123-phase at reduced oxygen content and the formation of low-melting eutectics²²⁰ containing Cu(I) (at $770–800^\circ\text{C}$) was observed.^{218, 219} This made it possible to lower the growth temperature of single crystals of the 123-phase (down to $\sim 910^\circ\text{C}$ at $p_{\text{O}_2} = 5 \times 10^2–2 \times 10^4 \text{ Pa}$)²²⁰ and to prepare thick films on a silver substrate [$T_m(\text{Ag}) \approx 960^\circ\text{C}$] as well as rather dense bulky polycrystalline specimens.^{13, 221, 222} An original synthetic method consisting of isothermal crystallisation accompanied by a slow increase in the partial pressure of oxygen has been reported.^{218, 220} In this case, the process begins at a low partial pressure of oxygen and is completed in pure oxygen (the so-called 'Isothermal Melt Crystallisation' of IMC method).

Obviously, the density of superconducting materials should be maximum. However, the specimens prepared by melt solidification processes change their linear dimensions and shapes during oxygen exchange,^{9, 11, 55, 129} which results in an increase in their volumes and in the formation of a well-developed pore system which can hardly be removed. This problem is usually considered as applied to bismuth-containing high-temperature superconducting silver-sheathed tapes.²³ Unfortunately, almost no studies on this effect in high-temperature superconducting R–Ba–Cu–O materials have been reported, though it also plays a negative role, especially in the fabrication of materials with high critical transport currents. Experiments have shown that the main factors affecting the oxygen exchange between a sample and a gas phase are the phase composition, chemical homogeneity, relative content of Cu(I) in the solid phase, partial pressure of oxygen and the procedure used for compacting the sample.^{9, 129}

Currently, the 123-phases containing 'light' RE metals (La, Nd, Sm and Eu) are often synthesised using the single-crystal growth and preparation of melt-processed ceramics in an inert atmosphere. This is first of all due to the necessity of decreasing the degree of REE substitution for Ba in solid solutions in order to increase the transition temperature to the superconducting state.^{7, 8}

Formation of single-domain structure. Taking into account the grain boundary models considered above, it can be assumed that the most favourable way of fabricating the HTSC capable of carrying strong critical transport currents is to prepare textured materials.^{223–231} Attempts at preparing superconducting ceramics with oriented (plate- or rod-like) structure were based on conventional texturing procedures such as slow cooling in a uniform temperature field ($\text{grad } T = 0$), slow cooling in a temperature gradient field ($\text{grad } T > 0$) without moving a specimen (versions of the Bridgman method: 'Vertical Gradient Freezing' or VGF, 'Seeded Directional Solidification' or SDS), a gradient crystallisation with a moving hot zone (the 'Zone Melting' or ZM method) and the use of seed crystals (the 'Top-Seeded-Melt-Growth' or TSMG method). Non-traditional methods, *e.g.*, crystallisation along the concentration gradient (the so-called 'Constitutional-Gradient-Melt-Growth' (CGMG) and 'Geometrically-Organised-Growth-Evaluation' (GEORGE) processes) are also used.

Introduction of artificial nucleation centres of the 123-phase is an efficient method for controlling the nucleation. Such centres are formed by introducing relatively large seed crystals of REE-containing analogues of the 123-phase with higher peritectic decomposition temperature.²²³ Usually, Sm123 ($T_p \approx 1050^\circ\text{C}$) and Nd123 ($T_p \approx 1085^\circ\text{C}$) phases are used as seed crystals. As a rule, the seed crystals are placed on top of a dense substrate (a pellet or a rod). Then the melt–crystallisation cycle is performed using the temperature gradient or movement of the hot zone along the sample. The seed crystal with higher melting temperature initiates the growth of the desired phase along the direction of

propagation of the crystallisation front, which results in the formation of giant pseudo-single-crystal domains whose dimensions are comparable with those of the sample.^{7, 8, 224–226}

It is noteworthy that the orientation of pseudo-single crystals thus formed virtually coincides with that of the seed crystal, therefore the growth direction of the 123-phase is readily controllable. This is probably due to the epitaxial character of the process on the faces of the seed crystal, the unit cell parameters of which are close to those of the desired 123-phase. Often, the observed formation of differently oriented domains indicates complexity of the actual growth mechanism.⁸ It was proposed to coat the 'non-working' surface of the seed-crystallising specimens with compounds that form the Yb123-phase with a lower peritectic decomposition temperature, thus preventing crystallisation on the lateral surface of the pellet.²²⁵ Single crystals of magnesium oxide and strontium titanate were also proposed as seed crystals; however, no epitaxy was observed because of the chemical reaction between the melt and seed crystals and the formation of a buffer layer of the reaction products, so the efficiency of using such seed crystals decreases drastically.^{6, 7}

If the seed crystals are introduced at the beginning of melt crystallisation in the course of its cooling, it is possible to obtain large-grain specimens of high quality. The 'Constant-Undercooling-Solidification-Processing' (CUSP) method,^{8, 226} consisting in isothermal crystallisation of the 123-phase after introduction of a seed crystal into the hot zone, is a modification of the above-mentioned approach. Unfortunately, it is difficult to introduce a large number of oriented seed crystals anisotropically distributed in the bulk of the sample, which is necessary for the corresponding texturing of a high-temperature superconducting material (the 'Composite Reaction Texturing' or CRT method).²²⁷ Only a few studies concerning the introduction of multiple seed crystals either into the bulk or on the surface of specimens have been reported so far.²²⁸

Magnetically induced alignment (MIA)^{229, 230} is performed using REE atoms with large magnetic moments (Gd, Dy and Ho). The degree of magnetically induced texturing of the specimens prepared even by ordinary sintering increases in proportion to the applied magnetic field. Combination of this approach with crystallisation from the melt increases its efficiency, which reaches an optimum value in magnetic fields higher than 1 T.²³⁰

Mention should be made of the original CGMG method in which crystallisation is driven by the gradient of the REE concentration in the melt, resulting from varying the concentration of REE (e.g., Yb and Y) with different peritectic decomposition temperatures.²³¹ It is believed that this method can serve as a basis for the development of a process of preparation of long-length textured materials including tapes sheathed with highly oriented 123-phase.²²⁸

Chemical modification and generation of efficient pinning centres. The 'Oxygen-Controlled-Melt-Growth' (OCMG) method is a new method for the preparation of high-temperature superconducting materials at reduced partial pressure of oxygen (0.1 mol. %–1 mol. % O₂).^{7, 232} It is based on the ability of REE with the largest ionic radii (in particular, Nd, Sm, Eu and Gd) to form solid solutions of the R_{1+x}Ba_{2-x}Cu₃O_z type. Crystallisation from the melt at reduced partial pressure of oxygen results in a considerable decrease in the degree of barium substitution and in appreciable increase in the transition temperature to the superconducting state (up to 95–96 K).^{7, 8, 76, 86, 88} This is also connected⁸⁸ with possible cation ordering in the crystal lattice, e.g., with the formation of pairs of neodymium ions in the barium positions, which results in the ordering of the oxygen sublattice. At the same time, domains with fluctuations of chemical composition can appear in such a superconducting matrix. These domains are efficient pinning centres because of the strong suppression of superconductivity therein in nonzero magnetic fields, which results in the peak effect (see Fig. 4).^{7, 8}

The advantage of the pinning centres thus generated over point defects consists in higher efficiency of modulations of

chemical composition of the structure at relatively high temperatures (the liquid nitrogen temperature) corresponding to the operating mode of high-temperature superconducting materials. The formation of these types of pinning centres that were not observed for the Y123-phases is the major advantage of the OCMG method, which allows the preparation of superconducting materials with record characteristics.⁷

Several reasons for the appearance of pinning centres are discussed in different models.^{7, 8, 76, 232–234} The first of them is connected with random fluctuations of the Nd:Ba ratio in the superconducting matrix due to local fluctuations of temperature, *p*O₂ and the melt composition during the growth of the pseudo-single-crystal domains (for the OCMG method). The next reason is the formation of a quasi-ordered nanostructure as a result of spinodal decomposition of the solid solution caused by post-crystallisation annealing. Third, it is the formation of clusters, oxygen vacancies and twin boundaries in the case of nonuniform oxygen distribution in the superconducting matrix. Next, the pinning centres can appear due to the formation of highly disperse inclusions of the R422-phases and redistribution of cations between the matrix and these non-superconducting inclusions. Finally, antistructural defects produced in the course of (probable) mutual exchange of Nd³⁺ and Ba²⁺ ions between the corresponding crystallographic positions can also result in the appearance of pinning centres (see S.12).

The peak effect observed in all R123-phases including R = Y is associated with the presence of local oxygen-deficient regions characterised by lower *T*_c as compared to that of the entire matrix.^{233, 234} It is assumed²³³ that this effect increases due to the presence of impurities (e.g., the components of the crucible) which reduce the oxygen mobility and favour its nonuniform distribution. It was hypothesised⁹³ that nonuniformity of the oxygen distribution in the materials based on the Y123-phases can be due to the spinodal decomposition of the solution formed by the YBa₂Cu₃O₆ and YBa₂Cu₃O₇ phases.

An alternative model^{7, 8, 91, 92} relating the peak effect in the materials based on the R123-phases (R = Nd, Sm, Eu, Gd) to the fluctuations of the cation composition does not contradict the preceding model since it considers variations of the cation composition as a primary phenomenon responsible for a side effect, *viz.*, nonuniform distribution of oxygen. The possibility was reported^{7, 8, 92} of controlling the peak effect by different parameters of the process, such as the post-crystallisation annealing temperature, oxidation degree of the specimens and introduction of a 'cocktail' of REE dopants.

c. Methods of single-crystal growth

Unlike the production technology of polycrystalline materials, single-crystal growth is focused on growth of chemically and structurally homogeneous crystals of a specified size, shape, composition and controllable low level of defects and impurities. Meeting these requirements allows the crystals to be used in basic or applied investigations, e.g., in structural analysis,^{17, 235, 236} spectroscopy,^{237, 238} studies of oxygen diffusion,^{154, 157} atomic force microscopy,^{7, 8, 12} measurements of fundamental physical constants,¹⁹ etc.^{8, 239}

Anisotropy of the rate of crystal growth along crystallographic directions depends in a complex manner on the nature of REE and conditions of crystallisation.⁸ This can be due to the crystallographic anisotropy, different face energies and different mechanisms of the face growth. In turn, the growth anisotropy causes changes in the morphology and shape of the entire crystal. For instance, the crystals grown by spontaneous crystallisation are usually thin plates oriented perpendicular to the {001} direction,^{126, 240, 241} since the growth rate of the {100} faces is approximately five times higher than that of the {001} faces at high cooling rates (kinetic control). If the rate of melt cooling decreases down to 0.5–1.0 K h⁻¹, thick prisms-parallelepipeds or even isometric crystals are formed.²⁴¹ The {101}, {011} and {111} faces grow under these conditions along with the {100},

{010} and {001} faces, which indicates a quasi-equilibrium crystal growth (thermodynamic control).¹²⁶

The method of top-seeded crystal pulling from supercooled melt is characterised by a rather low supersaturation.^{8, 114, 239, 242} Such factors as the melt hydrodynamics and the distribution of temperature and concentration near the growing single crystal begin playing a significant role in this case (see S.13). By controlling the pulling rate and taking into account the growth anisotropy it is possible to obtain various 'bulk' single crystals, e.g., pyramidal crystals with expanded bases, large isometric crystals with a small angle of inclination of edges, pyramidal crystals with 'concave' bottom face and cylindrical crystals.^{8, 114, 239, 243} Other crystallisation methods allow the obtaining of needle-shaped and plate-like single crystals and crystals in the form of parallelepipeds as well.^{244–249} Thus, modern crystallisation methods make it possible to grow the HTSC crystals of any desired shape.

Crystallisation from melts is strongly affected by the nature of RE elements. In particular, introduction of 'light' REE can cause a chain of interrelated 'domino'-like changes in the characteristics of the R123-phases. The chain is as follows: an increase in the 'geometrical' stability → an increase in the thermal and thermodynamic stability → an increase in both the peritectic decomposition temperature and dissolution enthalpy of the R123-phases in melts → an increase in the solubility of REE and a decrease in the slope of the liquidus near the peritectic decomposition temperature, a decrease in the viscosity and acceleration of diffusion of the components in the melt. As a result, the crystallisation rate of the R123-phases containing 'light' REE (especially, Nd and Sm) should be higher than that of the same phases containing 'heavy' REE (Y, Yb, etc.) at a given supercooling degree of the melt, which favours the preparation of larger Nd123, Sm123, etc., crystals.¹¹⁴ The predicted regularities of the growth rate of 123-phases with different REE are observed experimentally, which can be seen from comparison of the growth rates along the direction of pulling the crystals grown by the modified Czochralski method:^{8, 114}

Phase	Y123	Y123	Pr123	Nd123
Atmosphere	air	oxygen	air	air
Growth rate /mm h ⁻¹	0.075–0.108	0.16	0.1	0.24

The growth rate of the crystals of a mixed (Y,R)123-phase was increased by doping the melt with samarium and neodymium.¹¹⁴

Unfortunately, the advantages of using 'light' REE to assist single-crystal growth and preparation of 'melt-processed' ceramics are combined with problems in controlling the chemical composition of products due to cation nonstoichiometry of the 123-phases containing 'light' RE elements. A simplified consideration of crystallisation in the frame of the Y₂BaCuO₅–Ba₃Cu₅O₈ quasibinary system is possible only for the 'point' Y123-phase (Fig. 25). In the case of systems whose phase diagrams contain regions where solid solutions can exist,⁸ the C° compositional point moves from the melt region L or a 422–L (PrBaO₃–L) two-phase region of the peritectic melt (at T = T_b), which contains particles of 'secondary phases' at elevated temperatures, to the R123ss–L two-phase region where the compositions of equilibrium solid [c(ss)] and liquid [c(L)] phases are determined at T_s < T_b (T_b > T_p) by tie-lines.

The ratio of the coefficients of cation diffusion in the melt plays a particularly important role in the establishment of an interrelation between the true compositions of the liquid and solid phases in the case of steady-state crystal growth. Obviously, the close values of these coefficients favour the choice of a tie-line that is the closest to the equilibrium tie-line. If the diffusion coefficient of a given cation is lower than those of other cations, the true tie-line is shifted with respect to the equilibrium tie-line.⁸ As a rule, the differences between the diffusion coefficients are not too large and the use of equilibrium phase diagrams makes it possible to correctly (quantitatively) predict the compositions of phases that crystallise under given conditions.

Figure 25. Supersolidus phase diagrams and single-crystal growth of HTSC.

Analysis of the data presented in Table 4 indicates that the volume of single crystals of the R123-phases can be appreciably increased and their perfection can be essentially improved²⁵⁰ using two modifications of the Czochralski method [the 'Solute-Rich-Liquid-Crystal-Pulling' (SRL-CP) and 'Top-Seeded-Solution-Growth' (TSSG) procedures].⁸ This is a universal method since it allows one to grow large single crystals of almost all R123-phases (R = Y, Nd, Sm, Pr) and (R₁R₂)Ba₂Cu₃O_z (R₁ = Y, R₂ = Sm, Nd) solid solutions^{8, 80, 81, 114, 251} as well as Nd_{1+x}Ba_{2-x}Cu₃O_z, Pr_{1+x}Ba_{2-x}Cu₃O_z, Nd_{1+x}Ba_{2-x}Cu_{3-y}.Ga_yO_z, YBa₂Cu_{3-y}Zn_yO_z phases, etc. According to the reported data,²⁵² superconducting crystals of the Pr123-phase can be obtained by the 'Top-Seeded-Floating-Zone' (TSFZ) procedure⁸ at reduced partial pressure of oxygen (see S.14).

Considerable attention has been paid recently on the development of growth methods of single-crystal high-temperature superconducting whiskers.^{76, 244, 253–256} The growth of whiskers in the systems with regions of solid solutions of the Bi–Sr–Ca–Cu–O^{254–256} and R–Ba–Cu–O (R = Sm,²⁴⁴ Nd⁷⁶) types was reported. It is known that this type of crystals possesses unique electrophysical²⁵³ and mechanical²⁵⁷ properties.

4. Preparation of long-length composites

Almost all the HTSC materials considered above (except for single crystals) are composites comprising the superconducting matrix and non-superconducting phases that determine specific properties and areas of application of a particular composite. For instance, highly disperse powders prepared by the chemical homogenisation methods are usually a mixture of different phases and dopants. The components of a film–substrate pair affect strongly each other. Large-grain ceramics are also a composite containing 'secondary phases' as inclusions in the superconducting matrix.

High-temperature superconducting silver-sheathed tapes are a typical example of industrial superconducting composites.^{16, 23, 54} To prevent thermoresistive instability of such tapes, they are fabricated as multifilament wires in which disappearance of superconductivity due to a local overheating above T_c will cause the current to flow round the resistive area through adjacent superconducting cores. Usually, superconducting wires are made of bismuth- or (more rarely) thallium-containing HTSC which possess higher plasticity and can be textured much easier than the

^a $\Delta M(60 \text{ K}, 10 \text{ mT})/\Delta M(5 \text{ K}, 1 \text{ T})$, where ΔM is the width of a hysteresis loop; this value for the undoped phase equals 0.01.

materials based on the R123-phases.^{258–263} Additionally, rather low melting temperatures of bismuth-containing HTSC provide a wider choice of metals and alloys for fabricating the sheath.

Silver is one of the most widely used materials for the outer sheath. It is plastic and relatively available, has high electrical and heat conductivity, causes no decrease in the transition temperature to the superconducting state of HTSC and serves as a specific membrane for oxygen exchange between the superconducting cores inside the tape and the gas atmosphere outside the tape. This system is closed as regards the mass transfer of bismuth, calcium, strontium and copper oxides. In addition, the walls of silver-sheathed tapes can favour nucleation and oriented grain growth near the surface areas of HTSC adjacent to the sheath,^{23, 54, 263} especially in the case of tapes with planar (ribbons) or pseudo-1D (multifilamentary wires) geometry. Often, the strength characteristics of the sheath are improved using the effect of dispersion hardening, *e.g.*, due to the formation of the MgO microcrystals in the silver matrix upon oxidation of silver–magnesium alloys by atmospheric oxygen.

The essential feature required of superconducting silver-sheathed tapes is that they be capable of carrying heavy currents. This first of all requires the attainment of perfect mutual orientation of highly anisotropic superconducting crystallites and exclusion of weak links between them. The negative effect of ‘secondary phases’ and gas evolution on peritectic melting or high-temperature annealing, which can cause a nonuniform current flow through the cross section of the tape, local violation of the optimum orientation of the HTSC grains and even shut off the orifice of the wire of size 1–30 μm , should also be prevented.

The optimum microstructure is usually formed by varying the composition, external gas atmosphere and thermal annealing regime. This requires a detailed knowledge of the phase diagrams.^{53, 54, 69, 263} To attain high transport characteristics of high-temperature superconducting tapes, it is also appropriate to use the methods of chemical homogenisation for preparation of highly disperse chemically and granulometrically homogeneous carbon-free powders for filling the silver sheathes that should undergo a plastic deformation. The methods used in the fabrication of superconducting silver-sheathed tapes should include (i) modern processes for the preparation of composites (‘powder-in-tube’, ‘tube-in-tube’, ‘rod-in-tube’ methods, *etc.*), (ii) thermomechanical treatment (repeated drawing and rolling) resulting in elongation of the silver sheath filled with powder by a factor of several tens, in an appreciable increase in the density of the superconducting cores inside the tape and in forced orientation of the HTSC grains along the deformation axis and (iii) low-temperature vacuum annealing to optimise the oxygen content inside the tape and to prevent bubbling.

Thus, it is now possible to fabricate tapes with a microstructure close to the desired one using modern processes and

production methods. However, the fundamental problem associated with a dramatic decrease in the critical currents of bismuth-containing HTSC (compared to other types of HTSC and first of all, to R123-phases) on raising the temperature or an increase in external magnetic field (see Fig. 4) remains unsolved. Therefore, the operating temperatures of bismuth-containing tapes are lowered to the liquid hydrogen temperature (20 K), despite the fact that their T_c values (90–110 K) are higher than the boiling point of a cheap coolant, liquid nitrogen (77 K), which is effectively used with other types of HTSC.

The most promising way of increasing the critical current density for bismuth-containing high-temperature superconducting materials is associated with the preparation of composites with uniformly distributed microscopic inclusions of non-superconducting phases formed by the constituents of the system or by introducing ‘alien’ phases compatible with the HTSC.^{264–270} The main characteristics of the composites thus prepared (homologues of the 2212- and 2223-bismuth-containing HTSC) are presented in Table 5. As can be seen, the most pronounced positive effect is observed with zirconates and stannates, although there are many phases compatible with the high-temperature superconducting matrix which do not result in appreciable decrease in its T_c and do not suppress the HTSC formation dynamics. At the same time, measurements of physical properties indicate an increased stability of superconducting characteristics of the composites.²⁷⁰ Obviously, this promising investigation line will be developed in the future.

V. Practical applications of high-temperature superconducting materials

The possibility of practical applications of high-temperature superconducting materials has opened fresh opportunities for microelectronics, medicine, production of efficient energy storage and power transmission systems and industry as a whole.^{7, 8, 15, 16}

The use of high-temperature superconducting films allowed production of small-scale systems belonging to a new generation of communication devices including electromagnetic screens, modulators, antennas, commutators, filters of microwave and pulse signals, multilayered film hetero-structures including dielectric, ferroelectric and normal metal layers in addition to the HTSC layers. Such films made it possible to develop bolometers operating in the millimetre, submillimetre and infrared bands, basic circuit arrangements of superfast computers, ultrasensitive tomographs and diagnostic devices capable of responding even to changes in the mental condition of a man (measuring devices based on the Josephson effect).

High-temperature superconducting tapes with high superconducting characteristics can actually be used in practice for

production of super-power magnets and lines for nondissipative transmission of electrical power. Currently, silver-sheathed tapes can be manufactured commercially. Large-scale production and wide use of these tapes are still limited by high cost. Nevertheless, many small-scale systems and test lines are already at work.

The prospects of using HTSC based on the 123-phase are associated with the possibility of production of bulky items of a rather simple shape using the most suitable and operationally convenient methods. Such items can be divided into two classes. The first of them comprises the specimens characterised by a high ability to shield the external magnetic field or to be repelled by the field. This ability can be characterised by the so-called levitation force, which is dependent on the intracrystallite critical current density. The other class comprises the specimens of high-temperature superconducting materials with high transport (intercrystallite) current. In the future, such ceramic devices can find practical use in the production of permanent magnets with 'frozen-in' magnetic flux, magnetic repulsion trains (the MAGLEV project), flying wheels, bearings rotating virtually without friction, efficient and economical motors, super-power generators and transformers, magnetic separators, superconducting relays, fast current limiters, powerful nondissipative electrical current leads, medical tomographs, powerful magnetic systems for thermonuclear fusion and accelerators of elementary particles (new-generation Tocamac) and, finally, magnetohydrodynamic generators.

Preparation of substrates in thin film technology and micro-electronics seems to be the most realistic practical use of large single crystals of HTSC. Such substrates should be characterised by small mismatch between the unit cell parameters and those of materials of the films, have close TEC values and favour epitaxial growth of films. Additionally, all crystallochemical and thermomechanical parameters of high-temperature superconducting single-crystal substrates can be precisely adjusted by using solid solutions with different types of substitution of the yttrium and barium positions.

Supplement

S.1. The presence of a metastable orthorhombic BaCu_3O_4 phase [$a = 10.986(3)$, $b = 5.503(1)$, $c = 3.923(1)$ Å] was found in thin films of the R123-phase.²⁷¹ Stabilisation of this phase requires the formation of a coherent interface between the phase and surrounding high-temperature superconducting matrix. The BaCu_3O_4 phase decomposes if the film thickness exceeds ~ 0.3 μm .

S.2. Discrepancies in determination of the limits of oxygen nonstoichiometry in BaCuO_{2+z} can be due to the formation of oxycarbonates [e.g., $\text{Ba}_{44}\text{Cu}_{48}(\text{CO}_3)_6\text{O}_{87.9}$, see Aranda and Attfield²⁷²] or to an ambiguous assignment of the specimens with other cation compositions to this phase.^{273, 274} A reliable thermodynamic assessment of the Ba–Cu–O system was reported.²⁷³ The oxygen nonstoichiometry in the Ba_2CuO_3 -, BaCuO_2 - and $\text{Ba}_2\text{Cu}_3\text{O}_5$ -phases was also discussed.^{274–276}

S.3. The low-temperature decomposition of $\text{NdBa}_2\text{Cu}_3\text{O}_z$ was considered.²⁷⁷ It was established that degradation of superconducting properties of high-quality polycrystalline specimens ($T_c = 94$ K) in the temperature range 450–750 °C occurs nonlinearly depending on the 'ageing' temperature and duration of low-temperature isothermal annealing. Prolonged annealing at 400–600 °C for 450 h in air can result only in a slight decrease in T_c after complete oxidation of the sample ($T_c = 89$ K), whereas the annealing at 700 °C for 165 h brings about a decrease in T_c by 11 K.

S.4. The first reliable determination of the structure of a low-temperature (oxidised) modification of the $\text{Nd}_{1.9}\text{Ba}_{1.1}\text{Cu}_3\text{O}_z$ -phase using the data of X-ray, electron and neutron diffraction experiments and IR and Raman spectroscopy was reported recently.²⁷⁸

Studies carried out by neutron diffraction, differential scanning calorimetry, Raman and Mössbauer spectroscopy and EXAFS have confirmed that, unlike the $\text{NdBa}_2\text{Cu}_3\text{O}_z$ -phase, oxidation of the $\text{Nd}_{1.9}\text{Ba}_{1.1}\text{Cu}_3\text{O}_z$ -phase can occur owing to 'one-dimensional' oxygen diffusion along the b axis of the structure. This is accompanied by a second order phase transition resulting in the appearance of an inversion centre (the high-temperature modification has the $Amm2$ space group vs. the $Ammm$ group for the low-temperature modification²⁷⁸), ordering of the oxygen sublattice and coupled zigzag-shaped displacements of copper atoms from the 'ideal' positions at the centres of perovskite-like structural blocks, which is most likely due to 'compression' of the structure along the long axis c caused by introduction of extra oxygen atoms.²⁷⁹

S.5. Discussion of the charge transfer between the superconducting planes and dielectric block using the results obtained by X-ray structural analysis and Raman spectroscopy can also be found elsewhere.^{278, 280}

S.6. At a given partial pressure of oxygen, the compositions with the minimum $x(S_1)$ and maximum $x(S_2)$ substitution degrees in the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution are fixed, because they correspond to the invariant quinary equilibria (the number of degrees of freedom is $4 - 5 + 2 - 1 = 0$)

The corresponding phase transformation temperatures are also fixed, which provides the optimum conditions for achieving the above-mentioned substitution degrees. For instance, it was experimentally established that a temperature range between 985 and 1030 °C is optimum for preparation of the $\text{NdBa}_2\text{Cu}_3\text{O}_z$ phase with $T_c \simeq 94$ K (at $p_{\text{O}_2} = 0.21$ atm).²⁸¹

S.7. One of the most promising and intensively developing universal approaches to computer simulation of crystallisation of HTSC systems is the phase field concept for multiphase systems (PFCMS).²⁸² In the classical nucleation models, the liquid–solid interface is assumed to be infinitely thin. The PFCMS model considers a liquid–solid interface of finite thickness. Obviously, this is a great stride toward deriving a fundamental generalisation of crystallisation mechanisms. An additional continuous function (the phase field) is also introduced in this model, which plays the role of the order parameter used for identification of the regions of the liquid and solid states. In the simplest case (one solid phase in melt), the phase field can be described using a function $p(x, t)$ whose values vary between 0 and 1. If $p(x, t) = 1$, then at a point x and at instant t the system is in the solid state, whereas $p(x, t) = 0$ corresponds to the liquid. The liquid–solid interface is described by all $p(x, t)$ values between 0 and 1. The following equation for the phase field function was derived²⁸² by minimising the density of the free energy of the system

$$\tau[\dot{p}(x, t)] = \varepsilon \nabla^2 p(x, t) - f'(p) + m(p, T, c).$$

This equation includes most of the physically important melt solidification parameters such as the (free) energy gradient ε ; the crystallisation front propagation velocity (by means of the orientation-dependent function τ , which describes an anisotropic or facet growth); the derivative $f'(p)$ of the potential determining the phase boundary stability under equilibrium conditions, as well as the driving force $m(p, T, c)$ of the process, which is proportional to the degree of deviation from thermodynamic equilibrium and should include the temperature dependence $T(x, t)$ and the concentration profile of the distribution of constituents (c). The necessity of inclusion of the function c is explained by considering the diffusion processes occurring in the system (e.g., the dissolution rate of the solid phases in the melt).

S.8. The mechanism of the needle-shaped crystal growth under isothermal conditions remains unclear as yet. At the same time, this phenomenon is not observed for those REE of the yttrium subgroup whose R123-phases do not form the barium ← REE substitution solid solutions. It was also established²⁸¹ that the reason for growth of the needle-shaped crystals is closely related to the features of the phase diagram of the Nd–Ba–Cu–O system, in particular, to the increased deviation of the composition of the equilibrium phase of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ solid solution towards $x > 0$ which occurs on raising the temperature. In this case, the phase with $x = 0$ decomposes on heating with the formation of a solid solution with $x \approx 0.1$, a non-superconducting $\text{Nd}_4\text{Ba}_2\text{Cu}_2\text{O}_{10}$ phase and a melt L. At the initial moment, the composition of the liquid phase L can differ from the equilibrium composition, thus providing the driving force for the growth of $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ and $\text{Nd}_4\text{Ba}_2\text{Cu}_2\text{O}_{10}$ crystals not only under isothermal conditions, but (probably) also even with increasing temperature (mention may be made here that single crystals of HTSC are usually obtained by cooling of melts).

S.9. Single-phase specimens of mercury-containing HTSC and especially mercury-containing crystals can hardly be obtained because of extremely high volatility of mercury and its compounds. Therefore, the preparation of the crystals of the most promising Hg1223-homologue with unique physical characteristics²⁸³ by the ampoule synthesis is of considerable interest. Single crystals of $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_z$ ($n < 4$) with $T_c \approx 130$ K were synthesised by spontaneous crystallisation from PbO or BaCuO_2 –CuO flux in a crucible made of stabilised zirconium dioxide (crystallisation temperature $930 < T < 1070$ °C) in an autoclave at an Ar pressure of $(10–15) \times 10^3$ atm.^{284, 285} Introduction of rhenium in order to stabilise the structure makes it also possible to grow single crystals of $\text{Hg}_{0.75}\text{Re}_{0.22}\text{Ba}_2\text{Ca}_5\text{Cu}_6\text{O}_{15}$ ($T_c = 100$ K) and $\text{Hg}_{1-x}\text{Re}_x\text{Ba}_2\text{Ca}_6\text{Cu}_7\text{O}_{16+4x+z}$ ($T_c = 84$ K) homologues.⁶⁸

S.10. The uniqueness of the HTSC–manganite hetero-structure²⁸⁶ shown in Fig. 21 is that it comprises two promising and intensively studied phases with nonlinear electrophysical properties, viz., the superconducting cuprate phase and the manganite phase exhibiting a giant magnetoresistance effect. Such hetero-structures are promising for the use in microelectronics.

A microstrip resonator can be considered as an example of devices manufactured using conventional elements (HTSC-films and a dielectric substrate). In this case, the double-sided deposition of a superconducting film on the single-crystal substrate was carried out by CVD methods.²⁸⁷

S.11. Phases of the $\text{RBa}_2\text{Cu}_3\text{O}_z$ type can be synthesised over a period of about 10 to 30 min at 500–550 °C using a mechanoactivated decomposite mixture, i.e., a mixture of copper-free and copper-rich reagents ($\text{Y}_4\text{Ba}_3\text{O}_9$ and CuO) compacted at 250 °C.²⁸⁸

S.12. Recently, the formation of antisite defects in the barium and neodymium sublattices in the fully oxidised $\text{NdBa}_2\text{Cu}_3\text{O}_{6.9}$ phase with a low transition temperature to the superconducting state was found by X-ray spectral and X-ray structural analysis and by Raman spectroscopy.²⁷⁹

S.13. A cuprate melt considered as a high-temperature solvent is characterised by a density from 4.8 to 5.4 g cm^{−3}. The minimum density is observed for an eutectic composition 28 mol. % BaO:72 mol. % CuO.²⁸⁹ Such melts have similar temperature dependences of the surface tension and viscosities which increase as the BaO concentration increases.²⁸⁹ Above 955 °C, the surface tension coefficient of the melt lies in the range $\sim 0.3–0.6$ N m^{−1}. The calculated radii of the viscous flow units suggest that the melts have a ‘slightly ionic’ nature and a low aggregation degree of the ions in the melt. The melts exhibit a mixed (mostly electron-type) conductivity.

Two factors should be considered when discussing the limiting stages of single-crystal growth from a liquid (in particular, by the modified Czochralski method). First, this is the steady-state

growth of the single crystal. This requires meeting the condition for the balance of the amount of R_2O_3 in the flux and that necessary for the deposition of the R123-phase on a crystal face, written over the liquid–solid interface. Second, crystallisation can be characterised by relatively high near-boundary supersaturation with respect to R_2O_3 (in the so-called boundary layer) due to kinetically hindered crystal face growth. The following approximate formula for the crystal face growth rate (v), which includes the diffusion of Y^{3+} ions in the melt, was proposed⁸ under some assumptions as a first approximation.

$$v = \frac{D_L^{2/3} \omega^{1/2} [(T_b - T_p)/m_L^{211} + (T_p - T_i)/m_L^{123}]}{1.6v^{1/6}(c_s^{123} - c_i)}$$

Here, D_L is the coefficient of bulk diffusion from the Y_2O_3 source phase (Y_2BaCuO_5) contacting the melt at the temperature T_b to the face of the $\text{YBa}_2\text{Cu}_3\text{O}_z$ crystal (the peritectic decomposition temperature T_p) that grows from the melt at the temperature T_i ; ω is the angular velocity of crystal rotation; m_L^{211} and m_L^{123} are the slopes of the tangent to the liquidus above and below T_p ; v is the kinematic viscosity of the melt; and c_s^{123} and c_i are the concentrations of Y^{3+} ions in the solid phase (crystal) and in the melt near the growing crystal, respectively. The maximum crystal face growth rate that can be achieved in the absence of kinetic complications is $v_{\max} \approx 0.36$ mm h^{−1}. However, it is 3 times higher than that observed experimentally (0.108 mm h^{−1}). This indicates that the growth of single crystals of the Y123-phase using the modified Czochralski method is likely to be controlled not only by diffusion of the components through the melt, but also by the interphase kinetics of deposition of the Y123-phase.

The hydrodynamic conditions of the experiments on the growth of large HTSC-crystals and their effects on the morphological features of $\text{RBa}_2\text{Cu}_3\text{O}_z$ crystals have been analysed in detail using the generalised ‘dimensionless analysis’ approach.²⁹⁰ Growth of a crystal by the modified Czochralski method is characterised by an increase in the diameter of the crystal with time, which continuously changes the conditions for crystal growth. Generally, the relative contribution of convection due to (i) the density difference between the melts with different temperatures (natural convection) and (ii) rotation of the crystal (forced convection) can be assessed as the ratio of the Reynolds and Grashof numbers. The dimensionless temperature

$$\Theta = \frac{T_i - T_{\text{top}}}{T_b - T_{\text{top}}}$$

of the ‘crystal–melt’ contact surface (T_i) and the top region of the crucible (T_{top}), normalised to the overall temperature gradient between the bottom (T_b) and top regions of the crucible can be estimated (from experimental data) as $\Theta = 0.47\text{Re}^{0.028}\text{Pr}^{0.041}\text{Gr}^{0.019}\text{Dsc}^{0.064} + 0.10$ (Dsc is the geometrical factor). According to this expression, the steady-state crystal growth requires a precise control over the rotation velocity taking into account the increase in the crystal diameter during the growth. Otherwise, a crucible of a large diameter should be used.

S.14. The results of recent studies confirm the existence of a superconducting $\text{PrBa}_2\text{Cu}_3\text{O}_7$ phase; however, this issue remains a moot question as yet.^{291, 292}

Abstract. The most important methods of synthesis and purification of carbon nanotubes, a new form of material, are described. The prospects for increasing the scale of preparation processes and for more extensive application of nanotubes are evaluated. The bibliography includes 282 references.

I. Introduction

Immediately after they had been discovered in 1991,¹ carbon nanotubes (nanotubulenes, hereinafter, NT) attracted so much attention of scientists of various professions that the discoverer, Iijima, soon became and still remains one of the most cited researchers in the field of nano-sized materials. The reason for this interest is not the unusual structure of these compounds, as in the case of fullerenes (although this also plays a certain role) but rather the prospects that are opened by the properties of NT for materials science.

The journal *Fullerene Science and Technology*, having the word 'technology' in its title, was founded in 1992; during the decade which has passed since the discovery of fullerenes (by 1995), 150 patents for their use were granted in the USA;² reviews dealing with commercialisation of the manufacture and use of fullerenes appeared;³ however, there are still no data on the large-scale implementation of any patented method or, even more so, on the appearance of a new line of research in the materials science.

The situation with NT is absolutely different: as early as 1992–1993, the main fields of their potential application took shape and design of the first prototypes of future devices started. Some applications of NT were inherited from fullerenes (electrodes for chemical cells, safe sources of hydrogen in transport devices, optical filters), other applications coincide with those of carbon fibres (high-strength composites), and some fields of application are due to the unique properties of NT themselves (semiconductor devices, field emitters, probes of tunnelling microscopes, 'quantum wires'). It is clear that this is by no means the full

list of currently known applications of NT. It is not without reason that a recent review⁴ is entitled 'Nanotubes: a revolution in materials science and electronics'. As Buchachenko has noted vividly, carbon nanotubes made it possible 'to pass from fine words to impressive deeds'.⁵

Certainly, fullerenes, too, are finding and will be finding application (the rapidly progressing chemistry of fullerenes is now at an early stage of development); however, NT as materials have already clearly separated from their three-dimensional relatives.

Defect-free carbon NT are formed as a result of rolling of planar atomic network graphite sheets (graphenes) into seamless cylinders with diameters of ~1 to 120–150 nm and with lengths of up to hundreds micrometers. There exist three forms of NT: achiral NT of the 'armchair' type (two sides of each hexagon are oriented perpendicular to the NT axis), achiral 'zigzag' NT (two sides of each hexagon are parallel to the NT axis) and chiral or helical NT (each pair of the hexagon sides is arranged at an angle other than 0 or 90° relative to the NT axis).

The structures of NT are usually described by means of two indices, n and m , which are related unambiguously to the NT diameter (d) and the chiral angle (θ , characterising the deviation from the 'zigzag' configuration and ranging from 0 to 30°) (Fig. 1).

$$d = \frac{a\sqrt{3(n^2 + m^2 + mn)}}{\pi},$$

where a are the interatomic distances in the planar network,

$$\theta = \arctan\left(-\frac{\sqrt{3m}}{2n+m}\right).$$

Thus achiral NT of the ‘armchair’ type are characterised by indices (n, n) , those of the ‘zigzag’ type have indices $(n, 0)$ and chiral ones are described by (n, m) .

Nanotubes can be single- or multi-walled; the number of walls is theoretically unlimited but normally it does not exceed a few dozen. The distances between the neighbouring shells are close to the interlayer spacing in graphite (0.34 nm); thus, the smallest diameter of carbon NT is ~ 0.7 nm. The diameter of the second and subsequent coaxial atomic layers is stipulated by the diameter of the innermost layer. In this connection, the structure of NT resembles that of onion fullerenes; if the inner shell is C_{60} , the second shell is C_{240} , the third one is C_{540} , etc. The spatial accordance of the structures of NT layers, *i.e.* retention of interatomic distances close to 0.34 nm is possible only provided that the chiral angle changes on passing from layer to layer.

The specific structural features of NT can hamper their use as materials — synthesis gives NT with different structures. Multi-walled NT are much more diversified; therefore, more uniform single-walled NT, which, in addition, usually contain fewer defects, are preferred for the design of functional materials.

In most cases, the tips of NT are covered by hemispherical or conical caps, which contain not only hexagons but also pentagons, in which the configuration of the carbon atoms is less stable. These caps are somewhat more chemically reactive than the lateral surfaces. The hemispherical caps resemble ‘halves’ of fullerene molecules. Thus the NT (10,10), isolated rather frequently, are capped by halves of spherical C_{240} fullerene.

Synthesis of NT can give a tough precipitate consisting of sintered NT, a somewhat softer precipitate of densely stacked NT, a rubbery material consisting of entangled NT (‘paper’, ‘mats’), a three-dimensional network of long fibres (‘lace collar’, ‘web’), or a textured material consisting of parallel or nearly parallel (but arranged at a distance from one another) NT on a substrate (‘forest’). Structures looking like a ‘sea-urchin’ and NT as helices (see below) have also been described.

Nanotubes tend to form relatively stable aggregates (they are referred to as bundles or ‘ropes’), in which the axes of individual NT are parallel to one another, the shortest distance between them being ~ 0.32 nm (Fig. 2). These aggregates arise due to van der Waals forces.

Figure 2. Schematic structure of bundles of single-walled NT.

In the majority of cases, the synthesis of carbon NT is accompanied by the formation of other carbon modifications — fullerenes, nanoparticles and amorphous carbon. The yields of NT and side products are determined by the conditions of synthesis; the removal of side products is an important stage in the synthesis of NT.

Good prospects for the design of new functional and structural materials are opened by modification of carbon NT, which can be accomplished by the following methods:

- (1) filling of the inner cavities of NT with substances which alter their electronic, magnetic or mechanical properties;
- (2) ‘grafting’ of functional groups to the tips of NT;
- (3) replacement of some of the carbon atoms in NT by atoms of other elements;
- (4) partial or complete cleavage of double bonds on the lateral surfaces of NT by adding one or another reagent;

(5) intercalation (insertion) of ‘guest’ atoms or molecules into the intertubular space of NT bundles.

In addition, NT can be used as templates in the template syntheses of nanotubular or nano-rod materials for various purposes.

The scope of this review is restricted to the methods of synthesis of NT because these methods are important for the development of studies and projects related to NT. They should lay the grounds for the future commercial manufacture. Attention is focussed on recent studies.

The publication in 1999 of a Russian review devoted to the structure, electronic properties and morphology of NT⁶ facilitated the performance of this task. Earlier Russian reviews dealing with the mechanisms of the formation of fullerenes, nanoparticles and NT^{7,8} were also useful; however, they are somewhat less significant because lots of newer studies have appeared.

Apart from carbon NT, those containing B and N atoms are also briefly considered in this review. These NT can be synthesised either from carbon NT or simultaneously with them.

II. Electric-arc synthesis

It is known that an electric arc develops a temperature of up to 4000 °C, its ‘burning’ being accompanied by transfer of a substance between the electrodes. In 1990, electric arc-synthesis with graphite electrodes under an atmosphere of inert gases was first used to prepare fullerenes in relatively large amounts.⁹ It is among the products of arc synthesis that Iijima discovered carbon NT in 1991.¹ Subsequently, this procedure has been modified and used in many laboratories of different countries.

1. Principles of the method

The first synthesis of NT in relatively large (gram) amounts was also performed in Japan.¹⁰ The electric-arc synthesis was carried out under a helium atmosphere using graphite electrodes — an anode 8 mm in diameter and a cathode 12 mm in diameter — located at a distance of less than 1 mm from each other. The current in the arc reached 100 A (current density ~ 150 A cm⁻²) and the voltage was 10 to 35 V. The rate of the growth of the cathode deposit was ~ 1 mm min⁻¹. Some of the graphite evaporated from the anode turned into carbon black and soot, which were deposited on the walls of the reaction chamber, and some was deposited at the cathode. The outer solid layer of the cathode deposit contained sintered NT and nanoparticles, which could not be separated. The purity and yield of NT depended appreciably on the helium pressure — the formation of NT started at ~ 13 kPa, and at 66–332 kPa, the cathode deposit contained only NT and nanoparticles. The optimum pressure was 67 kPa; in this case, $\sim 75\%$ of the electrode material consumed was deposited at the cathode, the yield of NT, which were accumulated in the inner, black, relatively soft part of the deposit being $\sim 25\%$.

The yield of NT attained in an argon flow was much lower than that in a helium flow.

Analysis of the results of the first studies on the structure and synthesis of NT^{10–14} allowed Ebbesen^{15, 16} to note some characteristic features. The material formed has a hierarchical structure, in which tens or hundreds of individual multi-walled NT with diameters of 2–20 nm and nearly equal lengths (microns or tens of microns) are joined into regularly organised bundles resembling ropes. These ropes are combined into fibres with a diameter of ~ 50 μ m, while the fibres are joined into threads having even greater diameters (about a millimeter) and visible with the naked eye. The larger the bundle, the more disordered can it be.

The formation of columns ~ 50 μ m in diameter consisting of NT and arranged parallel to the electrode axis has been reported.¹⁷ This study is notable due to the setup used; it had movable vertical electrodes with a diameter of 19 mm, which (as well as the arc area) could be cooled during the process. (In the conventional arc syntheses, the cathode and anode diameters are different, the anode diameter being smaller than the cathode

diameter.) Using this setup controlled by a computer, the researchers were able to deposit $\sim 90\%$ of the substance at the cathode and to obtain thus high-quality multi-walled NT. The current in the arc of this setup reached 250–300 A, although the current density at the beginning of the process was even lower than the standard value and amounted to $70\text{--}80\text{ A cm}^{-2}$. Upon annealing in air at $650\text{ }^{\circ}\text{C}$, the columns were etched being replaced by channels surrounded by entangled NT.

An increase in the electrode diameter normally causes sintering and cracking of NT. A dense greyish product is accumulated in the inner part of the cathode deposit, instead of the easily extractable black material. This phenomenon was initially explained by insufficiently high temperature of the synthesis;¹⁸ however, the assumption that the temperature was, conversely, too high seems more reasonable.¹⁷

The decrease in the anode diameter from 12.7 to 8.0 mm with the cathode diameter (25.4 mm) and current density (140 A cm^{-2}) remaining the same increased the yield of NT. An increase in the pressure of helium (which is believed to quench NT) from 6.6 to 101 kPa also resulted in an almost proportional increase in the rate of growth of the deposit.¹⁸ However, according to Ando and Iijima,¹⁹ variation of the yield of NT as a function of gas pressure passes through a maximum, the position of which corresponds to 7 kPa in the case of Ar or CH_4 and to 3 kPa for He. In the opinion of Wang *et al.*,¹⁸ the discharge used in the synthesis of NT is quasi-continuous and has a characteristic interruption frequency of $\sim 8\text{ Hz}$. The discharge is initiated between the closest sections of the electrodes and, after some amount of graphite has been evaporated from the anode (which extends the discharge), it ‘jumps’ to the neighbouring section and thus becomes shorter. Travelling of the arc over the electrode surface changes presumably the sites of localisation of NT.

Lozovik *et al.*⁷ believe that an arc discharge between graphite electrodes has two modes of operation, a noisy and a quiet one, transition from one mode to the other being induced by changes in the current density. A high current density and a low inert gas pressure (noisy mode) result in the predominant formation of fullerenes, while nanoparticles and NT are formed predominantly at a relatively low current density and a high pressure (quiet mode).

A thorough investigation of the cross-sections of bundles obtained by the arc method showed that NT do not have, as a rule, a cylindrical shape.²⁰ The cross-sections of NT look like polyhedra or ellipses with numerous defects including edge dislocations. The structures of NT are intermediate between the ‘Russian doll’ model (coaxial seamless cylinders) and the ‘folded carpet’ (‘scroll’) model. In earlier studies, either model has been preferred, although the methods used in the investigations did not allow one to reveal the differences between them.²¹ Moreover, it was found that the ‘scroll’ model is too regular to describe many NT and, in some cases, the ‘papier-mache’ model (separate fragments applied onto one another) should be accepted (Fig. 3).²²

Some disordering of the structure is due to the fact that NT are formed in the arc under non-equilibrium conditions and to the stress arising upon joining of individual NT into bundles. The presence of a large number of defects in multi-walled NT obtained in an electric arc is confirmed by experiments on their intercalation.^{23, 24}

It has been suggested²⁵ that bundles are formed under the influence of an electric field, their length, diameter and the manner of laying being dependent on the electric field strength. However, in reality, bundles can be formed even without electric fields. Nevertheless, it is beyond doubt that the field has an influence on the morphology of the products of arc synthesis.

The yield and shape of NT formed in an arc discharge plasma depend not only on the main arc discharge variables (the voltage between the electrodes, the current strength and density, temperature of the plasma) and parameters related to the discharge

Figure 3. Structure models of multi-walled NT. (a) ‘russian doll’; (b) ‘scroll’; (c) ‘papier-mache’.

variables (the pressure and composition of the inert or reacting gas) but also on the gas flow rate, on the dimensions of the reaction chamber, and on the duration and the scale of the process. The configuration of cooling devices if they are present (determines the size and shape of temperature fields) and the power of cooling devices (determines the heat removal), the nature and purity of the electrode materials and several other parameters that can hardly be quantitatively evaluated are also significant.^{10, 15–19, 26} The main parameters governing the yield of NT — the rates of NT growth and quenching — depend on numerous variables which are far from being fully taken into account in experimental studies. This accounts for some contradictions, hampers comparison of the results and often makes them poorly reproducible. The absence of theoretical models (related to the setup geometry), which makes scaling impossible, might be due to the same reasons.

The mechanism of the formation of NT in an arc discharge has not yet been unambiguously elucidated, although it is discussed in many studies. There exist two main opposing models. According to one model, growth of NT advances due to the addition of carbon atoms or fragments from the vapour phase to the dangling bonds at the tips of open NT, whereas according to the other model, they add to the topological defects in the caps of closed NT. In recent years, preference is given to the former model, because the occurrence of ‘edge-to-edge’ (‘lip–lip’) interactions has been proved. They prevent the formation of caps in multi-walled NT due to the formation of ‘fluctuating’ (closure–rupture) C–C bonds at the tips of two or three neighbouring coaxial NT.^{27, 28}

The role of the electric field in the mechanism of the formation of NT is obviously overstated in some publications. It has been shown^{16, 29} that this role is far from being paramount, the NT growth involving simultaneously charged (C^+ *etc.*) and neutral (C_2 *etc.*) carbon species. The difference between the main carbon sources might account for the formation of two types of condensed products, NT and polyhedral particles. It is also unlikely that the tips of NT growing at the cathode in an arc discharge are opened due to strong electric fields.³⁰

The experimental studies considered above describe the preparation of multi-walled NT. The formation of single-walled NT was first observed by Ajayan and Iijima,³¹ but this study has not been adequately appreciated, later studies being regarded as the pioneering ones.^{32, 33} Both groups of researchers cited^{32, 33} performed the synthesis in the presence of catalytic additives. This opened up a new chapter in the history of NT.

2. The influence of catalytic additives

The pioneering studies^{32, 33} somewhat contradict each other in details but coincide in the main point stating that the introduction of small amounts (1%–2%) of transition metals such as Fe, Co, Ni or their mixtures into the graphite anode influences appreciably the shape and the yield of NT and, in some cases, also localisation of the NT-containing product in the reaction chamber.

Subsequently, admixtures of Li, Cu, Ag, Zn, Cd, B, Al, In, Y, La, lanthanides, Si, Ge, Sn, Ti, Hf, Pb, Sb, Bi, S, Se, Cr, W, Mn, Ru, Pd, Pt, mixtures of two metals or of a metal with a nonmetal and several carbides and oxides were tested.^{28, 34–37} It was found that vaporisation of an anode containing Co, Co–Ni, Co–Y, Co–Fe, Ni, Ni–Y, Ni–Lu and Ni–Fe gives deposits looking

like a lace collar or a soft belt being formed around the cathode deposit. They contain single-walled NT mixed with amorphous carbon and metal particles, the NT having diameters of 1.2–1.4 nm and being joined into more or less ordered bundles. The tips of single-walled NT are closed and contain no metal particles. Upon evaporation of graphite anodes with Ni–Y and Co–Y admixtures, the content of single-walled NT in the deposits reaches 70%–90%.³⁷ The yield of NT also markedly increases when a Co–Pt mixture is used.³⁸

Some catalysts (Cu; Cu with Ni, Pt, Y or Fe; Ni; Ni with Y, Lu or Fe) caused the formation of a ‘web’, which hung between the cathode and the walls of the chamber. This web, as well as the deposit on the chamber walls, contained fullerenes, amorphous carbon, flat graphite particles and small amounts of single-walled NT. In some cases, a rubber-like deposit was formed on the walls; it could be detached as pieces or ribbons (Fig. 4).³⁹

Figure 4. Setup for electric arc synthesis and localisation of various products;

(1) to vacuum pump; (2) filter; (3) viewing window; (4) cathode; (5) nozzle for the removal of the cooling water; (6) graphite electrodes; (7) web-like precipitate; (8) cathode deposit; (9) rubber-like deposit around the cathode; (10) filling material (a mixture of powdered graphite with a metal); (11) fullerene- and NT-containing soot on the walls; (12) anode; (13) nozzle for the supply of cooling water; (14) voltmeter; (15) helium inlet; (16) power supply.

The addition of sulfur to a Co catalyst also resulted in a greater amount of the web-like product and higher NT yields and in a quite noticeable scatter in the NT diameters (from 1 to 6 nm).⁴⁰ Evaporation of Co and S simultaneously with graphite changed the shapes of the resulting products and led to the evolution of multi-walled NT in the middle of the cathode deposit, multi- and single-walled NT together with many other particles in the rubber-like deposit around the cathode, and single-walled NT in the web-like material.³⁹

Kiang *et al.*⁴⁰ believe that the multi- and single-walled NT are formed *via* different mechanisms and that Co and S induce the formation of single-walled NT directly in the gas phase and prevent the NT tips from closing. Since sulfur itself does not catalyse the formation of NT, its role seems to reduce to the stabilisation of dangling bonds.

The addition of Bi and Pb also causes an increase in the NT diameter. The carbon ring structures formed in the gas phase are believed to play an important role in the mechanism of formation of single-walled NT. The most stable ring structures are those containing 10 to 40 carbon atoms, which form $C_{m}C_n$ clusters together with Co atoms. It is these clusters that function as catalysts, while S, Bi and Pb stabilise the ring structures.⁴¹

The results of studies on the catalysed arc synthesis of single-walled NT are summarised in Table 1.⁴² It can be seen that the diameter of NT obtained in this way varies from 0.6 to 6 nm.

Table 1. Characteristics of NT prepared by arc discharge synthesis in the presence of catalysts.⁴²

Catalyst	Diameter of NT /nm		Composition of crystallites ^a
	limits	average	
Fe	0.7–1.6	0.80, 1.05 ^b	Fe ₃ C
Fe	0.6–1.3	0.7–0.8	—
Co	0.9–2.4	1.3, 1.5 ^b	Co
Co	0.6–1.8	—	Co in a graphite shell
Ni	1.2–1.5	—	Ni in polyhedral particles
Ni	0.6–1.3	0.7–0.8	—
Fe + Ni	0.9–3.1	1.7	—
Fe + Ni	> 0.6	1.3–1.8	—
Co + Ni	> 0.6	1.2–1.3	—
Co + S	1.0–6.0	1.3, 1.5 ^b	Co and Co in polyhedral particles
Co + Bi	0.8–5.0	1.2, 1.5 ^b	—
Co + Pb	0.7–4.0	—	—
Co + Pt	~2	—	CoPt
Y	1.1–1.7	—	YC ₂ in polyhedral particles
Cu	1–4	—	Cu in polyhedral particles
None	> 2	—	—

^a The crystallites are located inside NT or polyhedral particles (see Section III.3). ^b The curve for the distribution of NT over diameters exhibits two maxima.

The mechanism of the catalytic action of metals in the formation of single-walled NT implies adsorption of carbon atoms on the surface of metal particles and their free migration over the surface to the base of a growing NT.⁴³ It was shown experimentally that the catalytic reaction can follow either of two routes, depending on the size of the metal catalyst particles. If the particle size (average diameter) is several tens of nanometers, which is much greater than the NT diameter (~1 nm), many closed NT sprout from one particle. If the particle size is not larger than the NT diameter, the particle moves together with the growing NT tip. The results of molecular dynamics modelling⁴³ confirmed the probability of the former pathway, involving migration of adsorbed carbon atoms to the NT base and the ‘root’ growth of NT. It should be borne in mind, however, that this model is of limited utility. It does not take into account the fact that NT formed in arc synthesis contain lots of defects and that a stream of carbon atoms directed towards growing NT has the greatest intensity near the NT tips. In addition, the conditions of vapour condensation in different sections of a setup, as well as in different setups are nonequivalent, which results in the formation of particles with dissimilar morphologies.

Nevertheless, the modelling made it possible to explain why multi-walled NT are not formed in the presence of catalytic additives (this would require cooperative processes, associated with consistent interaction of numerous particles), why single-walled NT always have relatively small diameters (the growth of NT is initiated on the surface bulges of metal particles and the diameter of these bulges is small with respect to the height), and why mixed catalysts are often more efficient than one-component ones (this is due to the enhancement of carbon adsorption, to the change in the activation energy of the NT growth, and to the formation of a surface with a large number of bulges).

Apparently, single-walled NT are even more prone to form bundles, which are combined in ‘ropes’ with a two-dimensional triangular crystal lattice.^{37, 44, 45}

Journier and Bernier,²⁶ who surveyed studies on catalytic arc synthesis, have rightly stated that the yield and the shape of NT can differ substantially even when the same metal is used, depending on the metal concentration, pressure of the inert gas, current strength (or density), and the geometry of the arc setup.

A special role in the arc synthesis of NT is played by boron, the introduction of which as B, B₂O₃ or BN induces the formation of a large number of well graphitised long (up to 20 µm) NT with boron-containing caps.⁴⁶ In this case, B₄C crystals, large fullerenes and BC₃ nanotubes are produced in addition to carbon NT. The presence of boron in the gas phase decreases appreciably the concentration of C₂ fragments in the plasma zone and the contents of fullerenes in the wall deposit.⁴⁷ Since the C₂ clusters are the main source of condensed structures, the introduction of boron can change the mechanism of the formation of NT. Note that the arc setup used in the study cited⁴⁷ differed only slightly in geometry and electric parameters from the conventional setups used for the synthesis of carbon NT [anode and cathode diameters 6 mm (a cathode with a diameter of 200 mm was also tested), distance between the electrodes 1 mm, current 80 or 150 A, voltage 25 or 40 V, respectively, gas pressure 27–67 kPa].

In some studies the formation of carbon NT, separate areas of which were made of BN has been noted.

Under certain conditions, for example, upon evaporation of BN or mixtures of B or BN with graphite, boron carbides, nitride, and carbonitrides can form 'self-contained' NT.^{48–51} The use of HfB₂ (see Refs 52, 53) or ZrB₂ (see 54, 55) electrodes for the electric arc synthesis in a stream of N₂ results in the formation of BN nanotubes. If BC₄N serves as the electrode material,^{56, 57} NT containing B, C and N (or BN) are produced; when the electrodes are made of graphite with the addition of BN,⁴⁸ the process yields NT containing BC₂N and BC₃. However, in the latter case, the composition of NT is nonuniform along the length of the tubes.

Unique multi-walled NT have been prepared by Suenaga *et al.*,⁵⁸ who also used HfB₂ and graphite as the electrode materials; several inner shells consisted of carbon, several central shells (embracing the carbon shells) were made of BN, and some outer shells were again carbon. The mechanism of formation of these NT (they evolved together with polyhedral particles, which also contained layers with different compositions) is totally unclear. The inner layers might grow upon diffusion from an NT tip; however, the probability of this process is low. Since the electronic properties of C and BN layers are different, this result brought about the idea of designing electronic devices with radial heterojunctions.

Studies on the catalytic synthesis have much in common with the studies on the synthesis of NT the inner cavity of which is filled with one or another substance.

3. Preparation of filled nanotubes

Filling of the inner cavity of NT (encapsulation) is a route to the development of a great number of novel nanomaterials of various classes and functions (materials with specific electronic, magnetic, optical, or mechanical properties, catalysts, sorbents). Some of them could be used as a type of 'NT–filler' nanocomposite, while other require that the carbon shell be removed (burned out). Particular attention is devoted to the preparation of 'quantum wires', *i.e.*, conducting materials with a diameter of several nanometers, whose conductivity is close to truly one-dimensional conductivity. The possibility of using NT and nano-rods in nanotechnological devices is being discussed.

The first study on filling NT was performed in 1993.⁵⁹ Mixtures of NT with Pb were annealed in air at ~400 °C. In the presence of O₂, the molten metal opened the tips of NT, removed the hemispherical caps and was sucked into the inner cavities of the NT by capillary action. However, it has been reported⁶⁰ that lead is able to fill NT only at pressures of 1000 to 10 000 atm; hence, under the conditions described above, NT were filled by lead compounds rather than by lead metal. Indeed, it has been shown that heating of a mixture of Pb₃O₄ with NT for 9 h at 700 °C results in opening and filling of the NT.⁶¹ Encapsulation of molten V₂O₅, PbO, Bi₂O₃ (see Refs 62, 63), MoO₃ (see Ref. 64) and AgNO₃ (see Refs 65, 66) into open NT has also been reported.

Even before the discovery of NT, the arc method has been used to prepare endohedral fullerenes⁶⁷ and nanoparticles encapsulated

into a multilayered graphite shells.^{68, 69} Therefore, it comes as no surprise that filling of NT can occur directly during the arc synthesis. Ordinary and filled NT are obtained under different conditions, in particular, filled NT are formed at lower temperatures (1000 to 2000 °C).

Yttrium carbide was the first substance detected inside NT prepared in an arc.^{70–72} According to an estimate,³⁵ yttrium is encapsulated into NT more easily than many other metals, although this feature can hardly be related to the enthalpy of formation of YC₂. Later, carbides of other lanthanides and Mn have also been encapsulated into NT.^{73–75} Carbides have been formed when metal-doped graphite anodes have been used because carbides are the species most stable in the presence of carbon. However, in some cases, elementary substances have also been detected inside NT, for example, Mn,⁷⁶ Cu, Ge^{77–79} and even small amounts of Y.⁷² These elements either do not form stable carbides or are liberated in an arc discharge under an H₂ atmosphere.

Thus copper forms no stable carbides and does not catalyse the formation of NT or fullerenes; therefore, the mechanism of its encapsulation differs from the mechanism of insertion of other metals.⁷⁸ Evaporation of a graphite anode in a hydrogen plasma in the presence of copper gives rise to polycyclic aromatic hydrocarbons, which form graphite shells around Cu particles.^{78, 79} The formation of filled NT upon joint evaporation of pyrene and Cu or Ge (this was done using a Cu anode with a cavity filled with pyrene and a W cathode)⁸⁰ was considered^{78, 79} as direct evidence supporting the above statement.

Metals with different volatilities show different behaviour during encapsulation.⁸¹ Some substances fill long NT giving continuous crystals with lengths of up to 1 µm (Cr, Ni, Sm, Gd, Dy, Yb, S, Se, Ge, Sb); other substances fill only short NT (Al, Bi, Te), and some other elements form inclusions separated from one another inside NT (Co, Fe, Pd).^{36, 82–85} In a study of encapsulation of high-melting transition metal carbides (NbC, TaC, MoC), an exceptionally stable face-centred form of the carbide MoC was discovered.⁸⁵ Nanotubes containing B₄C in the inner cavity have also been prepared.⁸⁶

The operation conditions used in these studies^{70–83} did not differ much from those used for the synthesis of NT. Thus Setlur *et al.*⁷⁸ used electrodes with a diameter of 10 mm located at a distance of 0.25 to 2.0 mm; the current was 100 A, the voltage was 20 V and the gas pressure ranged from 1.3 to 6.7 kPa. In another series of studies,^{82–84} the corresponding parameters were 9 mm, 1 mm, 100–110 A, 20–30 V and 60 kPa.

Sulfur plays a special role in the formation of filled NT.⁸⁴ Sulfur can be contained in a graphite anode as a minor impurity; it promotes filling of NT with other elements. In some cases, sulfur enters NT as a sulfide but more frequently it is not present in the filling material. This effect of sulfur has been explained⁸⁴ by the fact that sulfur forms clusters with carbon in the gas phase; this ensures transportation of sulfur to the growing NT, where it promotes graphitisation of NT and reconstruction of a metal surface, resulting in the exposure of catalytically more active crystallographic planes. At the final stages of the process, sulfur is removed from the graphite shell of the NT. These results are similar to the data reported in earlier publications.^{39, 40} In some cases, sulfur suppresses the formation of single-walled NT.

The technique of filling NT under the conditions of arc synthesis suffers from a severe drawback — this process is hardly controllable. The yield of filled NT and the composition, structure and morphology of encapsulated substances cannot be governed in the majority of cases.

4. Modifications of arc synthesis

The use of an alternating-current arc and electrodes with identical diameters changes substantially the pattern of the process, namely, the products are formed on the chamber walls rather than at the electrodes, new forms of NT being produced together with the known ones.^{87, 88} The yields and forms of some products

also depend on whether the electrodes are mounted in the vertical or horizontal position.

A series of publications^{19, 89–91} deal with the formation of multi-walled NT under a methane atmosphere. This process differs from the conventional one (performed under an inert gas) in the fact that, under some conditions, the formation of NT is not accompanied by evolution of fullerenes or nanoparticles. At high partial pressures of methane, relatively thick multi-walled NT are formed and at low pressures (1–3 kPa), thin and long multi-walled NT are produced. The optimal conditions for the formation of thin NT for the vertical mounting of electrodes with a diameter of 6 mm are the following: methane pressure 2.7 kPa, current 30 A.

Later, the authors of the above series of studies arrived at the conclusion that, since CH₄ decomposes in an arc to give C₂H₂ and H₂, the synthesis of NT should better be performed in a stream of H₂ (see Refs 92–95).[†] Some advantages of using H₂ have been mentioned above in the consideration of copper encapsulation. A certain role in the formation of NT can also be attributed to the high heat capacity of H₂, owing to which it can efficiently quench NT.⁹⁶ When the process is performed at 'plasma' temperatures, the fact that the energy of ionisation (the first ionisation potential) of H₂ is half that of He also becomes significant.

Rather long NT are formed even at an H₂ pressure of 7 kPa; their yield at a pressure of 13 kPa is comparable with the yield attained in the atmosphere of He at 66 kPa. Many NT prepared in a flow of H₂ have a narrow inner channel; they are open and usually high-quality NT (having few nanoparticles on the outer surface). The thinnest and longest multi-walled NT were prepared at H₂ pressures of 6.7–11 kPa.

The arc synthesis in an atmosphere of H₂ differs appreciably from the synthesis in inert or hydrocarbon media because the temperature developed in the atmosphere of H₂ is higher. This provided grounds for assuming that C⁺ ions participate in the formation of NT in an H₂ medium.⁹² It is also assumed that either H₂ molecules or H atoms add to the dangling bonds of growing NT and thus prevent closure of these bonds and, in addition, eliminate the possibility of the formation of amorphous carbon.⁹² The addition of H₂ is evidenced by the fact that an increase in the partial pressure of H₂ results in higher yields of open NT. The mechanism involved may be similar to the mechanism of the formation of diamond from the gas phase. Particles of various natures are produced; however, under a hydrogen atmosphere, the most reactive ones are completely or partially gasified (etched).

Yokomichi *et al.*⁹⁷ have attempted to prepare NT in a CF₄ medium. It has been assumed that the F atoms formed upon decomposition of CF₄ would attach to the dangling bonds and prevent them from closing, thus influencing the process of NT formation. This assumption largely proved to be correct; in any case, no fullerenes were formed together with NT. The synthesis was carried out using a setup with electrodes 5 mm in diameter at a current of 20–60 A and a CF₄ pressure ranging from 2.7 to 53 kPa. Under the optimal conditions (20–40 A, 6.7–13.3 kPa), multi-walled NT were synthesised with an outer and inner diameters of 20 and 5 nm, respectively; they did not differ much from the NT obtained in a flow of He.

The researchers cited⁹⁷ studied the influence of the main parameters of the process (medium, gas pressure and current) on the yield of NT and polyhedral particles and on the length of NT and compared their data with those reported in other publications; the results were summarised in a table (Table 2). In particular, it follows from this table that the processes occurring in an atmosphere of CF₄ and CH₄ are fairly similar. However, the data of Table 2 should be treated with caution because this way of presenting the information does not show, for example, that in

Table 2. Influence of the increase in the gas pressure and in the current on the main characteristics of electric-arc synthesis of NT under atmospheres of various gases.⁹⁷

Medium	Yield of NT	Length of NT	Yield of nano-particles
CF ₄	decreases	increases	decreases
He	increases	does not change	does not change
CH ₄	decreases	increases	does not change
H ₂	decreases	does not change	does not change

some cases, the plots for the variation of the yield vs current pass through a maximum.

Koprinarov *et al.*⁹⁸ have attempted to devise a continuous electric arc process and to make up for the consumption of graphite due to evaporation by supplying CH₄. For this purpose, they used the 'reverse method', *i.e.* the area of the anode in the setup used was an order of magnitude greater than the area of the cathode. The products of electric-arc synthesis were found to contain fullerenes, polyhedral particles and single-walled and multi-walled NT. The nanotubes had different lengths and structures. Some of them were partly single-walled and partly multi-walled structures; this indicates that various sections of NT grew at different rates. The 'reverse method' offers no advantages over the conventional method.

Carbonised coal can be used as the electrode material instead of graphite;⁹⁹ however, the presence of non-volatile impurities causes contamination of NT; hence, in the majority of studies, high-purity graphite is the material of choice.

The main drawback of the arc method is low output. This is demonstrated by a publication³⁷ in which synthesis in a He flow in the presence of Ni and Y introduced in a graphite anode gave only 2 g of NT over a period of 2 min. After that, the setup had to be disassembled to replace electrodes and take the products out.

III. Laser-assisted synthesis

Fullerenes were first obtained by the laser method in 1985; however, only 10 years later, this method was employed to prepare NT.^{100, 101} The first setup was a 50-cm quartz tube with a diameter of 2.5 cm containing a graphite rod 1.25 cm in diameter arranged along the tube axis. The tube was evacuated and simultaneously heated to 1200 °C. After that, Ar was supplied (pressure 66.5 kPa, linear gas velocity 0.2–2.0 cm s^{−1}). The target was exposed to a laser beam with a wavelength of 532 nm (Nd laser), a pulse frequency of 10 Hz, a pulse power of 250 mJ, and a pulse duration of 10 ns. The surface of the target was scanned by a laser spot with a diameter of 3 or 6 mm. The products of evaporation (multi-walled NT and nanoparticles) were collected on a cooled copper finger, on the walls of the tube, and on the reverse side of the graphite target (Fig. 5).

Figure 5. Scheme of the laser setup; (1) furnace heated to 1200 °C; (2) neodymium laser; (3) graphite target; (4) water-cooled collector.

[†] Subsequently, the same conclusions have been drawn by other investigators.⁹⁶

The daily output of the first setup was up to 80 mg of a nanomaterial containing NT. The process had to be terminated because the tube was clogged near the target with a web-like material which also contained NT. By using a tube with a diameter of 3.8 cm, all other conditions remaining almost the same, another group of researchers attained a higher yield of a rubbery material containing single-walled NT. In this case, the output was 200 mg per experiment (3–5 h).¹⁰² It was noted that distribution of the NT over diameters depends on the radiation wavelength (either 532 or 1064 nm).¹⁰²

An increase in the diameter of the reaction tube to 5 cm was even more effective. This setup can afford ~ 1 g of the material (containing 60%–90% of NT) per 24 h.¹⁰³

Subsequently, one laser was replaced by two lasers (wavelengths 532 and 1064 nm), which emitted alternately, the interval between the pulses being 42 ns, and the power of a pulse was increased to 490 and 550 mJ, respectively.¹⁰³ This made it possible to ‘knock down’ the plums formed. Subsequently the tube diameter was doubled once again; in addition, alternation of the side of the target exposed to radiation and beam scanning were used. As a consequence, the yield of products containing 40%–50% of NT reached 20 g during 48 h of continuous operation.¹⁰³

Yudasaka *et al.*¹⁰⁴ used a modified setup with two targets, one made of a graphite powder and the other made of a metal or an alloy.

Study of the influence of the pressure of Ar and the furnace temperature on the yield and properties of the laser ablation product has shown that at pressures below 13 kPa only amorphous carbon is formed, while NT appear in the products, together with amorphous carbon, above 26 kPa.¹⁰⁵

An increase in the furnace temperature from 780 to 1050 °C resulted, in the presence of catalysts, in an increase in the average diameter of single-walled NT from 0.8 to 1.51 nm, although the yield of NT at low temperatures was relatively low.¹⁰⁶

The yield and the shape of NT prepared by the laser method are determined by fewer parameters than those of the NT obtained by the electric-arc synthesis. Perhaps, this is why markedly higher yields of NT have been attained in the laser-assisted synthesis. The temperature of the area from which graphite is evaporated and the temperature gradient in the gas phase near this area can be considered to be the crucial factors. Unfortunately, in the experiments described above these parameters have been determined insufficiently definitely if at all (the measurements were hampered by the beam scanning over the target surface). Instead, properties influencing the temperature of evaporation were measured (the furnace temperature, laser radiation power, diameter of the light spot on the target, the velocity of the spot migration, the gas pressure, and the gas flow rate).

The introduction into graphite of small amounts of catalysts led to the formation of single-walled NT, which, unlike those obtained in arc, were only slightly covered by amorphous carbon particles.^{101, 107} Mixtures of Co with Ni (0.6 at.% each) and of Co with Pt (0.6 at.% and 0.2 at.%) proved to be the best catalysts. When these mixtures were used, the yield of single-walled NT exceeded 70%, which is tens or hundreds times higher than the yields attained using individual metals as the catalysts. High yields have also been obtained with mixtures of Ni with Pt.¹⁰⁰

The use of a mixture of two noble metals, Rh and Pd, mixed with graphite in a laser-assisted synthesis afforded single-walled NT with diameters of 1.0–1.5 nm.¹⁰⁸ Only mixtures of Cu with Ni were found to be substantially less active than copper itself.¹⁰⁰

The mechanism of the catalytic formation of single-walled NT upon laser ablation proposed by Thess *et al.*¹⁰⁷ was defined as the ‘scooter’ mechanism. According to this mechanism, individual atoms of Ni, Co or other catalytically active metals are adsorbed on the open tips of the curved C_n ($n \leq 50$) graphene fragments and ‘scoot’ around the tips, thus promoting removal of all carbon structures except for the energetically preferred ones.

Clusters comprising 10 to 100 closed-tip nanotubes formed ‘ropes’, 10 to 50 of which composed bundles. A more detailed study of the ‘ropes’ showed that they are polycrystals, the sizes of separate grains ranging from 10 to 100 nm (the typical size is 10 to 20 nm); their cross-sections are oval and the predominant aspect ratio is ~ 3 .¹⁰⁹

Some of the NT are clustered into 5–15 nm thick ‘ropes’ forming rings with diameters of 300–500 nm.¹¹⁰

The products of laser-assisted synthesis were found to contain an interesting type of NT, so-called ‘nano-peas’, which are chains composed of spherical C_{60} molecules located inside single-walled NT with a diameter of 1.3–1.4 nm.¹¹¹

The laser method also makes it possible to prepare NT from BN;^{112–115} however, the experimental conditions employed in this case differed sharply from those used to prepare carbon NT; specifically, high and superhigh pressures were used. The process induced by laser heating of hexagonal BN in a diamond anvil at a high pressure under an atmosphere of N_2 has an interesting feature, namely, cubic BN appears at the bottom of the NT formed.¹¹⁵ The mechanism of formation of NT from BN upon laser evaporation at superhigh pressures might include a stage of surface diffusion of molecules from the bottom of an NT to its tip, which implies restriction of the NT length.¹¹⁶

Laser ablation of a complex target (C, Si, BN) at near-atmospheric pressure accompanied by chemical reactions can be used to synthesise axial NT. This type of NT with diameters of several tens of nanometers and with lengths of up to 50 mm contained a core of β -SiC, an intermediate layer of amorphous SiO and an outer shell of BN and C.¹¹⁷ The study cited aimed at designing coaxial nano-sized electronic devices with heterojunctions.

In addition to the neodymium laser, a CO_2 laser has also been tested for the synthesis of carbon NT.¹¹⁸

IV. Other methods of graphite vaporisation

The conclusion that fullerenes and NT are formed in the vapour phase, irrespective of the way used to vaporise graphite or another form of carbon, was drawn fairly long ago and has been confirmed in a number of publications. Thus Ebbsen *et al.*¹¹⁹ proved, using isotope dilution, that NT (as well as fullerenes) are formed exactly from carbon vapour. Apart from the arc- and laser-induced evaporation of graphite considered above, NT are also prepared using resistivity vaporisation and vaporisation induced by electron or ion beams or by sunlight.

1. Resistivity vaporisation

Heating a 0.5-mm graphite foil by Joule heat *in vacuo* (10^{-6} Pa) and cooling the resulting vapour to -30 °C resulted in NT being deposited on the surface of single-crystalline graphite.^{120–123} The rate of deposition of NT with a diameter of 1–4 nm was 0.5 A s^{-1} . The NT were capped and combined in arrays. This method permits the preparation of particles having diverse shapes — single-walled and multi-walled NT, NT bundles and nano-cones, the yield of single-walled NT ranging from several percent to 80%–90%.

2. Electron- or ion-beam vaporisation

The first experiments on the preparation of NT by electron-beam vaporisation of high-purity (99.99%) reactor grade graphite *in vacuo* (10^{-3} Pa) and deposition on various substrates (Si, quartz, graphite, ceramics, anodised Al) were performed in Russia back in 1992.¹²⁴ The resulting condensate was a 0.01–10- μm thick film consisting of NT with a diameter of ~ 1 nm. Separate NT were joined in fibres ~ 5 nm in diameter, while the fibres were clustered in cables with a diameter of 10–30 nm. The tubular texture was retained throughout the whole film thickness; moreover, variation of the angle between the direction of the stream of carbon particles and the substrate surface resulted in the formation of inclined

textures. Kosakovskaya *et al.*¹²⁴ measured a large number of film characteristics and noted anisotropy of film properties.

Nanotubes have also been formed on bombardment of high-purity graphite with Ar^+ ions with an energy of 60 keV in a high vacuum at a normal angle of incidence.¹²⁵ Polyhedral nanoparticles were isolated together with NT.

Exposure of hexagonal BN to an electron beam gave NT;¹²⁶ as in the study described above,¹¹⁵ in this case, too, the formation of seeds of cubic boron nitride at an initial stage was assumed. The irradiation with electrons with a current density of $10\text{--}20\text{ A cm}^{-2}$ at a voltage of 300 kV resulted in annealing of most of defects and in almost complete ordering of the BN walls of the NT.¹¹² An electron beam with a current density of 150 A cm^{-2} at an accelerating voltage of 400 kV ensured the formation of multi-walled coaxial BN clusters.¹²⁷

Irradiation of boron-containing carbon with electrons gave carbon NT doped with boron.¹²⁸

The role of the gas phase in this process and in other processes described above is obscure; therefore, the term 'vaporisation' is used only conditionally.

3. Sunlight-induced vaporisation

The studies dealing with the use of solar concentrators for the preparation of NT have been briefly surveyed in a publication.²⁶ These studies were carried out only in France. A setup producing a temperature of about 3000 K at the focus was developed. Evaporation of pure graphite gave only a small amount of soot, whereas vaporisation of a graphite powder with catalysts gave rise to NT. The type of NT formed (single-walled, multi-walled or bamboo-like) and the amount of impurities were governed by the catalyst and the gas pressure in the process, *i.e.*, by the same parameters as in the case of electric-arc and laser-assisted syntheses, described above and studied much more extensively. In the presence of Co, single-walled NT with a diameter of 1–2 nm were found in the soot deposit and NT bundles with diameters of more than 20 nm containing no admixture of amorphous carbon were found in the web-like deposit.

V. Pyrolysis of hydrocarbons and decomposition of CO

1. Catalytic pyrolysis

Catalytic pyrolysis of hydrocarbons had been used to prepare carbon fibres even before the discovery of NT and fullerenes. Nanotubes were first synthesised by this method in 1993.¹²⁹ The course of the process is influenced by the temperature, the overall pressure, the initial hydrocarbon used and its partial pressure, the nature and characteristics of the catalyst (first of all, the particle size, which could determine the diameter of the NT), and the nature of the catalyst support. The pyrolysis can result in layers of amorphous carbon or graphite formed around catalyst particles, carbon fibres and multi-walled or single-walled NT.²⁶ The length of NT and the degree of their coverage by amorphous carbon particles depend on the duration of the process.

a. Pyrolysis of acetylene

Acetylene is used most often for pyrolysis. José-Yacamán *et al.*¹²⁹ carried out acetylene pyrolysis at 500 °C and atmospheric pressure over a graphite catalyst containing 2.5% of Fe. The concentration of acetylene in the diluent (N_2) was 9%. It was noted that graphite particles are formed initially around the Fe particles and this is followed by growth of NT with diameters of 5–20 nm and lengths of up to 50 μm . Nine different catalysts (Fe, Co, Ni and Cu supported on three materials — flake graphite, SiO_2 or HY zeolite) have been assayed;^{130, 131} the effects of the flow rate, the temperature and duration of the pyrolysis on the yield and quality of NT have been studied. An increase in the temperature from 500 to 800 °C influences only slightly the length of NT but increases the yield of amorphous carbon (amorphous carbon constitutes up to 50% of the deposit even under the optimal conditions). Longer

pyrolysis times result in higher relative yields and greater lengths and diameters of NT. The replacement of the inert diluting gas by H_2 barely influences the growth of NT. In all cases, the structure of NT was defective. A graphite coating was formed around the catalyst particles and multi-walled NT were 'extruded' from it.

Testing of Fe catalysts prepared by various procedures showed¹³² that Fe supported on SiO_2 provides the best results. The greatest yield of NT was attained when C_2H_2 was pyrolysed at 700 °C. The outer and inner diameters of NT were, on the average, 10–20 and 5–8 nm, respectively.

As a further development of the study cited,¹³² pyrolysis of C_2H_2 over Fe particles in mesoporous SiO_2 has been carried out.¹³³ The catalyst was prepared by hydrolysis of tetraethoxysilane in a solution of $\text{Fe}(\text{NO}_3)_3$ followed by reduction with an $\text{H}_2\text{--N}_2$ mixture at 550 °C. The diameter of NT ($\sim 30\text{ nm}$) obtained at 700 °C from an acetylene–nitrogen gas mixture (9% of C_2H_2) was nearly equal to the diameter of pores in SiO_2 . It has been assumed that NT with a smaller diameter can also be obtained in this way. Each NT contained 40 to 50 shells and was located at a distance of $\sim 100\text{ nm}$ from the closest neighbours; thus, the deposit looked like a 'forest' consisting of nanotube 'stems' parallel to one another. The rate of the growth of NT was about $25\text{ }\mu\text{m h}^{-1}$. In the initial stages, NT were free from the amorphous carbon impurity; however, as the duration of the pyrolysis and, correspondingly, the length of NT increased (the NT grew to a length of 50–100 μm over a period of 2–5 h), the 'stems' bent and amorphous carbon appeared on their surface. The main obstacle hampering the conducting of larger-scale process is the difficulty of manufacturing substrates with large dimensions because they are subject to shrinkage and cracking.

An improved method for the synthesis of a supported Fe catalyst has been proposed.^{134, 135} The method was based on the deposition of a film of a $\text{Fe}(\text{NO}_3)_3$ -containing gel onto a 30–50 μm quartz plate, the removal of excess water and other solvents and drying at 80 °C. As this was done, the gel cracked into pieces with an area of 5–20 mm^2 each. These pieces were calcined *in vacuo* and then the iron was reduced to give small (5–50 nm) iron particles distributed uniformly over the surface.

Pyrolysis of a $\text{C}_2\text{H}_2\text{--N}_2$ mixture containing 9% of acetylene at 600 °C and a pressure of 24 kPa in the presence of this catalyst made it possible to obtain NT in very high yields. The outer diameter of NT amounted to 30–40 nm and the inner diameter was 10–15 nm. They consisted of 10–30 coaxial layers. Individual NT were located at distances of $\sim 100\text{ nm}$ from one another. The rate of the growth was $30\text{--}40\text{ }\mu\text{m h}^{-1}$ and the length of NT (attained in 48 h) was $\sim 2\text{ mm}$. The greatest area coated by NT was 15 mm^2 . No formation of polyhedral particles was detected. The layer of NT was easily separable from the substrate.

A mechanism consisting in the NT growth on the side of a free tip, which is covered by a catalyst particle, has been proposed for this process.¹³⁵ The micrographs of NT obtained by the transmission electron microscopy, which are presented in a study cited,¹³⁵ show an iron particle at the tip of the NT and a top-shaped cavity at the NT base. These results are at variance with the data of José-Yacamán *et al.*¹²⁹ It has been considered initially that the reaction mechanism should include the formation and decomposition (upon supersaturation) of 'active' metal carbides. This mechanism was consistent with the fact that the growth of NT, which has stopped after cooling of the carbonised catalyst, is resumed after the subsequent heating. The root growth of NT can proceed by a mechanism described previously and assuming the surface diffusion of carbon atoms to the bulges on the catalyst surface;⁴³ in this case, dehydrogenation of C_2H_2 on the catalyst surface to give H_2 rather than mere adsorption of carbon can be the first stage of pyrolysis. A mechanism involving immersion of small C_n clusters into the caps of NT has also been considered. It should be stated that catalytic pyrolysis of the same hydrocarbon (C_2H_2) present in the same concentration in N_2 (9%) at similar temperatures (500 and 600 °C) can follow absolutely different

mechanisms depending on the pressure in the system, the method used to prepare the catalyst and other factors.

Pyrolysis of C_2H_2 over Fe-containing catalysts supported on various materials including SiO_2 has been considered in several other publications.^{136–139} It was noted that, in addition to the NT described above, helical and even branched NT can be formed.

Apart from iron, cobalt also exhibits high activity in the pyrolytic decomposition of C_2H_2 .¹³⁶ The materials used as supports for this metal include SiO_2 ,^{137, 140, 141} NaY zeolite¹³⁷ and Al_2O_3 .¹⁴² The procedure for the preparation of Co catalysts, in particular, the pH of precipitation of the metal salt from a solution, influences appreciably the quality of NT.¹⁴¹ Biro *et al.*¹⁴³ have classified NT into two groups: 'raft-like arrays' with a diameter of 1 nm and single ones with a diameter of 10 nm. Remarkable NT with a coil structure were also isolated upon pyrolytic decomposition of C_2H_2 over Co.

Nanotubes of this type have been studied in detail.¹⁴⁴ It was shown by high-resolution electron microscopy that the coils consist of several straight sections, the junctions of which can contain disordered areas. The convolutions closely adjoin one another, the NT forming them being 'flattened', *i.e.* compressed along the coil axis.

A certain catalytic activity in the formation of NT from C_2H_2 is displayed by Ni and Mn oxides, while platinum metals proved to be poor catalysts.¹³⁶ However, a catalyst promoting the formation of very long NT was prepared from $Pt_5(CNC_8H_9)_{10}$.

Catalyst particles can be introduced into a support by impregnating it with aqueous solutions of salts followed by decomposition of the salts, by chemical vapour deposition using organometallic compounds, or by electrodeposition. The size of metal particles can range from several nanometers to tens of nanometers.

Zeolites, especially NaY zeolite, make good supports for the catalysts of acetylene pyrolysis.¹³⁷

The synthesis described in Refs 133–135 should actually be categorised as a template synthesis. Membranes prepared by anodic oxidation of Al are also good templates for the catalytic synthesis of NT.¹³⁹ These membranes contain parallel closely packed hexagonal channels (pores) running throughout the whole bulk. By varying the conditions of anodic treatment, one can control the pore diameter (2–500 nm), the membrane thickness (50–500 nm) and the pore density (10^7 – 10^{12} cm⁻²). The Al_2O_3 membranes are transparent and stable up to a temperature of at least 1000 °C; the chemical properties of their surface can change upon the addition of hydroxy groups.

Recently a template synthesis of NT by pyrolysis of C_2H_2 in the presence of a mixed catalyst has been performed.¹⁴⁵ Commercial zeolite samples were impregnated with aqueous solutions of Co and V acetates and used in the process immediately after drying. The pyrolysis was carried out at 700 °C. This procedure yielded well graphitised and relatively thin NT (10–12 shells, outer diameter 8–10 nm, inner diameter 2.5–2.8 nm). The role of the vanadium additive is unknown; the mechanism proposed in the study cited¹⁴⁵ and involving the transition of metal compounds to the gas phase seems doubtful.

b. Pyrolysis of methane, ethylene and propylene

It has been noted in a publication¹³⁷ devoted to the pyrolysis of acetylene that the use of methane, ethylene or propylene instead of acetylene either does not give NT or gives them in low yields. However, in some studies, conditions have been selected under which pyrolysis of these compounds does yield NT. Thus a deposit consisting of NT to an extent of 90% was obtained from CH_4 at 600 °C in the presence of the $Ni_xMg_{1-x}O$ catalyst, prepared from Ni and MgO, in which some Ni atoms were located on the catalyst surface as aggregates.^{146, 147} The synthesis of NT with a length of > 20 μm from a CH_4 – H_2 mixture in the presence of Fe particles has been reported.¹⁴⁸ An interesting point in this study¹⁴⁸ is that NT were synthesised using a microwave setup (Fig. 6), widely employed for the preparation of diamond films. However, the

Figure 6. Setup for plasma-activated chemical deposition from the gas phase. The pressure of the mixture of CH_4 and H_2 at the inlet is 0.13 Pa, the substrate temperature is 370–950 °C; (1) microwave antenna; (2) quartz window; (3) gas inlet; (4) viewing window; (5) plasma discharge; (6) to the optical emission spectrometer; (7) substrate; (8) an energy-sensitive graphite stand; (9) drive to a stepper motor; (10) to a vacuum pump.

synthesis of single-walled NT carried out at Stanford University (USA) appears the most impressive.^{149, 150} In this study, methods of nanotechnology were employed. The catalyst was applied to a silicon plate as micron-sized islets. To this end, square holes were made in a poly(methyl methacrylate) film by electron-beam lithography and then the catalyst precursor was deposited onto the film from a methanol solution containing $Fe(NO_3)_3$, $MoO_2(acac)_2$ and Al_2O_3 particles. Subsequently the solvent and the film were removed, the catalyst was heated in argon, and, finally, pyrolysis of CH_4 was carried out.

During pyrolysis, very straight NT with diameters of 1–3 nm and lengths of up to 20 μm containing no topological defects were formed on the catalyst islets over a period of 10 min. Some NT served as bridges between neighbouring catalyst islets and thus formed electric contacts. An increase in the process duration to several hours resulted in thicker NT.

This method is rather straightforward and easily reproducible; it can be used to prepare NT on substrates having large areas.

The $CoSi_2$ formed upon the deposition of cobalt onto silicon also catalyses the formation of NT from CH_4 .¹⁵¹

The use of ethylene for the template catalytic synthesis of single-walled NT on porous Al_2O_3 plates has been described.^{152, 153} Pyrolysis of propylene^{132, 137, 139} and pyrolysis of polyethylene over a Ni catalyst have been reported.^{154, 155}

c. Pyrolysis of benzene and other aromatic compounds

Benzene can also serve as the initial hydrocarbon for the synthesis of NT; this synthesis can be carried out using the equipment designed for the preparation of carbon fibres from C_6H_6 .¹⁵⁶ It was noted that the growth of NT and carbon fibres follow different mechanisms; indeed, catalyst particles were detected at the tips of the fibres, whereas the NT usually had conical caps free from inclusions. The preparation of NT from a C_6H_6 – H_2 mixture over an Fe catalyst requires as a rule lower partial pressures of C_6H_6 and lower temperatures than the synthesis of fibres. In some cases, the growth of NT is replaced by the growth of solid fibres. Solid fibres and NT prepared from the same hydrocarbon in single-type equipment differ markedly in mechanical properties — the fibres are easily broken on bending, whereas NT exhibit flexibility and elasticity.

Pyrolysis of C_6H_6 over Co supported on SiO_2 affords simultaneously bent and helical NT and fibres,¹⁵⁷ the ratio of the yields of NT and fibers being determined by the size of the catalyst particles and the composition of the reaction mixture. A catalyst containing a higher proportion of Co (5 mass %) and consisting of larger particles (11 nm) results in a higher proportion of fibres than a catalyst with a lower metal content (0.5 mass %) and a

medium particle size (7 nm). The replacement of the gas diluent H_2 by N_2 increases the yield of NT.

The helical NT resulting from the pyrolysis of C_6H_6 differ from those formed upon the pyrolysis of C_2H_2 (see above¹⁴⁴); they are multi-walled NT, the distance between the shells being intermediate between the corresponding distances in ordinary and turbostratic graphites. The shells themselves are largely disordered.¹⁵⁷ Among other reasons, the formation of such structures might be due to the addition of hydrogen (the diluent of benzene) to the dangling bonds of NT. However, the catalyst particles exert a greater influence. This hypothesis is consistent with the model proposed by Amelinckx *et al.*,¹⁵⁸ which assumes that the growth of NT progresses on the side of a free tip having an encapsulated catalyst particle.

Deposits of NT with a definite texture can be obtained from gaseous C_6H_6 . Thus pyrolysis of C_6H_6 on a profiled substrate with scratched parallel grooves gives rise to NT arranged parallel to the substrate surface and growing from the upper edges to the centres of the grooves.¹⁵⁹ It was suggested that irregularities on the upper edges of the grooves exhibit enhanced catalytic activity.

A similar expedient has been used in the pyrolysis of 2-amino-4,6-dichloro-*s*-triazine.^{160,161} A 10- to 100-nm thick Co film was sprayed onto a SiO_2 plate. Then 1 to 20 μm wide tracks spaced 100–200 μm apart were etched on the substrate using a laser. The substrate was placed in a furnace the coating downwards and pyrolysis was carried out at 950 °C. This gave rise to NT bundles having a strictly identical length and very close outer diameters (30–50 nm). The NT obtained in this way contained up to 5% of nitrogen. When the plate was placed in the furnace the coating upwards, the situation changed sharply; strongly twisted NT were formed.¹⁶¹ This outcome has not yet been adequately interpreted.

The researchers believe that etching of the Co film gives rise to energy-saturated metal or metal oxide clusters, which are deposited along the track edges. Hydrogen chloride, arising upon decomposition of triazine, can convert Co into volatile $CoCl_2$ and thus influence the catalytically active particles at the tips of NT. The growth of NT is terminated when the catalyst species have lost activity or have been completely evaporated as the chloride.

Pyrolysis of tris(aminotriazine) (melamine) and cyanuric acid over etched Co, Ni, or Fe films occurred in a similar way.

A mixture of gaseous phenylacetylene and thiophene with He¹⁶² and a mixture of 2-methyl-1,2'-dinaphthyl ketone with He¹⁶³ in the presence of a Ni catalyst have also been used for the pyrolytic synthesis of NT. It is noted in both studies that at the first stage of pyrolysis, Ni particles are coated with a graphite layer; this is followed by the nucleation and growth of NT. The temperature of choice is 700 °C. Yudasaka *et al.*¹⁶³ proposed an original procedure for the preparation of the catalyst. They sputtered a metal film on a quartz glass substrate and heated it *in vacuo*. The size of the Ni particles thus formed was determined by the thickness of the deposited film; in the optimal case, it was 20–30 nm. It has been concluded¹⁶² that NT are 'extruded' from Ni_3C particles; Yudasaka *et al.*¹⁶³ noted an important role of the shape of Ni nanoparticles.

2. Pyrolysis in the presence of a 'floating catalyst'

A conventional supported catalyst is coated, sooner or later, by a layer of the products of pyrolysis of hydrocarbons and is thus deactivated. The introduction into the system of catalyst precursors as volatile compounds which decompose to give catalytically active species directly in the reaction area could, in principle, permit one to avoid the catalyst deactivation and to bring the process of pyrolysis closer to a continuous process.

There are only a few publications in which this approach has been employed. Thus decomposition of Ni phthalocyanine at 700 and 800 °C has resulted in the synthesis of NT containing some nitrogen.¹⁶⁴ These NT were multi-walled particles with large (~200 nm), small (10 nm) or variable diameters, their length reaching 6 μm . It has been assumed¹⁶⁴ that the mechanism of

the NT growth includes encirclement (encapsulation) of Ni particles with a carbon layer, graphitisation of this layer, the change in the shape of Ni particles, the appearance of seeds and the growth of NT. The Ni particle inside the NT can either migrate from the substrate to the growing tip or remain in a particular section of the NT, forming a node point.

Decomposition of Fe and Co phthalocyanines is also accompanied by the formation of NT, whereas Cu phthalocyanine gives neither NT nor graphitised particles.

Ferrocene has been used as the 'floating catalyst' in the pyrolysis of thiophene.¹⁶⁵ Unlike the study cited above,¹⁶⁴ in this case, single-walled NT were produced. The process was carried out at 1100–1200 °C for 1 to 30 min. This yielded a large amount of long and relatively thick 'ropes' and ribbons coloured silvery black. Some of the ribbons were semitransparent and not attached to the surface. The longest 'ropes' were 3–4 cm long and had a diameter of 0.1 mm, while the ribbons were up to several millimeters wide. Each 'rope' and each ribbon consisted of several thousands of vaguely oriented threads, comprised by bundles of well oriented closely packed single-walled NT. The diameter of the bundles ranged from several to forty nanometers, the average diameter of the NT being 1.7 nm. It was found that the bundles are formed in the reaction area and carried away with the gas stream; outside the area they stick together forming 'ropes' or ribbons.

Pyrolysis of ferrocene and its mixtures with C_2H_2 has also been studied.¹⁶⁶

3. Decomposition of CO

Thermal decomposition of CO (disproportionation to CO_2 and carbon) differs sharply from the pyrolysis of hydrocarbons from the thermodynamic viewpoint; at atmospheric pressure and low temperatures (300–750 K), the equilibrium yield of carbon is nearly quantitative, while at higher temperatures and lower pressures, it diminishes. Conversely, the yield of carbon in the pyrolysis of C_2H_2 and CH_4 increases as the temperature rises and the pressure is reduced and approaches a quantitative yield at 1250–1500 K.

In this respect, carbon monoxide may seem to be a less convenient starting compound for the synthesis of NT. However, for kinetic reasons, a hydrocarbon is more difficult to heat to a temperature above 800–900 °C (before it is brought in contact with the catalyst) than CO; hence, carbon monoxide offers some advantages.

The first study¹⁶⁷ on the catalytic decomposition of CO to give NT was carried out in 1995, *i.e.* much later than NT were synthesised by other methods. Decomposition of a CO– CO_2 gas mixture (20% of CO) was carried out at 500 °C over the Ni/Al_2O_3 catalyst. A graphitised shell was formed around the Ni particle; nanotubes protruded out of this shell. The introduction of hydrogen into the gas mixture changed appreciably the morphology of the deposit.

Thermal decomposition of neat CO over a Ni–Co catalyst supported on Al_2O_3 was performed at 1200 °C at a pressure somewhat higher than atmospheric.¹⁶⁸ This process gave rise to single-walled NT.

The preparation of an active molybdenum catalyst used for the synthesis of NT from CO was an important achievement. The catalyst was prepared by impregnation of alumina with a methanol solution of bis(acetylacetonato)dioxomolybdenum followed by heating to 200 °C. The diameter of NT formed in the presence of this catalyst was 1–5 nm. Catalyst particles with sizes of several nanometers were detected on the tips of many of the NT. This provided grounds for proposing a mechanism of the growth, which was called the 'skull-cap' mechanism. According to this mechanism, a catalyst particle promotes dehydrogenation of the hydrocarbon molecules deposited on the particle from the gas phase. Carbon diffuses to the open tip of the NT (where the catalyst particle is located) over the catalyst surface or through the bulk and is embedded in the NT structure. It is the coating

consisting of chemisorbed carbon atoms on the surface of the catalyst particle that is referred to as 'skull-cap'. It prevents the formation of dangling bonds. Micrographs of single-walled NT with catalyst particles located on the open tip and having a size equal to the NT diameter were reported.¹⁶⁸

Testing of the Ni–MgO,^{146,169} Co–MgO¹⁷⁰ and Ni–AlPO₄¹⁶⁹ systems as catalysts for decomposition of CO gave positive results. Not only multi-walled NT¹⁴⁷ but also single-walled NT containing no deposit of amorphous carbon on the external surface have been synthesised from CO.

None of the proposed mechanisms¹⁷¹ is able to explain the influence of the nature of the initial gas on the morphology of NT and other structures.

4. Synthesis of nanotubes containing B–C–N, C–N and B–N

It has been noted above that the catalytic pyrolysis of triazine gives rise to nitrogen-containing NT.¹⁶⁰ The pyrolysis of CH₃CN·BCl₃ at 900–1000 °C over a Co powder afforded fibres and NT of the composition B_xC_yN_z with various morphologies.¹⁷² Nanotubes of the composition C₃₈N, the properties of which differed markedly from those of carbon NT, were obtained from pyridine in the presence of a Co catalyst; the nanotubes BC₂₈N were synthesised from the adduct (CH₃)₃N·BH₃.¹⁷³ All the nanotubes thus prepared were multi-walled. Since the yield of NT in the pyrolysis of the adduct NH₃·BH₃ was very low, it was proposed that coating of metal particles with graphite is a necessary initial stage in the formation of boron- and nitrogen-containing NT.

The data available to date are still inadequate for drawing definite conclusions about the reaction mechanisms, although the shape of some NT provided grounds for speaking about the unusual phenomenon of periodic motion of the catalyst particles located inside the NT along the NT axis.¹⁷² Previously a similar mechanism had been described for purely carbon NT with a bamboo-like structure.¹⁷⁴

VI. Growth of nanotubes by decomposition of metal carbides

When performing arc synthesis, researchers have noticed that particles of catalysts (carbides) are first covered by an envelope of several graphitised layers, which serve as the source for the growth of NT.¹⁷⁵ The mechanism of formation of such a structure (which has been termed 'sea-urchin') includes the formation of super-saturated solutions of carbon in a metal or metal carbide, subsequent segregation of carbon from these solutions and the 'root' growth of NT. 'Sea-urchins' were formed on particles of YC₂,^{71,175} LaC₂,¹⁷⁶ GdC₂,¹⁷⁷ Ni₃C,¹⁷⁸ TiC¹⁷⁹ and other carbides.

Heating of silicon carbonitride under a static atmosphere of N₂ at 1400 °C or in a flow of N₂ at 1850 °C resulted in the synthesis of multi-walled NT with a diameter of 10–25 nm and with a length of up to 1 µm.¹⁸⁰ According to a publication which appeared almost simultaneously,¹⁸¹ laser ablation of α-SiC resulted in sublimation of silicon and the formation of NT on its surface. Soon this process was even more simplified; in particular, laser treatment was replaced by resistivity heating of powdered¹⁸² or single-crystalline¹⁸³ silicon carbide. Heating of powdered silicon carbide *in vacuo* at 1600–1700 °C allowed preparation of NT on a relatively large area over a period of 10–15 min. These NT grew at right angles to the external surface of the powder; they were substantially shorter than those obtained by the arc method but longer than those prepared by the laser ablation of SiC. Even more uniform NT ('a forest') were synthesised at a temperature of 1700 °C and a pressure of 1.3×10^{-2} Pa on a $3 \times 5 \times 0.34$ mm plate. They grew to a length of 0.15 µm over a period of 30 min and were distinguished by a fairly regular mutual orientation. Apparently, this procedure is the simplest way of producing cathodes for field electron emitters.

Small amounts of NT were formed in Fe–Ni and Fe–Ni–Co alloys containing carbon^{184,185} and in complex solid solutions containing Fe₃C.¹⁸⁶ During subsequent studies, this procedure could be modified for the preparation of NT-containing composites possessing specific properties.

VII. Other methods

1. Synthesis in the flame

Combustion of hydrocarbons in oxygen is employed for the synthesis of diamonds (see, for example, Ref. 187) and fullerenes.¹⁸⁸ Nanotubes can also be prepared in this way.¹⁸⁹ It is of interest that the C:O ratios, which were equal to 1.06, 1.07 and 0.86–1.00 for the combustion of C₂H₂, C₂H₄ and C₆H₆, respectively, are close to the optimal values for the synthesis of diamond. However, these processes were carried out under different conditions — in the synthesis of diamond, the inner cone of the flame was directed at a substrate cooled to a particular temperature, whereas in the preparation of NT, catalysts were used.

The data on the synthesis of NT in flames are too scarce to analyse them, as has been done for the synthesis of diamonds (see, for example, Refs 190, 191). It is possible that NT, like diamonds, can be synthesised using any carbon compound, no matter what other chemical elements (halogens, sulfur, nitrogen, phosphorus, silicon, boron, *etc.*) are contained in the compound.

2. Electrolysis of molten salts

Nanotubes can also be synthesised without participation of a gas phase, namely, in ionic salt melts. The electrolysis of molten LiCl at temperatures above 600 °C in a cell with carbon anode and cathode causes a heavy erosion of the cathode and appearance of sludge in the melt, which can be washed by water and toluene after cooling the melt.¹⁹² In addition to spheroidal and polyhedral particles, multi-walled (2–10 walls) NT with a diameter of 2–10 nm were detected in the sludge. The current density has a strong influence on the yield of NT. The yield and the quality of NT also depend substantially on the temperature of the melt and the nature of the salt used (LiCl, NaCl or KCl).¹⁹³ The electrolysis should not be carried out for a long time because the sludge can short circuit the electrodes.

The electrolysis of a LiCl–SnCl₂ melt resulted in the synthesis of NT filled with β-Sn, *i.e.* a nanowire.⁸⁵

3. Chlorination of carbides and other methods

According to a publication,¹⁹⁴ back in the 1960s, multi-walled NT were obtained by chlorination of SiC and TaC at 800–850 °C; the electron micrograph of these NT was published in 1978 in a book.¹⁹⁵ Presumably, the coke that had been prepared using a graphite electric heater (with a temperature of at least 2500 °C) and employed for the synthesis of carbides, served as the source of NT.

There also exist other methods for the synthesis of NT, for example, pyrolysis of the powdered polymer prepared by polyesterification of oxalic acid and ethylene glycol,²⁶ and the reaction of metallic Cs with nanoporous carbon, prepared from a mixture of polyfurfuryl alcohol and polyethylene glycol, carried out at 50 °C.¹⁹⁶

A method for the synthesis of NT similar to that described in Ref. 148, has been proposed by Küttel *et al.*¹⁹⁷ The researchers prepared NT in a microwave discharge using a setup for the plasma synthesis of diamond coatings and a CH₄ (2%)–H₂ (98%) mixture at a pressure of 0.4 kPa; Ni or Fe islets were applied preliminarily on the substrate, the temperature of the substrate being only slightly higher than the optimum temperature for the synthesis of diamonds (900–1000 °C). The deposit had a 'spaghetti' structure and consisted of NT with a diameter of 20–60 nm and a length of up to 100 µm entangled with one another and firmly attached to the substrate. The catalyst particles remained near the NT 'roots' during the synthesis.

The same researchers were able to perform the synthesis of NT using the 'classical' setup used for chemical vapour deposition of diamonds, namely a hot-filament reactor. Since setups similar to that used by Küttel *et al.*¹⁹⁷ are widely employed in dozens of laboratories in many countries and do not need to be modified for switching to the preparation of NT, further development of these methods for the synthesis of NT may be expected.

Recently, syntheses of NT by heating carbon black with boron at 2200 °C and by detonation of 2,4,6-triazidotriazine have been described.¹⁹⁸ An interesting feature of the latter method (explosive synthesis) is that it permits preparation of NT with a record-breaking inner diameter equal to 80–120 nm (although they are formed in a very low yield).

VIII. Purification and opening of nanotubes

Detailed investigation into the properties of NT and some of their practical applications require individual and uniform open-tip NT containing no impurities. However, they are usually obtained as bundles consisting of NT with different lengths, capped at one tip and contaminated with impurities. Therefore, techniques for purification and opening of NT are as important as the methods used to synthesise them.

Unlike fullerenes, neither individual NT nor, all the more so, bundles are soluble in any solvent, which complicates the problem of their purification. Nevertheless, several techniques which permit more or less successful purification of NT have been proposed. The methods are based on the following characteristic features of NT.

The materials that typically contaminate NT (fullerenes, polyhedral graphitised particles, amorphous carbon) are more reactive than NT and some of them (for example, fullerenes) are soluble in organic solvents. Sections of NT with a higher density of defects also exhibit higher reactivity than defect-free NT. This refers first of all to the caps at the NT tips, which contain not only six-membered but also five-membered carbon rings. The carbon atoms in these rings are more reactive. The sections on the lateral surfaces of bent NT possess similar properties because kinks would be impossible without insertion of either five-membered (positive curvature) or seven-membered (negative curvature) carbon rings in a net consisting of standard six-membered rings. Finally, enhanced reactivity is also characteristic of the atoms at the edge dislocations of NT (the 'scroll' or 'papier-mache' structure), in which dangling bonds are concentrated together with defects arising upon replacement of carbon atoms by atoms of other elements.

Multi-walled NT, which are normally more defective than single-walled ones, are more reactive, whereas NT annealed at high temperatures (annealing leads to elimination of defects) are less reactive. Nanotubes filled with metals or metal carbides differ in density from empty NT.

The methods used to purify nanotubes can be divided into three groups — chemical, physicochemical and mechanical.

1. Chemical methods

The simplest method for opening NT is selective oxidation of the caps, which can be carried out by gases, melts or aqueous solutions.

The gaseous oxidants used for this purpose are O₂ (see Ref. 62), air,¹⁹⁹ CO₂ (see Ref. 200) and oxygen plasma.²⁰¹ The maximum rates of oxidation with air are attained at 420 °C for C₆₀, at 645 °C for graphite and at 695 °C for NT or nanoparticles.¹⁹⁹ Oxidation with O₂ or with air proceeds most efficiently at 650–750 °C.

Even at 550 °C, a gas flow containing 1% of O₂ causes disordering of the outer shells of NT and formation of wells with a diameter of 2–10 nm on their surface; as a consequence, thin NT swell up.²⁰² At 750 °C, gasification readily occurs at the sites of cracks, defects or deformations.

After opening of NT, the oxidation slows down, whereas oxidation of nanoparticles goes on until they are completely eliminated.²⁰³ However, complete elimination of nanoparticles requires that more than 99% of the initial material be oxidised. Meanwhile, even after 95% oxidation, a sample contains only 10%–20% of the initial NT. This is due to the fact that not only caps but also lateral walls of the NT are oxidised. As this takes place, multi-walled NT become thinner and some of them are completely gasified.

To purify multi-walled NT in air, heating by IR radiation can be used.²⁰⁴ In particular, a 0.1-mm thick spongy paste with an area of ~10 mm² consisting of multi-walled NT was obtained in this way from the products of arc synthesis in an H₂ flow. In some cases, it is sufficient to heat the material in air at 500–600 °C for 30 min.²⁰⁵

Purification can also be carried out in hydrogen plasma.²⁰¹ However, in practice, purification of multi-walled NT from amorphous carbon is carried out by treatment in an H₂–N₂ mixture at 900 °C.¹³⁷

The method of oxidation in melts^{59,61} has not been further developed.

In the case of single-walled NT, oxidation in aqueous solutions is apparently the most important method. The most frequently encountered procedure is refluxing in concentrated (60%–70%) HNO₃.^{109,203,206–208} The products of catalytic synthesis are freed simultaneously from the inevitable metal impurities. After refluxing for 4.5 h, the loss of mass in the material obtained by the arc method was less than 2%; as a result, 80% of NT became open.²⁰⁶ Refluxing of 10 g of the initial material produced by the laser ablation method in 1 litre of a 2–3 M solution of HNO₃ for 45 h resulted in a 70% loss of weight.¹⁰⁸

Apart from treatment with nitric acid or after this treatment, NT are made to react with mixtures of HNO₃ with H₂SO₄ and of H₂SO₄ with H₂O₂ (see Ref. 103). In some cases, H₃IO₅ and HClO₄ (see Ref. 209) or solutions based on concentrated HCl²¹⁰ have been used instead of HNO₃. Other compounds used as oxidants include H₂O₂, K₂Cr₂O₇, KMnO₄, solutions of Ru and Os chlorides in a solution of NaIO₃, *etc.* Some of the oxidants (acidic solutions of H₂O₂ and K₂Cr₂O₇) proved to be much less selective and efficient than HNO₃, some other (solutions of KMnO₄ containing MnO₂ or CrO₃) exhibited medium activity, and a group of reagents (solutions of Ru and Os chlorides in a solution of NaIO₃) exhibited a very high reactivity and ensured opening of up to 80%–90% of NT at 100 °C.^{211,212}

Oxidation in solutions can be combined with filling of NT (for this purpose, a soluble metal salt is added to the solution^{206,210}) or with chemisorption of metals on the NT surface.²¹³ Chemisorption is due to the fact that upon treatment with an acid, the surface of NT is coated with the acidic groups COOH, which can react with metal ions. The quantity of the Pd²⁺ ions absorbed was found to be strictly correlated with the concentration of acidic groups on closed or open NT.²¹³ An especially high density of acidic groups is attained by using a mixture of H₂SO₄ with HNO₃; these groups promote deposition of finely dispersed metal clusters on the NT surface (see, for example, Ref. 214). The data on wetting, filling and coating of NT have been briefly surveyed in a publication.²¹⁵

Foreign particles can be removed using organic solvents, for example, toluene, carbon disulfide and other solvents, while metal particles can be removed with the aid of acids.

In a pioneering study dealing with purification of NT,²¹⁶ chemical modification of NT by grafting dichlorocarbene to the graphene wall at a double bond has been proposed. In a later publication,²¹⁷ preparation of soluble NT has been reported. The researchers attached a long-chain amide in place of the carboxy groups at the tips of cut single-walled NT. This was attained by treatment of NT with thionyl chloride (70 °C, 24 h) and then with octadecylamine (90–100 °C, 96 h). The product was readily soluble in chloroform, dichloromethane, aromatic compounds

and CS₂. These studies open up new prospects for the development of more facile methods for the purification, separation, study, description and application of NT.²¹⁸

2. Physicochemical and mechanical methods

In recent years, a number of physicochemical and mechanical techniques for the purification of NT have been proposed. They are briefly described below. A physicochemical method, chromatography, has been used to purify both multi-walled²¹⁹ and single-walled NT.²²⁰ The initial NT are dispersed in aqueous media, the dispersions being stabilised by adding surfactants. After separation of the material into fractions using a column with a porous glass packing (with an average diameter of pores of 300 nm), NT are isolated from the individual fractions by centrifuging. Thus not only impurities are removed but, in addition, NT of different lengths are separated.

'Cutting' of NT into 100–300-nm long sections has been reported.²²¹

The foundations of an electrophoretic method for the purification of NT (as a suspension in isopropyl alcohol) have been outlined in a study.²²²

Various mechanical procedures for the purification of NT are known. They include sonication, microfiltration and centrifuging.^{103, 199, 206–208, 223–225} Many of these procedures are labour-consuming and include large numbers of stages; in some cases, they are used only in combination with chemical methods. Sonication increases the density of defects, especially, in multi-walled NT. The ability of individual NT to form bundles ('ropes') manifests itself not only during the synthesis but also in the purification — in some cases, the purified material contains bundles with greater diameters than the initial material. Under some conditions of sonication in acids, the bundles of NT assume a ring shape with a diameter of 0.25–0.55 μm .²²⁶

Particular examples of combined strategies for the purification of single-walled NT can be found in the literature.^{103, 208}

IX. Conclusion

Methods for the synthesis of NT are fewer in number, judging by reviews,^{3, 7} than methods for the synthesis of fullerenes. Nevertheless, the main range of these methods has already taken shape and now the question is what of these methods are best suited for the large-scale synthesis of NT.

Different methods can only be compared conventionally because in most cases, the necessary characteristics are not fully available or not reported at all. First of all, methods that require vacuum or elevated pressures should be distinguished from the procedures of synthesis at ambient pressure. The former are less productive. The vaporisation of graphite induced by electron or ion beams and the use of diamond anvils also imposes some restrictions on the productivity. It is also expedient to classify as a separate group those methods that cannot be easily made continuous, for example, electrolysis or explosive synthesis.

Many investigators agree in the opinion that the most widely used electric-arc and laser-ablation methods are applicable only on a laboratory scale, whereas pyrolysis should become the most important commercial method.^{131, 156, 165, 227} This method is similar in many respects to the pyrolytic method long employed for the production of carbon fibres both in the presence and in the absence of catalysts. The necessary equipment is relatively simple. It is the pyrolytic method that was used to prepare the longest known thread-like bundles of NT and macroscopic ribbons ('mats') of interwoven NT.¹⁶⁵

The advantages of the pyrolytic method are manifested especially clearly in the production of ordered structures by deposition of NT onto a smooth substrate with a supported catalyst or onto a porous template. Neither arc nor laser methods can give such structures. Mechanical expedients have been developed which allow laying of NT of any origin parallel to one another (for example, dispersion in a matrix made of a polymeric

resin followed by cutting thin slices of the composite²²⁸ or microfiltration of a suspension in ethanol through specific ceramic filters followed by transfer onto a plastic surface²²⁹). However, they are all much more complicated and much less elegant than catalytic pyrolysis and cannot in full measure compete with it.

Ordered structures from NT prepared by the pyrolytic method are best suited for template synthesis, *i.e.* application of metals, for example, Ni or Co on their surface,^{142, 230, 231} for deposition of oxides,⁶³ carbides^{232–235} or gallium nitride,²³⁶ for the preparation of catalysts, sorbents, membranes for electrochemical cells,¹⁵² field emitters and artificial muscles (actuators).

Pyrolysis of hydrocarbons in flame¹⁸⁸ and in plasma¹⁹⁶ are also promising because both methods are facile and can be implemented in a continuous mode. Diamond coatings are already prepared on an industrial scale by means of plasma devices; the principal (perhaps, the only) condition for using them for the synthesis of NT is the presence of an appropriate catalyst on the substrate.

However, it may happen that NT meant for particular purposes will be prepared by other methods which have not yet been tested, for example, in plasma jet devices. However, the use of solar energy concentrators for the preparation of NT can hardly be expected in Russia, because the intensity of solar radiation in Russia is relatively low and the level of development of this method does not surpass that for other methods of heating.²³⁷

Studies of carbon NT have provoked interest in the preparation of nanotubes consisting of other inorganic compounds. Tubular structures are possible for a fairly large number of inorganic compounds of various classes.²³⁸ Studies on the synthesis of NT from BC_x, BN, BC_xN_y and CN_x are only at the beginning; however, in this case, too, pyrolytic methods would apparently prove to be the most convenient.

The problem of the synthesis of NT with identical geometries might be solved using the method proposed by Smalley, namely, selection of homogeneous seed NT and their further growth by pyrolysis of hydrocarbons (<http://www.dtic.mil/dusdst/agenda/agenda31999.html>).

A complicated synthetic task would be routine preparation of NT with reproducible heterojunctions (variation of diameter, chirality or chemical composition); some enthusiasts believe that this could serve as the basis for the nascent nanoelectronics. The design of nanomechanical devices in which NT are expected to serve as important and abundant parts will also require great efforts.

* * *

Since this manuscript was prepared for the publication, new journal papers and Internet sites devoted to the synthesis of carbon NT have appeared (or become available).

Thus the mechanism of formation of carbon NT, nanowires and nanoparticles in an electric arc burning under a hydrogen atmosphere has been described. The participation of polycyclic aromatic hydrocarbons in the synthesis of NT has been confirmed. A direct correlation between the ability of H₂ to remove graphenes from an anode and the yield of NT has been elucidated.²³⁹

It was found that only three platinum metals, Rh, Pd and Pt, induce the formation of single-walled NT in an electric arc, whereas mixtures of metals (Ru–Pd, Rh–Pd, Ru–Rh, Ru–Pt and Pd–Pt) exhibit low or zero activity; only a Rh–Pt mixture (1 : 1 or 5 : 2) is active in this process.²⁴⁰ At a helium pressure of 78 kPa over a Rh–Pt catalyst, NT with approximately equal diameters (1.28 $\pm$ 0.07 nm) were formed. A 10–12 fold decrease in the helium pressure resulted in the growth of nanotubes of different diameters (0.7–1.3 nm).

A novel method for the synthesis of NT in a pulsed arc setup has been developed.²⁴¹ The highest yield of NT was attained in a

flow of Ar or Kr at temperatures of $> 1000\text{ }^{\circ}\text{C}$ and pulse duration of $> 1\text{ }\mu\text{s}$.

Interesting results concerning growing of NT by the electric-arc method have been obtained in a study by Chang *et al.*,²⁴² who used an anode with a diameter of 6 mm and a 10-mm thick disk 30 mm in diameter as a cathode. Both electrodes were intensely cooled with water and the electrolysis was carried out in a self-sustained mode (interelectrode distance 3–4 mm, voltage 20 V, current 55–65 A, helium pressure 67 kPa). The cathode deposit was formed on an area with a diameter close to the anode diameter. The morphology of the deposit differed appreciably from the standard morphology. A bed of chaotically entangled slightly bent NT (diameter 10–40 nm, length $> 30\text{ }\mu\text{m}$), the axes of which were oriented randomly, was located under a thin tough shell. These NT had no defects, contained no amorphous carbon impurity and could be purified from the nanoparticle impurity by merely keeping in air (850 $^{\circ}\text{C}$, 1 h). The intense cooling of the electrodes and gases near the cathode as well as the large distance between the electrodes, which influences the mode of the current passage, is assumed to be largely responsible for the sharp change in the morphology and properties of the arc synthesis products.

A detailed study of some parameters of the laser-induced thermal synthesis of NT has been reported.^{243,244} In particular, it was found that the amount of carbon being vaporised from the target is determined by the intensity of laser radiation, while the course of the chemical reaction yielding NT is governed by the temperature in the furnace. The rate of evaporation of catalysts (Ni and Co) is affected by both parameters. The laser radiation intensity has a slight influence on the diameter of NT, while a decrease in the furnace temperature results in smaller diameters.²⁴³ The increase in the delay between single laser pulses from 0.1 to 120 s has almost no influence on the structure of single-walled NT but decreases the yield of the web-like product.²⁴⁴ It has been shown theoretically²⁴⁵ that the use of shorter pulses (picoseconds instead of nanoseconds) and higher frequencies (tens of megahertz) brings the synthesis of NT closer to a quasi-continuous mode.

It has been shown²⁴⁶ that the laser-assisted synthesis of NT in the presence of Ni and Co can also be performed in a flow of N_2 .

The application of a continuous-wave CO_2 laser to the synthesis of NT without additional furnace heating of the target is a method new in principle.²⁴⁷ In this study, a vertical setup was used with a rotating target moving along its axis (a rod 6 mm in diameter) and made of a mixture of graphite with a catalyst. A hot zone with a diameter of $\sim 1\text{ cm}$ was formed around the laser spot; this resulted in local heating of the gas flow and prevented the plasma from cooling too fast. The synthesis was carried out under Ar. When the radiation power was 250 W and the diameter of the laser spot was $\sim 1\text{ mm}$, the vaporisation rate reached 200 mg h^{-1} . The yield of single-walled NT in the presence of Ni–Y or Ni–Co catalysts was $\sim 20\%$ based on the amount of the vaporised material.

French investigators have successfully tested a prototype of a 1000-kW solar concentrator for the synthesis of NT (<http://www.uiuc.edu/cnrs/Cnrspresse/en352a3.htm>).

The formation of NT on irradiation of graphite with high-energy Ne^+ , Kr^+ and Xe^+ ions has been studied.²⁴⁸

Numerous publications in 1998–1999 were devoted to the pyrolytic synthesis of NT. For instance, the influence of the substrate on the catalytic pyrolysis of C_2H_2 in the presence of Co or Fe has been considered.²⁴⁹ The influence of the natures of the catalyst (Fe_2O_3 , CoO , NiO or their mixtures) and the support (Al_2O_3 or SiO_2 with a specific surface area of 100 and $300\text{ m}^2\text{ g}^{-1}$, respectively) on the formation of single-walled NT in the pyrolysis of pure CH_4 has been studied.²⁵⁰ Relying on the fact that the tips of growing NT contained no catalyst particles, the researchers²⁵⁰ concluded that the process followed a ‘root’ growth mechanism. The highest yield of individual NT was attained with the $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$ catalyst.

The pyrolysis of metallocenes and $\text{Fe}(\text{CO})_5$ mixed with C_2H_2 or C_6H_6 has been studied.^{251,252} It was found that the content of the amorphous carbon impurity can be diminished by introducing H_2 into the gas phase.

The conduct of the pyrolysis of C_2H_2 by means of a hot filament with plasma activation permitted the substrate temperature to be decreased to $650\text{ }^{\circ}\text{C}$.^{253,254} Yet another novelty was the use of an NH_3 admixture, which was found to function as a catalyst. The diameter of the NT produced in this way was dictated by the thickness of the Ni film sprayed preliminarily onto a glass substrate and varied from 20 to 100 nm. The growth rate was several times higher than that attained in earlier studies (see, for example, Ref. 133) and was equal to $120\text{ }\mu\text{m h}^{-1}$.

Pyrolysis of naphthalene vapour in the presence of $\text{Cr}(\text{CO})_6$ vapour with ‘anode field activation’ was performed for the first time.²⁵⁵ The process at a voltage of 4–6 kV, an anode temperature of 1100–1200 $^{\circ}\text{C}$ and a vapour pressure of $\sim 8\text{ Pa}$ afforded carbon NT with Cr nano-rods protruding from their inner cavity. These rods had a strictly invariant diameter ($\sim 10\text{ nm}$) along the full length (up to $0.5\text{ }\mu\text{m}$). The attempts to accomplish a similar process with $\text{Mo}(\text{CO})_6$ or $\text{W}(\text{CO})_6$ failed.

Yet another modification of the pyrolytic synthesis of NT includes two-stage heating *in vacuo* (first at 350–450 $^{\circ}\text{C}$ and then at 500–800 $^{\circ}\text{C}$) of tripropylamine introduced in the channels of $\text{AlPO}_4\cdot 5$ single crystals.²⁵⁶ The NT thus formed had equal diameters and equal lengths; however, they proved to be unstable with respect to HCl.

Nanotubes consisting of a new promising material, carbon nitride, have been prepared on a graphite substrate from a $\text{C}_2\text{H}_2\text{--N}_2$ mixture in a microwave plasma using a bias potential.²⁵⁷ A peculiar method for the synthesis of B,N-containing NT is based on the replacement of C atoms in carbon NT by B and N atoms upon the reaction of NT with B_2O_3 vapour diluted with N_2 .²⁵⁸ The preparation of multi-walled NT filled with molten UCl_4 or its mixtures with KCl has been described.²⁵⁹

A method for purification of NT (prepared by the pyrolysis of C_2H_2 over Co introduced into NaY zeolite) has been described, which involves dissolution of impurities in hydrofluoric acid and subsequent oxidation of NT with a solution of KMnO_4 or air.²⁶⁰

A fairly comprehensive study²⁶¹ is devoted to the behaviour of NT treated with a mixture of concentrated HNO_3 and H_2SO_4 . The presence of acid functional groups on the surface of these NT makes it possible to prepare viscoelastic gels; on drying, solid materials or films with specific structures and properties can be obtained. Under particular conditions, the dispersions can be converted into a material reminiscent of liquid crystals.

Fullerenes have been synthesised by irradiation of $\text{C}_6\text{H}_6\text{--O}_2$ or $\text{C}_6\text{H}_6\text{--N}_2\text{O}$ mixtures with a CO_2 laser in the presence of SF_6 .²⁶² This method might also enable the synthesis of NT.

The preparation of Langmuir–Blodgett films from matrix-diluted single-walled NT and application of the films onto various surfaces using micelle-like aggregates has been reported.²⁶³ Soluble carbon NT coated with poly(phenylacetylene) have been synthesised.²⁶⁴

Many of the studies mentioned above were reported at the conference on commercialisation of the achievements in the large-scale production of carbon NT (USA, Washington, April 1999; <http://www.knowledgefoundation.com/carbon.html>). The prospects for the investigation and use of NT-based materials were also discussed at the conference of the Materials Research Society (USA, Boston, December 1998), which has been described in a brief review.¹⁹⁷

Studies on the application of NT in electronics were surveyed by Johnson at the International Conference on Solid-State Circuits (USA, San-Francisco, January 1999; <http://www.eet.com/story/OEG19990217S0045>).

Several new promising fields of application of NT have appeared quite recently. The greatest interest was aroused by the development of a prototype of artificial muscles, actuators, activated by application of a low electric potential, which was

reported by an international group of scientists^{265–268} (see also M Fox *Infoseek News* May 21, 1999; http://www.mpg.de/news99/news26_99.html; and <http://www.msnpc.com/news/271534.asp>). A new route to the design of NT-based parts of electronic devices (amplifiers, switches, logical elements) was discovered.²⁶⁹ The possibility of isotope separation with the aid of NT²⁷⁰ and of using NT for nanolithography²⁷¹ was demonstrated. An electrode manufactured from a single NT was developed and tested.^{272, 273}

Recent reviews and issues of journals devoted to NT are also worth mentioning.^{274–282}

Abstract. Approaches to the preparation of organic–inorganic nanocomposites are considered from a unified viewpoint for the first time. The major problems in the development of this new line of research in materials technology, which has arisen on the border of the science of polymers, colloid chemistry and physical chemistry of the ultradisperse state, are discussed. The main methods for the formation of composite materials and polymer–inorganic cross-linked hybrids with interpenetrating networks are analysed. Primary attention is given to sol-gel procedures for their preparation, including template processes, which occur under conditions of strict stereochemical orientation of reactants, intercalation of monomers and polymers into porous and layered matrices and their intracrystalline and post-intercalation transformations. Methods for the synthesis and properties of metallopolymeric polymolecular Langmuir–Blodgett films, which are peculiar supramolecular ensembles incorporating nanosized metal-containing particles, are discussed. The generality of the processes of formation of organic–inorganic nanocomposites in living and nonliving natural objects is demonstrated and the major fields of application of nanocomposites are considered. The bibliography includes 566 references.

I. Introduction

The science dealing with nanocomposites, which belong to the class of composite materials characterised by nanometer sizes of their structural elements (particles of metals, metalloids, their oxides, chalcogenides, *etc.*), has arisen in recent years on the border of different areas of knowledge. Apparently, the term ‘nanocomposites’ was proposed for the first time by Theng in 1970.¹ In the literature, the terms ‘hybrid nanocomposites,’ ‘nanohybrids’ and ‘nanostructural composites’ are generally used and the terms ‘metallomatrix composites,’ ‘monophase hybrids,’ *etc.* are more rarely used for describing materials

consisting of an organic phase (polymer) and a nanodispersed mineral phase. If a polymer of biological origin serves as a component or a precursor of these polymer–inorganic materials, the term ‘nanobiocomposites’ is used.

An organic phase can capture metal-containing particles into a ‘trap’ of a peculiar kind, *viz.*, into an oxopolymeric network or a polymeric unit with appropriate parameters. Silicon, aluminium, titanium, zirconium, vanadium and molybdenum oxides, glasses, clays, layered silicates and zeolites, metal phosphates and chalcogenides, iron oxychloride and graphite are used as inorganic precursors. Zeolites (molecular sieves) are of particular interest since methods for control over their pore sizes are well known. Not only carbon-chain but also organoelement (generally, organosilicon) polymers are used as a polymeric component. In the resulting nanocomposite materials, distances between networks and layers formed by polymeric and inorganic ingredients and sizes of particles formed, including metal-containing particles, are nanometric.^{2,3}

Generally, hybrid nanocomposites exhibit a synergism of the properties of the initial components. These compounds are characterised by an enhanced mechanical strength and thermal stability and provide optimum heat transfer.^{4,5} In metallomatrix composites, the strength and hardness of soft metals, for example, of aluminium, are enhanced. These materials possess good thermochemical, rheological, electrical and optical properties.^{6–8} These compounds are used as chromatographic carriers, membrane materials,⁹ optical and magnetic materials, components of polymeric compositions, carriers and catalysts of various reactions (see Section VIII).

Currently, numerous procedures for the preparation of nanocomposite materials are available. Recently, the major synthetic approaches (evaporation of elemental metal with its deposition on polymeric matrices, plasma-induced polymerisation, vacuum evaporation of metals, thermal decompositions of precursors in the presence of polymers and reduction of metal ions using different procedures, including electrochemical, *etc.*) have been surveyed in reviews.^{2,3} However, the uniform distribution of ingredients is generally difficult to achieve when hybrid nanocomposites are prepared with the use of the above-mentioned procedures resulting in the nonuniformity of the properties of the material. The following three principal procedures are most commonly employed: (1) the sol-gel method; (2) intercalation of polymers and nanoparticles into layered structures (including

polymerisation *in situ*) with the use of approaches applied in the chemistry of intracrystalline structures ('guest–host' systems); (3) a combination of polymerisation and formation of nanosized particles, which provides homogeneous dispersion of an inorganic component (which is often a specific filler) in a polymeric matrix.

In the last decade, these procedures, particularly, the first and second methods, have received primary attention. The properties and procedures for the synthesis of metallopolymeric Langmuir–Blodgett films are being extensively studied. The results of investigations in this field are summarised in a number of monographs and reviews^{10–34} as well as in special issues of journals.^{35–37} Note that nanocomposites containing not only synthetic but also natural molecules, including biologically active macromolecules, can be conveniently prepared using the above procedures. These procedures have been used for constructing biosensors, enzyme electrodes and other materials based on enzymes. These materials have already found use in biochemistry, medicine, biotechnology and the technology of environmental control.

In the present review, procedures for the preparation of hybrid organic–inorganic nanocomposites are considered from a unified viewpoint and the generality of the processes of their formation in living and nonliving natural objects is demonstrated. Thanks to the help of colleagues from different countries who responded to my requests and sent copies of their latest articles, the review surveys fresh results and the data under consideration were generally published within the last decade.

II. Preparation of hybrid nanocomposites by the sol-gel method

From the ecological viewpoint, optimum procedures for the preparation of composite materials are those without outflow, in particular, the sol-gel method (sol-gel or spin-on-glass process). The latter method allows one to exclude numerous stages of washing because compounds, which are used as the initial compounds, do not contaminate the final product. The sol-gel method is a convenient procedure for the preparation of dispersed materials, which are often called ceramers. This method is based on polymerisation reactions of inorganic compounds (formation of metalloxo polymers in solutions) and involves the following stages: (1) preparation of a solution, (2) formation of a gel, (3) drying and (4) thermal treatment. It is common practice to use metal alkoxides $M(OR)_n$ ($M = \text{Si, Ti, Zr, VO, Zn, Al, Sn, Ce, Mo, W, lanthanides, etc.}$; $R = \text{Alk or Ar}$), which are hydrolysed upon addition of water, as the starting compounds. The reactions are carried out in organic solvents. Subsequent polymerisation (condensation) affords a gel. For example, when $n = 4$

This method is sometimes called 'a one-stage procedure' because both reactions, *viz.*, hydrolysis and condensation, are catalysed by the same compound (by acid, base or, sometimes, by a nucleophilic catalyst, such as NaF).^{14, 38} These reactions with the participation of $Si(OR)_4$ have long been known. Apparently, the preparation of monodisperse TiO_2 particles by hydrolysis of alkoxides has been described for the first time by Barringer and Bowen.^{39, 40}

It is needless to say that the real process is much more complicated and occurs according to a multiple-route mechanism. Generally, metal oxoalkoxides $MO_n(OR)_m$, including polynuclear compounds, are formed as intermediates. Thus hydrolysis of $Ti(OR)_4$ proceeds in two stages,^{27, 41} *viz.*, nucleophilic replacement of the alkoxy group by the hydroxy group and condensation in the course of which oxo and hydroxo bridges are formed. It was demonstrated that the rates of these reactions are comparable.⁴² The $Ti_xO_y(OR)_{4x-2y}$ compounds were isolated and characterised.⁴³ Generally, the controlled synthesis of hybrid nanocompo-

sites based on zirconium alkoxysilanes and alkoxides proceeds according to Scheme 1.

Scheme 1

1. Formation of complex **1**:

2. Hydrolysis:

3. Condensation to form latent water:

4. Addition of complex **1** and removal of free and latent water by condensation:

5. Addition of a photoinitiator:

The following reaction conditions are of great importance: the use of catalysts, including polymeric catalysts (for example, polystyrenesulfonic acid⁴⁴); the nature of the alkoxy group and of metal [for example, $Ti(OBu)_4$ is hydrolysed almost 150 times more slowly than $Ti(OEt)_4$ (see Ref. 45)]; the use of alkoxides of a mixed type, particularly, with chelate ligands (β -diketonate, α - or β -hydroxy acid, polyol, *etc.*); the degree of association of alkoxides {for example, in the case of $[Ti(OEt)_4]_m$ $m = 2$ or 3}; the formation of oxo or alkoxo cluster structures [for example, $Ti_{18}O_{22}(OBu)_{26}(acac)_2$] in the course of hydrolysis. The reactivity of alkoxides $M^{IV}(OR)_4$ increases in the series $Si \ll Sn$ and $Ti < Zr < Ce$.⁴⁶ The ionic radius of the M atom (0.04 and 0.06 nm; and 0.064, 0.087 and 0.102 nm, respectively), its coordination number (4 and 6; and 6, 7 and 8, respectively) and the degree of its nonsaturation (the difference between the coordination number and the valence; 0 and 2; and 2, 3 and 4, respectively) increase in the same order.⁴⁷ However, the $H_2O : M(OR)_4$ ratio (γ) is of prime importance. Thus in the case of $VO(OPr^i)_3$, a homogeneous transparent gel with an alkoxide polymer network is formed in *n*-propanol if $\gamma = 3$, whereas if $\gamma > 100$, the resulting gel attains a quite different structure, which prevents the formation of an inclusion compound. Besides, the formation of a gel is affected by the nature of the medium, the concentration of the initial solution of an alkoxide, the presence of a stabiliser and the reaction temperature.^{48–50} The thermal effects of hydrolysis of $Ti(OR)_4$ in ROH increase when $\gamma = 0.2–1$, whereupon they remain virtually unchanged. This corresponds to the thermal effect of replacement of one alkoxy group by the hydroxy group.⁵¹ The solid phase with composition $TiO_x(OBu)_{4-2x} \cdot yBuOH$ was obtained upon hydrolysis of $Ti(OBu)_4$ in butyl alcohol through intermediate formation of $TiO(OBu)_2$.^{45, 51} The x and y values increase as the concentration of titanium alkoxide in a solution increases. Unfortunately, the effect of the nature of the solvent (generally, alcohols) on these processes has received little attention in experimental studies. It is known that hydroxy-containing compounds (for example, AlkOH, HOH or R_3SiOH) can take an active part in transesterification in the systems

The nature of metal and the ligand in alkoxides affects substantially these reactions.^{52–54} Thus $\text{Ti}(\text{OPr}^i)_4$ and $\text{OV}(\text{OPr}^i)_3$, which are often used as cocondensates in the preparation of nanocomposites by the sol-gel method,⁵⁵ act as catalysts in transesterification of tetramethoxy- and tetraethoxysilanes (TMOS and TEOS, respectively).

Therefore, the sol-gel process involves hydrolysis, polymerisation (chemically controlled condensation) of a gel precursor, nucleation and growth of particles followed by their agglomeration.^{56,57} TMOS and TEOS are most often used as precursors. They form silica gel structures ('host') about a dopant ('guest'), thus creating a specific cage trap. Nucleation proceeds through formation of a polynuclear complex. Its concentration increases until slight supersaturation, which is determined by the solubility of the complex, is achieved. From this time on, new nuclei do not form and only the available nuclei grow. To put it differently, these processes are analogous to the processes of formation of nanosized particles in polymers.² In the stage of formation of a gel (gelatination), it can be impregnated with ions of different metals.

The resulting oxopolymers have structures of ultrathin porous networks with pore sizes of 1–10 nm similar to the structures of zeolites. Their specific surface (S_{spec}) varies in the range of 130–1260 $\text{m}^2 \text{g}^{-1}$ depending on the conditions of the synthesis, and the bulk density is 0.05–0.10 g cm^{-3} . Thus molecular sieves based on silicon oxides, which are characterised by different mesopore structures and S_{spec} of $\sim 1000 \text{m}^2 \text{g}^{-1}$, were prepared by the sol-gel method in the presence of surfactants.^{58,59} The specific surface of the powder prepared by hydrolysis of $\text{Ti}(\text{OEt})_4$ was 200–300 $\text{m}^2 \text{g}^{-1}$; S_{spec} of hydrolysis products of $\text{Ti}(\text{OBu})_4$ strongly depends on the concentration of the initial solution of alkoxide and attains 490 $\text{m}^2 \text{g}^{-1}$ at the concentration of 1.0 mol litre⁻¹.⁴⁵ Concentrated aggregatively stable hydrosols (containing up to 40 mass % of TiO_2) can be prepared⁶⁰ by secondary dispersion of xerogels formed after drying of the sol (the TiO_2 content is ~ 85 mass %) at 100 °C for 2 h. The sol contains crystalline TiO_2 particles of an average size ~ 3 nm. These particles are a mixture of two polymorphic modifications of TiO_2 , *viz.*, rutile and anatase, with the latter slightly predominating. The third modification (brookite) is formed much more rarely. In these systems, single crystals of the anatase phase are often metastable. Compounds containing labile vinyl, methacrylate, epoxy and other groups can act as cross-linking agents (see Scheme 1). The conditions of drying in the course of which volatile components are removed determine the texture of the product. Thus coarse-dispersion xerogels can form upon prolonged drying in air due to coalescence of gel particles. Under conditions precluding the action of capillary forces, highly dispersed aerogels are formed. The formation of the structure and texture of the product is completed in the stage of thermal treatment.^{10, 61–65}

The sol-gel method with the use of highly dispersed silica gel in a polar solvent is applied in microencapsulation of photochromic fluorescent compounds,⁶⁶ scintillators¹⁷ and porphyrins. A sol-gel matrix for encapsulation is prepared by simultaneous hydrolysis of $\text{Si}(\text{OEt})_4$ – $\text{Zr}(\text{OBu})_4$ and other alkoxides.^{67–69} Thermally stable materials, which are used in nonlinear optics, can be prepared by introducing, for example, azo dyes into TMOS by the sol-gel method.⁷⁰ Although these systems (except for biologically active systems; see Section IV) are not considered in this review, they are structurally similar to nanocomposites and are prepared according to analogous procedures. Thus the introduction of methyl methacrylate (MMA), in which an organic dye of the perylene type was dissolved, into a xerogel followed by thermal or UV polymerisation, afforded a coimpregnated SiO_2 –poly-methyl methacrylate–dye system.^{71,72} The technique for sublimation dehydration of impregnated gels was developed.⁷³ This technique allows one to prevent redistribution of labile components in the matrix in the course of drying.

Sol-gel materials are classified by a mode of formation and types of bonds between organic, organometallic and inorganic

components.¹⁷ Organic groups introduced into $\text{R}_n\text{Si}(\text{OR}^2)_{4-n}$ serve two functions,^{74,75} *viz.*, modify a network (ORMOSIL, organically modified silicates) and form a network (ORMOCER, organically modified ceramics). However, this classification has not yet received ample recognition. Low-percentage and high-percentage composites contain 2 vol. %–30 vol. % and up to 45 vol. %–75 vol. % of ceramics, respectively. Thus a material under the name 'rubber ormosil' (based on TEOS and polydimethylsiloxane with $M_w = 1700$) contains more than 70 vol. % of an inorganic component.^{76,77}

Hybrid nanocomposites are primarily classified by the type of interphase interactions between components. Thus nanocomposites whose macrostructures are determined by the presence of van der Waals, hydrogen or hydrophilic–hydrophobic interactions are known. These are, for example, amorphous inorganic nanocomposites, which are prepared from silicon-, titanium-, aluminium- or zirconium-containing oxopolymers formed *in situ* in a medium of a soluble organic polymer. Formally, this process consists in homogeneous formation of a nanosized filler in a medium of a polymer. Poly(*n*-butyl acrylate), polyphosphazene, polyvinylpyrrolidone (PVP), poly(*N,N*-dimethylacrylamide), *etc.* were prepared according to this procedure.^{78–82} An alternative procedure involves the insertion of a polymer (or its precursor) into an oxogel, which is formed by mixing of metal alkoxides or by their impregnation into pores of an oxide xerogel network. Either organic molecules or polymers are inserted as 'guests' into nanocomposites of another type.

The one-stage formation of oxogels and polymers is exemplified by sol-gel polymerisation (including electrochemical polymerisation) of the so-called silanised monomers, *viz.*, *N*-[3-(trimethoxysilyl)propyl]pyrrole,^{83,84} 2,5-bis(trimethoxysilyl)thiophene⁸⁵ and trimethoxysilylferrocene derivatives.⁸⁶

Hybrid network composites in which organic and inorganic components are linked through strong covalent or ionic bonds have received primary attention. These networks are generally prepared according to two procedures: (1) secondary networks are formed in primary networks, which are functionalised as required; (2) two different networks (including interpenetrating networks) are simultaneously formed from molecular precursors of a different nature, which enter into different reactions (polyaddition, polycondensation, metathesis polymerisation, hydrolysis–condensation, *etc.*). This line of investigation is in a primitive state of development and reliable examples of realisation of this approach are few in number.^{87–89} Initially, it was attempted to use solutions of polymers. However, the formation of a gel was accompanied by uncontrolled phase separation to yield a heterogeneous material. More homogeneous sol-gel materials were prepared⁹⁰ by acid-catalysed hydrolysis simultaneously with condensation of $\text{HO}(\text{PES})\text{OH}$ [PES is (polyethersulfone)] and TEOS or TMOS in DMF.

Inorganic and polymeric components are linked *via* deep interactions. Thus poly(ethersulfone) chains are linked through $\text{—SiO}_2\text{—}$ units. Their condensation affords nanoparticles (Fig. 1).⁹¹

Bonding of TEOS, diethoxydimethylsilane or their mixture with sulfo groups of perfluoroalkylsulfonate ionomers (under the commercial name Nafion) in which the SO_3H^+ groups form clusters with sizes 3–5 nm affords a hybrid heterogeneous material Nafion/ SiO_2 (Nafion/ORMOSIL).^{92–96} Studies by differential scanning calorimetry demonstrated that a broad endothermic peak of the initial NafionH^+ at 215 °C was shifted to the lower-temperature region as the ratio of the components of the reaction mixture was changed. This is associated with condensation between the sulfo groups of Nafion and the silanol groups. In the course of the sol-gel process with the participation of TEOS and the styrene–maleic anhydride copolymer in the presence of a

Figure 1. Formation of a hybrid nanocomposite in the reaction of PES with bridging $-\text{SiO}_2-$ groups.

binding agent, *viz.*, (3-aminopropyl)triethoxysilane, a covalent bond between polymeric and inorganic components was also formed.⁹⁷ In this case, particles with sizes < 20 nm were formed.

A series of monolithic hybrid materials containing 23 vol. %–100 vol. % of an inorganic component were prepared by the sol-gel method starting from SiO_2 and the copolymer of methyl methacrylate with 3-(trimethoxysilyl)propyl methacrylate.^{98,99}

Polyimide composite materials containing nanosized SiO_2 or TiO_2 particles possess the high mechanical strength due to their ability to form three-dimensional inorganic networks.^{100,101} Polyimide–polysilsesquioxane[†] composites were prepared, for example, by condensation of 1,1-bis(4-aminophenyl)-2,2,2-trifluoro-1-phenylethane with a derivative of pyromellitic anhydride and aminophenyltrimethoxysilane (simultaneously with imidisation at 250 – 350 °C).^{104–107} In this case, films of hybrid nanocomposites containing 32%–70% of homogeneously dis-

[†]Polysilsesquioxanes (PSO) belong to a class of three-dimensional organosilicon oligomers of the general formula $(\text{RSiO}_{1.5})_n$ containing the inorganic cubic Si_3O_{12} nucleus. These compounds have polyhedral structures with different symmetries and are key intermediates in the formation of various nanocomposites (see, for example, Ref. 102). Thus the synthesis and properties of hyperelastic materials, which have been prepared by copolymerisation of 4-methylstyrene and oligomeric silsesquioxane macromers, have been reported recently.¹⁰³

persed SiO_2 with particle sizes of 0.5 – 7 nm were obtained (Scheme 2). Polyamide– SiO_2 compositions were prepared *in situ* by suspending SiO_2 nanoparticles (which were sometimes preliminarily modified with aminobutyric acid) in a polymerised ϵ -caproamide at high temperature.^{108,109} This approach provides homogeneous distribution of SiO_2 owing to which the mechanical properties of nanocomposites are improved, the glass transition temperature rises and the rate of crystallisation is increased.

Analogous nanocomposites were also prepared¹⁷ based on analogues of polyimides, *viz.*, polyoxazolines, including those containing triethoxysilane groups.^{110–112}

Metathesis polymerisation accompanied by opening of the ring and free-radical addition of cyclic alcohols appears to be the optimum procedure for the synthesis of hybrid SiO_2 –polymer nanocomposites exhibiting the minimum shrinkage.^{31,113–115} The synchronous formation of interpenetrating networks occurs as a result of competitive reactions of polymerisation and hydrolysis of silicon alkoxide under the action of the nucleophilic catalyst NaF followed by condensation.

It is known that sols are thermodynamically unstable systems with high surface free energies. It is necessary to stabilise these systems by special techniques, for example, by controlling pH of the system. When the sol-gel method is used, nanosized particles or their precursors are stabilised through adsorption of special monomeric molecules on the sol surface.^{116–119} Thus carboxylic acids (including polymeric acids^{106,120}) are strongly bound to the surface of SiO_2 , ZrO_2 , TiO_2 or Al_2O_3 particles. Amines are specifically adsorbed on metallic Pd or Au particles. Thiols are even more specific reagents for Au. Controlled hydrolysis with the use of bifunctional molecules containing a double bond along with hydrolysed silane or ZrOR groups affords the corresponding precursors (see Scheme 1). These precursors incorporate ZrO_2 particles of size ~ 2 nm, which can undergo copolymerisation, for example, with methacrylic acid (MAA). The latter simultaneously acts as a surface modifier due to the presence of a double bond.

Scheme 2

Alkoxide Zr(OR)_4 is readily hydrolysed. Direct hydrolysis of the latter affords a precipitate of $\text{ZrO}_2 \cdot n\text{H}_2\text{O}$, which is unsuitable for the preparation of a homogeneous composite material. In strongly acidic media, a flocculent hydrated gel layer is present on the surface of these particles. This layer contributes significantly to the stability towards aggregation.¹²¹ It is believed¹²² that this layer makes it possible to perform repeated peptisation of ZrO_2 from a xerogel. When bound to MAA, Zr(OR)_4 is hydrolysed more slowly and hence well-dispersed nanosized ZrO_2 particles are formed in the presence of latent water. Silanes modified with MAA undergo copolymerisation. In this case, the resulting silicon-containing polymer is used as a matrix material for nanosized zirconium particles (Fig. 2).⁷⁶ A convenient procedure for the synthesis of these nanocomposites involves dispersion copolymerisation of monomers containing trialkoxysilyl groups.^{123–127} Thus statistical copolymerisation of silicon–magnesium monomers affords beads of sizes 100–500 nm from which organic compounds are removed upon heating to 1000 °C in the presence of wet air. The sizes of the final particles are ~ 100 nm.¹²⁸

AIBN is an initiator [2,2'-azobis(isobutyronitrile)].

A nanocomposite material was prepared starting from methacryloxypropyltrimethoxysilane.⁷⁶ The reaction of equimolar amounts of Zr(OR)_4 and MAA yielded a product, which was mixed with silane. The latter was preliminarily hydrolysed and condensed in the presence of 0.5 M HCl, and then H_2O was added. A photoinitiator and alcohol were introduced into the resulting mixture to control the viscosity and then a support was submerged in the mixture thus depositing a thin film of a photosensitive material.

Hybrid nanocomposite materials are prepared from metal-containing monomers, such as alkoxy derivatives of Ti and V of the general formula $\text{Ti(OR}^1)_3(\text{OR}^2)$ ¹²⁹ or $\text{OV(OR}^1)_3\text{--}_n(\text{OR}^2)_n$,¹³⁰ respectively, where R^2OH is ethylene glycol monomethacrylate, 2-hydroxyethyl methacrylate, furfuryl alcohol, 1,1-dimethylpent-4-en-2-yn-1-ol, propargyl alcohol or other unsaturated alcohols,

which are able to undergo polymerisation. Radical polymerisation of metal-containing monomers affords polymers with side chains containing alkoxy groups of titanium¹³¹ or vanadium.¹³² The reactions of MAA with alkoxy derivatives of titanium yield metal-containing monomers $[\text{CH}_2=\text{C}(\text{Me})\text{COO}]\cdot\text{Ti(OR)}_3$ ($\text{R} = \text{Et, CH}_2\text{Bu}^t$ or Bu^t).¹³³ Based on these compounds, nontoxic, self-polished and anticontamination coatings were prepared by free-radical copolymerisation with MMA or by etherification of the resulting polymer and titanium tetraalkoxide.¹³⁴

Polytitanosiloxanes are prepared in one stage by simultaneous controlled hydrolysis (actually, cocondensation) of Si(OEt)_4 and $\text{Ti(OPr)}_2(\text{acac})_2$.¹³⁴ In this case, a ladder polymer containing Si--O--Si and Si--O--Ti units is formed. Their ratio depends on the conditions of the synthesis and can reach 10:1, respectively. This ratio determines the time of gel formation and the possibility of formation of fiber ceramics upon annealing of the material (500–900 °C).¹³⁵ The structures, the mechanism of growth and the properties of siloxane composites containing the silicon, titanium and mixed titanium-silicon phases (including those prepared *in situ*) were considered in more detail in the review.¹³⁶

The sol-gel method was used¹³⁷ for the synthesis of titanium–silicon nanocomposites based on perfluorosulfonate ionomers as well as for the preparation of nanosized particles with sizes 10–50 nm [from Ti(OR)_4 and Zr(OR)_4] incorporated into matrices of a copolymer of styrene and 4-vinylphenol,¹³⁸ *etc.* These approaches can also be used for the activation of surface polymers, for example, perfluorinated polymers [such as polytetrafluoroethylene (PTFE) or copolymers of tetrafluoroethylene with hexafluoropropylene] by their treatment with SiCl_4 followed by controlled hydrolysis.^{139, 140}

Metal (primarily, titanium and silicon) alkoxides are used as cross-linking reagents for many natural polymers (polysaccharides, cellulose derivatives, vegetable oils, *etc.*)^{141, 142}. These polymers contain highly active hydroxy groups, which can form oxopolymers *in situ*. Organic networks are also formed in the reactions of low-molecular-weight compounds containing several hydroxy groups (for example, anthracenobisresorcinol and its derivatives) with $(\text{Pr}^i\text{O})_2\text{TiCl}_2$.¹⁴³

Cocondensation of macromers containing trialkoxysilyl groups with the best known polymers [modified polystyrene (PS), polyoxazoline, polyimide, polyethylene glycol (PEG), polyetherketones, polymethyl methacrylate and derivatives of polytetramethylene oxide] is a convenient procedure for the preparation of telechelic polymer networks.^{106, 144–150}

The insertion of highly dispersed SiO_2 particles into a polymerised system is also widely used for the preparation of nanocomposite materials. Although a survey of this problem is beyond the scope of the present review, let us consider several most prominent, in our opinion, examples. In aqueous media, spherical SiO_2 particles possessing a high specific surface act as peculiar dispersing agents. In this manner, particles of a raspberry-shaped composite with sizes 100–300 nm were formed in polyaniline– SiO_2 or polypyrrole– SiO_2 systems.^{151–156} In the course of polymerisation initiated by the redox $\text{FeCl}_3 \cdot 6\text{H}_2\text{O} - (\text{NH}_4)_2\text{S}_2\text{O}_8$ system, not only spherical but also fiber-shaped SiO_2 particles were introduced into polypyrrole formed.¹⁵⁷ The particle sizes vary within 80–200 nm as the SiO_2 : polypyrrole ratio changes.

Composites based on SnO_2 , which are used in lithography, are prepared by oxidation and cross-linking in films.^{158, 159} Tin-containing polymers (for example, poly(4-[(trimethylstannyl)methyl]styrene);¹⁶⁰ its synthesis was reported in Refs 161 and 162) are used as precursors of SnO_2 . Photoirradiation of polymers followed by their pyrolysis in air results in simultaneous formation of SnO_2 particles and a polymer network in which the polymers are incorporated. In this case, the C–Sn bonds are cleaved to form radicals of the benzyl and trimethylstannyl types. The former

Figure 2. Use of functionalised silanes for cross-linking of organic and inorganic components of the system.

react with atmospheric oxygen on film surfaces. The latter undergo recombination to form networks.

Hybrid nanocomposites based on nanosized Au¹⁶³ and TiO₂ particles¹⁶⁴ were also prepared using reverse micelles. A surfactant (for example, didodecyltrimethylammonium bromide) was added to toluene with the resulting formation of reverse micelles into which AuCl₃ and a precursor gel, *viz.*, TEOS, were introduced. The LiBH₄–THF system was used as a reducing agent. Subsequent hydrolysis and condensation afforded Au particles impregnated into the wet gel. Their sizes depend on the H₂O : Si ratio and the concentration of the surfactant. After immobilisation on the surface of highly dispersed SiO₂ with the use of bifunctional aminosilane (MeO)₃Si(CH₂)₃NH(CH₂)₂NH₂ (see the review¹⁷), colloidal gold particles were stabilised with dodecanethiol.¹⁶⁵ Subsequent treatment of these particles with thiol resulted in the cleavage of bonds with SiO₂ and the particles became labile. Repeated immobilisation–stabilisation events led to the growth of two-dimensional highly ordered ~ 10 nm thick layers in which particles are linked together (Fig. 3).

It is best to prepare reverse micelles with the use of sodium bis(2-ethylhexyl)sulfosuccinate (SBES).¹⁶⁶ For example, Ti(OPr^{*i*})₄ was dissolved in reverse micelles, which were formed from isooctane and SBES and contained a calculated amount of water. In this case, the alkoxide slowly diffused into micelles and then was hydrolysed and condensed in these micelles as in microreactors. This procedure was used for the preparation of TiO₂ nanoparticles, which were extracted and dispersed in a solution of fluorinated polyimide. When a polymer–TiO₂ composite was deposited on a glass plate followed by thermal treatment (at 300 °C under an atmosphere of N₂ for 30 min), an optical film waveguide was formed. Therefore, one of the advantages of the preparation of these nanocomposites in a solution of a polymer is the possibility of formation of transparent films (in this case, yellow titanium complexes are not formed). The thermal stability of the above-described materials (4% of TiO₂) is almost identical to that of the initial polymer. This indicates that the thermal characteristics of the ‘host’ polymer remain virtually unchanged upon impregnation of TiO₂. In some cases, simple mixing of ingredients, *viz.*, a polyimide solution and a sol-gel precursor, which leads to phase separation, is sufficient to form a polymer–inorganic nanocomposite.

Compounds containing epoxysilane groups can form networks as well.^{167–170} Thus alkoxysilane (**2**) is a binder providing the compatibility of TEOS with polyacids.^{167, 168}

The component compositions of hybrid nanocomposites, which were prepared by the gel-sol method based on SiO₂ and an ethylene oxide–epichlorohydrin copolymer, were 71 : 29–29 : 71. Acid condensation of TEOS in a THF solution afforded an inorganic network.^{171, 172} These networks can also be prepared with the use of alkoxy derivatives of aluminium.

The morphology and fractal structures of these materials were studied. It is known¹⁷³ that the structures of aggregates are characterised by the fractal dimension D ($1 \leq D \leq 3$), which may have a meaning of an exponent in the equation relating the weight of the M particles to their characteristic size R

$$M \approx R^D.$$

For surface fractals with the uniform density, $D = 3$. The self-similarity or scale invariance of the fractal aggregate implies that the structure of the aggregate, on the average, remains unchanged on the interval as extended as is wished and any its portion is similar to the aggregate as a whole. When the surface is dealt with, the D value equal to 2 corresponds to the smooth surface and the D value equal to 3 corresponds to the maximum roughness.

The fractal dimensions of polymeric and colloidal samples of the TiO₂ aerogel with high values of S_{spec} (prepared by the sol-gel method and dried with CO₂ in the supercritical state), which were calculated by different methods, were compared. These values are virtually identical (2.6–2.8). The fractal surfaces of colloidal particles are only slightly less regular than those of polymeric aerogels.¹⁷⁴ This indicates that at the nanosize level, the morphology is determined in the early stages of the process and depends only slightly on the conditions of the synthesis, whereas on the mesolevel, it is the conditions of the synthesis that have a determining effect on the morphology.

Studies of the condensation of TEOS in a polysiloxane network demonstrated^{14, 136} that fractal models typical of solutions were not observed upon matrix polymerisation. Owing to large molecular weights of the matrix and the polymer formed, the entropy of the mixture decreases resulting in phase separation. Particular conditions are required to prevent phase separation in the system. However, phase separation always occurs when the concentration of SiO₂ is > 5%, which enhances the mechanical strength of composites. When TiO₂ nanoparticles were precipitated *in situ*, the maximum bulk domains (up to 5% of filling) were formed. These nanocomposites rank below systems with SiO₂ in strengths.¹⁷⁵

Of special note is the use of the sol-gel method for performing ‘template syntheses.’ In this case, nanocomposites are formed through ‘assembly’ from components under conditions of a strictly defined stereochemical orientation of the reagents. These conditions and primarily a small reaction volume (due to which reacting molecules can approach each other more closely than in

Figure 3. Preparation of hybrid materials with the use of reverse micelles: (A) immobilisation of colloidal Au particles; (B) exchange of alkanethiol molecules and cleavage of the Au–NH₂ bonds; (C) rapid regeneration of the layer on complete binding of Au particles.

solutions or in the solid phase) promote the so-called ‘mild’ template synthesis in the course of which the ‘assembly’ occurs under normal conditions (sometimes even at room temperature). For example, this procedure was used¹⁷⁶ for the preparation of tubular semiconducting nanostructures based on TiO₂ [from Ti(OPrⁱ)₄], commercial template membranes based on Al₂O₃ with the pore diameters of 22 and 200 nm¹⁷⁷ and fibrous structures based on ZnO (from zinc acetate¹⁷⁸) and WO₃.¹⁷⁹ These materials are excellent photocatalysts. The template synthesis is described in more detail below (Section V). The template sol-gel syntheses in fibres, nanotubes or micro- and nanoporous membranes were surveyed in detail in the review.¹⁸⁰ This procedure was used for the preparation of fibrous electrode materials based on V₂O₅¹⁸¹ and semiconducting oxide materials, such as MnO₂,¹⁸² Co₃O₄,¹⁸³ ZnO, WO₃, *etc.* The template synthesis of tubular nanostructural nanocomposites of the semiconductor-conductor type (as nanotubes or nanowires) was performed¹⁷⁶ starting from TiO₂ in Al₂O₃ pores followed by polymerisation of monomers.^{184, 185}

III. Preparation of nanohybrid multimetallic materials by the sol-gel method

Nanocomposites based on heterometallic ceramics, for example, on perovskite with the ABO₃ structure, can be synthesised by the sol-gel method. These materials (primarily, film and epitaxially oriented materials) possess specific ferro-, piezo- and pyroelectric properties and are widely used in electronics and optoelectronics.¹⁸⁶ The naturally occurring mineral perovskite CaTiO₃ has the pseudocubic crystal lattice. Perovskites, for example PbTiO₃, are generally prepared by calcination of a mixture of PbO and TiO₂, which is ground using a vibrational mill, at temperatures higher than 600 °C (synthesis *ex situ*). However, PbO is toxic and the presence of its phase in the final product is undesirable. The sol-gel technique for the preparation of perovskite PbTiO₃ is free from these drawbacks.¹⁸⁷ A mixture of Ti(OPrⁱ)₄, Pb(AcO)₂·3H₂O, ethylene glycol and citric acid taken in a ratio of 1 : 1 : 40 : 10, respectively, was stirred at 50 °C. Then the resulting citrate metal complexes were subjected to polymerisation at 130 °C and to pyrolysis at 300 °C. The resulting powdered precursor was calcined in air at 400–600 °C for 2 h to obtain thin PbTiO₃ films, which retained the properties of a bulk material. Different versions of the sol-gel syntheses of PbTiO₃ were described in the literature in detail. Thus polymeric films, which were prepared by mixing BaTiO₃ with solutions or melts of polymers, were studied.^{188, 189} However, in this case particles were nonhomogeneously distributed and their agglomeration occurred. An alternative hydrothermal procedure for the synthesis of these nanocomposites was proposed.¹⁹⁰ According to this procedure, BaTiO₃ particles prepared from Ba(OH)₂ and titanium diisopropoxide bis(ethylacetoacetate) at temperatures higher than 100 °C were grown in a polymeric matrix (in a polybutadiene–polystyrene block copolymer, *etc.*¹⁹¹). These materials can potentially serve as components of conducting compositions (see, for example, Ref. 192). Structurally homogeneous BaTiO₃ nanocomposites can only be prepared using the sol-gel method.¹⁹³ One of versions of this procedure involves solid-phase polymerisation of organometallic precursors followed by pyrolysis.¹⁹⁴

Polymerisation was also used for the preparation¹⁹⁵ of BaSnO₃ with the perovskite structure. The synthesis was carried out analogously to the synthesis of PbTiO₃ (see above) but at a different temperature and with the use of BaCO₃, SnCl₂·4.5H₂O, ethylene glycol and citric acid taken in a ratio of 1 : 1 : 40 : 10, respectively, as the starting compounds. Other multicomponent

ceramics of the perovskite type, *viz.*, SrTiO₃, NdAlO₃, SrBi₂Ta₂O₉ and superconducting ceramics YBa₂Cu₃O_{7-δ}, were also prepared by the sol-gel method (see below). The application of this method to the synthesis of these materials (the use of metallochelates and decomposition of organometallic precursors) was described in more detail in the study.¹⁹⁶ In the present review, let us note only that single-phase thin KTiOPO₄ films, which exhibit remarkable optical properties and high thermal stability, can be prepared according to this procedure; Ti(OEt)₄, KOEt and different sources of phosphorus [(EtO)₂P(O)(OH), (EtO)P(O)(OH)₂, P(OH)₂Me, P(OMe)₃, *etc.*], among which (BuⁿO)₂P(O)(OH) is an optimum source, are used as precursors.¹⁹⁷

Heteropolymetallates of the type of Keggin’s acids H₃PW₁₂O₄₀ and H₄SiW₁₂O₄₀, which are incorporated into organic–inorganic structures, may be assigned to the group of polymetallic nanocomposites.^{17, 117} These materials possess good electrochemical properties and can be potentially used in the holography. Nanocomposites based on these materials can be prepared according to two procedures, *viz.*, by mixing polymetallates (spheres of diameter ~ 1 nm) with TEOS [taken in a ratio of (2–6) : 10] and tetraethylene glycol or by introducing polymetallates into organosilanes.

Specific clusters, *viz.*, oxometallates containing W–O–Si units, which are inserted into the side chain of the polymer, were synthesised by the reactions of substituted trichlorosilanes RSiCl₃ (R = CH₂ = CH, CH₂ = CHCH₂, CH₂ = C(Me)CH₂ or CH = CHPh) with the polyanion K₄SiW₁₁O₃₉. In this case, cluster-containing monomers with composition [SiW₁₁O₄₀(SiR₂)₂]^{4–} were formed.¹⁷ Polymerisation was carried out under the action of radical initiators. The products were characterised by different methods, including ¹³C and ²⁹Si NMR spectroscopy. The yield of the polymer and the chain length depend on the reactivities of unsaturated groups R and increase in the series CH₂CH << CH₂ = CHCH₂ < CH₂ = C(Me)CH₂ < CH = CHPh. The structure of this polymer is schematically shown in Fig. 4. The syntheses of oxoclusters of transition metals Nb₄(μ₂-OMc)₄(μ₂-O)₄(OPrⁱ)₈, Ti₆O₄(OEt)₈(OMc)₈ (OMc is methacrylate) and Zr₁₀(μ₄-O)₂(μ₃-O)₄(μ₃-OH)₄(μ₂-OPrⁿ)₈·(OPrⁿ)₁₀(AllylAc)₆ (AllylAc is allyl acetoacetate)¹⁹⁸ by controlled hydrolysis of different metal alkoxides in the presence of complex-forming agents (OMc or AllylAc) were also reported. These compounds consist of the metal oxide nucleus and peripheral ligands, which can undergo polymerisation. The latter are responsible for the formation of a cluster network. The construction of stable ensembles of nanoblocks requires that clusters possess rather high lability and high reactivity. For example, the thermodynamical stability of titanium oxo clusters and their resistance to hydrolysis depend both on the size and the oxo(alkoxo) group:titanium ratio. With the aim of retaining

Figure 4. Structure of the hybrid polymer-inorganic material based on the {SiW₁₁O₄₀[Si(CHPh = CH)₂]^{4–} polyanion.

their molecular structures, polymerisation should be performed in anhydrous organic solvents.¹⁹⁹

The syntheses of three-dimensional oxovanadium borophosphates with open frameworks^{200–202} and polyborozinylamines, which are precursors of metal-containing matrix composites containing metal borides and nitrides,²⁰³ are also available.

The possibilities of modification of materials prepared by the sol-gel method with different transition metals are being extensively studied (see, for example, Refs 204 and 205). For example, mesoporous materials M41S were prepared based on molecular sieves NCM-41 or MCM-48 modified with solutions of NH_4VO_3 or ZrOCl_2 in a mixture with polyoxoethylene stearate. Solutions of NH_4VO_3 or ZrOCl_2 acted as precursors of transition metal ions.²⁰⁶ Nanoparticles (50–60 nm) of cobalt carbide immobilised in a silicon matrix were obtained.²⁰⁷

Mesopores of MCM-41 matrices were modified²⁰⁸ with the *trans*- $[\text{Co}(\text{en})_2\text{Cl}_2]^+$ or $[\text{Co}(\text{en})_3]^{3+}$ complexes (en is ethylenediamine) stabilised by ammonium salts.

Hydrolytic condensation of cyclopentadienyltitanium chloride with silsesquioxane (the product of incomplete condensation of cyclopentyltrichlorosilane) followed by calcination of titanium-containing oligosilsesquioxane afforded microporous titanium–silicon oxides with S_{spec} of up to $780\text{ m}^2\text{ g}^{-1}$.²⁰⁹ In the stage of sol-gel polymerisation, metal clusters can be introduced into nanocomposites. Thus the trihydrosilyl group was inserted into a cluster with a known composition, *viz.*, $(\mu_3\text{-HC})\text{Co}_3(\text{CO})_9$, and then it was subjected to heterocondensation.²¹⁰

In the resulting xerogel, the unimodal distribution of the particles was observed. The sizes of the particles were 10–46 nm (the average diameter was 25 nm). The Os_3 , PtSn , Fe_2P , Co_2P and Ni_2P nanoclusters can be introduced into a composite analogously (by incorporation into a complex with a bifunctional ligand containing the reactive alkoxy- or hydroxysilyl group).²¹¹ The insertion of Pd^{2+} ions,²¹² Cu^{2+} ions,²¹³ *etc.* into poly(ethyltrimethylsilane) formed was described. The structures of organometallic–inorganic diblock copolymers, in particular, the structure of the ferrocenyldimethylsilane–dimethylsiloxane block copolymer, were studied.²¹⁴ In a hexane solution, the latter copolymer exists as long rod-shaped cylindrical micelles in which the iron-containing nucleus is placed in a ‘case’ (crown) formed from polydimethylsiloxane blocks. The micelle of this type comprises up to 2000 polymeric molecules and decomposes under the action of ultrasonics to form short cylinders containing ~ 700 molecules.

To perform heterogenisation of metal complex catalysts (see Section VIII), metal compounds are bound to an inorganic matrix

through a bidentate phosphorus-containing ligand of the $[\text{Ph}_2\text{P}(\text{CH}_2)_2\text{CO}_2]\text{EO}_x(\text{OR})_{3-2x}$ type ($\text{E} = \text{Ti}$ or Zr ; $\text{R} = \text{Alk}$).²¹⁵ Thus the reactions of such ligands with tungsten carbonyl afforded products $\text{W}(\text{CO})_5[\text{Ph}_2\text{PXE}(\text{OR})_{3-2x}]$, which are potential precursors for the sol-gel synthesis. Cocondensation of these precursors (analogous to the above-described condensation of metal clusters with TMOS) gave²¹⁶ xerogel nanocomposites with composition $\text{SiO}_2(\text{xerogel}) \cdot x\text{M}_y\text{P}_z$ ^{216–218} ($\text{M} = \text{Ru}$, Ga or In , $y = z = 1$; $\text{M} = \text{Pt}$, $y = 1$, $z = 2$; $\text{M} = \text{Fe}$, Co , Ni or Rh , $y = 2$, $z = 1$; $\text{M} = \text{Cd}$, $y = 3$, $z = 1$; $\text{M} = \text{Pd}$, $y = 5$, $z = 2$) and even bimetallic $\text{SiO}_2(\text{xerogel}) \cdot \text{Zn}(\text{Cd})\text{GeP}_2$ composites.²¹⁷ Immobilisation of the $[\eta^6\text{-PhSi}(\text{OMe})_3]\text{-Cr}(\text{CO})_3$ complex in a highly dispersed amorphous xerogel ($S_{\text{spec}} = 500\text{--}1800\text{ m}^2\text{ g}^{-1}$) in the course of sol-gel polymerisation (NH_4F catalyst) made it possible to prepare a single-phase hybrid of inorganic oxide and an organic network polymer containing (1,4-phenylene)siloxane bridges of the ‘nucleus–shell’ type.²¹⁹ Vacuum thermolysis (393 K, 24 h, < 1 Torr) of this composite even at 389 K resulted in elimination of carbonyl groups to form zero-valent chromium nanoparticles of sizes 1.0–10.0 nm in pores of the xerogel (Fig. 5). Under normal conditions, thermal elimination of carbonyl groups of the composite proceeded only at 400 °C. In the latter case, chromium in the low oxidation state was formed.²²⁰

Figure 5. Structure of a single-phase hybrid of the ‘nucleus–shell’ type; (1) a shell, (2) a nanoparticle of zero-valent chromium.

Tricarbonylmolybdenum groups were introduced into the resulting polysilane according to the polymer-analogous conversion method. For this purpose, poly(methylphenylsilane) was treated with the $\text{Mo}(\text{CO})_3\text{Py}_3$ complex.²²¹

Nanolayer silanisation of inorganic surfaces of the TiO_2 , Al_2O_3 or Fe_2O_3 types, including the introduction of Fe_2O_3 into mesopores of silicates,²²² CaCO_3 , BaSO_4 , *etc.*, is widely used. Generally,^{223–226} a thin layer of silanol derivatives and a dimethylsiloxane oil are deposited on inorganic surfaces and heated to 250–280 °C. In this case, siloxane bonds are cleaved, the terminal groups of the polymer chain react with hydroxy groups of inorganic surfaces and the chains are cross-linked through methylene and siloxane bridges or oligomers. As a result, particles, which are stable to hydrolysis and extraction with different solvents, are formed. For example, $\text{Zr}(\text{OBu})_4$ modifies the aluminium surface.²²⁷ Zirconium groups are linked upon treatment with the poly(ethylene–acrylic acid) copolymer (PE-co-PAA) containing 5 mass % of units of acrylic acid.²²⁸

The adsorption properties of these materials are changed due to formation of a hydrophobic layer and the material becomes moisture-stable. When Ti and Au layers 5 and 50 nm thick, respectively, were deposited on the activated polydimethylsiloxane surface, ordered structures were formed.^{229, 230}

The coating of the surface of inorganic particles (including metals or their oxides) is often used in the technology of powder preparation to form structures of the 'nucleus-shell' type, which possess additional useful properties. Thus SnO_2 or In_2O_3 particles are coated with chelate polymers swelling in water (for example, those containing $\text{In}^{3+} - \text{SiO}_2$ or $\text{In}^{3+} - \text{Sn}^{2+} - \text{SiO}_2$ as well as Ag^+), which were preliminarily subjected to appropriate treatment. These particles exhibit the surface conductivity and are used for the preparation of thermally stable conducting films possessing antistatic properties, *etc.*^{231–233}

Therefore, several procedures for the insertion of a polymer into an inorganic material by the sol-gel method are available. Thus silanes containing two different functional groups can be used. One of these groups reacts with a monomeric unit of the macromolecule and the second group reacts with the sol-gel precursor resulting in the formation of a bond between the side group of the polymer and the sol-gel network. Sometimes special binding agents are additionally added. For example, the surface of highly dispersed SiO_2 was modified with aminobutyric acid and the resulting product was dried, dispersed in ϵ -caproamide and subjected to initiated polymerisation at 90 °C.²³⁴ If the concentration of SiO_2 particles is ≤ 5 mass % (the distance between the particles is 50–110 nm), they are homogeneously distributed in the composite. At concentrations of > 10 mass %, aggregation of particles starts. Layered nanohybrid materials (see Section V) were prepared²³⁵ by the reactions of $\text{Zn}(\text{OH})_2$, ZnO or a Zn/Al alloy with carboxylic acids or their oxychlorides. The 'guest': 'host' ratio in these composites varies from 0.75 : 0.25 to 0.9 : 0.1. The morphology of the particles changes from fibrous to platelet depending on the nature of the reacting components, the interlayer distance increasing in the range of 1.61–2.01 nm.

Recently, the sol-gel procedures for the preparation of ceramics based on aluminosilicates, *viz.*, carboxylates of the general formula $[\text{Al}(\text{O})_x(\text{OH})_y(\text{OOCR})_z]_n$, have been analysed.²³⁶ At the stage of formation, the $\text{M}(\text{acac})_n$ complex ($\text{M} = \text{Ca}^{2+}$, Mn^{2+} , Y^{3+} , *etc.*) can be additionally introduced into ceramics.^{237, 238} Metallic Co and Fe and their alloys, which were formed upon reduction of the corresponding nitrates with hydrogen, were dispersed in an aluminosilicate matrix. The matrix was synthesised by the sol-gel method from $(\text{BuO})_2\text{AlOSi}(\text{OEt})_3$ and possesses dielectric properties. In this case, nanocomposites with the particle size of ~ 20 nm possessing magnetic properties were obtained²³⁹ (Fig. 6).

One of new trends today in the field under consideration is to use carbon dioxide in the supercritical state as a solvent in the course of sol-gel polymerisation or in the stage of extraction of the resulting product. To perform the sol-gel process according to this procedure, the initial alkoxysilane is mixed with anhydrous 99% HCO_2H . Then polymerisation of the mixture is carried out in

Figure 6. Diffusion and adsorption of metal ions in pores of the 'host' and the structure of the composite before (a) and after (b) thermal treatment.

supercritical CO_2 in an autoclave (40 °C, 41.4–55.2 MPa). The formation of the gel proceeds over 12 h and then CO_2 is slowly removed (8 h). This is favourable for the formation of highly porous monolithic composites with the meso- and macroarchitecture of the pores.²⁴⁰ Components, which sharply enhance the ability of SiO_2 to adsorb water, are also introduced at the stage of formation. For example, selective water adsorbents, such as CaCl_2 and LiBr , bind up to 53 mass % of H_2O .^{241, 242}

Colloidal dispersions of trimetallic $\text{Au}-\text{Pb}-\text{Cd}$ particles (the diameter is 33 nm) containing the gold nucleus with a 18 nm thick lead mantle are formed by γ -irradiation of salts of the corresponding metals.²⁴³ In this case (when nanocomposites contain three or more different metals, *i.e.*, they are multimetallic nanohybrids), studies of the structures of these particles is a challenging task. At the same time, these materials have already found use as precursors in the production of superconducting ceramics, special multicomponent steels, *etc.* When traditional approaches are employed, a polymer either is formed in a previously prepared inorganic matrix or is inserted into the latter. Multimetallic nanocomposites are formed either in a polymeric matrix *in situ* or simultaneously with the latter.

It is known that standard methods for the preparation of blends in the production of high- T_c superconducting ceramics (direct mixing of oxides, carbonates, oxalates, nitrates and other metal salts) give rather poorly reproducible results. This is due not only to the heterogeneity of grinding and mixing of the solid initial components but also due to complex physicochemical and mechanochemical conversions that occur in the course of the preparation of samples. As a result, microheterogeneities appear and different phases, including nonconducting phases, are formed resulting in low-quality high- T_c superconducting ceramics with a blurred superconducting transition (Meissner effect). A structurally homogeneous superconducting ceramic of the $\text{YBa}_2\text{Cu}_3\text{O}_7$ type was formed when the initial components [for example, $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, $\text{Ba}(\text{NO}_3)_2$ and $\text{Cu}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$] were mixed on the molecular level (in solution). After evaporation of the solvent (congruent evaporation), a homogeneous dispersion of a precursor of a high- T_c superconducting ceramic was obtained. With the aim of preparing composite materials, either a high- T_c superconducting ceramic is introduced into a polymeric matrix or this ceramic is prepared in the presence of a polymeric matrix. For example, in the first case, a dispersed high- T_c superconducting phase, *viz.*, $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (ceramic Y-123), $(\text{Pb}_x\text{Bi}_{1-x})_2\text{Ca}_2.\text{Sr}_2\text{Cu}_3\text{O}_y$,²⁴⁴ or $\text{Tl}_2\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_y$,²⁴⁵ with $T_c \sim 90, 110$ and 125 K, respectively, was introduced into a polymeric polychlorotrifluoroethylene, polyvinylchloride or rubber matrix. The ceramic content is 50%–75%. The optimum compositions combine advantages of a high- T_c superconductor (high T_c , good magnetic properties and magnetic levitation) and of polymers (mechanical strength, flexibility, simplicity of processing of products and resistance to atmospheric effects, aggressive media, *etc.*). In addition, the preparation of compositions allows one to eliminate drawbacks of a high- T_c superconducting ceramics, *viz.*,

the high porosity, the friability, the susceptibility to degradation, *etc.* However, rather large (micrometer) ceramic particles are inserted into a polymer according to this procedure.

In the second case, polymeric matrices containing metal ions dispersed on the molecular level are used (including the preparation of nanosized particles in the course of polymerisation or polycondensation). For example, citrates of different metals in aqueous solutions of acrylamide are polymerised in the presence of radical initiators and chain carriers (*N,N,N',N'*-tetraethylenediamine) to form a gelatinous phase.²⁴⁶ In this case, metal cations were trapped into a polyacrylamide gel much as occurs in the sol-gel synthesis. After calcination, ultrathin multicomponent oxide powders, such as $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ or LaAlO_3 , were obtained. The formation of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramics was performed with the use of acrylic or methacrylic acid as chelating ligands²⁴⁷ or with the use of polymer-salt solutions based on polymeric alcohols or acids, PEG or PVPr.^{248–250} The sizes of all salt crystals formed in the presence of any one polymer are substantially smaller than those obtained upon crystallisation of pure salt solutions. This is associated with complex formation in solutions as well as with adsorption of macromolecules on nuclei of crystallisation although it is not inconceivable that recrystallisation occurs simultaneously due to the presence of the concentration gradient of the components within the thickness of the film. Homogeneous films are most often formed because their formation occurs not only on the surface but also in the volume. It is essential that the final sizes of crystallites of the ceramics in the resulting powders should be approximately equal to their sizes in films.

The polymer-analogous conversion method was used for the preparation of the Y^{3+} , Ba^{2+} and Cu^{2+} complexes with polymethacrylic acid^{251,252} and of the YBC chelates with polyamides^{253,254} [gelatinisation with polyvinyl alcohol (PVA) can also be used].²⁵⁵ The superconducting ceramics based on these metalopolymers has $T_c = 80\text{--}92\text{ K}$, and the critical current density (J_c) is $150\text{--}160\text{ A cm}^{-2}$. Not only powders but also films and fibres can be prepared from these ceramics. (For this purpose, YBC-epoxy composites prepared from epoxide polymers are also suitable.²⁵⁶)

For example, long ($> 200\text{ cm}$) fibres 1 mm in diameter were formed from thermoplastic gels based on Y-123 ceramics and PVA.²⁵⁷ Calcined fibres have $T_c = 92\text{--}94\text{ K}$. These fibres form materials characterised by different J_c values depending on the degree of saponification (DS) and the content of the Y-123 ceramics in these materials.^{258–260} The critical current density has the minimum value when DS = 67 mol. % and the maximum value ($J_c = 3.5 \times 10^4\text{ A cm}^{-2}$, 77 K) when DS = 81 mol. %. This parameter is also affected by the conditions of treatment (calcination and pyrolysis) of samples, which is associated with the peculiarities of the distribution of the ceramics over fibres.

Nanocomposite materials based on high- T_c superconductors are also prepared by polymerisation of acrylic acid in a mixture with aqueous solutions of Y^{3+} nitrate and Ba^{2+} and Cu^{2+} acetates.²⁴⁷

One of the most promising approaches to the polymer synthesis of high- T_c superconductors involves copolymerisation of metal-containing monomers.²⁶¹ If metal ions are introduced into molecules of the monomer before copolymerisation, these ions are distributed in the polymer more uniformly. For this purpose, acrylates or acrylamide complexes of Y^{3+} , Ba^{2+} or Cu^{2+} were mixed in a molar ratio of 1:2:3, dissolved in a minimum amount of methanol, dried and subjected to solid-phase copolymerisation.²⁶² Acrylamide complexes of Bi^{3+} , Pb^{2+} , Sr^{2+} , Ca^{2+} and Cu^{2+} taken in a molar ratio of 2:0.3:2:2:3 were treated according to the same procedure (copolymerisation was carried out in concentrated aqueous solutions).²⁶³ The organic phase was calcined out from the resulting metal-containing copolymers. The properties of these high- T_c superconducting ceramics are shown in Fig. 7. Analysis of the temperature dependence of the electrical resistance (R) demonstrated that these ceramics behave as metals at $T < T_c$,

Figure 7. Temperature dependence of the electrical resistance and the magnetic susceptibility of high- T_c superconducting ceramics: (a) ceramics from a copolymer of Y, Ba and Cu acrylates; (b) ceramics prepared by spontaneous copolymerisation of acrylamide complexes of Bi, Ca, Sr, Pb and Cu.

although T_c of these ceramics are not as high as those of single crystals. It is known that the properties of polycrystalline samples in the normal state depend to a greater extent on the quality of intergrain contacts than on the structure of grains as such. The widths of superconducting transitions in the range of 0.1–0.9 of the value corresponding to complete resistance drop is no more than 2–3 K, which is close to the characteristics of the best samples of high- T_c superconducting ceramics. The character of the temperature dependence of the magnetic susceptibility (χ) is also indicative of the sharp transition and of the presence of the only superconducting phase. In this case, the complete volume of diamagnetic shielding of the phase, which is estimated from a lead reference compound, reaches 100%. The characteristics of superconducting bismuth cuprates are of particular importance. The reproducible synthesis of the latter is a challenging task. Generally, these compounds contain admixtures of a phase with $T_c = 85\text{ K}$ due to the microheterogeneity of the ceramics and the successive phase transitions $2201 \rightarrow 2212 \rightarrow 2223$. Products prepared by spontaneous copolymerisation are well reproducible single-phase samples with $T_c = 110\text{ K}$ and a critical current density of up to 240 A cm^{-2} . Apparently, this approach can also be used for the preparation of other single-phase materials in the nanocrystalline state.

The preparation of multicomponent steels of the M50 type (alloys containing 4.0 mass %, 4.5 mass %, 1.0 mass % and 0.8 mass % of Cr, Mo, V and C, respectively, and Fe as the remainder) may become an important field of application of nanostructured polymetallic materials. These steels are primarily used in aircraft construction for the preparation of supporting bearings, in gas turbine engines, *etc.*^{264,265} Generally, M50 steels contain substantial amounts of micron-sized carbon particles, which initiate the formation of fatigue cracks in the material of bearings. The mechanical properties of these structured materials would be expected to be improved as sizes of grains deposited on defects decrease (healing of microcracks); PVPr is used as a polymeric surfactant; $\text{Fe}(\text{CO})_5$, $\text{Cr}(\text{Et}_x\text{C}_6\text{H}_{6-x})_2$, $\text{Mo}(\text{Et}_x\text{C}_6\text{H}_{6-x})_2$ ($x = 0\text{--}4$) and $\text{V}(\text{CO})_6$ serve as precursors of the M50 steel. The process is carried out in dry decalin under ultrasonic irradiation (sonochemical synthesis). After removal of the solvent and the gaseous phase, colloidal particles have an average diameter of 7 nm and exist as a homogeneous alloy. Another procedure involves reduction of precursors of the M50

steel (FeCl_3 , MoCl_3 , CrCl_3 or VCl_3) with lithium triethylborohydride in THF followed by removal of solid LiCl by sublimation *in vacuo* at high temperature. Probably, these approaches will also be useful in the design of magnetic materials, for example, those based on polymetallic nanosized particles of the $\text{LaSrCr}_x\text{Ni}_{1-x}\text{O}_{4+\delta}$ type, *etc.* Thus a procedure for the preparation of the $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ceramics ($x = 0, 0.2, 0.4$ or 0.6) has been proposed recently.²⁶⁶ This procedure involves preliminary polymer synthesis consisting in binding of metal nitrates with a gel precursor from PEG ($M_w = 20\,000$) taken in certain ratios. Autoignition occurred at 300°C and NO_3 groups served as an oxidising agent. Subsequent thermal treatment of the combustion product afforded a homogeneous perovskite phase (see above). Its morphology and S_{spec} ($1-7\text{ m}^2\text{ g}^{-1}$; the sizes of crystallites were $24-150\text{ nm}$) depended on the reagent ratio and reaction conditions. A ceramic with cadmium and lanthanum additives with composition $\text{Pb}_{0.85}\text{Cd}_{0.05}\text{La}_{0.10}\text{Ti}_{0.975}\text{O}_3$ was prepared by the sol-gel method from metal acetates and $\text{Ti}(\text{O}i\text{Bu})_4$.²⁶⁷ Thin silicon films can be coated with this material in the stage of concentration of the solution (before drying). Subsequent thermolysis is carried out according to a standard procedure.

IV. Preparation of template synthetic nanobiocomposites by the sol-gel method

The sol-gel method provides considerable possibilities for the preparation of a series of nanohybrid materials in which biologically active macromolecules can be encapsulated at the stage of formation of ceramics, glasses and other inorganic composites (see, for example, Refs 268 and 269). The biological objects can be enzymes, catalytic antibodies, noncatalytic proteins, polynucleic acids and microbial, plant and animal cells²⁷⁰⁻²⁷² used in biocatalysis, for immunodiagnostics, as biooptical agents, various adsorbents, *etc.*^{268, 273-275}

Biomolecules (active enzymes) were encapsulated into a sol-gel matrix for the first time in 1990.²⁷⁶ About 40 different types of hybrid bioceramic materials whose inorganic matrices contain silicon, titanium and zirconium oxides, TiO_2 -cellulose composites, *etc.* were described.²⁷⁷ Recently, bioceramic sensors, solid electrolytes, electrochemical biosensors, *etc.* have been surveyed in a review.²⁷⁸ Moderate temperatures and mild conditions of hydrolysis and polymerisation of monomeric alkoxides make it possible to trap proteins in the stage of formation of the matrix, thus preventing their denaturation. The high stability of the biomolecules trapped, the inertness, the large specific surface, the porosity and the optical transparency of the matrix facilitate heterogenisation because of which the sol-gel method of immobilisation is very attractive. Below are considered the principal approaches.

Proteins, such as copper-zinc superoxide dismutase, cytochrome, myoglobin, hemoglobin and bacteriorhodopsin, were encapsulated into a porous silica gel matrix prepared by the sol-gel method. The matrix effectively retains these biomolecules without loss in their enzymatic activity and changes in their spectral properties,²⁷⁹ does not preclude the approach of small molecules to the reaction centre and does not hinder transport of the reaction products. Heterogenisation of glucose oxidase and peroxidase, which are used as active solid-phase elements of glucosensors, was carried out according to the same procedure. The spectral characteristics of a gel containing oxalate oxidase and peroxidase are changed upon storage in aqueous solutions of oxalic acid.

Antibodies bound in such a manner are used in medicine, immunochromatography, immunosensors, *etc.* For example, immunoglobulins which are trapped retain their ability to bind external antigens from solutions.²⁸⁰ Antibodies 14D9 incorporated in sol-gel matrices catalyse different reactions, including hydrolysis of cyclic acetals, ketals, epoxides, *etc.*²⁸¹ The ability of the sol-gel matrix containing 10% of PEG and antiatrazine antibodies to bind atrazine was studied.²⁸² This matrix recognises

and binds atrazine and widely distributed herbicides in solutions. In this case, neither leaching of antibodies nor nonspecific physical sorption of atrazine on a ceramic matrix occur. A decrease in the activity was not observed for at least 2 months, while the activity in solutions decreased by 40% in this period. In addition, the use of the sol-gel method excludes the necessity of purifying immunoglobulin. It should be emphasised that these materials have other advantages, such as the enhanced thermal and pH stability, the possibility to monitor easily the enzymatic reactions both in pores and in the body of the matrix by spectral methods, the convenience of storage, the possibility of the repeated use, *etc.*²⁸³

Enzymes, which act as bioreactors (biodoped polymers), were immobilised according to the above-described procedure.¹²⁵⁻¹²⁷ For this purpose, chemically active terminal groups of enzymes and active bonds of dopants of the ceramics, for example of $\text{Sn}-\text{Cl}$, were used.²⁸⁴

R is an enzyme.

For example, alcohol dehydrogenase was immobilised into nanotubes of TiO_2 , which was prepared by template synthesis, according to this mechanism. This enzyme retained its ability to oxidise ethanol for more than 4 days (NAD^+ cofactor, phosphate buffer, pH 8).¹⁸⁰ Since nanotubes are open at both ends, this configuration allows one to use them as a flow reactor. These examples are large in number. They involve also covalent binding of antibodies with the aim of functionalising sol-gel films.²⁸⁰

Of considerable interest are procedures for the modification of matrices (including surfaces of metal oxides,²⁸⁵ silicates, siloxanes, hybrid sol-gel polymers) with different polyols (most often with glycerol) and their ethers followed by binding of trypsin, cytochrome *c*, superoxide dismutase, glucose oxidase, phospholipase D, *etc.*²⁸⁶ Bioencapsulants exhibit activity, which is almost identical to that of nonimmobilised enzymes. Besides, the former possess the high stability and exhibit the substantially better properties than materials prepared by the standard sol-gel method. Vinyl groups are grafted to the surface of SiO_2 particles (by treating aminosilica gel with acryloyl chloride) and copolymerisation of the resulting product with acrylamide and acrylic acid or *N,N*-dimethylaminopropylacrylamide is performed in the presence of a cross-linking agent and glucose oxidase.²⁸⁷ After removal of the protein from these nanocomposites, a molecular impression (template) remains. This template recognises glucose oxidases in protein mixtures.²⁸⁸ The so-called template approach based on the formation of porous silicate films about a specific reagent, which is then removed, using the sol-gel method was described. Template films prepared based on 3-hydroxytyramine²⁸⁹ have the higher affinity for this substrate than for structurally related molecules, including serotonin, dihydroxynaphthalene, *etc.*, and do not possess the affinity for negatively charged or large molecules, including the Tyr-Gly-Gly peptide. Apparently, the porosity of the film as well as steric, hydrophobic and electrostatic interactions play an important role in controlled penetration of different molecules through this film.

The formation of an organised material by the sol-gel method can be performed according to four procedures:²⁹⁰ (1) formation of self-assembling organic templates (transcription syntheses); (2) cooperative assembly of ensembles, *viz.*, template and building blocks (synergistic syntheses); (3) morphosynthesis in which organised nonlinear chemical environments, *viz.*, reaction fields (static, reorganisation, transition) are used for the construction of models;²⁹¹ (4) combination of these methods (integrated synthesis). This strategy (reaction ensemble $\rightarrow$ replication $\rightarrow$ metamorphism) resembles the general scheme of mineralisation. It can be exemplified by template-directed syntheses of ordered meso-

Figure 8. Electron micrograph of a coccus-like coat of the one-celled algae *Emiliana huxleyi*.²⁹²

forms and organoclays, microframework structures, including those with the use of bacterial templates. In particular, a coat of the one-celled algae *Emiliana huxleyi* consists of radially arranged hammer-shaped single crystals of calcite, which are crystallographically oriented and have a specific species form. The crystallographic orientation is retained in fossil casts, which is indicative of the control over nucleation on the molecular level (Fig. 8). This fact is most pronounced in the reproduction of hierarchic macrostructured organised silica gels. Multicellular fibres from *Bacillus subtilis* (Fig. 9) can serve as an example of scale organic 3D-templates.²⁹² Nanosized magnetic (Fe_3O_4), semiconducting (CdS) or TiO_2 particles, which has been preliminarily prepared, were introduced into macroscopic filaments upon swelling in colloids.²⁹³ Dried fibres (the diameter was 500 nm) were coated with a thin (30–70 nm) layer of aggregated colloidal particles. Negatively charged magnetic colloids exhibit the good permeability and reproduce the bacterial superstructure. Neutral CdS particles partially penetrate into the filament, but their major portion remains on the surface of the filament. Positively charged TiO_2 sols form only a surface coating. Removal of a bacterial component from a magnetic composite upon heating afforded structural collapse.

Figure 9. Scheme of formation of an organised macroporous SiO_2 structure with the use of bacterial templates, *viz.*, bacterial filaments with the structure of multicellular fibers (A), mineralisation of interfibre spaces of filaments (B) and the formation of macroporous replica upon drying (C).

To summarise, nanohybrid materials are widespread and are of considerable importance both in nonliving and living nature.^{2, 268, 273} Binding and decomposition of different organic compounds, the cycles of compounds and energy in nature and the formation of many useful minerals occur with the participation of nanohybrid materials. Outstanding possibilities are opened up in the field of the design of molecular-organised self-assembled systems, including nanobiomaterials. The protein environment is favourable to the preparation of complicatedly organised (both in form and composition) products. For example, perovskites (BaTiO_3 , SrTiO_3 or NaNbO_3) whose synthetic analogues are considered in Section III can be involved in processes of bioaggregation.²⁹⁴ It is believed^{295, 296} that finely monodispersed

precursors of high- T_c superconducting ceramics could be formed based on bacterial objects.

V. Intercalation of polymers into porous and layered nanostructures

Sometimes products prepared by the sol-gel method or by intercalation can be distinguished only by their past history. No less than 5000 studies dealing with problems of intercalation of organic, organometallic and inorganic compounds as well as with the properties of the resulting products were published up to 1994 inclusive,²⁹⁷ though the major body of information has been obtained during the last 5–10 years.

Natural layered silicates, the so-called smectites (or smectite clays) are most often used for the preparation of nanocomposites under consideration. Their structures, selected physicochemical properties and the nature of the active surface are considered in a review²⁹⁸ and monographs.^{20, 299} These are very widespread minerals to which hectorite and montmorillonite $[\text{AlMg}(\text{OH})_2(\text{O}_4)]^{5-}[\text{Si}_2\text{O}_5]^{4+}[\text{Na}, n\text{H}_2\text{O}]^+$ (MMN) with structures of the mica type belong. Crystals of MMN consist of alternating tetrahedral silicate layers of the cations condensed with negatively charged octahedral layers of metal oxides. However, unlike mica, the cations in these minerals are readily exchanged for other ions, including transition metal ions. The exchange occurs predominantly in layers containing solvated sodium cations. Intracrystal cavities can swell when they are filled with organic solvents. The degree of swelling depends on the nature of the cations within the layers and on the negative charge density on the silicate layers. Aluminosilicates and magnesiosilicates belong to clays whose nature is determined by the type of the octahedral metal. Within the lattice, Mg^{2+} and Al^{3+} can isomorphically replace Al^{3+} and Si^{4+} , respectively. The cations are hydrated and the layers readily swell and accommodate large cations or a substantial amount of water. In addition, most of inorganic oxides contain surface hydroxy groups, which actively bind metal ions. Crystalline rigid 'host' matrices with a controlled system of percolation nanometer-sized pores, which can be occupied by atomic or molecular 'guest' structures (clusters, nanosized particles, inorganic coordination polymers of the CdS type, large molecules of the C_{60} fullerene type and polymer units synthesised *in situ*^{20, 300–303}) are rather well studied. Thus intercalation of buckminster fullerene functionalised with ethylenediamine into a mica-like silicate of the fluorhectorite type has been described.³⁰⁰ Many procedures for the introduction of polymers in 'host' matrices are available. These hybrid nanocomposites are of technological interest because their properties are substantially improved compared to those of materials filled according to a standard procedure.^{304–306} For example, these materials prepared by thermal synthesis are generally metastable (in particular, due to flaking of the polymer from the inorganic component).

The properties of intercalated hybrid nanocomposites are determined by a number of characteristics, particularly, by the sizes of their inner open-pore systems. These properties were considered in many reviews (see, for example Refs 20 and 307–311). Intercalation systems are divided into two types according to their architecture and properties.³⁰⁹ The systems of the first type are characterised by the presence of rigid pores with a constant volume, the parallel isolation of lattice channels and the interrelation between the channels of the network. The location, the concentration and the spatial distribution of 'guests' are governed by the topology, the chemical nature and the reactivity of the inner surface of the 'host'. The matrix of the latter can be additionally dispersed and functionalised or long-chain surfactants can be intercalated into this matrix. In addition, the choice of 'guests' is limited by the minimum size of cross-linked channels, which leads to selective intercalation into induced spatial matrices (of the types of molecular sieves or membrane films). Systems of the second type are characterised by a low dimensionality of the

'host' lattice, *i.e.*, by the structures of the 'layer' or 'chain' types. As a result, the pores are 'flexible' and their sizes can be adapted to the size of the 'guest.' In layered systems, the basal (intralayer) space comprises ~ 5 nm. The thickness of the layer, for example, in perovskite varies in the range of 0.5–2.2 nm. From the viewpoint of the electronic properties, the matrix lattice of the 'guest' may have no effect on the intercalation–deintercalation process (this is true for lattices of dielectrics, *viz.*, of zeolites, layered aluminosilicates, metallophosphates, *etc.*, the intercalation behaviour of which is determined primarily by the acid–base and exchange properties). 'Guest' lattices possessing the electronic conductivity (semiconductors and metals) are a special case. Upon intercalation, redox reactions with electron (ion) transfer occur in these materials resulting in a substantial change in the physical properties of the 'host' matrix.

The inclusion of monomer molecules into pores of a 'host' followed by their controlled conversions into polymeric, oligomeric or hybrid-sandwich products (postintercalation conversions *in situ*) belong to the most interesting group of intracrystalline chemical reactions. This field has been rather well studied (see, for example, Refs 312–314). Intercalation of the appropriate monomer causes delamination and dispersion of 'host' layers, which is accompanied by polymerisation to form a linear or cross-linked polymeric matrix. This procedure was used for the insertion of polyesters,³¹⁵ PVPr^{316–318} and poly(ethylene oxide) (PEO)³¹⁹ into silicates and for the insertion of PVPr,³²⁰ polyimide^{321, 322} and poly(ϵ -caprolactam)^{305, 306} into kaolin. (When polymerisation was performed within kaolin, the resulting composites were nondelaminated products.) The most interesting hybrid nanocomposites were prepared from polyconjugated conducting polymers (which are often considered as materials for the preparation of battery plate), such as polyaniline,^{323, 324} poly(2-ethylaniline), poly(*p*-phenylene), polythiophene, polypyrrole^{323, 325} or pyrolysed polyacrylonitrile³²⁶ in different matrices.^{327–329} In this case, a great diversity of procedures can be used, *viz.*, the enclosure of a polymer into a gel,³³⁰ the use of salt solutions of the corresponding polymers [for example, polyaniline hydrochloride in an acid-methanolic solution or a sulfonium salt of poly(*p*-phenylene) soluble in many solvents], *etc.* The results of early studies in this field were summarised in the review.²⁹⁷ Thus oxidative polymerisation of pyrrole, dithiophene,^{331, 332} tetrahydrofuran³³³ and aniline³³⁴ in an FeOCl lattice was described. Intercalated aniline forms hydrogen bonds with chlorine atoms of the lattice, and polymerisation occurs along the (101) lattice diagonal. However, the conductivity of the resulting polymer is somewhat decreased. This lattice appeared to be suitable for oxidative polymerisation of aniline introduced from an aprotic solvent.^{331, 335, 336} The molecular formula of the resulting product was $(C_6H_5NH_2)_{0.28}FeOCl$.[‡] The zigzag polymer chains with $M_w = 6100$, which are comparable with the FeOCl lattice, are extended along the direction of the 'host' crystal and along the

hydrogen bonds between the NH groups and the chlorine atoms of the layers of the lattice. The $Fe^{2+} : Fe^{3+}$ ratio is $\sim 1 : 9$. The polymeric intercalate behaves as a *p*-type semiconductor (the conductivity of a single crystal is $1.5 \times 10^{-2} \text{ S cm}^{-1}$). Its prolonged oxidation in air afforded a mixture of polyaniline and β -FeOOH. Recently,³⁴⁰ it was proposed to use the α -RuCl₃ matrix, which is structurally similar to FeCl₃, for the preparation of lamellar nanocomposites of this type. The product of oxidative polymerisation of aniline in this matrix has the composition $(C_6H_5NH_2)_xRuCl_3$ ($0.5 < x < 0.6$). Its conductivity at room temperature is $\sim 2 \text{ S cm}^{-1}$, which is more than three orders of magnitude higher than that of the initial α -RuCl₃.

Postintercalation polymerisation of aniline was carried out in air at 130° in phosphate layers of α -Zr(HPO₄)₂·H₂O,^{341–343} VOPO₄,³⁴⁴ H₂O₂·PO₄·4H₂O,^{342, 345} layered acidic zirconium–copper phosphates,¹⁹ layered double hydroxides³⁴⁶ as well as in layers of $HM^1M^2O_6 \cdot H_2O$ ($M^1 = Nb$ or Ta ; $M^2 = Mo$ or W ^{347–349}), molybdenum sulfide,³⁵⁰ porous zeolites of the mordenite type,^{351, 352} MCM-41,³⁵¹ in layers of perovskite,³⁵³ mica-like silicates,³⁵⁴ *etc.*³⁵⁵ The resulting products are generally dielectrics. Polyoxometallates as 'host' matrices can serve as ideal models of 'molecular batteries' because they contain a small number (generally 6–8) of W or Mo atoms linked through oxygen bridges. Their spatial and electronic structures were adequately characterised.³⁵⁶ Chemical (electrochemical) polymerisation of pyrrole in Keggin's structures $H_3PM_{12}O_{40}$ ($M = W$ or Mo) was described.^{357, 358} Sometimes additional chemical reactions are carried out with the aim of converting these products into nanocomposites. For example, $(Bu_4N)_5Na_3[(1,5-COD)M \cdot P_2W_{15}Nb_3O_{62}]$ ($M = Ir$ or Rh ; 1,5-COD is 1,5-cyclooctadiene) was reduced with hydrogen in acetone.^{359, 360} These hybrid nanocomposites can be completed with phosphomolybdate anions (Scheme 3). The composition of the product corresponds to the formula $C_6H_5N \cdot (PM_{12}O_{40})_{0.116}$. Photochemical polymerisation of a diacetylene, *viz.*, 3,5-octadiyne, in layers of Mg, Mn or Zn phosphates was also reported.³¹¹

It can be suggested that under the appropriate conditions, monomers occupy virtually the entire space of pores or the whole interlayer space. Subsequent oxidative polymerisation ('redox-intercalation polymerisation')³⁵¹ was carried out in the presence of molecular oxygen (as an electron acceptor) and a redox-active 'host' (a catalyst of electron transfer). In this connection, layered silicates containing metal ions, which initiate polymerisation of an intercalated monomer, are of particular interest. Thus when Na^+ ions in hectorite are replaced by Cu^{2+} (sometimes by Fe^{3+}), styrene undergoes polymerisation¹⁶³ both in pores and on the surface. The polymer has a 'brush-like' structure, which indicates that the inorganic surface possesses an orienting effect. This effect decreases as the chain grows and moves away from the surface.

N-Vinylcarbazole is polymerised in MMN at 64 °C (in a benzene solution at 50 °C) due to the presence of cations in MMN.^{361, 362} The thickness of the intercalated layer of 'guest–host' particles is 33 ± 10 nm and the conductivity of this nanocomposite ($10^{-6} \text{ S cm}^{-1}$) is 10 orders of magnitude higher than that of polyvinylcarbazole.

Intercalated polystyrene exists in two forms.¹⁷⁵ One of them possesses the enhanced rigidity due apparently to a higher degree of ordering of the polymer. The improvement in physicochemical properties of intercalated polystyrene was observed also in the model PS–MMN system.³⁶³

Redox intercalation polymerisation of aniline, pyrrole and dithiophene with the use of a V₂O₅ xerogel affords polyconjugated

‡ The method consisting in quantitative removal of a polymer from an inorganic 'host,' its repeated dissolution and investigation could be an important technique for the analysis of polymers in these hybrid materials. However, although studies on the extraction of polymers from layered nanocomposites have been reported,^{6, 336, 337, 338} this field is poorly understood. Recently, rapid and quantitative extraction of PEO from the $K_x(C_2H_4O)_4M_{1-x/2}PS_2$ composite ($M = Mn$ or Cd) with an aqueous tetraethylammonium salt under normal conditions has been carried out.³³⁹ This process was analysed in detail and the kinetic regularities were revealed.

anisotropic polymers.^{364–366} Intercalation is accompanied by polymerisation. In this case, the chain growth initially occurs within the xerogel and is associated with transport of molecular oxygen. The V_2O_5 xerogel acts as a catalyst. A conducting polymer with different polyaniline: V_2O_5 ratios is formed with the participation of mixed-valence (V^{4+}/V^{5+}) ‘host’ lamellae ordered along one direction. The material consists of alternating layers of vanadium oxide and the polymer. Physicochemical studies demonstrated that polyaniline was formed as a salt. Ageing of the material in air facilitates partial oxidation of the inorganic framework and oxidative binding of polyaniline in the intralamellar space. The resulting polymer is ‘frozen’ due to the formation of a $NH\cdots OV$ hydrogen bond. A detailed analysis^{351, 367} of the insertion of aniline, its competitive polymerisation into MoO_3 and the formation of the nanocomposite $(C_6H_5NH_2)_{0.24} \cdot MoO_3$ structures, including those with the use of a low-temperature intercalation procedure,³⁶⁷ was carried out. It was found that polyaniline chains expand layers and change the potential surface thus decreasing the polarisability of the lattice.⁸ The polyaniline chains intercalated in MoO_3 oxide $(NH_4)_2S_2O_8$.¹⁹⁷ Oxidative polymerisation of aniline, pyrrole or thiophene monomers intercalated in layered aluminosilicates affords highly oriented ‘host–guest’ layers. It was found³² that radiation polymerisation of acrylonitrile and acrylic acid in MMN inclusion compounds afforded stereoregular (which are most likely syndiotactic) polymers.

Let us consider the most interesting procedures for the synthesis of one-dimensional nanocomposites based on intercalation into a matrix. An aqueous Au colloid (the particle size was 12 nm) stabilised with citric acid was introduced into pores of a Al_2O_3 filtration membrane (the average pore diameter was 20 nm) and oxidative polymerisation of pyrrole was performed *in situ* in these pores by adding an aqueous $Fe(ClO_4)_3$ solution.^{369, 370} After dissolution of the membrane in 0.5 M KOH, a suspension of one-dimensional colloid-polyppyrrrole nanostructures was obtained (Fig. 10).

Figure 10. Template synthesis of one-dimensional Au–polyppyrrrole nanostructures in a Al_2O_3 membrane.

To construct solid light-sensitive solar cells, TiO_2 particles of size ~ 20 nm (prepared from $TiCl_3$, pH 2.5) are obtained at the surface of a photochemical electrode. Simultaneously, polypyrrole, which is formed upon electrochemical polymerisation of pyrrole adsorbed in electrode pores, precipitates on these particles.^{371, 372} These structurally controlled ‘templates’ are analogues of self-assembling supramolecular ensembles. Note that the procedure for the preparation of supramolecular systems for molecular recognition comprising chromophores, semiconductors and cluster aggregates, which perform special optical and electronic functions, is analogous to the above-considered preparation of nanobiocomposites.^{311, 373, 374}

One-dimensional parallel polyaniline chains prepared *in situ* can be encapsulated into structures with wide pores and large (the

diameter is ~ 3 nm) channels. In this case, the chains take a fibre shape and exhibit microwave conductivity.^{351, 375, 376}

An alternative to polymerisation *in situ* involves direct intercalation of macromolecules into layered structures, most often into silicates. The insertion of polymer molecules into layered ‘host’ lattices is of interest from different points of view. First, the construction of organic–inorganic polylayered composites becomes possible. Second, the intercalation physical chemistry by itself and the role of intercalation in the fact that the system gains electronic conductivity (for example, in the construction of reversible electrodes³⁰⁸) or improved physicochemical properties (nylon-layered silicate nanocomposites,^{377, 378} hybrid epoxide-clay composites,³²² nanomaterials based on hectorite and polyaniline, polythiophene or polypyrrole,³⁷⁹ etc.) are of interest.

The insertion of PEO into layers of mica-like sheet silicates in the reactions of a melt of the polymer with the ‘host’ Na^+ - or NH_4^+ -exchange lattice is one of a few examples of direct intercalation of polymers.³⁸⁰ Poly(ethylene oxide) is also inserted into lamellar networks of $V_2O_5 \cdot nH_2O$, MoO_3 ,^{337, 338, 381–383} $MnPS_3$, $CdPS_3$,^{381, 384} etc. Thus an aqueous solution of PEO ($M_w = 10^5$) reacts with an aqueous gel of $V_2O_5 \cdot nH_2O$ to form a composite after removal of water. In this case, the interlayer distance increases from 1.155 to 1.32 nm. Alkali metal ions react with PEO to form inclusion compounds, which can also be inserted into layers of ionic silicates, for example, into MMN. The distance between the layers of the PEO– Li^+ salt complexes intercalated in MMN is 0.8 nm, and the PEO chain adopts a slightly strained helicoid conformation.

Poly(ethylene oxide)– LiX systems find wide application as polymeric electrodes and solid electrolytes. However, these questions are beyond the scope of the present review and were considered in detail, for example, in the monographs.^{385–387} These systems are rather often used in combination with ceramic fillers (of the $LiAlO_2$, Al_2O_3 , TiO_2 , etc. types). Let us give only one example.³⁸⁸ Thus 10% of nanosized TiO_2 (13 nm) or Al_2O_3 (5.8 nm) particles were dispersed in acetonitrile with $LiClO_4$ and then PEO was added (the $LiClO_4$: PEO molar ratio was 1 : 8). The conductivity of the resulting polymer–inorganic nanocomposite is 10^{-4} and 10^{-5} S cm^{-1} at 50 and 30 °C, respectively. Recently,³⁸⁹ the preparation of a series of new hybrid polymer–inorganic electrolytes, which contain the aluminium atom in the main chain and Li^+ ions, by cocondensation of $LiAl(OR)_2H_2$ with organosilicon precursors has been reported.

The intercalation of polymers³⁹⁰ (PS,³⁹¹ PEO,³⁸⁰ polypropylene,^{392–394} etc.) from their melts into a silicate lattice is also a promising procedure. A molecular-dynamic model, theoretical calculations and the kinetics of formation of these intercalates were considered in the study.³⁹⁰ A new line of investigation involves direct hydrothermal crystallisation of silicate layers from a polymer gel.^{395, 396} This approach extends the range of intercalated polymers because it allows one to use compounds, which do not contain functional groups.

Activation of surfaces, layers and ‘host’ pores, including activation under the action of ultrasonics, is of importance in the processes under consideration. Thus Ni particles (10–40 nm) are deposited on submicrospherical silica gel.³⁹⁷ When a solution of $Ni(CO)_4$ in decalin was irradiated with ultrasonics, the Ni–C bonds were cleaved simultaneously with activation of the SiO_2 surface (the removal of adsorbed water, the cleavage of Si–O–Si bonds and the formation of free Si–O bonds). An alternative procedure involves the reaction of metallic nickel with activated silanol groups of the surface to form Si–O–Ni bonds. These centres serve as nuclei for further growth of Ni particles. Amorphous superparamagnetic Ni clusters were converted at 400 °C into a crystalline ferromagnetic material. This mechanism is realised to some extent for other dehydrated surfaces as well. For example, Al_2O_3 and metal carbonyls $M(CO)_n$ form Al–O–M structures.³⁹⁸ In such a manner gold nanosized particles were stabilised in a silica gel monolith.³⁹⁹ Thermolysis

§ Recently, the geometric structures and vibrational properties of complexes of polyenes with aluminium atoms as a constituent were studied by the *ab initio* quantum-chemical method in the Hartree–Fock approximation.³⁶⁸

of rhodium carbonyl on the Al_2O_3 surface afforded small Rh clusters.⁴⁰⁰

Nanocomposites self-assembled as $(\text{M}/\text{P})_n$ multilayers (M and P are nanosized oppositely charged layers of an inorganic component and a polymer, respectively) are worthy of special notice. These nanocomposites possess a variety of valuable properties, which makes it possible to use them, in particular, in the optical engineering for the production of displays.^{401–407} A great variety of procedures for the layer-by-layer assembly of polyelectrolytes and clays,^{408–413} lamellar zirconium phosphates⁴¹⁴ and colloidal metal particles^{415,416} were proposed. Using anionic MMN and positively charged poly(diallylmethylammonium chloride) (PDAMAC) as an example, the mechanism of formation of these materials on the surface of nanoplates from glass, quartz, silver, gold and even Teflon was considered in detail and the processes of defect formation were studied.⁴¹⁷ Successive submersion of plates into a solution of the P component or in a suspension of M leads to an increase in the number of layers (n). Each event is accompanied by an increase in the thickness of the P and M layers by 1.6 and 2.5 nm, respectively. The formation of multilayers involves several stages. First, adsorption on the substrate surface occurs, which is determined by electrostatic and van der Waals interactions. In this case, the structural hierarchy of the M layers provides limitless possibilities of their application as templates for a great variety of molecules and clusters,^{24, 418–422} which can be inserted between swollen layers or inside the M plates and can also be located on their surface. Second, the M component is strongly and irreversibly (which was confirmed by physicochemical studies) adsorbed on the oppositely charged polymeric electrolyte to form a very closely packed plane-oriented layer. Irregular M layers cannot provide complete coating of intercalated layers due to which overlapped stacks are formed. Interphase irregularities, which are independent of the nature of the substrate, exceed the thickness of the M/P layer. The control over the process can be performed by applying an external stress to the system in the course of self-assembly. In practice, a wide variety of these procedures were realised. For example, the PDAMAC polyelectrolyte and SiO_2 nanoparticles (the diameter was 25 nm) were successively deposited on the surface of a polystyrene latex. As a result of adsorption, a three-component polylayered material is formed (Fig. 11) in which the thickness of one, two and four SiO_2 –polymer layers are 60, 120 and 240 nm, respectively. The method of self-assembling of multilayers was also used for the preparation of nickel phthalocyaninetetrasulfonate–PDAMAC nanocomposites in which the average thickness of the M/P layer was 1.05 nm.⁴²³

Figure 11. Scheme of self-assembly of a polylayer composite based on PS latex, SiO_2 and PDAMAC; (1) adsorption of polyelectrolyte, (2) adsorption of SiO_2 , (3) adsorption of a polycation.

Layered nanostructures were prepared⁴²⁴ with the use of liquid-crystalline polymers containing ionic groups; MMN or hydrotalcite $[\text{AlMg}_2(\text{OH})_2(\text{OH})_4]^+ [0.5 \text{ CO}_3, \text{ OH}, \text{ Cl}]^-$ was used as an inorganic component. According to different estimates, the average thickness of the M/P pair is 4.9 nm. It is believed that the electrostatic self-assembly promotes tight contacts between the components and the establishment of this molecular organisation, which allows one to prepare new types of liquid-crystalline structures with unusual properties. Apparently, the layer-by-layer assembly of aluminosilicate–polyelectrolyte nanocomposites is a promising procedure for the design of new membrane materials.⁴²⁵ In this review, hybrid nanocomposites, which were prepared, for example, by emulsion or gas-phase

polymerisation of traditional monomers (most often, styrene, MMA, aniline, ethylene, propylene, *etc.*) in the presence of different organophilic minerals, are not considered although these approaches are undoubtedly of interest by themselves (see, for example, Ref. 426). Thus emulsion polymerisation of the epoxy prepolymer (a product of condensation of equimolar amounts of bisphenol A with epichlorohydrin) in the presence of $\text{Na}^+ - \text{MMN}$ was accompanied by the insertion of the polymer into the basal space of the smectite clay, which expanded from 0.96 to 1.64 nm.⁴²⁷ A micelle with the monomer rather than the monomer as such was inserted into the body of the 'host,' which swelled in aqueous media. The resulting composite exhibits a higher thermal stability than that of the corresponding homopolymer. A hydrogel containing 3.5 mass % of MMN,⁴²⁸ which possesses the lower critical solution temperature ($\sim 32^\circ\text{C}$) than that of the nonmodified product, was prepared according to the same procedure (copolymerisation of *N*-isopropylacrylamide and *N,N'*-methylenebisacrylamide as a cross-linking agent in aqueous suspensions of MMN).⁴²⁹

Layered graphite inclusion compounds (LGC) were studied in detail. Graphite can be considered as an aromatic macromolecule. The number of aromatic rings in this molecule is ~ 1000 and the period of identity (the distance between the parallel planes) is 0.335 nm. Since the bonds between the parallel carbon layers in graphite are virtually absent (the energy of the interlayer interaction is only 16.8 J mol^{-1}), monomolecular layers of different compounds, including metal ions, can be inserted into graphite to form layered (laminated) compounds.⁴³⁰ Graphite inclusion compounds are generally prepared by the reactions of graphite with vapours or solutions of metals in strongly ionising solvents, with low-boiling chlorides or with cationic metal complexes. These compounds are divided into products of the first, second and subsequent stages of insertion depending on the number of carbon layers separating two adjacent layers of the metal inserted. The nature of bonds in these LGC depends on the nature of the metal. For example, in the cases of Fe, Co, Ni, Mn and Cu, van der Waals interactions exist. Sometimes when the π -electron density of graphite is transferred to the inserted metal layer, the carbon network of graphite becomes a peculiar polymeric ligand. In the case of alkali metals, this bond is formed as a result of electron transfer from the metal atoms to the conduction band of the adjacent graphite layer, *i.e.*, due to electrostatic interactions between the positively charged metal ions and free electrons of the conduction band of graphite (this problem was considered in more detail in Ref. 431).

In the course of reduction of inserted metal ions, they may partially leave layered stacks and reduction may occur on the outer surface of graphite. In such a manner nanosized particles, for example, of titanium are inserted into the imperfect lattice of graphite.⁴³² Many metals are inserted into graphite under high pressure in combination with shift deformation.⁴³³ Nanosized cobalt particles inserted into the graphite lattice according to this procedure exhibit the unusual magnetic and thermal properties.⁴³⁴

Therefore, intercalation chemistry provides virtually limitless possibilities for the construction of hybrid nanocomposites. Presently, the major effects attendant on the processes of formation of these materials are revealed. The structural organisation and the principal properties of these materials have been studied. The number of studies in this field is gradually increasing, which allows one to predict the design of materials of new types. For example, the synthesis of nanocomposites of a new interesting class, *viz.*, of hybrid materials containing azamacrocycles (gallium phosphates, *etc.*), has been reported recently.⁴³⁵ A start has been made on studies on intercalation (by the ionic exchange method) of nitrate groups of biomolecules, *viz.*, of nucleosidemonophosphates and DNA, into layered double hydroxides of the $\text{Mg}_2\text{Al}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$ type ('anionic clays').⁴³⁶ Nanocomposites containing metal chalcogenide as a structural element ('host') are of special interest.

VI. Metal chalcogenide – polymer inclusion nanocomposites

Metal chalcogenide–polymer inclusion nanocomposites are rather well studied. The results of studies were surveyed in the monographs.^{437, 438}

Apparently, intercalation in the CdS structure has received much attention.⁴³⁹ Film composites are most generally prepared with the use of a solution of the corresponding precursor followed by the synthesis *in situ*.⁴⁴⁰ For example, $\text{Zr}(\text{OPr})_4$ in propanol was hydrolysed with an aqueous solution of acetic acid, and solutions of cadmium acetate and ammonium thiocyanate were added.⁴⁴¹ The composition was coated onto a glass support and treated as in the case of the sol-gel method (see Section II). The cryochemical treatment of gels impregnated with Cd^{2+} , Pb^{2+} or Zn^{2+} salts followed by sulfiding with hydrogen sulfide in the gaseous phase, afforded nanoparticles of sulfides with sizes from 3–7 to 30–100 nm in a SiO_2 matrix.⁷³ The formation of the dispersed CuS phase in a polyacrylic acid–polyvinyl alcohol polymeric matrix proceeds through the stages of formation of sulfur-containing copper complexes, associates, amorphous clusters and, finally, crystalline CuS nanoparticles.⁴⁴² The specific structure of the interfacial layer and limitations imposed by diffusion in the swollen polymeric matrix are responsible for the characteristic features of formation of small (~ 4 nm) particles, the character of their distribution in the matrix and the aggregative stability.

If the anion is readily polarised and the cation possesses strong polarising properties, the compounds with composition MX_2 have layered structures. The distinguishing feature of these layered materials (of the MoS_2 or TaS_2 types) characterised by the low charge density of the layer is their ability to decompose into nanosized building blocks under appropriate conditions and to form colloidal solutions. In molybdenum dichalcogenide, a layer of molybdenum atoms is located between layers of chalcogen atoms, and packs are formed from these triple layers. In this case, bonds within the packs are substantially stronger than those between two packs linked only through van der Waals forces.⁴⁴³ The exfoliation procedure has been developed in sufficient detail.^{444, 445} Plastic superconducting electromagnetic materials can be prepared based on nanocomposites.⁴⁴⁶ Intercalation of PVPr, PEO and PEG from aqueous solutions into monolayers of suspended NbSe_2 [it is known that the latter is of one the best superconductors among layered dichalcogenides ($T_c = 7.2$ K)] was reported.⁴⁴⁷ The compositions and the selected properties of the resulting nanocomposites are given in Table 1.

A polymer is inserted into the WS_2 phase according to the same mechanism.⁴⁴⁸

Table 1. Properties of intercalated polymer– NbSe_2 nanocomposites.

Composite	d / nm	Thermal stability in N_2 / °C	Conductivity / S cm^{-1}	T_c / K
(PVPr) _{0.14} NbSe ₂	2.40	310	140	7.1
(PEO) _{0.94} NbSe ₂	1.96	224	250	6.5
(PEG) _{0.80} NbSe ₂	1.88	233	240	7.0

In the case of delamination, the insertion of a polymer can occur according to the ‘host–guest’ mechanism. Then intercalated systems are deposited by removing the solvent or by increasing the concentration of the electrolyte. Direct intercalation of polyaniline into the interlayer space of MoS_2 ($d = 1.037$ nm) through formation of colloidal suspensions has been described.³⁵¹

The polypyrrole– MoS_2 nanocomposite, which is a product of oxidative polymerisation *in situ* under kinetically restricted conditions, is a p -type conductor. Its electronic conductivity is three orders of magnitude higher than that of the initial MoS_2 compound.⁴⁴⁹ Intercalation of PEO into a delaminated suspension of TiS_2 or MoS_2 was carried out.⁴⁵⁰ In aqueous solutions, nanocomposites of linear polyethyleneimine in layers of MoS_2 , MoSe_2 , TiS_2 or MPS_3 ($M = \text{Mn}$ or Cd)⁴⁵¹ as well as composites of polyethyleneimine or poly(styrene 4-sulfonate) in TiO_2 – PbS layers possessing semiconducting properties were prepared.⁴⁵²

Nanocrystals of semiconductors based on metal chalcogenides immobilised into polymeric matrices exhibit luminescent properties. This is primarily true for nanocrystals of CdSe ,^{453, 454} CdS – Ag ,⁴⁵⁵ ZnS and ZnS – CuS .^{456, 457} Composites based on ZnS – CuS , which contain crystals with dimensions ~ 2 nm in a polymeric matrix, were prepared by copolymerisation of acrylates of the corresponding metals with styrene followed by treatment of the solution of the resulting copolymer with hydrogen sulfide in chloroform.⁴⁵⁸ These composites possess good photo- and electroluminescent properties. It should be noted that a precipitate did not form from the resulting almost colourless organosol even after one year.

Metal chalcogenides with more complex layered structures, for example, PbNb_2S_5 and SmNb_2S_4 , can also be decomposed and subjected to intercalation.⁴⁵⁹ In polar solvents, one-dimensional ‘host’ phases form colloidal systems with MMo_3Se_3 ($M = \text{Li}$, Na or In). These systems contain monodisperse negatively charged condensed cluster chains $(\text{Mo}_3\text{Se}_3^-)_n$. The structures of these systems (which are also called pseudo-one-dimensional metals) have been described in sufficient detail.⁴⁶⁰ They are of interest in the design of materials with nanowire (or molecular-wire) morphology. For this purpose, block radical polymerisation of dilute (10^{-3} – 10^{-4} mol litre⁻¹) solutions of these ‘rigid rods’ in a solvating monomer (vinylene carbonate) is performed in the presence of a cross-linking agent.^{461, 462} The system rapidly solidifies, and the polymeric matrix provides capture, association

Figure 12. Electron microphotograph of a ‘nanowire’ (a) and ‘nanocable’ (b).

and isolation of the inorganic phase. The nanocomposite contains individual isotropic nanowires 0.6–2 nm in diameter and 5–10 nm in length. Polymerisation of more concentrated solutions (10^{-2} mol litre $^{-1}$) affords nanocomposites as oriented multiwires ('nanocables') 2–4 nm in diameter and ~500–1500 nm in length. Each 'nanocable' contains 5–20 'nanowires' (Fig. 12a, b). The molecular weight of the inorganic chain (wire) is estimated at $\sim 10^5$. The conductivity is 10^2 – 10^3 S cm $^{-1}$, *i.e.*, it is approximately equal to the conductivity of the (LiMo₃Se₃)_n film.

Therefore, intercalation of polymers into the interlayer space of chalcogenides is an extensively and fruitfully developing field of the technology for the preparation of nanocomposites, although many problems, particularly, those associated with the mechanism of insertion and 'guest–host' interactions are still not completely understood. In conclusion, let us give several more examples of these nanocomposites. Polymeric films based on nanosized particles (10–16 nm) of chalcogenides ZnS,⁴⁶³ as well as of Cu₂S–CdS–ZnS and different polymers, CdS⁴⁶⁴ and β -cyclodextrin were described. The inner diameter of the cavity of the latter is 1.53 nm,⁴⁶⁵ which is substantially smaller than the sizes of the nanosized particles. Nevertheless, monodisperse complex structures with the participation of β -cyclodextrin are formed. It was suggested⁴⁶⁴ that these structures are formed as a result of binding of monodisperse complexes with excess sulfide anions and cadmium cations to form CdS– β -cyclodextrin–S^{2–} aggregates.

VII. Metallopolymeric Langmuir–Blodgett films — self-organised hybrid nanocomposites

Metal-containing nanoparticles inserted into Langmuir–Blodgett films (LBF) belong to yet another promising class of materials for the preparation of nanocomposites. Procedures for the synthesis of self-organised inorganic component–surfactant composites, which have been developed in recent years, made it possible to prepare new two-dimensional composite materials.^{58, 466, 467} Generally, the sizes of the elements of these materials are no more than 2–10 nm.

Polymolecular LBF are used for the preparation of highly oriented ultrathin films possessing the special properties, which are determined by their supramolecular structures. Different sensor groups or their precursors possessing nonlinear optical properties can be inserted into these self-organised layers (in some cases, metal complexes, clusters or nanosized particles are inserted). Finally, LBF are used for modelling surface and biological processes (see, for example, Ref. 468). Supramolecular ensembles with mesosized periodicity (intermediates between materials of atomic and macroscopic sizes) are subjects of supramolecular chemistry, *viz.*, constructional chemistry of intermolecular bonds.

Although this line of investigation is still in a primitive state of progress, its methodology has already been developed. The technique for the preparation of Langmuir–Blodgett films was modified, when applied to this methodology. Heterogeneous polar nanolayers are prepared on the surface of a subphase (deionised water) at a given constant surface pressure π , which has the dimensionality mN m $^{-1}$. The pressure is measured using a Wilhelmy balance in a specially designed apparatus with two-section baths controlled by microprocessor electronic units and a computer with the use of the constant automated monitoring of the technological process.⁴⁶⁹ Successive transfer (by methods of Langmuir–Blodgett's vertical lift or Langmuir–Scheffer's horizontal lift) of these layers in the liquid-crystalline state to a solid support allows one to design sufficiently complex molecular planar structures possessing different properties. Metal particles in LBF can exist as a 'two-dimensional gas' (if their concentration on the surface is small and they do not interact with each other). Three-dimensional states, *viz.*, the 'gaseous' (the distance between the molecules is substantially larger than their sizes), 'liquid' (the

distance between the molecules is comparable with their sizes), 'liquid-crystalline' (the lability of the molecule in the plane of the monolayer is retained) and 'solid' states, are formed as the two-dimensional gas is compressed.

Two procedures for the formation of nanosized particles in these films are distinguished. The first of them is based on a combination of the principles of colloid chemistry and self-organisation and growth of monolayers.^{470–472} In this case, the formation of nanosized particles (for example, by chemical and photochemical reduction of aqueous solutions of metal salts) is performed in the presence of stabilisation agents and components forming LBF. The resulting layers act as specific templates.^{472–474} This approach is also of interest as regards studies of biomimetic processes of mineralisation, including studies with the use of the sol-gel method considered above.

The second procedure consists in deposition of LBF on the surface of stabilised nanosized particles and insertion of these particles into polylayers (with the participation of functional groups), including layers of an inorganic nature. For example, LBF based on amphiphilic Ru²⁺ complexes was immobilised on a monolayer of hectorite.⁴⁷⁵ In this case, lamellar films and polylayers were formed. Langmuir–Blodgett films with a specified organisation either were formed directly on the surface of colloidal particles or were formed on the water surface and then were transferred to a support of nanosized particles with the use of the Langmuir–Blodgett technique.^{476–479} Thus a gold hydrosol stabilised with 4-carboxy thiophene was immobilised on a monolayer of octadecylamine by the electrostatic method.⁴⁸⁰ The charge on the film was controlled by changing pH. Multilayer films with different densities of the Au–octadecylamine clusters with dimensions 10 ± 3 nm can be prepared according to this procedure; the films contain from 2 to 20 monolayers (the surface pressure in the monolayer is 25 mN m $^{-1}$ and the film area (*A*) is 0.37 nm² molecule $^{-1}$). Apparently, the method of immobilisation of nanosized particles on LBF has a number of advantages over the chemical insertion of metal ions into LBF followed by assembly of clusters, *viz.*, the deformation of films is excluded, ordering of the lamellar phase is not disrupted and various nanosized particles, including bi- and polymetallic particles, can be used by choosing appropriate hydrosol mixtures. When particles are immobilised on LBF, not only adsorption or chemical interactions occur, but also a higher recognition level is achieved. Examples are provided by self-organisation of monolayers of alkylsiloxanes, fatty acids, dialkyl sulfides or thiols on surfaces of Al, Au, SiO₂, *etc.*^{481, 482} Thus two processes occur on the mosaic Au–Al₂O₃ surface, *viz.*, recognition of the 'own' support (selective adsorption) and self-organisation of diphilic thiol (on Au regions of the support) and acid (on Al₂O₃ of the support).

However, the majority of studies were devoted to self-organised hybrid nanocomposites based on mononuclear complexes (in particular, on CdS), procedures for the assembly of nanosized particles from these complexes, investigations of the quantum dimensional effects typical of semiconducting nanoparticles, and practical applications of these nanocomposites.^{483, 484} It was demonstrated that a dispersion of CdS particles (2.65–3.4 nm) stabilised with dodecylbenzenesulfonic acid in CHCl₃ spreads over a water surface to form stable monolayers of nanosized particles.^{485, 486} According to the π –*A* compression isotherms, an increase in the π value leads to the transition from the 'gaseous' state to a close-packed monolayer of particles and, finally, to a polylayer. The resulting LBF are characterised by $A = 0.65$ – 1.1 nm² particle $^{-1}$, which is close to the corresponding values for the hexagonally packed rigid spheres (0.608 – 0.887 nm² particle $^{-1}$). The transfer of these monolayers to a solid support by the Langmuir–Blodgett method produces polylayers of dimensionally quantised CdS clusters. Their optical density increases linearly as the number of monolayers transferred increases.

The formation of nanosized semiconducting particles in LBF *in situ* by the reactions of metal ions with H₂S or Na₂S has been

One of the promising approaches of electrochemical synthesis involves the formation of two-dimensional (Langmuir) monolayers of nanosized particles under monolayer matrices of surfactants, which are present on the surface of an electrolytic solution,

Classical LBF can be prepared with the use of not only low-molecular-weight but also polymeric systems. In this case, with the aim of imparting the hydrophobicity to the chain, thus providing the formation of monolayers, the chain is functionalised either using polymer-analogous conversions or by grafting side chains, which can respond to the external factors. As in the case of the preparation of nanocomposites of other types, polymerisation of functional monomers and their copolymerisation with monomers, which serve as spacer units, are also used. In principle, diphilic LBF based on polymers have advantages over polymolecular films based on low-molecular-weight compounds, if for no other reason than their higher stability. These materials support the required density of a monolayer upon formation of a film (an

equilibrium pressure of spreading of monolayers is a more rigorous criterion for their thermodynamical stability). To solve some applied problems, it is necessary to introduce functional groups of different types into LBF monolayers. For example, components of a redox pair can serve as such functional groups. However, serious limitations emerge when employing low-molecular-weight reagents because diphilic compounds are not mixed at the molecular level and phase separation occurs. The use of polymers allows one to solve this problem rather readily. The effect of the composition and the structure of polymers and copolymers as well as of the external conditions on the formation and properties of organised polymeric monolayers and LBF on surfaces of liquids and solids were analysed in detail in a review.⁵⁰³ The formation of LBF was performed with the use of polymeric metal complexes based on porphyrins and phthalocyanines.^{504, 505} For example, the diphilic properties can be imparted to polymers by copolymerisation of long-chain α -alkenes with maleic acid, maleic anhydride and other compounds⁵⁰⁶ because the carboxyl group is a convenient fragment for binding a metal complex. When reagents, such as 4-aminomethylpyridine, are used for the opening of the anhydride ring, groups capable of providing donor-acceptor bonding of metals possessing coordination vacancies are formed in the polymer. This procedure was used for binding tris(phenanthroline)iron(II) sulfate or bis(salicylidenoaminopropyl)aminocobalt(II) to diphilic copolymers, *viz.*, to copolymers of maleic acid-pyridinemonoamide with octadecene or maleic acid-picolinemonoamide with *N,N*-dioctadecylacrylamide.⁵⁰⁷ The dependence of the surface tension π on the area of the monolayer per molecule (A) at the air-water interface is shown in Fig. 13. The type of isotherm for the film formation is determined by the concentration of a metal complex because its dimensions are substantially larger compared to the area of monomeric units (it is assumed that a cubic complex molecule is located nearly parallel to the water surface). At concentrations of the complex higher than 10^{-7} mol litre $^{-1}$, this fact is of considerable importance in the organisation of a monolayer. After compression ($\pi = 25$ mN m $^{-1}$), a stable homogeneous monolayer is formed. However, the stability is lost at concentrations of $\sim 10^{-4}$ mol litre $^{-1}$.

An important point is that one monolayer as a component of a multilayer system can contain metal complexes of two different types. Their bonding by two functional groups possessing opposite properties prevents phase separation.

Recently, the preparation of mono- and polylayer LBF based on a copolyimide the chain of which contains carbazole groups (as an electron donor) and copper phthalocyanine has been reported.⁵⁰⁸ The stack molecular organisation of the layers and

small intermolecular distances in these LBF ensure the high lability of the charge and impart the good photoconducting properties to LBF.⁵⁰⁹

Regular ensembles of nanocomposites organised in LBF multilayers are also constructed through electrostatic interactions between charged sol nanoparticles dispersed in a subphase and charged monolayers of the surface (for example, between anionic nanoparticles and a cationic polyelectrolyte).⁴⁰⁸ This procedure was used for the synthesis of regular nanowire TiO $_2$ -PVC-arachidic acid composites (PVC is polyvinylcarbazole) based on cross-linked polycationic PVC, which was prepared by electrochemical polymerisation of *N*-vinylcarbazole in the presence of NaClO $_4$, and a sol of thallium oxide (*n*-type semiconductor).⁵¹⁰ The resulting polymeric layer (2.7 nm) serves as a peculiar template coated with regularly organised TiO $_2$ particles (3.2 nm). The resulting 5.5 nm thick monolayers can be transferred layer-by-layer to the hydrophobic surface ($\pi = 25$ mN m $^{-1}$). Evidently, this method will gain wide acceptance because electrochemical polymerisation allows one to produce a large number of positively charged conducting polymers, for example, polyaniline, polypyrrole, polythiophene, *etc.*⁵¹¹

Apparently, this mechanism is also realised in the formation of self-organised layers of TiO $_2$ on SO $_2$ -functionalised polymer surfaces⁵¹² as well as in the preparation of ordered TiO $_2$ layers on poly(sodium 4-styrenesulfonate) (PSS). TiO $_2$ particles (~ 3 nm), which were prepared by acid hydrolysis of TiCl $_4$, formed organised layered structures on surfaces of polymers of the cationic type, *viz.*, on superthin (~ 1 nm) PSS or PDA-MAC.⁵¹³ Optically transparent LBF organised on the molecular level and containing up to 120 layers (60 bilayers) were formed on surfaces of various substrates, *viz.*, metal, silicon or a polymer cleaned with a 5% *N*-2-(2-aminoethyl)-3-aminopropyltrimethoxysilane solution. The thickness of the bilayer was estimated at 3.6 nm. It is expected that this procedure will allow one to realise various combinations of materials with semiconducting metal-dielectric structures containing nanosized units of the *p-n*-, *p-n-p*-, *n-p-n*-, *etc.* types. Recently, polylayer (2–12 layers) films of hybrid nanocomposites with the $N \rightarrow Cd$ coordination bond have been prepared by the reaction of poly(4-vinylpyridine) (P4VP) with nanosized particles of cadmium sulfide.⁵¹⁴

Nanocomposites of yet another type, *viz.*, clusters in a Langmuir monolayer, are of interest for the design of metal-film materials used in the electronics as well as for the modelling of structures of fixed catalysts. For example, the reaction of Os $_3$ (CO) $_{11}$ (NCCH $_3$) with self-organised layers of (3-mercaptopropyl)trimethoxysilane on a gold surface resulted in the disruption of the well-organised thiol surface to form cluster aggregates (the diameter was 1.0–2.2 nm).⁵¹⁵ Layer-by-layer adsorption of one- and two-dimensional complexes of the [Cd $_4$ L $_4$] $^{8+}$ type, which are characterised by the octahedral coordination, on monomolecular poly(ethyleneimine hydrochloride) and polystyrenesulfonate films on silicon can be considered to be an efficient method for the preparation of new metal-containing supramolecular thin films.⁵¹⁶

Particular attention is given to metal clusters in LBF deposited on the surface of highly oriented pyrolytic graphite (HOPG). Their application allows one to solve many catalytic problems as well as to prepare stable reproducible tunnel nanostructures. The Rh $_4$ (CO) $_{12}$ and (NEt $_4$) $_2$ [Pt $_{12}$ (CO) $_{24}$] $^{2+}$ clusters sorbed on HOPG from solutions of organic solvents were studied by scanning tunnel microscopy.⁵¹⁷ Under laser irradiation, these clusters underwent decarbonylation and transformation to highly dispersed Pt crystallites of dimensions 1.8×0.5 nm bound to the graphite surface.⁵¹⁸ The procedure for the deposition of isolated 'naked' silver clusters on the HOPG surface with the topography characterised by planar dimensions of 3–5 nm and the height of 2–3 nm and the technique for the 'assembly' of their ligand shell from PPh $_3$ were developed.⁵¹⁹ The voltammetric characteristics of individual clusters on the surface of freshly cleaved HOPG were measured. The insertion of the clusters into monolayers of stearic

Figure 13. Isotherm of the film formation of maleic acid-pyridinemonoamide-octadecene copolymers on different sub-phases: (1) an aqueous solution of an alkali with pH 10, (2–5) solutions of [bis(salicylideneaminopropyl)amine]cobalt(II) with the concentration/mol litre $^{-1}$: (2) 10^{-7} , (3) 10^{-6} , (4) 10^{-5} and (5) 10^{-4} .

acid and their transfer to the HOPG surface also afforded cluster-containing LBF.⁵²⁰ In the resulting monolayer, the cluster molecules form an ordered two-dimensional lattice. By this means the problem of fixing of clusters on the surface was solved and the reproducible one-electron mode of tunneling was realised at room temperature. The regularities of the insertion of cluster molecules (Pd₃, Pt₅ and Pd₁₀) into LBF and their voltammetric characteristics were analysed in the study.⁵²¹ A multilayer LBF was transferred from magnesium stearate (from a monolayer of stearic acid to the surface of aqueous solutions of MgCl₂) to the HOPG surface in the disrupted state; the surface per molecule is 0.15 nm², $\pi = 36$ mN m⁻¹ (see Ref. 494).

The above-considered examples demonstrate that metal-containing Langmuir–Blodgett films, including those based on nanosized particles and clusters, are of considerable interest for the preparation of hybrid organised nanocomposites.

VIII. Major fields of application of hybrid nanocomposites

When considering synthetic problems, we have already drawn attention to the properties of the resulting nanocomposites and to the possibilities of their practical application. Undoubtedly, these problems merit detailed consideration. In the present review, only the major problems are briefly analysed.

Hybrid nanocomposites are primarily used for the preparation of plastic materials possessing semiconducting and superconducting properties. Among them are nanowires on polymeric matrices, films with special properties,³⁰⁹ and different-purpose ceramics, including membranes, luminophors, antireflection and reflecting coatings on optical units, carriers and catalysts, reinforcing agents for plastics and rubbers, binders, adsorbents for pharmaceutical and cosmetic industry, *etc.*^{116, 522–527} The recent review²⁷⁸ devoted to the use of materials prepared by the sol-gel method in electrochemistry includes more than 300 references. Optical waveguides were constructed based on hybrid polymer-inorganic nanomaterials, which were prepared by the same procedure and possess improved thermal and mechanical properties compared to the starting polymers.^{164, 528, 529}

Nanoparticles, for example SiO₂, TiO₂, CdS, CaCO₃ and BaSO₄, including those formed by the sol-gel method, are used as specific fillers, because the properties of materials are noticeably improved at a substantially lower concentration in a matrix than those prepared with the use of standard fillers. Thus when fillers are inserted into composites by mechanical dispersion using mixing equipment (the size particles is ~ 1 μ m), it is necessary that up to 40 mass %–50 mass % of the filler should be taken for 100 mass % of polyisopropylene to attain the required reinforcing effect, whereas the same effect is achieved by the insertion of only 0.6 mass %–0.8 mass % of a filler *in situ*.⁵³⁰ Highly filled (up to 75%) composite materials based on nanosized particles of the high-T_c superconductor Tl₂Ba₂Ca₂Cu₃O_y ($T_c = 125$ K) and polychlorotrifluoroethylene possess improved physicochemical and thermal characteristics and stability to atmospheric moisture.⁵³¹ These materials can be used for the design of cryoelectronic instruments, levitation equipment and magnetic screens.

Recently, efforts have been made to describe the viscoelastic properties of a composite taking into account the specificity of interactions between segments of the macromolecules and the active centres of the nanoparticles. The Kerner equation, which relates the elastic modulus of a composite upon simple extension to the portion ϕ of the inorganic phase, was modified⁵³² when applied to systems with strong interactions between nanoparticles and a polymer. Based on scaling theory, the equilibrium mechanical properties of a complex of colloidal particles and macromolecules some segments of which are adsorbed on active centres on the surface of particles (which are 'polynodes' of a network of the nanocomposite) were described.⁵³³ Under deformation and changes of the temperature, some segments leave the surface and the fragment of the macromolecular chain linking the surfaces of

two particles is increased by the same number of the segments. If this fact is taken into account, two nontrivial conclusions can be made: (1) the elastic properties of the composite are not only determined by the volume fraction of filling but are also inversely proportional to the linear size of the particles; (2) the shift modulus of the nanocomposite, unlike the shift modulus of nonfilled polymeric networks, does not approach zero as the temperature is extrapolated to zero. These conclusions agree well with the results of studies of the relaxation mechanical properties of the composite as well as the dependence of its viscosity on the molecular and structural parameters, such as the energy of interaction between the segment of the macromolecule and the active centre of the nanoparticle, the number of segments of the macromolecule, their size, the ϕ value, the particle size (the diameter is ≤ 30 nm) and the temperature.⁵³³

Let us briefly consider the conducting properties of hybrid nanocomposites. These properties are manifested only with particular inorganic component: polymer ratios when current-conducting channels of fractal metal-containing clusters are formed in a polymeric matrix for one reason or other. The highest conductivity is achieved when the composite is converted into a network of interrelated current-conducting chains, *i.e.*, it has a percolation structure (see, for example, Ref. 534). To put it differently, critical concentrations of the filler ϕ_{cr} (the percolation threshold) exist above which ($\phi > \phi_{cr}$) the conductivity sharply increases.

With a knowledge of the percolation threshold, the minimum necessary filling of conducting composites can be predicted. For example, ϕ_{cr} for epoxysilicon resin filled with spherical particles of dispersed nickel is 0.25 and the critical parameter (X_{cr}) determined by the number of bonds at conducting nodes in the lattice of the solid is 0.30.⁵³⁵

The conductivity of metallopolymeric nanocomposites is substantially affected by the dispersity of an inorganic component. Different nanocomposites are characterised by different relationships between the conductivity and the metal content. The percolation threshold of composites based on layered pyromellitimide films containing inserted silver particles is attained when the filler content is > 9 mass %. At the same time, when silver nanosized particles (10–15 nm), which are prepared in the course of thermolysis of a prepolymer [a solution of silver acetate in poly(pyromellitimide acid)], are uniformly distributed over a film, the composite does not take on the conducting properties at the same filler content. The dielectric characteristics of films ($\sigma = 10^{-15} - 10^{-12}$ S m⁻¹) are retained at a high level, which is in many respects associated with the presence of a substantial fraction of dielectric polymeric interlayers between conducting particles of the filler.

It is possible to enhance the conductivity of polymeric composites as a result of the formation of a filler as 'nucleus' (conductor or dielectric)–'shell' (conductor) constructions. This is of practical interest primarily in the technology of the production of glues and varnishes. For example, the conductivity of dielectric SnO₂ particles coated with a silver layer (8 vol. %) using thermal treatment of a precursor, *viz.*, an Ag(I)-containing polymer, is substantially increased ($\sigma = 1 \times 10^{-3}$ S m⁻¹), whereas $\sigma = 2 \times 10^{-7}$ S m⁻¹ for a mechanical mixture of SnO₂ and Ag powders (16 vol. %).⁵³⁶

Particular attention has been given to multicomponent metal-containing hybrid nanocomposites, which find use in the production of electrode materials for galvanic cells,⁵³⁷ high-T_c superconducting ceramics, *etc.* Materials prepared by the sol-gel method are used as piezoelectric ceramic fillers in acoustic converters as well as in the medical diagnostics. Thus coatings with dense homogeneous microstructures possessing the enhanced mechanical strength and improved piezoelectric characteristics were formed by sheet rolling (413 K, 20–30 MPa) of polymer–ceramic mixtures of polyvinylidene fluoride with PbTiO₃ (up to 65 vol. %).⁵³⁸

The preparation of modifying thin (3–7 nm) magnetic coatings by electrochemical methods has considerable promise. In particular, organosilanes are coated with a film containing α -Fe (70 at. % of Fe), magnetite Fe_3O_4 and an admixture of Fe_2O_3 .⁵³⁹

Sometimes magnetically active particles are introduced into different gels, *viz.*, into silicon,⁵⁴⁰ polyacrylamide,⁵⁴¹ poly(ethylene oxide)⁵⁴² *etc.* gels.⁵⁴³

To improve the electrophysical and magnetic characteristics of nanocomposites, ferroplastics are often formed in magnetic fields. In this case, magnetic orientation occurs. Thus neodymium ferrite is prepared in fields with the intensity of 3×10^{-4} – 3×10^{-3} T and then it is subjected to the mechanochemical action (pressing,⁵⁴¹ treatment between Bridgman's anvils⁵⁴³ or a combination of these procedures⁵⁴⁴). This makes it possible to produce magnetically filled matrices with oriented chain structures, which are used in the techniques for the production of varnishes and films and are of considerable interest as elements of systems for data recording. The formation of coatings under conditions of hardening in a variable magnetic field makes it possible to prevent precipitation of nanoparticles, which are either concentrated closer to the film surface or uniformly distributed throughout the body of the film. These materials are used as drug carriers as well as for the magnetic recording of data, magneto-separation and the preparation of composites possessing the magneto-optical properties and magnetic liquids (for example, oligoorganosiloxanes). Organometallic ferromagnetics based on polymetalloorganosiloxanes possess peculiar magnetic properties.^{545, 546}

Hybrid polymer-inorganic nanocomposites are characterised by a unique combination of the optical and semiconducting properties associated with the sensitivity of plasmon vibrations (the frequency, the intensity, the shape and the width of the band) not only to the nature of the matrix and the morphology of the nanocomposite but also to the particle size. The character of interactions between the electronic and atomic subsystems changes substantially as the linear sizes of semiconductor particles decrease to values comparable with the electron wavelengths, which is manifested in the quantum dimensional effects, *viz.*, in nonlinear optical effects, doubling of the frequency of the incident radiation (generation of the second harmonic), the 'blue shift' of the exciton absorption band, *etc.* The ability of these nanocomposites to form films and the ease of their treatment make it possible to use them for the preparation of dispersing optical elements, band-pass light filters and other high-quality thin-filmed coatings (only ~ 5 – 20 nm thick), which are used in the optoelectronics. For example, the production of modern integrated circuits is based on the so-called planar technology combining processes of the nanolithography (the formation of nanosized surface figures as lines and dots) and the etching. With the aim of decreasing the sizes of elements of optoelectronic integrated circuits to < 100 nm, new techniques of the lithography (in particular, electron-ray, ion-beam and X-ray) as well as new procedures for the dry etching (plasma-chemical, reactive ionic, *etc.*) are used.

Almost all materials of this kind are characterised by a nonlinearity of the optical properties manifested in a substantial strengthening of the local field of the light wave. The latter is quantitatively characterised by the third-order susceptibility, the nonlinear indices of refraction and the nonlinear absorption coefficient. These effects are widely used in spectroscopic practice (local nonperturbing methods of diagnostics, electron-optical image converters, *etc.*). This is particularly true of sol-gel glasses based on CdS, nanohybrid composites based on polymers and SiO_2 (or V_2O_5), Langmuir–Blodgett films, *etc.*⁵⁴⁷ If the sizes of semiconducting nanosized particles in matrices are much smaller than the wavelength of the exciting field ($\ll \lambda/20$), the nonlinear optical properties manifest themselves in the fact that 'quantum points' appear in nanocomposites (quantum-point polymers).^{548–550} There is a definite relationship between the wavelength of the exciting radiation and the sizes of nanoparticles.

Nanocomposites of this type can be used as active layers of light-emitting diodes.⁵⁵¹

In the previous sections, procedures for the insertion of transition metal ions into polymers in the stage of the sol-gel synthesis or intercalation have already been mentioned. The materials thus obtained serve, for example, for the preparation of coloured light guides, which have a broad spectrum of applications, *viz.*, from storage elements to highly sensitive detectors.

Let us consider the use of hybrid nanocomposites in catalytic, most often hydrogenation, processes. Under conditions of formation of catalysts and hydrogen adsorption, dislocations are fixed at interblock boundaries of polymer-stabilised nanoparticles. These particles have highly active surfaces and developed internal structures. A polymeric matrix hinders smoothing of numerous defects upon catalyst ageing. Of prime importance in the catalysis is a knowledge of the surface composition and S_{spec} and the possibility to control these parameters. The inherent size of nanosized particles is comparable with the molecular sizes of the compound subjected to catalytic conversion. This fact is responsible for the characteristic features of the kinetics and the mechanism of the reactions with the participation of nanosized particles. In particular, the high efficiency of colloid-metallic catalysts in multiple-electron processes results from the fact that these catalysts are 'reservoirs,' which can readily incorporate electrons.

Polymer-stabilised metal nanoparticles are primarily of theoretical interest as excellent models for studying the influence of the dimensional effects on the catalytic activity. Using these particles as examples, many concepts of the fundamental theories of catalysis can be verified. In addition, since nanocomposites are involved both in homogeneous and heterogeneous catalytic processes, they provide an additional possibility of revealing the relationships between homogeneous, heterogeneous and enzyme catalysis.⁵⁵² In a number of characteristics, these nanocomposites are similar to homogeneous catalysts although they also inherit the principal features of heterogeneous contacts. Thus huge Pd_{561} clusters can be considered as a bridge between homogeneous and heterogeneous catalysts.⁵⁵³ Composites based on nanosized particles of platinum and other metals, which are incorporated into glassy carbon matrices, can be assigned to the same type of catalysts.⁵⁵⁴ Of particular interest are catalysts based on organic–inorganic hybrid materials in which catalytically active metals incorporated into an oxide network are dispersed. For example, highly dispersed heterogeneous catalysts in a SiO_2 network prepared from substituted alkoxysilanes are known (see the review⁵⁵⁵).

Protective polymeric coating prevents poisoning of a metallopolymeric catalyst by potential catalytic poisons of the dibenzothiophene type.

Nanocomposites exhibit the high catalytic activity in elimination of hydrogen under the action of visible light⁵⁵⁶ [for example, the ethylenediaminetetraacetate (electron donor)– $\text{Ru}^{2+}(\text{bipy})_3$ (photocatalyst)–methyl viologen (electron acceptor) system]. Substantial success has been achieved in charge separation as well as in the design of efficient photocatalysts with the use of semiconducting nanomaterials (primarily, based on TiO_2) prepared by the sol-gel method (see the reviews^{557, 558}). The additional introduction of transition metal ions (for example, of copper^{559, 560}) in the stage of formation of these materials substantially enhances the efficiency of the photocatalytic reaction. These systems exhibit high activity also in low-temperature oxidation of CO .^{561, 562}

The use of polymer-protected nanoparticles can contribute new specific features to catalysis. A platinum sol as well as Pt on Al_2O_3 are the well-known enantioselective catalysts of hydrogenation processes.⁵⁶³ The potential possibilities of the use of hybrid nanocomposites in catalysis are far from all realised.⁵⁶⁴

IX. Conclusion

To summarise, a great diversity of aspects of the chemistry of nanocomposites is progressing extensively. In the coming years, procedures for the synthesis of multicomponent materials based on ecologically pure solid-state reactions will be developed. Apparently, the use of alcoholates or oxoalcoholates of nontraditional metals, for example,⁵⁶⁵ of Ta^{5+} or Nb^{5+} , in sol-gel procedures will have promise. This refers equally to new intercalation systems. Procedures for the preparation of hybrid materials of the 'network-in-network' type will be studied in more detail. The mechanism of their phase separation and the structures of the resulting nanocomposites will be elucidated. These materials will be formed with the use of monomers, which are traditionally used for the preparation of network polymers, including interpenetrating networks. A search for the optimum modes of formation of new types of lattices ('host' and 'guest' components in intercalated nanocomposites) is still in progress and studies of intracrystalline 'host-guest' interactions and their effect on the electronic properties of complex systems are being continued. For this purpose, it is necessary to reveal principal mechanisms of the orientation effect of pores and interlayer formations on the crystallinity and the stereoregularity of the polymer formed, which is one of the fundamental problems of physical chemistry of polymers and composite materials by itself. The approaches to the preparation of organic-inorganic nanocomposites surveyed in this review may be useful in the synthesis of different single-phase crystalline nanometal-ceramic products with complex compositions, for example, the MgM_2O_4 - α - Al_2O_3 systems ($\text{M} = \text{Al}$ or Cr) (< 10 nm). These products can also be synthesised with the use of Grignard reagents. Theoretical studies of the nature of bonds between metals (Fe, Ni, Cu and Ag) and the surface oxygen anion in cluster models started by Johnson and Pepper⁵⁶⁶ will help in the understanding of the structures of these materials. The use of LBF, which incorporate isolated cluster molecules or nanosized particles, in molecular electronics may have considerable promise. Finally, the nanophase materials technology requires the appropriate scientific support, i.e., the construction of new instruments as well as the development of techniques for working with nanosized materials.

The generality of many processes occurring both in the living and nonliving nature can give impetus to studies of nanobiocomposites. In this review, a reasonably fair, though incomplete, picture of applications of nanobiocomposites to studies of organised matter and the preparation of hybrid bioceramic nanomaterials is given.

The statements that the science and engineering will be developed on the nanosized level in the XXI century seem to be realistic because nanometer sizes of individual elements (for example, densities of the arrangement of microelectronic elements on crystal surfaces) are attained in many traditional technologies.

The structure-property relationship is the fundamental problem of modern chemistry and physics of hybrid nanocomposites. A great deal needs to be done before this problem is solved.

This review was supported by the Russian Foundation for Basic Research (Project No. 98-03-32353).

V. Disulfides	90
VI. Conclusion	92

Abstract. Published data on thermolysis of organic compounds of divalent sulfur and on thermal synthesis involving these compounds are summarised. The bibliography includes 201 references.

I. Introduction

Among the great variety of the ways of formation and chemical transformations of organic compounds of divalent sulfur, the thermal reactions, *i.e.*, the processes which occur at elevated temperatures in the absence of catalysts or promoters, take a special place. Such reactions proceeding in the earth's crust over millions of years have led to the formation of sulfur-bearing components of combustible fossils.

Mankind has dealt with the thermal reactions of sulfurous compounds from time immemorial, whenever a sulfur-containing material of organic origin is subjected to thermal treatment.

All combustible fossils, *viz.*, oil, bituminous and brown coals, oil-shales and natural gas, contain some amount of sulfur compounds. Therefore, high-temperature reactions of formation and thermal transformations of organosulfur compounds accompany virtually all processes of thermal fossil treatment. These are, for instance, the distillation and cracking of high-boiling oil fractions at temperatures from 300 to 800 °C and dry-distillation of bituminous and brown coals, oil-shales and peat at 450–1000 °C.

Thermal reactions of organosulfur compounds were studied in the very early stages of the development of chemistry as a science. However, the detailed exploration of these processes was started only in the past century.

The interest in thermal reactions of particular sulfur-containing organic compounds and in high-temperature syntheses involving these compounds is caused by the necessity to solve a number of problems, the most important of which are listed below.

1. The utilisation of sulfur-containing wastes in oil-refining, gas-, coal- and pulp-processing industries.

2. The development of thermal methods for the synthesis of organic and organosulfur compounds which are difficult to obtain alternatively.

3. Mechanistic studies of free-radical thermal reactions of sulfur-containing organic compounds occurring with involvement of free radicals. The development of methods for the generation of thiyl radicals, the evaluation of their reactivities and possible utilisation in high-temperature synthesis.

4. The generation of labile sulfur-containing intermediates, *e.g.*, thioformaldehyde, ethylenethiol, thioketones, sulfines, sulfenes, sulfenic acids, dialkylsilanethiols, *etc.*, using the flash pyrolysis technique and the development of methods for the detection of such intermediates.

The present review is devoted to the thermal transformations of organic compounds of divalent sulfur, except for thiones, and to the latest achievements in the field of high-temperature synthesis involving these compounds. Earlier, only a few papers^{1,2} with a brief survey of the literature on these issues have been published.

II. Thiols

1. Alkanethiols

Pyrolysis of alkanethiols in the gas phase at temperatures above 425 °C yields hydrogen sulfide and alkenes as the major products.^{3,4} The degree of decomposition of alkanethiols increases with an increase in the reaction time and temperature.⁵ Aliphatic hydrocarbons do not react with alkanethiols or products of their decomposition. Benzene accelerates thermolysis of alkanethiols, whereas carbon dioxide or hydrogen inhibit this process. Higher homologues of alkanethiols are somewhat less stable than the lower ones. Linear alkanethiols are more stable than their branched isomers,⁶ especially at higher temperatures (475 °C).

Hydrogen sulfide, hydrogen and methane are the pyrolysis products of methanethiol.⁵ Dialkyl sulfides, thiophene, hydrogen sulfide and elementary sulfur have been found among the thermolysis products of other alkanethiols.⁴ The decomposition is catalysed by metal sulfides and inhibited by cyclohexene.⁷ Since in both cases the ratio of the surface to the volume of a reactor does not affect the reaction rate,⁸ a free-radical chain mechanism for the thermolysis of alkanethiols has been suggested.^{6,9}

Received 12 October 1999

Uspekhi Khimii 69 (1) 90–104 (2000); translated by S V Chapyshev

The main process is accompanied by parallel reactions (4) and (5).

The thermal decomposition of *n*- and *sec*-butanethiols in a flow system follows a molecular mechanism involving the synchronous abstraction of hydrogen from the α -carbon atom *via* a cyclic transition state.¹⁰

The decomposition of 1,1-dimethylethanethiol under the same conditions follows a free-radical mechanism.⁹

The activation energy for reaction (8) was found to be 7 kcal mol⁻¹. The pyrolysis of isomeric butanethiols in a static system occurs as a homolytic process in accordance with Eqns (1)–(8).⁸ The thermal decomposition of cyclohexanethiol at 420–470 °C and under reduced pressure leads to the formation of hydrogen sulfide and cyclohexene.¹¹ Hydrogen sulfide accelerates this process, while cyclohexene retards it. In the presence of sulfur dioxide or over activated carbon at 425 °C, cyclohexanethiol is converted into benzenethiol.¹² α -Toluenethiol decomposes more readily than the lower alkanethiols yielding hydrogen sulfide and 1,2-diphenylethane.^{4–6} Ethanethiol is converted into thiirane and hydrogen sulfide on heating *in vacuo*.¹³

Most of the data available suggest a free-radical mechanism of alkanethiol decomposition, the initial step of which involves the cleavage of the C–S bond and generation of an $\cdot\text{SH}$ radical. The activation energy of this reaction presumably equals the energy of the C–S bond dissociation. Owing to the generation of thiyl radicals, high-temperature reactions of alkanethiols with aryl halides can take place yielding the corresponding arenethiols.¹⁴

2. Arenethiols

Decomposition of benzenethiol begins at about 200 °C.¹⁵ At 530–600 °C, benzenethiol, its derivatives and naphthalenethiol are converted into the corresponding diaryl sulfides.¹⁶ These reactions are catalysed by copper sulfide, cadmium sulfide and activated carbon; in the presence of these catalysts conversions occur at lower temperatures (300–500 °C).^{17,18} The *cis*–*trans* isomerisation of the C_{Ar}S–H bond takes place on flash vacuum pyrolysis of benzenethiols at 70–600 °C.¹⁹ Under reduced pressure of ozone, benzenethiol decomposes at 30–125 °C to form oxygen, carbon dioxide, sulfur dioxide and polymeric products depositing on the reactor walls.²⁰

Benzenethiol reacts with acetylene at 550–590 °C to give benzo[b]thiophene. A similar reaction with propargyl alcohol at 450–630 °C yields benzo[b]thiophene (**1**) and 3-methylbenzo[b]thiophene. It is supposed that pyrolysis of benzenethiol involves the generation of thiyl radicals, which add to the triple bonds of the substrates.²¹

Gas-phase reactions of benzenethiol with chlorobenzene and its *para*-substituted derivatives **2a–d** at 500–600 °C lead to symmetrical (**3a**) and unsymmetrical diaryl sulfides (**3b–d**).^{22,23}

X = H (**a**), Me (**b**), OMe (**c**), Cl (**d**).

Analogous diaryl sulfides are formed in the gas-phase reactions of *para*-substituted arenethiols with chlorobenzene at 500–620 °C.

The Arrhenius rate constants for these reactions have been determined.^{23,24}

$\bar{n}$	k / litre mol ⁻¹ s ⁻¹
H	$3.89 \times 10^{10} \exp(-149.90/RT)$
Me	$3.48 \times 10^9 \exp(-140.20/RT)$
OMe	$4.20 \times 10^8 \exp(-116.57/RT)$
Cl	$7.76 \times 10^{13} \exp(-206.1/RT)$

Benzenethiol reacts in the gas phase at 400–530 °C with 1,2-dichloroethene (a 3 : 1 mixture of *E*- and *Z*-isomers) to give β -chlorovinyl phenyl sulfide (a 1 : 1 mixture of *E*- and *Z*-isomers) in 84% yield.²⁵ The reaction of benzenethiol with β -bromostyrene in the liquid phase at 140–160 °C leads to phenyl β -styryl sulfide.²⁶ At 125–215 °C, benzenethiol readily reacts with 2- and 4-bromophenols, 1-bromo-2-naphthol, 1-bromonaphthalene and 1-bromoanthracene to form the corresponding aryl phenyl sulfides.²⁷

o-Chlorobenzenethiol and *o*-chloromethylbenzenethiol eliminate hydrogen chloride on flash vacuum pyrolysis.¹⁹ At 700 °C in vacuum, hydroxymethylbenzenethiol is converted into benzothiethene (**4**).²⁸

When a mixture of toluenethiol and ³⁵S-labelled ditolyl disulfide is heated, isotope exchange between thiyl radicals occurs. This process is accelerated by UV irradiation (Scheme 1). The reaction rate does not depend on the thiol concentration and is determined by the proneness of a disulfide to generate thiyl radicals as a result of S–S bond cleavage.²⁹

Scheme 1

7-Aminobenzo[*b*]thiophene and benzothiazole are the major products in the gas-phase reaction of 2-aminobenzenethiol with acetylene at 450–600 °C. The maximum yields of these products (39% and 41%, respectively) are achieved at 600 °C.³⁰

Pyrolysis of sodium 2-bromobenzenethiolate or its derivatives results in thianthrene or a 1:1 mixture of the corresponding isomeric thianthrenes **5** and **6**, thus suggesting the intermediate generation of short-lived thiirene **7**.^{31,32}

Flash vacuum pyrolysis of 2-mercaptobenzoic acid at 610 °C gives rise to benzothiet-2-one (**8**) and 1,4-dihydrofulvenethione (**9**).³³

Similarly, 3-mercapto-2-naphthoic acid is converted into naphtho[2,3-*b*]thiet-2-one (**10**) on flash vacuum pyrolysis at 840 °C.³⁴

Naphthalene-1-thiol reacts with acetylene at 410–700 °C to form naphtho[1,2-*b*]thiophene (**11**) and 1-thiaphenylene (**12**) in 47% and 60% maximum yields, respectively.³⁵

3. Hetarenethiols

The gas-phase reaction of 2-thiophenethiol (**13**) with acetylene at 500–600 °C affords thieno[2,3-*b*]thiophene (**14**) together with bis(2-thienyl) sulfide (**15**), thiophene and benzo[*b*]thiophene.³⁶ The complex character of transformations of 2-thiophenethiol is caused by the initial cleavage of the S–H and C–S bonds and the generation of radicals **16** and **17**, which either react with acetylene or recombine.

4,4,5,5,6,6-Hexafluorocyclopenta[*b*]thiophene (**18**) is the main co-pyrolysis product of 2-thiophenethiol with tetrafluoroethylene at 620–640 °C; 4,4,5,5,6,6,7,7-octafluorocyclohexa[*b*]thiophene (**19**) is also formed.³⁷

The reaction mechanism involves the generation of difluorocarbene from tetrafluoroethylene, the replacement of the thiol group in 2-thiophenethiol by this carbene and the subsequent addition of the C-centered radical thus formed to tetrafluoroethylene. The product **19** is formed due to the elimination of the SH group from the parent thiol and the reaction of thienyl radical with tetrafluoroethylene.

Bromothiophenethiols are unstable and decompose on distillation with elimination of hydrogen bromide and hydrogen sulfide.³⁸

III. Sulfides

Thermal decomposition of organic sulfides usually involves cleavage of the C–S bonds. The strength of this bond is different in different compounds. In dialkyl sulfides, either only the *3p*-orbitals³⁹ or the hybrid *sp*- and *spd*-orbitals^{40,41} are involved in the formation of the C–S σ -bond. The sulfur atom in sulfides can exhibit both electron-donating and electron-withdrawing properties. The latter is true when electron-withdrawing substituents are present in the α -positions to the sulfur atom. In the absence of such substituents the electron-withdrawing properties of the sulfur atom are not so pronounced, since its *3d*-orbitals in the ground state are diffuse and the energy of their occupation by an electron cannot be compensated by the energy of covalent bond formation. The presence of electron-withdrawing substituents in sulfides favours the localisation of a positive charge on the sulfur atom, thus weakening the C–S bond. The lone electron pairs of the sulfur atoms in sulfides can conjugate with the π -system of a multiple bond or an aromatic ring (contribution of the structures with the $2p\pi$ – $3p\pi$ bond). Owing to this effect, vinyl and aryl sulfides are rather weak electron donors and are characterised by high strengths of their C–S bonds.

1. Dialkyl sulfides and their derivatives

Studies on the pyrolysis of dialkyl sulfides were begun in 1928 with the aim of elucidation of the course of transformations of sulfur-containing components of raw oil and oil products upon refining.⁴² It was found that diethyl sulfide decomposes at 500 °C to form considerable amounts of hydrogen sulfide, gaseous hydrocarbons (38 mass %) and ethanethiol (10 mass %).^{42, 43} Diisopentyl sulfide is much more stable. The products of its pyrolysis at 500 °C contain mostly the recovered diisopentyl sulfide, 3-methylbutane-1-thiol and thiophene derivatives. Among the gaseous products, alkanes (64%), alkenes (30%), hydrogen sulfide and hydrogen (0.5%) have been found. Dibutyl sulfide decomposes at 500 °C rather rapidly to form hydrogen sulfide and thiols; the thermolysis is accelerated in the presence of benzene and decelerated in the presence of n-heptane. In a vacuum, dibutyl sulfide decomposes at 380–410 °C yielding ethylene and polysulfides.⁴⁴ Isobutylene, hydrogen sulfide, isobutane, 1,1-dimethylethanethiol and sulfur are the pyrolysis products of di(*tert*-butyl) sulfide in a static system at 25–250 Torr and 360–413 °C. In the presence of cyclohexane, the yield of the thiol is sharply increased, while the yield of hydrogen sulfide is diminished several-fold and sulfur is not formed at all. In a flow system at 446–466 °C, small amounts of ethane, ethylene, propane, propylene and butene are also formed.⁴⁵ Thermal stabilities of most dialkyl sulfides both in pure form and in solutions of Surakhansk kerosene (fraction with b.p. 180–200 °C) have been determined.⁴⁶

The decomposition of dialkyl sulfides in the gas phase at 400–800 °C to yield hydrogen sulfide and the corresponding alkenes follows a free-radical mechanism involving the intermediate formation of alkanethiols (Scheme 2).^{42, 47–49}

If the pyrolysis of alkanethiols is carried out in vacuum (0.1 Torr), the yield of hydrogen sulfide is quantitative. Both unsymmetrical dialkyl sulfides and those with branched aliphatic chains are less thermally stable than symmetrical di(*n*-alkyl) sulfides.

Dialkyl sulfides bearing methyl groups in the β -position are converted into the corresponding alkenes and hydrogen sulfide on flash vacuum pyrolysis at about 1000 K.

All derivatives with an α -methyl group and thiirane are more thermally stable and decompose at higher temperatures.⁵⁰

Thiirane is the most stable sulfide despite the strain in its molecule. It forms ethylene, acetylene and hydrogen sulfide at 1270 K.⁵⁰

A new reaction pathway in the thermal decomposition of di(*n*-alkyl) sulfide leading to ethylenethiol and its further conversion into thiophene was found later.^{51, 52} Most likely, ethylenethiol is generated from dimethyl sulfide and other dialkyl sulfides according to a scheme common for all dialkyl sulfides through the initial formation of thiirane and its subsequent isomerisation.

Thiophene is formed from butyl sulfide mostly as the result of an intramolecular cyclisation of the butenethiyl radical **20**.

The gas-phase reactions of dialkyl sulfides with chlorobenzene or 2-chlorothiophene lead to benzo[*b*]thiophene (**1**) and thienothiophenes, respectively.^{52–55}

The reaction of dimethyl sulfide with vinyl chloride in the gas phase at 430–450 °C is accompanied by the formation of 1,1-bis(methylthio)ethane in 30% yield.⁵⁶

Thermolysis of aliphatic sulfides in non-polar solvents (heptane, nonane, octane, decalin) under pressure occurs at 140–250 °C. In these reactions, sulfides and thiols can exchange their RS groups in accordance with the Scheme 1. Highest sulfides and lowest thiols have higher exchange rates.^{48, 57}

Decomposition of aliphatic sulfides at 300–400 °C in melts of ZnCl₂–HCl, ZnCl₂–LiCl, ZnCl₂–SnCl₂, SnCl₂–KCl, ZnCl₂–KCl–NaCl, CuCl–KCl–NaCl eutectics leads to a mixture of alkanes, C₂–C₄ alkenes and hydrogen. Complexes of the (Pr₃S)₃(ZnCl₂)₂ type are formed as intermediate products. In zinc-containing eutectics, sulfides decompose faster to form predominantly alkenes the structures of which correspond to those of the alkyl chains in the starting sulfides. Sulfur is liberated as ZnS, which is then dissolved in the melt.⁵⁸

Thermal decomposition of benzyl methyl sulfide and substituted 1,2-bis(benzylthio)ethanes proceeds according to the Scheme 2.^{5, 59}

Polyethylene sulfide decomposes at 230 °C to form hydrogen sulfide, ethane and a small amount of ethanethiol. The activation energy for this reaction corresponds to the energy of a homolytic cleavage of the C–S bond in macromolecular chains of polyethylene sulfide.⁶⁰

Thermolysis of bis(2-ethoxyethyl) sulfide, 1,1-bis(ethylthio)ethane and 1,3-bis(propylthio)propane involves the initial cleavage of the C–S bonds and occurs in accordance with reactions (1)–(4). The dissociation energies of the C–S bonds in these compounds have been calculated.⁶¹

Heating of dialkyl dithioacetals to 130 °C results in the elimination of a thiol and the formation of the corresponding vinyl sulfide.^{62–64}

R¹ = Alk, Ar; R² = Alk.

The main process is accompanied by the 1,2-migration of the thiyl group and the formation of the saturated sulfide **21** according the following scheme.^{65–68}

Hexakis(alkylthio)- and tetrakis(methylthio)bis(trimethylsilyl)ethanes undergo thermolysis at 110 °C to form the corresponding ethylene derivatives **22** as the result of the alkylthiyl radical elimination.⁶⁹

Vacuum pyrolysis of tetrakis(trifluoromethylthio)methane at 400 °C and 1–1.5 Torr leads mainly to bis(trifluoromethyl) trithiocarbonate together with small amounts of bis(trifluoromethyl) sulfide, bis(trifluoromethyl) disulfide and tetrakis(trifluoromethylthio)ethylene. The latter is formed as the major product on pyrolysis of tetrakis(trifluoromethylthio)methane at 400 °C under atmospheric pressure. The reaction mechanism involves the formation of free radicals and carbenes.⁷⁰

(a) 400 °C, 1 Torr; (b) 400 °C, 760 Torr.

Hexakis(trifluoromethylthio)ethane undergoes the C–C bond dissociation producing tris(trifluoromethylthio)methyl radicals even at 30 °C.⁷¹

2-Chloroethyl methyl sulfide eliminates hydrogen chloride at 360–400 °C.⁷² The rate of its decomposition at 400 °C is 234-fold higher than that for ethyl chloride or ethylene chlorohydrin.⁷²

2-Alkylthioethyl acetates eliminate acetic acid at 460–465 °C to form the corresponding alkyl vinyl sulfides.⁷³

R = Me, Buⁿ, Bu^t, Bn.

2-Alkylthio-1-methylethyl acetates are converted into a mixture of 1- and 3-(alkylthio)propenes at 500 °C. 3-Isomers are predominant at 400 °C and short contact times.⁷⁴

Gas-phase thermolysis of alkyl and cycloalkyl allyl sulfides at 400–500 °C is accompanied by a molecular rearrangement involving either four- or six-membered cyclic transition states and leading to the corresponding alkenes and thioaldehyde.⁷⁵

Upon flash pyrolysis at 600–650 °C, allyl sulfides **23** eliminate propene and are converted into the corresponding thiocarbonyl compounds.^{76,77}

Thioacrolein and thiobenzaldehyde have been found in the pyrolysis products of diallyl and allyl benzyl sulfides.^{76,78} 1,3-Bis(allylthio)propane decomposes at 520 °C to form unstable compounds which are rapidly converted into a polymer built of –S(CH₂)₃S– units.⁷⁹ The extent of isomerisation of a *cis*-rotamer of methyl vinyl sulfide into the *gauche*-rotamer at 200–600 °C is 20%.⁸⁰

2. Vinyl and ethynyl sulfides

Thermolysis of *tert*-butyl 1-propenyl sulfide at 340–390 °C proceeds tenfold faster than that of di(*tert*-butyl) sulfide and is not inhibited by cyclohexene. Isobutene, isobutane and propenylthiyl trimer are the reaction products.⁴⁵

Heating of allyl 2,2-dichlorovinyl sulfide (**24**) at 160–180 °C and of allyl 1,2,2-trichlorovinyl sulfide (**25**) at 100–120 °C results in unusual rearrangements leading to 1,2-dichloropenta-1,4-diene and a mixture of 2,3-dichloro-5-chloromethyl-4,5-dihydrothiophene and 3,5,6-trichloro-3,4-dihydropyran-2*H*-thione, respectively. The mechanism of the reactions involves a [3,3]-sigmatropic rearrangement and the formation of thiirane intermediates.⁸¹

Gas-phase pyrolysis of divinyl sulfide at 450–560 °C gives rise to thiophene in 40% yield.⁸² At 440–460 °C, 2-chlorovinyl sulfide is converted into 2- and 3-chlorothiophene predominantly through the involvement of the *trans*-isomer in this heterocyclisation.⁸³

X = H, Cl.

Thermolysis of di(1-propenyl) sulfide (**26**) in the gas phase at 460–540 °C leads to propenethiol, thiophene, methylthiophenes and 2-ethylthiophene. Heterocycles are formed as the result of the intramolecular cyclisation of the sulfide, involving the intermediate formation of radicals **27** and **28**.⁸⁴

Upon pyrolysis (580 °C) under an atmosphere of nitrogen, alkyl β-styryl sulfides undergo intramolecular heterocyclisation to

give the corresponding benzo[*b*]thiophene derivatives in 50%–70% yields.⁸⁵

$R^1, R^2, R^3 = \text{Alk, Ph.}$

2-Alkoxy(acyloxy)-3-alkyl(aryl)thiocyclobutadienes are converted into the corresponding dienes on heating to 350 °C as the result of the cleavage of the C(1)–C(4) bond in the rings.⁸⁶

$R^1, R^2 = \text{Me, Ph, CO}_2\text{Me, 4-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, \text{COMe.}$

Pyrolysis of 3,4-bis(methylthio)cyclobutene-1,2-dione at 450 °C leads to the ring opening with the formation of bis(methylthio)acetylene and CO. At 550 °C, hydrogen sulfide and methanethiol are also formed in this reaction.⁸⁷

Allyl and propargyl 1,1-dicyano-2-ethoxyvinyl sulfides undergo the Claisen rearrangement on distillation being converted into the corresponding *O*-ethyl thiocarboxylates **29**.⁸⁸

$\text{R} = \text{CH}_2\text{CH}=\text{CH}_2, \text{CH}_2\text{C}\equiv\text{CH.}$

On heating, ketene allyl thioacetals **30** are converted into α -allyl dithiocarboxylates.^{89–91}

$\text{X, Y} = \text{CO}_2\text{Me, CO}_2\text{Et, CN, Ac, Bz etc.}; \text{R}^1 = \text{Al, Alk}; \text{R}^2 = \text{Al.}$

Ketene allenyl thioacetals undergo the Claisen rearrangement on heating to 80–100 °C to form ethyl acetylenedithiocarboxylates, while ketene ethynyl thioacetals are converted at 100–140 °C into dithiocarboxylates containing the allene fragment.^{92,93} In some cases, the latter undergo partial or complete heterocyclisation on distillation to form 2*H*-thiopyrans or substituted thiophenes.

Vacuum pyrolysis of *tert*-butynyl ethynyl sulfide at 500 °C results in the formation of thioketene (**31**), which is more stable than its tautomers, *viz.*, thiirane and ethylthiol.⁹⁴

On heating to 250 °C, dibenzyl sulfide is converted into stilbene with liberation of hydrogen sulfide. The latter partly reduces stilbene to toluene. This produces sulfur which reacts with stilbene to give tetraphenylthiophene.⁹⁵

3. Aryl and hetaryl sulfides

Pyrolysis of a mixture of methyl phenyl sulfide and toluene vapours at 600 °C leads to methane, benzenethiol and dibenzyl. This free-radical reaction was proved to follow a monomolecular mechanism.⁹⁶

The kinetics of the thermal decomposition of methyl phenyl sulfide and benzyl methyl sulfide at low pressure was studied, and the dissociation energies of the PhS–Me and PhCH₂–SMe bonds were found to be 67.5 and 59.4 kcal mol^{–1}, respectively.⁹⁷ The enthalpies of the formation of radicals MeS[•] and PhS[•] are 34.2 and 56.8 kcal mol^{–1}, respectively.⁹⁷

Heating of benzyl phenyl sulfide to 250–270 °C leads to a mixture of liquid and gaseous products, *viz.*, toluene, 1,2-diphenylethane, biphenyl, diphenylmethane, stilbene, benzenethiol, tetraphenylthiophene, benzaldehyde, hydrogen sulfide and carbon dioxide. The yield of benzenethiol reaches 31%.⁹⁸

Flash pyrolysis of benzyl phenyl sulfide in vacuum at 800 °C results in the formation of 1,2-diphenylethane and diphenyl disulfide, which are the recombination products of benzyl and phenethyl radicals, respectively.⁹⁹

1,2-Bis(phenylthio)ethane and its derivatives decompose at 350 °C to form benzenethiol, diphenyl disulfide and the corresponding alkene. The reaction occurs stereospecifically as a *trans*-elimination. Radicals **32a** and **32b** are converted into the corresponding butenes much more rapidly than they isomerise.¹⁰⁰

Decomposition of hexakis(phenylthio)ethane begins at 100 °C to generate tris(phenylthio)methyl radicals detectable by EPR spectroscopy.^{101–104} The cleavage of the C–C bond in hexakis(phenylthio)ethane is mostly caused by steric factors (repulsion of the ArS substituents). The disproportionation of the (ArS)₃C[•] radicals is responsible for the formation of the major reaction products.¹⁰¹

On heating to 200 °C, allyl aryl sulfides undergo the thio-Claisen rearrangement.¹⁰⁵

Allyl 2-benzofuryl and allyl 2-benzothieryl sulfides behave similarly on heating. In the latter case, the rearrangement product undergoes further heterocyclisation.^{106, 107} The thioallyl rearrangement usually precedes the thio-Claisen rearrangement in allyl aryl sulfides. Mechanisms involving the intermediacy of free radicals or a four-membered transition state have been considered for these rearrangements.¹⁰⁸

On flash vacuum pyrolysis, allyl phenyl sulfide undergoes initial cleavage of its C—SPh bond resulting in the formation of phenylthiyl and allyl radicals and their subsequent dimerisation.⁵⁰

The gas-phase reactions of alkyl phenyl and allyl phenyl sulfides with acetylene at 480–600 °C occur selectively yielding benzo[*b*]thiophene (**1**) as the addition product of phenylthiyl radicals to the triple bond of acetylene.¹⁰⁹

R = Me, Et, Prⁱ, All.

Benzothiophene (**1**) was obtained in the highest yield starting from allyl phenyl sulfide, and this reaction occurs at lower temperature. At 600 °C, vinyl phenyl sulfide undergoes an intramolecular cyclisation to form benzothiophene.¹¹⁰

Pyrolysis of bis(phenylthio)acetylene at 560 °C leads to diphenyl sulfide, benzenethiol, thianthrene (**33**) and benzothiophene (**1**). The reaction involves the generation and subsequent transformations of phenyl and phenylthioethynylthiyl radicals.¹¹¹ In the presence of chlorobenzene, diphenyl sulfide is formed upon its reaction with phenylthiyl radicals.

Diaryl sulfides differ from other diorganyl sulfides in that they possess rather strong C—S bonds. These sulfides are usually stable at 400–600 °C, while at higher temperature they undergo intramolecular cyclisations. Thus at 700–750 °C, diphenyl sulfide, phenyl *o*-tolyl sulfide and 2-hydroxyphenyl phenyl sulfide are

converted into dibenzothiophene, thioxanthene and 4-hydroxy-dibenzothiophene, respectively.¹¹² Dithienyl sulfide is less stable: it decomposes at 500–600 °C to give thiophene, isomeric thiophenethiols and bithienyls and also isomerises into 2,3-dithienyl sulfide. These conversions result from the addition of thiyl radicals to the double bonds of thiophene and to the sulfur atom of sulfides.¹¹³

4. Sulfenyl halides and sulfonium salts

Heating of alkanesulfonyl chlorides to 100 °C affords alkyl chlorides in low yield.¹¹⁴ Flash pyrolysis of methanesulfonyl chloride at 590 °C leads to thioformaldehyde.¹¹⁵ Benzenesulfonyl chloride decomposes at 100 °C to form chlorobenzene, diphenyl disulfide and sulfur monochloride. At 90 °C, 4-methyl- and 4-methoxy-benzenesulfonyl chlorides eliminate sulfur to yield the corresponding *para*-substituted chlorobenzenes.¹¹⁴

Phenyldiarylsulfonium halides undergo complete thermolysis at 250 °C yielding a mixture of aryl halides and diaryl sulfides containing all possible combinations of the aryl substituents in their molecules. A pair 2,5-Me₂C₆H₃X and 4-MeC₆H₄SPh is formed in the highest yield upon pyrolysis of (2,5-dimethylphenyl)(phenyl)(*p*-tolyl)sulfonium chloride.¹¹⁶

5. Cyclic sulfides

Thiirane (ethylene sulfide) is the simplest three-membered cyclic sulfide with a thermodynamically unfavourable three-centre dipolar atomic system which is, however, stabilised by the efficient involvement of the non-bonding orbitals of the heteroatom into the frontal interactions.¹¹⁷ A characteristic feature of thiirane and its derivatives is their capacity to split the sulfur atom off yielding the corresponding alkene. The conditions required for this reaction, which can sometimes occur at temperatures below 0 °C, depend on the nature of substituents in the thiirane ring. As usual, the substituents exerting the —E-effect and many π -donating systems facilitate the desulfuration.

Thiirane itself decomposes completely in the gas phase at 250 °C into ethylene and elementary sulfur. This is a first-order homolytic reaction the activation energy of which is 40.2 kcal mol^{–1}. Since this value is lower than the enthalpies of the direct elimination of the sulfur atom from the thiirane ring or of the cleavage of this ring, both these processes can be ruled out from mechanistic considerations. A reaction mechanism involving the intermediacy of the excited thiirane has been suggested.^{118, 119}

This mechanism is supported by the complete stereospecificity of the low-temperature thermolysis of *cis*- and *trans*-2,3-dimethylthiiranes.¹¹⁸

Gas-phase pyrolysis of thiirane at 500–600 °C results in the formation of hydrogen sulfide, ethylenethiol, thiophene, benzo-thiophene and hydrocarbons C₁–C₄ (Ref. 120). Alkyl-, cyclo-alkyl-, 2-aryl- and 2,3-diaryl-thiiranes eliminate sulfur on distillation or moderate heating.^{121–124} Only tetraarylthiiranes decompose at higher temperature (180–215 °C) to form tetraaryl-ethylenes.^{125, 126}

Ar = Ph, 4-MeOC₆H₄, 4-BrC₆H₄, 4-Me₂NC₆H₄ etc.

3,3-Dichloro-2,2-diphenylthiirane undergoes a similar reaction.¹²⁷

Thermal transformations of 3-bromo- and 3,3-dibromo-2,2-diphenylthiiranes are accompanied by intramolecular cyclisations of the initially generated thiyl radicals without elimination of sulfur.¹²⁷

3-Chloro-2,2-diphenyl-3-X-thiiranes also cyclise into the corresponding benzothiophenes on heating.^{128, 129}

Tetrafluorothiirane is distinguished by its high thermal stability. Its partial conversion into difluorothioformaldehyde, tetrafluoroethylene and a number of other products takes place only at 430 °C.¹³⁰

On thermolysis at 340 °C, *cis*- and *trans*-divinylthiiranes undergo the Cope rearrangement into 4,5-dihydrothiepane (34).¹³¹

Dihydrothiophene, thiophene and *cis*- and *trans*-1-phenylbutadienes are the thermolysis products of *cis*- and *trans*-2-vinyl-3-phenylthiiranes at 360–400 °C.¹³¹ When the concentration of thiirane is relatively high, a bimolecular mechanism predominates.¹³² With a decrease in the concentration of thiirane in the reaction, monomolecular desulfurisation becomes the main process.

Pyrolysis of *cis*- (35a) and *trans*-2,3-diethynylthiiranes (35b) in a solution (toluene-*d*₈, 100 °C) yields only sulfur-free alkenes. If the pyrolysis of *cis*-isomer 35a is carried out in a flow system, thienocyclobutadiene is formed in 6% yield along with alkenes. This diene dimerises on standing in benzene solution.

Thus, the data presented here show that in the thermal decomposition of thiirane and its derivatives at temperatures up to 200–350 °C the elimination of sulfur is the main process. The isomerisation of the thiirane ring into an ethylenethiol form is observed only for bromine-substituted diphenylthiiranes. Divinylthiiranes also undergo intramolecular rearrangements. The high-temperature (up to 1000 °C) thermolysis of thiiranes results mostly in the cleavage of the C–S bond in the thiirane ring and its partial isomerisation into ethylenethiol rather than in elimination of sulfur. Unstable biradicals and thiyl radicals thereby formed undergo further decomposition into hydrogen sulfide, hydrocarbons and thiophene.¹²⁰

Four-membered sulfur-containing heterocycles are rather unstable. Thietane (trimethylene sulfide) decomposes on heating to 95 °C. Its thermal destruction in vacuum (250 °C, 10 Torr) leads to an oily polymer and small amounts of hydrogen sulfide, ethylene, ethane, propene and propane.^{117, 131} Thioformaldehyde is the product of the flash pyrolysis of thietane at 1000 °C.¹³³ Photolysis of thietane, 3-ethyl-2-propylthietane and 3-methylthietane in the gas phase, solution and glassy matrices was shown¹³⁴ to involve the cleavage of the C–S bonds and the formation of 1,4-biradicals. Derivatives of thiete (thiacyclobutene) undergo polymerisation even at room temperature. They are relatively stable only in solution.¹³⁵

Five-membered sulfur-containing heterocycles are more stable. Thiolane is stable below 450 °C. The extent of its decomposition at 500 °C is 10% and that at 550 °C is 60%; the products formed include thiophene, hydrogen sulfide and hydrocarbons. 1-Thiaindan decomposes at 450 °C into hydrogen sulfide and thiols.¹³⁶

Thermal decomposition of 2,5-dihydrothiophene at 600 °C leads to thiophene and hydrogen in the ratio of 1:1 along with hydrogen sulfide and polymeric products. Hydrogen is liberated in this reaction synchronously with other products.^{119, 137}

Benzo[b]thiophen-2(3*H*)-one is converted into benzothiophene on flash vacuum pyrolysis (700 °C, 0.05 Torr).¹³⁸

2,3-Dihydrothiophene-2,3-diones and their analogues eliminate CO on flash vacuum pyrolysis to form the corresponding thietones.¹³⁹

Thiophene is stable up to 800 °C, while at 850 °C it decomposes to give a mixture of isomeric bithienyls, benzothiophene, phenylthiophene (7%–8% overall yield) and gaseous products.¹⁴⁰ In a flow-recycling system, the yields of isomeric bithienyls, benzothiophene and phenylthiophene are 30%, 20% and 10%, respectively. Hydrogen sulfide accelerates the thermal transformation of thiophene into isomeric bithienyls, among which 2,3'- and 3,3'-isomers predominate (95% total yield).¹⁴¹

Hydrogen sulfide, thiophene and benzene are the main pyrolysis products of 2-methylthiophene at 825 °C. Aromatic compounds are formed in this reaction as the result of condensations of intermediate radicals and carbenes.¹⁴²

2,3-Dichlorothiophene undergoes the condensation into tetrachloro-3,3'-bithienyl at 560–570 °C.¹⁴³

Vacuum pyrolysis of 1-(2-thienyl)buta-1,3-diene at 525–575 °C and 0.1–1.0 Torr leads to 4,5-dihydrobenzo[b]thiophene.¹⁴⁴

2-Chlorophenyl(2-thienyl)dichlorosilane undergoes heterocyclisation at 480–700 °C.¹⁴⁵

Vacuum thermolysis of thiophene-2,3-dicarboxylic anhydride at 500 °C (1–5 Torr) in a flow system leads to annelated thiophenes, which can be considered as analogues of anthraquinone and fluorenone.¹⁴⁶

Six-membered sulfur-containing heterocycles are less stable than thiophene and its derivatives. Under an argon atmosphere, dihydro-2*H*-thiopyrans undergo rearrangements into the corresponding thiophenes and dihydrothiophene on heating to 260 °C.¹⁴⁷

Fused dihydro-2*H*-thiopyrans undergo a retro-Diels–Alder reaction on flash vacuum pyrolysis.¹⁴⁸

Tetrasubstituted 4-thiapyrones rearrange into the corresponding 2-thiapyrones on heating to 200–250 °C.¹⁴⁹

On flash vacuum pyrolysis, the polynuclear cyclic sulfide **36** eliminates the sulfur atom to form a cyclophane-like hydrocarbon.¹⁵⁰

Benzothiophene and dibenzothiophene are fairly stable in the gas phase. Both the aromatic and thiophene rings are hydrogenated in the reaction of benzothiophene with atomic hydrogen at 150 °C. At 560 °C, only the thiophene ring is hydrogenated providing vinyl phenyl sulfide.^{151, 152} Octachloro-2,3-dihydrobenzothiophene is converted into hexachlorobenzothiophene at 200–250 °C.¹⁵³

Dibenzothiophene does not decompose up to 900 °C. Thianthrene decomposes partially at 550 °C to form dibenzothiophene and benzene. Due to the high stability of these heterocycles, not all sulfur from cyclic sulfides is lost on pyrolysis of coals.¹⁵⁴

The direction of the gas-phase thermolysis of dithiacycloalkanes and alkenes depends on the nature of the heterocycle. The vacuum thermolysis of 1,3-dithianes⁷⁷ and -dithietanes^{155, 156} at 300–750 °C leads to their cleavage into starting monomers, viz., thioaldehydes and thioketenes.

R = H, Ph.

R¹ = CN; R² = CN, COMe, COOEt.

Bis(trifluoromethyl) thioketene is obtained on pyrolysis of its dimer **37** at 650 °C; it can be stored in a sealed tube for several months.¹⁵⁷ Hydrogen sulfide, tetrakis(trifluoromethyl)allene and perfluoroisobutylene are the other products of this reaction.

Thioketenes were characterised by photoelectron spectroscopy (PES) and isolated in the form of dimers or adducts of 1,3-dipolar cycloaddition reactions.

Dicyanothioketene is formed in the vacuum pyrolysis of 2-(4-oxo-1,3-dithietane-2-ylidene)malononitrile (470 °C, 0.05 Torr). However, this thioketene appeared to be extremely unstable and was characterised only by PES.¹⁵⁸

Dithiaspirocycloalkanes with five- and six-membered rings undergo pyrolysis at 600 °C to give cyclopentanethione or cyclohexanethione.¹⁵⁹ Ethylenedithioketal of quadricyclanone undergoes extensive fragmentation at 200 °C to form benzene and hydrogen sulfide.¹⁶⁰

On flash pyrolysis, 1,3-dithiol-2-one (**38**) and its derivatives lose CO to give the corresponding dithietes.¹⁶¹

Dithiete and ethylene are formed in the flash vacuum pyrolysis of 2,3-dihydrodithiine at 700 °C.¹⁶¹

Flash pyrolysis of 1,2-diphenyl-5,6-dihydro-1,4-dithiine at 720 °C (0.1 Torr) involves the elimination of ethylene and leads to polymers which are converted into tetraphenyldithiine on heating in decalin.¹⁶² 1,2-Dithietes or α-dithiones are presumably the intermediate products in these reactions.

The main direction in the flash vacuum thermolysis of 1,4-dithiines at 700 °C involves the extrusion of sulfur and the formation of thiophene.¹⁶¹

Substituted 1,4-dithiines eliminate sulfur even on heating to only 200 °C.^{163–165}

1,3,5-Trithiane and its derivatives decompose to the starting monomers on pyrolysis. Thus thioformaldehyde is formed from trithiane at 600 °C in vacuum.^{166, 167}

Pyrolysis of 2,4,6-trimethyl-1,3,5-trithiane at 600 °C in vacuum leads to monomeric thioacetaldehyde, which has a lifetime of

10 s;^{166, 167} at 450–600 °C and normal pressure; ethylenethiol and thiophene are formed. Thiophene is obtained as the result of the initial isomerisation of thioacetaldehyde and subsequent intermolecular condensation of ethylenethiol.¹⁶⁸

Vacuum pyrolysis of hexamethyltrithiane at 500 °C leads to thioacetone, while at 900 °C it yields thioketene, which results from the thermal decomposition of thioacetone.¹⁶⁹ Under ordinary conditions, monomeric thioacetone is stable for only a few minutes.

The fact that thiobenzaldehyde trimer and high-molecular-mass thiobenzaldehyde polymer decompose at 150 °C producing sulfur and stilbene from which tetraphenylthiophene is formed at 250 °C was established back in the past century.^{170, 171}

Heating of thioacetophenone trimer with rapid distillation of the thermolysis products yields monomeric thioacetophenone. The latter, as well as its trimer, is converted into 2,4-diphenylthiophene, stilbene and ethylbenzene on heating.¹⁷²

IV. Hydrodisulfides

Hydrodisulfides (RSSH) are unstable compounds and are often formed as intermediates in the thermolysis of organic disulfides. Thus the thermal decomposition of di(*tert*-butyl) disulfide apparently results in the initial formation of *tert*-butyl hydrodisulfide, which then rapidly decomposes into isobutene and H₂S.¹⁷³

Diphenylmethyl dihydrodisulfide (**39**) decomposes at 120 °C to form diphenylmethane, bis(diphenylmethyl) tetrasulfide (**40**) and hydrogen sulfide. The reaction involves the initial generation of thiyl radicals **41**, which further react with the starting hydrodisulfide according to a free-radical chain mechanism.¹⁷⁴

V. Disulfides

Organic disulfides are less stable than the corresponding sulfides and therefore readily undergo diverse transformations and react with organic compounds under the liquid- and gas-phase thermolysis conditions.

1. Dialkyl disulfides

Decomposition of dialkyl disulfides begins at temperatures approximately 200–250 °C lower than those required for the thermolysis of the corresponding sulfides.⁴⁵ Temperatures at which dialkyl disulfides decompose completely were determined by PES and decrease with an increase in the length and the branching of an alkyl chain in disulfides (from 1100 K for Me₂S₂ to 690 K for Bu₂S₂).⁵⁰

The corresponding thiols, alkyl sulfides, hydrogen sulfide, saturated and unsaturated hydrocarbons are the main products in the gas-phase pyrolysis of dialkyl disulfides at 500 °C. Also, a small amount of thiophene is formed.⁴⁹ At higher temperatures (580–610 °C), carbon disulfide is the major liquid product (23.5% yield) in the pyrolysis of dimethyl disulfide. From diethyl disulfide under the same conditions, carbon disulfide is formed in only 9.5% yield.¹⁷⁵ Flash vacuum pyrolysis of dimethyl disulfide at 300–700 °C leads to methanethiol and thioformaldehyde, while at 900 °C it mainly yields carbon disulfide.^{77, 176} The addition of methanethiol to the reaction does not affect its rate, whereas hydrogen sulfide substantially accelerates the pyrolysis of dimethyl disulfide.¹⁷⁷ Thioformaldehyde and methanethiol were detected and characterised by PES. Both molecular and radical mechanisms are assumed to be responsible for their formation.^{47, 178–180}

The reactions of thiyl radicals with the starting disulfide lead to its complete decomposition. Vacuum pyrolysis of diethyl disulfide occurs in a similar way.¹⁷⁸ Flash pyrolysis of diisopropyl disulfide presumably occurs through the stage of formation of isopropyl hydrodisulfide (**42**), since more stable propane-2-thiol was not found among the pyrolysis products.⁵⁰

A liquid product obtained upon gas-phase pyrolysis of di(*n*-butyl) disulfide at 500–550 °C represents pure thiophene (40%–60% yield). Gaseous hydrocarbons C₁–C₄ and hydrogen sulfide are the other products.¹⁸¹ The reaction mechanism involves the thermal generation of butylthiyl radicals and their intramolecular cyclisation into dihydrothiophene with its further dehydrogenation.^{137, 182}

Gas-phase pyrolysis of di(*tert*-butyl) disulfide at 330–400 °C in both a flow and a static systems (60–212 Torr) leads to isobutene and *tert*-butyl hydrosulfide. The latter then decomposes into sulfur and hydrogen sulfide on the reactor walls.¹⁸³

Carbon disulfide, hydrogen sulfide, acetylene and methane are formed at 1127 °C.⁴⁵ Since the C–S bond in di(*tert*-butyl) disulfide is weaker than the S–S bond, thiyl radicals are not formed. The initial cleavage of the C–S bond can only induce a short chain process

The formation of isobutane (5% and 13% yields in a flow and a static systems, respectively) confirms this scheme.⁴⁵

Thermal decomposition of bis(diphenylmethyl) disulfide at 150–200 °C leads to thiobenzophenone, diphenylmethane and sulfur. The reaction rate is increased with an increase in temperature.¹⁸⁴

Diallyl disulfide eliminates sulfur on flash pyrolysis. The allyl radical formed in this reaction was isolated in an argon matrix and characterised by UV, IR and EPR spectroscopy.¹⁸⁵

Bis(triphenylmethyl) polysulfides decompose on refluxing in benzene to form hexaphenylethane and sulfur. The thermal stability of $\text{Ph}_3\text{CS}_n\text{CPh}_3$ is decreased with the change in n as follows: $1 > 3 > 4 > 2$ (Ref. 186)

2. Unsaturated, aromatic and heteroaromatic disulfides

Bis(1-methylthiopropenyl) (**43a**) or bis(1-methylthio-2-phenylvinyl) disulfides (**43b**) cyclise into tetra-substituted thiophenes at 100–200 °C. The reactions involve a [3,3]-sigmatropic Cope rearrangement of compounds **43a,b** into the corresponding dithio esters **44a,b** and the elimination of hydrogen sulfide from the latter.^{187, 188}

Benzenethiol and thianthrene are formed from diphenyl disulfide on heating to 260–300 °C in an inert atmosphere. This reaction follows a free-radical mechanism.¹⁸⁹

Analogous products are formed in the thermolysis of bis(4-methylphenyl) disulfide. The formation of phenethyl radicals in the vacuum pyrolysis of diphenyl and 2,2'-dinaphthyl disulfides (400–700 °C) was proved by EPR spectroscopy (in a liquid nitrogen matrix).¹⁹⁰

Thermolysis of diphenyl disulfide at 180–250 °C in an atmosphere of hydrogen sulfide leads to benzenethiol and diphenyl sulfide. The maximum yield of benzenethiol (52%) is achieved at 180 °C, while diphenyl sulfide is the major reaction product (82%) at 250 °C. Benzenethiol and diphenyl sulfide result from two parallel reactions.¹⁹¹

The liberation of sulfur in the thermolysis of diphenyl disulfide predominates at high temperatures and is apparently induced by hydrogen sulfide.

Thermolysis of diaryl disulfides in refluxing tetralin results in the formation of the corresponding arenethiols and 1,2,3,4-tetrahydro-1-arylthionaphthenes.¹⁹²

The following reaction mechanism has been suggested¹⁹²

RH is tetralin, $\text{R}^\bullet$ is a radical derived from tetralin.

The reaction is induced by arylthiyl radicals generated on the thermal dissociation of the S—S bond in diaryl disulfides. The arylthiyl radicals abstract the α -hydrogen from tetralin producing tetralinyl radicals, which react either with thiyl or other tetralinyl radicals. Based on the results of kinetic and UV studies, an assumption that arylthiyl radicals are π -radicals has been put forward.¹⁹²

Diphenyl disulfides with substituents in the *para*-positions of the benzene rings decompose more rapidly. The order in the change in the reaction rates depending on the nature of substituents ($\text{MeO} > \text{Cl} \simeq \text{Me} > \text{H}$) correlates with the stability of the respective thiyl radicals. The latter is increased with the strengthening of the resonance interaction between the substituent and the benzene ring.

Di(2-thienyl) disulfide eliminates sulfur to form di(2-thienyl) sulfide on heating to 130–180 °C in an atmosphere of hydrogen sulfide.¹⁹³

3. Thermal reactions involving disulfides

Thiyl radicals generated on thermal decomposition of dialkyl disulfides can substitute the halogen atom at the sp^2 -hybridised carbon atom and add to the triple bond of acetylene and its derivatives. These reactions predominantly yield heterocyclic compounds of the thiophene series.

The gas-phase reaction of 2-chlorothiophene with diethyl polysulfides at 560 °C leads to a 4:1 mixture of thieno[2,3-*b*]thiophene (**46**) and thieno[3,2-*b*]thiophene (**47**) (in up to 33% overall yield). Thieno[2,3-*b*]thiophene is formed as the result of the addition of vinylthiyl radicals **45** generated from diethyl polysulfides to 2-chlorothiophene and subsequent heterocyclisation.⁵⁵

Both isomeric thienothiophenes are formed in parallel addition reactions of vinylthiyl radicals to thiophene. The latter is obtained on reduction of 2-chlorothiophene with hydrogen sulfide

Chlorobenzene reacts with dialkyl disulfides in the gas phase in a similar way.¹⁹⁴

Aryl bromides effectively react with a diphenyl disulfide–hydrogen sulfide system at 125–240 °C to form aryl phenyl sulfides (49%–84% yields).¹⁹⁵ The reactions occur at a lower temperature if a π -donating substituent is present in the benzene ring of aryl bromides.

Ar = Ph, 2-HOC₆H₄, 4-HOC₆H₄, 4-EtC₆H₄, 4-CNC₆H₄, 1-naphthyl, 2-hydroxy-1-naphthyl.

Phenyl radicals generated from diphenyl disulfide substitute the bromine atom in aryl bromides, thus inducing the reactions. These radicals are generated again in the reaction chain propagation stage, playing also a role as hydrogen atom acceptors from hydrogen sulfide.¹⁹⁵

Dialkyl polysulfides react with acetylene in the gas phase at 470–520 °C to form thiophene (up to 60% yield) and isomeric thienothiophenes. Thiophene arises as the addition product of vinylthiyl radicals **45**, generated on the thermolysis of dialkyl polysulfides, to acetylene.¹⁹⁶

Isomeric thienothiophenes **46** and **47** are formed due to the addition of vinylthiyl radicals **45** to thiophene. The so-called ‘disulfide oil’ representing a mixture of dimethyl, diethyl and ethyl methyl disulfides can be used instead of diethyl disulfide in the reaction with acetylene. On pyrolysis, all these disulfides generate vinylthiyl radicals **45**, which then are trapped by acetylene.¹⁷⁵ However, the yield of thiophene in this case is lower than that obtained from pure diethyl disulfide.¹⁹⁷ If a mixture of diethyl disulfide and diethyl selenide is used in the reaction with acetylene, the yield of thiophene is increased up to 92%.¹⁹⁸

The reaction of 2-chlorothiophene with a diethyl disulfide–acetylene system at 650–700 °C leads to thiophene and thieno[2,3-*b*]thiophene (**46**).¹⁹⁹ Thiophene results from the reaction of acetylene with the vinylthiyl radicals **45**. Thieno[2,3-*b*]thiophene (**46**) is formed due to the reaction of acetylene with 2-thienylthiyl radicals **16** generated *in situ* from 2-chlorothiophene and hydrogen sulfide (the thermolysis product of diethyl disulfide). Acetylene is a more efficient scavenger of thiyl radicals than 2-chlorothiophene; its addition suppresses the competing reaction leading to di(2-thienyl) sulfide.¹⁹⁹

The gas-phase reaction of dimethyl di- or trisulfide with propargyl alcohol at 500 °C leads to 1,2-dithiol-3-one (**48**).²⁰⁰ In this reaction, propargyl alcohol acts as a scavenger of MeSS[•] radicals

Dimethylthiophenes (a mixture of 3,4-, 2,3- and 2,4-isomers) are the main products in the gas-phase reaction of dimethyl di- or trisulfide with a mixture of 1,2- and 1,3-dimethylenecyclobutanes at 450–500 °C.²⁰¹ The reaction involves cyclobutane ring-opening by methylthiyl radicals.

$n = 2, 3$.

Benzo[*b*]thiophene is selectively formed in the gas-phase reaction of diphenyl disulfide with acetylene at 500 °C.²¹

In the gas phase, acetylene reacts with 1,1-dinaphthyl disulfide in the same way as it does with naphthalene-1-thiol (see Section II.2).³⁵

VI. Conclusion

Thus, as can be seen from the data presented here, the thermal reactions of organic compounds of divalent sulfur produce both thiyl radicals and such highly reactive intermediates as thioformaldehyde and its homologues, ethylenethiol, thioketene, etc.

Further transformations of these intermediates and their reactions with thiyl radicals and organic additives result in a great variety of the products obtained on thermolysis and pyrolysis of sulfur-containing organic compounds. Many of these processes are highly selective and can be used for the synthesis of compounds inaccessible by other methods.

VII. Conclusion	102

Abstract. The most reliable values of the basic thermodynamic parameters of the C₆₀ and C₇₀ fullerenes are recommended based on the analysis of the published data and original calculations, viz., enthalpies of formation in the solid and gaseous states, saturated vapour pressures, enthalpies of sublimation, enthalpies of phase transitions, heat capacities, entropies in the condensed state and heat capacities and entropies in the ideal gas state. The factors influencing the results of thermodynamic studies of fullerenes are discussed. Various aspects of crystal structure determination, PVT-relationships and frequencies of normal modes of the C₆₀ and C₇₀ fullerenes are considered in order to interpret and correlate the thermodynamic data and extend them to a wide temperature range. The bibliography includes 135 references.

I. Introduction

The need for the knowledge of thermodynamic properties of fullerenes arises not only from the interest in this unusual class of compounds or the quest for efficient ways of their preparation and practical use. The fullerenes have now become the 'proving ground' for testing virtually all the modern methods of predicting the structure and properties of solids, fluids and ensembles of particles. Therefore, the well-grounded and reliable values of the basic thermodynamic parameters of these compounds are of great importance. Although the extensive literature on fullerenes is available (including reviews^{1–5}), their thermodynamic properties are known less reliably than those of many other 'ordinary' compounds. The publication of a specialised review⁶ devoted to the studies of thermodynamic properties of fullerenes was followed by the appearance of many new communications. However, their results were often contradictory. The main reason for the contradictions seems to lie in the specific properties of fullerenes, which are more sensitive to the sample prehistory and conditions of the experiment than the properties of ordinary organic substances. Understanding of this fact came gradually in the course of thermodynamic and other studies, so that the lack of information at the time of publication of an article often did not enable the

authors to assess the influence of various factors on the final result of their measurements. Therefore, any report on thermodynamic properties of fullerenes should be considered in the light of the overall information available on these compounds with the details of the experiment taken into account.

Based on such an analysis (the experimental data published between 1987 and 1998 have been surveyed), the present review recommends values for the most important thermodynamic parameters of the C₆₀ and C₇₀ fullerenes. The following criteria were used in selecting the experimental data and establishing the recommended values. The characterisation of samples and experimental procedures should be exhaustive in order to rule out the influence of known factors affecting the results of measurements. Preference was given to the results available for the sublimates whose purity and stability were confirmed by independent studies. The precision of the techniques used and reproducibility of the results were taken into account. Thus the heat capacity values measured by adiabatic calorimetry (AdC) were considered to be the most reliable. An agreement between the results obtained by various authors as well as between the thermodynamic parameters of each of the fullerenes were also taken into consideration.

II. Behaviour of fullerenes in thermodynamic studies

The effect of impurities and chemical instability of fullerenes are the factors that hamper the determination of their thermodynamic properties most seriously. Conventional purification procedures and methods of purity control applied to organic compounds appeared to be inefficient for fullerenes which show a tendency towards co-crystallisation with the solvent molecules. Even small amounts of impurities significantly affect various properties of fullerenes. Thus, the phase transition temperature⁷ (T_{tr}) of C₆₀ shifts from 260.7 K to 243 K or to 245 K in the presence of benzene⁸ or toluene admixtures. Also an additional heat capacity anomaly appears at 232 or 239 K, respectively. Two additional heat capacity anomalies,⁹ at 185 and 425 K appear in the C₆₀ sample crystallised from carbon disulfide due seemingly to the presence of a CS₂ impurity. The anomaly observed at 185 K disappears after annealing the sample at 425–500 K. The C₆₀ crystals grown from a solution of fullerene in carbon disulfide are monoclinic, the temperature of the 'ordinary' phase transition being shifted in such crystals to 242 K.¹⁰ The rhombohedral C₆₀ crystals grown from a toluene–hexane solution (the purity is 99.9% from mass spectrometric measurements) undergo a phase

Uspekhi Khimii 69 (2) 107–117 (2000); translated by E Kravchenko

transition associated with a diffuse anomaly of the heat capacity at 239 K.¹¹ It was found that an adduct of the C₇₀ fullerene with toluene (C₇₀·C₇H₈) exhibits heat capacity anomalies at 195 and 430 K (the latter is due to an irreversible decomposition of the adduct).¹² After the decomposition of the adduct, a heat capacity anomaly¹² at 304 K and two phase transitions¹³ at 277.4 and 340.0 K were observed in the sample. It was also found out that several heat capacity peaks observed upon phase transition in C₆₀ are due to the C₇₀ impurity present in the sample.¹⁴

It was found that fullerenes absorb (or adsorb) large amounts of oxygen and, probably, water.¹⁵ Pellet-like samples were kept in a moist oxygen atmosphere under pressure of 30 bar. It was measured that C₆₀ absorbs 30–60 g mol^{−1} in 0.5 h and C₇₀, more than 150 g mol^{−1} in ~24 h. Although these estimates¹⁵ are seemingly overstated (the specific surface of the C₆₀ samples measured with liquid nitrogen¹⁶ was ~3 m² g^{−1}), the uncontrolled adsorption could affect the results of combustion experiments. Two maxima on the temperature curve of desorption of oxygen and other substances plotted for a C₆₀ sample indicate¹⁷ that impurities are absorbed by both the surface and the bulk of a substance. The location of impurities in polycrystalline fullerene C₆₀ has been studied in detail;¹⁶ it was found that the solvent molecules were mainly adsorbed on the surface of microcrystals, whereas upon thermal treatment, they could be fixed in cavities of the baked crystals. This may be a reason why it is difficult to purify fullerenes by heating *in vacuo*.

The thermodynamic properties of fullerenes were reported to depend on the size of crystals in a sample.^{18–21} A finely crystalline C₆₀ sample (**1**) of brown colour which contained 0.004 mol of C₇₀ (from HPLC measurements) exhibited a fall in the phase transition temperature ($T_{tr} = 258.6$ K), a decrease in the enthalpy of combustion ($\Delta_c U^\circ = -35\,896$ J g^{−1}) and incomplete yield of CO₂ in the combustion products (approximately 99.8%) as compared to similar characteristics ($T_{tr} = 260.9$ K; $\Delta_c U^\circ = -36\,030$ J g^{−1}; the yield of CO₂ upon combustion is 100.00 ± 0.04%) exhibited by a chromatographically pure coarsely crystalline C₆₀ sample (**2**) of black colour.²¹ Both samples were dried under the same conditions: for several hours at 440–520 K and a pressure of 0.001 Pa. Kolesov *et al.*²¹ suggest however that the changes in the properties of the sample **1** could be caused by impurities either occluded upon its fast crystallisation or adsorbed by its developed surface.

It was found^{19,20} that the C₆₀ crystals become progressively less capable of solid-state transitions as they are ground. Skokan *et al.*¹⁶ examined this phenomenon in detail to conclude that this results from the defects accumulated in the crystals, the effect of solvent impurity not being involved.

At fairly high temperatures (700 K and above) at which most of the reported effusion measurements have been made, partial decomposition of samples can occur. Thus, a nonvolatile residue (8%) was detected in C₆₀ after it had been sublimed at 1273 K in a nitrogen atmosphere and dried *in vacuo* at 700 K.²² A sample of C₆₀ purified by sublimation at 673 K (the sample purity was 99% from mass spectrometric measurements²³) yielded 5% of a nonvolatile residue after it had been sublimed at 973–1073 K in a nitrogen or an argon atmosphere. After sublimation of the 99.98% pure C₆₀ fullerene, 0.1%–0.3% of the substance still remained nonvolatile, the evaporation of the first half of the sample being followed by a not fully understood fall of the saturated vapour pressure.²⁴ It is suggested that partial transformation of fullerenes into nonvolatile amorphous carbon at 700–740 K may result from contamination of the initial sample with remains of organic solvents.²⁵ Fullerene C₇₀ (98.5% pure, the main impurity being C₆₀) contained 6%–8% of nonvolatile deposit (amorphous carbon) after mass loss of 1% had been detected at 450 K and a cycle of effusive measurements had been performed.²⁶ A sublimed sample was evaporated nearly completely in a repeat run, although some pressure fall was observed in the effusive measurements in carbon cells at 800–900 K and a small amount of nonvolatile deposit was still detected. Destruc-

tion of the C₆₀ and C₇₀ fullerene molecules in the vapour phase²⁷ begins at 2650 and 2440 K, respectively, and in the condensed state,^{28,29} above 1000–1073 K, the temperature limits depending on the nature and content of impurities.²⁵

Therefore, the following strategies appear to be efficient in the preparation of pure specimens suitable for thermodynamic studies: growth of large-sized crystals^{16,21} and sublimation of fullerenes *in vacuo*.^{24,26,30,31} If, prior to sublimation, a sample is dried at a gradually increasing temperature, the major portion of the solvent is probably removed before the degradation (amorphisation) of the basic substance begins.

Experience gained by various researchers suggests^{15,17} that the protection from traces of oxygen is particularly necessary in the sublimation. Fullerenes are known to be vigorously oxidised by oxygen at elevated (> 500 K) temperatures.^{23,32–34} However, under exposure to either high-energy photons or visible light (0.5–5.0 eV), the photoinduced oxidation of the fullerenes by atmospheric oxygen becomes possible at room and even low (20 K) temperatures.³⁵ This imposes additional requirements for the preparatory conditions and purification of fullerenes intended for thermodynamic studies.

Methods of purity control of the samples used for thermodynamic measurements are of principal importance. HPLC is a traditional method which allows determination of the degree of separation of fullerenes with different compositions and the C₆₀O content.¹⁵ It is significant to establish to what extent the organic solvents used for the sample preparation (benzene, toluene, xylene, carbon disulfide, diethyl ether, *etc.*) have been removed. The presence of benzene impurity is determined using ¹H NMR,³⁶ although the sensitivity of the method may be insufficiently high.³⁷ The hydrogen content in a C₆₀ sample is measured by activation analysis.³⁸ The C₆₀ sample was heated in a sealed tube in a nitrogen atmosphere (673 K, 10 min) and the vapour phase was then analysed by GLC.³⁹ Unfortunately, total removal of impurities as well as their constant chemical composition are questionable under such conditions. Volatile substances released upon gradual heating of a C₆₀ sample were analysed by mass spectrometry,¹⁷ but no quantitative estimates of the impurity content were made. The phase transition temperatures and a proportion of nonvolatile deposit found after the sublimation may serve as indirect criteria of the sample purity.

The lack of details in some papers describing the prehistory of samples and methods of their study does not enable one to evaluate the effect of the above-listed factors on the results of measurements of thermodynamic properties.

III. Enthalpies of formation of C₆₀ and C₇₀

The measured enthalpies of combustion and formation of C₆₀ are listed in Table 1. The scatter in the standard combustion energies amounts to ~0.6% (from −35 914 to −36 124 J g^{−1}) which is

Table 1. The enthalpies of combustion and formation of C₆₀.

more than an order of magnitude higher than the experimental error of measurement by combustion calorimetry of organic substances without heteroatoms. The reasons for such a scatter may be the factors that counteract each other, *e.g.*, organic solvent impurities like toluene which are characterised by the heats of combustion of large absolute values (-42382 J g^{-1}) and adsorbed oxygen and water which increase the apparent weight of a sample. The problems of precise determination of the enthalpies of combustion of fullerenes are discussed in a review,⁴⁰ and the enthalpies of formation of carbon clusters in relation to their structures and sizes are analysed in a review.⁴¹ The scatter of the reported enthalpies of combustion $\Delta_c H^\circ$ lies within 0.12%,^{15,21,39,42} The results of earlier publications lie outside this interval. Five experiments performed on presumably one of the best C₆₀ samples (purified by sublimation)¹⁵ gave, for unclear reasons, a wide dispersion of the results. Kolesov *et al.*²¹ examined a specially prepared coarsely crystalline sample; an analysis of the combustion products gave the CO₂ yield of $100.00 \pm 0.04\%$. A similar result was obtained³⁹ (see Table 1) using large samples (of approximately 0.5 g) and an original GLC-analysis of organic solvent contaminations in fullerene (0.013 mass % of diethyl ether and 0.007 mass % of *o*-xylene). Later, An *et al.*⁴² gave the enthalpy of C₆₀ combustion which was slightly different from their previous result.³⁹ Therefore, the value $\Delta_f H^\circ(\text{cr}) = 2346 \pm 12 \text{ kJ mol}^{-1}$ which is an average of the published data^{21,42} is recommended for the enthalpy of formation of C₆₀ in the crystalline state.

The enthalpy of formation in the gaseous state is $\Delta_f H^\circ(\text{g}) = 2530 \pm 13 \text{ kJ mol}^{-1}$, the enthalpy of sublimation of C₆₀ ($\Delta_{\text{sub}} H^\circ = 183.7 \pm 5.1 \text{ kJ mol}^{-1}$) being taken into account.

The measured combustion energy values $\Delta_c U$ for the C₇₀ fullerene (Table 2) are scattered even wider, over more than 0.7% (from $-35 587$ to $-35 828 \text{ J g}^{-1}$). The reasons for the scatter are evidently similar to those for C₆₀. The uncertainty of the crystal composition of C₇₀ at 298.15 K which is discussed

below cannot have a notable effect on the error in determination of the enthalpy of formation, because the energy difference between different crystal modifications of C₇₀ is two orders of magnitude smaller. It is likely that the best sample of this fullerene purified by sublimation was studied by Beckhaus *et al.*,¹⁵ therefore their results are recommended as most reliable. Only in one publication⁴⁴ was the amount of CO₂ in the combustion products measured to find a yield of $99.81 \pm 0.02\%$. Assuming that the material balance on carbon⁴⁴ was upset due to the presence of inert impurities (adsorbed gases or water) in the C₇₀ finely crystalline sample and relating the heat of combustion to the appropriate amount of CO₂, one obtains the value $\Delta_c U^\circ = -35 732.5 \pm 42 \text{ J g}^{-1}$, which is close to that given by Beckhaus *et al.*¹⁵ The data by Diogo *et al.*⁴⁵ are also close to the latter value¹⁵, but one cannot say, judging from the results of HPLC analysis of C₇₀ fullerene,⁴⁵ whether toluene was completely removed from the sample. We cannot offer an explanation of a low absolute value of the enthalpy of C₇₀ combustion reported by An *et al.*⁴²

Thus, the recommended value for the enthalpy of formation¹⁵ of C₇₀ is $\Delta_f H^\circ(\text{cr}) = 2555 \pm 22 \text{ kJ mol}^{-1}$. With the enthalpy of sublimation of C₇₀ $\Delta_{\text{sub}} H_{298.15}^\circ = 200.3 \pm 6.1 \text{ kJ mol}^{-1}$ taken into account, the enthalpy of formation in the gaseous state at 298.15 K is $\Delta_f H^\circ(\text{g}) = 2755 \pm 23 \text{ kJ mol}^{-1}$.

IV. Heat capacities in the condensed state and thermodynamics of phase transitions in C₆₀ and C₇₀

It is now commonly accepted that the C₆₀ fullerene crystallises at $T = 298.15 \text{ K}$ and pressure $P = 1 \text{ atm}$ in a face-centred cubic lattice with $a = 14.152 \text{ \AA}$ and $d = 1.69 \text{ g cm}^{-3}$ (see Ref. 17). Molecular rotation in such a crystal results in an orientational disorder. Upon cooling below 260 K, a solid-state transition occurs. In the low-temperature modification,^{46,47} the C₆₀ molecules have four different orientations in space making a simple cubic lattice. Some rotational degrees of freedom are retained in this case. The remaining rotational degrees of freedom freeze upon vitrification of the crystal⁴⁸ at around 90 K. From calorimetric measurements, the vitrification temperatures are $T_g = 86.8$ (see Ref. 49) and 86.0 K (see Ref. 7). The residual entropy of C₆₀ at 0 K was estimated to be 4.7 ± 0.5 (see Ref. 50) and $4.9 \text{ J K}^{-1} \text{ mol}^{-1}$ (see Ref. 7). Although the estimation procedures are not indisputable, we see little reasons for revising the results. As reported by Willart *et al.*,⁵¹ no other transitions occur in an impurity-free C₆₀ sample at atmospheric pressure.

Table 3 lists the measured enthalpies of phase transition $\Delta_{\text{tr}} H$ in C₆₀ around 260 K. Probable reasons for the scatter in T_{tr} and

Table 3. Thermodynamic characteristics of a solid-state transition in C₆₀.

T_{tr} / K	$\Delta_{\text{tr}} H / \text{kJ mol}^{-1}$	Sample	Method	Note	Ref.

Extracted with a benzene–hexane mixture, chromatography, dried at 523 K for 24 h, single crystal	MC	120–300	11
Extracted with toluene, chromatography, dried at 400 K, 99.98 % pure ^d	AdC	5–339	7

Note. MC is modulation calorimetry. ^a From mass spectra and Raman spectra; ^b no phase transitions occur upon further heating to 950 K; ^c from HPLC measurements; ^d from HPLC and X-ray diffraction.

$\Delta_{tr}H$ values were discussed in Section II. In addition, the transition is not isothermal (2N-type according to the classification of Westrum and McCullough⁵⁵), which makes difficult both the interpretation of the calorimetric data and the choice of the heat capacity baseline in the calculation of the enthalpy of phase transition. This seems to account for the large value of $\Delta_{tr}H$ reported by Dworkin *et al.*¹⁹ The values^{7,49} of $\Delta_{tr}H$ measured by an adiabatic calorimetry are in good agreement with each other. The values measured in 1993 using differential scanning calorimetry (DSC) are fairly close to them.^{19,47,54} For the calculation of the entropy of the crystalline C_{60} , one should know the value of $\Delta_{tr}H$ together with the heat capacity values, which rules out the use of $\Delta_{tr}H$ averaged over several published data. Therefore, we recommend the values⁷ $T_{tr} = 260.7$ K and $\Delta_{tr}H = 7.46 \pm 0.15$ kJ mol^{−1} which are consistent with the heat capacity values recommended in the same publication.⁷

The heat capacities of C_{60} samples of different qualities measured by various methods are listed in Table 4. All the published results except for the data given in Refs 7, 37, 53 were presented only in a graphical form to show a fairly good agreement with each other (except for the data³⁷). Thus, the recommended values of thermodynamic parameters for the solid C_{60} in the interval 0–1000 K (Table 5) were listed based on the heat capacities measured by AdC⁷ in the range 5–340 K and by DSC⁵³ in the range 340–560 K. Because the Debye characteristic temperature of fullerenes is low, it is important to know their heat capacity below 5 K. Allowance is made in Table 5 for the heat capacities of C_{60} in the range 0–10 K which were measured by a thermal relaxation method (the graphical data⁵⁶). We extended the heat capacity values to the interval 560–1000 K by a procedure described by Jin *et al.*⁵³ The heat capacity C_V of a crystal was represented by a sum of contributions of the lattice (C_{lat}) and intramolecular (C_{int}) vibrations

$$C_V = C_{lat} + C_{int}.$$

The contribution of the intramolecular vibrations was calculated by methods of statistical thermodynamics using the set of normal modes chosen as described in Section VI. The contribution of the lattice translational modes at $T > 298.15$ K was taken to be $3R$, whereas that of the librational modes (or molecular rotation in a crystal) was calculated for the hindered rotation of the C_{60} molecules using a harmonic potential. The effective value of the potential barrier to molecular rotation (5 kJ mol^{−1}) was chosen to provide the best fit of the calculated heat capacities with their measured values in the range 300–560 K. A relatively low value of the potential barrier is qualitatively consistent with both

the spherical shape of the C_{60} molecule and the absence of heat capacity jump upon the solid-phase transition.⁵⁷

^a A 3 : 1 mixture of C₆₀ and C₇₀.

C_P was calculated from C_V by the relationship

$$C_P - C_V = \frac{\alpha^2}{\beta} V_m T,$$

where α is the volume expansion coefficient, β is the isothermal compressibility coefficient, V_m is the molar volume. The following values were accepted for α and β at 300 K: $\alpha = 4.6 \times 10^{-5} K^{-1}$, $\beta = 1.55 \times 10^{-10} Pa^{-1}$ (Table 6). At this temperature, the difference $C_P - C_V$ was as low as $1.8 J K^{-1} mol^{-1}$, which appeared to be much less than the value estimated by Jin *et al.*⁵³. The difference $C_P - C_V$ was extended to $T = 1000 K$ using the procedure described by the same authors

$$C_P - C_V = k C_V T, \quad (1)$$

the value of k ($1.16 \times 10^{-5} K^{-1}$) was calculated from the data at 300 K.

The calculated heat capacities of the C₆₀ crystal (Fig. 1) are in good agreement with those measured by DSC⁵³ in the interval 500–550 K, whereas at 300 K, they are $11 J K^{-1} mol^{-1}$ (or $\sim 2\%$) less than the values measured by AdC.⁷ We estimate the error of the entropy determination of C₆₀ to be ± 2 and $\pm 13 J K^{-1} mol^{-1}$ at 298.15 and 860 K, respectively.

The Debye characteristic temperature of C₆₀ estimated from the heat capacity measurements in the interval 0–5 K amounts to $\sim 46 K$, which is close to the value predicted based on the law of corresponding states with the inert gases (40 K).⁵

Figure 1. The heat capacity of the C₆₀ fullerene vs. temperature. (1) the DSC data;⁵³ (2) the AdC smoothed data;⁷ (3) our calculations.

In a recent paper,¹³ the data reported on the heat capacity^{65–67} and thermodynamics of phase transitions^{12,68} in C₇₀ were compared and commented. We are also aware of reports^{69–72} the results of which require no revision.¹³ The phase state of C₇₀ fullerene is influenced by the sample prehistory.^{73–79} A crystal I in the high-temperature phase characterised by an isotropic molecular rotation can form either a hexagonal or a face-centred lattice. With time, it transforms to a crystal having a face-centred lattice which however comprises 10%–20% of a hexagonal phase. Upon cooling, the crystal I converts to the crystal II characterised by partially frozen rotational degrees of freedom and having either a rhombohedral or a distorted hexagonal ($c/a = 1.82$) structure with considerable admixture of hexagonal or rhombohedral phases, respectively. Upon further cooling, a monoclinic phase III arises which, unlike the low-temperature C₆₀ fullerene crystal, does not undergo transition to the vitreous state. At increased pressure, the transition to the phase III splits into two phase transitions. Some researchers report that the double peak on the heat capacity curve is observed also at atmospheric pressure and explain this phenomenon by either a mixture of the crystal phases present in a sample or successively proceeding phase transitions. It might be suggested from the aforesaid that two modifications of the low-temperature monoclinic crystal are available and the residual entropy of C₇₀ is not zero at 0 K. Unfortunately, the latter could not be estimated. Note that according to Ref. 13, the transformation of the crystal III to II (Table 7) is associated with one peak on the heat capacity curve.

We calculated the thermodynamic parameters of solid C₇₀ in the range 0–340 K (Table 8) based on the heat capacities measured by AdC.¹³ To our knowledge, the report¹³ is the only one which gives the numerical values of heat capacities of C₇₀ in this temperature range. In the range 340–560 K, we used the heat capacities measured by DSC.^{13,65} The heat capacity of C₇₀ was earlier extended to $T = 1000 K$ (see Refs 26 and 65); we made an extension by a procedure identical to that for C₆₀. The contribution of intramolecular vibrations was calculated using the same set of frequencies as that accepted for the calculation of the thermodynamic properties in the ideal gas state (see Section VI). The translational contribution of the lattice heat capacity was accepted to be $3R$, the librational one was calculated for the hindered rotation of the C₇₀ molecules using the harmonic potential. To give the calculated heat capacity the best fit to its measured values in the range 300–560 K, the effective potential barrier to molecular rotation was chosen to be $3 kJ mol^{-1}$. The difference $C_P - C_V$ was estimated to be $2.6 J K^{-1} mol^{-1}$ at $T = 365 K$ assuming $\alpha = 4.6 \times 10^{-5} K^{-1}$ and $\beta = 1.25 \times 10^{-10} Pa^{-1}$ (see Ref. 80). It was extended to a high-temperature region using Eqn (1). The value of k ($9.44 \times 10^{-6} K^{-1}$) was calculated from the data at 365 K.

The calculated heat capacities of crystalline C₇₀ (Fig. 2) are close to their experimental values at all the temperatures except for those around 400 K where they are $30 J K^{-1} mol^{-1}$ ($\sim 4\%$) larger than those measured by DSC.⁶⁵ In that region, the curve lies below the line connecting the adjacent regions, the reason being as yet unexplained. We estimate the error in the entropy determination of C₇₀ to be ± 3 and $\pm 15 J K^{-1} mol^{-1}$ at 298.15 and 843.5 K, respectively.

Note that in the interval 100–1000 K, excluding the phase transition areas, the heat capacities per carbon atom of the C₆₀

and C_{70} fullerenes are similar to those of graphite, although these are markedly different in the molecular composition and the crystal structure. It is noteworthy that unlike most organic substances, the temperature dependence of the heat capacities of fullerenes exhibits two inflections, which are caused by low Debye temperatures (~ 46 K and ~ 40 K for C_{60} and C_{70} , respectively) and low libration frequencies. When temperature increases from 0 to ~ 30 – 50 K, both the Debye and librational contributions to the fullerene lattice heat capacity approach their limiting values $3R$, whereas the intramolecular contributions still remain small in

**Figure 2.** The heat capacity of the C_{70} fullerene vs. temperature; (1) the DSC data;⁶⁵ (2) the AdC smoothed data;¹³ (3) our calculations.

this temperature range. In the range 30–50 K, the heat capacity remains relatively stable varying within 40–50 $\text{J K}^{-1} \text{mol}^{-1}$ (close to $6R$), which indicates that the Debye and librational contributions to the heat capacity are saturated. For most of organic substances, such a saturation occurs at higher temperatures being masked by an increasing contribution of the intramolecular vibrations.

Various computational approaches, from the Debye models with adjustable parameters^{22,56} to those based on the examination^{81,67} and integration^{53,82} of phonon spectra of crystals may give a key to a more comprehensive interpretation of the heat capacities of fullerenes in the condensed state. Both theoretical^{83–87} and experimental^{88,89} data on the fullerene lattice vibrations can be found in the literature.

V. Saturated vapour pressures and enthalpies of sublimation of fullerenes

The results of a recent extensive study by Piacente *et al.*²⁴ gave the saturated vapour pressure (P) and the enthalpy of sublimation of C_{60} measured by the Knudsen method, which is one of the most precise methods for measuring low vapour pressures. The problems of sample purity and stability (see Section II) were closely examined, and earlier publications^{23,25,90–96} were surveyed.²⁴ We are also aware of other reports.^{97–103} Most of the results are merely consistent with those by Piacente *et al.*²⁴ in order of magnitude. The methods of measurement and preparatory procedures described²⁴ suggest that the following values of saturated vapour pressure and enthalpy of sublimation are most reliable:

$$\ln P(\text{kPa}) = (19.07 \pm 0.46) - (21\,078 \pm 350)/T \quad (T = 730\text{--}990 \text{ K}),$$

$$\Delta_{\text{sub}}H_{860} = 175.3 \pm 2.9 \text{ kJ mol}^{-1}.$$

It follows from these values and the data listed in Table 5 that at $T = 860$ K and $P = 1$ bar, the experimental magnitude of entropy of C_{60} in the gaseous state amounts to $S_{860}(\text{g}) = 1481 \pm 14 \text{ J K}^{-1} \text{mol}^{-1}$. With the heat capacity of the crystal (see Section IV) and the results of statistical calculations of the heat capacity of a gas (see Section VI) taken into account, the enthalpy of sublimation of C_{60} at $T = 298.15$ K was recalculated:

$$\Delta_{\text{sub}}H^\circ = 183.7 \pm 5.1 \text{ kJ mol}^{-1}.$$

The saturated vapour pressure and enthalpy of sublimation of C_{70} were determined by Piacente *et al.* in their extended research.²⁶ In addition to the reports^{25,92–94,104} discussed in Ref. 26, we are also aware of other publications (Refs 101 and 105). The values

$$\ln P(\text{kPa}) = (19.30 \pm 0.35) - (22\,835 \pm 370)/T \quad (T = 783\text{--}904 \text{ K}),$$

$$\Delta_{\text{sub}}H_{843.5} = 189.9 \pm 3.1 \text{ kJ mol}^{-1},$$

determined for the freshly sublimed C_{70} sample²⁶ are recommended as most reliable by the same reasoning as those for C_{60} .

Based on these values and the data listed in Table 8, one can deduce that the experimental value of the entropy of C_{70} in the gaseous state amounts to $S_{843.5}(\text{g}) = 1653 \pm 16 \text{ J K}^{-1} \text{mol}^{-1}$ at $T = 843.5$ K and $P = 1$ bar. With the crystal heat capacity (see Section IV) and the results of statistical calculations of the heat capacity of a gas (see Section VI) taken into account, the enthalpy of sublimation of C_{70} at $T = 298.15$ K was recalculated to be

$$\Delta_{\text{sub}}H^\circ = 200.3 \pm 6.1 \text{ kJ mol}^{-1}.$$

VI. Thermodynamic properties of C_{60} and C_{70} in the ideal gas state

Thermodynamic properties of fullerenes in the gaseous state were calculated by the methods of statistical thermodynamics.^{6,24,26} All the calculated entropy values of C_{60} appeared to be lower than the experimental ones (see Section V). In our opinion, the most reasonable set of frequencies of normal modes was used by

Piacente *et al.*²⁴ They averaged the values measured using IR¹⁰⁶ and Raman spectroscopy,^{107–109} inelastic neutron scattering^{110,111} and those derived from the calculations of the normal modes.¹¹² It appeared that the statistical calculation carried out using the average frequencies of normal modes gives the entropy of gaseous C₆₀ which is closest to its experimental value. Schettino *et al.*¹⁰⁶ gave also a short survey of the spectroscopy and assignment of the C₆₀ vibration frequencies. Later, other reviews on IR spectroscopy of fullerenes¹¹³ and assignment of the C₆₀ vibration frequencies^{114–121} were published. To our knowledge, no contradictions exist at present as to the interpretation of the C₆₀ molecular vibration frequencies.

In the present review, the thermodynamic parameters of fullerenes in the ideal gas state were calculated as described by Frenkel *et al.*¹²² The translational contributions of C₆₀ and C₇₀ were calculated using their molecular masses equal to 720.66 and 840.77, respectively. In the calculation of rotational contributions, the symmetry numbers 60 and 10 and the products of the principal moments of inertia ($I_A I_B I_C$) equal to 1.00×10^{-129} and 2.50×10^{-129} kg³ m⁶ were used for C₆₀ and C₇₀, respectively. The two latter values were calculated by the models fairly consistent with the X-ray structural results¹²³ (for C₆₀) and the electron diffraction data¹²⁴ (for C₇₀). The scatter in the entropy values of C₆₀ in the gaseous state does not exceed 0.2 J K⁻¹ mol⁻¹, although different estimates of the moments of inertia are available in different publications. The frequencies of normal modes of C₆₀ (Table 9) were averaged over the measured values.¹⁰⁶ The contribution of the excited electronic states (assuming that all the remaining contributions are independent on the electronic state of molecules) was estimated from the relative energies of one-electron states (Table 10). According to the model used, the contribution of the excited electronic states to the heat capacity of C₆₀ at temperatures above 3000 K amounts to 5 J K⁻¹ mol⁻¹, whereas a similar contribution to the entropy is reached at 4500 K. The calculated value of S_{860}° (1463.8 J K⁻¹ mol⁻¹, Table 11) is 17 J K⁻¹ mol⁻¹ smaller than that determined experimentally (1481 ± 14 J K⁻¹ mol⁻¹). Therefore, 17 J K⁻¹ mol⁻¹ can be considered as the error in calculation of the entropy of C₆₀ in the gaseous state. This comprises ~1.5% of the vibrational contribution to the entropy, as in the case of the cage hydrocarbons C₁₁H₁₄ and C₁₄H₁₆ with rigid carbon skeletons.^{129,130} To make both the entropy of fullerenes in the gaseous state and the heat capacity of a crystal (see Section IV) consistent with the experimental data, we examined a possibility to revise the C₆₀ vibration frequencies. In order for the calculated entropy of C₆₀ in the gaseous state to be equal to its measured value, one has to reduce the wave numbers hence breaking the agreement of the calculated heat capacity of a crystal

Note. I, see Ref. 125; II, see Ref. 126; III, see Refs 127 and 128; IV, the energies used in the calculations of contributions of the excited electronic states to the thermodynamic parameters (Table 11).

with the experiment. Therefore, the agreement currently available between the thermodynamic and molecular data on the C₆₀ fullerenes seems to be the best at present.

The set of frequencies of the C₇₀ normal modes (Table 12) was obtained by averaging the experimental values (the IR^{114,131,132} and Raman^{114,131} spectroscopic data) based on the reported frequency assignment^{133,134} (see Ref. 26). The report¹³³ was followed by publication of the data¹¹³ on IR spectroscopy of fullerenes and assignments of frequencies of the C₇₀ normal modes^{115,117,118,121} which require no revision.^{133,134}

The calculated value of $S_{843.5}^\circ$ (1669.2 J K⁻¹ mol⁻¹) is 16 J K⁻¹ mol⁻¹ larger than the experimental one (1653 ± 16 J K⁻¹ mol⁻¹). This difference can be considered as the uncertainty in the calculated entropy of C₇₀ in the gaseous state. Unfortunately, we have no information on a reasonably complete set of the excited electronic state energies for the C₇₀ molecule. The experiments^{127,135} provide evidence that the low-lying electronically excited states are expected to have slightly lower energies than those of C₆₀. Nevertheless, it is believed that only at temperatures above 3000 K does the neglect of the excited electronic state contributions increase significantly the error in the calculation of the entropy of C₇₀ in the gaseous state.

Table 11. The thermodynamic properties of the C₆₀ and C₇₀ fullerenes [S° , C_p° , $(H-H_0)/T$ and $-(G-H_0)/T$ in J K⁻¹ mol⁻¹; $\Delta_f H^\circ$ and $\Delta_f G^\circ$ in kJ mol⁻¹] in the ideal gas state at 101 325 Pa.

VII. Conclusion

Based on the analysis of the published data, the values of the most important thermodynamic parameters are recommended for the C₆₀ and C₇₀ fullerenes in the crystalline state in the temperature range 0–1000 K and in the gaseous state in the range 100–5000 K. We believe that their further refinement will be made within the limits of error outlined in the present review.

II. Synthesis of alkenyliodonium salts	106
III. Reactions of alkenyliodonium salts	111
IV. Conclusion	118

Abstract. New data on the synthesis and chemical transformations of alkenyliodonium salts are summarised and analysed. The bibliography includes 146 references.

I. Introduction

The first synthesis of a three-coordinated iodine with at least one C–I bond was reported by Willgerodt in 1886.¹ Following preparation of (dichloro- λ^3 -iodanyl)benzene[†] (**1**) by chlorination of iodobenzene, Willgerodt soon synthesised (diacetoxy- λ^3 -iodanyl)benzene (**2**) and other organic derivatives of three- and poly-coordinated iodine. By the time of the publication by Willgerodt in 1914 of his comprehensive treatise² on the chemistry of hypervalent iodine that summarised the data on the synthesis of tri- and pentavalent iodine-containing organic compounds, about 500 such compounds were already known. Among them, diaryliodonium salts **3** were examined most thoroughly.

The chemistry of organic compounds of polyvalent iodine was the subject of several reviews (see, for example, Refs 3–5). However, because of rapid development of this chemistry, it is nearly impossible at the moment to consider all its aspects in the framework of only one publication.

A brief review⁶ has been published on iodonium salts; they were also considered in a chapter of a monograph⁷ devoted to organic compounds of polyvalent iodine. The chemistry of

diacyloxyiodanylarenes was treated in a special review⁸ and the application of these compounds as oxidising reagents is described in a monograph.⁹ A review¹⁰ devoted to the use of compounds of polyvalent iodine, mostly organic compounds, has also been published. Interesting data on the chemistry of iodonium salts can be found in the book ‘The Problems of Organic Chemistry’^{11,12} and those on the chemistry of diacyloxyiodanylarenes in two other books;^{13,14} derivatives of iodosylarenes are discussed in a separate review.¹⁵

Organic compounds of three- and poly-coordinated iodine are widely used as reagents in modern organic chemistry. Particular areas of synthetic application of these compounds vary depending on their structures, *viz.*, on the number of organic ligands at the iodine atom^{4,7} and on the electronegativity and nucleofugality of their heteroatomic ligands.

All compounds of polyvalent iodine can be conventionally divided into several groups. The first one comprises compounds with one carbon ligand (RIX₂ and RIX₄), *viz.*, hydroxy(sulfonyloxy)- λ^3 -iodanylarenes, periodinanes, substituted benzoiodoxols and azides of trivalent iodine.^{8,10,16–30} Compounds of this group are employed for selective oxidation of various organic substrates. The second group of polyvalent iodine compounds includes iodonium salts R₂I⁺X[–] with two carbon ligands.^{8,10,16–30} Iodonium salts do not possess strong oxidising properties and are mainly employed as precursors of nucleophilic species resulting from transformations of an organic ligand.

Depending on the nature of the organic ligand R, iodonium salts, in turn, can be conventionally classified as alkyl-, polyfluoroalkyl-, alkenyl- and alkynyl-iodonium salts. Most of alkyl-iodonium salts Alk₂I⁺X[–] or Alk(Ph)I⁺X[–], with a few exceptions,³¹ are unstable and therefore have not been exploited in organic synthesis. On the contrary, polyfluoroalkyliodonium salts R_f(Ph)I⁺X[–] are stable and represent effective electrophilic polyfluoroalkylating reagents.³² Compounds of three-coordinated iodine with three organic ligands are, as a rule, unstable at room temperature; only a few stable representatives of this class are known to date.^{33–35}

Derivatives of the type **4** containing an alkynyl group as a substituent were unknown until recently. The intense development of the chemistry of alkenyliodonium salts **5** began only recently, although the first representative of this class of compounds was described back in 1914.²

At the moment, synthetic aspects of the chemistry of alkynyl-iodonium salts are well developed and discussed in detail, for

[†] This naming is given in accord with IUPAC Nomenclature of Organic Compounds (Recommendations 1993). Furthermore, symbol λ^3 can be omitted from the names of iodine-containing compounds.

example, in monographs^{36–38} and reviews^{25,39,40} One of these reviews²⁵ contains a section treating the chemistry of alkenyliodonium salts. This chemistry was also briefly considered in another review⁴¹ devoted to organic compounds of polyvalent iodine. However, new important results obtained recently in this field deserve generalisation.

It is the purpose of this review to systematise and analyse the data on the synthesis and properties of alkenyliodonium salts which were mainly published over the last 10–15 years. Earlier publications are cited only as may be necessary for the better elucidation of the issues in question.

II. Synthesis of alkenyliodonium salts

In recent decades, the interest in alkenyliodonium salts has sharply increased. Alkenyliodonium salts bearing not only alkyl, but also aryl, triflate, mesylate and other substituents at the double bond were synthesised. These compounds were demonstrated to be very promising intermediates for organic synthesis.

At present, several types of alkenyliodonium salts are known, viz., those with one (**5**) or two (**6–8**) alkenyl groups and also cyclic alkenyliodonium salts of the type **9** and **10**.

Several methods for the synthesis of alkenyliodonium salts have been described earlier.⁷ However, none of them has been really convenient until recently. At present, a number of new methods have been developed, however, these did not receive much attention in relevant reviews.^{25,41} Taking this fact into account, we systematise in this Section the published data on the synthesis of alkenyliodonium salts.

These syntheses are based on the use of electrophilic λ^3 -iodanes. Among compounds of polyvalent iodine, the Koser reagent **11**, complexes of iodosylbenzene **12** and **13**, alkynyliodonium salts **4**, the iodosylbenzene trifluoromethanesulfonic acid complex **14**, cyano(hydroxy)- λ^3 -iodanylbenzene triflate and tosylate (**15a,b**), fluoro(hydroxy)- λ^3 -iodanylbenzene sulfonates (**16a,b**) are the key reagents.

1. Syntheses starting from dichloro- λ^3 -iodanylbenzene and dichloro- λ^3 -iodanylalkenes

Early methods for the synthesis of alkenyliodonium salts were based on the reactions of organometallic derivatives of alkynes with dichloroiodanylarenes. Using this approach, alkenyliodonium salts **17a,b** have been synthesised.² However, on the whole, this method was rather ineffective and had a number of limitations.

R = H, Ar = Ph (**17a**); R = Me, Ar = C₆H₄Me-2 (**17b**).

Later, the reactions of organomercuric derivatives of alkenes with dichloroiodanylarenes were proposed to synthesise alkenyliodonium salts.^{42–44} Thus the treatment of *trans*-chlorovinylmercuric chloride with various dichloroiodanylarenes in dilute hydrochloric acid results in arylvinyliodonium mercurates **19** in 5%–53% yields. The latter can be converted into the corresponding arylvinyliodonium chlorides **17a,c–k** upon treatment with hydrogen sulfide.

Ar = Ph (**a**), 2-MeC₆H₄ (**c**), 3-MeC₆H₄ (**d**), 4-MeC₆H₄ (**e**), 2-ClC₆H₄ (**f**), 3-ClC₆H₄ (**g**), 4-ClC₆H₄ (**h**), 2-MeOC₆H₄ (**i**), 4-MeOC₆H₄ (**j**), 3-NO₂C₆H₄ (**k**); X = Cl·HgCl₂, Cl·2 HgCl₂.

The reaction of vinyl- or styryltrichlorostannane with dichloroiodanylbenzene (**1**) leads to alkenyliodonium salts **20** or **21**.^{45,46}

1-Chloro-2-dichloroiodanylethylene **22** has been synthesised for the first time by the reaction of *trans*-chloroiodoethylene with chlorine.⁴⁷ Later, compound **22** was obtained in high yield by the reaction of acetylene with iodine trichloride.⁴⁸ Compound **22** is unstable at room temperature, but can be stored below –20 °C for two months without noticeable changes. This reagent is employed for the synthesis of alkenyliodonium salts. Thus its reactions with silver acetylide or phenyltrichlorostannane afford compounds **23** and **24**.⁴⁶

Diphenyliodonium chloride rather than a vinylidonium salt of the type **24** is formed from 1-dichloroiodanyl-2-iodoethylene in 50% yield.⁴³ Organolithium derivatives react with compound **22** to give cyclic iodonium salts **25** and **26**.⁴⁹

It should be noted that the reaction of dichloroiodanylbenzene with an equivalent amount of vinylolithium in THF at –70 °C affords diphenyliodonium chloride in low yield (5%).⁴⁹

2. Syntheses starting from dihydroxy- λ^3 -iodanylbenzene tosylate

The availability of iodanylbenzene derivatives, their reasonable stabilities on storage and fair solubilities enable the use of these compounds in the synthesis of alkenyliodonium salts. The reac-

tions of dihydroxy- λ^3 -iodanylbenzene tosylate (**11**) with 3-amino- and 3-ethoxy-5,5-dimethylcyclohex-2-enone in chloroform result in the formation of vinyliodonium salts **27a,b** in 87% and 40% yields, respectively.⁵⁰ The reaction mechanism presumably involves the initial attack by the hydroxy(phenyl)iodonium ion on the double bond followed by the deprotonation of the intermediate **28** and the exchange reaction of aryl(vinyl)iodonium hydroxide **29** with *p*-toluenesulfonic acid.

X = NH₂ (**a**), OEt (**b**).

The condensation of uracil with diacetoxyiodanylbenzene in DMF in the presence of TsOH · H₂O leads to compound **30** in 78% yield.⁵¹ The reaction apparently involves the intermediate formation of the tosylate **11**.

More general and simple procedure for the synthesis of (β-tosyloxyvinyl)iodonium tosylate **31** includes the reactions of dihydroxyiodanylbenzene tosylate (**11**) with terminal alkynes.^{52–56}

R = Prⁿ (**a**), Buⁿ (**b**), n-C₅H₁₁ (**c**), Prⁱ (**d**), sec-C₄H₉ (**e**), Buⁱ (**f**), cyclo-C₆H₁₁ (**g**), Bu^t (**h**), Ph (**i**).

Depending on the nature of the substituent in terminal alkynes, either alkenyl- or alkynyliodonium salts or their mixture are formed.⁵⁴ Thus pent-1-yne yields the alkenyliodonium salt **31a** exclusively (58%), 3,3-dimethylbut-1-yne gives alkynyliodonium tosylate **32h** (74%), while 3-methylbut-1-yne affords a mixture of alkenyl- (**31d**) (11%) and alkynyl-iodonium salts **32d** (15%). A correlation was found between the degree of branching in the substituent and the direction of the reactions. Thus alkynyliodonium salts are formed if the substituent is more branched than the isopropyl group (*e.g.*, Bu^t and cyclo-C₆H₁₁). Mixtures of both salts are obtained from 3-methylbut-1-yne and 4-methylpent-1-yne, which are branched in the β-position.

Trimethylsilylacetylene reacts with compound **11** with the elimination of the trimethylsilyl group to give phenyl(2-tosyloxyvinyl)iodonium tosylate.⁵⁴ Disubstituted acetylenes react with compound **11** producing vinyliodonium salts in up to 62% yield.⁵³

R¹, R² = Me, Buⁿ, n-C₅H₁₁, Ph.

The reactions of compound **11** with alkenes were also studied.⁵³ Alkenyliodonium salt **33** (5%) was found to be a product of the reaction with 1,1-diphenylethylene.

Methyl 3-aminocrotonate **34** reacts with the tosylate **11** at 20 °C to give [2-amino-1-methoxycarbonyl-(*E*)-prop-1-enyl]phenyliodonium tosylate (**35**) as the major product.⁵⁷

3. Syntheses starting from iodosylbenzene in the presence of Lewis acids

The first general method for the synthesis of alkenyliodonium salts was suggested in the mid-1980s.^{58, 59} It was based on the reactions of silylated alkenes with iodosylbenzene in the presence of Lewis acids. These reactions proceed stereoselectively in the presence of boron trifluoride diethyl etherate to afford alkenyliodonium tetrafluoroborates **36** in high yields. The preparation of a wide range of diverse alkenyliodonium salts has demonstrated the versatility of this procedure. The yields of the reaction products reached 89%.

R¹ = H, Me, n-C₈H₁₇, Ph(CH₂)₂; R² = H, Me, n-C₈H₁₇, Ph, PhCH₂, Ph(CH₂)₂, *p*-BrC₆H₄OCH₂, *p*-ClC₆H₄(CH₂)₂.

Using this approach, cyclic alkenyliodonium salts, *viz.*, 4-*R*-cyclohex-1-enyl(phenyl)iodonium tetrafluoroborates **37a,b**, were synthesised.^{58, 59}

R = H (**a**), Bu^t (**b**).

The reaction of 1-trimethylsilyldec-1-ene with iodosylbenzene in the presence of boron trifluoride diethyl etherate yields dec-1-yne.^{60, 61} Using NMR spectroscopy, it was shown that the reaction with the alkene **38a** occurs *via* unstable alkenyl(phenyl)iodonium salt **39a**.⁵⁸ Treatment of salts **39a–e** with an aqueous solution of KClO₄ allowed the synthesis and characterisation of stable (*Z*)-alkenyliodonium perchlorates **39a–e**.⁶¹

R = n-C₈H₁₇ (**a**), Me₂CH(CH₂)₄ (**b**), cyclo-C₅H₉CH₂ (**c**), Ph (**d**), Ph(CH₂)₃ (**e**).

Electrophilic addition of the complex of PhIO with BF₃ · Et₂O to allenes was used to synthesise alkenyliodonium salts. Thus salt **40a** was obtained by the reaction of diethyl 1-methoxy-4-methylpenta-2,3-dien-2-ylphosphonate (**41**) with 2 equivs of iodosylbenzene in the presence of boron trifluoride diethyl etherate.⁶² The respective perchlorate **40b** was obtained in 48% yield upon treatment of the reaction mixture with a saturated aqueous solution of LiClO₄. The salt **40** is also formed in the reaction of the allene **41** with a system PhIF₂ – BF₃ · Et₂O.⁶²

$$X = \text{BF}_4 \text{ (a)}, \text{ClO}_4 \text{ (b)}.$$

The unusual reaction course is explained by a *Z*-orientation of the electrophilic fragment I(Ph)F relative to the phosphoryl group in the intermediate **42**. In all the structures examined so far,^{63–71} resulting from electrophilic additions to allenylphosphonates, *E*-orientation of the substituents at the double bond was mainly observed, which favoured the formation of oxaphospholenes.

The reactions of alkynyltrimethylsilanes with iodosylbenzene in the presence of BF_3 or $\text{Et}_3\text{O}^+ \cdot \text{BF}_4^-$ lead to alkynyliodonium compounds.⁷²⁻⁷⁷

R = Ph, PhCH₂, PhCH₂CH₂, n-C₈H₁₇, cyclo-C₆H₁₁;
Ar = 4-MeC₆H₄, 4-NO₂C₆H₄.

The addition of PhIO to trimethylsilylacetylene in the presence of triethyloxonium tetrafluoroborate or boron trifluoride diethyl etherate results in the formation of (*E*)-(2-ethoxyvinyl-1-trimethylsilyl)phenyliodonium tetrafluoroborate in 68% yield.⁷⁸ Treatment of compound **43** with tetra-*n*-butylammonium fluoride or triethylamine leads to vinylidonium salt **44**. The reaction presumably occurs *via* an intermediate ylide **45**.⁷⁸

A method allowing the stereoselective synthesis of alkenyliodonium salts from boronic acids or their esters has been described.⁷⁹ The reactions of (*Z*)-2-bromovinyl(diisopropoxy)-boranes with diacetoxyiodanylbenzene in dichloromethane at 0 °C under nitrogen followed by the anion exchange led to (*Z*)-phenyl(vinyl)iodonium tetrafluoroborates. In addition to the iodonium salt **46b**, (*Z*)-2-bromodec-2-enal (9%), 2,2-dibromodec-1-enal (3%) and (*Z*)-1,2-dibromodec-1-ene (5%) were also formed.

If the reactions are carried out in the presence of boron trifluoride etherate, the yields of alkenyliodonium salts are increased to 85%.

$$R = \text{Bu}^n \text{ (a)}, n\text{-C}_8\text{H}_{17} \text{ (b)}.$$

The yields of the salts **46** also depend on the nature of the solvent; in dichloromethane, benzene, ethyl acetate and methanol, they are higher (> 80%) than in acetonitrile and diethyl ether.

Alkoxyboranes also produce alkenyliodonium salts in reactions with other derivatives of I(III), *viz.*, with PhIO in the presence of boron trifluoride etherate, dihydroxyiodanylbenzene tosylate (**11**) or PhI(OCOCF₃)₂.⁷⁹ When (*Z*)-2-bromohex-1-enyl(diisopropoxy)borane reacted with bis(trifluoroacetoxy)iodanylbenzene, [(*Z*)-2-bromohex-1-enyl]phenyliodonium trifluoroacetate was isolated from the reaction mixture together with the respective tetrafluoroborate as the major product.

The reaction of (*E*)-(diisopropoxy)hex-1-enylborane (**47a**) with $\text{PhI}(\text{OAc})_2 - \text{BF}_3 \cdot \text{Et}_2\text{O}$ results in the stereoselective formation of (*E*)-vinyliodonium salt **48** (47%) and hexenal as a side-product (12%).

$$R_2 = (\text{OPr}^i)_2 \text{ (a)}, -\text{OCMe}_2\text{CMe}_2\text{O}- \text{ (b)},$$

(c).

Vinylboronic acids **49** react with $\text{PhI}(\text{OAc})_2 - \text{BF}_3 \cdot \text{Et}_2\text{O}$ in dichloromethane at 0 °C under nitrogen to form vinyliodonium salts **36**.⁷⁹ This procedure allows the synthesis of not only mono-, but also bis(vinyliodonium) salts from the corresponding vinylboronic acids.⁷⁹

$$R^1 = n\text{-C}_4\text{H}_9, n\text{-C}_8\text{H}_{17}, \text{Ph}(\text{CH}_2)_3, \text{Cl}(\text{CH}_2)_3, \text{NC}(\text{CH}_2)_3, \\ \text{cyclo-C}_5\text{H}_9\text{CH}_2, \text{Me}_2\text{CH}(\text{CH}_2)_2, \text{Bu}^t, \text{Ph}; R^2 = \text{H}, \text{Me}, \text{Ph}.$$

4. Syntheses based on the activation of iodosylbenzene with trifluoromethanesulfonic acid or its derivatives

Yet another method for the synthesis of alkenyliodonium salts is based on the reactions of alkynes with PhIO–HOTf (**14**), PhIO–Tf₂O or PhIO–Me₃SiOTf systems.^{80–82} These reactions occur stereoselectively yielding (*E*)-alkenyliodonium salts **50**. Complex **14** is generated *in situ* either from a 1:1 mixture of iodosylbenzene and trifluoromethanesulfonic acid or from a 1:2 mixture of diacetoxyiodanylbenzene and TFOH·H₂O.

R = H, Prⁿ, Buⁿ, n-C₆H₁₃, Ph.

Disubstituted acetylenes also react with the complex **14** stereoselectively to form (*E*)-alkenyliodonium salts.⁸²

R = Me, Et.

However, only alkynyliodonium triflate **51** is formed in 42% yield in the reaction of sterically hindered 3,3-dimethylbut-1-yne with PhIO–HOTf.⁸²

Activation of bis(iodosyl)benzene with trimethylsilyl triflate followed by treatment with appropriate terminal alkynes afford bis(alkenyliodonium) salts **52** in 50%–66% yields.⁸³

R = H, Me, Et, Ph.

The reaction of iodosylbenzene with 2 equivs of trifluoromethanesulfonic acid or with an equimolar amount of Tf₂O produces the iodanyl-iodonium derivative **53**. The latter readily reacts with terminal alkynes to give the corresponding *E*-alkenyliodonium salts **54**.^{84, 85}

R = Prⁿ, Buⁿ, n-C₆H₁₃.

It should be noted that 1-trimethylsilylalkynes react with the reagent **53** with the elimination of the trimethylsilyl group to form the corresponding mono(alkynyl)iodonium salts.⁸⁵

5. Syntheses starting from cyano(hydroxy)-λ³-iodanylbenzene triflate

A more versatile method for the synthesis of alkenyliodonium salts that allows the introduction of a wide range of different substituents at the double bond is based on the reactions of cyano(hydroxy)-λ³-iodanylbenzene sulfonates **15a,b** with tin-substituted alkenes.^{86–88}

R¹, R² = Me, Buⁿ, Et, Ph; X = OTf (a), OTs (b).

The reactions proceed under mild conditions and stereoselectively afford alkenyliodonium salts in high yields. Using this approach, phenyl(vinyl)iodonium triflate was synthesised starting from tributyl(vinyl)stannane.⁸⁸

6. Syntheses starting from alkynyliodonium salts

The reactions of alkynyliodonium salts with nucleophiles in protic solvents represent a convenient approach to stereoselective synthesis of (*Z*)-β-functionalised alkenyliodonium salts. The ratio between the substitution and addition products depends on the nature of the counterion and nucleophile. When trimethylsilyl azide is used as a source of nucleophilic species (in the presence of water), the addition products are formed in high yields, and it is employed for the preparation of (*Z*)-(β-azidoalkenyl)iodonium salts **55**.⁸⁹

R = Me, Bu^t, n-C₈H₁₇, cyclo-C₅H₉CH₂.

However, the reactions of alkynyliodonium tosylates with sodium azide in the presence of methanol result in the corresponding (*Z*)-(β-azidoalkenyl)iodonium tosylates in relatively low yields.⁹⁰

1-(*Z*)-(β-Azidovinyl)-3*H*-2,1λ³-benzooxaionol-3-one triflates **57** have been obtained by the reactions of alkynyliodonium salts **56** with sodium azide in the presence of 18-crown-6.⁹¹ The initial intramolecular hydrogen transfer followed by cyclisation involving the *ortho*-carboxy group may account for such unusual stereochemistry of the azide addition.

R = Buⁿ, n-C₆H₁₃, n-C₈H₁₇, n-C₁₀H₂₁;
(a) NaN₃, 18-C-6, CH₂Cl₂, –80 to 20 °C.

Stereoselective synthesis of (*Z*)-(β-halogenovinyl)iodonium salts **58** by the reactions of alkynyliodonium tetrafluoroborates with halide anions in an acid medium has been effected.^{92, 93} Fluoride anion does not react under these conditions, while the addition of iodide anion results in a complex mixture of products probably due to the low stability of the primary addition products.⁹² (*Z*)-(β-Halogenovinyl)iodonium salts **58** are useful precursors for halogenoalkylidene carbenes.⁹³

R = PhCH₂, PhCH₂CH₂, Bu^t, n-C₈H₁₇, cyclo-C₅H₉CH₂; X = Cl, Br.

The conjugate addition of sulfinic acids in methanol affords stereoselectively (*Z*)-(β-sulfonylvinyliodonium salts.^{94, 95}

$\text{R}^1 = \text{Me}, \text{Ph}(\text{CH}_2)_3, n\text{-C}_8\text{H}_{17}, \text{cyclo-C}_5\text{H}_9\text{CH}_2, \text{HO}(\text{CH}_2)_2, \text{cyclo-C}_6\text{H}_{11}(\text{CH}_2)_2; \text{R}^2 = \text{Ph}, 4\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, \text{Bu}^n.$

Recently, a similar approach was used to synthesise (*Z*)-(β -acetoxyvinyl)phenyliodonium bromides **59**.⁹⁶ The reaction sequence includes the conjugate addition of sodium acetate to alkynyliodonium salts in acetic acid and anion exchange in an aqueous solution of sodium bromide. The yields of the products **59** depend on the amount of sodium acetate added. The use of 0.1 equiv. of sodium acetate is optimum; the addition of a greater amount of sodium acetate decreases the yields of the targeted products considerably.⁹⁶

$\text{R} = \text{Me}, \text{Bu}^t, n\text{-C}_8\text{H}_{17}.$

Alkynyliodonium salts represent activated electron-deficient alkynes with a highly polarised triple bond. Owing to their dipolar structures, these compounds can be used as dipolarophiles in a variety of cycloaddition reactions. This provides a way to the synthesis of diverse alkenyliodonium salts.

Thus (arylethynyl)iodonium tosylates react with nitrile oxides **60a,b** to form cycloadducts in high yields.⁹⁷ The reaction of [(4-methoxyphenyl)ethynyl]iodonium tosylate under similar conditions leads to a 1 : 1 mixture of two isomeric adducts **61a** and **61b** in 60% overall yield.⁹⁷

$\text{Ar}^1 = \text{Ph}, 2\text{-ClC}_6\text{H}_4; \text{Ar}^2 = \text{Mes} \text{ (a)}, 2,6\text{-Cl}_2\text{C}_6\text{H}_3 \text{ (b)}.$

Nitrone **62** reacts with (phenylethynyl)iodonium tosylate to give adduct **63**.⁹⁷

Diazocarbonyl compounds **64** form the corresponding cycloadducts **65** in the reactions with phenyl(2-trimethylsilyl)ethynyl)iodonium triflate.⁹⁸

$\text{R} = \text{OMe}, \text{OEt}, \text{Ph}, \text{Bu}^t.$

Methyl and phenyl azides react with alkynyliodonium triflates on heating in tetrahydrofuran or acetonitrile to give triazolyl-iodonium salts **66**.⁹⁸

$\text{R}^1 = \text{H}, \text{Bu}^t; \text{R}^2 = \text{Me}, \text{Ph}.$

Alkynyliodonium salts can add not only to 1,3-dipolarophiles, but also to 1,3-dienes.⁹⁹ Adducts **67–69** are obtained as stable, crystalline compounds. Owing to the presence of two functional groups, these adducts can then be used in further reactions.

$\text{R} = \text{CN}, \text{Ts}, \text{PhCO}, \text{furan-C(O)}, \text{thiophene-C(O)}.$

The reactions of alkynyliodonium salts with unsymmetrically substituted dienes **70** lead to mixtures of two regioisomeric cyclohexadienes **71** and **72** in 62%–84% overall yields.¹⁰⁰ Usually, the regioselectivity of the reactions with 2-substituted dienes is low, whereas 1-substituted dienes react more regioselectively. Thus the reaction of penta-1,3-diene with the alkynyliodonium salt **73** leads exclusively to the regioisomer **74**, the structure of which was unequivocally established by X-diffraction analysis.¹⁰⁰

$\text{R}^1 = \text{CN}, \text{Ts}, \text{PhCO}, \text{furan-C(O)}, \text{thiophene-C(O)}, \text{Me}_2\text{NC(O)};$
 $\text{R}^2, \text{R}^3 = \text{H}, \text{Me}, \text{Et}, \text{Bu}^t.$

Acetylene bisiodonium salt **75** is more reactive and readily enters into reactions with cyclopentadiene, furan and 1,3-diphenylisobenzofuran in acetonitrile under mild conditions.¹⁰¹ The adducts **76a,b** and **77** are stable and can be used in further reactions with various nucleophiles or in cross-couplings with alkynes.^{102–104}

X = CH₂ (**a**), O (**b**).

7. Synthesis starting from fluoro(hydroxy)- λ^3 -iodanylarene sulfonates

Most of trivalent iodine organic derivatives employed in the synthesis of stable vinyliodonium salts are insufficiently reactive. Their electrophilicity can be enhanced if these compounds are converted into derivatives of strong acids containing highly nucleofugal groups as ligands. In this approach, reactive iodonium compounds are obtained in two steps, and the first step is the synthesis of readily available I(III)-derivatives from aryl iodides.

A new one-step procedure for the generation of iodonianylarenes directly from aryl iodides has been proposed recently.^{105–108} It was found that oxidation of aryl iodides with fluoroxenon sulfonate results in the formation of iodonium salts **16a,b**. The latter represent convenient starting compounds for the synthesis of diverse diaryl- and alkenyl-iodonium sulfonates. Compounds **16a,b** can also be obtained by the reactions of difluoriodanilyarenes with the respective sulfonic acid, its anhydride or trimethylsilyl ester.¹⁰⁵

$$Z = \text{Tf}(\mathbf{a}), \text{Ms}(\mathbf{b}).$$

The fact that the reagents **16a,b** contain the highly nucleofugal sulfonate group makes them important. These compounds probably have an ionic structure. It is worth noting that the reagents **16** represent only a specific example of compounds of the general formula $[\text{ArI}^+ \text{X Z}^-]$ where X and Z denote a heteroatomic substituent and a nucleofugal group, respectively. For example, derivatives with $\text{X} = \text{OH}$, $\text{Z} = \text{OTf}$;⁸² $\text{X} = \text{OH}$, $\text{Z} = \text{FSO}_3$;⁴¹ $\text{X} = \text{OH}$, $\text{Z} = \text{HSO}_4$;⁷ $\text{X} = \text{OH}$, $\text{Z} = \text{BF}_4$;⁴¹ $\text{X} = \text{F}$, $\text{Z} = \text{BF}_4$ (Refs 41, 62) are also known. In most instances, the structures of these compounds have not been strictly established. Several of them were deduced on the grounds of chemical transformations of these intermediates in reactions with various organic substrates. For example, the reactions with alkynes, aromatic compounds and enol silyl ethers gave rise to iodonium salts^{41, 58, 59, 62, 82} and β -diketones.⁴¹

Fluoro(hydroxy)iodanylarene sulfonates **16** react stereoselectively with terminal alkynes to form (*E*)-[β -(sulfonyloxy)alk-1-

enyl](aryl)iodonium sulfonates **78**;^{105, 109} the structure of one of these compounds was proved by X-diffraction analysis.¹⁰⁸

Z = Tf, Ms; Ar = Ph, 4-MeC₆H₄, 2-MeC₆H₄, 4-NO₂C₆H₄;

R = H, Prⁿ, Buⁿ, n-C₈H₁₇, CH₂OH, CH₂OMe, CH₂Cl, CH₂CH₂OH.

Earlier, (*E*)-(2-trifluoromethylsulfonyloxyvinyl)(aryl)iodonium sulfonates **78** were obtained by the electrophilic addition of the [PhIO–HOTf] reagent to alkynes.⁸² However, the synthesis of β -functionalised vinyliodonium salts by this method required an additional step including the conversion of iodobenzene into iodosobenzene followed by the activation of the latter with methanesulfonic acid. Compared with this procedure, the use of a novel oxidant, *viz.*, fluoroxenon sulfonate, which already contains the sulfonate group, allows a one-step preparation of β -functionalised vinyliodonium salts directly from iodobenzene and terminal alkynes. In addition, the reagents **16** are more reactive towards alkynes than the system [PhIO–HOTf], and readily enter into reactions even at $-70\text{ }^{\circ}\text{C}$. This method was shown to be suitable for the synthesis of bis(alkenyl)-*p*-phenyleneiodonium salts **52**.¹¹⁰

$$R = \text{H, Me, Et, Ph, Pr}^n, n\text{-C}_8\text{H}_{17}, \text{CH}_2\text{Cl}.$$

It is important to note that exclusively *Z*-alkenylidonium salts are formed in the reactions with phenyl(trimethylsilyl)acetylene.^{106, 109} The structure of one of such salts has definitively been established by means of X-diffraction analysis.¹⁰⁶ This stereochemical result differs in principle from other cases where adducts of iodosobenzene with fluorosulfonic or trifluoromethanesulfonic acid^{81, 82} reacted with alkynes to give *E*- β -substituted iodonium salts. It should also be noted that the reactions of other alkynyl-trimethylsilanes with the reagents **16a,b** give rise to the corresponding alkynylidonium salts.

Z = Tf: Ar = Ph (58%), *p*-MeC₆H₄ (53%); Z = Ms, Ar = Ph (56%);

(a) R = Ph, HOZ, CH₂Cl₂, -78 to 20 °C;

(b) R = H, Buⁿ, Bu^t, MeOCH₂, CH₂Cl; CH₂Cl₂, -78 to 20 °C.

III. Reactions of alkenyliodonium salts

Exploration of chemical properties of alkenyliodonium salts was begun only in the mid-1980s. Although the majority of alkenyliodonium salts are rather stable compounds and can be stored for a relatively long time without any noticeable changes, most of them undergo thermal destruction on heating. As a rule, the thermal decomposition of alkenyliodonium salts involves the cleavage of a bond between I^+ and the carbon atom of the alkenyl fragment. Thermolysis of *trans*-chlorovinylidonium salts is accompanied by the formation of acetylene.^{42,43,46} Iodobenzene and vinyl bromide in the ratio of 1 : 1 are formed upon thermal decom-

position of solid phenyl(vinyl)iodonium bromide **79**; no other products have been detected.⁴⁶ Thermal decomposition of a cyclic iodonium salt **80**, which occurs at a melting temperature, leads to a mixture of substituted *cis*- and *trans*-stilbenes **81**.⁴⁹

Alkenyliodonium salts undergo solvolysis and fragmentation. The mechanism of solvolysis of (4-*tert*-butylcyclohex-1-enyl)phenyliodonium tetrafluoroborate (**37b**) in ethanol and aqueous solutions was examined.¹¹¹ It was shown that the phenyliodonio group is about 10⁶ times as good a leaving group as the triflate. In addition to the expected products, *viz.*, **82** and iodobenzene, the solvolysis also yielded the internal return product **83** and a small amount of 4-*tert*-butylcyclohexene (**84**) resulting from a single-electron transfer. A mechanism involving initial heterolysis to form a contact ion pair **85** followed by a single-electron transfer to lead to an intermediate **86** was suggested. However, a possibility that the species **86** is formed upon homolysis of the C–I⁺ bond is also not excluded.

(a) C–I⁺ bond heterolysis; (b) C–I⁺ bond homolysis; (c) single-electron transfer; (d) ROH (solvolysis); (e) internal return; (g) –PhI.

Fragmentations of 2,2-disubstituted alkenyliodonium salts **87a,b** in CDCl₃ follow a similar mechanism. However, in this case, triflates **91** and **92** are formed as the products of a cationic rearrangement of an intermediate **90** together with the solvolysis products **88** and **89**.¹¹²

R¹ = R² = Me, X = CF₃ (**87a**); R¹ = Ph, R² = Et, X = H (**87b**).

Obviously, the presence of the I⁺ArX[–] fragment significantly affects the electron density distribution not only in the groups vicinal to this fragment, but also in the molecule as a whole. Thus according to the ¹H NMR spectra of *E*- and *Z*-alkenyliodonium salts, the α-proton of the alkenyl group (with respect to the I⁺Ar fragment) is rather acidic.^{58, 61} The I⁺ArX[–] group is also responsible for the substantially enhanced C–H acidity of some other compounds.¹¹³

Being highly acidic, the α-hydrogen atom can readily be removed from alkenyliodonium salts even by such weak bases as amines.^{78, 114} An exchange of deuterium for the α-vinyl proton and to form deuterio-derivative **94** takes place upon treatment of (*E*)-(2-ethoxyvinyl)phenyliodonium salt **93** with triethylamine and D₂O in THF. The reaction presumably involves the intermediate formation of a vinylidene ylide **45**.¹¹⁴

1. Generation of alkylidenecarbenes from vinylidene salts

Owing to the high nucleofugality of the I⁺ArX[–] group, vinylidene salts readily undergo reductive elimination of iodobenzene generating thereby highly reactive alkylidenecarbenes. The latter can further transform into cyclopentenones through an intramolecular regioselective insertion into the C–H bond (1,5-insertion). Thus α-elimination in the iodonium salt **95** followed by the 1,5-insertion in the species **96** proceed under mild conditions (Et₃N, 25 °C) yielding 2-methylbicyclo[3.3.0]oct-1-ene (**97**). Similarly, the ketone **99** is obtained from the iodonium salt **98**.¹¹⁵ This procedure can also be applied to alkenyliodonium salts bearing the OH group. Thus compound **100** eliminates iodobenzene to produce carbene **101**, which then inserts into the O–H bond to form 2,3-dihydrofuran derivative **102**.⁹⁵

Reactions of deuterated alkenyliodonium salts **103** with triethylamine at 0 °C lead to terminal alkynes **104** (10% deuterium) and **105** (89% deuterium) in quantitative yields. The compositions of the reaction products indicate that alkylidenecarbenes predominantly arise through α-elimination and subsequent 1,2-hydrogen shift rather than through a *syn*-β-elimination process.¹¹⁵ The absence, in the reaction mixture, of cyclopentene

derivatives suggests that the 1,2- α -hydrogen shift following 1,5-insertion of alkylidenecarbenes into the C–H bond is very unfavourable.¹¹⁶

Elimination of iodobenzene from iodonium salts **106a,b** under the action of potassium *tert*-butoxide leads to alkynes **107a,b** as the main products. The α -phenylthio and α -phenylsulfonyl groups in alkylidenecarbenes **108a,b** are good leaving groups. Their migration apparently occurs *via* sulfonium ylides.⁹⁵ In contrast to compounds **106a,b**, an iodonium salt with the α -phenylsulfonyl group gives predominantly 2-phenylsulfonylbicyclo[3.3.0]oct-1-ene (**109**) (the ratio **109** : **110** = 4 : 1). This shows that the carbene **111** preferentially inserts into the C–H bond rather than undergoes migration of the sulfur-containing substituent despite the very good migrating ability of this group.¹¹⁶

Reactions of halogen-containing alkenyliodonium salts of similar structures yield different products depending on the nature of the halogen atom in these salts. Thus chlorine-substituted salt **112a** gives a 38 : 62 mixture of the product of 1,5-insertion of a carbene into the C–H bond (**113a**) and the rearrangement product (**114a**). Only bromoalkyne **114b** is formed from the bromine-substituted salt **112b** due to the more preferable migration of the bromine atom in the carbene **115b**.⁹³

X = Cl (**a**), Br (**b**).

α -Halogenoalkylidenecarbenes are generated in the α -elimination of iodobenzene from (*Z*)-(2-halogenoalkenyl)iodonium salts (route *a*). However, in this case the reaction apparently also involves the more stereoelectronically favourable base-induced *anti*- β -elimination of HX giving rise to alkynyliodonium salts (route *b*). The Michael addition of a halide ion and subsequent reductive elimination of iodobenzene lead to the final products.^{93, 117, 118}

Possible transformations of the carbene formed were elucidated in a cross-reaction of (*Z*)-(2-bromoalkenyl)iodonium **116** and alkynyliodonium tetrafluoroborates **117** with sodium hydrogencarbonate. Alkynes **118** and **114b** were formed in the ratio 7 : 3, thus indicating that α -bromoalkylidenecarbene is generated through both α -elimination of the phenyliodonio group and *anti*- β -elimination of hydrogen bromide.⁹³

2-Bromovinylidonium salt **116** more readily undergoes *anti*- β -elimination than the 2-chlorovinylidonium salt **119**. This follows from the fact that a 78 : 13 : 9 mixture of compounds **118**, **120** and **121** is formed in the cross-reaction of both salts with NaHCO₃.⁹³

The direction of reactions involving the intermediacy of alkylidenecarbenes was found^{119–121} to be also dependent on the nature of solvent employed. In diethyl ether or THF, the complexation of alkylidenecarbenes with these solvents, *viz.*, the formation of oxonium ylides, was observed. Thus treatment of alkenyliodonium salt **122** with triethylamine in THF yields a mixture of products **123–125** formed as the result of 1,5-insertion of the carbene **127** into the C–H bond, 1,2-migration of the butyl group and also the reaction of salt **122** with triethylamine. In addition, a nucleophilic attack of the intermediate carbene **127** on tetrahydrofuran to form oxonium ylide **128** and further transformation of the latter into compound **126** *via* oxonium salt **129** also occur.¹²²

The course of the reactions is also controlled by the temperature (Table 1). On lowering the reaction temperature, the yields of the products **123**–**125** derived from alkylidenecarbene **127** are decreased, and the yield of the ether **126** derived from vinyl-oxonium ylide **128** is increased. These effects were explained as the reversibility of the process of oxonium ylide **128** formation, although no solid proof for the existence of an equilibrium between free alkylidenecarbenes and oxonium ylides was obtained.

Table 1. The ratio of the reaction products of compound **122** with Et₃N in THF.

Temperature /°C	Time /h	Overall yield (%)	Yields of reaction products (%)				Ratio (123 + 124 + 125) : 126
			123	124	125	126	
60	10	90	74	14	<1	2	98:2
40	10	95	75	11	<1	9	90:10
20	10	99	75	8	1	15	85:15
0	10	98	71	3	1	23	77:23
0 ^a	10	78	48	2	1	27	65:35
0 ^b	10	87	44	2	1	40	54:46
0 ^c	10	92	44	3	3	42	54:46

Note. The reaction mixture was preliminarily kept for 2 days at: ^a –20 °C; ^b –40 °C; ^c –60 °C.

An alkylidenecarbene generated from the alkenyliodonium salt **130** adds to alkenes to give alkylidenecyclopropanes **131**.¹²³ Its addition to *cis*- and *trans*-4-methylpent-2-enes occurs stereospecifically.

The ratio of isomeric cyclopentenes **133** and **134** formed upon treatment of both *Z*- and *E*-isomers of the iodonium salt **132** with Bu^tOK is 1:1 and is independent of the geometry of the starting compounds or the reaction conditions. This suggests the partic-

ipation of the alkylidenecarbene as an intermediate species in this reaction.¹¹⁵

Complete loss of regioselectivity testifies that this intermediate species represents a 'true' carbene (structure **A**) rather than a carbenoid (structure **B**) in which the 'memory effect' would be preserved to some extent.

In the presence of sulfides, alkylidenecarbenes give vinyl-sulfonium salts as the products of onium species transformations. An assumption that these reactions occur *via* free alkylidenecarbenes was put forward on the grounds of stereochemical studies.¹²² Thus (*E*)-vinylsulfonium salt (*E*)-**136** was the major product [the ratio (*E*)-**136** : (*Z*)-**136** is 69 : 31] in the reactions of both *E*- and *Z*-iodonium salts **135** with diisopropylamine in the presence of diphenyl sulfide. Such stereoselectivity most likely results from different bulkiness of two α-substituents in the alkylidenecarbenes formed.

The ρ constants for the reactions of 2-methyl-1-propyliodene, generated from the salt **130**, with different styrene derivatives in the presence of Et₃N and Bu^tOK have been determined (–0.56 and –0.55, respectively) by measuring relative rates for these reaction.¹²³ Since free alkylidenecarbenes are relatively 'soft' nucleophiles, their reactions usually have small negative ρ values. In contrast, carbenoids generated from other precursors possess much more pronounced electrophilic properties and therefore their reactions have high negative ρ values.

2. Vinylic nucleophilic substitution in alkenyliodonium salts.

The arylidonio group is known to be one of the best leaving groups in nucleophilic substitution reactions.^{111, 124} Owing to the capability of aryl(vinyl)iodonium salts to generate vinylic cations under remarkably mild conditions, these salts can formally be considered as vinylic cation equivalents. The reactions of (4-*tert*-butylcyclohex-1-enyl)phenyliodonium tetrafluoroborate **37b** with various nucleophiles^{58, 59} are exemplified in Scheme 1.

Alkylation of alkenyliodonium salts with organometallic compounds to give substituted cyclohexenes **137** occurs successfully only with lithium organocuprates; other organometallic compounds are oxidised by the iodonium salt **37b**. Substitutions by halide ions in the presence of the respective copper(I) halides in DMF at 20 °C result in nearly quantitative yields of products. Good product yield is also obtained in the reaction with cyanide ion. The salt **37b** reacts with sodium nitrite in the presence of copper(II) sulfate to give nitroalkene **138** without any traces of

nitrite. The reaction with sodium benzenethiolate yields (4-*tert*-butylcyclohex-1-enyl) phenyl sulfide (**139**), while with indandione enolate it leads to the C-vinylation product **140** (see also Ref. 125). Vinyl iodonium salt **37b** is carbonylated in methanol in the presence of palladium salts as catalysts to afford ester **141**.

Reactions of several nucleophiles with 2-azidoalkenyl-iodonium salts **142** prepared *in situ* by the addition of sodium azide to alkynyliodonium salts have been studied.⁹⁰ In all cases, the iodine-containing fragment was substituted by nucleophiles.

Nucleophilic substitutions of vinyl iodonium salts in the presence of copper compounds occur stereospecifically with retention of the initial configuration.^{126, 127} This was the reason to reject an idea of a free-radical mechanism for such reactions. Instead, a mechanism involving the intermediacy of three-coordinated iodine species **143** and three-coordinated copper **144** was suggested.^{102, 126, 127}

The stereochemistry of vinylic nucleophilic substitution has been studied in detail in the reactions of alkenyl(phenyl)iodonium salts **36a, b** with Ph_2CuLi in tetrahydrofuran. It was found that compound **36a** gives the products in high yields and with complete retention of the initial configuration. By contrast, the reactions of compound **36b** are accompanied by elimination to form the corresponding alkyne.⁵⁸

The substitution of the iodine-containing fragment in vinyl iodonium salts by halide, under the action of tetrabutylammonium halides in dichloromethane in the absence of copper(I) halides, occurs with inversion of configuration, which competes with elimination and the formation of alkynes.¹²⁸ Transformations of α - and β -deuterated substrates were examined in order to elucidate the mechanism of these reactions. Based on the results obtained¹²⁸ it was concluded that elimination in the reactions with $\text{Bu}_4\text{N}^+\text{F}^-$ results from the initial attack by the fluoride ion on the α -hydrogen atom followed by rearrangement of the carbene formed.

By contrast, other halide ions react through the β -elimination mechanism. The yields of elimination products are increased in the series: $\text{I}^- < \text{Br}^- < \text{Cl}^- < \text{F}^-$; the dependence on the nature of a substituent at the C(2) atom has the order: *n*-alkyl < benzyl < phenyl. Stereoselectivity of the reactions decreases in the same order. With an increase in the excess of tetrabutylammonium halide in the reaction, a noticeable drop in the ratio alkyne : vinyl halide is observed, thus indirectly confirming the proposed reaction scheme.¹²⁸

Nucleophilic substitutions of the iodine-containing fragment in the iodonium salt **35** occur, as a rule, in good yields (Table 2); the ratio of stereoisomers depends on the nature of the nucleophile and the reaction conditions.⁵⁷

Table 2. Nucleophilic substitution of the iodine-containing fragment in compound **35**.

Product 145	X	Reaction conditions			Yield (%)
		reagent	solvent	time /h	
a	Br	Bu ₄ N ⁺ Br [−]	CH ₂ Cl ₂	12	78
b	NO ₂	NaNO ₂ , CuSO ₄	DMF, H ₂ O	12	20
c	TsO	TsONa	DMF	12	25
d	CN	KCN	DMF, H ₂ O	12	60
e	Et ₂ N	Et ₂ NH	CH ₂ Cl ₂	4	80
f			CH ₂ Cl ₂	4	83

Bisiodonium salts **76a,b** react with anionic nucleophiles to form the nucleophilic substitution products of the phenyliodonio group (**146** and **147**).^{102–104}

Z = O (**a**), CH₂ (**b**); (a) CH≡CR, BuLi, CuCN, CH₂Cl₂, −78 to 25 °C, 12 h, R = SiMe₃, Bu^t, Buⁿ, Ph; (b) NaX, CuX; X = Br, I, CN, PhCOO.

Nucleophilic substitutions in (Z)-(2-phenylsulfonyl)alkenyl-iodonium salts **148** with tetrabutylammonium halides or sodium benzenesulfonate proceed with retention of configurations.^{94, 129–132}

Heterocyclic iodonium salts also undergo nucleophilic substitution. Thus the reactions of compound **40b** with nucleophiles lead to the corresponding cyclic adducts through a two-step addition–elimination process and/or reductive elimination following attack by a nucleophile on the iodine atom (Scheme 2).⁶² Perchlorate **40b** reacts with sodium azide in acetonitrile to give vinyl azide **149** in nearly quantitative yield. The reactions of compound **40b** with sodium methoxide and sodium ethoxide in the respective alcohol afford vinyl ethers **150** in 83% and 91% yields, respectively. Compound **40b** reacts with a mixture of equimolar amounts of potassium and copper(I) iodides to give vinylic iodide **151** in 67% yield. In the reaction with triphenylphosphine, vinylic iodide **151** and the phenylation product of triphenylphosphine, *viz.*, tetraphenylphosphonium perchlorate (22% yield), are formed along with the expected vinylphosphonium salt **153** (20% yield).

Scheme 2

3. Vinylation of aromatic compounds with vinyliodonium salts

As is known, direct introduction of the vinylic group into aromatics by electrophilic substitution is rather inefficient because of the low reactivities of vinyl halides. Unlike vinyl halides, vinyliodonium salts do enter into the reactions of electrophilic aromatic substitution. These substitutions can proceed as an intramolecular process to lead to cyclic systems, if vinyliodonium salts have suitable structures.¹³³ Compared with Friedel–Crafts reactions they proceed under milder conditions and in the absence of catalysts.

X = CH₂, O; R¹, R² = H, Me, Cl, Br.

(Z)-Alkenyliodonium salts do not cyclise under the same conditions. An S_E(Ar)-substitution mechanism was suggested¹³³ in which iodobenzene is eliminated from the intermediate iodocyclopropane, though other mechanisms cannot be ruled out.

4. Palladium-catalysed cross-coupling

Vinyliodonium salts were found to undergo cross-couplings with activated alkenes. The reactions conditions are milder than those used in the Heck reaction. Thus salts **154** and **36c** are carbonylated in the presence of palladium at 20 °C with complete retention of configurations to form α,β-unsaturated esters **155** and **156**.^{58, 134}

Enynones **157** were synthesised from alkenyliodonium salt **36c** and terminal alkynes under similar conditions in the presence of copper iodide.¹³⁵

R = Bu (76%), Ph (88%).

A highly stereoselective synthesis of conjugated dienes **158** is accomplished at 20 °C.¹³⁶

R¹ = H, Buⁿ, OTs; R² = Buⁿ, Ph, OTs,  ;

R³ = Ph, COMe, CO₂Me, CHO; X = OTs, BF₄.

An asymmetrical version of the Heck reaction was implemented in the presence of a chiral ligand, viz., (*R*)-2,2'-bis(diphenylphosphino)-1,1'-binaphthyl [(*R*)-BINAP].¹³⁷

Furthermore, in the presence of palladium, alkenyliodonium salts react under mild conditions with alkynyl-,⁸⁶ allyl-¹³⁸ and alkenylstannanes.^{86, 138} The reactions with alkenylstannanes occur faster but less selectively to give various unidentified compounds along with the major product.

160

R ¹	R ²	R ³	Yield of 160 (%)
Bu ⁿ	Bu ⁿ	Ph	77
Me	Et	Ph	64
Et	Me	Ph	66
Bu ⁿ	Bu ⁿ	Bu ^t CO	66
Bu ⁿ	Et	C(O)N(CH ₂) ₄	67

R¹ = R² = Me (70%), R¹ = Buⁿ, R² = Et (60%);
R¹ = R² = Buⁿ (65%); R¹ = Et; R² = Buⁿ (76%).

Terminal alkynes readily react with alkenyl(aryl)iodonium salts bearing the TfO group in the β-position at 30–40 °C in DMF : H₂O (6 : 1) to form enynes **163** in high yields.¹³⁹

163 (59%–77%)

R¹ = Buⁿ, H, CH₂OMe, Ph; R² = n-C₈H₁₇, Ph, CH₂OMe, SiMe₃, CH₂Cl, Prⁿ.

The reaction rates were found to be higher in polar solvents.¹³⁹ Small variations in the basicity of amines almost do not affect the reaction rates and the yields of the coupling products. Complexes of palladium with triphenylphosphine ligands were found to be the most efficient. The addition of CuI instead of CuI does not affect the reaction rates. An induction period (~1–2 h) is observed in the CuCl-catalysed reactions, after which the reaction rates become the same as in the case of CuI. The optimum ratio of PdCl₂(PPh₃)₂ to CuI is 2 : 3. The reaction rates are increased on addition of water to the system DMF–Et₃N–[Pd], this effect depending on the palladium catalyst employed. Thus the maximum rate acceleration on addition of water is observed in the presence of PdCl₂(PPh₃)₂.

In aqueous media in the presence of ligand-free palladium catalysts, unsubstituted alkenyliodonium salts also enter into reactions with terminal alkynes.¹⁴⁰

Alkenyliodonium salts react with allylic alcohols [in the presence of Pd(OAc)₂ (see Ref. 141) or a polymeric palladium catalyst¹⁴²] and allylic cyclic carbonates.¹⁴³

R = H, n-C₅H₁₁.

In the presence of palladium catalysts, alkenyliodonium salts also undergo the cross-coupling reactions with organoelement compounds.^{144–146} Thus, in the reaction of phenyl(styryl)-iodonium tetrafluoroborate **36c** with vinylfluorosilanes, only the β-styryl group was transformed to afford the cross-coupling products, dienes **164**, in high yields.¹⁴⁵

$\text{R}^1 = \text{Bu}^n, \text{Ph}; \text{R}_3 = \text{MeF}_2, \text{F}_3, \text{Me}_2\text{F};$

(a) $\eta^3\text{-C}_3\text{H}_5\text{PdCl}_2$, KF or $\text{Bu}_4\text{N}^+\text{F}^-$, DMF, 20 °C, 5 min.

To account for the palladium-catalysed reactions of vinylfluorosilanes with alkenyliodonium salts, a mechanism involving the interaction of an electrophilic alkenyliodonium salt with catalytically active Pd(0), the reductive elimination of iodobenzene to form alkenylpalladium tetrafluoroborate and the transmetallation reaction with vinylfluorosilanes was proposed.¹⁴⁵

Carbonylation of alkenyliodonium salts in the presence of Pd complexes^{145,146} can serve as a convenient procedure for the synthesis of unsaturated ketones, viz., **165** and **166**. Enyne **167** is smoothly obtained on coupling of alkynylfluoromethylsilane with the iodonium salt **36c**.¹⁴⁵

(b) $\eta^3\text{-C}_3\text{H}_5\text{PdCl}_2$, $\text{Bu}_4\text{N}^+\text{F}^-$, DME, CO (1 atm), 20 °C, 5 min.

(c) $\eta^3\text{-C}_3\text{H}_5\text{PdCl}_2$, KF or $\text{Bu}_4\text{N}^+\text{F}^-$, DMF, 20 °C, 5 min;

(d) $\eta^3\text{-C}_3\text{H}_5\text{PdCl}_2$, $\text{Bu}_4\text{N}^+\text{F}^-$, DME, CO (1 atm), 20 °C, 5 min.

The cross-coupling of alkenyliodonium salt **36c** with a large series of boronates in the system $\text{Pd}(\text{PPh}_3)_4\text{--Na}_2\text{CO}_3\text{--DMF--H}_2\text{O}$ has been effected and in all cases the cross-coupling product **168** was obtained in virtually quantitative yield.¹⁴⁴

(a) $[\text{Pd}(\text{PPh}_3)_4]$, Na_2CO_3 , DME : $\text{H}_2\text{O} = 4 : 1$, 20 °C, 10 min.

IV. Conclusion

From the data presented in this review one can see that alkenyliodonium salts are of interest for synthetic organic chemistry. These compounds are rather effective oxidants and can readily undergo free-radical transformations. They also possess high electrophilicities, which can be changed within a wide range by varying the ligands at the iodine atom, and are featured by the presence of the highly nucleofugal iodine-containing group.

Alkenyliodonium salts with several functional groups attract ever-growing interest. Such reagents allow the introduction into substrates of rather complex fragments under mild conditions.

Abstract. The published data on the synthesis of organoaluminium compounds involving metal complex catalysts are generalised and systematised. Hydro-, carbo- and cycloalumination reactions of alkenes, conjugated dienes and alkynes catalysed by Ti and Zr complexes are considered in detail. The use of organoaluminium reagents in organic synthesis and novel reactions involving these compounds are discussed. The bibliography includes 240 references.

I. Introduction

About 40 years have passed since the discovery by Ziegler *et al.*¹ of a direct method for the synthesis of trialkylalanes based on the reaction of alkenes with activated aluminium and hydrogen. In this period, organoaluminium compounds (OAC) have become indispensable tools in practical synthetic and organometallic chemistry.

Fundamental studies into the chemistry of OAC carried out in the 1960's^{2–8} have formed the basis for the development of industrial methods for their synthesis. Special mention should be made of the investigations carried out by prominent Soviet specialists Zakharkin,^{9,10} Zhigach^{11,12} and Korneev^{13,14} who have developed and industrialised a wide range of practically important OAC including co-catalysts for polymerisation and oligomerisation of alkenes and dienes.¹⁵

The manufacture of OAC has considerably stimulated the interest of investigators in these compounds as promising reagents for fine organic and organometallic synthesis. The most important fields of their application include thermal hydroalumination of alkenes, dienes and alkynes; reduction of carbonyl compounds, esters and nitriles; synthesis of higher OAC and selective functionalisation of unsaturated compounds. The results of these studies are summarised in numerous reviews and monographs (see, *e.g.*, Refs 16–20).

Studies by Tolstikov *et al.* (see Refs 18 and 19) deserve special mention, since they generalise the data on OAC as efficient reagents for organic synthesis. Thus the recently published monograph by Kouchin and Tolstikov¹⁹ provides a systematic description of the published data concerning the synthesis and conversions of OAC since 1970; however, more recent studies carried out in the last decade have not been cited in this book. Meanwhile, the fact that modern studies into the chemistry of OAC widely employ metal complex catalysis has made it possible not only to alter the strategy of organoaluminium synthesis but also to develop chemo-, regio- and stereoselective synthetic procedures for obtaining novel classes of OAC under mild conditions; these methods compete favourably with traditional approaches which utilise elevated pressures and temperatures.

The most efficient and widely employed catalysts for the reactions with OAC include Ti and Zr complexes and, in a lesser degree, Hf-, Co-, Ni-, V- and rare-earth element-containing compounds.

About ten years have passed since the publication of the reviews^{16,17} dealing with the application of metal complex catalysts based on Ti and Zr complexes in the synthesis and transformations of OAC. Numerous publications appeared in this decade and they were devoted to non-traditional catalytic methods for the synthesis of OAC. The present review summarises the most important published data on the application of metal complex catalysts in the synthesis of OAC by catalytic hydro-, carbo- and cyclo-metallation of alkenes, dienes and alkynes using the simplest alkylaluminium compounds and aluminium hydrides and systematises the data on the synthetic conversions of OAC in the presence of transition metal complexes.

II. Catalytic hydroalumination of alkenes

Thermal hydroalumination of mono-, di- and trisubstituted alkenes with OAC containing an Al–H bond is still one of the most popular methods for the synthesis of higher OAC.^{18–20} Unfortunately, this method suffers from a number of disadvantages which considerably restrict its application, *viz.*, hydroalumination has to be carried out at elevated temperatures (70–150 °C); moreover, this reaction is not suitable for all types of alkenes, since the presence of functional groups strongly complicates the results of reactions.

The reaction of LiAlH₄ with α -alkenes in the presence of Ti and Zr complexes is one of the first examples of catalytic hydro-

alumination under mild conditions (0–20 °C).²¹ This novel procedure allows the synthesis of lithium tetraalkylalanates in 60% to 100% yields. Sato *et al.*²¹ who studied the mechanism of catalytic hydroalumination of alkenes with LiAlH_4 in the presence of Zr complexes suggested that this reaction generates active hydride zirconium complexes **1**, which hydrozirconate alkenes with the formation of alkylzirconium complexes **2**. Transalkylation of the latter with LiAlH_4 gives lithium tetraalkylalanates **3**.

Using hydroalumination of hex-1-ene with lithium aluminium hydride as an example, it was shown²² that TiCl_4 , VCl_4 , Cp_2TiCl_2 and Cp_2ZrCl_2 manifest high catalytic activity comparable with that of ZrCl_4 . In the case of VCl_4 and Cp_2TiCl_2 , hydroalumination products were formed together with hex-2-ene resulting from isomerisation of the original hex-1-ene. The isomerisation of terminal alkenes in the presence of Cp_2TiCl_2 is shown in Scheme 1. The coordination of the central atom of the catalyst with an alkene results in the corresponding alkyltitanium σ -complex **4** in which the transfer of the hydride ion is accompanied by the formation of a complex **5** in the presence of an excess of the α -alkene. Decomposition of the complex **5** yields a mixture of stereoisomeric hex-2-enes.²³

Scheme 1

In their reactivities in the hydroalumination reaction, aluminium hydrides and alkenes can be arranged in the following orders:²⁴ $\text{LiAlH}_4 > \text{AlH}_3 > \text{AlH}_2\text{Cl} > \text{AlHCl}_2$; $\text{RCH}=\text{CH}_2 > \text{R}_2\text{C}=\text{CH}_2 > \text{RCH}=\text{CHR}$.

Co, Ni and Fe chlorides,^{25,26} Cr²⁷ and U²⁸ salts and transition metal complexes immobilised on inorganic²⁹ or polymeric supports^{29,30} can be used as catalysts in hydroalumination reactions. In contrast with thermal hydroalumination, catalytic hydroalumination in the presence of Zr and Ti complexes can also be performed in the presence of such functionally substituted alkenes as allylic alcohols and ethers.^{31–33}

Subsequent one-pot conversions of lithium tetraalkylalanates are of considerable practical interest. Thus cross-coupling of lithium tetraalkylalanates formed *in situ* with allyl halides in the presence of copper salts [CuBr , CuI , CuCN , CuCl_2 , $\text{Cu}(\text{OAc})_2$] yields alkenes which are three carbon atoms longer than the starting compounds;³⁴ the CuCl -catalysed reaction with propargyl bromide yields terminal allenes in high yields.³⁵ This reaction is one of the simplest and most convenient procedures for one-step conversion of alkenes into the corresponding allenes.

Later, cross-coupling was successfully extended to allenyl bromide,³⁶ carboxylic acid halides,³⁷ acrolein³⁸ and methyl vinyl ketone.^{38,39} Catalytic hydroalumination with LiAlH_4 and subsequent functionalisation of the alkylalanates formed makes it possible to convert the starting alkenes into the corresponding organic halides,⁴⁰ acetates⁴¹ or organoboron compounds⁴² in one step.

Unlike reactions with terminal alkenes, hydroalumination of 1,3-dienes with LiAlH_4 or NaAlH_4 in the presence of catalysts, such as Cp_2TiCl_2 or TiCl_4 occurs less selectively and affords 1,2-, 1,4- and 3,4-addition products.^{43,44}

Along with complex aluminium hydrides, readily available alkylaluminium hydrides are also used for catalytic hydroalumination of alkenes. In the example of hydroalumination of a mixture of isomeric decenes with Bu_2AlH in the presence of catalytic amounts of $\text{Ti}(\text{O}i\text{Bu})_4$, it was established that the terminal double bond enters into the reaction 154 times faster than the *cis*-disubstituted bond and 241 times faster than the *trans*-disubstituted bond.⁴⁵

Hydroalumination of hexa-1,5-dienes with Bu_2AlH has a number of specific features. In the presence of $\text{Ti}(\text{O}i\text{Bu})_4$ as a catalyst (1.5 mol.%)⁴⁶ and without it⁵ hydroalumination occurs, which is followed by intramolecular cyclisation. However, when the reaction is carried out in solvents containing electron-donor atoms (N, O, S, P), no cyclisation takes place and the α,ω -dialuminium compound **6** is formed instead.⁴⁶ These data suggest that in the course of hydroalumination the starting hydrometallating reagent readily forms donor-acceptor complexes with the solvent owing to the lone electron pair of the heteroatom, which prevents the intramolecular cyclisation.

$[\text{Ti}] = \text{Ti}(\text{O}i\text{Bu})_4$, $\text{al} = 1/3 \text{ Al}$.

Commercially available diisobutylaluminium hydride can be used as an efficient hydroaluminating reagent for linear and cyclic mono-, di- and trienes including those containing functional groups. Zirconium complexes proved to be the most active catalysts in these reactions.^{16,47} Thus Bu_2AlH hydroaluminate α -, α,β -disubstituted and cyclic alkenes in high yields in the presence of ZrCl_4 even at $\sim 20^\circ\text{C}$ (3–6 h).⁴⁸ The use of titanium-containing catalysts results in the formation of side products as a result of isomerisation of the original alkenes.²³ This reaction virtually does not occur in the absence of the catalysts.

An analysis of the literature data on hydrozirconation of alkenes⁴⁹ prompts a conclusion that hydroalumination yields reactive zirconium hydride intermediates able to hydrozirconate alkenes; further transmetalation of alkyl and cycloalkyl zirconium complexes results in higher OAC.⁴⁸

Studies by Tolstikov *et al.*⁵⁰ have shown that zirconium chloroalkoxides $(\text{RO})_n\text{ZrCl}_{4-n}$ are more reactive catalysts of the hydroalumination reaction than ZrCl_4 or $\text{Zr}(\text{O}i\text{Bu})_4$. Therefore, a mixture of ZrCl_4 with Bu^iOH , MeOH , EtOH and Pr^nOH is used to obtain a reactive catalyst. The rate of cycloalkene hydroalumination depends on the ring size and decreases in the following order: $\text{C}_5 > \text{C}_6 > \text{C}_7 > \text{C}_{12} > \text{C}_8$.

Hydroalumination of the C_{60} fullerene with Bu_2^iAlH in the presence of ZrCl_4 or $(\text{RO})_n\text{ZrCl}_{4-n}$ at $\sim 20^\circ\text{C}$ $\{\text{C}_{60}:[\text{Al}] = 1:(100-300), 24 \text{ h, toluene}\}$ was carried out by Ibragimov *et al.*^{51,52} Data from hydrolysis and deuteriolysis of fullerene-containing OAC suggest that these reaction conditions favour the formation of both hydro- and carboalumination products (total yield $\sim 90\%$).

al = $1/3 \text{ Al}$.

Bis(dialkylamino)alanes manifest high reactivity in hydroalumination of alkenes, however, only in the presence of Cp_2TiCl_2 .^{53,54} These compounds hydroaluminate α -alkenes, methyldienealkanes and aliphatic disubstituted alkenes in practically quantitative yields. Cycloalkenes are less reactive in this reaction. Tri- and tetrasubstituted alkenes cannot be involved in this reaction.

The advantage of bis(dialkylamino)alanes over dialkylalanes is in the feasibility to use them for catalytic hydroalumination of conjugated dienes; however, the selectivity of these reactions is rather low as in the case of complex hydrides.^{55,56}

(a) $(\text{Pr}^i\text{N})_2\text{AlH}$, Cp_2TiCl_2 , THF, 12 h, 20°C ; (b) H_2O (55%).

Dichloroalane which reacts with alkenes in the presence of boron derivatives to give the corresponding higher alkyl-dichloroaluminium compounds **7**, is used as a reactive hydroaluminating reagent.⁵⁷⁻⁶⁰

$[\text{B}] = \text{PhB}(\text{OH})_2$, $\text{B}(\text{OH})_3$, Et_3B , $\text{B}(\text{OMe})_3$, 9-borabicyclo[3.3.1]nonane (9-BBN), BF_3OEt_2 .

Hydroalumination of disubstituted alkenes with Bu_3^iAl in the presence of Ti^{4+} or Zr^{4+} salts at $110-120^\circ\text{C}$ gives predominantly OAC **8**.⁶¹ Apparently, the catalyst induces the isomerisation of the disubstituted double bond in the original alkenes into the terminal bond which is much more readily hydroaluminated with Bu_3^iAl .

The yield of reaction products in hydroalumination of alkenes with Bu_3^iAl strongly depends on the nature of the catalyst. Thus in the presence of catalytic amounts of Cp_2ZrCl_2 , higher trialkylalanes can be synthesised from terminal alkenes and AlBu_3^i in high yields (0°C , 6 h).⁶² This reaction does not take place in the absence of the catalyst. Such a high reactivity of Bu_3^iAl in the presence of Cp_2ZrCl_2 can be attributed to the formation of zirconium hydrides **9**,^{63,64} which hydrometallate alkenes at low temperatures to give the complex **10**. Subsequent transmetalation of alkylzirconium complexes results in alkylalanes **11**.

Hydroalumination of terminal alkenes with yet another hydroaluminating reagent, *viz.*, AlEt_3 in the presence of Cp_2TiCl_2 , follows a similar path and yields alkyl(diethyl)alanes **12**.⁶⁵

Higher dialkylaluminium chlorides cannot be synthesised by thermal transalkylation with Bu_2^iAlCl ; therefore, the use of Bu_2^iAlCl for Cp_2ZrCl_2 -catalysed hydroalumination of alkenes⁶⁶ which gives nearly quantitative yields should be regarded as a significant breakthrough.

This reaction involves non-conjugated di- and trialkenes (including cyclic and functionally substituted ones).⁶⁷ Hydroalumination of norbornenes with Bu_2^iAlCl is stereoselective and affords the corresponding cycloalkylhalogenoalanes.⁶⁸ The reactions involving 4-vinylcyclohexene and dicyclopentadiene result in bi- and tri-cyclic halogenoalanes.

The Cp_2ZrCl_2 -catalysed hydroalumination of cyclohexene with Bu_2^iAlCl was successfully employed to obtain tricyclohexyltin chloride (**13**).⁶⁹

(2,6-Di-*tert*-butyl-4-methylphenoxy)diisobutylaluminium (**14**) was recommended for use as a regio- and stereoselective reagent for hydroalumination of alkenes and carbonyl compounds in the presence of a two-component catalyst, Cp_2ZrCl_2 –aluminium hydride (1:1).⁷⁰

Because of the low reactivity of reagent **14**, hydroalumination should be performed at high temperature (145 °C); however, the presence of a bulky aryloxy substituent ensures high regioselectivity of this reaction.

It was shown^{71, 72} that the exchange reaction between optically active solvates ($\text{L}^* \cdot \text{Bu}_3^i\text{Al}$) and disubstituted terminal alkenes in the presence of a nickel(II)–*N*-methylsalicylideneamine complex **15** gives optically active trialkylalanes; their further oxidation or hydrolysis results in optically active alcohols or hydrocarbons. (–)-*N,N*-Dimethylmenthylamine, (+)-(*S,S*)-2,3-dimethoxy-1,4-bis(*N,N*-dimethylamino)butane, (+)-*N,N*-dimethylbornylamine, (+)-(*R*)-*N,N*-dimethyl-1-phenylethylamine, *etc.* were used as chiral ligands which form solvates with AlBu_3^i .^{71, 72}

Hydroalumination of oxabicycloalkenes with Bu_2^iAlH can be carried out in the presence of $\text{Ni}(\text{COD})_2$ (COD is cyclooctadiene) or its derivatives with phosphines;⁷³ the regio- and enantioselectivity of this reaction largely depend on the ligand environment of the central atom of the catalyst.

III. Catalytic hydroalumination of alkynes

Non-catalysed hydroalumination of disubstituted acetylenes can be achieved by using Bu_2^iAlH , Et_2AlH or Bu_3^iAl under sufficiently mild conditions but is characterised by low selectivity, since the vinylalanes formed in this reaction undergo further transformations.²⁰ Hydrolysis of vinylalanes results in 1,2-disubstituted alkenes with a *Z*- or an *E*-configuration depending on the nature of the starting hydroaluminating reagent,⁷⁴ the structure of the alkyne⁷⁵ and the solvent.⁷⁶

In the presence of transition metal complexes, hydroalumination of alkynes sometimes occurs with higher selectivity and in higher yields. For example, the reaction of oct-1-yne with Bu_2^iAlH in the presence of stoichiometric amounts of methylcuprate (1.25 h, 20 °C) and subsequent hydrolysis of the reaction mixture give oct-1-ene in a quantitative yield.⁷⁷

(a) Bu_2^iAlH , MeMgBr , CuCl , LiCl , THF; (b) H_2O (100%).

Hydroalumination of monosubstituted acetylenes normally yields a mixture of alkenes and alkanes, since mono- and dihydroalumination of the triple bond occur simultaneously. Selective mono- or dihydroalumination of alkynes can be carried out in the presence of Fe or Ni salts.²⁶

(a) LiAlH_4 , FeCl_2 , ~20 °C, 24 h; (b) H_2O (94%); (c) LiAlH_4 , NiCl_2 , ~20 °C, 24 h; (d) H_2O (99%).

Hydroalumination of mono- and disubstituted acetylenes with LiAlH_4 in the presence of TiCl_4 or Cp_2TiCl_2 can be carried out with high selectivity. Thus the reaction of oct-4-yne or hex-2-yne with hydride aluminium complexes [LiAlH_4 , NaAlH_4 , LiAlMe_3H , NaAlMe_3H , $\text{NaAl}(\text{OCH}_2\text{CH}_2\text{OMe})_2\text{H}_2$] in the presence of catalytic amounts of Cp_2TiCl_2 in THF yields alkenylalanes after 2 h at 20 °C; hydrolysis of the latter results in *cis*-oct-4-ene and *cis*-hex-2-ene, respectively (yields ~100%).⁷⁸ Aminoalanes can also be used for hydroalumination of alkynes.⁵³ In this case, hydroalumination of disubstituted acetylenes occurs with high selectivity and under milder conditions than that of terminal alkynes. Thus in the presence of 5 mol. % of Cp_2TiCl_2 , the reaction of methylphenylacetylene with $(\text{PrN})_2\text{AlH}$ gives alkenylalanes in a total yield of >95%.⁵⁴ The reaction of aminoalanes with disubstituted acetylenes predominantly occurs as the *cis*-addition, which makes it possible to use this method for the synthesis of *Z*-alkenes.

$\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Bu}^n$, $n\text{-C}_6\text{H}_{13}$, Ph ; $\text{R}^1 = \text{R}^2 = \text{Ph}$.

The composition of the reaction mixture depends on temperature, solvent and reaction time. Thus hydroalumination of hex-2-yne with $(\text{PrN})_2\text{AlH}$ in benzene at 0 °C yields a mixture of alkenylalanes with *trans*- and *cis*-configurations of the substituents. Their hydrolysis yields a mixture of isomeric hex-2-enes.⁵⁴

The aluminium-magnesium reagent **16** ($\text{Bu}_3^i\text{Al} - \text{Bu}^i\text{MgBr}$)⁷⁹ the efficiency of which is comparable with that of 9-BBN was

recommended for stereoselective hydrometallation of disubstituted acetylenes. This method is especially efficient in the conversions of disubstituted acetylenes into *Z*-alkenes. In the presence of 2 mol.% Cp_2TiCl_2 , the reaction with an excess of this reagent (3–10 equiv.) occurs at 20 °C and is completed within 20 min. *Z*-Alkenes are formed in 95%–98% yields and with ~98%–100% selectivity.

The recently synthesised reagents $\text{Bu}_2^i\text{AlCl}-\text{Cp}_2\text{TiCl}_2$ and $\text{Et}_3\text{Al}-\text{Cp}_2\text{TiCl}_2$, designed for selective hydroalumination of disubstituted acetylenes into the corresponding unsaturated OAC **17** and **18** the stereoselectivity of which is close to 100%, deserve special attention.^{80–82} Hydrolysis of OAC **17** and **18** results in *Z*-alkenes. Depending on the structure of the original alkynes and reaction conditions, 5% to 30% of alkadienylalanes are formed together with alkenylalanes. The structure of the unsaturated OAC **17** and **18** has been established by spectral methods.⁸³

Hydroalumination of disubstituted acetylenes with Bu_3^iAl in the presence of catalytic amounts of Cp_2ZrCl_2 is accompanied by the formation of isomeric alkenylalanes, their hydrolysis affords alkenes **19** and **20** (~1:1).^{84,85} Under analogous conditions, terminal alkynes yield a mixture (~1:1) of mono- and 1,1-dialuminium compounds in practically quantitative yields.⁸⁴

(a) Bu_3^iAl , Cp_2ZrCl_2 ; (b) D_2O .

In contrast with hydroalumination with $\text{Et}_3\text{Al}-\text{Cp}_2\text{TiCl}_2$,⁸¹ the reaction of disubstituted acetylenes with Pr_3^iAl in the presence of Cp_2ZrCl_2 occurs less selectively and gives a mixture of isomeric alkenylalanes (total yield 63%) and alumacyclopentadiene (38%).⁸⁴

It should be noted that selective hydroalumination of terminal alkynes with trialkylalanes R_3Al [$\text{R} = \text{Et}, \text{Bu}^i, \text{EtCH}(\text{Me})\text{CH}_2$] does not take place if Fe or Ni complexes substituted titanium- or zirconium-containing catalysts. In this case, the alkenylalanes formed undergo further conversions; subsequent hydrolysis results in a complex mixture of alkenes, 1,3-dienes and trialkyl-substituted benzenes.^{86,87}

Hydroalumination of mono- and disubstituted acetylenes has found wide application in synthetic organic chemistry, particularly in the synthesis of practically valuable trisubstituted alkenes,⁷⁶ substituted 1,3-dienes,⁸⁸ alk-1-en-3-ynes,⁸⁹ alkenylsilanes and alkenyl sulfones,^{90,91} 1-alkyl-2-halogenocyclopropanes,⁹² *Z*-alkenes,⁹³ etc.

Hydroalumination of allenes (both thermal with Bu_2^iAlH ,⁹⁴ and that with the use of LiAlH_4 in THF in the presence of catalytic amounts of Ti or Zr complexes, e.g., Cp_2TiCl_2 , TiCl_4 , TiCl_3 , ZrCl_4 or Cp_2ZrCl_2) is non-selective.⁹⁵ This reaction may be highly regioselective with the use of HAlCl_2 in the presence of catalytic amounts of organoboranes.^{95,96}

Thus in the majority of cases, stereoselective hydroalumination of alkynes and allenes occurs under mild conditions. Hydrolysis of the resulting higher alkenylalanes affords *Z*-alkenes in high yields.

IV. Carboalumination of alkenes catalysed by titanium and zirconium complexes

Catalytic carboalumination of unsaturated compounds gives an access to novel types of higher OAC. It is known⁹⁷ that carboalumination of terminal alkenes in the absence of catalysts usually occurs under drastic conditions and is accompanied by side reactions of hydro- and dehydroalumination. In the presence of metal complex catalysts, carboalumination proceeds under milder conditions and with higher selectivity.

The first examples of catalytic carboalumination of alkenes aimed at the synthesis of higher dialkylhalogenoalanes were described in 1979.⁹⁸ This method is based on a consecutive insertion of ethylene at the Al–C bond in the presence of low-valent Ti complexes. This reaction results in the formation of higher OAC (dialkylaluminium chlorides) with the number of carbon atoms from 4 to 30.

The reaction of terminal alkenes with Et_2AlCl in the presence of 0.3 mol.%–3.0 mol.% $\text{Ti}(\text{O}i\text{Bu})_4$ or TiCl_4 was studied by Dzhemilev *et al.*⁹⁹ It was found that Et_2AlCl carboaluminates alkenes even at ~20 °C; this reaction proceeds with high regioselectivity and affords the corresponding higher dialkylaluminium chlorides **21** in high yields.

This reaction is of general character and is successfully employed in the synthesis of OAC and in directed synthesis of natural compounds.^{99–101}

Carboalumination of terminal alkenes with 3-alkyl-1-chloroalumacyclopentanes was used to obtain other cyclic OAC, e.g., 1-chloro-3,6-disubstituted alumacycloheptanes.¹⁰²

Dialkylhalogenoalanes, such as Et_2AlCl and Me_2AlCl , carboaluminate substituted norbornenes in the presence of catalytic amounts of Ti complexes [Cp_2TiCl_2 , $\text{Ti}(\text{acac})_2\text{Cl}_2$, TiCl_4] with high stereoselectivity; subsequent hydrolysis results in alkylated norbornanes.^{103,104}

Carboalumination of terminal alkenes with Me_3Al in the presence of chiral derivatives of zirconocene, *e.g.*, bis(1-neomenthylindenyl)zirconium dichloride, bis(1-neo-isomenthyl-4,5,6,7-tetrahydroindenyl)zirconium dichloride, *etc.* with subsequent oxidation of alanes is used in a highly enantioselective synthesis of optically active alcohols.¹⁰⁵

$\text{R} = \text{C}_6\text{H}_{13}, \text{Pr}^i\text{CH}_2, \text{Ph}, \text{PhCH}_2, \text{HO}(\text{CH}_2)_4, \text{Et}_2\text{N}(\text{CH}_2)_3;$

The direction of the reaction of trialkylalanes with alkenes depends on the solvent used. Thus carboalumination in 1,1-dichloroethane proceeds with high enantioselectivity in the presence of catalytic amounts of chiral zirconium catalysts.¹⁰⁶

$[\text{Zr}]$, bis(1-neomenthylindenyl)zirconium dichloride.

Carboalumination of terminal alkenes with Me_3Al is selective when a two-component catalyst $\text{Cp}_2^*\text{ZrMe}_2 - \text{B}(\text{C}_6\text{F}_5)_3$ ($\text{Cp}^* = \eta^5\text{-C}_5\text{Me}_5$) (toluene, 0°C , ~ 3 h) is used.¹⁰⁷

$\text{R} = \text{H}_2\text{C=C(Me)(CH}_2)_2, \text{Me(CH}_2)_2.$

In contrast with terminal alkenes, hexa-1,5-diene, hepta-1,6-diene, octa-1,7-diene and their N-, O- and Si-containing derivatives react with trialkylalanes¹⁰⁷ or dialkylhalogenoalanes¹⁰⁸ in the presence of Zr- or Ti-containing complex catalysts to give, as a rule, cycloalkylmethylalanes or their heterocyclic analogues.

(a) Me_3Al , $\text{Cp}_2^*\text{ZrMe}_2$, $\text{B}(\text{C}_6\text{F}_5)_3$, 0°C ; $\text{Cp}^* = \eta^5\text{-C}_5\text{Me}_5$; $\text{X} = (\text{CH}_2)_n, \text{R}_2\text{Si}, \text{PhN}, \text{CHOSiR}_3$ (51%–88%); (b) R_2AlCl , $\text{Ti}(\text{OPr}^i)_4$; $\text{R} = \text{Et}, \text{Pr}^n, \text{Bu}^i$; $\text{X} = \text{CH}_2$; (c) $[\text{O}]$.

Negishi *et al.*¹⁰⁸ carried out cascade carboalumination of 5-vinylnona-1,8-diene in the presence of Et_2AlCl and $\text{Ti}(\text{OPr}^i)_4$ as a catalyst.

Catalytic carboalumination of non-conjugated dienes in the presence of Zr, Cp_2ZrX_2 or $\text{Cp}_2^*\text{ZrX}_2$ complexes ($\text{X} = \text{Cl}, \text{Me}$; $\text{Cp}^* = \eta^5\text{-C}_5\text{Me}_5$) and methylalumoxane $-\text{[Al(Me)O]}_n-$ was used for diastereo- and enantioselective cyclopolymerisation of hexa-1,5-diene. The diastereoselectivity of this reaction depends on the original catalyst. Catalysis with Cp_2ZrMe_2 at -78°C results in a polymer *trans*-**22** (yield 91%), whereas in the case of $\text{Cp}_2^*\text{ZrCl}_2$ the yield of *trans*-**22** is 14% at -25°C .¹⁰⁹ Cyclopolymerisation of hexa-1,5-diene in the presence of a chiral zirconium catalyst, (+)-(*S*)-**23**, and methylalumoxane gives the chiral polymer (–)-**22** [*trans*-isomer (68%), $[\alpha] = -49.3^\circ$].^{110, 111}

In the presence of $\text{Zr}(\text{OBu})_4$, terminal alkenes are alkylated with Et_2AlCl into position 2; alkenes **24** are formed in one step and with high selectivity.¹¹²

Ethylation of ethylene with Et_2AlCl in the presence of zirconium catalysts, *e.g.*, $\text{Zr}(\text{OBu}^n)_4$, $\text{Zr}(\text{OR})_n\text{Cl}_{4-n}$, served as the basis for the synthesis of but-1-ene.¹¹³

The reaction of dec-1-ene with AlEt_3 in the presence of Cp_2ZrCl_2 yields hydro- (**26**) and carboalumination (**27**) products as well as 1,1-dialkylethylenes **25**.¹⁰⁶

Reactions of trialkylalanes with terminal alkenes (including functionally substituted ones) in the presence of 2 equivalents of Cp_2TiCl_2 and trialkylaluminium in CH_2Cl_2 also result in 1,1-disubstituted alkenes. According to Barber *et al.*,¹¹⁴ carboalumination of alkenes under these conditions affords trialkylalanes which contain hydrocarbon radicals with an *iso*-structure;

they undergo β -hydride elimination by titanium complexes to give the corresponding alkenes in sufficiently high yields (45%–85%).

$R^1 = \text{C}_8\text{H}_{17}, \text{MeCO}_2(\text{CH}_2)_4, \text{Br}(\text{CH}_2)_4, \text{NC}(\text{CH}_2)_4; R^2 = \text{Me, Et, Bu}^n.$

Homoallylic alcohols react with Et_2AlCl in a non-selective manner. This reaction can be accomplished only in the presence of stoichiometric amounts of Ti-containing compounds, *e.g.*, Cp_2TiCl_2 , TiCl_4 , $\text{Ti}(\text{acac})_2\text{Cl}_2$.^{114–117} Carbometallation results in two regioisomeric products (**28** and **29**) and is accompanied by side reactions, such as hydrometallation, hydrogenation, isomerisation and β -hydride elimination.

It is believed^{114–117} that the reaction of Et_2AlCl with titanium compounds results in the formation of the corresponding ethyl-titanium complexes which are active in further carbometallation of terminal alkenes. Subsequent hydrolysis affords isomeric alcohols **28** and **29**.

In a continuation of these studies, the reaction of intramolecular carbometallation in the presence of EtAlCl_2 was further extended to the selective synthesis of substituted cyclopentanes from 1-bromohex-5-enes.^{118–120} The role of EtAlCl_2 complexes consists in the activation of the intermediate titanium complex **30**.

Thus the carboalumination of alkenes with the simplest organoaluminium compounds catalysed by transition metal complexes permits simultaneous formation of C–C and Al–C bonds with high regio- and stereoselectivities. Further transformations of the organoaluminium compounds formed in the process make it possible to obtain alcohols, aldehydes, acids and other compounds.

V. Carboalumination of alkynes catalysed by transition metal complexes

The reaction of gaseous acetylene with trialkylalanes occurs under mild conditions ($40\text{--}60^\circ\text{C}$) with high stereoselectivity and results in *Z*-alkenyldialkylalanes, this being one of the simplest examples of carboalumination of alkynes with OAC.⁷⁴ The features of this non-catalytic reaction and alkenylalane conversions are documented in a substantial body of literature (see, *e.g.*, Refs 18–20 and 121). Catalytic carboalumination of alkynes has been extensively generalised (*cf.*, *e.g.*, Refs 17, 47, 122–125). The present review considers the synthesis of alkenylalanes by catalytic carboalumination of alkynes with trialkyl- and halogenoalkylalanes.

Carboalumination of mono- and disubstituted acetylenes is carried out in the presence of transition metal compounds derived from Fe,⁸⁶ Mn, Ni, Ti,^{126–130} Zr¹³¹ and Cu salts and complexes;^{132–134} this reaction utilises trialkylalanes (Et_3Al , Bu_3Al , $[\text{EtCH}(\text{Me})\text{CH}_2]_3\text{Al}$),⁸⁶ chlorodialkylalanes (Me_2AlCl ,¹³⁵ Et_2AlCl ,¹³¹ Pr^nAlCl),¹³¹ allyl-, benzylalanes¹³⁶ and alumocuprates^{132–134} as carbometallating reagents. Such reactions are generally non-selective and yield a complex mixture of regioisomers.

A two-component system proposed by Negishi *et al.*^{137–139} which contains AlMe_3 and catalytic amounts of Cp_2ZrCl_2 is one of the most efficient reagents for acetylene carbometallation presently available. Later, this system was modified by addition of H_2O .¹⁴⁰

Yoshida and Negishi¹⁴¹ have initially proposed that Cp_2ZrCl_2 -catalysed carboalumination of alkynes involved methylation of Cp_2ZrCl_2 with trimethylaluminium to give MeZrCp_2Cl and Me_2AlCl . Subsequent carbocyclozirconation of the alkyne yields the corresponding alkenylzirconium derivatives; their transmetalation with Me_2AlCl results in alkenyldimethylalanes with simultaneous regeneration of the catalyst. The reaction mechanism included the existence of a reversible reaction where the methyl group or the methyl radical is transferred from the Al atom to the Zr atom as can be evidenced from the NMR data. However, further investigations^{142, 143} showed that this reaction involves direct carboalumination of alkynes.

Carboalumination of alkynes resulted in a great number of practically important organoaluminium and organic compounds. Thus an elegant method was proposed for the synthesis of isoprene linear trimers **31** and **32** by stereo- and regiospecific cross-coupling of geranyl and neryl chlorides with alkadienylaluminium **33**.¹⁴⁴ The reagent **33** was synthesised by carboalumination of vinylacetylene with trimethylaluminium in the presence of catalytic amounts of Cp_2ZrCl_2 .

Catalytic carboalumination of terminal alkynes with AlMe_3 with subsequent functionalisation of the alkenylalanes formed was used for the synthesis of natural isoprenoids, *e.g.*, geraniol,¹⁴⁵ monocyclofarnesol¹⁴⁶ and farnesol.¹⁴⁷

An efficient procedure has been developed for the synthesis of polyenic hydrocarbons of different structure (including those containing conjugated double bonds) using alkenylalanes and catalytic amounts of phosphine complexes of Ni or Pd.¹⁴⁸

A similar approach was used in the synthesis of cyclic and acyclic functionally substituted unsaturated compounds.^{149, 150}

The ability of alkenylalanes to enter into the cross-coupling reactions with organic halides was used as the basis for a new method of synthesis of substituted cyclobutenes. Thus carboalumination of silylated alkynes **34** with trimethylaluminium under mild conditions yields alkenylalanes **35** containing a good leaving group X. Intramolecular cyclisation of the intermediates **35** results in 1-methyl-2-(trimethylsilyl)cyclobutene (**36**).¹⁵¹

X = Cl, Br, I, OTs.

Carbometallation of ω -halogen-substituted 1-trimethylsilylalk-1-ynes or enynes with alkyl derivatives of Al, Zn or Li followed by intramolecular cyclisation of the organometallic compounds formed allows one to synthesise substituted cycloalkenes in high yields.^{152–154} 5-Bromo-1-trimethylsilylpent-1-yne (**37**) is the least prone to intramolecular cyclisation; it generates alkenylalane **38** in 60% yield. The iodo-substituted alkynylalane **39** enters into the carboalumination reaction to give the dialuminium derivative **40**; treatment of the latter with I_2 gives iodo-substituted cyclopentene.¹⁵⁵

Cp_2ZrCl_2 -Catalysed carboalumination of mono- and disubstituted acetylenes or 1,3-diynes is an example of an efficient regio- and stereoselective synthesis of trisubstituted alkenes, homoallylic alcohols, esters of α,β -unsaturated acid and 1,4-disilylated 1,3-enynes.^{156–159}

Alkenylalanes obtained by carboalumination of alkynes are extremely useful for introducing alkenyl groups into the β -position of cyclic enones. This approach was used, for example, in the preparation of key compounds for the synthesis of prostaglandins.^{160, 161}

Transmetalation of alkenylalanes with organoboron or organozirconium compounds occurs under mild conditions (25 °C, 1 h) and affords the corresponding alkenylboron- (**41**) or -organozirconium (**42**) compounds which can further be used in terpenoid syntheses.¹⁶²

In recent years, catalytic carboalumination of alkynes has found wide application in the synthesis of natural and biologically active compounds, *e.g.*, brassinolide,¹⁶³ milbemycin,^{164–166} zoapatanol,¹⁶⁷ mabcen fragments,¹⁶⁸ synthetic precursors of lophotoxin and pukalide,¹⁶⁹ mokupalide,¹⁷⁰ trichoverrol B,¹⁷¹ verrucarins,¹⁷² *etc.*

VI. Cycloalumination of alkenes in the presence of zirconium- and titanium-containing catalysts

The methods developed in the late 1980's dealt mainly with the synthesis of alkyl-, cycloalkyl-, alkenyl- and vinylalanes. Data on the possibility of preparative synthesis of stable three- and five-membered OAC were practically absent in the literature. The first report on a regioselective synthesis of previously unknown five-

membered OAC (alumacyclopentanes, ACP) was published as late as in 1989.¹⁷³

Later, it was found that this reaction is versatile and allows one to perform a one-step synthesis of five-membered OAC from AlEt_3 and terminal alkenes in nearly quantitative yields. This reaction was termed as ‘catalytic cycloalumination of unsaturated compounds’^{174–177} or ‘cyclic carboalumination’.^{84, 178}

O-, *N*- and *S*-containing alkenes and norbornenes also undergo cycloalumination to give the corresponding ACP.^{179, 180} The cycloalumination of norbornenes is highly selective and results in the formation of five-membered metallocycles **43** having an *exo*-configuration.¹⁷⁹

$\text{X} = \text{OR}^1, \text{SR}^1, \text{NR}^1$.

Substitution of higher OAC for AlEt_3 affords predominantly *trans*-3,4-disubstituted ACP **44–46**.¹⁸¹

This is accompanied by the formation of 2,4-dialkyl-substituted alumacyclopentanes (5%–12%); the latter undergo intramolecular β -hydride conversions into *E*-alkenylalanes **47** and, after hydrolysis, into *E*-alkenes **48**.¹⁸¹

After substitution of dihalogenoalanes for higher trialkylalanes, the cycloalumination of terminal alkenes occurs more selectively and gives *trans*-3,4-dialkyl-substituted ACP. In contrast with previously developed procedures;^{173, 179, 180} the reactive catalytic intermediate, *viz.*, Cp_2Zr , is generated in these reactions by reduction of Cp_2ZrCl_2 in THF by Mg activated with RAlCl_2 . This approach enables the synthesis of 1-alkyl-, 1-alkoxy-, 1-dialkylamino- and 1-halogeno-*trans*-3,4-dialkyl-substituted alumacyclopentanes **49** from α -alkenes, dihalogenoalanes and metallic magnesium (which is a halogenide ion acceptor) in the presence of catalytic amounts of Cp_2ZrCl_2 or ZrCl_4 (yields 70%–90%).^{182–184} The structure of substituted alumacyclopentanes, the position of substituents and their configuration were established by spectral methods.^{185, 186}

$\text{R}^1 = \text{Alk, RO, R}_2\text{N}$; $\text{R}^2 = \text{Alk}(\text{C}_3\text{--C}_{20})$; $[\text{Zr}] = \text{Cp}_2\text{ZrCl}_2, \text{ZrCl}_4$.

The incorporation of an alkene molecule into the Al–C bond of 3-alkyl-substituted ACP in the presence of Ti complexes is an efficient procedure for obtaining 1-ethyl-3,6-dialkyl-substituted alumacycloheptanes **50**.¹⁰² The cleavage of the Al–C bond in ACP in the presence of nickel catalysts results in the unsaturated OAC **51**¹⁸⁷ or 2-alkyl-substituted 1,3-dienes **52** in quantitative yields (Scheme 2).¹⁸⁸

Scheme 2

ACP was used in the synthesis of different classes of compounds (see Scheme 2). They are active co-catalysts in co-telomerisation reactions as well as in one-pot conversions of α -alkenes into 1,4-butanediols **53**,¹⁸⁹ thiolane 1-oxides **54**,¹⁹⁰ cyclobutanes **55**,^{191, 192} cyclopropanes **56**,¹⁹³ thiophanes **57**, selenophanes **58**,^{194, 195} phospholanes **59**,¹⁹⁶ α,ω -dienes¹⁹⁷ and optically active hydrocarbons **60**.¹⁹⁸

ACP were used as intermediates in preparative syntheses of 2-alkyl-substituted 1,3-dienes **52** (β -vinylation¹⁸⁸), 1,1-dialkylethylenes **61** (reductive β -vinylation^{187, 199}), branched hydrocarbons **62** (reductive β -ethylation²⁰⁰) and iodo-derivatives **63** (reductive β -iodoethylation²⁰¹) from alkenes (Scheme 3).

The use of ACP offers a simple approach to the synthesis of linear *E*-isoprenoids **64** and **65** with a definite number of the C_5 fragments.²⁰² Alumacyclopentanes can be used in the synthesis of biologically active compounds, *e.g.*, pheromones of pine sawfly, German cockroach and mealworms *Tribolium confusum* and *Tribolium castaneum* (Scheme 4).^{203–206}

Scheme 3

A method for the synthesis of 3-alkyl-substituted ACP from α -alkenes and AlEt_3 (see Refs 173, 179, 180) was recently modified through the application of more readily available and less pyrophoric reagents. This novel procedure is also based on the *in situ* generation of an active catalytic species, *viz.*, Cp_2Zr , from Cp_2ZrCl_2 and simultaneous introduction of α -alkene and ethylene molecules, synthesised *in situ* from dichloroethane and metallic Mg, into the coordination sphere of the central atom of the catalyst.^{207,208} The main product of this reaction is 3-alkyl-substituted ACP; 1-ethyl-*trans*-3,4-dialkyl-substituted ACP **66** is formed as a by-product ($\sim 6:1$).

(a) Cp_2ZrCl_2 , Mg, $\text{C}_2\text{H}_4\text{Cl}_2$, THF, 20°C .

Substitution of R_2AlCl for RAlCl_2 gives substituted 1,4-dialuminiobutanes **67** and **68** which represent a novel class of acyclic OAC. This reaction was studied rather comprehensively for numerous α -alkenes and structurally different OAC.²⁰⁹

$\text{R}^1 = \text{OR}^3, \text{NR}_2^3, \text{R}^3\text{S}, \text{Alk}(\text{C}_3-\text{C}_{20})$.

In 1997, Dzhemilev *et al.* developed a method for the synthesis of a previously unknown class of metallacycles, *viz.*, alumacyclopropanes. Cycloalumination of arylalkenes (styrene, *o*- and *p*-methylstyrene and 1,4-diphenylbuta-1,3-diene) with ethylaluminum dichloride in the presence of metallic magnesium as a chloride ion acceptor and Cp_2TiCl_2 yielded alumacyclopropanes (yields 80%).²¹⁰

Treatment of the C_{60} fullerene with EtAlCl_2 in the presence of Cp_2TiCl_2 and Mg yielded the organometallic compounds **69** containing alumacyclopropane fragments.^{207,211} Cycloalumination of C_{60} probably involves titanacyclopropane intermediates, $\text{Cp}_2\text{Ti}(\eta^2-\text{C}_{60})$;²¹² transmetalation of the latter with EtAlCl_2 results in fullerenic alumacyclopropanes **69**.

$n = 1-6$.

Cp_2ZrCl_2 -Catalysed cycloalumination of the C_{60} fullerene with AlEt_3 recently carried out by Dzhemilev *et al.*^{213,214} gave the organometallic derivatives of C_{60} containing alumacyclopentane fragments. Organometallic fullerene derivatives containing two alumacyclopentane fragments are formed in toluene ($\sim 22^\circ\text{C}$, 36 h) at the $\text{C}_{60}:\text{AlEt}_3$ ratio of 1:30 (total yield $\sim 80\%$). At the $\text{C}_{60}:\text{AlEt}_3$ ratio of 1:300, up to 12 alumacyclopentane fragments can be introduced into the C_{60} molecule.

$n = 30, 300; m = 2-12$.

Scheme 4

In contrast with aliphatic alkenes, cycloalumination of terminal aryl-substituted alkenes with AlEt_3 in the presence of Cp_2ZrCl_2 occurs less selectively. Thus a mixture of mono- and disubstituted arylalumacyclopentanes and 2-aryl-1-ethylalumacyclopentane are formed in a total yield > 90% (**70**:**71**:**72**:**73**:**74** ~ 50:25:15:3:7).^{207, 215}

$\text{R} = \text{Ph}, 2\text{-MeC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4$.

The reaction of R_2AlCl with arylalkenes catalysed by Cp_2TiCl_2 was used in the synthesis of 1,2-dialuminomethanes **75**.²¹⁵

VII. Catalytic cycloalumination of alkynes

Simple procedures have been developed for the synthesis of unsaturated cyclic OAC from saturated three- and five-membered cyclic OAC in the presence of titanium- and zirconium-containing metal complex catalysts. Thus cycloalumination of disubstituted acetylenes with triethylaluminium in the presence of catalytic amounts of Cp_2ZrCl_2 gave 2,3-dialkyl(aryl)-substituted alumacyclopent-2-enes **77**.^{216, 217} Carboalumination of disubstituted acetylenes in halogen-containing solvents yields acyclic alkenylalanes.⁸⁴ The nature of the solvent plays a crucial role in the formation of intermediate titanium- and zirconium-containing metallacycles **76**, the key intermediates in the synthesis of alumacyclopentenes **77**.^{84, 218}

The structure of alumacyclopentenes **77** was established by spectral methods²¹⁷ and by their conversions. Thus hydrolysis of compounds **77** with D_2O gave trisubstituted alkenes **78** (Scheme 5).²¹⁷ Dealumination of OAC **77** in the presence of catalytic amounts of palladium phosphine complexes results in 1,2-disubstituted cyclobutenes **79**.²¹⁹ In the presence of an excess of dimethyl sulfate, compounds **77** are readily transformed into 1,1-dialkyl-substituted cyclopropanes **81**. Cross-coupling of OAC **77** with allyl halides results in 4,5-disubstituted 1,4(Z),9-decatrienes **80** (see Scheme 5).²²⁰

In 1998, Negishi *et al.*¹⁷⁸ carried out the synthesis of bicyclic alumacyclopentenes **82** by intramolecular cycloalumination of enynes **83** in the presence of catalytic amounts of Cp_2ZrCl_2 .

Subsequent treatment of OAC **82** with CO_2 or BrCH_2OMe resulted in the corresponding cyclopentenones **84** and vinylcyclopropanes **85**.

$n = 1, 2$.

A modified procedure for the synthesis of 1-ethyl-2,3-dialkyl(aryl)alumacyclopent-2-enes **77** from disubstituted acetylenes and ethylene generated *in situ* from dichloroethane and activated metallic magnesium has been recently developed by Ramazanov *et al.*^{221, 222} This reaction yields the corresponding alumacyclopentenes **86** and alumacyclopentadienes **87** as by-products (5%–30%).

The synthesis of alumacyclopentenes **88** by cycloalumination of 1,2-disubstituted acetylenes using alkyl-dichloroalanes²²³ in the presence of Ti complexes is one of the most substantial achievements in the synthesis of small alumacycles. Presumably, these reaction conditions favour the generation of titanacyclopentene intermediates,^{224–235} their transmetalation with dihalogenoalanes results in the corresponding trisubstituted alumacyclopentenes **88**.^{223, 236–238}

$\text{R}^1 = \text{Alk}, \text{Ph}; \text{R}^2 = \text{Alk}, \text{OR}^3, \text{NR}_2^3$.

In contrast with 1,2-disubstituted acetylenes, terminal alkynes react with AlCl_3 in the presence of Ti complexes less selectively. This reaction yields alumacyclopentadienes **87** along with alumacycloprenes **88**.

The synthesis of 1,2-dialuminoethylenes **89** by the reaction of 1,2-disubstituted acetylenes with R_2AlCl under the action of catalytic amounts of Cp_2TiCl_2 in the presence of a chloride ion acceptor (activated Mg) has been carried out by Dzhemilev *et al.*²³⁹

1-Ethyl-2,3,4,5-tetraalkyl-1-alumacyclopenta-2,4-dienes **87** were synthesised with high selectivity by cycloalumination of 1,2-dialkyl-substituted acetylenes using EtAlCl_2 in the presence of Cp_2ZrCl_2 (5 mol.%, $\sim 23^\circ\text{C}$, TTF).^{221,240} The content of alumacycloprenes in the reaction mixture does not exceed 5%–7%.

$\text{R} = \text{Alk}(\text{C}_3 - \text{C}_{10})$.

VIII. Conclusion

In the past 10–15 years, organoaluminium compounds have gained popularity in the practice of synthetic organic and organometallic chemistry along with organomagnesium reagents.

The catalytic reactions of hydro-, carbo- and cycloalumination of alkenes, dienes and alkynes are carried out under mild conditions and yield OAC with high regio- and stereoselectivity. Thus OAC were used in the synthesis of the major classes of natural compounds, such as vitamins, antibiotics, alkaloids, steroids, carbohydrates, prostaglandins, isoprenoids, drugs, *etc.*

We are convinced that future syntheses will widely employ organoaluminium compounds and will be aimed at obtaining novel co-catalysts for oligomerisation and polymerisation reactions and efficient reagents for regio- and stereoselective reduction and alkylation of unsaturated compounds as well as at the development of non-traditional approaches to the design of organic and organometallic compounds and most advanced chemical technologies.

IV. Other reactions	148
V. Conclusion	148

Abstract. The data on catalytic dehydrocondensation of organylsilanes with the formation of Si—Si bonds are systematised and generalised. The mechanism and general features (the effects of the nature of the reactants and the catalyst, the solvent and the reaction conditions) of these reactions catalysed by cyclopentadienyl complexes of transition metals are considered. Electrochemical and other procedures for the dehydrocondensation of organylsilanes are discussed. The bibliography includes 220 references.

I. Introduction

Organosilicon compounds with Si—H bonds, in particular, organylsilanes of the $R_{4-n}SiH_n$ type ($n = 1-3$), are highly reactive substances.¹ In this connection, these compounds are of considerable theoretical and practical interest.

Thus addition of silanes to unsaturated substrates containing the C=C, C=N, N=N, C=O, C≡C or N≡N bonds, *viz.*, hydrosilylation,² is one of the most important procedures for the synthesis of various organosilicon compounds.¹⁻⁸ This unique reaction makes it possible to form Si—C bonds as well as Si—O—C and Si—N—C groups in one stage.

Y = R_2C , O, HN *etc.*

Organylsilanes, unlike their formal analogues, *viz.*, hydrocarbons, readily enter into dehydrocondensation reactions with OH, NH, SH and CH acids. Dehydrocondensation reactions with different compounds, such as water, alcohols, phenols, inorganic and carboxylic acids, amines, thiols, *etc.*, have been well studied.

Y = O, S, NH; R = H, Alk, Ar, Ac *etc.*

Hydrosilylation and dehydrocondensation are most often catalysed by transition metal compounds and nucleophiles. Examples of the use of dehydrocondensation of organylsilanes for the preparation of organosilicon compounds are shown in Scheme 1.

Scheme 1

Synthetic applications of dehydrocondensation of silanes with hydroxy-containing organic compounds and the mechanism of this reaction have been adequately surveyed in the reviews.^{1,9-14} Of more recent investigations, studies on alcoholysis of mono-, di- and trisubstituted silanes with saturated and unsaturated primary and secondary alcohols and diols in the presence of complexes of copper $\{[Ph_3PCuH]_6\}$,¹⁵ titanium¹⁶ and manganese $\{[Mn(CO)_4Br]_2\}$ ¹⁷ as well as in the presence of soluble platinum, palladium, nickel, ruthenium and rhodium complexes fixed on silica gel,¹⁸⁻²⁰ and studies on alcoholysis of disilanes in the presence of tetrabutylammonium fluoride²¹ are worthy of note.

Dehydrocondensation of silanes with phenols, ammonia, amines, thiols and carboxylic acids are less well understood.¹¹ Of the recent advances, phenolysis catalysed by potassium fluoride^{22,23} and ammonolysis (with ammonia or hydrazines) of phenylmethyl-, diphenylmethyl- and methyldichlorosilanes in the presence of dimethyltitanocene²⁴⁻²⁷ should be mentioned. The synthesis of quaternary ammonium difluorosilicates by the reactions of $R_2^1R^2SiH$ with $R_3^2R^4N^+HF_2^-$ was reported.²⁸ The reactions of unsaturated organic acids with dimethylchlorosilane followed by intramolecular hydrosilylation of the resulting β,γ -unsaturated acyloxysilanes catalysed by Pt(II) 1,5-cyclooctadiene (COD) complexes afford silaoxacyclopentanones. The latter can

Uspekhi Khimii 69 (2) 150–165 (2000); translated by T N Safonova

be converted into esters of hydroxycarboxylic acids. This method was used in the stereoselective synthesis of methyl ester of (2*S*,3*R*)-3-hydroxy-*N*-Boc-proline.²⁹ Products of hydrosilylation of styrene, 1-octyne and phenylacetylene with phenyl- and diphenylsilane enter into dehydrocondensation reactions with arenethiols ArSH (Ar = Ph, 4-MeC₆H₄ or 4-MeOC₆H₄) in the presence of rhodium tris(triphenylphosphine) chloride.³⁰

Dehydrocondensation of octacarbonyldicobalt complexes of mono-, di- and triethynylsilanes (**1–3**) in the absence of nucleophilic or metal complex catalysts occurs through interactions between the Si–H bond and water, alcohols, carboxylic acids, primary amines, *etc.*^{31, 32}

Dehydrocondensation of silanes with CH acids (alkanes, alkenes, alkynes and their derivatives) has been studied in sufficient detail.^{11, 33–39}

Dehydrocondensation of organosilicon compounds containing Si–H bonds to form disilanes has remained poorly studied for a long time and attracted considerable attention only recently.

Organosilicon compounds containing Si–Si bonds have attracted growing interest because they can be used as starting compounds in the synthesis of organic and inorganic derivatives of oligo- and polysilanes possessing specific structural, electronic, optical and chemical properties.^{40, 41} These oligo- and polysilanes find use in the production of ceramic materials,^{42–64} semiconductors,^{4, 42, 48, 49, 65–69} photoresistors,^{42, 44, 46, 48, 49, 70–77} photoinitiators of polymerisation of alkenes, *etc.*⁴²

In this review, studies on dehydrocondensation of organylsilanes (which is sometimes wrongly called ‘dehydropolymerisation’⁴²) accompanied by the formation of Si–Si bonds are surveyed.

II. Catalytic dehydrocondensation of organylhydrosilanes

1. Catalysis by compounds of Group IIIB elements

The data on the use of complex compounds of Group IIIB elements as catalysts of dehydrocondensation of silanes are scarce.

The activation energies and the enthalpies of dehydrocondensation of monosilane in the presence of complexes of lanthanides M (M = Sc, Y, La, Lu or Sm), which were calculated in a study,⁷⁸ indicate that this reaction can in principle proceed. It is believed that the first stage of the process involves silylation of intermediate **4**. The second stage leads to the formation of disilane and regeneration of intermediate **4**.

Of Group IIIB elements, only derivatives of lanthanides and actinides, as far as is known, are active in dehydrocondensation.^{78–80} Thus PhSiH₃ in the presence of Cp^{*}₂NdCH(SiMe₃)₂ (Cp^{*} = η⁵-C₅Me₅) was converted into oily polyphenylsilane with a molecular weight (*M*) of 600 at 80 °C during two days.⁸⁰

The dimeric hydride complex of lanthanocene [Cp^{*}₂LaH]₂ is also an active catalyst of dehydrocondensation of phenylsi-

lane.^{80, 81} In this case, a mixture of PhSiH₂SiH₂Ph and (PhSiH₂)₂SiHPh was formed from PhSiH₃.

Cyclopentadienyl complexes of actinides also catalyse dehydrocondensation of organylsilanes. Thus cyclopentadienyl derivatives of dimethyluranium and dimethylthorium converted phenylsilane into 1,2-diphenyldisilane (M = Th) or an oligomer (M = U) in 70% and 30% yields, respectively, even at room temperature during 6 h.⁸²

M = U, Th.

Dimethylmetallocenes, which are actinide derivatives, rank below isostructural titanocenes and zirconocenes in the catalytic activity.⁸²

Dehydrocondensation of silanes of the Si_aH_bR_c¹ type [R¹ = Alk, Ar, alkenyl, AlkO, Hal or NHR²; *a* ≥ 2; *b* ≥ 1; (*b* + *c*) = (2*a* + 2)] occurs under an inert atmosphere in the presence of Cp₂MR₂³ (M = Th or U).^{83–85}

2. Catalysis by compounds of Group IVB elements

a. Catalysis by alkyl- and arylmetallocenes CpMR₃, Cp₂MR₂ and Cp₂MPh₂

Dehydrocondensation of silanes, such as PhSiH₃, MeSiH(OR)₂ and HSi(OR)₃, in the presence of dimethyltitanocene was first reported by Harrod and coworkers in 1984.⁸⁶ The above-mentioned silanes react with dimethyltitanocene in a hydrocarbon solvent or without a solvent at room temperature to give the titanium hydride complex and the corresponding disilane derivatives.

Trialkyl- and triarylsilanes as well as chlorosilanes do not undergo dehydrocondensation even at 80–120 °C.^{82, 86, 87}

More recently, Harrod and coworkers published a series of studies^{82, 88–100} on dehydrocondensation of monosubstituted silanes (RSiH₃, where R = Ph, Bn or C₆H₁₃), disubstituted silanes (R¹R²SiH₂, where R¹ = R² = Ph or R¹ = Ph and R² = Bu), trialkoxysilanes (RO)₃SiH (R = Me or Et), Me(EtO)₂SiH and 1,3,5,7-tetramethylcyclotetrasilane catalysed by dialkyltitanocenes Cp₂MR₂ (M = Ti or Zr; R = Me or Bn but not Ph). Later on, the series of catalysts of dehydrocondensation of silanes was substantially extended. It was demonstrated^{82, 89–91} that mono-(cyclopentadienyl)trialkyl and di(cyclopentadienyl)dialkyl derivatives of Group IVB metals (Ti, Zr and Hf) exhibit a high catalytic activity in this reaction.

The most important advantage of the above catalysts over inorganic compounds,^{24, 29, 101–107} complex and organometallic compounds^{108, 109} is their ability to catalyse the formation of oligomers containing 10–20 silicon atoms in the chains under rather mild conditions (Table. 1).

The catalytic activity of sterically hindered (cyclopentadienyl)trimethyltitanium as well as of its zirconium analogue in dehydrocondensation of phenylsilane is low.⁸² Attempts to perform dehydrocondensation of phenylsilane in the presence of Cp₂HfMe₂ at 20 or 90 °C (12 h) were unsuccessful.

Generally, dehydrocondensation of silanes RSiH₃ catalysed by dimethyltitanocene or dimethylzirconocene affords a mixture of linear and cyclic oligomers the ratio of which depends on the nature of the initial silane and the reaction conditions.^{92, 93, 112}

Thus phenylsilane forms predominantly linear oligomers, whereas hexylsilane produces a mixture of linear and cyclic oligomers. In the presence of dimethyltitanocene, benzylsilane was converted predominantly into hexabenzylcyclohexasilane (the yield was ~ 35%).⁹²

Table 1. Comparative catalytic activities of metallocenes of derivatives of Groups IV – VII elements in dehydrocondensation of organylhydrosilanes RSiH₃ and R₂SiH₂.

^a In the presence of a hydrogen acceptor; ^b the highest degree of polymerisation; ^c in the presence of cyclooctene; ^d 52% of unidentified oligomers; ^e in the presence of dec-1-ene.

The reactivity of RSiH₃ upon catalysis by dimethyltitanocene decreases in the following series (the relative reaction rates at 20 °C are given in parentheses): Ph (13) > Bn (1) = C₆H₁₃ (1). In the reactions catalysed by dimethylzirconocene, the reactivity changes in the following order: Ph (100) > Bn (15) > C₆H₁₃ (5).⁹¹

Zirconocenes catalyse dehydrocondensation of substituted phenylsilanes XC₆H₄SiH₃ containing the fluoroalkyl, alkoxy, aryloxy, acyloxy, hydroxy or alkylamino groups in the benzene

ring.¹¹⁰ Thus a polymer with the molecular weight of 1330 was prepared from 4-(dimethylamino)phenylsilane.¹¹⁰

The only convenient procedure for the synthesis of polymethylsilane involves dehydrocondensation of methylsilane catalysed by dimethyltitanocene or dimethylzirconocene at 50 °C and 10 atm.⁹² The molecular weight of the resulting cross-linked polymethylsilane is rather high (~ 10 000).

Disubstituted silanes, such as MeSiH₂Ph and Ph₂SiH₂, are less reactive than RSiH₃. In the presence of dimethyltitanocene or

dimethylzirconocene at 60–80 °C, these silanes form predominantly dimers and trimers, *viz.*, $\text{RH}_2\text{SiSiH}_2\text{R}$ and $(\text{R}_2\text{SiH})_2\cdot\text{SiHR}$.^{91,92} The catalytic activity of metallocenes Cp_2MMe_2 in this reaction decreases in the series $\text{Zr} > \text{Ti} \gg \text{Hf}$.^{89,91,92} When zirconocene, which was prepared *in situ* by the reaction of Cp_2ZrCl_2 with BuLi, was used as a catalyst, methylphenylsilane was converted into the linear $\text{H}(\text{MePhSi})_n\text{H}$ oligomer, where $n = 5$ or 6.¹¹³ Unlike methylphenylsilane, butylmethylsilane^{91,92} as well as other silanes R_3SiH (see Ref. 42) remained unchanged in the presence of dimethyltitanocene or dimethylzirconocene even at 100 °C.

Dehydrocondensation of dibenzosilaheterocycles **5a–d** was studied.¹¹²

R = H: $n = 1$ (**a**), 2 (**b**), 0 (**c**);
R = Bu^t, $n = 0$ (**d**).

Dehydrocondensation of 9,10-dihydro-9-silaanthracene **5a** in the presence of dimethyltitanocene at 20 °C does not occur. In the reaction catalysed by dimethylzirconocene at 90 °C, the corresponding trimer is formed in high yield. Under analogous conditions in the presence of the same catalysts, 10,11-dihydro-5H-dibenzo[*b,f*]silepine (**5b**) remains unchanged. Silafluorene (**5c**) is converted into a pentamer, which is insoluble in the usual organic solvents, upon catalysis by dimethyltitanocene in toluene in the absence of oxygen for 29 h.

Titanium and zirconium complexes with the [2-(diisopropylamino)ethyl]cyclopentadienyl ligand, *viz.*, $[\text{Cp}(\text{CH}_2)_2\text{NPr}_2]_2\text{MMe}_2$ ($\text{M} = \text{Ti}$ or Zr), $[\text{Cp}(\text{CH}_2)_2\text{NPr}_2]_2\text{TiBr}_2$ and $[\text{Cp}(\text{CH}_2)_2\cdot\text{NPr}_2]_2\text{Ti}(\text{OPh})_2$, were suggested as efficient catalysts of dehydrocondensation of phenylsilane.¹¹⁴

Binary mixtures of dimethyltitanocene with one equivalent of trialkyl- or alkylarylphosphine are used as catalysts of dehydrocondensation of PhSiH_3 , MePhSiH_2 , Ph_2SiH_2 and BnSiH_3 .^{97–99} In these cases, microcrystalline products are formed.

Nakano and coworkers⁴⁹ succeeded in performing dehydrocondensation of triphenyl-, diphenyl- and methylphenylsilanes in the presence of Cp_2TiPh_2 (under an argon atmosphere, 110 °C, 24 h). In this case, 1,1,2,2-tetraphenyldisilane (72%) formed from diphenylsilane, whereas 1,2,3-trimethyl-1,2,3-triphenyltrisilane (32%) and 1,2-dimethyl-1,2-diphenyldisilane (14%) were obtained from methylphenylsilane. When cyclooctene was used as an acceptor of hydrogen, which was eliminated upon dehydrocondensation, the yield of trisilane was increased to 80%. Dehydrocondensation of phenylsilane under analogous conditions proceeds more readily to yield polyphenylsilanes containing terminal hydrogen atoms ($M = 340–17\,300$). The reaction of phenylsilane in the presence of Cp_2TiPh_2 at 140 °C for 3 h afforded a cyclic six-membered silane.¹¹⁵ Under analogous conditions, triethylsilane generates hexaethyldisilane in insignificant yield (0.6%).

Dehydrocondensation of 1,2-diphenyldisilane catalysed by dimethyltitanocene or dimethylzirconocene proceeds very rapidly. Thus the $\text{H}(\text{PhSiH})_4$ tetramer was obtained in 40% yield after 30 min.⁹¹ Apparently, the presence of PhSiH_3 and $\text{H}(\text{PhHSi})_2\cdot\text{SiH}_2\text{Ph}$ among the reaction products results from competitive disproportionation of the initial 1,2-diphenyldisilane

The enhanced reactivity of 1,2-diphenyldisilane is determined by the lower energy of the Si–H bonds in the $-\text{H}_2\text{Si}-\text{SiH}_2-$ fragment compared to their energy in the SiH_3 group.

Dehydrocondensation of silanes of the $\text{Si}_a\text{H}_b\text{R}_c$ type [$\text{R} = \text{Alk}$, Ar , alkenyl, AlkO , Hal or NR_2 ; $a \geq 2$; $b \geq 1$; $(b + c) = (2a + 2)$] catalysed by dialkylmetallocenes Cp_2MAlk_2 ($\text{M} = \text{Ti}$, Zr or Hf) afforded liquid linear polymers containing from three to seven monomer units.^{83–85}

Dehydrocondensation of phenylsilane with 1,2-dimethyldisilane in the presence of Cp_2MMe_2 ($\text{M} = \text{Ti}$ or Zr) yielded the $\text{H}[(\text{MeSiH})_x(\text{PhSiH})_y]_n\text{H}$ oligomer.¹¹⁶

The reaction of $\text{Me}_2\text{HSiSiH}_2\text{Me}$ with 1,2-dimethyldisilane afforded the $\text{H}[(\text{MeSi})_x(\text{Me}_2\text{Si})_y]_n\text{H}$ oligomer. The structures of these oligomers were established by GLC-mass spectrometry.¹¹⁶

b. Catalysis by alkoxy- and aryloxymetallocenes and titanium alkoxides

Dehydrocondensation of phenyl-, diphenyl- and dibutylsilane catalysed by dialkoxy-, diphenoxytitanocene, its derivatives $\text{Cp}_2\text{Ti}(\text{OR})_2$ ($\text{R} = \text{Alk}$, Ph , 4- MeC_6H_4 , 4- MeOC_6H_4 , 4- ClC_6H_4 or 4- CNC_6H_4) or diphenoxyzirconocene $\text{Cp}_2\text{Zr}(\text{OPh})_2$ was studied.^{117–120} Dehydrocondensation of PhSiH_3 afforded a mixture of linear and cyclic oligomers (15 min, 50 °C, the total yield was 25%). In this case, the reaction rate and the compositions of the resulting oligomers are comparable with those observed in the reactions with the use of Cp_2TiMe_2 (see Ref. 87) or the $\text{Cp}_2\text{TiCl}_2-2\text{BuLi}$ binary mixture¹¹³ as catalysts.

In the presence of $\text{Cp}_2\text{Ti}(\text{OPh})_2$ at 100 °C, diphenylsilane formed the $\text{Ph}_2\text{SiHSiHPh}_2$ dimer in 10% yield.¹¹¹ In the presence of 5 mol. % of $\text{Cp}_2\text{Ti}(\text{OPh})_2$ at 110 °C, dibutylsilane gave mono- and diphenoxy derivatives due to the interaction with the catalyst.

For the reaction to start, preliminary heating of the reaction mixture is required. In this case, an induction period from 15 to 120 min was observed. Probably, the reduction of the Ti–OPh bonds in the catalyst to form an intermediate hydride complex occurs in one of the initial stages.¹¹⁹ Diphenoxytitanocene derivatives containing substituents in the benzene ring, *viz.*, $\text{Cp}_2\text{Ti}(\text{OC}_6\text{H}_4\text{X}-4)_2$ ($\text{X} = \text{Me}$, Cl , CN or OMe), exhibit higher catalytic activity. In the presence of these complexes even at 20 °C, phenylsilane yielded products identical to those obtained at 50 °C in the presence of diphenoxytitanocene (see Table 1).¹¹⁹

Dehydrocondensation of diphenylsilane catalysed by diphenoxyzirconocene occurs at 20 °C with elimination of hydrogen. However, an induction period was also observed and prior heating (50 °C, 15 min) of the reaction mixture is required. In this case, the amount of cyclic oligomers among the reaction products is smaller than that obtained with the use of diphenoxytitanocene.¹¹⁹

Dehydrocondensation of phenylsilane in the presence of dicyclopentadienylzirconium dimethoxide as a catalyst was reported.¹²¹

Dehydrocondensation of 1,4-disilapentane catalysed by diphenoxytitanocene was described.¹¹⁹ The rate of this reaction is smaller than that in the case of phenylsilane and is close to that observed with the use of dimethyltitanocene or the $\text{Cp}_2\text{TiCl}_2-2\text{BuLi}$ system as catalysts.¹²² Initially, the catalyst was activated at 0 °C and then the reaction was performed at 20 °C. In this case, exclusively SiH_3 groups reacted resulting in a linear oligomer containing the SiMeH_2 fragments. This oligomer was converted into an insoluble cross-linked polymer upon heating.¹¹⁹

Alkoxy derivatives of titanium, which do not contain cyclopentadienyl ligands, such as $\text{Ti}(\text{OPr}^i)_4$ or $\text{MeTi}(\text{OPr}^i)_3$, were also used as catalysts of dehydrocondensation of alkyl- and arylsilanes.¹¹⁷

c. Catalysis by metallocene chlorides and the $\text{Cp}_2\text{MHal}_2-\text{RLi}(\text{RMgX})$ systems

Metallocene dichlorides Cp_2MCl_2 are similar to Cp_2MMe_2 ($\text{M} = \text{Ti}$ or Zr) in catalytic activity.^{90,123} The activity of Cp_2HfCl_2 is substantially lower than that of Cp_2HfMe_2 , but it can be enhanced by adding MeLi in a molecular ratio of 1:2. In this case, both chlorine atoms are apparently completely replaced by

the methyl groups. Dehydrocondensation of phenylsilane in the presence of a mixture of Cp_2HfCl_2 and MeLi afforded cyclophenylsilanes in 15% yield.⁹⁰ When the reagents were taken in a ratio of 1:3 or 1:4, the yield of $(\text{PhSiH})_n$ was only 25%; the molecular weights of the resulting phenylcyclodisilanes were larger than those obtained with the use of dimethyltitanocene or dimethylzirconocene as a catalyst.⁹⁰ When a mixture of [1,2-bis(tetrahydroindenyl)ethane]dichlorozirconium with MeLi taken in a ratio of 1:2 was used, cyclophenylsilanes were formed in 42% yield.¹²³

Dehydrocondensation of phenylsilane catalysed by zirconocene derivatives of the $\text{Cp}_2\text{ZrX(Y)}$ type ($\text{X} = \text{H}$ or Cl and $\text{Y} = \text{Cl}$ or Alk) yields stereoregular polyphenylsilane in good yields.^{124–126}

It was expected⁹⁰ that dehydrocondensation of phenylsilane catalysed by Zr complexes containing ethylenebis(tetrahydroindenyl) or -indenyl ligands would also afford stereoregular polyphenylsilanes, unlike the reactions catalysed by biscyclopentadienyl complexes of Ti and Zr, which yield atactic polymers. According to the data of ^1H NMR spectroscopy and gel-permeation chromatography, this reaction afforded a mixture of linear and cyclic oligomers, which hindered the interpretation of the microstructure of the resulting polymer. It should be remembered that, for example, nine stereoisomers of hexaphenylcyclohexasilane possessing 23 chiral centres can exist.⁹⁰

Dehydrocondensation of hydrosilanes RSiH_3 ($\text{R} = \text{Bu}^n$, C_6H_{13} or Ph) catalysed by the $\text{Cp}_2\text{MCl}_2-2\text{BuLi}$ system ($\text{M} = \text{Ti}$, Zr or Hf) was studied in detail.^{127–130} The course of the reaction was monitored by gas chromatography and GLC-mass spectrometry. Dehydrocondensation of phenylsilane afforded linear oligomers with $M = 1775$ and 614 ($M_w:M_n = 1.17$ and 1.01 , respectively, when Cp_2ZrCl_2 was used) and $M = 1308$ and 600 ($M_w:M_n = 1.09$ and 1.03 , respectively, when Cp_2TiCl_2 was used). Therefore, the molecular weight of the dehydrocondensation products of phenylsilane is affected by the nature of the catalyst. The molecular weight increases in the series $\text{Hf} \ll \text{Ti} \ll \text{Zr}$, as in the case of the use of individual metallocenes.⁸² Dehydrocondensation of diphenylsilane catalysed by the $\text{Cp}_2\text{HfCl}_2-2\text{BuLi}$ system at 20°C for 1 h yielded only 1,1,2,2-tetraphenyldisilane. When the temperature was increased to 50°C , higher oligomers up to decaphenylpentasilane (the yield was 17%) were also obtained after 5 h. Under analogous conditions, butylsilane in the presence of the $\text{Cp}_2\text{MCl}_2-2\text{BuLi}$ system ($\text{M} = \text{Ti}$ or Zr) was converted into a mixture of linear and cyclic oligomers containing up to 11 silicon atoms. Two individual diastereomers of tetrabutyltetrasilane were isolated from this mixture. It is remarkable that the ratio of the diastereomers remained unchanged in the course of the reaction if $\text{M} = \text{Ti}$, whereas in the case of $\text{M} = \text{Zr}$, the diastereomers were formed at different rates.

Hexylsilane in the presence of the $\text{Cp}_2\text{ZrCl}_2-2\text{BuLi}$ system forms linear and cyclic tetra- and heptamers.¹²⁷

Dehydrocondensation of $\text{R}^1\text{R}^2\text{SiH}_2$ ($\text{R}^1 = \text{Ph}$ and $\text{R}^2 = \text{Me}$; $\text{R}^1 = \text{R}^2 = \text{Ph}$; or $\text{R}^1 = 3\text{-MeC}_6\text{H}_4$ and $\text{R}^2 = \text{Me}$) and dibenzosilaheterocycles **5a,b,d** in the presence of the $\text{Cp}_2\text{MCl}_2-2\text{BuLi}$ system ($\text{M} = \text{Ti}$, Zr or Hf) was studied.¹¹³ In the case of dehydrocondensation of MePhSiH_2 (90°C , 24 h), the activity of these catalysts increases in the series $\text{Hf} < \text{Ti} < \text{Zr}$. Linear oligomers containing from 2 to 8 silicon atoms are the major reaction products. At $20\text{--}90^\circ\text{C}$, more sterically hindered diphenylsilane yields only tetraphenyldisilane. Silafluorene (**5d**) reacted analogously to give (after 2 h) the corresponding disilane in 82% yield. Dehydrocondensation of 9,10-dihydro-9-silaanthracene (**5a**) in the presence of the binary catalyst proceeds substantially more slowly than the reaction with the use of dimethyltitanocene.

Dibenzosilolepine (**5b**) remained unchanged at 90°C in the presence of any catalytic system based on zirconium. The use of ethyl-, isopropyl- or butylmagnesium chlorides instead of BuLi (90°C , 24 h, toluene) led to a substantial decrease in the proportion of tri- and tetramers. The binary $\text{Cp}_2\text{ZrCl}_2-\text{BuLi}$ system is an efficient catalyst of dehydrocondensation of diorganylsilanes, but its use, unlike dimethyltitanocene, leads predominantly to the formation of short-chain oligomers.¹¹³

Syndiotactic polyphenylsilanes with high M_w ($> 10\,000$) were prepared by dehydrocondensation of phenylsilane in the presence of a mixture of the zirconium complex $\{\text{Cp}^*[\text{Cp}(\text{CH}_2)_n\text{NMe}_2]\text{ZrCl}_2$ ($n = 2$ or 3) or $\text{Cp}^*[\text{Cp}(\text{CH}_2)_n\text{CHMe}_2]\text{ZrCl}_2$ ($n = 1$ or 2) with two equivalents of BuLi .^{131,132}

The catalytic activity of pure dimethyltitanocene as well as of its mixture with butyllithium decreases substantially in the presence of atmospheric oxygen.¹²²

Dehydrocondensation of silanes [both symmetrical, *viz.*, $\text{H}(\text{PhMeSi})_2\text{H}$ and $\text{H}(\text{BuMeSi})_2\text{H}$, and unsymmetrical, *viz.*, $\text{HPh}_2\text{SiSiPhMeH}$, $\text{HPhMeSiSiMe}_2\text{H}$, HPhMeSiSiPrMeH and $\text{HPh}_2\text{SiSiPhH}_2$] catalysed by the $\text{Cp}_2\text{MCl}_2-2\text{BuLi}$ system ($\text{M} = \text{Ti}$ or Zr) in the presence of cyclooctene was studied.^{133,134} When the disilane:cyclooctene: Cp_2MCl_2 ratio was $30:(>30):1$, trisilanes were rapidly formed from $\text{HPh}_2\text{SiSiPhMeH}$ and $\text{HPhMeSiSiMe}_2\text{H}$. The products were identified by GLC-mass spectrometry. Dehydrocondensation of $\text{HPh}_2\text{SiSiPhH}_2$ afforded Ph_2SiH_2 and PhSiH_3 , which were subsequently converted into a mixture of linear and cyclic polysilanes. These data indicate that dehydrocondensation is accompanied by the cleavage of the Si–Si bond in the initial disilane.

Dehydrocondensation of RSiH_3 and $\text{RH}_2\text{SiSiH}_2\text{R}$, where the R substituent is the $\text{Cp}(\text{CO})_2\text{Fe}$ metallocene group, was performed in the presence of the $\text{Cp}_2\text{MCl}_2-\text{BuLi}$ system ($\text{M} = \text{Ti}$ or Zr). Dehydrocondensation of $\text{Cp}(\text{CO})_2\text{FeSiH}_3$ and $\text{Cp}(\text{CO})_2\text{FeSiH}_2\text{SiH}_2\text{Fe}(\text{CO})_2\text{Cp}$ gave organometallic oligosilanes characterised by spectroscopic and chromatographic methods.¹³⁵

Dehydrocondensation of 2,4-disilapentane catalysed by the $\text{Cp}_2\text{ZrCl}_2-2\text{BuLi}$ or $\text{Cp}_2\text{TiCl}_2-2\text{MeLi}$ system afforded new poly(silacarbo)silanes containing the SiCH_2Si fragments in the main chain.^{43,128}

(a) $\text{Cp}_2\text{ZrCl}_2-2\text{BuLi}$; (b) $\text{Cp}_2\text{TiCl}_2-2\text{MeLi}$.

This reaction yielded predominantly oligomers (50%–80%), while di- and trimeric products were formed in insignificant amounts. The yields of oligomers depend substantially on the nature of the metal atom in the metallocene, the duration of the reaction and the concentration of the monomer. The $\text{Cp}_2\text{ZrCl}_2-2\text{BuLi}$ catalytic system is more efficient than the $\text{Cp}_2\text{TiCl}_2-2\text{MeLi}$ system (the yields of oligomers are 80% and 50%, respectively). The degree of condensation of these monomers is somewhat higher than that of PhMeSiH_2 ; the resulting polymers are characterised by moderate M values, which indicates that they are partially cross-linked.^{86,89,113} The higher reactivity of 2,4-disilapentane compared to phenylmethylsilane is attributable to the favourable steric factors.

d. Catalysis by the $\text{Cp}_2\text{MCl}_2-\text{Al}$ system

Dehydrocondensation of 3-arylpropylsilanes **6a–g** as well as of 2-phenyl-1,3-disilapropane [$\text{H}_3\text{SiCH}_2\text{CH}(\text{Ph})\text{CH}_2\text{SiH}_3$, **7**] catalysed by the $\text{Cp}_2\text{MCl}_2-\text{Al}$ system ($\text{M} = \text{Ti}$ or Hf) was performed.^{44,45}

$\text{Ar} = \text{Ph}$ (**a**), 4- MeC_6H_4 (**b**), 2,5- $\text{Me}_2\text{C}_6\text{H}_3$ (**c**), ClC_6H_4 (**d**, mixture of isomers), 4- $\text{MeC}_6\text{H}_3\text{Cl}$ (**e**, mixture of isomers), PhOC_6H_4 (**f**, mixture of isomers), C_{10}H_7 (**g**, mixture of isomers).

Substituted polysilanes **8a–g** prepared from compounds **6a–g** have predominantly linear structures and molecular weights from 800 to 1028 (the degree of polymerisation is 3–7, $M = \text{Hf}$) and from 800 to 1300 (the degree of polymerisation is 6–16, $M = \text{Ti}$), *i.e.*, the molecular weights are higher than those of the analogous polyarylsilanes synthesised in the presence of other catalytic systems.^{42,46} The catalytic activity of the $\text{Cp}_2\text{HfCl}_2\text{–Al}$ system is lower than that of its titanium analogue (the yields of polysilanes are 31%–84% and 79%–99%, respectively).

The reaction rate increases both as the concentration of the catalyst increases [from 0.5 mol. % to 10 mol. % ($M = \text{Ti}$) or from 1.0 mol. % to 6.5 mol. % ($M = \text{Hf}$)] and as the reaction temperature increases to 90 °C. Dehydrocondensation of compound **7** catalysed by the $\text{Cp}_2\text{TiCl}_2\text{–Al}$ system proceeded smoothly and the total yield of polysilanes reached 90%.⁴⁴ Two polymeric reaction products were isolated from the resulting mixture by column chromatography. One of these products is a viscous weakly cross-linked soluble polysilane ($M_w = 1046$, $M_n = 819$, $n = 11$) and the second product is a completely cross-linked insoluble white solid polymer.

Dehydrocondensation of organylsilanes **6b** and **6d**, **6b** and **6f** or **6d** and **6f** catalysed by the $\text{Cp}_2\text{TiCl}_2\text{–Al}$ system afforded the corresponding cooligomers (the yields were 51%–86%) with $M_w = 678\text{–}994$ and $M_n = 405\text{–}538$ (the degree of copolymerisation was 7).⁴⁴

e. Catalysis by the ternary $\text{Cp}_2\text{MCl}_2\text{–RLi–B}(\text{C}_6\text{F}_5)_3$ system and by the cationic bis(cyclopentadienyl) complexes of zirconium and hafnium

Dehydrocondensation of phenylsilanes in the presence of the ternary Cp_2MCl_2 ($\text{CpCp}^*\text{MCl}_2$)–2 BuLi– $\text{B}(\text{C}_6\text{F}_5)_3$ catalytic system ($M = \text{Ti}$, Zr or Hf) afforded polyphenylsilanes with $M = 10\,910\text{–}13\,790$.^{47,95,96} It is remarkable that when the reaction was performed in the presence of only $\text{B}(\text{C}_6\text{F}_5)_3$ at 20 °C for 10 days, the molecular weight of the resulting polyphenylsilane reached only 2450. In both cases, the ratio between linear and cyclic polymers remained the same.⁴⁷ The addition of $\text{B}(\text{C}_6\text{F}_5)_3$ to the $\text{Cp}_2\text{MCl}_2\text{–BuLi}$ catalytic system changes the ratio between the cyclic and linear dehydrocondensation products from 45:55 to 15:85. The catalytic activity of zirconocenes both in the presence of $\text{B}(\text{C}_6\text{F}_5)_3$ and in its absence increases in the series $\text{Cp}_2^*\text{Zr} \ll \text{Cp}_2\text{Zr} \approx (\text{MeC}_5\text{H}_4)_2\text{Zr} < \text{CpCp}^*\text{Zr}$ (*cf.* Ref. 136). The $\text{Cp}_2\text{TiMe}_2\text{–B}(\text{C}_6\text{F}_5)_3$ and $[\text{Cp}_2\text{ZrMe}(\text{THF})](\text{BPh}_4)$ systems, which are successfully used for the polymerisation of alkenes,¹³⁷ do not catalyse dehydrocondensation of phenylsilane.⁴⁷

Dehydrocondensation of organylsilanes in the presence of the ternary catalytic system, which contains Group IVB metallocene, a trimethylsilyl derivative of alkali metal and THF, has been described.¹³⁸ Thus a polymer with $M = 6800$ was prepared from phenylsilane in the presence of the $\text{Cp}_2\text{HfCl}_2\text{–Me}_3\text{SiLi–THF}$ system.

Dehydrocondensation of phenylsilane in the presence of cationic bis(cyclopentadienyl) complexes of Zr and Hf was studied. These complexes were prepared *in situ* by the reactions of Cp_2MMe_2 ($M = \text{Zr}$ or Hf) with $[\text{Bu}_3\text{NH}]^+[\text{B}(\text{3,5-Me}_2\text{C}_6\text{H}_3)_4]^-$ or $[\text{PhMe}_2\text{NH}]^+[\text{B}(\text{C}_6\text{F}_5)_4]^-$.⁴⁸ The activity of these catalysts appeared to be low. The total yield of cyclophenylsilanes at 23 °C is no higher than 13%. Dehydrocondensation with the use of the $\text{CpCp}^*\text{ZrMe}_2\text{–}[\text{Bu}_3\text{NH}]^+[\text{B}(\text{3,5-Me}_2\text{C}_6\text{H}_3)_4]^-$ system as a catalyst (23 °C, 1 h) affords linear and cyclic polyphenylsilanes with rather low M values (up to 2810). In this case, variations in the anion and the metal atom in the metallocene (Zr or Hf) have no substantial effect on the course of the process.⁴⁸

f. Catalysis by metallocenes containing organosilicon groups at the metal atom

Metallocenes (Ti, Zr or Hf) containing organosilicon groups at the metal atom were also suggested as catalysts of dehydrocon-

densation of organosilanes. In the presence of these catalysts, di- and trisubstituted silanes form linear (at ≤ 60 °C) or cyclic (at ≥ 80 °C) polysilanes.^{48,65,91,94,100,139–147} For example, dehydrocondensation of phenylsilane catalysed by $\text{Cp}_2\text{Ti}(\text{CH}_2\text{SiMe}_3)_2$ afforded linear polysilane (92%, $M = 1890$) and cyclic oligophenylsilane (95%, $M = 738$) at 30 °C (24 h) and 80 °C, respectively.¹³⁹

Dehydrocondensation of arylsilanes $\text{RC}_6\text{H}_4\text{SiH}_3$ ($R = \text{H}$, 4-Me, 3-Me, 2-Me, 4- CF_3 , 3- CF_3 or 2- CF_3) in the presence of $\text{Cp}_2\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Me}$ yielded poly(trifluoromethylphenyl)-, poly(methylphenyl)silanes and polyphenylsilane.⁶⁵ In the dehydrocondensation process, the reactivity of $\text{RC}_6\text{H}_4\text{SiH}_3$ decreases depending on the radical R in the series (the relative reaction rates are given in parentheses) 4- CF_3 (1.34) $\approx$ 3- CF_3 (1.33) $>$ H (1.00) $>$ 4-Me (0.95) $\approx$ 3-Me (0.93) $\gg$ 2-Me (0.18) $\approx$ 2- CF_3 (0.14). These data indicate that the reaction rate is influenced both by the electronic and steric effects of the substituents in the aromatic core. 2-Substituted phenylsilanes exhibit the lowest activities. The molecular weights of poly(trifluoromethylphenyl)silanes and polyphenylsilanes obtained under analogous conditions are much the same.

Silyl complexes of zirconocene and hafnocene of the $\text{CpCp}'\text{M}(\text{SiR}^1)_3\text{R}^2$ type ($\text{Cp}' = \text{Cp}$ or Cp^* ; $M = \text{Zr}$ or Hf ; $\text{R}^1 = \text{Me}$, Ph or SiMe_3 ; $\text{R}^2 = \text{Alk}$, SiMe_3 or Cl) are also efficient catalysts of dehydrocondensation of arylsilanes. In these cases, the molecular weights of linear and cyclic polymers vary over wide ranges depending on the nature of the catalyst and the reaction conditions.^{48,140–142}

Phenylsilane in the presence of $\text{Cp}_2\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Me}$ or $\text{Cp}_2\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ formed polymers with $M = 990$ and polymers with $M = 1240$ containing from 10 to 20 SiHPh monomer units after 15 min and 7 h, respectively. Phenylcyclasilane (containing from 5 to 8 silicon atoms) was identified among these polymers.^{14,48} It should be noted that polyphenylsilane with $M_n = 560$ was obtained upon catalysis by dimethylzirconocene during 24 h. Zirconocenes with mixed cyclopentadienyl ligands (nonsubstituted or partially or completely methylated) appeared to be more active catalysts in these reactions. The molecular weight of the linear polymer $\text{H}(\text{PhHSi})_n\text{H}$ formed in the presence of $\text{CpCp}^*\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Me}$ reached 3000 and 5260 after 15 min and 48 h, respectively. Linear and cyclic polymers contain about 70 silicon atoms in the polysilane chains (see Table 1).⁴⁸

Dehydrocondensation of methylphenyl- and diphenylsilanes catalysed by alkyne zirconocene and titanocene complexes of the $\text{Cp}_2\text{M}(\text{L})(\text{RC}\equiv\text{CSiMe}_3)$ type ($M = \text{Ti}$ or Zr ; $\text{L} = \text{THF}$ or Py) affords oligomers. Under these conditions, phenylsilane forms polymers.^{148,149}

The catalytic activities of the zirconium and titanium complexes, *viz.*, $(\eta^5\text{-C}_5\text{H}_4\text{SiMe}_3)_2\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ (**9**) and $\text{Cp}_2\text{Ti}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ (**10**), respectively, in dehydrocondensation of phenylsilane and dibutylstannane were studied.¹⁴³ According to the data of GLC-mass spectrometry, a viscous mixture of linear $\text{H}(\text{PhHSi})_n\text{H}$ and cyclic $(\text{PhSiH})_n$ ($n = 5$ or 6) oligomers ($M_n = 900$, $M_w = 1810$) was formed from phenylsilane in the presence of the complex **9** after 24 h. Under analogous conditions, a mixture of linear and cyclic polysilanes with $M_n = 1870$ and $M_w = 3280$ was formed upon catalysis by the $\text{CpCp}^*\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ complex, which does not contain the trimethylsilyl group in the cyclopentadienyl ring. Dehydrocondensation of dibutylstannane in the presence of the complex **9** affords polybutylstannanes with a broad molecular weight distribution spectrum ($M_w = 4800$, $M_n = 1420$). The reaction of the complex **10** with an equivalent amount of phenylsilane in C_6D_6 gave a mixture of the metathesis product **11** and the reductive elimination product **12** in a ratio of 2:1 in quantitative yield.¹⁴³

Dehydrocondensation of 1,4- $\text{RH}_2\text{SiC}_6\text{H}_4\text{SiH}_2\text{R}$ ($R = \text{Me}$, Et or C_6H_{13}) catalysed by $\text{CpCp}^*\text{Zr}[\text{Si}(\text{SiMe}_3)_3]\text{Me}$ under mild

conditions (20 °C) afforded linear oligomers $\text{RH}_2\text{Si}(\text{C}_6\text{H}_4\text{SiHR})_n\text{C}_6\text{H}_4\text{SiHR}$. Further heating of the resulting mixture of oligomers ($\text{R} = \text{Me}$ or Et) led to an increase in the molecular weight due to partial cross-linking of the polymer chains through free Si–H groups. Thermolysis of the insoluble cross-linked polymer $\text{EtH}_2\text{Si}(\text{C}_6\text{H}_4\text{SiHEtSiHEt})_n\text{C}_6\text{H}_4\text{SiH}_2\text{Et}$ at 1100 °C afforded ceramics in higher yield (67%) than that with the use of the corresponding low-molecular-weight oligomers (35%).¹⁵⁰

It was reported that the $\text{Cp}_2\text{Zr}(\text{OMe})_2 - (\text{Me}_3\text{Si})_3\text{SiLi} - 3 \text{ THF}$ ternary system was used as a catalyst of dehydrocondensation of phenylsilane.¹²¹

g. Catalysis by ansa-metalloenes

Dehydrocondensation of phenyl- and methylphenylsilane catalysed by ansa-metalloenes (**13a–f**),^{144, 145, 151, 152} which are used for the preparation of iso- and syndiotactic polypropylenes, was studied.^{153, 154}

$\text{E} = \text{Si}; \text{M} = \text{Ti} \text{ (a)}, \text{Zr} \text{ (b)}, \text{Hf} \text{ (c)}$
 $\text{E} = \text{C}; \text{M} = \text{Ti} \text{ (d)}, \text{Zr} \text{ (e)}, \text{Hf} \text{ (f)}$

Methylphenylsilane in the presence of ansa-metalloenes with a BuLi cocatalyst (the ratio is 22 : 1 : 2) in toluene at 90 °C formed low-molecular-weight oligomers, viz., the corresponding di-, tri- and tetrasilanes. In this case, tetramers existed in the reaction mixture in insignificant amounts (1.8%–5.5% according to the GLC data). In the presence of ansa-hafnocene, tetrasilane is not formed at all. The activity of ansa-metalloenes, which was estimated from the yield of disilane after 24 h, decreases in the series $\text{Ti} > \text{Hf} > \text{Zr}$.

Catalyst	13a	13c	13b	13d	13f	13e
Yield of disilane according to GLC (%)	36	30	22	58	37	25

The activity of metallocene dichlorides in dehydrocondensation of methylphenylsilane decreases in the series $\text{Hf} (37) > \text{Ti} (32) > \text{Zr} (15)$ (the yields of disilane according to the GLC data are given in parentheses). 1,2-Dimethyl-1,2-diphenyldisilane and 1,2,3-trimethyl-1,2,3-triphenyltrisilane prepared from methylphenylsilane exist as mixtures of diastereomers. Dehydrocondensation of phenylsilane catalysed by ansa-metalloenes (Ti , Zr or Hf) in the absence of a solvent affords a mixture of linear and cyclic polyphenylsilanes. In this case, the molecular weight of the linear polymer increases in the series $\text{Ti} < \text{Zr} < \text{Hf}$.¹⁴⁴ Under analogous conditions (the silane : complex : BuLi ratio is 24 : 1 : 2, 13–24 h, 20 °C), the molecular weight of polyphenylsilanes prepared in the absence of ansa-metalloenes is always lower than that obtained with the use of usual metallocenes.

e. Catalysis by binuclear titanium and zirconium complexes

Dehydrocondensation of phenyl-, benzyl-, hexyl- and diphenylsilanes catalysed by the binuclear titanium complexes $\text{Cp}_2\text{Ti}(\mu\text{-HSiHPh})_2\text{TiCp}_2$ and $\text{Cp}_2\text{Ti}(\mu\text{-H})(\mu\text{-HSiHPh})\text{TiCp}_2$ generally affords oligomers.¹⁰⁰ Alkenes, the activating action of which increases in the series cyclohexene < 2-pentene < 1-pentene ~ norbornene ~ styrene, are used as cocatalysts, which substantially enhance the rate of this reaction.

It was reported¹⁴⁶ that binuclear titanocene complexes can be used as catalysts of dehydrocondensation of phenylsilane, for example

These reactions give mixtures of linear and cyclic polyphenylsilanes;¹⁴⁶ BuLi is used as a cocatalyst.

3. Catalysis by compounds of Group VB–VIIB elements

The data on the use of compounds of Group VB–VIIB metals as catalysts of dehydrocondensation of organylsilanes are scarce. Vanadocene Cp_2V and dimethylvanadocene Cp_2VMe_2 do not catalyse this reaction at 20 °C.⁸² However, phenylsilane in boiling toluene in the presence of these compounds was converted into a mixture of the $\text{PhH}_2\text{SiSiH}_2\text{Ph}$ dimer (40%) and the $(\text{PhSiH}_2)_2\text{SiHPh}$ trimer (20%). Under analogous conditions (100–120 °C, 123 h), higher metallocenes Cp_2M ($\text{M} = \text{Nb}$ or Ta) do not catalyse dehydrocondensation of phenylsilane. Neither at high temperature (115–120 °C) nor upon UV irradiation is this reaction catalysed by hydride complexes of niobium or tantalum Cp_2MH_3 ($\text{M} = \text{Nb}$ or Ta),⁸² whereas phenylsilane actively undergoes dimerisation in the presence of trimethylsilyl derivatives of tantalocene $\text{Cp}^*\text{Ta}(\text{SiMe}_3)\text{Cl}_3$. In this case, reduction products of the catalyst, viz., trimethylsilane and the tantalum hydride complex $[\text{Cp}^*\text{TaHCl}_3]_n$, are formed along with 1,2-diphenyldisilane.⁴⁶

Cyclopentadienyl complexes of chromium, molybdenum and tungsten, viz., Cp_2Cr , Cp_2MoH_2 and Cp_2WH_2 , do not catalyse dehydrocondensation of PhSiH_3 at room temperature as well as under irradiation.⁸² Cyclopentadienyl chromium complexes, such as $(\eta^6\text{-H}_3\text{SiC}_6\text{H}_5)\text{Cr}(\text{CO})_3$, act as catalysts of dehydrocondensation of silanes. In this case, the corresponding polysilanes containing chromium carbonyls in the side chain are formed.¹⁵⁵

Some binary carbonyl complexes of manganese catalyse dehydrocondensation of phenylsilane at 100 °C.⁶⁸

4. Catalysis by compounds of Group VIIIB elements

The use of platinum complexes as catalysts of dehydrocondensation of pentamethyldisilane and symmetrical tetramethyldisilane was reported for the first time in 1970.¹⁵⁶ Later on, these reactions were described as disproportionations catalysed by phosphine complexes of platinum metals.¹⁵⁷

It was found that penta- and tetramethyldisilanes were converted into the $(\text{Me}_3\text{SiSiMe}_2)_2$ dimer or a mixture of $\text{H}(\text{Me}_2\text{SiSiMe}_2)_n\text{H}$ oligomers ($n = 2-6$), respectively, in the presence of platinum bis(triethylphosphine) dichloride at 90 °C (18 h).^{156–158}

$\text{R} = \text{H}, \text{Me}; n = 2-6; \text{cat} = \textit{trans}\text{-}[\text{PtCl}_2(\text{PEt}_3)_2], [\text{NiCl}_2(\text{PEt}_3)_2] \text{ etc.}$

The ethylenebisphosphine complex of platinum $[\text{C}_2\text{H}_4\text{Pt}(\text{PPh}_3)_2]$ at room temperature does not induce dehydrocondensation of silanes, such as Ph_3SiH , Me_2PhSiH , Et_3SiH and $(\text{EtO})_3\text{SiH}$.^{109, 112} However, MePhSiH_2 and Et_2SiH_2 in the presence of this complex were converted into the corresponding dimers in 27% and 95% yields, respectively.¹⁰⁹ It is remarkable that in the case of Et_2SiH_2 , dehydrocondensation occurs more readily than hydrosilylation of 1-hexene. In attempting to perform hydrosilylation of 1-hexene with a mixture of Et_3SiH and Et_2SiH_2 , only dehydrocondensation products $\text{Et}_2\text{HSiSiHEt}_2$ and $\text{Et}_2\text{HSiSiEt}_3$ were obtained in a ratio 7 : 1. In this case, hexaethyldisilane was not formed. The dehydrocondensation product, viz., tetraethyldisilane, was also not detected upon hydrosilylation of 1-hexene with diethyldisilane in the presence of H_2PtCl_6 (Spier's catalyst) or Ph_2PtCl_2 .¹⁰⁹

Dehydrocondensation of acyclic and cyclic disubstituted silanes $\text{R}^1\text{R}^2\text{SiH}_2$ [R^1 and $\text{R}^2 = \text{Alk}$, $(\text{CH}_2)_n$ ($n = 3-5$) or 1,2- C_6H_4] catalysed by the $\text{Pt}(\text{COD})_2$ or $\text{Me}_2\text{Pt}(\text{COD})$ complexes affords polysilanes with high molecular weights (M_w up to 40 000; M_n up to 39 000) in 60%–95% yields.¹⁵⁹

Dehydrocondensation of dimethylphenylsilane in the presence of platinum complexes with different phosphine ligands was

studied.¹⁶⁰ Their catalytic activities are rather low. The exception is the $\text{Pt}(\text{PPhMe}_2)_4$ complex in the presence of which the yield of 1,1,2,2-tetramethyl-1,2-diphenyldisilane reaches 50%. Methylphenylsilane in the presence of $\text{Pt}(\text{PPhMe}_2)_4$ forms 1,2-dimethyl-tetraphenyldisilane in low yield.¹⁶⁰ Platinum black as well as PtO_2 , $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ and $(\text{PhCN})_2\text{PtCl}_2$ do not catalyse dehydrocondensation of dimethylphenylsilane.¹⁶⁰

A procedure for the dehydrocondensation of substituted oligosilanes of the general formula $\text{H}_a\text{Si}_b\text{R}_c$ [$\text{R} = \text{Alk}$, Ar , alkenyl, AlkO , Hal or R_2N ; $a \geq 1$; $b \geq 2$; $(a + c) = (2b + 2)$] in the presence of dialkylidicyclopentadienyl Pt or Rh complexes was covered by a patent.⁸³

In 1973, $(\text{Ph}_3\text{P})_3\text{RhCl}$ (Wilkinson's complex) was suggested as a catalyst of dehydrocondensation of hydrosilanes.¹⁰⁸ In its presence, methylphenylsilane was converted into a mixture of 1,2-dimethyl-1,2-diphenyldisilane (14%) and 1,2,3-trimethyl-1,2,3-triphenyltrisilane (30%) at 70 °C for 1 h. Under analogous conditions, 1,1,2,2-tetraphenyldisilane was formed from diphenylsilane in 38% yield. 1,2-Diphenylsilane and 1,2,3-triphenyltrisilane were obtained from phenylsilane. 1,1,2,2-Tetraethylidisilane and 1,1,2,2,3,3-hexaethyltrisilane were obtained from diethylsilane. Dehydrocondensation of dibenzosilaheterocycles **5a–d** in the presence of $(\text{Ph}_3\text{P})_3\text{RhCl}$ proceeds according to the following scheme^{108, 112, 161}

The drawback of Wilkinson's catalyst is the fact that it promotes oxidation of Si–Si bonds to Si–O–Si groups when the reaction is performed in air.^{109, 113}

The possible reaction mechanism involves the formation of the silylene rhodium(II) complex **14** as an intermediate, which appears as a result of β -elimination of the hydrogen molecule from the rhodium(I) complex **15**.

The results of dehydrocondensation of disubstituted silanes in the presence of $(\text{Ph}_3\text{P})_3\text{RhCl}$ are given in Table 2.¹¹² The conversion of R_2SiH_2 decreases in the series **5c,d** (100%) > **5a** (83%) > Ph_2SiH_2 (59%) > **5b** (10%).¹¹³ The addition of cyclohexene as an acceptor of hydrogen does not affect the activity of silanes. In attempting to perform dehydrocondensation of dihydrosilaanthracene (**5a**) in the presence of the $[\text{Rh}(\text{COD})(\text{PPh}_3)_2]\text{PF}_6$ complex (37 °C, 25 h), only the corresponding disiloxane was isolated in 33% yield.¹¹²

Dehydrocondensation of methylphenylsilane catalysed by different rhodium complexes has been studied. In these reactions, a dimer and a trimer were obtained as by-products (Table 3).⁵⁰

Table 2. Dehydrocondensation of diorganylsilanes in the presence of Wilkinson's catalyst (0.4 mol. %, 10 h, 25 °C).¹¹²

R_2SiH_2	Yield of the reaction products (%)				
	R_2SiH_2	dimer	trimer	disiloxane	other products

$[\text{RhCl}_4(\text{H}_2\text{O})_2]^- \text{X}^+$ (see ^a)		2	100	31.2	25.8	8.8

^a $\text{X} = \text{NH}(\text{C}_8\text{H}_{13})_3$.

Dehydrocondensation of diphenylsilane catalysed by carbene rhodium complexes (20 °C, 18 h) afforded predominantly 1,1,2,2-tetraphenyldisilane.¹⁶² The reaction was monitored by GLC. It was demonstrated that the disilane $\text{Ph}_2\text{HSiSiHPh}_2$, which was initially formed, was then oxidised by atmospheric oxygen to the corresponding disiloxane.

Hydrosilylation with diethylsilane catalysed by complexes of Group VIII metals involves the dimerisation of diethylsilane as a competitive process. The relative rate constants of dehydrocondensation of diethylsilane (18 °C, 75 h) depending on the catalyst were determined.¹⁰⁹ These constants change in the following order (k_{rel} are given in parentheses):

The reactivity of silanes in dehydrocondensation decreases in the series $\text{RSiH}_3 > \text{R}_2\text{SiH}_2 \gg \text{R}_3\text{SiH}$. Dimethylphenylsilane in the presence of platinum complexes undergoes only dimerisation.

Dehydrocondensation of compounds of the $\text{A}(\text{SiH}_3)_2$ type [$\text{A} = \text{CH}_2$, $\text{Alk}(\text{CH}_2)_n$, $\text{Me}_3\text{Si}(\text{CH}_2)_n$ ($n = 2-7$) or $\text{Me}_3\text{Si}(\text{CH}_2)_m$ ($m = 3-8$)] catalysed by $\text{HRh}(\text{CO})(\text{PPh}_3)_3$ was studied. The reactions afforded polysilanes, which were further converted into silicon carbide.¹⁶³

Dehydrocondensation of 1,4-bis(trihydrosilyl)benzene in the presence of $\text{RuCl}_2[\text{P}(\text{C}_6\text{H}_4\text{Me-4})_3]_3$ afforded a white polymer ($M = 1170$) containing alternating $\text{SiH}_2\text{C}_6\text{H}_4$ groups.^{164, 165}

5. Reaction mechanism

Dehydrocondensation of organylsilanes is a promising procedure for the formation of Si–Si bonds. This procedure is suitable for the preparation of polyorganylsilanes with the controlled chain length. However, the majority of the published studies generally dealt with the preparative aspects of this reaction. The difference in the reaction conditions and sometimes the contradictory results do not allow one to propose the mechanism of catalytic dehydrocondensation of organylhydrosilanes with assurance.

Presently, three rather justified schemes of the process proceeding in stages are available. These schemes are interrelated and complement each other.

1. Harrod's mechanism involves oxidative addition of organylsilanes to complex-forming metal followed by α -elimination of

the RH molecule ($R = \text{Alk}$ or Ar) to form a silylene complex of the $\text{Cp}_2\text{M}=\text{SiHR}$ type ($M = \text{Ti}$ or Zr) as an active catalytic intermediate. The latter forms polyorganylsilanes through a series of successive conversions with the participation of organylsilane.

2. Tilley's mechanism is based on the metathesis of the σ -bond. The reaction proceeds through a four-centre transition state containing the $M-H$, $M-Si$, $Si-H$ and $Si-Si$ bonds followed by the metathesis of the $M-Si$ σ -bond and the formation of dehydrocondensation products $\text{H}(\text{SiHR})_n\text{H}$.

3. Hengge's mechanism involves silylene $\text{Me}_2\text{Si:}$, which is formed in a four-centre transition state according to a β -elimination reaction of a new type, as an active catalytic intermediate. Dimethylsilylene is then inserted into the $Si-H$ or $Si-Si$ bonds to form linear or branched oligomers, respectively.

Let us consider these mechanisms in more detail.

Harrod and coworkers^{68, 87, 89, 93} suggested two schemes of the dehydrocondensation mechanism for organylsilanes (Scheme 2).

One of the schemes⁸⁷ assumes that the bridging hydride complex **16** is formed as an active catalytic intermediate. This scheme involves oxidative addition of silane to metallocene to form the complex **17** followed by α -elimination of MeRSiH_2 . The resulting Cp_2Ti reacts with silane to give the complex **16**, which accomplishes the chain growth (Scheme 2, pathway *a*).

Pathway *a*

Pathway *b*

However, the high catalytic activity of possible intermediates of dehydrocondensation, *viz.*, the Ti and Zr complexes of type **17** containing $\mu\text{-H}$ and $\mu\text{-Si}$ bonds, was not confirmed.^{87, 89, 91, 94, 100}

Later on, Harrod and coworkers⁹³ suggested that the silylene complexes **18** and **19** are intermediates in dehydrocondensation. The complex **19** can be formed upon elimination of hydrogen from the hydride complex **20**. The chain growth occurs through the repeated insertion of the newly formed silylene complex into the $M-Si$ bond (Scheme 2, pathway *b*). This scheme adequately describes the formation of the linear polyphenylsilanes $\text{H}(\text{PhSiH})_n\text{H}$ and $\text{H}(\text{Ph}_2\text{Si})_2\text{H}$ from PhSiH_3 and Ph_2SiH_2 , respectively.

The formation of cyclic products upon dehydrocondensation of PhSiH_3 and $\text{PhCH}_2\text{SiH}_3$ in the presence of dimethyltitanocene or dimethylzirconocene proceeds through the intermolecular metathesis of the terminal SiH_2 group and the $M-Si$ bond of the growing terminus of the chain.⁶⁸ This process is most probable when the chain contains six Si atoms.

$M = \text{Ti, Zr}$.

The second pathway, which involves the cleavage of the $Si-Si$ bond by a particular reactive intermediate and intermolecular metathesis, is also possible.

$M = \text{Ti, Zr}$.

The scheme proposed by Harrod does not explain why only tetraorganylsilanes rather than higher oligomers are formed from diorganylsilane.

An alternative reaction mechanism was proposed¹¹² to account for the formation of cyclic oligomers, for example, of 1,2,3-triphenyltrisilane from Ph_2SiH_2 in the presence of titanocene or zirconocene complexes. This mechanism involves either dehydrocondensation of Ph_2SiH_2 with the resulting $\text{Ph}_2\text{SiHSiHPh}_2$ (which is formed, probably, through a silylene complex) or disproportionation of 1,1,2,2-tetraphenyldisilane.

However, it was established¹⁶¹ that the dimeric product of dehydrocondensation of 9,10-dihydro-9-silaanthracene in the presence of Wilkinson's catalyst formed the corresponding trimer only in 7% yield, *i.e.*, disproportionation is not the major process.

Silylene complexes of type **18** or **19** are very attractive compounds for explaining the mechanism of dehydrocondensation of silanes. These compounds have been extensively studied in the last decade.¹⁶⁶ Base-stabilised silylene complexes of transition metals, which are used in different catalytic (hydrosilylation¹⁰⁸) and photochemical¹⁶⁷ reactions, are known.

Nevertheless, it is believed⁴⁶ that silylene metal complexes cannot be intermediates of dehydrocondensation for two reasons. First, during catalytic dehydrocondensation of organylsilanes, complexes of the $\text{CpCp}^*\text{M}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ type are quantitatively converted into the corresponding polymeric complexes $[\text{CpCp}^*\text{MHCl}]_n$.¹⁴² Only one σ -bond of complex-forming metal is used in the course of dehydrocondensation. At the same time, the participation of at least two σ -bonds is necessary for the formation of the silylene complex followed by its reaction. Second, the formation of silylene complexes through α -elimination of the RH molecule should result in complexes of the $\text{M}(\text{SiHR}^1\text{R}^2)\text{R}^3$ type (R^1, R^2 and $\text{R}^3 = \text{H}$ or Alk). Several mixed alkylsilyl complexes containing $Si-H$ bonds were isolated. However, the latter do not undergo decomposition with α -elimination of substituents at the silicon atom. Only one instance where decomposition proceeds through α -elimination of the hydrogen atom from the alkyl group at the silicon atom is known.¹⁶⁸ This reaction afforded dimesitylsilane in quantitative yield along with an unidentified zirconium-containing compound. Methane was not detected among the reaction products.

Tilley¹³⁶ suggested an alternative mechanism of dehydrocondensation of organylsilanes, which was called the metathesis of the σ -bond. This mechanism was confirmed by the kinetic data obtained by monitoring the process by ^1H NMR spectroscopy in C_6D_6 .^{46, 48, 142, 169} In this case, the cyclopentadienyl tris(trimethylsilyl) hafnium complex **21**, which exhibits lower reactivity and higher stability compared to the isostructural titanium and zirconium complexes, was used as a catalyst.

These authors also synthesised and studied the behaviour of other silylated cyclopentadienyl hafnium complexes, *viz.*, $\text{CpCp}^*\text{Hf}(\text{SiHR}^1\text{R}^2)\text{Cl}$ ($\text{R}^1 = \text{H}$ and $\text{R}^2 = \text{Ph}$, 4-MeC₆H₄, Mes, Bn or *cyclo*-C₆H₁₁; $\text{R}^1 = \text{R}^2 = \text{Ph}$; or $\text{R}^1 = \text{Me}$ and $\text{R}^2 = \text{Ph}$), in dehydrocondensation of PhSiH₃.^{141, 170} The general second order of the reaction, first order with respect both to the catalyst and the organylsilane, were established. The activation parameters of the process ($\Delta H^\ddagger = 68.5 \text{ kJ mol}^{-1}$, $\Delta S^\ddagger = -27 \text{ kJ mol}^{-1} \text{ K}^{-1}$) and the kinetic isotopic effect ($k_{\text{H}}/k_{\text{D}} = 2.5$) correspond to the values observed for the reactions of hydrocarbons proceeding through the metathesis of the σ -bond.^{170, 171}

$\text{R}^1, \text{R}^2 = \text{H}, \text{Alk}, \text{Ar};$

$\text{L}_n\text{M} = \text{Cp}_2^*\text{Sc}, \text{Cp}_2^*\text{Y}, \text{Cp}_2^*\text{Lu}, [(\text{Me}_3\text{Si})_2\text{N}]_3\text{U}, \text{etc.}$

The kinetics of thermal decomposition of $\text{CpCp}^*.\text{Hf}(\text{SiH}_2\text{Ph})\text{Cl}$, which obeys a second-order equation with $\Delta H^\ddagger = 81.5 \text{ kJ mol}^{-1}$ and $S^\ddagger = -21 \text{ kJ mol}^{-1} \text{ K}^{-1}$, was studied.¹⁴² The four-centre transition state **A** was suggested for the dehydrocondensation process.

Decomposition of the hafnium complex was performed in the presence of efficient traps of silylene, such as Et₃SiH, (cyclo-C₆H₁₁)₃SiH, Ph₂SiH₂ or MePhSiH₂, which had no effect on the reaction rate. It is suggested that a hydride complex, which reacts predominantly with the sterically most accessible terminal SiH₂R group of the polysilane chain, is an active catalytic species in the reaction. This leads to the appearance of the polysilyl group in the coordination sphere about the metal atom. The formation of the Si–Si bonds (chain growth) occurs through the two-stage metathesis of the σ -bond *via* the four-centre transition states **B** and **C**.¹⁴²

Slow oligomerisation of phenylsilane catalysed by $\text{CpCp}^*.\text{Hf}(\text{SiH}_2\text{Ph})\text{Cl}$ was used as a model reaction. In this process, intermediates of dehydrocondensation, for example, $\text{CpCp}^*\text{Hf}(\text{SiHPhSiH}_2\text{Ph})\text{Cl}$, were identified. This complex was prepared by independent synthesis from $\text{CpCp}^*\text{Hf}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$ as two diastereomers, which were detected in the course of the reaction by ¹H NMR spectroscopy. The addition of two equivalents of phenylsilane to $\text{CpCp}^*\text{Hf}(\text{SiH}_2\text{Ph})\text{Cl}$ afforded (after

24 h) $[\text{CpCp}^*\text{HfHCl}]_n$ (33%) and a mixture of $\text{CpCp}^*\text{Hf}[\text{SiH}(\text{Ph})\text{SiH}_2\text{Ph}]\text{Cl}$, $\text{PhH}_2\text{SiSiH}_2\text{Ph}$ and $\text{PhH}_2\text{Si}-\text{SiH}(\text{Ph})\text{SiH}_2\text{Ph}$ in a ratio of 3:2:3. Dehydrocondensation of PhSiH₃ catalysed by Cp^*HfH_2 afforded also free oligophenylsilanes. Due to steric hindrance, this hafnium hydride reacts with the Si–H bond very slowly, which makes it possible to observe the conversion of phenylsilane into 1,2-diphenyldisilane. The latter is even more slowly converted into 1,2,3-triphenyltrisilane, and apparently, finally into 1,2,3,4-tetraphenyltetrasilane. The correlation between the concentration of the silane and the reaction time indicates that the cleavage of the Si–Si bond is an important stage of the process. Within the framework of this mechanism, the formation of cyclic oligomers is attributed to the intramolecular metathesis of $\text{R}(\text{RSiH})_n\text{H}$, where $n = 5$ (Scheme 3).¹²⁷ The metathesis with the participation of the terminal Si–H (pathway *a*) or Si–Si (pathway *b*) bonds affords five- or six-membered rings. The metathesis with the participation of the exocyclic Si–H bonds (pathway *c*) can lead to rings containing organosilicon substituents.

Scheme 3

The suggested multistage mechanism of dehydrocondensation of organylsilanes can serve as the basis for the design of new catalysts, *viz.*, coordinatively unsaturated electrophilic metal hydride complexes, which can participate in the concerted process of metathesis of the σ -bond.

The proposed mechanism explains many aspects of dehydrocondensation, including steric requirements imposed on the catalyst and the substrate as well as the formation of rather short polymer chains. However, this mechanism inadequately explains the difference in the behaviour of, on the one hand, the silyl complexes of zirconium and hafnium and, on the other hand, of the titanium complexes.

The mechanism of metathesis of the σ -bond was also used for the explanation of the regularities of other dehydrocondensation reactions, *viz.*, the reaction of RSiH_3 catalysed by the $\text{Cp}_2\text{MCl}_2-2\text{BuLi}$ binary system or Cp_2MMe_2 ,¹²⁹ the reaction of $\text{R}^1\text{R}^2\text{SiH}_2$ in the presence of Wilkinson's complex¹¹² and the reaction of 2,4-disilapentane in the presence of titanocene or zirconocene.⁴³

Hengge and Weinberger¹⁷² suggested yet another mechanism of dehydrocondensation of organylsilanes in the presence of dimethylzirconocene with the use of autocondensation of 1,2,3-trimethyltrisilane and a mixture of diastereomers of 1,2,3,4-tetramethyltetrasilane as a model reaction. The conversions of these oligomers cannot be explained in the context of Harrod's mechanism^{87, 89} because α -elimination should be accompanied by evolution of CH₄.

Dimethylsilylene $\text{Me}_2\text{Si}:$ was suggested as an intermediate in dehydrocondensation of $\text{Me}_3\text{SiSiMe}_2\text{H}$ and $\text{HMe}_2\text{SiSiMe}_2\text{H}$ in the presence of Cp_2ZrMe_2 (**22**, Scheme 4). This intermediate is formed from the intermediate silyl metal complex **23** as a result of β -elimination. This process is not the classical elimination of an organic substituent at the β position with respect to the metal atom. This mechanism can more likely be considered as β -bonding

Scheme 4
Pathway a. Formation of the active catalytic L_2M molecule

Pathway b. Dehydrocondensation

Pathway c. Insertion of silylene into the Si–H bond

Pathway d. Insertion of silylene into the Si–Si bond

upon destruction of a four-centre transition state accompanied by elimination of the resulting residue, *viz.*, the so-called elimination of the β -bond (Scheme 4, pathways *a,b*). The resulting dimethylsilylene can be inserted both into the Si–H bond (Scheme 4, pathway *c*) and into the Si–Si bond (Scheme 4, pathway *d*) of the initial pentamethyltrisilane to form the heptamethyltrisilane **24**.

Two pathways of dehydrocondensation of diorganylsilanes and higher silanes are possible, *viz.*, the metathesis of the σ -bond resulting in the formation of linear polymers with evolution of H_2

Scheme 5

Pathway a. Linear metathesis of the σ -bond of $H(MeHSi)_3H$

Pathway b. Branched metathesis of the σ -bond of $H(MeHSi)_3H$

(Scheme 5, pathway *a*) or the β -elimination with evolution of $MeSiH_3$ (Scheme 5, pathway *b*) to form a branched polymer.

We believe that the mechanism suggested by Tilley,⁴⁶ which is based both on the kinetic data and on the identification of the intermediate reaction products, is the most probable one among the above-considered mechanisms of catalytic dehydrocondensation of organylsilanes. The mechanism suggested by Hengge¹⁷² attracts attention because it involves a new type of elimination reactions, *viz.*, the elimination of the β -bond.

III. Electrochemical dehydrocondensation of organylhydrosilanes

Electrochemical reactions are used for the synthesis of various organosilicon compounds, including functionally substituted compounds.¹⁷³ Methods for the cathodic electroreduction of organylchlorosilanes to form substituted disilanes^{174–177} and oligo- and polysilanes^{178–182} have been developed. Since organylchlorosilanes are difficult to reduce, cathodic processes with their participation generally require preliminary electrogeneration of carbanions (or other nucleophiles), which then replace the chlorine atoms bound to the silicon atoms.¹⁷³ Most of cathodic reactions based on organylchlorosilanes are variations of this process.

Anodic reactions of organosilicon compounds are more diversified, though less well studied, than cathodic reduction processes.^{173, 183–186}

Electroreduction of mono-, di- and triorganylsilanes $RSiH_3$ ($R = Ph$ or $n-C_6H_{13}$), $R^1R^2SiH_2$ (R^1 and $R^2 = Me$ or Ph) and R_3SiH ($R = Et$ or EtO) on metallic (Pt , Au or Hg)^{187–190} and nonmetallic (glassy-carbon)¹⁹¹ electrodes was studied. The reactions were performed in acetonitrile in the presence of Bu_4NBF_4 (see Refs 187–190) or $LiClO_4$.¹⁹¹ Organylsilanes have low oxidation potentials on metallic electrodes (the $E_{Red/Ox}$ value varies from -0.05 to 0.7 V). On the contrary, the oxidation potential of dimethylphenylsilane on a glassy-carbon electrode is rather high ($E_{Red/Ox} = 2.2$ V). Preparative electrooxidation of Me_2PhSiH in the DME– Bu_4NClO_4 system (DME is dimethoxyethane) in the presence of $CuCl$ or $CuCl_2$ affords a mixture of compounds. The formation of the latter can be described by the following scheme.¹⁹¹

Chlorodimethylphenylsilane is formed in a yield from 46% to 95% depending on the degree of oxidation of copper and the quantity of electricity passed. Under these conditions, 1,1,2,2-tetramethyl-1,2-diphenyldisilane is formed in insignificant yield. When the supporting electrolyte was changed for Bu_4NBF_4 , fluorodimethylphenylsilane predominantly formed (the yield was 90%). In this case, the exchange reaction of the initially formed $Me_2PhSiCl$ with BF_4^- apparently proceeded.^{180, 192–194}

The oxidation potentials of the initial monomeric organylsilanes¹⁹⁰ are ~ 200 mV lower than the oxidation potentials of polyorganylsilanes, which hinders oxidation of the latter with the cleavage of the Si–Si bond.¹⁷³

Electrolysis of methylphenyl- and diphenylsilane in the DME– Bu_4NBF_4 system with the use of a platinum cathode and a platinum anode for 5.3 h afforded the corresponding oligomers.^{195, 196}

$R = Me: n = 2–6; R = Ph: n = 2–5.$

According to GLC data, the dehydrocondensation product of methylphenylsilane, which is characterised by $M_n = 454$ and the molecular distribution coefficient $M_w/M_n = 1.05$, is a mixture of at least five compounds. 1,2-Dimethyl-1,2-diphenyldisilane

($n = 2$, $M = 242$, the yield was 10%) and 1,2,3-trimethyl-1,2,3-triphenylsilane ($n = 3$, $M = 362$, the yield was 14%) were identified in the reaction mixture by mass spectrometry. The yields of methylphenyloligosilanes with $n = 4$ and 5 were 16% and 6%, respectively.¹⁸⁵ Under analogous conditions, diphenylsilane was predominantly converted into the dimer, *viz.*, 1,1,2,2-tetraphenyldisilane (the conversion was 38%), in 23% yield. Apparently, silyl radical cations are intermediates in this anodic reaction. Then these radical cations attack the corresponding monomers or oligomers to form the Si–Si bond.

Polyorganylsilanes of the $H(RHSi)_nH$ type are formed upon electrolysis of organylsilanes R^1SiH_3 ($R^1 = \text{Alk}$, Ar or $\text{CH}_2\text{CH}_2\text{R}^2$, where R^2 is a perfluoroalkyl group) in an organic solvent containing an appropriate electrolyte. Previously unknown oligo- and polyfluoroalkylsilanes with $M = 200$ –5000 were synthesised according to this procedure in high yields.¹⁹⁷

Electrolysis of organylchlorosilanes $RSiH_nCl_{3-n}$ ($n = 1$ or 2) in the THF– Bu_4NBF_4 system in an undivided cell yields two different condensation products depending on the metal of the electrodes.¹⁹⁸ Electrolysis of methylphenylchlorosilane with the use of a stainless steel cathode and a subcritical anode affords predominantly 1,2-dimethyl-1,2-diphenyldisilane, which is formed upon cathodic reduction with elimination of chlorine.

When platinum electrodes are used, the cathodic reduction is suppressed and the anodic oxidation becomes the predominant reaction. In this case, the Si–Si bond is formed through the elimination of the proton on an anode.

Radical cations formed upon electrochemical oxidation of triorganylsilanes R_3SiH were identified as adducts with tetracyanoethylene¹⁹⁹ or cyclohexene.^{188, 189, 200} The lifetime of the radical cation $\text{Et}_3\text{SiH}^{+\cdot}$, which was detected by the rotating disk-ring electrode method, is 0.003–0.006 s.^{188, 189}

In the absence of radical traps, these radical cations decompose with liberation of the hydrogen atom.

IV. Other reactions

Dehydrocondensation of organylsilanes can also occur under the action of di-*tert*-butyl peroxide.^{201–203} Thus the reaction of dimethylcyclopropylsilane with di-*tert*-butyl peroxide afforded tetramethyl-1,2-di(cyclopropyl)disilane in small yield,²⁰² whereas the reaction of dimethylphenylsilane gave a mixture of $\text{PhMe}_2\text{Si} - \text{SiMe}_2\text{H}$ (2%), $\text{PhMe}_2\text{SiSiMe}_3$ (6%), $\text{Ph}_2\text{MeSiSiMe}_3$ (3%) and $\text{PhMe}_2\text{SiSiMe}_2\text{Ph}$ (3%) in insignificant yield.²⁰³ Disilane was prepared by the reaction of di-*tert*-butyl peroxide with dimethyl(2-thienyl)silane in noticeable yield (26%).²⁰³

Recently, it was found that triethylsilane underwent dehydrocondensation to form hexaethyldisilane in the reaction with germanium or tin dihalides.^{204–206}

$\text{X} = \text{Cl}, \text{I}$.

The reaction of triethylsilane with tetrachlorogermanium affords a mixture of hexaethyldisilane and triethylchlorosilane in a ratio of 1 : 3.^{204, 205}

The reactions of germanium dichloride with Et_3SiH proceed readily in more or less polar solvents (CD_3CN or CD_2Cl_2) but do not proceed in nonpolar solvents (C_6D_6). Tetrachlorogermanium reacts with Et_3SiH only in a polar solvent (CD_3CN). It is believed that electron transfer to form the $[\text{Et}_3\text{SiH}^{+\cdot}\text{GeCl}_2^-]$ and $[\text{Et}_3\text{SiH}^{+\cdot}\text{GeCl}_4^-]$ radical ion pairs, respectively, is the key stage of these reactions.

Thermal and photochemical decomposition of bis(triorganylsilyl)mercury and -cadmium **22a,b** can be considered as a two-stage procedure for the dehydrocondensation of triorganylsilanes to form hexaorganyldisilanes.^{207–212} The compounds **22a,b** were prepared by the reactions of triorganylsilanes with dialkyl derivatives of mercury and cadmium.^{207, 209, 213}

$\text{M} = \text{Hg (a)}, \text{Cd (b)}$.

The reaction proceeds according to the radical mechanism through intermediate formation of the $R_3\text{Si}^{\cdot}$ radicals.^{214–217} The latter not only can undergo recombination but also can react with the solvent (particularly, in a photochemical process).^{213, 218–220}

Thermolysis of bis(triphenylsilyl)mercury, -zinc and -barium derivatives proceeds with elimination of free metal.²¹⁰ Hexaphenyldisilane is formed from the mercury derivative. The barium and zinc compounds give tetraphenyldisilane and diphenylsilylene. The latter undergoes subsequent oligomerisation.²¹²

Bis(methyldichlorosilyl)- and bis(dimethylchlorosilyl)-mercury, which were prepared under UV irradiation of a mixture of bis(trimethylsilylmethyl)mercury and the corresponding methyldichloro- or dimethylchlorosilane, spontaneously decompose above -79°C with elimination of mercury to form substituted disilanes.²¹²

V. Conclusion

To summarise, dehydrocondensation of organosilicon compounds containing Si–H bonds is a promising procedure for the preparation of linear and cyclic oligo- and polyorganylsilanes $H(R^1R^2Si)_nH$ and $-(\text{SiR}^1\text{R}^2)_n-$, which find use as precursors of ceramics, semiconductors, photoresistors, photoinitiators of polymerisation of alkenes, *etc.*

Group IVB metallocenes Cp_2ML_2 ($\text{M} = \text{Ti}, \text{Zr}$ or Hf ; $\text{L} = \text{H}$, Alk , OAlk , Ar or Hal) and their binary systems with promoters, such as alkylolithium, triorganylphosphines, aluminium, *etc.*, are the most efficient catalysts of dehydrocondensation. These compounds allow one to prepare linear and cyclic polysilanes under rather mild conditions. The catalytic activity of metallocenes decreases in the $\text{Zr} > \text{Ti} \gg \text{Hf}$ series depending on the nature of the central metal atom. When heteronuclear metallocenes are used, monosilanes RSiH_3 are more active than diorganylsilanes R_2SiH_2 , while triorganylsilanes R_3SiH do not undergo dehydrocondensation.

As for the mechanism of dehydrocondensation, it is evidently nontrivial and complicated. Apparently, further studies will be aimed at elucidating details of the mechanism, which can allow one to elaborate an approach to the choice of catalysts for the purpose of enhancing the selectivity of a procedure for the preparation of polysilanes with the desired structures.

Abstract. Empirical relations describing the reactivity of reagents in radical addition reactions and the results of quantum-chemical calculations of the activation energy of these processes are considered. The experimental data obtained for the addition of atoms and radicals to molecules with multiple bonds are analysed in terms of the parabolic model. The following characteristics and factors are shown to affect the activation energy of radical addition: the reaction enthalpy, the strength of the arising bond, the radius of the atom having a free valence, the presence of a π bond adjacent to the reaction centre, the interaction of two polar groups, the multidipole interaction, the steric factor, the non-linearity of the reaction centre, and the force constants of the reacting bonds. The bibliography includes 85 references.

I. Introduction

Radical addition to unsaturated compounds underlies the modern technology for production of polymers, copolymers and oligomers.^{1–5} These reactions proceed during pyrolysis of hydrocarbons, halogenation of alkenes or oxidation of unsaturated compounds.^{6–9} They are widely used in the synthesis of diverse medicines.^{10–14} The addition of hydrogen atoms and hydroxyl radicals to unsaturated, aromatic and heterocyclic compounds is involved in the photolysis and radiolysis of organic materials and biological objects.⁷ The problem of reactivity of compounds in the addition of atoms and radicals to double $C=C$ bonds has been widely discussed and is still debated.^{3, 6, 8, 15–24} Two factors which exert substantial influence on these processes have been noted,

namely, heat (enthalpy) of the reaction and the interaction of polar groups of the reactants in the transition state (the so-called polar factor). Quantum-chemical calculations showed that the reaction centre in the transition state is non-linear.¹⁶ When interpreting the results of these calculations, researchers restricted themselves to consideration of only three factors influencing the activation energy of addition, namely, the reaction enthalpy, the interaction of polar groups and the steric effect.^{25–39}

Analysis of the experimental data (on activation energies) obtained in the studies of radical abstraction reactions in terms of the parabolic model showed that, apart from the factors mentioned above, there is a whole series of other factors that determine the activation energy of an elementary step.^{40–42} The author of this review has analysed an extensive array of experimental data concerning radical addition reactions in terms of the parabolic model for this type of reaction.^{43–53} The results of this analysis are presented in detail in this review.

II. Enthalpy and entropy of radical addition

The radical addition reactions

involve the rupture of the $C=C$ π bond and the formation of a $C-X$ σ bond. A σ bond is normally stronger than a π bond; hence, radical addition is an exothermic reaction. This can be clearly seen when comparing the reaction enthalpies ΔH and the strengths of the bonds being formed $D(Et-X)$ given in Table 1; the stronger the $Et-X$ bond, the larger the $-\Delta H$ value. Yet another important factor influencing the reaction enthalpy is the energy of stabilisation of the radical $XCH_2C^{\cdot}HY$ formed: the higher this energy, the greater the heat of the addition of the $X^{\cdot}$ radical to an alkene. Stabilisation energy can be characterised as the difference between the strengths of the $C-H$ bonds in $Pr-H$ and $EtYHC-H$. Below we present the data characterising the contribution to the enthalpy of this reaction of the stabilisation

Table 1. Bond strength (kJ mol^{-1}), enthalpy (kJ mol^{-1}), entropy ($\text{J mol}^{-1} \text{K}^{-1}$) and Gibbs energy (kJ mol^{-1}) for the addition of atoms and $X^\bullet$ radicals to ethylene ($T = 298 \text{ K}$).

$X^\bullet$	$D(\text{Et}-X)$	$-\Delta H$	$-\Delta S$	$-\Delta G$
$\text{H}^\bullet$	422	150	84	125
$\text{Cl}^\bullet$	352	82	88	56
$\text{C}^\bullet\text{H}_3$	370	100	122	64
$\text{Me}_2\text{C}^\bullet\text{H}$	364	92	134	52
$\text{PhC}^\bullet\text{H}_2$	318	63	122	27
$\text{N}^\bullet\text{H}_2$	353	81	109	49
$\text{HO}^\bullet$	343	122	100	93
$\text{CH}_3\text{O}^\bullet$	352	82	118	46
$\text{HO}_2^\bullet$	327	63	134	23

energy of the $\text{MeCH}_2\text{C}^\bullet\text{HY}$ radical, resulting from the addition of a methyl radical to the monomer $\text{CH}_2=\text{CHY}$.

Y	H	C(O)OMe	Cl	CN	Ph
$D_{\text{Pr-H}} - D_{\text{EtYHC-H}}$ / kJ mol^{-1}	0.0	23.2	24.1	33.6	57.9
$-\Delta H / \text{kJ mol}^{-1}$	95.8	102.0	104.3	129.7	143.0

It can be seen that the greater the energy of radical stabilisation, the smaller the reaction enthalpy.

All the addition reactions are accompanied by a decrease in entropy (two species are combined to give one species, see Table 1). Therefore, for addition reactions, $\Delta G < \Delta H$ (ΔG is the Gibbs energy) and, when the temperature is sufficiently high, exothermic addition is reversible because $\Delta G = \Delta H - T\Delta S$.

Free radical addition can be considered to be reversible if the equilibrium concentration of the $X^\bullet$ radicals is commensurate with the concentration of the $\text{XCH}_2\text{C}^\bullet\text{HY}$ radicals formed, i.e. if the $[\text{X}^\bullet]:[\text{XCH}_2\text{C}^\bullet\text{HY}]$ ratio in the equilibrium state is not smaller than 0.05. When $[\text{CH}_2=\text{CHY}] = 10 \text{ mol litre}^{-1}$ and $T = 300 \text{ K}$, this condition results in the inequality $K \geq 200$ (K is the equilibrium constant). In turn, $-RT \ln K = \Delta G$; therefore, $\Delta G \leq -RT \ln 200 = -13 \text{ kJ mol}^{-1}$. For addition reactions, $\Delta S \approx -100 \text{ J mol}^{-1} \text{K}^{-1}$; therefore, the enthalpy of irreversible addition of $X^\bullet$ to an alkene

$$\Delta H = \Delta G + T\Delta S$$

should be smaller than -43 kJ mol^{-1} (at $T = 300 \text{ K}$).

The ΔH values for radical addition reactions listed in Table 1 comply with this condition. Naturally, as the temperature rises, the boundary value of ΔH increases in absolute magnitude.

III. Empirical correlation equations

Activation energy and heat of reaction. A linear correlation between the change in the activation energy (ΔE) of the monomer addition to a macroradical and the change in the heat of the reaction (Δq) of the type

$$\Delta E = -\alpha' \Delta q, \quad (1)$$

where α' is an empirical factor of proportionality, was found by Evans *et al.*⁵⁴ Later, N N Semenov confirmed this correlation and extended it to a wider range of addition reactions.¹⁵ However, even for a narrow series of reactions, for example, for the addition of methyl radical to $\text{CH}_2=\text{CHY}$, this correlation is nothing but a trend. Indeed, the correlation coefficient for the variation of $\Delta \log k$ as a function of Δq is 0.85 (k is the reaction rate constant).⁵⁵ Evidently, apart from the heat of reaction, other factors also influence the activation energy.

The Alfrey and Price $Q-e$ scheme⁵⁶ takes account of two factors affecting activation energy, namely, the energy of stabilisation of the radical formed in the reaction and the interaction

between polar groups in the radical and the monomer. This scheme was based on the analysis of empirical rate constants for copolymerisation. The rate constant for the reaction of a radical with a monomer is postulated to have the following form:

$$k_{12} = P_1 Q_2 \exp(-e_1 e_2), \quad (2)$$

where the factors P_1 and Q_2 reflect the reactivity and e_1 and e_2 are the charges of the radical and the monomer, respectively. The Q and e parameters are calculated from the corresponding rate constants for copolymerisation. When developing the $Q-e$ scheme, the researchers assumed that the charges on the molecule and on the radical are equal and constant (polarisation in the transition state was not taken into account) and that the copolymerisation rate constants do not depend on the dielectric constant of the medium. Subsequently, these assumptions have been criticised.² The $Q-e$ scheme made it possible to systematise the vast experimental information on radical copolymerisation of various monomers. It permits rough prediction of the rate constants for copolymerisation. The Q and e values for monomers in radical polymerisation are listed in Table 2.

Table 2. Correlation parameters for the reactivity of monomers towards radical polymerisation in terms of the Alfrey–Price (Q , e), Bamford–Jenkins (α , β) and Ito–Matsuda (K , P) schemes.^{56–62}

Monomer	Q	e	α	β	K	P
$\text{CH}_2=\text{CHPh}$	1.00	−0.80	0.00	4.85	2.28	1.00

$\text{CH}_2=\text{CHOCOMe}$	0.03	−0.88	0.0	3.00	−1.36	0.81
$\text{CH}_2=\text{CHCN}$	0.48	0.12	−3.0	5.30	0.89	−1.00
$\text{CH}_2=\text{CHOEt}$	0.02	−1.17	0.0	2.97	−0.59	1.63
$\text{CH}_2=\text{CMePh}$	0.98	−0.81	−1.0	4.72	1.30	1.69
$\text{CH}_2=\text{CMeCO}_2\text{Me}$	0.78	0.40	—	4.90	1.89	0.25
$\text{CH}_2=\text{CHCH}=\text{CH}_2$	1.70	−0.50	0.0	5.03	—	1.00
$\text{CH}_2=\text{CMeCH}=\text{CH}_2$	1.99	−0.55	0.0	4.92	—	1.09
$\text{CH}_2=\text{CClCH}=\text{CH}_2$	10.52	1.20	−1.5	5.82	—	0.10
$\text{CH}\equiv\text{CPh}$	0.45	0.5	0.5	4.41	—	1.00

The Bamford and Jenkins $\alpha-\beta$ scheme.⁵⁷ These researchers suggested that the reactivities of a radical and a monomer should be described by three parameters, namely, rate constant for the reaction of the macroradical (for example, $\text{R}^{1\bullet}$) with toluene (k_T)

the product of coefficient α with the Hammett constant σ , which takes into account the polar effect, and the coefficient β , reflecting the difference between the radical reactivities towards the monomer and towards toluene. Thus the equation for the rate constant for the addition of $\text{R}^{1\bullet}$ to the monomer M_1 is represented as follows:

$$\ln k_{11} = \ln k_T + \alpha_1 \sigma_1 + \beta_1; \quad (3)$$

the coefficients σ_1 and β_1 are calculated from the dependence of $\ln(k_{11}/k_T)$ on σ , and the rate constant k_T is determined experimentally at $T = 333 \text{ K}$. The values of α and β for a number of monomers are listed in Table 2.

The relationship between the parameters of the Alfrey–Price and Bamford–Jenkins schemes is expressed by the following equations:⁵⁸

$$-e_1(e_1 - e_2) = \sigma_1(\alpha_1 - \alpha_2), \quad (4)$$

$$\ln Q_1 - \ln Q_2 = \beta_1 - \beta_2.$$

The Ito and Matsuda K - P scheme.^{59–62} In terms of this scheme, the activation energy of an addition reaction is represented as the sum of two terms, E_1 and E_2 . The first term E_1 is proportional to the change in the Gibbs energy in the reversible addition of the thiyl radical $\text{XC}_6\text{H}_5\text{S}^\bullet$ to the monomer, $E_1 \sim \log K$, where K is the equilibrium constant of the reaction

The second term E_2 reflects the contribution of the polar interaction between the radical and the monomer to the activation energy. The contribution of the Gibbs energy to the activation energy is determined by the coefficient present in the linear dependence on $\log K$ of the logarithm of the rate constant (k_X) for the addition of the $\text{XC}_6\text{H}_4\text{S}^\bullet$ radical to the monomer $\text{CH}_2=\text{CHY}$

$$\Delta \log k_X = \alpha_Y \Delta \log K. \quad (5)$$

The α_Y value depends on the nature of the substituent Y in the monomer, this dependence being used to estimate the contribution of the polar effect to the activation energy. This contribution is characterised by the increment P

$$P = \alpha_Y + 2(\alpha_Y - \alpha_{\text{styrene}}). \quad (6)$$

The parameters K and P are listed in Table 2. Parameters of the Ito–Matsuda scheme are related to the parameters of the Alfrey–Price approach by simple relations:⁶²

$$\begin{aligned} \log Q &= 0.49 K - 0.93, \\ e &= 0.91 P + 0.95. \end{aligned} \quad (7)$$

All the above schemes include, in essence, different variants of empirical linear equations in which the rate constants for chain propagation in the free radical polymerisation are brought into correlation with thermodynamic [heat, Hammett constant (σ), the change in the Gibbs energy in the equilibrium reaction] and kinetic (logarithms of the rate constants of the reference reaction and the reaction under study) characteristics of the addition reaction.

IV. Quantum-chemical calculations of the activation energy

Quantum-chemical methods are widely used to study addition reactions.^{26–39} The results obtained, in particular, the activation energies, depend significantly on the programme chosen for calculations. For example, Wong *et al.*³⁸ calculated the activation energy of the methyl radical addition to ethylene using the QCISD(T) programme package. The results of calculations by this programme are in good agreement with experimental data.

When atoms approach one another and a transition state is formed, the bond angles at the carbon atom attacked by an atom or radical substantially change. Figure 1 shows the configuration of atoms in the transition state for the addition of substituted methyl radicals $\text{XC}^\bullet\text{H}_2$ to substituted ethylenes $\text{CH}_2=\text{CHY}$.³⁸ The geometry of the transition state is characterised by the distance $r(\text{C}-\text{C})$, the angle of attack $\varphi_{\text{at}} = \varphi(\text{CCC})$ and the pyramidal angle $\varphi_{\text{pyr}} = \varphi(\text{HCC})$. The last-mentioned parameter

Figure 1. Geometry of the reaction centre in the transition state for the addition of substituted methyl radicals ($\text{XC}^\bullet\text{H}_2$) to substituted ethylenes ($\text{CH}_2=\text{CHY}$).³⁸

Table 3. Interatomic distances and bond angles in the reaction centre and the activation energies for the addition of the $\text{XC}^\bullet\text{H}_2$ radicals to ethylene (quantum-chemical calculations).³⁸

CN	2.173	109.3	28.0	42.3

is the angle of deviation of the two $\text{C}-\text{H}$ bonds of ethylene from the plane in which they have been located in the initial molecule (the four hydrogens and both carbons of ethylene lie in one plane). Table 3 presents the values of the three above parameters and the activation energies for the addition of methyl radicals and the $\text{C}^\bullet\text{H}_2\text{OH}$ and $\text{C}^\bullet\text{H}_2\text{CN}$ radicals to ethylene.³⁸

The energy profile of the addition reaction is calculated using specific quantum-chemical programmes as a superposition of four different electron configurations of the reactants, namely,^{38,39}

where D is the radical, A is the molecule, the arrows mark the orientation of the electrons involved in the reorganisation, and $(+)$ and $(-)$ are the charges on the radical and on the molecule. The results (the activation energies) thus obtained are considered with allowance for the influence of two values, namely, the reaction enthalpy and the polar effect.

V. The parabolic model of radical addition

Within the framework of the parabolic model, radical addition

is represented⁴³ as a result of intersection of two potential curves, each of them describing the potential energy of the stretching vibrations of atoms as a parabolic function of the amplitudes of vibrations of atoms in the outgoing (i) and incoming (f) bonds. In terms of the parabolic model, radical addition can be characterised by the following parameters (Fig. 2).

1. Reaction enthalpy ΔH_e

$$\Delta H_e = D_i - D_f + 0.5hL(v_i - v_f) = \Delta H + 0.5hL(v_i - v_f), \quad (8)$$

Figure 2. Diagram of the transition state for the hydrogen atom addition to ethylene in the coordinates of the amplitude of the stretching vibration of atoms in the reaction centre (r) and the potential energy of the stretching vibration (U) in terms of the parabolic model.⁴³

E_0, E'_0 are the zero-point energies of the corresponding bonds.

^a The value in parentheses is the number of determinations.

where D_i and D_f are dissociation energies, h is the Planck constant, L is the Avogadro number, and ν_i and ν_f are the stretching vibration frequencies of bonds i and f , respectively. The second term is the difference between the zero-point energies of the reacting bonds.

2. Activation energy E_e , which includes the zero-point energy of the bond being attacked ($0.5hL\nu_i$) and depends on the experimentally determined activation energy E

$$E_e = E + 0.5(hL\nu_i - RT). \quad (9)$$

3. Distance r_e , which is equal to the sum of the amplitudes of vibrations of the atoms of the reacting bonds in the transition state.

4. Parameters b_i and b_f , which are dynamic characteristics ($2b^2$ is the force constant) of the outgoing bond

$$b_i = \pi\nu_i(2\mu_i)^{1/2}$$

and the incoming bond

$$b_f = \pi\nu_f(2\mu_f)^{1/2},$$

where μ_i and μ_f are the reduced masses of atoms forming the bonds.

The above parameters are related to one another by the following expression:⁴²

$$br_e = \alpha(E_e - \Delta H_e)^{1/2} + E_e^{1/2}. \quad (10)$$

By using the parameter br_e , one can calculate characteristics of a whole group of reactions with $br_e = \text{const}$, for example, the activation energy of the thermally neutral reaction E_{e0} for $\Delta H_e = 0$

$$(E_{e0})^{1/2} = br_e(1 + \alpha)^{-1} \quad (11)$$

and the position of the transition state $r^\ddagger$ in the segment r_e

$$\frac{r^\ddagger}{r_e} = \frac{1}{1 + \alpha}. \quad (12)$$

As a rule, each reaction within one group is characterised by the same pre-exponential factor A (determined in relation to one reaction centre). This allows the activation energy to be expressed in terms of the rate constant k using the Arrhenius equation

$$E = RT \ln \frac{A}{k}. \quad (13)$$

Since for any elementary reaction, $E > 0$, relation (13) holds when $\Delta H_e > \Delta H_{e\min}$, whereas for $\Delta H_e < \Delta H_{e\min}$, the activation energy is very small and amounts to $0.5RT$. In accordance with the parabolic model, $\Delta H_{e\min}$ is related to br_e and α by the expression⁶³

$$\alpha^2 \Delta H_{e\min} = -(br_e)^2 + 2br_e(0.5hL\nu_i)^{1/2} + 0.5hL\nu_i(\alpha^2 - 1). \quad (14)$$

The physical, thermodynamic and kinetic parameters for 15 classes of reactions involving addition of atoms and radicals to carbon—carbon and carbon—oxygen multiple bonds are listed in Table 4.

The parabolic model makes it possible to develop an empirical hierarchy of addition reactions. All the known addition reactions are divided *a priori* into classes in accordance with the atomic structure of the reaction centre in the transition state. Each class is characterised by a pair of force constants of the outgoing and incoming bonds or by the parameters $b = b_i$ and $\alpha = b_i/b_f$ (see above). Subclasses are distinguished in each class. Each subclass is characterised by $r_e = \text{const}$ or $br_e = \text{const}$, which is confirmed by analysis of a large array of experimental results. This fact is illustrated, for example, by the data on the addition of a hydrogen atom to alkenes with various structures (Table 5). For thirty two reactions, $br_e = 24.50 \pm 0.40 \text{ kJ}^{1/2} \text{ mol}^{-1/2}$.

Each subclass of reactions can be described additionally by the energy of the thermally neutral reaction E_{e0} [see Eqn (11)] and by the threshold value $\Delta H_{e\min}$, for which $E = 0.5RT$ provided that

Table 6. Kinetic parameters E_{e0} (kJ mol^{-1}), $b(1 + \alpha)^{-1} \times 10^{-11}$ ($\text{kJ}^{1/2} \text{ mol}^{-1/2} \text{ m}^{-1}$), $r_e \times 10^{11}$ (m), $(r^\ddagger/r_e)_0$ and $-\Delta H_{e\min}$ (kJ mol^{-1}) calculated from Eqns (10)–(12) and (14) for addition reactions of various subclasses.^{44–50}

$\Delta H_e < \Delta H_{e\min}$ [see Eqn (14)]. The kinetic parameters for various subclasses of addition reactions are listed in Table 6. It can be seen that each subclass is characterised by individual values of these parameters. For instance, E_{e0} varies from 31.4 kJ mol^{-1} for the addition of PhS $^\cdot$ to 105.3 kJ mol^{-1} for the addition of the phenyl radical to an alkene double bond.

VI. The contribution of enthalpy of an addition reaction to its activation energy

The parabolic model postulates a non-linear relationship between the activation energy and the enthalpy of a reaction [see Eqn (10)]. The contribution of enthalpy to the activation energy ΔE_H can be estimated as the difference $\Delta E_H = E_e - E_{e0}$.

Transformation of Eqn (10) gives the following equation for ΔE_H as a function of ΔH_e ⁴²

$$\Delta E_H = \frac{2\alpha(br_e)^2}{\alpha^2 - 1} \left\{ \left[\frac{\Delta H_e(\alpha^2 - 1)}{(br_e)^2} - 1 \right]^{1/2} - 1 \right\} + \frac{\alpha^2 \Delta H_e^2}{\alpha^2 - 1}. \quad (15)$$

When the range of variation of ΔH_e is narrow, this dependence is close to linear

$$\Delta E_H = \frac{\alpha}{1 + \alpha} \Delta H_e + \frac{\alpha}{4(br_e)^2} \Delta H_e^2. \quad (16)$$

In a review,⁴² the E_{e0} values calculated from experimental br_e parameters made it possible to evaluate correctly the contribution of the enthalpy of addition to its activation energy. As an example, Table 7 presents the results of this comparison for two groups of addition reactions.

It can be seen that these reactions are highly exothermic and the contribution of enthalpy to the activation energy is fairly high; it varies from -43.6 to $-98.7 \text{ kJ mol}^{-1}$, *i.e.* amounts to 40%–50% of ΔH .

Table 7. Contribution of the reaction enthalpy ΔH to the activation energy ΔE_H .

R	Y	$-\Delta H/$ kJ mol $^{-1}$	$E_e/$ kJ mol $^{-1}$	$-\Delta E_H/$ kJ mol $^{-1}$

H	Ph	143.3	26.6	63.4
Ph	Ph	154.0	24.5	69.3

VII. Force constants of reacting bonds

The activation energy of a thermally neutral reaction is determined by two parameters — the distance r_e and the force constants of the reacting bonds α and b . In some classes of radical abstraction reactions, namely in those presented below,

only the force constants change on passing from one class to another; thus, only the parameters α and b determine the activation energy of a thermally neutral reaction.⁸⁰ There are no such examples among addition reactions; therefore, it is expedient to compare different classes of reactions assuming (conditionally) that $r_e = \text{const}$. The parameter r_e for each reaction was taken to be 3.713×10^{-11} m, as for the addition of the methyl radical to $CH_2=CRY$, while the parameters b_i and b_f were varied in conformity with the structure of the reaction centre. The calculations were carried out using Eqn (11).

Reaction	E_{e0} (calculated)/ kJ mol $^{-1}$	E_{e0} (exp)/ kJ mol $^{-1}$
$H^\bullet + C=C$	67.3	101.6
$H^\bullet + O=C$	73.2	102.9
$H^\bullet + C \equiv C$	81.3	125.2
$Me^\bullet + C=C$	82.6	82.6
$Me^\bullet + O=C$	74.9	68.1
$Me^\bullet + C \equiv C$	64.0	97.7

Comparison of the calculated and experimental E_{e0} values shows a substantial influence of, on the one hand, the force constants (the range of variation of E_{e0} is 64–83 kJ mol $^{-1}$) and, on the other hand, the parameter r_e [E_{e0} (calculated) $\neq E_{e0}$ (exp)].

VIII. Triplet repulsion in addition reactions

The activation energy of radical abstraction is influenced by the so-called triplet repulsion in the transition state.^{40, 42} This influence is manifested in the fact that the stronger the $X-R$ bond towards which the hydrogen atom moves in the thermally neutral reaction $X^\bullet + RH$, the higher the activation energy of this reaction. The triplet repulsion is due to the fact that three electrons cannot be accommodated in the bonding orbital of $X-C$; therefore, one electron occupies the non-bonding $X-C$ orbital. Meanwhile, the stronger the $X-C$ bond, the higher the energy of the non-bonding orbital and the higher the activation energy of abstraction.

How do matters stand with radical addition? Comparison of E_{e0} and r_e with the energy of dissociation of the resulting bond D_e has shown that this influence certainly does exist.^{44, 46, 48} The parameters E_{e0} and r_e are juxtaposed with the dissociation energy of the bond formed $D_e(X-C)$ in Table 8 and in Fig. 3. For reactions of one class, namely, $X^\bullet + CH_2=CHY$, the linear correlation $E_{e0} = \text{const} [D_e(X-C)]^2$ holds; $\text{const} = 5.95 \times 10^4$ mol kJ $^{-1}$. The following correlation was found to be fulfilled for reactions of all the thirteen classes considered:

$$r_e = a D_e(X-C), \quad (17)$$

where $a = (1.01 \pm 0.03) \times 10^{-13}$ for the addition of atoms and $a = (0.98 \pm 0.02) \times 10^{-13}$ m mol kJ $^{-1}$ for the addition of radicals (see Fig. 3). This correlation should be regarded as an empirical proof of the fact that the non-bonding orbital of the bond being

Figure 3. Correlation of the parameter r_e (parabolic model) with the strength $D_e(X-C)$ of the bond formed upon atom and radical addition to the $C=C$ and $C \equiv C$ multiple bonds;⁴⁷ (1) atom + $C=C$, (2) $X' + C=C$ or $C \equiv C$, (3) $H'(R') + O=C$.

$RO^\bullet + CH_2=CHY \longrightarrow ROCH_2C^\bullet HY$	65.2	3.617	359	1.01
$R^\bullet + O=CR^1R^2 \longrightarrow ROC^\bullet R^1R^2$	68.1	3.540	365	0.97

formed actually does participate in the generation of the activation energy of addition. The stronger this bond, the higher the energy of the non-bonding orbital and the higher the activation energy. Empirical correlation (17) can be used to estimate roughly the activation energies of diverse addition reactions.

IX. The influence of neighbouring π bonds on the activation energy of radical addition

Radical abstraction reactions that involve molecules with π bonds in the vicinity of the reaction centre are characterised by higher E_{e0} values than the corresponding reactions involving similar hydrocarbons without these bonds. This is due to triplet repulsion.^{41,42} In these reactions, the three electrons of the reaction centre interact with the neighbouring π electrons; as a consequence, the energy of the non-bonding orbital in the transition state increases and, hence, the activation energy also increases. Do neighbouring π bonds influence the E_{e0} values of radical addition? In order to answer this question, let us compare the br_e and E_{e0} parameters for the addition of $H^\bullet$, $C^\bullet H_3$, $RO^\bullet$, $RO_2^\bullet$, and $R_3Si^\bullet$ to the monomers $CH_2=CHY$ and monomers with double bonds in the α -position relative to the double bond being attacked. If the monomer contains an aromatic ring or a double bond in the α -position, the activation energy of a thermally neutral reaction increases; if there are two aromatic rings in the α -position, E_{e0} increases to even a greater extent (Table 9). The difference between $E_{e0}(\pi)$ and $E_{e0}(CH_2=CHY)$ can be used to estimate the contribution of this factor to the activation barrier⁴¹

$$\Delta E(\pi) = \Delta E_{e0}(\pi) - E_{e0}(CH_2=CHY). \quad (18)$$

Triplet repulsion also manifests itself in the reactions in question; for example, in the reaction

Table 9. Influence of a π bond adjacent to the reaction centre on the activation energy of the radical addition to alkenes.^{44–50}

Reaction	br_e^a	E_{e0}^b	ΔE_π^b	$\Delta D_e(\pi)^c$

^a Expressed in $\text{kJ}^{1/2} \text{mol}^{-1/2}$; ^b expressed in kJ mol^{-1} ; ^c $\Delta D_e(\pi)$ is the energy of triplet repulsion, kJ mol^{-1} .

a multicentre multielectron $R\cdots C\cdots C\cdots C$ bond arises in the transition state; this increases the strength of the bond, and, hence, enhances the triplet repulsion and its contribution to the activation energy. It can be seen from the data of Table 9 that this contribution can reach 20 kJ mol^{-1} . The increase in the dissociation energy $D_e(X-C)$ caused by this electron delocalisation can be estimated using relation (18).

The same trend is observed for the addition of the benzyl radical to the monomers $CH_2=CRY$ (see Table 10).⁴⁸ The average br_e and E_{e0} values for these reactions are $24.91 \pm 0.49 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ and $128.0 \text{ kJ mol}^{-1}$, respectively; the values for the addition of methyl radical are $19.93 \pm 0.4 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ and 82.6 kJ mol^{-1} . The greater E_{e0} value found in the case of the addition of benzyl radicals points to stronger triplet repulsion caused by electron delocalisation.

Table 10. Parameters br_e and E_{e0} for the addition of benzyl radicals to monomers $CH_2=CRY$.

R	Y	$br_e/\text{kJ}^{1/2} \text{mol}^{-1/2}$	$E_{e0}/\text{kJ mol}^{-1}$
Me	OMe	24.98	128.7
H	OEt	24.85	127.4
H	Ph	24.88	127.7
Me	Ph	24.93	128.2

The substantial influence of the π bonds located near the reaction centre on the activation energy can also be followed for the addition of methyl radicals to the $C=O$ group in *p*-benzoquinone. This can be clearly seen when comparing the corresponding parameters for the addition of a methyl radical to acetone and to *p*-benzoquinone.⁴⁹

R^1COR^2	$br_e/\text{kJ}^{1/2} \text{mol}^{-1/2}$	$E_{e0}/\text{kJ mol}^{-1}$	$10^{11}r_e/\text{m}$
Me_2CO	21.95	68.1	3.54
OC_6H_4O	23.15	81.1	3.86

The observed difference in the parameters is due most likely to the electron delocalisation in the aromatic ring and, hence, to the increase in the triplet repulsion. The difference between the E_{e0} values for the reactions considered amounts to 13 kJ mol^{-1} . For the addition of polystyrene radical to *p*-benzoquinone, $br_e = 25.03 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ and $E_{e0} = 94.8 \text{ kJ mol}^{-1}$. In this case, the E_{e0} value is 26.7 kJ mol^{-1} greater than that for the reaction of the methyl radical with acetone. The very large $\Delta E(\pi)$ value can be accounted for by the interaction of the π electrons of the two neighbouring benzene rings with the reaction centre.

The addition of peroxy radicals to alkenes deserves special discussion. This class of reaction is characterised by the parameter $br_e = 26.04 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ (see Ref. 45). Estimation of this parameter from relation (17) gives $br_e = 16.26 \text{ kJ}^{1/2} \text{mol}^{-1/2}$, which is much lower than the experimental value. One reason for this discrepancy, as in the case of reactions subject to the influence of π bonds, is as follows. In the $RO\cdots O\cdots C\cdots C$ transition state, the *p* electrons of the two oxygen atoms interact with the electrons of the atoms of the reaction centre; this increases the triplet repulsion and E_{e0} .

With allowance for the examples considered above, correlation (17) can be extended and written in the following form:

$$r_e = a[D_e + \Delta D_e(\pi)], \quad (19)$$

where $\Delta D_e(\pi)$ is the increase in the energy of the non-bonding orbital caused by delocalisation of the neighbouring π or *p* electrons. The $\Delta D_e(\pi)$ values are listed in Table 9.

X. The role of the radius of the atom carrying the free valence

The greater the radius of the atom carrying the free valence, the higher the E_{e0} for radical abstraction.⁴² Does the radius of the atom which attacks the double bond influence the activation energy of addition reactions? This question was answered as a result of analysis of experimental data on the addition of triethylsilyl and phenylthiyl radicals to alkenes.⁵⁰

Figure 4. Correlation between the ratio of the parameters r_e/D_e (parabolic model) and the length $r(X-C)$ of the incoming bond for the addition of the $R^\bullet$, $N^\bullet H_2$, $RO^\bullet$, $RS^\bullet$, and $R_3Si^\bullet$ radicals to alkenes (see also Table 11).⁵⁰

Since the strength of the $C-X$ (D_e) bond being formed influences the parameter r_e [see Eqn (17)], the characteristic to be compared for the addition of various radicals to alkenes is the r_e/D_e ratio (Table 11, Fig. 4). The lengths $r(C-X)$ of the bonds formed upon the addition of radicals such as $C^\bullet H_3$, $N^\bullet H_2$ and $RO^\bullet$ to the $C=C$ bond and upon the addition of $C^\bullet H_3$ to the $C=O$ bond are close; therefore, the ratio $r_e/D_e = \text{const}$. However, in the case of addition of $PhS^\bullet$ and $R_3Si^\bullet$ to the $C=C$ bond, the r_e/D_e ratio is much greater and a linear correlation is observed between r_e/D_e and $r(C-X)$. The correlation has the following form⁵⁰

Table 11. Strengths (D_e /kJ mol⁻¹) and lengths [$r(C-X)$ or $r(X-O)$ /m] of the bonds formed upon the addition of $X^\bullet$ radicals to $C=C$ or $C=O$ double bonds.⁵⁰

$CH_2=CMeOMe$	-6.5	-9.4	10.1	—	—	—
$CH_2=CHOAc$	-15.1	-11.2	17.5	9.5	7.3	11.5
$CH_2=CMeOAc$	-16.4	-4.3	19.5	—	—	—
$CH_2=CClMe$	-8.2	-4.4	10.8	—	—	—
$CH_2=CCl_2$	-10.2	-3.8	13.4	—	—	—
$CH_2=CHCOOMe$	-20.1	-1.4	13.1	-0.3	-2.0	—
$CH_2=CMeCOOMe$	—	-3.4	—	-5.2	-6.4	-4.7
$CH_2=CHCN$	-23.2	-0.9	13.8	-9.0	-10.8	-7.9

$$r_e = \frac{(1 + \alpha)}{b} E_{e0}^{1/2} = 8.81 \times 10^4 [r(C-X) - 0.42 \times 10^{-10}] D_e. \quad (20)$$

Thus, the radius of the atom carrying the free valence has a substantial influence on the activation barrier to the addition reaction — the greater the radius of this atom, the higher the activation energy. Apparently, this effect is due to repulsion in the transition state, the repulsion being due to the interaction between the electron shells of the double bond being attacked and the atom which attacks this bond.

XI. Interaction of two polar groups

The polar effect involved in radical addition has been repeatedly discussed in the scientific literature.^{3,6,19-25} The parabolic model opens up new prospects for the correct estimation of the polar effect. It permits one to determine the contribution of this effect to the activation energy. This contribution (ΔE_μ) is estimated by choosing a reference reaction which involves the same reaction centre but in which one or both reactants are non-polar. The reference reaction is characterised by the parameter br_e and the reaction with two polar reactants is characterised by the parameter $(br_e)_\mu$. The component of the activation energy caused by polar interaction (ΔE_μ) is calculated from the equation⁴²

$$\Delta E_\mu = [(br_e)_\mu^2 - (br_e)^2](1 + \alpha)^{-2}. \quad (21)$$

Table 12 presents the results of calculation of ΔE_μ for the reactions of six polar radicals with a number of polar monomers.^{45,46,81-83} It can be seen that the polar interaction in the transition states for the addition can either decrease ($\Delta E_\mu < 0$) or, in other cases, increase ($\Delta E_\mu > 0$) the activation energy. The ΔE_μ values vary from +19.5 to -23 kJ mol⁻¹, i.e. they can be rather large.

XII. Multidipole interaction in addition reactions

The multidipole interaction in a bimolecular reaction arises if one or both reactants contain several polar groups.⁸⁴ The multidipole effect shows itself as a deviation of the rate constant for the addition of a polar radical to a polyfunctional compound (calculated in relation to one reaction centre) from the rate constant for the addition to a monofunctional compound. The multidipole effect was discovered for radical abstraction of a hydrogen atom from polyfunctional esters induced by peroxy radicals.⁸⁴ Later, this effect has also been found in the addition of peroxy radicals to the double bonds of polyatomic unsaturated esters.⁸⁵ Table 13 summarises the results of calculations of the contribution of the multidipole effect to the activation energy performed using relation (21). A monofunctional ester of the corresponding structure served as the reference compound. It can be seen that the role of the multidipole interaction in these reactions is fairly low: the contribution of the interaction of several polar groups $\Delta \Delta E_\mu$ varies from 0.8 to 2.3 kJ mol⁻¹.

Table 13. Multidipole effect in the addition of cumeneperoxy radicals to unsaturated polyatomic esters (n is the number of reacting double bonds in the ester molecule).⁸⁵

Ester	k (323 K) ^a	k/n ^a	$\Delta\Delta E_{\mu}$ ^b
$\text{CH}_2 = \text{CHCO}_2\text{Me}$	0.50	0.50	0
$(\text{CH}_2 = \text{CHCO}_2\text{CH}_2)_2\text{CMe}_2$	0.76	0.38	0.8
$(\text{CH}_2 = \text{CHCO}_2\text{CH}_2)_2\text{CHOCOCH} = \text{CH}_2$	1.05	0.35	1.0
$(\text{CH}_2 = \text{CHCO}_2\text{CH}_2)_4\text{C}$	1.28	0.32	1.2
$\text{CH}_2 = \text{CMeCO}_2\text{Me}$	1.79	1.79	0
$(\text{CH}_2 = \text{CMeCO}_2\text{CH}_2)_2\text{CHOCOMeC} = \text{CH}_2$	3.93	1.31	0.9
$(\text{CH}_2 = \text{CMeCO}_2\text{CH}_2)_4\text{C}$	3.08	0.77	2.3

^a Expressed in litre $\text{mol}^{-1} \text{s}^{-1}$. ^b Expressed in kJ mol^{-1} .

The multidipole effect is also manifested in the addition of chlorine atoms to chloroalkenes. The scope of influence of this factor on the activation energy of these reactions can be judged from the data given in Table 14.

Table 14. Parameters br_e , ΔE_{μ} and $\Delta\Delta E_{\mu}$ for the addition of chloride to chloroalkenes.⁴⁴

Alkene	$br_e / \text{kJ}^{1/2} \text{mol}^{-1/2}$	$\Delta E_{\mu} / \text{kJ mol}^{-1}$	$-\Delta\Delta E_{\mu} / \text{kJ mol}^{-1}$
$\text{CH}_2 = \text{CHCl}$	21.23	17.0	0.0
<i>cis</i> - $\text{CHCl} = \text{CHCl}$	20.43	11.4	5.6
$\text{CH}_2 = \text{CCl}_2$	19.64	6.6	10.4
$\text{CHCl} = \text{CCl}_2$	20.50	11.8	5.2
$\text{CCl}_2 = \text{CCl}_2$	19.46	5.6	11.4

The interaction of a polar reaction centre with one polar C—Cl group increases the activation energy by 17 kJ mol^{-1} , whereas the interaction with several polar C—Cl groups, conversely, results in a lower activation energy.

XIII. Steric hindrance

The addition of trialkylsilyl radicals to 1,2-disubstituted ethylene derivatives is subject to a steric effect. This shows itself in the E_{e0} value for the $\text{Et}_3\text{Si}^\bullet$ addition to $\text{RCH} = \text{CHR}$ being greater than that for the addition of the same radical to $\text{CH}_2 = \text{CHR}$.⁵⁰ The contribution of steric repulsion to the activation energy can be characterised by the increment ΔE_s .

Alkene	$br_e / \text{kJ}^{1/2} \text{mol}^{-1/2}$	$E_{e0} / \text{kJ mol}^{-1}$	$\Delta E_s / \text{kJ mol}^{-1}$
$\text{CH}_2 = \text{CHR}$	26.46	76.6	0.0
$\text{RCH} = \text{CHR}$	27.54	83.0	6.4 ± 0.7

Table 15. Thermodynamic (ΔH , D_e in kJ mol^{-1}) and kinetic (α and E , E_{e0} in kJ mol^{-1}) parameters for the addition of radicals to the carbon and oxygen atoms of the carbonyl group.⁵¹

Reaction	α	ΔH	D_e	E	E_{e0}
$\text{H}^\bullet + \text{Me}_2\text{CO} \longrightarrow \text{Me}_2\text{CHO}^\bullet$	1.601	−53.3	406.5	39.8	82.5
$\text{H}^\bullet + \text{Me}_2\text{CO} \longrightarrow \text{Me}_2\text{C}^\bullet\text{OH}$	1.274	−102.2	459.7	41.8	138.0

$\text{MeO}^\bullet + \text{Me}_2\text{CO} \longrightarrow \text{Me}_2\text{C}^\bullet\text{O}_2\text{Me}$	1.850	157.6	164.1	164.0	11.2
$\text{Me}^\bullet + \text{Me}_2\text{CO} \longrightarrow \text{Me}_2(\text{MeOO})\text{CO}^\bullet$	1.931	48.8	290.0	60.0	33.7

No effect of this type is manifested for the addition of alkyl radicals to the same alkenes.⁴⁶ Evidently, the steric effect involved in the addition of trialkylsilyl radicals to 1,2-disubstituted ethylene derivatives is due to the repulsion between the carbon and silicon atoms, caused by the large size of the silicon atom, in the reaction centre of the transition state.

The addition of tris(*tert*-butyl)phenoxyl radical to styrene can serve as an example of reaction subject to the steric effect. This reaction is characterised by $br_e = 23.89 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ (see Ref. 49), whereas the addition of the *tert*-butoxyl radical to styrene (a reaction with a similar structure of the reaction centre) has the parameter $br_e = 21.09 \text{ kJ}^{1/2} \text{mol}^{-1/2}$ (see Ref. 49). The difference between these values is matched by the difference between the activation energies of the corresponding thermally neutral reactions, $\Delta E_{e0} = 21.6 \text{ kJ mol}^{-1}$; this can be regarded as a rough estimate of the energy of additional repulsion in the transition state of the reacting system. This repulsion in the transition state is brought about by two *tert*-butyl groups of the phenoxyl radical.

XIV. Competition between the addition of free radicals to the carbon and oxygen atoms of the carbonyl group

The reaction enthalpy and the triplet repulsion are two factors influencing appreciably the activation energy of addition. The triplet repulsion in the addition of atoms and radicals to the C=C bonds attached to the CH_2 and CHY groups does not differ much because the D_e values for these processes are close (see Section VIII). The difference between the reactivities of the CH_2 and CHY groups is determined by the energy of stabilisation of the radicals formed and thus by the reaction enthalpy.

A different situation is observed for the addition of radicals to C=O bonds. In this case, triplet repulsion which accompanies the addition of the $\text{X}^\bullet$ radical to carbon differs substantially from that involved in the addition to oxygen because of the different strengths of the resulting bonds, C—X and X—O. For example, the dissociation energies in ethanol are $D_e(\text{C—H}) = 417 \text{ kJ mol}^{-1}$ and $D_e(\text{O—H}) = 458 \text{ kJ mol}^{-1}$. Therefore, the ratio of the activation energies E_{e0} of the corresponding thermally neutral addition reactions, which is proportional to the $D_e^2(\text{C—H})/D_e^2(\text{O—H})$ ratio, is equal to 0.83 [see Eqns (11)–(17)]. Thus, two factors compete in the addition of atoms and radicals to a carbonyl group, namely, the enthalpy of the reaction and the triplet repulsion, which both influence the activation energy. The problem of competition between the addition of atoms and radicals to either carbon or oxygen atom of the carbonyl group has been considered in the literature.⁵¹ The thermodynamic and kinetic parameters of such addition are presented in Table 15. Analysis of the ΔH , E , and E_{e0} values leads to the following conclusions.

1. Hydrogen atoms add both to oxygen and to carbon, the corresponding rate constants being close (the difference between the activation energies is only 2 kJ mol^{-1}). This is due to the fact that the influence of the reaction enthalpy (see the ΔH values) is counterbalanced by the effect of triplet repulsion, which is higher for the hydrogen addition to oxygen: $\Delta H(\text{O}) - \Delta H(\text{C}) = -48.9 \text{ kJ mol}^{-1}$ but $E_{\text{e0}}(\text{C}) < E_{\text{e0}}(\text{O})$ and $\Delta E_{\text{e0}} = 55.5 \text{ kJ mol}^{-1}$. In this reaction, the thermodynamic (ΔE_H) and kinetic (E_{e0}) factors act in the opposite directions and cancel out each other.

2. When a methyl radical adds to the carbonyl group of acetone, the heat of the addition to carbon is greater than the heat of the addition to oxygen: $[\Delta H(\text{C}) - \Delta H(\text{O})] = -12.7 \text{ kJ mol}^{-1}$. However, due to the higher triplet repulsion [$E_{\text{e0}}(\text{C}) > E_{\text{e0}}(\text{O})$], the activation energy for the addition of the methyl radical to carbon is higher than that for its addition to oxygen [the difference between the activation energies $E(\text{C}) - E(\text{O}) = +12.3 \text{ kJ mol}^{-1}$]. In this case, triplet repulsion has the predominant influence on the energy. As a consequence, the more exothermic reaction has a higher activation energy.

3. In the addition of a methyl radical to the carbonyl group of acetophenone, both factors (thermodynamic and kinetic) act in the same direction (compare the ΔH and E_{e0}); therefore, the predominant pathway is the addition of the methyl radical to the oxygen atom, giving rise to a more stable benzyl radical: $\Delta E = E(\text{O}) - E(\text{C}) = 23 \text{ kJ mol}^{-1}$.

4. Hydroxyl and alkoxyl radicals add only to the carbon atom because this addition is exothermic, whereas the addition to oxygen is endothermic.

5. The addition of a peroxy radical to the carbonyl group is an endothermic reaction; the very high activation energy (60.0 kJ mol^{-1}) makes this process virtually impossible because the addition product would rapidly decompose to the starting compounds (see Section II).

XV. Comparison of radical addition and radical abstraction reactions

In a previous study,⁴¹ diverse reactions of radical abstraction have been analysed in terms of the parabolic model and ten structural and thermodynamic factors determining the activation energy of these reactions have been established. In this study, we distinguish factors which influence the activation energy of radical addition. Since both addition and abstraction reactions are analysed in terms of the same (parabolic) model, it is possible to compare these two absolutely different types of reactions regarding the character and the degree of influence of each factor on the activation energy.

Table 16 lists the factors that influence the activation barriers to both radical abstraction and addition. It can be seen that the factors having a positive influence on the activation energy of abstraction and addition include the reaction enthalpy, the force

Table 16. Factors influencing the activation energy of radical abstraction and addition.

Factor influencing the activation energy	Radical abstraction	Radical addition
Enthalpy	+	+
Force constants of the reacting bonds	+	+
Strength of the incoming bond	+	+
The presence of π -bonded groups	+	+
Different electronegativities of atoms in the reaction centre	—	no effect
Radius of the atom carrying a free valence	+	+
The presence of polar groups	$\pm$	$\pm$
Steric effect	+	+

Note. ‘Plus’ stands for an increase and ‘minus’ means a decrease in E due to the influence of this factor.

constants of the reacting bonds, the strength of the bond being formed, the radius of the attacking atom, and π bonds or bulky substituents present in the vicinity of the reaction centre. Polar groups (one or several) in the reactant molecules either increase or decrease the activation energy.

The difference between the abstraction and addition reactions is as follows. First, they differ in the geometry of the reaction centre. In the case of abstraction, the reaction centre is linear — all three atoms are aligned and this geometry ensures the minimum activation barrier. In the case of addition, since the molecular orbital of the π -C—C bond is arranged at an angle of 90° in relation to the line connecting the atoms, the reaction centre is a triangle (the three atoms X—C—C of the reaction centre are located at the vertices of a triangle with an X—C—C angle of 109° , see Fig. 1). Naturally, this distinction exerts an effect on the activation energy of addition. Second, the activation energy of abstraction is affected by the difference between the electronegativities of the atoms of the reaction centre, namely, the greater this difference, the lower the activation energy. No influence of this type has been noted in addition reactions.

It is pertinent to compare the activation parameters for various classes of addition reactions with the corresponding parameters of radical abstraction.⁴² The results of this comparison for five parameters and six subclasses of abstraction and addition are summarised in Table 17. The abstraction of a hydrogen atom in a thermally neutral reaction always proceeds more easily than the addition of a hydrogen atom to a double bond (see the E_{e0} values). This is due to the different geometries of the reaction centre in these reactions and to higher repulsion in the non-linear reaction centre. An important role is played by the

Table 17. Kinetic parameters of radical abstraction and addition.^{42, 44, 46, 52, 53}

Reaction	$E_{\text{e0}}/\text{kJ mol}^{-1}$	$10^{11}r_{\text{e}}/\text{m}$	dE/dH	$(r^{\neq}/r_{\text{e}})_0$	$\Delta H_{\text{e min}}/\text{kJ mol}^{-1}$

$\text{R}^{\cdot} + \text{O}=\text{CR}^1\text{R}^2 \longrightarrow \text{ROC}^{\cdot}\text{R}^1\text{R}^2$	68.1	3.540	0.61	0.39	112.2
$\text{H}^{\cdot} + \text{HOR} \longrightarrow \text{H}_2 + \text{RO}^{\cdot}$	38.3	2.812	0.53	0.47	33.5
$\text{H}^{\cdot} + \text{O}=\text{CR}^1\text{R}^2 \longrightarrow \text{HOC}^{\cdot}\text{R}^1\text{R}^2$	102.9	4.401	0.61	0.38	149.7

force constant of the bond being attacked (the force constant of a multiple bond is always greater than that of a single bond).

It is expedient to describe the variation of the activation energy of a radical reaction as a function of the reaction enthalpy by the derivative dE/dH at $\Delta H_e = 0$. This value is determined by the parameter α : $(dE/dH) = \alpha(1 + \alpha)^{-1}$. For abstraction reactions, it can be greater than, smaller than, or equal to 0.5. For addition reactions, this ratio is always greater than 0.5 because the force constant of a multiple bond is always greater than that for a single bond. Thus, the activation energy of addition depends on ΔH to a greater extent than the activation energy of abstraction.

The ratio $(r^\ddagger/r_e)_0 = (1 + \alpha)^{-1}$ characterises the position of the transition state on the segment r_e for $\Delta H_e = 0$. Any of the possible cases can be found among abstraction reactions — the $(r^\ddagger/r_e)_0$ ratio can be equal to, greater than, or smaller than 0.5. In the case of addition, $(r^\ddagger/r_e)_0 < 0.5$, i.e., an early transition state is always formed. As in the previous case, this is due to the fact that the force constant of a multiple bond is always higher than that of the σ bond arising and α is always > 1 .

XVI. Conclusion

The use of the parabolic model as a tool for the analysis of addition reactions proved to be exceptionally fruitful. This method provides the possibility of elucidating a number of characteristics and factors influencing the activation energy of addition, based on experimental data. The following factors were found to be the most important.

1. Reaction enthalpy ΔH_e . The dependence of the activation energy E_e on ΔH_e obeys a parabolic law, $\Delta E_e^{1/2} \sim \Delta H_e$. When the ΔH_e value is rather low ($\Delta H_e \leq \Delta H_{e\min}$), the activation energy does not depend on ΔH_e and is close to zero ($E = 0.5 RT$). The parameters b_r calculated from experimental data make it possible to determine E_e for any reaction of the given subclass.

2. Force constants of the reacting bonds (the b_i and b_r coefficients). The activation energy of a thermally neutral reaction E_{e0} is proportional to $[b_i b_r (b_i + b_r)^{-1}]^2$. Depending on which bonds are reorganised during the reaction, the activation energy can change by a factor of 2 due to the difference in the force constants of the reacting bonds alone (the b_i and b_r coefficients).

3. A significant role is played by the arrangement of atoms of the reaction centre. In the case of addition, it is non-linear (triangular); naturally, this affects the activation energy.

4. A substantial contribution to the activation energy is made by the energy of the non-bonding orbital of the resulting bond due to the triplet repulsion in the transition state. The stronger the bond being formed (D_e), the higher the activation energy E_{e0} . For reactions of the same class ($b = \text{const}$ and $\alpha = \text{const}$), $E_{e0} \sim D_e^2$; for reactions of different classes, the empirical dependence (17) holds.

5. Yet another factor is also related to the triplet repulsion, namely, the dependence of E_{e0} on the π bonds present in the vicinity of the reaction centre. This proximity increases the activation energy by 6–15 kJ mol⁻¹. A π bond near the reaction centre increases the electron density on the reaction centre, which increases the energy of the non-bonding orbital and, correspondingly, its contribution to the formation of the activation barrier.

6. The radius of the atom carrying the free valence and attacking the double bond is also significant and influences the activation barrier. The dependence of E_{e0} on the length of the bond being formed $r(C-X)$ is also non-linear [see Eqn (20)].

The activation energies of some subclasses of addition reactions also depend on several other factors, namely, the interaction of polar groups of two polar reactants (among the reactions studied, the contribution of the interaction of polar groups contained in the radical and in the molecule to the activation energy ranges from -25 to +15 kJ mol⁻¹); the multidipole interaction of several polar groups, and the steric factor.

Thus, in the case of both radical abstraction and radical addition, we come across a large variety of factors that influence

the reactivity of the reactants. The parabolic model makes it possible to identify these factors and to characterise the contribution of each of them to the activation energy in terms of an appropriate increment.

V. Conclusion	175

Abstract. The results of studies on sonochemical catalytic reactions are generalised. The effects of ultrasound on processes of preparation, activation and regeneration of catalysts as well as its influence on the course of catalytic reactions are considered. The advisability of ultrasonic treatment in different stages of catalytic processes is discussed. The bibliography includes 143 references.

I. Introduction

The effect of ultrasonic waves on chemical reactions was first revealed in 1927.¹ The number of publications devoted to studies of reactions which change considerably their rates or direction in an ultrasonic field is increased every year. As regards their sensitivity to acoustic vibrations, all sonochemical reactions may be divided into two groups: some reactions are accelerated in an ultrasonic field and can also occur in its absence, though at a lower rate, whereas others cannot occur at all without the action of ultrasound vibrations. For both groups of reactions, high-frequency (2–10 MHz), medium-frequency (20–100 kHz) and low-frequency (from 10 Hz) vibrations are applied.^{1–7} The classification of sonochemical reactions proposed by Margulis² envisages their following division:

- redox reactions in aqueous solutions between solutes and the products resulting from ultrasonic degradation of water (H, OH, H₂, H₂O₂);
- reactions between dissolved gases and substances in the vapour state under high pressure inside cavitation bubbles;
- chain reactions induced not by radical products obtained upon ultrasonication of water, but rather by another compound present in the system which is split upon cavitation;
- reactions involving macromolecules, including oscillatory reactions which acquired wide popularity in recent years;^{1,8}
- sonochemical reactions in non-aqueous systems;
- initiation of explosion in liquid and solid explosives.

According to this classification, nearly all the catalytic processes can be referred to the reactions in non-aqueous systems, because the main solvent or reagent in them is an organic substance, although water can also participate. For this reason, it seems more appropriate to divide catalytic processes with regard

to the type of catalysis (*e.g.*, homogeneous, heterogeneous) and also to classify them by the type of catalyst and the kind of reaction (hydrogenation, oxidation, *etc.*). This approach has been used in fundamental studies on sonochemistry^{1–5,9} and has become classical in the theory of catalysis.^{10,11} It was proposed to divide the results of the impact of acoustic vibrations on chemical processes into the so-called effects of the first and the second order.^{12–14} These are non-linear effects developing in a liquid upon propagation of high-intensity acoustic waves. However, this approach does not allow estimation of the extent of the influence of individual parameters of ultrasound on chemical reactions. Nonetheless, the equations describing each of these parameters and effects can be used for formalising the problems of mathematical simulation of the corresponding chemical processes.^{9,15}

The action of acoustic vibrations is highly diverse.¹⁶ Ultrasonic waves can accelerate chemical reactions owing to emulsification of liquid components,¹⁷ dispersion of solid components and catalysts, erosion of their surfaces, degassing, prevention of sedimentation or coagulation of the products, intense mixing, *etc.*^{18–20} The action of ultrasound on solid catalysts is far from being always reduced solely to dispersion, since under definite conditions their activities are much higher than those which could be expected after mere grinding of particles.^{1–3} Dispersion results in the increased interface area of reactants and occurs due to both the fragmentation of solid phase particles and the surface friction between the solid and liquid phases.^{21,22} As the thickness of the diffusion boundary layer is decreased, the number of effective collisions between the molecules of reactants is increased.²³ Erosion of solids under the action of low acoustic frequencies has the following feature: the use of medium- and high-frequency acoustic fields crumbles out rather large particles from the surface and it becomes rough, whereas low frequencies cause smoothing and ‘polishing’ of the surface, apparently owing to the crumbling out of microscopic particles.^{2,24,25}

The increase in the rates and selectivities of most chemical reactions in ultrasonic fields appears to be due to the occurrence of cavitation:^{26–29} acoustic waves induce the formation and growth of vapour/gas bubbles in a liquid, which oscillate, pulsate and coalesce. There are two basic approaches to the explanation of high-energy effects caused by cavitation, *viz.*, the thermal and electrical ones. In the thermal approach, these effects are associated with high temperature inside a cavitation bubble upon its adiabatic compression at a continuously increasing rate, whereas in the electrical approach these are related to a discharge inside the bubble resulting from the accumulation of electric charges on its walls.^{1,2,6,12} The electrical action of ultrasound can be exempli-

fied in the formation of hydrogen peroxide.¹ H₂O₂ is generated in microbubbles upon electric discharge in water vapour. First, the elementary processes of ionisation and excitation take place:

Hydrogen peroxide is formed upon recombination:

Hydrogen peroxide cannot be obtained by adiabatic compression of water vapour and a noble gas since this process occurs at high temperature. Hydrogen peroxide decomposes at a lower temperature than does water and therefore is not accumulated to an appreciable extent if only the thermal factors are involved in the adiabatic compression of a cavitation bubble under the action of ultrasound.

The effects of ultrasonic action are the reason for the ever-increasing interest in the use of sonochemical methods in organic synthesis and catalysis.^{30–37} Clearly, the necessity of joint investigation of such complex phenomena as catalysis and sonochemical effects does not promise rapid advances in the elucidation of the mechanism of catalysis in an ultrasonic field. Nonetheless, in some instances the action of ultrasound on catalytic processes has been studied in sufficient detail and the number of publications devoted to catalytic reactions in ultrasonic fields is rather large.^{38–46} Most experimental studies merely state the facts of intensification of processes, increased yields of products and higher catalytic activity without considering the mechanisms underlying the ultrasonic impacts leading to the above-mentioned effects.

As organic liquids are widely used as solvents or reagents, studies of sonochemical reactions in non-aqueous systems are of special significance. In most cases, the use of acoustic vibrations intensifies drastically chemical reactions in such systems.^{9, 21, 22, 47–49} Investigations into the mechanisms of sonochemical reactions in non-aqueous systems are complicated for the following three reasons: the results of these reactions are simultaneously affected by usual thermal and sonochemical effects; such processes occur in rather diverse systems; the action of ultrasound also leads to other concomitant physicochemical and colloidal-chemical effects, *e.g.*, emulsification, dispersion of solids, formation of microscopic bubbles, *etc.*

The present review is devoted to the consideration of the effects of ultrasonic vibrations on catalytic systems and catalysts in different stages of preparation for, and implementation of, chemical reactions.

II. Pre-reaction conditioning of catalysts

1. Ultrasonic treatment in the process of catalyst preparation

Acoustic vibrations are applied to the process of catalyst preparation in order to enhance its activity.⁵⁰

Ultrasound influences substantially the properties of platinum and palladium blacks.^{51–53} The blacks prepared by the reduction of H₂PtCl₆ or PdCl₂ with 40% formaldehyde under the action of ultrasonic waves (USW) of different frequencies in the presence of various gases increased their activities 1.5–2-fold compared to that of USW-nontreated blacks. The surface areas of platinum catalysts increased on the average from 15 to 18 m² g^{−1}. The basic characteristics of Pt and Pd blacks are listed in Table 1.

Magnetic susceptibility of catalysts is enhanced under the action of ultrasound. Paramagnetism of 'ultrasonic' blacks obtained under nitrogen is increased appreciably (about twofold), and it is almost not changed in the course of further training of these catalysts in vacuum. X-ray patterns of 'ultrasonic' blacks exhibit noticeable enhancement of the background, which points to the presence of a substantial amount of the atomic metal phase.

Table 1. Relative activity of platinum and palladium blacks prepared by ultrasonication in an atmosphere of different gases.

Preparation conditions		Activity in reactions ^a (%)

	548	158	79	173
	3000	58	70	30

^a The activity of USW-nontreated black in the corresponding reaction is taken as 100%.

The increase in the activity of Pt black in hydrogenation of hex-1-ene and oxidation of ethanol may be explained by the catalyst's increased surface. It is noteworthy that in the process of decomposition of H₂O₂ the effect due to USW is ~2.5 times stronger than that related to the increased surface. Consequently, ultrasound has a specific effect on the active centres of the catalyst. In the oxidation of ethanol, the Pt and Pd blacks prepared under definite conditions in an ultrasonic field proved to be less active than the control catalysts.

Probably, the application of an ultrasonic field induces the formation, on the surface of crystals, of the most disordered amorphous phase which contains active centres for decomposition of H₂O₂, whereas in the reactions of hydrogenation of hex-1-ene and oxidation of ethanol the amorphous phase possesses a decreased catalytic activity.⁵¹ The reason for enhanced activities of the ultrasonicated Pt blacks in the catalytic decomposition of hydrogen peroxide and their relatively low activities in the reactions of hydrogenation and oxidation consists in virtually all the amorphous phase being active in the reaction of decomposition of H₂O₂ since this simplest reaction can occur on active centres of any type. On the contrary, hydrogenation or oxidation require active centres with a more ordered structure which are not formed abundantly under the action of ultrasound. The increase of the reaction order¹ of hydrogenation of hex-1-ene on the ultrasonicated Pt black from zero to first order points to changes in the reaction mechanism. Thus, when discussing an increase or a decrease in the activity of a heterogeneous metal catalyst under the action of ultrasound, it should be indicated to what kind of reaction these changes are referred. This circumstance first established by Kobozev *et al.*⁵¹ should be taken into account in studies of heterogeneous catalytic systems.

As can be seen from Table 1, the nature of gases used in the preparation of blacks has a similar influence on different catalysts. Thus in the decomposition of H₂O₂, the blacks obtained under nitrogen are the most active. The blacks prepared in an ultrasonic field in air are noticeably deactivated possibly due to the adsorption on their surface of nitrogen oxides formed with the participation of the water sonolysis products.⁵³ Deactivation of 'ultrasonic' catalysts prepared in air is most strongly manifested in the hydrogenation reactions. Apparently, the enhanced chemisorption of nitrogen oxides and oxygen in an ultrasonic field

Table 2. Activity of platinum blacks ($\text{mmol s}^{-1} \text{g}^{-1}$) prepared by the reduction of H_2PtCl_6 solutions of different concentrations with hydrogen using ultrasonic fields and mechanical stirring.

Concentration of H_2PtCl_6 (mass %)	Decomposition of H_2O_2		Hydrogenation of hex-1-ene	
	I	II	I	II
0.05	0.37	0.72	—	—
0.10	0.28	0.14	0.19	0.25
0.25	0.21	0.065	0.17	0.071
0.50	0.27	0.062	0.068	0.049

Note. I, mechanical stirring; II, ultrasonication.

prevents the hydrogen uptake by the catalyst and reduces its hydrogenation activity.

It is noteworthy that the catalysts obtained from dilute solutions in an ultrasonic field are more active in the reactions of decomposition of H_2O_2 and hydrogenation of hex-1-ene (Table 2) than those prepared in the absence of USW. It appears that upon reduction of dilute solutions of H_2PtCl_6 in an ultrasonic field the dispersive action of ultrasound is better manifested, whereas upon reduction of concentrated solutions the effects of acceleration of crystallisation and coagulation under the action of ultrasound are predominant.⁵¹ One should, however, bear in mind that the results of studies^{51–53} were interpreted in terms of N I Kobozev's theory of active ensembles, which was not fully confirmed subsequently in the theory and practice of catalysis.

Some specific effects appear under the action of ultrasound in the process of preparation of adsorption catalysts.^{52,53} For example, ultrasonication (frequency 550 kHz, flux density 5.4 W cm^{-2}) of a system H_2PtCl_6 –silica gel, in which the support does not virtually adsorb H_2PtCl_6 , in a hydrogen atmosphere leads to the formation of a mechanical mixture of platinum black and silica gel, whereas in a system H_2PtCl_6 –alumogel, in which the support adsorbs H_2PtCl_6 well, the latter is reduced directly on alumogel under the action of ultrasound. The catalyst thus obtained is active in the hydrogenation of hex-1-ene, whereas the alumogel adsorption catalyst prepared without ultrasonication is inactive.

Ultrasound is successfully used for the preparation of catalysts supported on silica gel, alumina or lamellar inorganic materials. Thus the reduction of ammonium hexachloroplatinate in an acoustic field (frequency 440 kHz, intensity 5 W cm^{-2}) in the presence of suspended silica gel leads to an 80% increase in the surface of the metal compared to that of a sample obtained by mechanical stirring. This may rationalise the increase in the activity of highly dispersed catalysts $\text{Pd}/\text{Al}_2\text{O}_3$ or Pd/C in the reaction of reduction of acetophenone by hydrogen.⁵⁴

One of the stages in the proposed mechanism of catalytic hydrogenation is migration (spillover) of hydrogen to the adsorbed substrate molecules.⁵⁵ This explains the enhancement of the activity of a Pd/C catalyst obtained by the reduction of a palladium salt with formaldehyde under the action of ultrasound in the reaction of hydrogenation of nitrobenzene at 303 K.⁵⁶ In the case of ultrasonic treatment, the amount of hydrogen capable of participating in the spillover increases appreciably: after ultrasonication of the Pd/C catalyst (0.8 mass % Pd) the H : Pd ratio may reach 6.8.

Preliminary ultrasonic treatment of a Pt/SiO_2 catalyst intended for the hydrogenation of cinnamaldehyde resulted in a considerable increase in the selectivity of formation of cinnamic alcohol (up to 80%) and a twofold increase in the reaction rate. This effect is explained⁵⁷ by the formation on the support of effective metal centres providing for stronger substrate adsorption involving the $\text{C}=\text{O}$ bond.

Comparative studies of the profound reduction of the $\text{C}=\text{O}$ groups on H_2SO_4 -unmodified and -modified Pt catalysts with and without ultrasonic treatment also confirmed the activating action

of USW.^{58,59} This conclusion was drawn from the results of hydrogenation of the carbonyl group of ethyl 9-(2,3,4-trimethoxy-6-methylbenzoyl)nonanoate on a Pt/sibunit catalyst.

In the course of the experiment, the extent of the catalyst dispersion was monitored by a conductometric method. Analysis of the results obtained allowed one to conclude that the granulometric composition of the catalyst remained invariant under the action of USW with the intensity of up to 1 W cm^{-2} , while the reaction rate increased as the duration of ultrasonic pretreatment was prolonged from 15 to 30 s. The catalyst subjected to the USW action for 60 and 120 s exhibited lower activity. The increase in the ultrasonic flux density from 0.1 to 1 W cm^{-2} favoured the catalyst's activity, while its further increase to 3 W cm^{-2} resulted in the decrease in activity (Fig. 1). Deactivation of the catalyst upon increase in the duration and intensity of sonication may be explained by the restructuring of active centres associated with an appreciable modification of the morphology of the catalyst's surface. Examination of the catalyst's samples before and after sonication by electron microscopy confirmed this conclusion, which is in full agreement with the data reported by Garibyan *et al.*²⁵ X-Ray photoelectron spectroscopic data showed that the $\text{Pd(II)} : \text{Pd(0)}$ ratio increased after ultrasonic treatment. Assuming that the hydrogenation of the $\text{C}=\text{O}$ group proceeds on a bifunctional active centre $\text{Pd(0)}-\text{Pd}^{\delta+}$, the higher catalyst activity may be explained by the increased proportion of Pd(II) under the action of USW.^{31,32}

Figure 1. Dependence of the yield of the hydrogenation product of ethyl 9-(2,3,4-trimethoxy-6-methylbenzoyl)nonanoate on a Pt/sibunit catalyst on the reaction time (τ) and the USW intensity (W cm^{-2}): (1) 0.1; (2) 1; (3) 3; (4) without USW. The duration of ultrasonication was 30 s.

Systematic investigations of the impact of ultrasound on novel polymeric palladium catalytic systems containing metal colloids have led to a conclusion about an appreciable effect of acoustic vibrations on the activity of these catalysts in the selective hydrogenation of the triple bond of acetylenic alcohols to the double bond.^{60,61} High dispersion of the catalyst's active phase was attained also by ultrasonication in the stage of preparation of supported ruthenium catalysts.⁶² Ultrasound has a strong effect on the genesis and properties of alumogel,⁶³ which is widely used as the support for hydrogenation and dehydration catalysts and also as the support for the active phases of adsorption catalysts. The application of an ultrasonic field accelerates crystallisation of alumogel and its surface is increased by 40% compared to that of ultrasound-nontreated samples. This results in the formation of a secondary structure consisting of smaller aggregates with a

strongly developed surface and in higher hydrophilicity of particles, which prevents their aggregation.

The relevant literature carries a suggestion that cleavage of the carbon–carbon bonds occurs after their activation on ‘metal’ active centres.⁵⁵ The number of such centres appears to increase as a result of changes in the dispersion under the action of ultrasound leading to the acceleration of hydrogenolysis. Supported palladium and rhodium catalysts prepared on the base of TiO₂–SiO₂ gels under ultrasonic treatment possess higher activity than analogous systems non-treated with ultrasound and ensure the required selectivity in the hydrogenolysis of n-butane.⁶⁴

The catalytic activity of nickel obtained by the reduction of nickel oxalate at 583 K under the action of acoustic vibrations with a frequency of 25 kHz and an intensity of 3000 W cm^{–2} is increased by 87% in the reaction of hydrogenation of benzene (see Ref. 9). Probably, as in the case of Pt and Pd,^{5,59} this is related to the modification of the structure of the catalyst’s surface under the action of ultrasound. Similar effects were also observed when other nickel catalysts were used. Sonication in the course of reduction of nickel iodide with lithium has led to activated nickel which catalysed 1,4-addition of phenylsilane to α,β -unsaturated ketones and nitriles providing high yields (after hydrolysis) of hydrogenation products.⁶⁵ Activated nickel powder is also used in the synthesis of aminoarenes by reduction of nitroarenes. This catalyst is prepared by the reduction of anhydrous nickel chloride with potassium subjected to dispersion by ultrasound.⁶⁶

Ultrasonication gives a positive effect in the preparation of promoted and supported oxide catalysts which are used in the oxidative addition of methane (Na₂O–ZnO, Li₂O–MgO, La₂O₃–MgO, Sm₂O₃–MgO), oxidation of propylene (Na₂O–ZnO) and total oxidation of methanol to CO₂ (CuO–SiO₂).⁶⁷ Application of USW in the stage of impregnation increases the catalytic activity of oxides in oxidative processes. The use of the 10% Na₂O–ZnO catalyst thus obtained increases the methane conversion from 14% to 18% and raises the selectivity from 40% to 54%. On the activated 1% La₂O₃–MgO catalyst, the degree of conversion is increased insignificantly, whereas the selectivity is increased from 54% to 60%. The C₂H₄:C₂H₆ ratio is changed in favour of ethylene. A similar effect of an increase in the catalytic activity of manganese and chromium oxides was also observed in the heterogeneous oxidation of 1-hydroxyphosphonates.⁶⁸

According to Garibyan *et al.*,⁶⁷ the improvement of catalytic properties of oxides upon sonication may be due to changes in the number and structure (composition) of active centres, which is in agreement with the conclusions⁵² drawn from the study of oxidation of ethanol on platinum and palladium. The electron microscopy analysis of samples prepared with and without application of USW has shown that the application of ultrasound provided a more uniform distribution of components. This inference is consistent with the results of analysis of palladium catalysts.^{24,25} Promoter oxides present on ZnO or MgO in the form of agglomerates are dispersed on the support surface. The promoter increases the efflux of $\cdot\text{CH}_3$ and $\cdot\text{C}_2\text{H}_5$ radicals to the gas phase;⁶⁹ consequently, a uniform distribution of sodium and lanthanum ions reached under the action of USW favours the formation of radicals and prevents their capture by the surface. This results in an increased yield of C₂ hydrocarbons.

The use of the EPR method has shown that the activation of methane and ethane on ultrasound-treated catalysts provides higher concentrations of free radicals in the gas phase. On the USW-nontreated Sm₂O₃–MgO catalyst, the ratio of desorbed radicals [$\cdot\text{CH}_3$]:[$\cdot\text{C}_2\text{H}_5$] is equal to 0.9, whereas upon ultrasonication it increases to 1.75. This implies that in the latter case additional disintegration processes with the release of C₂H₄ take place in the course of formation of $\cdot\text{C}_2\text{H}_5$ radicals. Experiments on CH₄ conversion under atmospheric pressure showed that under the action of USW the [C₂H₆]:[C₂H₄] ratio is shifted in favour of ethylene. The ethyl radicals are decomposed either on the surface

or in the gas phase, *i.e.*, a radical mechanism without participation of a solvent is realised:

Incorporation of ions of a different valence (M⁺) into the lattice of alkaline-earth metal oxides leads to changes in the defect structure of the catalyst and its higher activity in the process under study. Ultrasonication results in the enhancement of this effect.

The extent of oxidation of propylene on the Na₂O–ZnO catalyst activated by 60-min ultrasonication increased by 4% compared to that on the USW-nontreated catalyst; the composition of products also changed.⁶⁷ the yield of hexadiene increased, while the amount of hydrogen and benzene decreased (Table 3). The Na₂O–ZnO system contains numerous unprotected ZnO centres on which oxidation does take place. Considerable content of hydrogen in the products is related to the possible dehydroaromatization of hexadiene on zinc oxide. In the catalyst subjected to the action of USW, sodium oxide covers the surface of zinc oxide uniformly and suppresses this process thus increasing the yield of hexadiene.

Table 3. Composition of the propylene oxidation products on a 10% Na₂O–ZnO catalyst. Reaction conditions: temperature, 843 K; contact time, 5.5 s; pressure, 1 atm.

[C ₃ H ₆] (vol.%)	Con- version (%)	Conditions of catalyst treatment	Composition of products (vol.%)				
			CO + CO ₂	H ₂	C ₂ H ₆	(C ₃ H ₅) ₂	MeOH
3.5	30	mechanical stirring	8.32	2.7	0.112	0.01	0.081
3.9	33.9	ultra- sonication	9.00	0.5	0.082	0.08	0.103

The same approaches were used in studies of the total oxidation of methanol on the 5% CuO–SiO₂ catalyst. The data on the temperature dependence of conversion of methanol in this system are listed in Table 4. The selectivity of CO₂ formation was found to be equal to 100% at all the temperatures studied. As can be seen from Table 4, irrespective of the SiO₂ porosity (catalysts 1 and 2 have the pore size 10²–10⁵ and 10–100 Å, respectively), the ultrasonic treatment in the stage of catalyst preparation increased the degree of conversion, which reached 86% at 668 K. The ultrasound-treated catalysts preserve their activities for a prolonged time. The phase composition of catalysts prepared by the method of thermal treatment at 623 K with and without sonication was also studied. The diffractograms of the catalysts of oxidation of methanol that have operated for the same time period point in both cases to the presence of only CuO phase,

Table 4. The temperature dependence of the methanol conversion into CO₂ on the 5% CuO–SiO₂ catalyst (1.5 vol.% MeOH in air).

Conditions of treatment	Conversion (%) at the temperature/K				
	573	598	623	648	668
Sample No. 1					
Mechanical stirring	20	43	56	66	75
Ultrasonication	43	60	65	77	86
Sample No. 2					
Mechanical stirring	33	43	48	67	73
Ultrasonication	40	50	66	70	86

although the activity of the ultrasound-treated catalyst remains at a high level. The sonication favours uniform distribution of the CuO phase over the SiO₂ surface. The CuO–SiO₂ samples prepared at 623 K with and without ultrasonication were studied before and after the reaction by the EPR method. The concentration of paramagnetic Cu²⁺ ions in the catalyst ultrasonicated before the reaction was one order of magnitude higher than that in the catalyst prepared in the usual manner. After the reaction, nearly equal low concentrations of copper ions were found on both catalysts. This may be explained by the degradation of the intermediate Cu₂(OH)₃NO₃ phase into CuO during the reaction.

Thus, the application of ultrasound for the preparation of promoted and supported catalysts enhances appreciably the efficiency of catalytic systems.

Ultrasonication of a suspension in the co-precipitation and ageing of copper, zinc and aluminium oxides enhanced noticeably the activity of the catalyst of methanol synthesis.⁷⁰ It was suggested that under the action of ultrasound the Cu:Zn:Al ratio in the catalyst precursor becomes the same as in the compound Cu₃Zn₃Al₂(OH)₁₆CO₃·4H₂O, *i.e.*, 3:3:2. The specific surface of the thus obtained highly dispersed Cu(Cu⁺), ZnO and Al₂O₃ particles as well as the yield of methanol depend linearly on the content of this hydrate-like phase.

Ultrasound is also used in the stage of precipitation in the preparation of catalysts and their precursors.⁷¹ Formation of agglomerates in mixed half-precipitated suspensions of (Cu/Zn)₂(OH)₂CO₃ under the action of acoustic waves of different intensity was studied. The application of ultrasound influences substantially the size of particles and the surface of agglomerates. The precursors precipitated by the low-intensity ultrasonication have basically small specific surface and are composed of small agglomerates. The precursors prepared using high-intensity USW are characterised by a more developed surface and formation of larger agglomerates. The MnO₂ catalyst prepared under the conditions of high-intensity ultrasonic treatment possesses higher activity as regards evolution of oxygen from H₂O₂ than that of an analogous but USW-nontreated catalyst.

The ultrasound treatment is also used for the preparation of electrode catalysts of the solid-oxide fuel cell.⁷² For example, the anode catalyst La_{1.8}Al_{0.2}O₃ is prepared by pyrolysis of an aqueous mixture of lanthanum and aluminium nitrates. This technique provides higher activity of the anode catalyst than that attained using other methods. The optimum conditions for the ultrasonic treatment are determined experimentally by monitoring the particle size and from the dependence of the quantity of deposited particles and their size on the concentration of an aqueous solution and temperature.

There is a possibility of sonochemical synthesis of various nanostructured materials using high-intensity ultrasound.⁷³ In the decomposition of organometallic compounds under the action of ultrasound, the specific surface of the solid phase composed of agglomerates and nanoclusters is increased. This technique was used to synthesise nanostructured metals and alloys from iron pentacarbonyl and cobalt tricarbonylnitrosyl; molybdenum carbide was prepared in this way from molybdenum hexacarbonyl. These materials represent active heterogeneous catalysts for reforming of hydrocarbons and hydrogenation of CO.

The use of surface acoustic waves and resonance vibrations makes it possible to prepare heterogeneous catalysts with artificially controllable functions.⁷⁴ For instance, thin films of catalysts were precipitated using horizontal surface-active waves generated on ferroelectric single crystals of LiNbO₃ and LiTaO₃. This resulted in an appreciable increase in the activities of Ag, Pd and Ni catalysts in the oxidation of ethanol and of Pd catalyst in the oxidation of CO. The enhancement of catalytic activity is related to the modification of the coefficients of electromechanical adhesion of ferroelectrics and to the state of the catalyst surface.

It should be noted that ultrasound not only influences the process of catalyst preparation but also enhances the activities of ready-to-use catalysts in various reactions.⁵⁹

2. The action of ultrasound on ready-to-use catalysts

Ultrasonication influences the genesis of crystalline catalysts, their properties and catalytic activities in various reactions and favours the increase in the size of solid particles irrespective of the nature of the material used.⁷⁵ An appreciable decrease in the particle size is particularly noticeable at a low metal content.⁷⁶ The removal of impurities from the metal surface makes an additional contribution to the enhancement of the catalyst's activity.⁵⁹

Asymmetric catalysis on metals implies the interaction of a substrate with an active centre formed as a result of coordination of a chiral modifier with the metal component of the catalyst.⁷⁷ Ultrasonic treatment of catalysts leads to an increased enantioselectivity of many processes, *e.g.*, hydrogenation of ethyl pyruvate to ethyl lactate on various platinum catalysts (Pt/C, Pt/Al₂O₃, Pt/SiO₂ and Pt/montmorillonite).⁷⁸ After the action of USW on the Pt/SiO₂ and Pt/montmorillonite catalysts, the enantioselectivity is enhanced substantially, the hydrogenation rate is increased by an order of magnitude compared to that on the untreated catalyst, while the yield of the target product reaches 100%. The enhanced activity can be due to the decreased size of the catalyst's particles (Table 5) and changes in their morphology. Initially, the size of platinum crystals ranges from 5 to 60 nm. After ultrasonication, small particles (3–5 nm) become predominant and their distribution is almost uniform. Apparently, this favours the formation of a large number of reactive different-ligand complexes and, consequently, enhances the catalyst's activity. Analogous results were obtained in the sonochemical treatment of a catalytic system Pt/Al₂O₃–quinidine in acetic acid.⁷⁹ In addition, sonication made possible the repeated use of the catalyst without its regeneration, *i.e.*, made the catalyst more stable.

Table 5. Mean diameter of metal particles in supported platinum catalysts before and after 30-min ultrasonication.⁷⁸

Catalyst	Diameter of particles /nm	
	before treatment	after treatment
5% Pt/C	3.0	2.5
3% Pt/SiO ₂	6.7	4.2
5% Pt/montmorillonite	3.7	3.8
5% Pt/Al ₂ O ₃	23.1	12.6

A number of studies were devoted to the investigation of the ultrasonic treatment of Raney nickel.^{22, 80–87} Sonication in water⁸⁰ with subsequent asymmetric modification yielded a highly efficient catalyst of enantioselective hydrogenation. The complex tartaric acid–NaBr–modified Raney nickel exhibits high enantioselectivity and catalytic activity in the hydrogenation of β-diketones and β-keto esters.^{81, 82}

According to Suslick and Casadonte,²² ultrasonic treatment (20 kHz, 50 W cm^{–2}) of a nickel powder (particle size 5 μm) in octane increased 10⁵ times its ability to catalyse hydrogenation of alkenes. Though, such a strong effect is in part due to the fact that the results were compared with an inactive form of nickel. The application of an acoustic field simplifies considerably the preparation of the catalyst. The initial hydrogenation rate reaches its maximum after preliminary 60-min ultrasonication of a sample, whereas further action of ultrasound decreases its catalytic activity (Fig. 2). The use of scanning electron microscopy showed that the acoustic field does not modify the particle size but influences noticeably the surface morphology. Sonolysis allows preparation of nickel with a specific surface close to that of Raney nickel. Initially, the surface of the crystalline structure is smoothed under the action of ultrasound and then the particles 'stick' to each other,^{22, 86} which is presumed to be the main reason for the decrease in the hydrogenation rate upon prolonged action of ultrasound. However, the effect of particle sticking is difficult to explain from the physical viewpoint, since for this process to occur, the particles should be heated to their melting temperature,

Figure 2. Dependence of the initial rate of hydrogenation of non-1-ene (w_0) on the duration of ultrasonic activation (τ) of nickel powder; temperature 273 K, pressure 1 atm.

which is possible if their minimal relative speed at the moment of collision¹ is $15\,000\text{ m s}^{-1}$, which is 30 times as high as the really observed one (500 m s^{-1}) and almost 10 times higher than the velocity of sound propagation in the liquid.

The ultrasound-treated platinum (mainly Pt/C), nickel and palladium catalysts are successfully used in reactions of hydrogenation and hydrosilylation of alkenes.^{83–85}

A catalytic system metal hydride–dialkylzinc activated by ultrasound is effective in the reduction of carbonyl compounds and epoxides (like the ultrasound-nontreated system) and in reactions of partial reduction of carboxylic acids to aldehydes.⁸⁸ This system is highly attractive owing to its accessibility, inexpensiveness and simplicity of handling and, hence, it may be particularly useful for the implementation of large-scale reduction processes.

The possibility of ultrasonic activation of polymerisation, aldol condensation, allylation and oxidation catalysts should also be noted. Ultrasonic treatment (20–500 kHz, 4–20 W cm^{-2}) of octane-suspended titanium trichloride, belonging to the group of the Ziegler–Natta catalysts, led to the decrease in the particle size from 15–40 to 0.1–5 μm . Crystalline polymers formed in the presence of this catalyst are more uniform with regard to their molecular mass than are polymers obtained on the ultrasound-nontreated catalyst. Similar results were also derived using other Ziegler–Natta catalysts.⁵ The application of ultrasound enhances the catalytic activity of the metal iodide-promoted BiCl_3 used as the catalyst of the Mukaiyama and Mukaiyama–Michael reactions.⁸⁹ The ultrasound has an accelerating effect on the systems BiCl_3 –1.5 ZnCl_2 or BiCl_3 –1.5 SnI_2 (5 mol. %), which catalyse the crossover aldolisation of acetophenone and benzaldehyde.

Ultrasound-activated palladium catalyses the heterogeneous allylation of carbonyl compounds with γ -substituted allyl alcohols in the presence of SnCl_2 in non-polar solvents (diethyl ether, diisopropyl ether and toluene).⁹⁰ The reaction proceeds regioselectively with high yields of 1,4-disubstituted but-3-en-1-ols; the regioselectivity (α -selectivity) of the reaction on ultrasound-activated palladium is the opposite of the regioselectivity (γ -selectivity) of the palladium-catalysed homogeneous carbonyl allylation in polar solvents.

Gariyban *et al.*²⁵ studied the effect of ultrasound in the stage of preparation of catalysts on their activities and selectivities in the oxidative condensation of methane, oxidation of propylene on $\text{Na}_2\text{O}/\text{ZnO}$ and profound oxidation of MeOH on CuO/SiO_2 .

It is noteworthy that the most interesting results were obtained when the ultrasound was involved in catalytic processes.

III. Sonochemical catalysis

1. Homogeneous catalysis

The application of ultrasound with the intensity sufficient for inducing cavitation leads to the acceleration of chemical reactions, which appears to be determined by the formation of free radicals.⁹¹

An extensive series of homogenous catalytic processes carried out under sonication have been studied. Thus Müller *et al.*⁹² demonstrated the possibility of the ultrasound-induced highly effective enantioselective chain elongation of labile fluorenylmethoxycarbonyl-protected amino acids by means of Wolf rearrangement of the corresponding α -diazo ketones at room temperature catalysed by silver ions. Donatti and Vollet⁹³ investigated hydrolysis of tetraethoxysilane at 312 K and mixtures of tetramethoxysilane and tetraethoxysilane at 308 K catalysed by hydrochloric or oxalic acid in an ultrasound field. It was shown that Lewis acids or sonication catalyse the condensation of imines with H-phosphonates bound to the Wang resins resulting in high yields of the corresponding α -aminoalkylphosphonates.⁹⁴ A number of diterpenoids were obtained by highly regioselective cycloaddition of styrenes to substituted 1,4-benzoquinones under the action of ultrasound in the presence of Lewis acids as catalysts.⁹⁵ The application of ultrasound increased appreciably the rate of addition of aldehydes to methyl acrylates catalysed by 1,4-diazabicyclooctane.⁹⁶ Ultrasonic waves with an amplitude of 120 μm accelerate decomposition of 2-chlorophenol in the presence of 200 mg litre^{-1} of H_2O_2 .⁹⁷ Under the action of ultrasonic vibrations, the condensation of indene or 2-nitrofluorene catalysed by bis(*p*-methoxyphenyl) telluroxide leads to the corresponding fulvenes in high yields.⁹⁸ Ultrasound is also used in the reactions involving fatty acids.⁹⁹ For example, an isomer of methyl 8-(5-hexyl-4,5-dihydro-3*H*-pyrrol-2-yl)octanoate can be synthesised from methyl ricinoleate in several ways. The highest yield (42%) is achieved and the minimum reaction time is necessary in the case where USW (20 kHz, 53 W cm^{-2}) are applied.

Let us consider in more detail oxidation and isomerisation reactions occurring under the action of USW. The results of studies of the effect of ultrasound on the liquid-phase oxidation of hydrocarbons by the radical-chain mechanism in the presence of 0.3% cobalt stearate are presented in Table 6. It is seen that the accumulation of oxygenated compounds is increased by 15%–30% under the action of USW. As the pressure increases, the oxidation rate also increases. The maximum acceleration of the process is reached at a frequency of $\sim 300\text{ kHz}$. It is of essence that in an ultrasonic field the oxidation rate remains invariant for a long time, whereas without ultrasonic treatment it reaches a maximum and then decreases appreciably. In the process of oxidation, cobalt stearate usually forms a micelle with the hydrocarbon, which is a reason for the decrease in the catalyst's activity. In an ultrasonic field, complexes of this type decompose or are not formed at all, and this prevents shielding of the catalyst by hydrocarbon molecules and enhances their stabilities because of which the reaction rate remains constant.

Table 6. Characteristics of the product of n-tetradecane oxidation at 385 K in the presence of cobalt stearate catalyst.

Characteristic	Without ultrasonic treatment	Under the action of ultrasound with a frequency of /kHz		
		300	600	1000
Acid number ^a	21.0	29.2	27.2	25.0
Ester number	10.6	14.9	14.2	13.7
Carbonyl number	22.4	28.1	26.4	27.4
Hydroxyl number	7.2	7.5	6.2	5.5
Sum of oxygenated compounds	61.2	79.1	73.9	71.6

^a In mg KOH per 100 g product.

It is of note that the oxidation rate decreases appreciably at an USW frequency of 16 kHz. This effect may be explained by several reasons: intense degasification of the hydrocarbon at low frequencies and high intensity of irradiation; chemical modification of the

catalyst's molecules; higher decomposition rate of peroxide compounds formed in the oxidation.

Oxidation of alkenes by oxygen in the presence of $\text{Mo}(\text{CO})_6$ with the formation of enols and epoxides was performed under the action of ultrasound.⁵ The primary sonochemical act in this process is presumed to be homolysis of the allylic C–H bond under the action of cavitation.

Under ultrasonic stirring, the homogeneous cationic ferroporphyrins become effective catalysts of cyclohexane oxidation in the presence of MeCN. At a total yield of 93%, the ratio of selectivities of the formation of epoxide, alcohol and ketone is 77 : 12 : 11.¹⁰⁰

Margulis²⁶ investigated the catalytic isomerisation of alk-1-enes into alk-2-enes in an ultrasonic field in the presence of metal carbonyls. In the presence of $\text{Fe}(\text{CO})_5$, isomerisation of pent-1-ene under the USW action (frequency 20 kHz, intensity 100 W cm^{-2}) proceeds at a constant rate for 1 h, then the catalyst's activity drops for a period of several hours due to the formation of dispersed metallic iron and a small amount of $\text{Fe}_3(\text{CO})_{12}$. High initial activity of carbonyl $\text{Fe}_2(\text{CO})_9$ decreases rapidly, since under the conditions of sonolysis it is transformed at a high rate into the complex $\text{Fe}(\text{CO})_5 \cdot \text{Fe}_3(\text{CO})_{12}$; however, even under prolonged exposure to ultrasound the complex does not undergo degradation with the liberation of metallic iron. The initial rate of catalytic isomerisation of pent-1-ene measured 5 min after the beginning of sonication is increased more than 10^6 times compared to the rate in the control experiment (without ultrasound).

It was shown that the efficiency of isomerisation decreases when alk-1-enes have substituents creating steric hindrances (Table 7). Therefore, isomerisation of 2-ethylpent-1-ene and allylbenzene is appreciably slower than that of pent-1-ene. Isomerisation of *cis*-stilbene virtually does not occur because of either the non-terminal position of the double bond or the difficulty of forming an intermediate complex with $\text{Fe}(\text{CO})_5$. According to the data from Table 7, the isomerisation rate of linear alk-1-enes changes in the order: pent-1-ene $\approx$ hex-1-ene $\gg$ oct-1-ene $>$ dec-1-ene.

Isomerisation of alkenes in an ultrasonic field in the presence of other metal carbonyls, not only iron carbonyls, was also studied. It is seen from Table 7 that in the presence of iron carbonyl *trans*- and *cis*-pent-2-enes are formed in the ratio

Table 7. Isomerisation of alk-1-enes in an ultrasonic field in the presence of $\text{Fe}(\text{CO})_5$.

Initial alkene	Products ^a	Relative isomerisation rate
Pent-1-ene	<i>trans</i> -pent-2-ene (77%) <i>cis</i> -pent-2-ene (23%)	1.0
Hex-1-ene	<i>trans</i> -hex-2-ene (74%) <i>cis</i> -hex-2-ene (26%)	1.1
2-Ethylpent-1-ene	2-ethylpent-2-ene	0.31
Oct-1-ene	<i>trans</i> - and <i>cis</i> -oct-2-enes	0.17
Dec-1-ene	<i>trans</i> - and <i>cis</i> -dec-2-enes	0.05
Allylbenzene	β -methylstyrene	0.02
<i>cis</i> -Stilbene	<i>trans</i> -stilbene	0.02

^a Yields are indicated in parentheses.

virtually close to the thermodynamic equilibrium. This ought to be expected, since irrespective of the presence or the absence of the ultrasonic field the same species remain catalytically active. However, in the presence of $\text{Ru}(\text{CO})_5$ and $\text{Ru}_3(\text{CO})_{12}$ other ratios of *cis*- and *trans*-isomers are obtained, which points to a different mechanism of catalytic action of ruthenium carbonyls and to the participation of different intermediates in the reaction. The catalytic activities of carbonyls in the isomerisation reaction under the action of USW decrease in the series: $\text{Ru}_3(\text{CO})_{12} > \text{Fe}(\text{CO})_5 > \text{Mo}(\text{CO})_6 > \text{Fe}_3(\text{CO})_{12} \gg \text{W}(\text{CO})_6 \approx \text{Cr}(\text{CO})_6$. The rates of photocatalytic isomerisation change in a different sequence: $\text{Fe}(\text{CO})_5 > \text{Fe}_3(\text{CO})_{12} > \text{Ru}_3(\text{CO})_{12} > \text{W}(\text{CO})_6 \approx \text{Mo}(\text{CO})_6 \gg \text{Cr}(\text{CO})_6$. In many cases, the ratios of *trans*- and *cis*-isomers in the sonocatalytic and photochemical isomerisations are similar; however, when $\text{Ru}_3(\text{CO})_{12}$ is used, they differ considerably and amount to 2.8 and 6.0, respectively.

These results suggest the existence of substantial differences in the mechanisms of sonochemical and photochemical initiation of the catalytic processes, the catalytic activity being higher in the first case. Experimental data support the suggestion that in both cases the stages in which hydrogen migrates from the β -position of the alkene to form an intermediate hydride, *viz.*, π -allylic complex, are analogous. In accordance with the commonly accepted scheme, sonolysis of $\text{Fe}(\text{CO})_5$ in the presence of an excess of pent-1-ene yields $[\text{Fe}(\text{CO})_4(\text{C}_5\text{H}_{10})]$, which is confirmed by IR spectroscopy.

Exposure to ultrasound not only enhances the rates of homogeneous catalytic reactions, but also increases the number of catalytic cycles. Ultrasound is a factor which influences the catalytic activity of iron(III) *meso*-tetrakis(2,6-dichlorophenyl)porphyrin chloride $[\text{Fe}(\text{TDCPP})\text{Cl}]$ in a homogeneous system¹⁰¹ where cyclohexanol is formed from cyclohexane by a classical mechanism of hydroxylation with the participation of iodosylbenzene: PhIO is reduced to iodobenzene with the oxidation of $[\text{Fe}(\text{TDCPP})\text{Cl}]$ resulting in the formation of catalytically active species of iron(IV)oxoporphyrin radical, which directly hydroxylates cyclohexane. The optimum conditions of this reaction have been established: $[\text{Fe}(\text{TDCPP})\text{Cl}] = 3 \times 10^{-4} \text{ mol litre}^{-1}$ in 1,2-dichloroethane, ultrasonic stirring at 273 K in an excess of PhIO. Ultrasound makes it possible to achieve an unusually high yield of cyclohexane (96%) and to increase more than twofold (from 45 to 96) the number of reaction cycles. The catalyst $[\text{Fe}(\text{TDCPP})\text{Cl}]$ acting in an ultrasonic field may be regarded as a good biomimetic model. This is a stable and selective catalyst allowing the preparation of cyclohexanol as the single product.

Application of an ultrasonic field (35–40 kHz) increases considerably the number of catalytic cycles involving a water-soluble rhodium catalyst for the hydroformylation of alkenes.⁵ The number of such cycles in the preparation of aldehydes under a pressure of 2.5 MPa in an aqueous solution containing a 1 : 1 mixture of carbon monoxide and hydrogen, hex-1-ene and the rhodium complex $\text{HRhCl}(\text{CO})[\text{P}(\text{C}_6\text{H}_4\text{SO}_3\text{H})_3]_3$ under the action of ultrasound is 11.34, whereas with mechanical stirring at a rate of 500 rpm it is 3.24.

Thus, ultrasound accelerates homogeneous catalytic reactions by modifying in some cases their mechanisms and increases the stability of homogeneous catalysts.

2. Heterogeneous catalysis

Acoustic vibrations can exert a dual effect on heterogeneous catalytic reactions. On the one hand, they favour mass transfer and, on the other hand, enhance the activity of catalysts.^{51, 102, 103} The use of ultrasound in heterogeneous reactions opens broad possibilities for the application of physical and chemical factors of acoustic impact. Difficulties of studying such factors are related to the absence of unequivocal and clear-cut concepts of the nature of the ultrasound effect on heterogeneous catalytic processes. At present, several tentative mechanisms of the effects observed may be discussed, but there is no answer so far to the question about which of them is predominant.²⁶

Table 8. Rates of NH_3 formation ($\mu\text{mol litre}^{-1} \text{ min}^{-1}$) in the sonolysis of water saturated with a mixture of N_2 and H_2 in the presence of metal catalysts.⁵¹

Catalyst	Rate of NH_3 formation ^a	Catalyst	Rate of NH_3 formation ^a
Rh (from RhCl_3)	2.5, 3.0	Rh black	1.4, 1.3
Pt (from H_2PtCl_6)	1.6, 2.0	Pt black	1.0, 0.9
Pd (from PdCl_2)	1.3, 1.5	Pd black	0.73, 0.80
Without catalyst	0.4	Rh black (without USW)	0.00

^a In most cases, there are two values derived from parallel experiments.

Let us consider the mechanism[†] of a heterogeneous catalytic reaction in an ultrasonic field exemplified in the synthesis of NH_3 . A remarkable effect has been observed: in water saturated with a mixture of N_2 and H_2 in the stoichiometric proportion, the rate of NH_3 formation under ultrasonic irradiation in the presence of platinum group metals as catalyst is rather high, whereas without ultrasound no reaction occurs whatsoever.⁵¹

Table 8 lists the rates of the NH_3 formation in the presence of different catalysts in the sonolysis (550 kHz, 4–5 W cm^{-2}) of water saturated with a mixture of N_2 and H_2 . The rate of NH_3 formation in the absence of catalysts is close to the rate of HNO_2 formation in the sonolysis of water in the nitrogen atmosphere (in addition to nitrous acid, H_2O_2 and HNO_3 are also formed as the reaction products).¹⁰⁴ Accordingly, it may be presumed that NH_3 is synthesised in an ultrasonic field non-catalytically in the gas phase with cavitation bubbles involving the excited nitrogen molecules, *e.g.*, the long-living metastable term $\text{N}_2^*(A^3\Sigma_u^+)$

In this case, ammonia is formed according to the following scheme:

It is possible¹⁰⁵ that, as in the case of the reaction in an electric discharge, the primary act in the sonochemical synthesis of NH_3 is the ionisation of nitrogen followed by the stage

and then by the stage which ultimately leads to the formation of ammonia.

Ultrasonic fields accelerate appreciably hydrogenation of unsaturated compounds,⁸¹ *e.g.*, indene, acenaphthylene, non-1-ene, α -methylstyrene and *trans*-benzylideneacetone.

Hydrogenation was carried out on a catalyst obtained by deposition of 10% Pd on activated carbon in the presence of formic acid as the hydrogen carrier. In an ultrasonic field, 100% hydrogenation of the double bonds at 298 K was reached within 1 h, whereas the aromatic rings remained intact. Without ultrasound, the reaction was considerably slower and the yield was 70% after 1 h and 90% after 2 h.

Ultrasonic field increased appreciably the hydrogenation rate of alkenes in anhydrous media in the presence of platinated carbon. It should be noted that the hydrogenation of acyclic

alkenes is accelerated to a greater extent than that of unsaturated cyclic hydrocarbons.²⁶

The rate of hydrogenation of acrylic acid on Pt black at 298 K in an acoustic field (440 kHz, 5 W cm^{-2}) is three times as high as that under mechanical stirring at 1000 rpm (see Ref. 106). The use of ultrasound (1 MHz, 3 W cm^{-2}) in the catalytic hydrogenation of olive oil on Raney nickel made it possible to reduce appreciably the residual concentration of unsaturated compounds in the product (the iodine number was 77.0 after hydrogenation for 3 h and 50.0 after hydrogenation in the ultrasonic field).¹⁰⁷

Under the action of ultrasound, anthracene can be reduced by lithium to its dianion. Addition of water leads to the formation of 9,10-dihydroanthracene. Under similar conditions, diphenylacetylene yields a radical anion which then dimerises. This dianion may be captured by some species,⁵ as is shown in the scheme:

Ultrasonic waves speed up not only hydrogenation, but also dehydrogenation, which seems to be due to the fact that both reactions occur by the same mechanism. For example, the degree of dehydrogenation of tetrahydronaphthalene to naphthalene in the presence of 3% Pd/C as a catalyst in diethylene glycol at 473 K reaches 55% after 6 h.¹⁰⁸ The use of ultrasound makes it possible to decrease the temperature to 453 K and to achieve the total conversion within the same time. The use of pulse ultrasound is as effective as continuous ultrasound. Dehydrogenation of triethylene glycol in dimethyl ether is much less sensitive to ultrasound.

Ultrasound makes it possible to increase the efficiency of the preparation of deuterium-labelled compounds.¹⁰⁹ The Raney nickel-catalysed hydrogen exchange for deuterium in a monosaccharide was performed in different solvents under the action of ultrasound. Deuterium was introduced with a high stereospecificity and regioselectivity.

Ultrasonication of a reaction mixture containing barium hydroxide increased the rates of the reactions and the yields of products involving aromatic aldehydes. For example, 4-chlorobenzaldehyde does not enter into the Cannizzaro reaction in the absence of ultrasound. The use of catalytic poisons which affect selectively the oxidative active centres made it possible to establish that this reaction occurs on the reduction centres, the catalytic cycle being initiated by a single-electron transfer from the catalyst to the substrate.⁵

Acceleration of the aldol condensation of ketones in an ultrasonic field in the presence of Al_2O_3 is confirmed by the following data:¹¹⁰ sonolysis of 1-tetralone in an argon atmosphere at 353 K for 24 h produces the hydroxy ketone in 80%–90% yield, whereas in the absence of ultrasound its yield is not more than 52% after 144 h.

The rate of the Ullmann coupling of 2-iodonitrobenzene in dimethylformamide in the presence of copper bronze at 333 K is increased 64-fold upon sonication.¹¹¹ If this process is performed in the usual manner, but using the pre-sonicated copper bronze, its rate also increases compared to the reaction rate on the ultrasound-nontreated copper bronze, though to a much lesser extent. This effect may be easily explained by the decrease in the size of metal powder particles under ultrasonic treatment. An appreciable acceleration of the reaction under the direct action of ultrasound results from the constant activation of the metal surface. In addition, the sonochemical process has two other advantages: it requires a considerably smaller excess of copper and excludes sticking of metal powder to the walls of the reaction vessel.

Sonication was also employed in the synthesis of α -amino acids using amino acid γ -anion equivalents.¹¹² The reaction of

[†] Unfortunately, the mechanism of catalytic synthesis of NH_3 in an ultrasonic field is not considered in the relevant literature; therefore, only some suggestions may be discussed.

activated zinc with a iodohomoalanine derivative yields alkylzinc iodide, which reacts in the presence of palladium catalysts with a number of electrophiles (aryl iodides and acid chlorides) producing the corresponding α -amino acid derivatives. Sufficiently high yields are obtained using tetrahydrofuran as the solvent in the former case; to reach high yields in the reactions with acid chlorides under the action of ultrasound, it is necessary to use a combination of toluene and dimethylacetamide. Furthermore, alkylzinc iodide may be transformed into a zinc–copper couple, which reacts with allyl halides and reactive acid chlorides to give sufficiently high yields of the corresponding adducts.

The accelerating effect of ultrasonic treatment was exemplified in the liquid-phase alkylation of benzene by cyclohexene yielding cyclohexylbenzene.¹¹³ The reaction was conducted on an AlCl_3 catalyst prepared by the method of chemical deposition on SiO_2 from the vapour phase. These catalysts are active below 273 K and can be regenerated. Despite the fact that the activity of the catalysts becomes lower in successive experiments, they can be used repeatedly. At least until the sixth cycle, the turnover number was 110. Apparently, reactions on solid catalysts are limited by the diffusion of reagents and/or products into the catalyst's pores. The ultrasonic impact in the course of catalytic reaction provides an accelerating effect, so that, depending on the size of the catalyst's particles, the reaction rate can increase by even one order of magnitude.

It is of note that the action of surface acoustic waves changes appreciably the activation energy and the reaction orders on oxidised catalytic surfaces, whereas on the reduced surfaces these changes prove to be much smaller. At a resonance frequency, oxidation of ethanol on palladium is accelerated 140–160 times, which may be explained by a stronger distortion of the lattice under these conditions.⁷²

The application of USW speeds up substantially β -hydroxylation of acrylonitrile at room temperature (the same effect was also revealed in a homogeneous reaction¹⁰¹) on a catalytic system comprising copper(I) oxide and tetramethylethylenediamine. With the use of USW, the yield of the β -adduct also increases from 30% (stirring) to 70%–75%.¹¹⁴ Ultrasonic acceleration of reactions on non-metal catalysts (using HSiCl_3 as the silylation agent) was not studied as thoroughly as that on metals,^{115,116} nonetheless, in these cases too the increase in the reaction rate is related to the increase in the specific surface of the solid reagent due to the decrease in the particle size upon cavitation and the improvement in the mass transfer of a liquid reagent to the solid phase surface.

The reaction route can also be changed under the action of ultrasound.⁵ Stirring aluminium oxide with KCN in a mixture of *p*-methylbenzyl bromide and toluene leads to the formation of products of the Friedel–Crafts reaction (in this case, aluminium oxide acts as a catalyst). Under the action of ultrasound, this reaction follows a different route: *p*-methylbenzyl cyanide is formed as a result of direct substitution of CN for Br.

The change in the composition of products upon sonication is presumed to be due to the saturation of the Lewis acid centres on the aluminium oxide surface with CN^- ions, which induces nucleophilic substitution.⁵

The reaction of aryl iodides with zinc powder accelerated by ultrasound yields arylzinc compounds which contain the electron-withdrawing groups, *viz.*, CO_2Me , $\text{C}(\text{O})\text{NMe}_2$, CN, Br, Cl and CF_3 . The presence of these groups provides fairly good yields of

asymmetric multifunctional biaryls in the catalytic synthesis with participation of $\text{Pd}(0)$.¹¹⁷

Ultrasonication is also employed in electrochemical processes for intensifying the electrode reactions, which may be exemplified in the sonovoltammetric reduction of nitrobenzene on glassy carbon and gold electrodes.¹¹⁸ The four-electron reduction of nitrobenzene in an alkaline solution (pH 13) was studied as a model. The mechanism of electrochemical reduction is known to be complex; it includes protonation and dehydration, the processes proceeding both on the surface and in bulk depending on the nature and the state of the electrode. In the absence and in the presence of ultrasound, the reduction of nitrobenzene on the glassy carbon electrodes includes a chemically reversible process followed by the irreversible three-electron reduction. The combined use of a rotating disc and sonovoltammetry permits one to decrease the capacity of the double layer.

Electrochemical dehalogenation of organic compounds in microemulsions of a system didodecyldimethylammonium bromide–water–dodecane under the action of ultrasound in the presence of zinc phthalocyanine as a catalyst proceeds faster than in a homogeneous system including toxic and expensive organic solvents.¹¹⁹

Thus, ultrasound accelerates the heterogeneous catalytic reactions owing to a better mass transfer, smaller size of the surface particles and creation of active centres on which the substrate undergoes specific transformation.

3. Phase-transfer catalysis

Ultrasound initiates and accelerates reactions in phase-transfer catalysis.^{120,121} The chemical effect of ultrasound in this case is also explained by the coalescence of cavitation bubbles, whereas its mechanical impact is associated with the formation of a highly dispersed emulsion which increases appreciably the interface area.

The mechanism of a typical phase-transfer reaction resembles the substitution mechanism. The overall equation

includes the catalytic cycle

where Q^+ is the cation of the phase-transfer catalyst (PTC).

Combined action of PTC and ultrasound in heterogeneous reactions can be exemplified in the reaction of benzyl chloride with solid sodium sulfide in the presence of tetrabutylammonium bromide as PTC and acetonitrile as the solvent.¹²²

The proposed mechanism includes two phase-transfer ion-exchange stages and the main reaction in the organic phase:

The results obtained upon the use of PTC and ultrasound and upon their combined action are shown in Fig. 3.

The catalytic cycle of transformation of benzyl chloride includes the transfer of sulfide anions to the organic phase. The influence of ultrasound on the molecular diffusion and dissolution of sodium sulfide in acetonitrile is minimal, whereas a slight increase in the conversion occurs owing to the development of

Figure 3. Results of the use of PTC and ultrasound in the reaction of benzyl sulfide formation (USW intensity, 150 W cm^{-2}): (1) without USW and PTC; (2) with USW; (3) 0.4% PTC; (4) 0.4% PTC + USW.

the interface where the reaction takes place, facilitation of mass transfer and effective stirring of the reagents as a result of cavitation. Combination of PTC and ultrasound gives a maximum increase in the conversion owing to the additive effect of their individual impacts on the system.

Ido *et al.*¹²³ investigated the possibility of the multiple use of phase-transfer catalysts. The catalyst (hexadecyltri-*n*-butylphosphonium bromide) is concentrated in the third phase formed between the organic (dodecane) and the aqueous (saturated KBr solution) phases. This interface catalyses substitution in benzyl chloride by bromide, the former being in the organic phase and the latter, in the aqueous phase. After completion of the reaction, the organic phase was removed and a new phase was introduced. The application of USW made it possible to avoid direct contact between the organic and the aqueous phase. The three phases were not mixed, the reagents were transferred across the interface under the impact of ultrasonic vibrations.

According to the theoretical concepts,⁴⁸ the chemical action of ultrasound is limited by the unpaired electron transfer. In this case, the reaction mechanism includes only ionic species; therefore, the effect of ultrasound is of physical nature. Ultrasound in fact increases the catalyst surface area since cavitation prevents agglomeration of particles.

Sonochemical acetylation of tertiary alkyl halides in the presence of zinc acetate was accomplished in the presence of PTC and under the action of ultrasound.¹²⁴ Alkylation of a glycine derivative by activated organohalogen compounds under the conditions of ultrasonic acceleration of phase transfer and subsequent hydrolysis of the products yielded aminoacylsultams and then, upon mild saponification, pure α -amino acids in a rather high overall yield.¹²⁵

In the example of the addition of ethyl malonate to chalcone in the presence of KOH and trimethylbenzylammonium chloride as PTC (the Michael reaction) it was shown that with ultrasonic stirring the reaction is complete in 2 min, instead of 1 h.⁸⁹

Allylation and benzylation of sodium 5- β -D-glucopyranosyl-1,3-dimethylbarbiturate in water were carried out with benzyl bromide in Me_2SO or allylic and benzylic bromides in the presence of PTC under sonication.¹²⁶

The application of ultrasound in combination with phase-transfer catalysts, crown-ethers and lithium chloride accelerated the transformation of 6-methoxytetralins into 8-methoxytetralins including the stages of cleavage and cyclisation by the intermolecular Friedel–Crafts alkylation.¹²⁷

It is noteworthy that in many cases the application of ultrasound makes it possible to avoid PTC. An example is the cyclopropanation of styrene in which the yield of 96% was reached within 1 h without PTC.¹²⁸

In the control reaction carried out under mechanical mixing the yield was only 30% after 16 h.

4. Enzymic catalysis

Recent studies show the possibility of the ultrasonic influence on enzymic reactions. Acoustic vibrations increase substantially the activity and decrease the size of subtilisin particles which catalyse trans-esterification in organic solvents, the changes in the USW amplitude having no effect on the reaction rate.¹²⁹ It was shown that the activity of enzymes depends on the duration of sonication. Thus a short-term action of ultrasound activates butyryl cholinesterase, whereas a prolonged action brings about partial dissociation of the tetrameric enzyme and its irreversible inactivation.¹³⁰ Total inactivation of peroxidases (lipoxenases and phenol oxidases) under the action of ultrasound and elevated temperatures is used in food technologies.¹³¹

Ultrasound was shown to influence hydrolysis of sucrose catalysed by invertase.¹³² The effect of ultrasound was studied over a wide range of changes in biochemical and physical conditions, such as pH, sucrose concentration and USW intensity. It was found that the reaction rate increases at low sucrose concentrations. At high concentrations, continuous ultrasonic vibrations have a more substantial influence on this enzymic reaction.

The rate of reactions catalysed by lipase from porcine pancreas is increased 3–60 times under the conditions of azeotropic distillation and 7–83 times under the action of ultrasound, the enantioselectivity being preserved in both cases.^{133, 134}

IV. Regeneration of catalysts

Traditional techniques for the regeneration of catalysts include their high-temperature calcination in the atmosphere of oxygen to remove organic residues.¹³⁵ However, the initial catalyst's activity is not recovered completely. The physical components of the ultrasonic action make it possible to use acoustic treatment for the effective regeneration of catalysts. Thus the initial activity of a brass catalyst used for the preparation of acetone from propan-2-ol recovered to 83% under the action of ultrasound (18–22 kHz, 6–20 W cm^{-2}) in a solution of sulfuric and nitric acids and sodium bichromate.⁵ Without ultrasound, the activity of this catalyst recovered only to 63%.

Ultrasound intensifies considerably the oxidative regeneration of the deactivated rhodium triphenylphosphine catalyst used in the hydroformylation of alkenes.¹³⁶

A nickel-molybdenum catalyst used for the cracking of hydrocarbons was regenerated by oxidation in air with the subsequent action of USW in low-viscosity oils.⁵ Similarly, a 30-min action of an acoustic field in water led to the regeneration of the activity of a catalyst of denitrification of waste gases (TiO_2 – V_2O_5).

Ultrasound restores totally the specific surface, porosity and activity of the palladium–aluminium catalyst APK-Z, which is used for the removal of nitrogen oxides from exhaust gases.¹³⁷ The activity of the 3% Pd/C catalyst in diethylene glycol used for the dehydrogenation of tetrahydronaphthalene and studied earlier in an analogous reaction without ultrasound¹³⁸ decreases in the course of the reaction, but it can be restored with the aid of ultrasound.¹⁰⁸

A series of studies^{24, 139–143} were devoted to the regeneration of the industrial ShPAK-0.5 catalyst (0.5% Pd/ Al_2O_3) modified by zinc acetate, pyridine and KOH. This catalyst is used for the selective hydrogenation of the triple bond of acetylenic alcohols to

Figure 4. Changes in the Zn:Pt ratio across the granule in subsurface layers of a fresh catalyst (1), exhausted catalyst (2) and a catalyst following sonication (3). The distance between the points is 0.05 mm.

the double bond in the synthesis of vitamin A and E intermediates. In the course of hydrogenation, the catalyst loses its activity and its selectivity is decreased. Besides, the use of physicochemical methods (X-ray spectral microanalysis, electron microscopy and X-ray photoelectron spectroscopy) showed that the catalyst's surface is changed substantially. The ultrasonic treatment with an intensity of 1 W cm^{-2} and a 3-min duration leads to the total recovery of the initial properties of the catalyst (Fig. 4).⁵⁴ After the ultrasonic treatment, the content of zinc and palladium in the surface layers of the regenerated catalysts becomes the same as that in the fresh sample. Probably, this is explained by the purification of the surface from coke deposits and the diffusion of the zinc atoms into the subsurface layer. The XPS data also point to a possible amorphisation of the structure of the catalyst's surface, which is at variance with the conclusions made in Refs 54 and 66.

V. Conclusion

The application of ultrasound in chemistry, particularly in catalysis, is one of the most fortunate examples of the use of non-conventional physical methods influencing a reaction system. The present review reflects only the basic results of studies of the applicability of USW for the preparation, activation and regeneration of various catalytic systems as well as for conducting catalytic reactions. The unique results of the action of ultrasound make rather attractive the prospects of its technological uses and are also of appreciable interest for fundamental research. Summing up the above considerations, let us emphasise the following most important moments.

It has been established that ultrasound increases the specific catalyst's surface, because cavitation prevents the agglomeration of particles. The action of ultrasound on solids, including catalysts, increases the content of small particles (3–5 nm) and modifies their lyophilicity. Under ultrasonic treatment, the increase in the activity of catalysts is often several orders of magnitude larger than the increase in their specific surface. This may be associated with a specific action of ultrasound on the nature of the active centres. The change in the nature of the active centres influences not only the catalytic activity but also the reaction selectivity, including enantioselectivity. In an ultrasonic field, the rate of catalytic reactions remains constant for a long time, i.e., the stability of a catalyst is enhanced. In addition, the acoustic waves can change the activation energy and the reaction orders. The combined use of phase-transfer catalysts and ultrasound provides a maximum increase in the degree of conversion owing to the addition of their individual impacts on the system. In a number of cases, the application of ultrasound makes it possible to conduct reactions without phase-transfer catalysts.

A topical problem is the use of USW and resonance vibrations for the creation of heterogeneous catalysts with adjustable functions. Heterogeneous reactions in a liquid phase are limited by the diffusion of the reagents and/or the product in the catalyst's pores.

The application of ultrasonic vibrations in the course of a catalytic reaction leads to a several-fold increase in its rate depending on the size of the catalyst particles.

The optimum USW parameters are individual for each catalyst and catalytic reaction. The ultrasonic treatment increases appreciably the spillover of hydrogen which explains higher activity of ultrasound-treated catalysts in hydrogenation reactions. The phenomenon of catalyst's deactivation, which is sometimes observed at a longer duration and a higher intensity of ultrasonic treatment, may be explained by the rearrangement of active centres, which is in turn related to the modification of the catalyst's surface.

The fundamental question about a detailed mechanism of catalysis in an ultrasonic field remains still open to debate. Solution of this problem is a priority issue in the catalysis and determines the prospects of the technological use of USW.

Abstract. Data on the heat-accumulating properties of melts are generalised. The principles and methods of thermal energy accumulation with the use of melts are considered. The problem of search for heat-accumulating materials with the required properties based on multi-component systems of anhydrous inorganic compounds is discussed. The bibliography includes 57 references.

I. Introduction

One of the major problems of the national economy, *viz.*, decreasing power consumption of production, can be solved by two methods. The first one is more efficient transformation of primary energy into electrical and thermal energy. This can be done by increasing the efficiency factor of power stations, by using cheaper fuel types or renewable energy sources, such as wind, geothermal sources, tides, sea waves, *etc.*

The second method of ever-growing importance involves increasing the efficiency of the energy utilisation by the consumer. The expenses for saving fuel and electric power are two to three times lower than those required for expanding the fuel and energy base. The following measures for improving the efficiency of energy usage by the consumers can be listed: transition to more perfect and less power-consuming technologies; use of secondary power resources; smoothing the time differences between the energy generation and energy demand schedules by means of accumulation.

Accumulation of electric energy is a difficult problem. The capacities of the existing electrochemical accumulators are insufficient for their use on an industrial scale. The promising superconducting electric power accumulators are still under development. The hydraulic methods for energy storage make it possible to accumulate significant amounts of energy; however, this involves large capital investment and impact on the environment (not always favourable).

Methods for the thermal energy accumulation have been developed in detail and tested under various conditions. The world energy crisis of the 1970s has confirmed once again the

urgency of the problem of the thermal energy accumulation followed by heat recovery and transformation into useful work.¹

Studies along these lines include two aspects, namely, the chemical-technological and technical-physical ones.^{2,3} The chemical-technological aspect includes choosing the heat-accumulating materials (HAM), studying their properties and selecting the accumulation method. The thermal energy accumulation and recovery methods involving melts are based on the following processes: heating compounds to a high temperature followed by heat release on cooling (heat accumulation due to the heat capacity of the solid and liquid phases); reversible first-order phase transitions (accumulation due to latent heat of phase transitions); reversible chemical reactions (chemical accumulation). The technical-physical aspect examines selection of the processes for the transformation and use of the stored energy.

National programmes on the thermal energy accumulation with the use of reliable and inexpensive accumulators have been developed in different countries and are now being implemented. The use of such accumulators enables one to replace the traditional fuel types (coal, natural gas) by non-traditional renewable energy sources^{4,5} as well as allows one to use the spent heat in chemical-technological processes or for heat supply.

However, an important drawback of heat accumulators is the high cost of accumulated energy, mainly because of the cost of the HAM. For this reason, the development of heat accumulators starts from the search for cheap HAM with high heat capacity and predetermined properties.

Synthesis of novel inorganic materials with predetermined properties requires complex studies of fusibility diagrams and physicochemical properties of multi-component systems by modern physicochemical methods, primarily those using computer 3D simulation methods.^{2,6–8}

Recent studies on HAM mostly deal with crystal hydrates of inorganic salts, salt eutectics and metal alloys traditionally used in this field. The present review generalises the data regarding the methods and principles of the thermal energy accumulation using melts of anhydrous inorganic compounds as the HAM. Criteria for the estimation of the heat-accumulating ability of melts and a new methodological approach to the development of HAM based on multi-component systems and study of their physicochemical properties are considered. Special attention is given to the systematisation of experimental data on the fusibility diagrams of multi-component systems.

II. Methods of the thermal energy accumulation with the use of melts

The most popular heat accumulators use melts as the HAM. They can accumulate thermal energy either due to the heat capacity of solid or liquid media or due to the latent heat of phase transitions and chemical reactions. Non-isothermal and isothermal accumulators are distinguished, depending on the mode of heat storage.

1. Heat accumulation due to the heat capacity of solid and liquid media

The most popular method of heat accumulation is that due to the heat capacity of liquid and solid media. A compound which accumulates heat due to the heat capacity of its different phases is called a heat-capacity compound. Heat accumulators with such a compound as the working medium are non-isothermal. They are used for the heat accumulation over a broad temperature range (several hundred degrees). The allowed temperature variation in an accumulator is normally specified (it is determined by the temperature of the heat source, the temperature of the heat-carrier, the temperature required by the consumer, and the temperature differences controlling the intensity of heat exchange during the accumulator charge and discharge phases). Water (for temperatures up to 100 °C), air, noble gases, melts of simple and complex inorganic compounds and technical oils can serve as heat-carriers.

If melts are used as heat-capacity HAM, it has to be taken into account that the specific heat is generally independent of temperature and is a constant. The specific energy stored by a heat-capacity heat accumulator is determined by the formula

$$Q = C_p \Delta T,$$

where C_p is the specific heat of the accumulator working medium at constant pressure; ΔT is the difference between the starting and final accumulation temperatures.

It is known from thermodynamics that the specific heat is the higher the smaller the relative molecular mass of the compound. Therefore, compounds with small molecular masses are used as working media for heat-capacity accumulators.

Of anhydrous inorganic compounds, systems based on oxides, the so-called refractory compounds, are used as the HAM most commonly. The properties of the most promising oxide-based HAM are analysed in Ref. 9. A great many experimental studies relate to the determination of the dependences of C_p , thermal conductivity factor (λ) and apparent density (ρ) on temperature and open porosity (O_p). In some cases, natural minerals and anhydrous inorganic compounds obtained from them are used, *e.g.* granite, sand, pebbles, gravel, cobble-stone, macadam, sand-pebble mixture, *etc.* Such heat-capacity HAM are inexpensive and readily accessible, are not corrosive with respect to construction materials, but have low effectiveness in terms of their thermal properties, which results in the low density of the accumulated energy.

The increase in the specific density of the heat-capacity HAM increases the specific heat, and hence the amount of accumulated heat in the bulk material. The materials based on magnesia have the highest heat capacity; these materials have sufficient thermal

conductivity in the temperature range 100–900 °C to be used as heat-capacity HAM (Table 1).

As the proportion of magnesia and the material apparent density increase, the thermal conductivity increases. The thermal conductivity of hyperdense heat-capacity HAM (3.55–3.97 kg m⁻³) exceeds 30 W m⁻¹ K⁻¹ at 100 °C, while it is less than 5 W m⁻¹ K⁻¹ for dense (3.00–3.50 kg m⁻³) and medium-density ones (1.83–2.96 kg m⁻³).⁹ Medium-density materials containing mixtures of magnesia with SiO₂, Al₂O₃, Cr₂O₃, or CaO and having an open porosity of 20%–30% are most efficient in terms of thermal conductivity (λ changes from 0.74–3.93 at 100 °C to 1.07–1.80 at 900 °C). Magnesia-based materials containing chromium oxide are the most heat-resistant (see Table 1).

2. Heat accumulation owing to the latent heat of phase transitions

The accumulation of heat with the use of the latent heat of phase transitions of anhydrous inorganic compounds is possible in the following changes in the state of aggregation:^{3,8} melting $\rightleftharpoons$ crystallisation, vapourisation $\rightleftharpoons$ condensation, sublimation and decomposition.

The heat-accumulating materials which accumulate heat due to phase transitions are called phase-transition HAM. The accumulators with such materials as the working media are isothermal.

The accumulators in which the latent heat of the melting $\rightleftharpoons$ crystallisation phase transition is used have good energetic characteristics. The principle of such an accumulator is based on the thermal energy absorption accompanying the crystal lattice destruction upon heating of a compound and energy liberation upon crystallisation of the melt on cooling.

In many technological processes, the only useful thermal energy is that accumulated due to the heat of phase transitions and due to the heat capacity of the material in the liquid phase.^{10–14} These processes include: maintaining the given operating temperature of steam at thermal and nuclear power plants; transformation of thermal energy into electrical energy through the Brighton cycle; thermal energy accumulation and transfer with the use of molten phase-transition HAM as heat-carriers; increasing the efficiency of non-traditional systems by compensating for the intermittent and non-steady nature of renewable energy sources (solar, wind, geothermal, *etc.*).

The type of the thermodynamic cycle and the nature of the HAM are determined by the operating temperature range of the heat accumulator. This primarily assumes a relationship between the characteristics of the main power system, the accumulator and the parameters of the cycle in which the mass and heat transfer occur. For example, Table 2 lists the efficiency values of three cycles. Yet another example: the maximum temperature of the hot source at a solar power station without radiation concentrating by local concentrators is about 100 °C. In this case, it is only possible to speak about a cycle with evaporation of the working media such as freons. However, these working media cause ecological problems if they leak. In this case, a perfect HAM would consist of eutectic compositions based on *n*-component mixtures of hydrates and anhydrous compounds with m.p. $\leq$ 100 °C.

The thermal characteristics of the most promising systems based on aluminium chloride and alkali metals with the heat-accumulating ability above 0.3 GJ m⁻³ are presented in Table 3.

Table 1. Heat-accumulating properties of oxide heat-capacity HAM in the temperature range 100–900 °C.

^a The accumulated energy is usually expressed as enthalpy/weight ratio $\Delta H/M$ or enthalpy/volume ratio $\Delta H/V$, therefore the dimensionalities are: (I) kJ kg⁻¹; (II) GJ m⁻³.

Judging by the data listed, the choice of phase-transition HAM for the accumulation of low-potential thermal energy is limited, particularly if one takes the cost of the accumulated energy into account.⁷

Studies of movement of the solidification (melting) frontier of HAM on a planar unit cell model of a heat accumulator¹⁵ were carried out using an eutectic three-metal alloy with composition (mass %) 50 Bi–31 Pb–19 Sn and the parameters: $T = 94.5$ °C, $\rho = 9590$ kg m⁻³, $\Delta H_m = 26.4$ kJ kg⁻¹, $C_p = 0.138$ kJ kg⁻¹ K⁻¹, $\lambda = 16.5$ W m⁻¹ K⁻¹ as a phase-transfer heat-accumulating material.

The heat-accumulating ability of metal alloys (> 0.2 GJ m⁻³) is ensured by their high densities, unlike the case of salt melts where this ability is ensured by the enthalpy of melting (see Table 3).

It has been shown (see, *e.g.*, Refs 8 and 16) that an efficient short-term accumulator of average-potential thermal energy can be represented by an accumulator that uses the heat of phase transitions (melting $\rightleftharpoons$ crystallisation) of mixtures of anhydrous inorganic compounds. These mixtures represent mainly n -component eutectic compositions of molten alkaline and alkaline-earth metal salts with melting points of 100–500 °C. The ranges of the melting points (m.p.) and ΔH_m for the recommended phase-transition HAM and the most promising eutectic compositions are given in Table 4.

Thermodynamic analysis of such systems shows^{8,19} that the highest heat-accumulating ability is characteristic of salt eutectics based on lithium nitrate possessing high heats of phase transition (370 kJ kg⁻¹) and thermal stability up to 500 °C and a melting point of 256 °C; in addition, these are not corrosive with respect to many structural materials and their alloys. Eutectic compositions containing only alkali and alkaline-earth metal nitrates (except for LiNO₃) can be used at operating temperatures only 30–50 °C higher than their melting points (due to decomposition).

26.9 NaCl–73.1 Sr(NO ₃) ₂	424	2152	244	252

^a The dimensionalities are: (I) kJ kg⁻¹; (II) MJ m⁻³.

High ΔH_m values are characteristic of alkali metal chlorides and sulfates, and hence intense heat liberation is observed on the DTA (or DSK) cooling curves for eutectic mixtures with lithium nitrate.¹⁶ Addition of alkali metal nitrates to halide-, sulfate- and carbonate-containing mixtures of alkali and alkaline-earth metals allows not only reduction of the operating temperature but also an increase in the heat-accumulating ability, as well as a decrease in the corrosive effect of these mixtures on structural materials.

The number of components in promising eutectic systems (n) ranges from 1 to 4. If $n > 4$, degeneration with respect to both the melting points and the physicochemical properties occurs; this increases the cost of the accumulated energy with the heat-accumulating ability being the same.

Technical and economic analysis showed that accumulators with high-temperature phase-transition HAM (m.p. > 500 °C) as the heat-carriers, particularly eutectic compositions of salt and metal multi-component systems, are most suitable for non-traditional energy sources.⁵ However, the development of such accumulators entails the solution of a number of complex technical problems (for example, the corrosion compatibility of the HAM with structural materials, intensification of heat exchange in the charge and discharge modes, regeneration of the HAM, *etc.*).

Of the phase-transition HAM used for the thermal energy accumulation, eutectic metal alloys possess the best thermal conductivities and stabilities. Analysis of published data on thermodynamic parameters of metal-based multi-component systems^{17,19} made it possible to single out the most promising ones for use as the working materials in heat accumulators (Table 5).

Of ionic compounds, alkali and alkaline-earth metal fluorides, chlorides, carbonates, and sulfates have the best thermal properties for the accumulation of high-potential thermal energy. Salt eutectics are the most power-intensive (due to the enthalpy of melting, see Table 6). The ΔH_m values were found experimentally or calculated using the additivity principle. The experimental studies of heat capacity were carried out using a continuous-heating calorimeter.¹⁷

From the viewpoint of thermal accumulation, salt systems have drawbacks such as rather low thermal conductivities and undesirable volume increase by 10%–30% upon melting; because of this, it is necessary to provide free volume for thermal expansion of the melt in the accumulators.

Prediction of the properties of ionic systems without experimental studies was carried out using the equation¹⁷

$$\Delta H_m = \Delta H_m^{\text{add}} + \Delta \Delta H_m,$$

where $\Delta H_m^{\text{add}} = \sum x_i \Delta H_{m,i}(T_e)$; x_i is the mole fraction of the i th component; $\Delta H_{m,i}(T_e)$ is the enthalpy of melting of the i th component referred to the temperature of the eutectic.

Comparison of the $\Delta \Delta H_m$ values and the enthalpy of mixing of melts ΔH_{mix} showed¹⁷ that

$$\Delta \Delta H_m = \Delta H_{\text{mix}}.$$

Eutectic mixtures containing salts of stable intersecting elements of mutual systems have the highest heat content.¹⁶ Several papers report on the finding of stable intersecting elements in three-, four- and five-component mutual systems and studying their heat-accumulating properties.^{20, 22}

3. Chemical accumulation

Chemical accumulation implies the energy accumulation and release by virtue of chemical reactions. The accumulated energy can be released as heat, electrical energy, light, or mechanical energy.

Depending on the type of the accumulated energy, one distinguishes thermochemical (energy is accumulated as heat) and electrochemical accumulators (energy is accumulated as electrical energy sometimes supplemented with some heat).

Both natural organic (coal, oil products, natural gas, *etc.*) and synthetic fuels (organic and inorganic) can serve as chemical accumulators. A special place among the compounds used as heat accumulators in thermochemical accumulators belongs to melts and alloys of naturally abundant compounds, such as metals, oxides, hydroxides, salts, *etc.* Simulation of the thermodynamics and thermochemistry of reactions involving these compounds facilitates essentially the selection of the HAM and the calculation of parameters of chemical accumulators.

The state-of-the-art in this field was considered in Ref. 8. Accumulation can be based on three main reaction types involving melts of inorganic compounds: (1) synthesis of complex coordination compounds,^{23–25} inclusion compounds²⁶ and ammonia complexes,^{27, 28} hydration of alkaline-earth metal oxides (CaO, MgO);^{29, 30} (2) decomposition of carbonates,³¹ sulfates,³² alkaline-earth metal hydroxides, ammonium hydrogensulfate (NH₄HSO₄),³³ metal hydrides;³⁴ (3) exchange decomposition in full conversion points in mutual multi-component systems formed by ionic melts of inorganic compounds (hydroxides, salts).⁴ Of interest are chemical reactions that involve ionic compounds³⁵ capable of reversible accumulation (Table 7).

The following scheme of exchange reactions in mutual multi-component systems serves as the basis of heat accumulation:

where AX, BY, AY, and BX are ionic compounds; n , m , c , d are the stoichiometric factors in the exchange reaction; Q is the heat effect of the reaction.

This type of processes is also used for the synthesis of diverse compounds. For instance, exchange decomposition occurring to the full conversion point of ternary mutual system Na,Ca/F,Cl is, on the one hand, the most efficient method to obtain calcium fluoride; on the other hand, this is a process that can be used in thermochemical accumulators ($Q = 519.72 \text{ kJ mol}^{-1}$).³⁶

It is recommended to use a powder mixture of equivalent quantities of calcium chloride and sodium fluoride for reversible accumulation.³⁷ The thermochemical equation of the reaction is

The reaction starts at 490 °C. The mixture can be heated to a maximum temperature of 600 °C.

If the specific heat effect of the exchange reaction is within $30 \leq Q < 250 \text{ kJ kg}^{-1}$, accumulation of thermal energy is an efficient side process to save energy in chemical technology. If $Q > 250 \text{ kJ kg}^{-1}$, the reaction is applicable as a working process in thermochemical accumulators.

The major problem in the development of chemical heat accumulators is the choice of chemical reactions that meet the following requirements:³ the heat effects of the reaction should be

Table 7. Thermodynamic characteristics of some exchange decomposition reactions in ternary mutual systems.³⁵

no less than *ca.* 250 kJ kg⁻¹ or *ca.* 1800 kJ litre⁻¹ if gaseous products are taken into account; the volume density of the accumulated energy should be as high as possible at a minimum possible volume of the reaction products.

4. Comparative analysis of the properties of heat-accumulating materials

The prospects of the development of heat accumulators in which accumulation and liberation of energy occur due to the heat-accumulating properties of melts of inorganic compounds are estimated using the following HAM parameters: specific volume, heat capacity, heat and phase transition temperature (in chemical reactions, in solid and liquid phases).

The heat-capacity heat accumulators are less thermally efficient in comparison with phase-transfer and thermochemical ones, because the considerable 'heat storage capacities' needed despite the HAM temperature increase in them requires a minimum quantity of thermal energy consumed.¹ However, heat-capacity heat accumulators are characterised by low cost and simplicity and hence they have found wide use.

The accumulators with the use of the heat effects of reversible phase transitions are characterised by high energy density, small HAM mass and virtually constant operating temperature; the temperature difference of the heat-carrier transferring heat to the consumer and the heat source charging the accumulator is determined only by the required heat transfer intensity. In heat-capacity accumulators, in most cases this difference also depends on the change in the working medium temperature.

The drawback of the isothermal phase-transfer accumulators is that one has to use a different working medium with a specific phase transition (melting) temperature for each required temperature. In practice, phase-transfer heat accumulation is partially combined with accumulation of physical heat, *i.e.* with heat-capacity accumulation. These are called hybrid accumulators; they are most popular for high-temperature short-term accumulation.²⁰

The thermochemical heat accumulators ensure the compactness of the accumulator for long-term heat storage and the absence of losses, as well as the possibility of accumulation at ambient temperature without recourse to thermal insulation. However, the limited number of cheap chemical compounds that meet the requirements for HAM is the main obstacle for the development of such accumulators.³⁸

Comparative analysis shows that phase-transition HAM accumulate an order of magnitude more heat than materials that do not undergo phase transitions. This stems from the fact that the phase transition enthalpies of many compounds are much higher than the heat-capacity effect, particularly upon accumulation of medium- and low-potential thermal energy where the operating temperature range is not very wide. The evaporating and sublimating HAM accumulate 3–5 times more heat than the melting

ones, while the HAM in thermochemical accumulators accumulate an order of magnitude more than the evaporating ones.¹⁸

The basic obstacles preventing the wide use of heat accumulators include insufficient development of problems regarding good thermal insulation from the environment, the absence of well-developed models for the calculation of heat and mass transfer in heterogeneous systems and for increasing the efficiency of electric power reproduction and accumulator power rating. In view of this, studies of the thermal, thermodynamic and technological characteristics of the available HAM as well as development of novel power-intensive materials with a wide operating temperature range are required. Solution of the above problems would ensure the effectiveness, high performance and low cost of energy accumulation. The hybrid (phase-transition and thermochemical) heat accumulators with melts of inorganic compounds as the HAM can prove to be the most promising for the development of durable heat-accumulating systems. The increase in the efficiency of power system can amount from 15%–25% (with heat-capacity accumulators) to 80%–85% (with thermochemical accumulators); in these cases, the cost of the heat accumulator is about 5% of the total power system cost.³⁹

For each power system, the choice of particular methods for the thermal energy accumulation is determined by both local conditions and the results of actual technical and economic calculations.

III. Criteria for the estimation of the heat-accumulating properties of melts

When choosing the accumulator type, one has to consider such factors as the methods for the supply and removal of energy, the amount of the stored energy, the operating temperature levels, the storage period, the heat transfer intensity, the investment and working costs, and the requirements for operational reliability and safety.

In the design of a heat accumulator, the prime thing is the search for a HAM the properties of which affect the majority of the above-mentioned factors. The choice of the material is primarily determined by the operating temperature level and the amount of the thermal energy to be accumulated. The basic requirements for the melts which can be used as the HAM are as follows: an acceptable melting point determining the accumulator operating temperature; high values of such specific quantities as the heat effect (which eventually determines the volume of the material used, and hence, the accumulator compactness and cost), the heat capacity, the thermal conductivity, the density; low viscosity in liquid phase and low thermal expansion coefficient; stability of the physicochemical parameters in the operating temperature range, *i.e.* the absence of chemical transformations; stability of the thermal and thermodynamic characteristics of the HAM; low vapour density; abundance in nature; low cost.^{2, 17}

There are also a number of operational requirements for melts, such as operating safety (the absence of explosion hazard or the presence of gaseous products easy to detect, environmental safety, the absence of hazardous pollution), easy heat absorption and liberation (the absence of supercooling and segregation), stability of physicochemical properties in multiple duty cycles, low corrosivity toward structural materials.

The performance of accumulators employing melts of inorganic compounds as the phase-transition HAM much depends on the extent of their supercooling (below the phase transition temperature) and on whether phase stratification occurs. In order that the heat of phase transition are used more completely, it is necessary to ensure minimum overcooling when the HAM crystallises.¹ This means that liberation of the accumulated energy occurs at a lower temperature than the HAM melting point; as a result, the accumulator may fail to operate at this temperature. Therefore, one of the major requirements for phase-transition HAM is that they should have an equilibrium crystallisation point where the fluid phase is transformed into solid one, avoiding a metastable supercooled state. This requires creating conditions where crystallisation occurs quickly, for example, by using an additive that accelerates this process.⁴⁰ Supercooling in the crystallisation is a minimum if the difference between the HAM melting points and the heat source temperature is 5–10 °C. This temperature range makes it possible to reduce thermal losses and the extent of supercooling of the melt; on the other hand, it is sufficient to provide good heat transfer when withdrawing heat from the HAM. If the supercooling of the melt is 5–10 °C, heat dissipation virtually stops, hence increasing the crystallisation rate is of importance.

Of anhydrous inorganic compounds that can be utilised for heat accumulation, only certain chlorides and nitrates (*e.g.*, calcium chloride and nitrate) and eutectic compositions containing more than 40 mass % of these compounds crystallise with supercooling. Borax, sodium silicate, and strontium and barium fluorides and chlorides can be used as the crystallisation stabilisers.

Segregation decreases the heat exchange between the solid and liquid phases, which necessitates continuous stirring of the HAM during crystallisation.¹⁷

When designing heat-accumulating systems, a comprehensive approach is required, including the development of a procedure for numerical solution of multi-parameter heat exchange problems with the use of thermodynamic analysis methods, theoretical and experimental simulation for optimisation and studies of the thermal and thermodynamic properties of HAM and operating parameters of the accumulators.

The final stage of studies involves the development of methods for optimisation of the design of heat-accumulating systems as regards the thermal and economic efficiencies and environmental safety.

IV. Principles for the development of heat-accumulating materials based on multi-component systems

Development of promising HAM calls for search for specific compounds or eutectic compositions that combine the above-mentioned properties in the optimum way. The search for such compounds is a complex problem, as certain properties can be combined in a material, while others cannot. Therefore, preliminary estimation of the thermal characteristics of the known HAM and the selection of physicochemical systems which can serve as a basis for creating new materials should be carried out with regard to the most important thermal accumulation parameters, such as temperature, specific enthalpy (heat capacity) and density.

Pure anhydrous inorganic compounds and their eutectic mixtures are promising as the HAM.²³ Unlike crystal hydrates, eutectic mixtures undergo melting and crystallisation at constant temperature, irrespective of the number of components. The search for eutectic compositions is carried out with the use of reference data bases on the physicochemical properties of compounds and the fusibility diagrams. The starting components of eutectics include metals, alkali and alkaline-earth metal oxides, hydroxides, nitrites, nitrates, halides, carbonates, sulfates and phosphates, which belong to traditional HAM, as well as transition metal compounds.

At present, the choice of compositions that meet the requirements for the HAM is limited, especially from the viewpoint of the accumulated energy cost. Therefore, directed development of HAM and study of their properties and technological characteristics are topics of current interest.⁴¹

Novel materials can be created using the results of studies of the phase diagrams and composition–property diagrams for various physicochemical systems as their theoretical base. The trend of an increase in the information output with minimisation of experiment is characteristic of modern research in the field of multi-component systems. This is achieved by using: (1) experiment planning with the use of modern rapid methods;⁴² (2) computer simulations with modern solid modelling methods;^{42–50} (3) development of fast methods and measuring instruments for studying the composition–property diagrams that require the use of automatic recording systems, systems for data collection and processing and those for controlling the experiment.^{51,52} The development of methods and measuring instruments that enable the study of a set of properties in one experiment improves not only the information output but also the quality of the experimental data, since the results of measuring the different properties refer to the same sample in the same state.^{53,54}

The above ways of optimisation in the study of the composition–property diagrams can be used independently of each other, but combining them is the most efficient. This is taken into account in the development of algorithms for computer programs required for the simulation and automation of the physicochemical analysis of multi-component systems.^{55–57}

Algorithmisation and programming imply the wide use of modern methods for the calculation, prediction and analysis, both for preliminary estimation of the physicochemical properties and composition–property diagrams and for subsequent processing of experimental data with the use of computer programs. Then the confirming experiments performed on the basis of complex methodology for the study of multi-component systems are minimised.⁴⁰

This approach allows one to establish the logical sequence of steps (from the choice of the starting components to the development of recommendations on the design of heat accumulators), to reduce the laboriousness of experimental studies, and to carry out directed, efficient and cost-effective choice of systems with pre-determined properties applicable as multi-purpose HAM.

A five-level algorithm has been suggested (Scheme 1) as a methodological basis for HAM development from melts² consisting of: zero level, statement of work (stage 0); first level, data analysis (stages 1 and 2); mathematical analysis level (stages 3 and 3a); experimental and theoretical level (stages 4–9); analytical level (stages 10 and 11).

The results of studies are presented graphically as the composition–property and property–property fusibility diagrams and in tabulated form.

The three basic rules should be observed in studies with the use of the algorithm suggested: (1) first, theoretical analysis as thorough as possible should be performed in each of the eleven stages; (2) a computer is used for work optimisation; (3) justified choice of compositions for subsequent studies is made in each level.

Scheme 1

V. Conclusion

Power plants used in various branches of industry are expensive, hence the increase in their efficiencies is a problem of vital importance. This problem can partially be solved by using accumulated energy. Presently, directed development and perfection of both heat accumulators and power-intensive working materials for them are under way.

The development of HAM implies not only the estimation of their chemical (corrosion activity), thermal (heat and mass transfer) properties and environmental safety but also the search for the optimum heat accumulator design with the use of simulation methods, calculation of its technical and cost efficiency and selection of structural materials.^{22–35}

The basic directions of chemical research on cost-effective HAM based on melts and their efficient operations include development of new and perfection of the existing methods of energy transformation and storage, search for new materials with controlled properties capable of serving as structural materials, heat accumulators and heat-carriers of heat accumulators, development of computerised methods for the simulation of the thermodynamics of heat and mass transfer in accumulators of particular design, optimisation of research and development efforts with the use of computers.

Depending on the required energy storage time period, buffer (15–60 min), short-term (up to 2–3 days) and long-term (week, month, season) accumulation types are distinguished. Accumulation of this duration is used in production of energy during 'peak hours' (hydroelectric, nuclear power plants), during cloudy hours (solar power plants), for supply of heat to stand-alone consumers and so on. It cannot be ruled out that development of power-intensive heat-accumulating systems using direct chemical transformation methods will result in considerable progress in heat and energy supply.

In order to select energetically and economically advantageous HAM, one has to know their thermal characteristics. Since an experimental study on the complex of properties that is required for estimating the heat-accumulating ability of a melt is commonly a complex task (in particular, reference equipment operated by skilled personnel and long measurements are necessary), it is very important to have methods for the prediction of the heat-accumulating properties of melts based on incomplete or indirect data.

An important place in obtaining the required information on the properties of HAM belongs to approximate calculation methods and prediction with the use of the system approach for discovering the relationship between the thermal properties (reaction heats) and the nature of the components.

The most efficient methods of HAM research are the calculation-experimental ones which combine theoretical calculations with experimental studies. In particular, the HAM properties can be determined with the use of the experimentally studied phase diagrams of multi-component systems. It is this methodological approach that is implied by algorithm considered above (see Scheme 1).

III. Instruments	193
IV. Test methods	193
V. Conclusion	197

Abstract. Data on sorption-spectroscopic and test methods for the determination of metal ions on the solid-phase of ion-exchange materials published over the past decade are reviewed. The advantages and disadvantages of ion-exchange materials are discussed. The detection limits and selectivity of these techniques are described. The bibliography includes 151 references.

I. Introduction

In recent years, well-known organic reagents have been employed in sorption-spectroscopic and test methods more extensively than in conventional photometry. These techniques, with the use of the same reagent, allow simultaneous gain in sensitivity and selectivity and considerable reduction of the assay time. Remarkable progress in the analytical chemistry of organic reagents has become possible, in particular, owing to the advent of a new generation of instruments for measuring absorption and reflection of solid materials and organic reagents and complexes immobilised on these solids, *i.e.*, the analytical forms of the elements subject to determination, and of compact mini-pumps with controllable flow rates and novel materials as carriers. All these factors have stimulated the development of a great variety of sorption-spectroscopic techniques for the determination of inorganic compounds using organic reagents.

Various materials, *e.g.*, paper, foamed polyurethanes, silica, cellulose, poly(vinyl chloride) and caprone membranes, fabrics, ion-exchange resins, *etc.*, are used as a solid phase in sorption spectroscopy. This review considers the published data on the use of ion-exchange materials as a solid phase.

II. Sorption-spectroscopic methods

Ion-exchange materials have long been in use as sorbents for the concentration and separation of elements.^{1–4} The history of selective sorption of metal ions on natural and synthetic materials has been described in a monograph.¹

Strongly acidic and strongly basic ion exchangers possess low selectivities. The main procedure for the enhancement of the selectivity of ion exchange materials is the introduction of complexing groups. Complexing sorbents can be synthesised by introducing covalently bound functional groups into the polymer^{1–4} or by modification of ion-exchange and non-ionic resins with organic reagents based on ion exchange or adsorption.^{5,6}

The sorbents with pendent chelating groups are well-known and have found wide application, though they have a number of drawbacks, such as difficulties of their synthesis, low reversibility of sorption–desorption processes, unsatisfactory kinetic characteristics, *etc.* On the other hand, these sorbents are efficient for the concentration and separation of elements with subsequent spectroscopic determination.

Modified ion-exchange resins prepared from conventional ion-exchange resins by sorption of organic reagents have found extensive use in recent years. Some characteristics of complexing sorbents for the concentration and separation of metal ions have been reviewed.⁵ This review considers various types of ion-exchange resins and modifying reagents, their ligand capacity, methods for the determination of metal ions and areas of application of complexing sorbents. It was shown that the retention of a modifying reagent on an ion-exchange resin depends on the type of the modifying reagent, pH of the aqueous solution of the reagent, the nature of the ion-exchange resin and of the exchangeable anion, the structure of resin grains and the stability of the sorbent in different media. The conditions for desorption of the modifying reagent are also described. Other parameters determining the retention and selectivity of metal ion separation on complexing sorbents include the stability of metal complexes with organic ligands and pH of the test solution; the mechanism of the metal ion sorption on a complexing sorbent is similar to that of complexation in aqueous media.

The methods used for the preparation of modified ion-exchangers, their properties and applications are described in a review.⁶ Such ion-exchangers are generally used for the selective and group concentration of elements, but their most valuable property is that they allow simultaneous concentration and determination of the corresponding elements. This has been employed in the most advanced directions of analytical chemistry, *viz.*, sorption-spectroscopic and test methods.

In the choice of optimum conditions for sorption-spectroscopic methods, one should take into account the fact that the behaviour of a complex compound in solution and on a solid phase may be different. The sensitivity and selectivity of the determination depend on the composition of the complex formed, on conditions of sorption and analysis, on the mode of immobi-

lisation of the reagent on the carrier, on kinetic features of the process and on many other factors.^{7–10}

Depending on the method used to detect the analytical signal, sorption-spectroscopic methods for the determination of elements with the use of modified ion-exchange resins (solid-phase spectrometry) are subdivided into sorption-luminescent, sorption-photometric and diffuse reflectance spectroscopy.

Sorption-luminescent methods are based on the measurement of parameters of the generation or quenching of luminescence in reactions occurring on a solid phase. These methods are not considered in this review.

Sorption-photometric methods (solid-phase photometry) entail the measurement of optical densities of concentrated substances in cells relative to a swollen standard ion-exchange resin having the same degree of granulation, in cuvettes, on neutral glasses or perforated discs, *etc.*, after a complex of the compound to be determined with the reagent has been formed on a solid phase. The methods based on the concentration of the ion to be determined either as such or as its complex on an original or a reagent-modified matrix with subsequent desorption of the complex compound and measurement of the optical density of the eluate, also refer to sorption-photometric methods.

Diffuse reflectance spectroscopy consists in the measurement of changes in the diffuse reflection of the solid phase containing a complex compound relative to an original or a reagent-modified solid phase. The latter two groups of sorption-spectroscopic techniques are closely interrelated and employ virtually identical terminology. The term 'sorption-photometric methods' is often applied to describe the methods involving measurement of the magnitude of diffuse reflection rather than optical density.

The absorption spectra of complexes in solution and the spectra recorded on a solid phase by using sorption-photometric methods are usually similar, which considerably simplifies comparison of their behaviour. The prospects for solid-phase spectrophotometry are considered in a review⁹ which describes its main advantages, such as the possibility of simultaneous concentration and preparation of analytical forms of concentrated substances which are best suited for further analysis, enhanced stabilities of compounds in the sorbent phase in comparison with those in solutions, increased selectivity of action of chromogenic reagents due to greater rigidity of the molecule fixed on a polymeric matrix. Other advantages include the possibility of using both water-insoluble organic reagents immobilised on ion-exchange resins and reactions yielding poorly soluble compounds or colloidal systems, fast reaction kinetics, high degree of extraction and high variability of the solution volume to the adsorbent mass ratio. The reproducibility of experimental results depends on the procedures used for measurement of the analytical signal and sampling.

1. Solid-phase photometry

Solid-phase photometry (ion-exchange photometry or ion-exchange resin absorptiometry) was originally proposed for detecting trace quantities of elements.^{11, 12} The ions to be determined can be immobilised on a solid phase in three different ways, *viz.*, (i) by sorption of the final complex, (ii) by sorption on an untreated ion-exchange resin followed by the formation of a complex on a solid phase and (iii) by sorption on an ion-exchange resin pretreated with a reagent. A design of a photometric cell suitable for a transparent ion-exchange resin for measuring optical density at appropriate wavelengths has been proposed. This method is characterised by high sensitivity and permits for measurement of microquantities of ions in complex mixtures. Thus the sensitivity of solid-phase photometry in the determination of bismuth exceeds that of conventional spectrophotometric procedures 320-fold. Solid-phase photometry was recommended for use in the analysis of natural waters without preliminary concentration of the elements to be determined.^{11, 12}

By virtue of higher sensitivity and selectivity which may be achieved by proper choice of a solid phase and a reagent, solid-

phase photometry is advantageous over spectrophotometry in the determination of nitrite, fluoride and phosphate ions as well as of metal ions, such as zirconium, titanium, copper and uranium.¹³

In the analysis of geological materials, niobium is adsorbed as a complex with sulfochlorophenol C on the anion-exchange resin AB-17,¹⁴ uranium(VI) is adsorbed on AB-17 modified with 2-(2-thiazolylazo)-5-diethylaminophenol.¹⁵ The detection limit for uranium and niobium oxide is $0.1 \mu\text{g ml}^{-1}$. Fe(II), Cu(II), Ni(II), Co(II) and Ti(IV) ions interfere with the determination of uranium. This method is time-consuming, since the sorption and masking of the interfering components take 30 min each.¹⁵

Vanadium(IV) and vanadium(V) are determined using Eriochrome cyanine R immobilised on an anion-exchanger Sephadex DEAE-25. Vanadium(IV) is sorbed first and then vanadium(V) following its reduction with ascorbic acid. Light absorption of the solid phase is measured at 563 and 585 nm in a 1-mm cell; the detection limits of four- and five-valent vanadium is 1.6 and 1.4 ng ml^{-1} , respectively. This method is used for the analysis of natural waters.¹⁶ Modification of the anion-exchanger Sephadex QAEA-2 with 5-bromosalicylhydroxamic acid resulted in a sorbent in which vanadium(V) forms a complex with an absorption maximum at 560 nm. A procedure has been developed for the determination of vanadium(V) with detection limits of 2.2, 1.3 and $0.5 \mu\text{g litre}^{-1}$ in samples with volumes of 100, 250 and 1000 ml and with shaking time 20, 30 and 50 min, respectively. This method was used for monitoring crude oil and drinking water for vanadium.¹⁷

The use of the first derivative of the absorption spectrum in solid-phase determinations increases the sensitivity of the method and diminishes the background effect. The detection limit in the determination of molybdenum with pyrocatechol violet on a solid phase in the analysis of water, soil and plant tissues is from 2 to 8 ng ml^{-1} . The complex (1 : 1) is adsorbed on an anion-exchanger of the dextran type. A cell with an optical path of 1 mm is used and absorption is monitored at 716 nm.¹⁸

Phenylfluorone is used as a complexing reagent for the determination of molybdenum(VI) in sea water; the first derivative of the absorption spectrum of the complex on a nitrocellulose membrane filter is recorded at 536 nm. The concentration of molybdenum in sea water near the Japanese coast was found to be equal to $10.8 \pm 0.4 \mu\text{g ml}^{-1}$ (see Ref. 19).

The method of the first derivative in solid phase spectrophotometry was used for the determination of zirconium on the anion-exchange resin AB-17 modified with Eriochrome Black T,²⁰ and for the determination of lead as an iodide complex on the cation-exchange resin KU-2 modified with Basic Blue K.^{21, 22} The detection limits for zirconium and lead are 0.01 and $0.09 \mu\text{g ml}^{-1}$, respectively.

Flow-injection analysis makes use of reagents immobilised on a solid phase. For example, in the determination of vanadium(V) in natural water, vanadium is first separated from accompanying components by column chromatography on Sephadex G-25, and then is made to react with 2-[2-(3,5-dibromopyridyl)azo]-5-dimethylaminobenzoic acid immobilised on the anion-exchange resin AG 1X2 in a flow of a formate buffer. The optical density of the complex formed is measured at 650 nm. The calibration curve is linear within the range of vanadium(V) concentrations from 2 to $10 \mu\text{g litre}^{-1}$; the productivity of analysis is 5 to 6 samples per hour.²³

Flow-injection systems can be used to determine nickel and zinc by solid-phase spectrophotometry owing to different sorption rates. Nickel and zinc complexes with 1-(2-thiazolylazo)-2-naphthol are adsorbed on silica gel C₁₈. Both complexes are adsorbed at a flow rate of 0.6 ml min^{-1} , but only the zinc complex is adsorbed at a flow rate of 1.5 ml min^{-1} . Analysis can be carried out at zinc and nickel concentrations from 0.1 to 2 mg litre^{-1} . The productivity of the method is 20 samples per hour. The procedure for the determination of zinc and nickel with the help of a flow-injection system was used in the analysis of copper alloys.²⁴

2. Diffuse reflectance spectroscopy

It can be noted that there are much fewer studies in which changes in optical density are measured as an analytical signal than studies making use of diffuse reflection coefficients.

The advantages of immobilisation of analytical reagents on the surface of carriers over photometry of solutions were discussed in a review.¹⁰ It was shown that the combination of sorption concentration with measurements of surface analytical signals makes it possible to reduce the detection limit of components that are detected by several orders of magnitude, while the use of adsorbents modified with specific organic reagents increases the selectivity of analysis. The same paper provides a classification of modified sorbents according to the type of the carrier and the modifying reagent and describes various procedures for the immobilisation of analytical reagents as well as different applications of the modified sorbents for analytical purposes. In particular, immobilisation of organic reagents from polar and non-polar solvents and their mixtures on different carriers under both static and dynamic conditions and after treatment of sorbents with high-frequency low-temperature plasma in the presence of the vapour of organic compounds is considered. Modification of sorbents with inorganic reagents is achieved by sorption or precipitation of metal hydroxides, oxides or salts on the surface. Composite materials based on modified sorbents are obtained in the casting of polyacrylonitrile fibres by filling them with finely dispersed sorbents.

The problem of what is to be called modified organic reagents, modified sorbents and immobilised reagents was raised in a study²⁵ where the terms 'modification' and 'immobilisation' referred to the analytical reagent rather than to the carrier. In their attempt to provide a more exact definition, the authors suggested that organic reagents were considered as modified if a second (or third) modifying (monomeric or polymeric) component reacts with an organic reagent and changes its properties, but no new chemical compound is formed. Upon immobilisation on a solid matrix, the reagent is modified with a polymeric ion-exchange resin. However, the majority of investigators use the following terminology: a reagent is immobilised on a carrier (solid phase), while the carrier (solid phase) is modified with the organic reagent.

The methodology of quantitative measurements in diffuse reflectance spectroscopy is described in the review.²⁶ This study deals with a description of the main factors which affect the accuracy and reproducibility of results of sorption-spectroscopic determination, *viz.*, the particle size, moisture content and magnitude of the mirror reflection superimposed on the diffuse reflection resulting in the distortion of the spectrum. An attempt to relate the analytical characteristics of reactions occurring in solution to those occurring on a solid phase were undertaken in order to predict the possibility of conducting photometric reactions on a solid phase. However, the sensitivity of the sorption-photometric procedure from the optical characteristics of the reagent and the product of the photometric reaction in solution cannot be established *a priori*. Nevertheless, the authors presume that the known values of molar absorption coefficients of complex compounds in solution and the known sensitivity of the sorption-photometric method can be used to predict, with a lesser than 20% error the values of the diffuse reflection coefficients for other compounds with known molar absorption coefficients for the same matrix.²⁶

A study of formation of mixed-ligand complexes of Zn(II), Cd(II), Pb(II) and Ag(I) on silica modified with thiourea derivatives revealed that the rate of formation of such surface complexes depends on the ratio of stability constants of metal–ligand complexes in solutions.²⁷

Modified silica is used for the determination of osmium(VIII) and palladium(II) in wet dedusting sludge and washing acids^{28,29} and for the determination of gold.³⁰ Gold is determined as the metal after thermal treatment of the sorbent and osmium is determined as the oxide. Analytical potentials of silica and foamed

polyurethanes containing *N*-propyl-*N'*-[1-(benzothiazolyl-2-thio)-2,2,2-trichloroethyl]ureido or 4-adamantyl-2-(2-hydroxy-1-naphthylazo)thiazolyl (AOT) groups were examined for possible determination of Pt(IV), Pd(II), Au(III), Ag(I), Cd(II) and Hg(II). It was shown that Hg(II) (pH 6.0–8.5) and Cd(II) (pH 9.5–11.0) are quantitatively retained on the AOT-containing sorbent.³¹

It was demonstrated³² that many regularities of formation of metal ion complexes with organic ligands on the surface of silica gel and in solution are identical for Fe(III), Cu(II), Co(II), Y(III) and La(III). In the case of easily hydrolysable ions, such as Zr(IV), Ti(IV), V(V), W(VI), Mo(VI) and kinetically inert platinum-group complexes, the irregularities are manifested in increased rates of complexation, enhanced complexing ability and formation of mixed-ligand complexes.

The sorption of dithizone (DT), 4,4'-bis(dimethylamino)thio-benzophenone, 4-(thiazol-2-ylazo)naphthol (TAN), 1,10-phenanthroline and high-molecular-weight quaternary ammonium salts (QAS) on silica gel (SG) and cellulose (C) was studied aimed at preparing solid-phase reagents for Hg(II), Ag(I), Pb(II), Zn(II) and Fe(III).^{33–35} It was shown that such sorbents are stable in aqueous solutions in a broad range of pH. The optimum conditions for the formation of Cu(II), Co(II) and Zn(II) complexes with TAN–SG, of Ag(I), Hg(II) and Pb(II) complexes with DT–SG, of Co(II) and Fe(III) thiocyanate and Bi(III) tetraiodide complexes with QAS–SG and QAS–C were established. To this end, a variety of sorption-spectroscopic and test methods as well as reactive indicator papers have been devised for express control of these metal ions in natural, drinking and waste waters and biological fluids. The detection limit for these metal ions lies in the range of 0.2 to 10 µg litre⁻¹ at a sample volume of 50–100 ml.

Optimum conditions for the sorption of Cd(II), Hg(II) and Pb(II) ions on Silochrom modified with 4-(thiazol-2-ylazo)resorcinol were found. These ions were sorbed from an acetate buffer pH 6.8–7.5 (15 ml) on the sorbent (0.3 g) upon shaking for 5–10 min. The concentration coefficient for Cd(II) and Pb(II) was 85, that for Hg(II) was 300. This procedure was used for the analysis of soils.³⁶

The cobalt complex with 1-(2-pyridylazo)-2-naphthol (PAN) is adsorbed on an unmodified silica gel and is firmly retained on the sorbent after acidification with up to 0.5 M HCl. This procedure allows selective determination of 2 to 10 µg of cobalt in drinking and mineral waters. Ballast components are desorbed upon subsequent acidification. The sorption is performed from 100- and 300-ml sample volumes under static conditions; the mass of the silica gel is 0.2 g.³⁷

1-(2-Pyridylazo)-2-naphthol immobilised on Silochrom C-120 is used for the determination of indium. The concentration coefficient for indium adsorbed from a 150-ml sample is 500.^{38,39}

Immobilisation of aluminone on silica gels containing different groups, with different particle diameters and pore sizes was studied as a sensitive layer of an optical sensor for copper.⁴⁰ Immobilisation produced a favourable effect manifested as a longwave shift of the absorption maximum, a decrease in pH for the complexation and an increase in sensitivity and selectivity. A procedure for the detection of copper in foodstuffs with a detection limit of 0.015 µg ml⁻¹ was developed.

Diffuse reflectance spectroscopy was used to study the completeness of sorption of Fe(II) and Fe(III) ions as complexes with catechol-3,5-disulfonic acid on the anion-exchange resin AB-17.⁴¹ This study demonstrated the possibility of separate determination of Fe(II) and Fe(III) ions; a test method was proposed for the determination of iron with a detection limit of 0.01 mg litre⁻¹. Fe(III) ions are determined at pH 3.5, while a sum of Fe(II) and Fe(III) ions, at pH 6–9. The measurements are performed at two wavelengths (500 and 540 nm); the concentrations of Fe ions are calculated from the following equations:

$$\text{Fe(III): } F_{500} = (5.7 \pm 0.05)c + (0.83 \pm 0.04),$$

$$F_{540} = (4.56 \pm 0.05)c + (0.66 \pm 0.04),$$

$$\text{Fe(II): } F_{500} = (4.59 \pm 0.28)c + (0.77 \pm 0.33),$$

$$F_{540} = (3.7 \pm 0.06)c + (0.04 \pm 0.03),$$

where F is the Gourevich–Kubelka–Munk function and c is the iron concentration ($\mu\text{g ml}^{-1}$). Iron ions are determined at concentrations from 0.03 to 6.4 $\mu\text{g ml}^{-1}$.

Colorimetric characteristics of coloured sorbates, *viz.*, luminosity (L), colour coordinates (A , B), saturation (S), brightness (Y), colour tone (T), shading (E), *etc.*, can be used for detecting analytical signals in diffuse reflectance spectroscopy in addition to the diffuse reflection coefficient (R) or the Gourevich–Kubelka–Munk function (F). The use of these colour characteristics as analytical signals makes it possible to determine dissociation constants of organic reagents and increases the sensitivity and accuracy of metal ion determinations. The use of ΔL and ΔY instead of ΔF (where Δ is the difference between the values of the corresponding coefficients for the complex and the reagent) decreases 4- to 20-fold the detection limit for cobalt, indium and nickel with immobilised reagents. According to sensitivity of determination, these values can be arranged in the following order: $\Delta F < \Delta A < \Delta S < \Delta L < \Delta Y$.^{42–49}

The Gourevich–Kubelka–Munk function, which allows the establishment of a correlation between analytical signals in the same photometric reaction occurring both in a solution and on a solid phase, is the most frequently used as the analytical signal. The simplest way to express the analytical signal is to present it as a difference in diffuse reflection coefficients of carriers after the passage of control and test solutions at the optimum wavelength.

The intensities of analytical signals depend on the efficiency of sorption of metal ions from solutions and the completeness of conversion of sorbed metals into coloured complex compounds on a solid-phase. The signals, in turn, depend on the acidity of test solutions (Fig. 1a), the mass of sorbent discs (Fig. 1b) and the composition of the reagent solution.

Figure 1. Dependence of the analytical signal of metal complexes on the solid phase of a fibrous sorbent filled with the cation-exchange resin KU-2 on the acidities of solutions (a) and the mass of the sorbent disc (b) in the determination of iron (1), nickel (2) and copper (3) with potassium thiocyanate, dimethylglyoxime and sodium diethyldithiocarbamate, respectively; (a): $c_M = 0.05$ (Fe), 0.1 (Ni), 0.1 mg litre⁻¹ (Cu); (b): $c_M = 0.05$ mg litre⁻¹.

3. Chemical optical sensors

Sorption-spectroscopic methods and immobilised organic reagents were used in the design of the so-called chemical optical sensors or sensitive elements.^{50–85} There are several different interpretations of the term ‘sensor’. Thus a chemical sensor is defined as a probe which provides direct information about the chemical composition of the environment. It consists of a physical transducer of analytical signals and a chemically selective layer.⁵² Chemical sensors are the main elements of a new generation of analytical devices, such as sensor analysers, which, together with a sensitive element, comprise sample injectors and various devices for the processing of signals and displaying the results, *viz.*, the

concentration of the tested substance.^{53,54} In other studies,^{55,56} a sensor is referred to as a primary device which selectively responds to changes in definite properties of the environment by converting this information into the corresponding electrical signals, *e.g.*, optical signals. We define a sensor as a sensitive element of a sensor analyser.

Sensors are supposed to be recoverable systems, *i.e.*, they must easily be reset after the assay is completed. Therefore, the material used as a solid phase should first of all be mechanically and chemically stable. Fibrous materials filled with ion-exchange resins largely meet these requirements.

These materials are cast from suspensions of finely dispersed ion-exchange resins in a solution of polyacrylonitrile in dimethylformamide. Pressing of suspensions through spinnerets produces thin porous polyacrylonitrile fibres filled with ion-exchanger particles. The diameter of a polyacrylonitrile fibre is 30 to 40 μm , the size of carrier particles is 5 to 10 μm , the degree of filling is 50 mass %–75 mass %. By virtue of their fibrous structure and high degree of dispersion of filling agents, such materials manifest remarkable kinetic properties.

Carriers represent white or light-yellow 0.1–0.2 mm thick fibrous plates having a density of 40 to 80 g m^{-2} which are stable in strongly acidic, neutral and weakly alkaline media. These plates are used to manufacture discs. Depending on their diameter, 10 or 20 mm, thickness and degree of filling, the mass of discs varies from 10 to 50 mg.

Prior to use, carriers (in the form of plates or prefabricated discs) are washed with 2 M HCl up to a negative reaction for Fe(III) with thiocyanate ions and then with water up to a negative reaction for chloride ions with silver nitrate and dried in air. Such carriers can be stored at room temperature for an indefinitely long period of time. Prior to use, plates are shaped into discs and swollen in water for at least 24 hours.

Immobilisation of analytical reagents is performed in a static or a dynamic regime. In the former case, the discs are kept in aqueous or aqueous–organic solutions of reagents (10^{-5} – 10^{-6} M) for 5–15 min and then washed with water. The concentration of the immobilised reagent varies from 10^{-6} to 10^{-4} mol litre⁻¹ g⁻¹. In the latter case, the reagent solution is dripped or pumped through the carrier disc placed in a cell with a sintered-glass filter using a peristaltic pump.

Filled fibrous sorbents can be used in both modified (*i.e.*, after immobilisation of the organic reagent) and in the original (colourless) form.

Ions to be determined are concentrated in different ways, *viz.*, directly from the test solution with subsequent detection on a solid phase, by concentration of a complex compound formed in the solution and by sorption of the ion in question on a carrier with an immobilised reagent.

Apparently, sorption of a preformed complex is the least appropriate solution of the problem of increasing the sensitivity and selectivity of the method. The advantages of discs with immobilised reagents are as follows: full readiness of the so-called sensitive element for the assay, simplicity and lack of necessity to prepare reagent solutions. Of their disadvantages one may relate limited durability and storage life; nor in all cases can they be recovered.

The obvious merits of colourless discs are that they are easily recovered and that the same discs can be used for the determination of different elements. Another advantage is that the storage life of carriers is not limited. Their demerits are as follows: the necessity to prepare reagent solutions and the need for an additional procedure, the so-called ‘development’, *viz.*, sorption of a reagent on a carrier after concentration of the ion in question.

On the whole, the main attraction of fibres filled with ion-exchange resins is the possibility to vary the degree of their filling and the nature of the ion exchanger and the reagent depending on a concrete selectivity problem. In contrast with other carriers, these materials represent both the sites for colour reactions and the means for concentration of ions to be tested and removal of

ballast components. They are resistant to mechanical actions and manifest high sorptive and kinetic properties, which ensures a high level of sensitivity, which can be attained by passing any volume of test solutions. The use of fibrous materials ensures easy sorption of reagents and tested ions (*e.g.*, by immersion of the carrier into the solution or by passing the solution through the carrier) and easy separation of the solid phase from the solution (*e.g.*, by decanting under static conditions or by pumping under dynamic conditions). This, in turn, allows easy automation of flow sorption-spectroscopic procedures and, if necessary, test operation without any devices based on visual detection.

Studies of fibres filled with ion-exchange resins used as sorbents follow two main lines which include sorption-spectroscopic determination of metal ions based on changes in their diffuse reflection upon complexation with organic reagents on a solid phase (carrier) and elaboration of test methods.

These studies were undertaken with the view of constructing recoverable systems which utilise exclusively fibrous sorbents with immobilised reagents as optical sensors. However, despite its indisputable advantages, this approach significantly restricts the potentials of a new carrier. It was found that organic reagents immobilised on carriers are not always effective in analytical reactions or they change their colour upon immobilisation. Regeneration of optical sensors with immobilised reagents is a complicated task. On repeated regeneration, organic reagents are either destroyed or washed off from the carrier with a regenerating solution. Nevertheless, in some cases sensitive elements can be recovered. Thus in the determination of lead with Xylenol Orange⁵¹ and in the determination of uranium with Arsenazo I,⁶⁴ the same sensitive element (the optical sensor) can be used for up to 20 assays. Most frequently, optical sensors cannot be regenerated at all, *e.g.*, a sensitive element for thorium with Xylenol Orange.⁵¹ It is economically more advantageous to replace a sensitive element used as a chemical optical sensor than to regenerate it.

Two types of sensitive elements or chemical optical sensors are presently being developed, *viz.*, fibrous materials filled with ion-exchange resins with and without organic reagents immobilised on them. In the latter case, the analytical reaction with an organic reagent is accomplished after sorption of the tested ion.

In the choice of a particular organic reagent, preference should be given to the most well-studied and accessible reagents possessing good analytical characteristics. Organic reagents containing acid groups are immobilised on materials filled with anion-exchange resins; while those containing basic groups are sorbed on cation-exchange resins. In a few studies, sorption was performed on ion-exchange fabrics with phosphate or vinylpyridinium groups.

Fixation of reagents on solid carriers occurs mainly due to the ion exchange mechanism and partially due to adsorption, formation of hydrogen bonds and other interactions.

Electron and EPR spectroscopy was used to study the properties of 1-(2-pyridylazo)-2-naphthol (PAN) immobilised on polyacrylonitrile fibres filled with finely dispersed ion-exchange resins and its complexes with copper(II).⁶⁶ In this study, fibres filled with different ion-exchange resins, *viz.*, KU-2, KB-4, AB-17 and A-5, were employed. The parameters of EPR spectra of copper complexes on a solid phase in the pH range of 1–8 were calculated. It was shown that immobilisation of PAN on a solid phase changes its state (*viz.*, the spread of individual ionic forms of the reagent is shifted and widened) and spectroscopic properties. If the concentration of the reagent exceeds 10^{-5} mol litre⁻¹ g⁻¹, this undergoes association on the surface of the carrier. The main contribution to the retention of PAN on these ion-exchange resins is due to ionogenic groups of the carrier; however, under certain conditions, adsorption begins to play a leading role, as is the case with the adsorption of PAN on KU-2 in alkaline media.

The role of the nature of the carrier in complexation is rather complicated and ambiguous and is manifested primarily in its competing interaction with metal ions. By using different carriers,

one can vary the concentration of the immobilised reagent on the surface and thus control its reactivity.

The second type of chemical optical sensors proved to be more advantageous than first type sensors. Their additional advantages are as follows. Since sorption and determination are separated by certain time interval, it is possible to introduce masking complexing agents in the concentration and determination steps, which considerably increases the selectivity of the reactions. Also, this particular type of sensor makes use of the original, colourless carriers. This circumstance has stimulated the development of new spectroscopic solid-phase methods (*e.g.*, determination of cations on a solid phase), which consists, for example, in the sorption of metal cations in the form of colourless or weakly coloured anionic complexes on anion-exchange resins and their subsequent detection in the most contrasting colour reaction. Thus the sensitivity of determination of Fe(III) with thiocyanate on the anion-exchange resin AB-17 increases considerably if iron is sorbed in the form of complexes with tartaric or glycolic acids (Fig. 2).^{67,68} Comparative data on iron determination with thiocyanate following sorption from solutions of glycolic acid on KU-2- or AB-17-containing fibres testify to a significant increase in selectivity. The selectivity factors are equal to 10 and 20 for Zn, 20 and 50 for Cd, 5 and 200 for the uranyl ion, $\ll 1$ and 10 for Bi and 100 and 3000 for oxalates and phosphates, respectively.

Figure 2. Reflection spectra of the iron thiocyanate complex formed upon sorption of Fe(III) from 0.01 M solutions of glycolic (1) and tartaric (2) acids and without addition of anions (3) on a fibrous material filled with the anion-exchange resin AB-17; $c_{\text{Fe}} = 0.2 \mu\text{g ml}^{-1}$.

The new methodology has made possible solid-phase determination of thorium with Arsenazo III. The latter is the best reagent for thorium; however, it changed its colour upon sorption on a carrier, which prevented the assay. If thorium in the form of the oxalate complex is sorbed on fibres containing an anion-exchange resin, it can be determined in the form of the complex with Arsenazo III on a solid phase in strongly acidic media. In this approach, the detection limit is 0.2 ng ml^{-1} (the sensitivity of photometric determination of thorium with Arsenazo III is $0.01 \mu\text{g ml}^{-1}$). Uranium, zirconium, titanium, lanthanum, iron, fluorides and phosphates do not interfere with the determination.^{69,70}

Fibrous adsorbents filled with ion-exchange resins (AB-17, A-5, KU-2) and the styrene–divinylbenzene copolymer containing no ionogenic groups were studied as possible carriers for a sensitive element for mercury with 4-phenylazo-3-aminorhodanine.⁷⁹ It was found that the reagent is tightly bound only to carriers containing ionogenic (both cationic and anionic) ion-exchange groups. However, the sensitive reaction of mercury with the immobilised reagent occurred only on fibres with the cation-exchange resin KU-2. A method has been developed for detecting mercury in waters with the detection limit of $0.02 \mu\text{g ml}^{-1}$.

Sensitive optical elements for uranium, mercury and lead have been proposed, which are based on the formation of complexes with Arsenazo III, dithizone and hexaoxacycloazochrome, respectively.⁸⁰ In these studies, polyamide, poly(ethylene terephthalate) and cellulose membranes were used as carriers.

These membranes are made of transparent or semi-transparent materials and are resistant to dilute alkalis and acids. Immobilisation of reagents is carried out in a static or a dynamic mode. In the dynamic mode, the solution is allowed to pass over the membrane surface if the pore diameter is less than 0.45 μm . In the case of larger pores, the solution is filtered through the membrane. The ranges of direct determination in water are 0.01 to 0.10 for uranium, 0.005 to 0.05 for mercury and 0.05 to 0.5 mg litre^{-1} for lead.

The possibility of selective determination of uranium(VI) at the level of $2 \times 10^{-8} \text{ mol litre}^{-1}$ in the presence of a 100-fold excess of thorium by diffuse reflectance spectroscopy has been demonstrated.^{81, 82} In these studies, polycapromamide and nylon

membrane filters were used as matrices. The diffuse reflection coefficient, R , is fixed at 660 nm for uranium and 680 nm for thorium and the uranium concentration is determined from a system of equations:

$$R = \varepsilon_U c_U l + \varepsilon_{Th} c_{Th} l,$$

$$c = c_U + c_{Th},$$

where R is the diffuse reflection coefficient, ε is the molar adsorption coefficient, c is the concentration (mol litre^{-1}) and l is the membrane thickness.

The conditions of sorption of azorhodanines, tyrodine and sulfonitrophenol M on polymeric carriers, e.g., caprone mem-

Notes. Abbreviations: PAN, 1-(2-pyridylazo)-2-naphthol; DETC, sodium diethyldithiocarbamate; EDTA, ethylenediaminetetraacetic acid; DMG, dimethylglyoxime; PAAP, 4-phenylazo-3-aminorhodanine; NDEA, *p*-nitrosodiethylaniline; XO, Xylenol Orange; PAR, 4-(2-pyridylazo)resorcinol; DPC, 1,5-diphenylcarbazine; DT, dithizone; F(I), fabric with vinylpyridine groups; F(II), fabric containing PO₃H₂ groups.

branes, fibrous materials filled with cation- and anion-exchange resins and fabrics with ionogenic groups, were studied in the development of sensitive elements for Hg(II), Cu(II), Ag(I), Au(III), Pt(IV) and Pd(II). It was shown that azorhodanines and sulfonitrophenol M immobilised on caprone membranes can be successfully used for the determination of these metal ions with the detection limit of 1 to 15 $\mu\text{g litre}^{-1}$.

A procedure has been developed^{83–85} for the determination of silver based on its sorption on discs from polyacrylonitrile fibre filled with the cation-exchange resin KU-2 with subsequent detection with rhodazole X; the detection limit is 5 $\mu\text{g litre}^{-1}$.

The main characteristics of methods for sorption-spectroscopic determination of metal ions which employ fibrous materials filled with ion-exchange resins and fabrics carrying ionogenic groups as solid phases are summarised in Table 1.

III. Instruments

Optical sensors for recording analytical signals are used in mini-devices of the well-known companies 'Specord', 'Spectroton', 'Pulsar' and 'Multitest', in mini-photometers 'Merck', *etc.* Recent publications describe two more devices. One of them was developed at the Institute of Analytic Instrumentation of the Russian Academy of Sciences and represents a small-size chemosensor analyser designed for the determination of pH and concentration of metal ions; its operation is based on the principle of reflective photometry of chemosensors made of optically transparent polymers containing organic reagents.⁸⁶ Its designers sought to build a specialised instrument for implementation of one or several similar analytical procedures with the aid of sensors having a universal configuration. This approach permits one to perform the measurements in three different regimes, *viz.*, measurements of light absorption of the tested object ($-\log R$) relative to the diffusely reflecting substrate or an analogous object with the known characteristics. The second and third regimes are intended for procedures utilising definite types of sensors and allow for calibration. Chemosensors for measuring pH and concentrations of Fe(III), copper and rare-earth metal ions at the level of 2×10^{-3} – 2×10^{-5} mol litre⁻¹ have been developed.

The apparatus (150 $\times$ 130 $\times$ 80 mm) has a weight of 1 kg (the volume of the samples varies from 5 to 70 μl) and can be used for measuring reflective properties of coloured reagent papers and multilayer sensitive elements. The measurements are performed at wavelengths from 530 to 700 nm. The duration of the exposure of the sensitive element to the sample is 90–120 s. The apparatus operates on alternating current or utilises the energy of internal accumulators.

The second instrument, *viz.*, the optical sensor analyser OSA-TM developed at the Scientific-and-Industrial Corporation 'Kvant' (Rostov-on-Don), is intended for environmental monitoring of natural, drinking and purified waste waters for heavy metals at the MPC and lower levels under both laboratory and field conditions.⁸⁷ It is designed as a colorimetric densitometer and is used for measuring diffuse reflection coefficients of optical sensors in flow-through cells as well as for measuring optical densities of coloured solutions in cells for liquid samples. This apparatus (370 $\times$ 220 $\times$ 100 mm) has a weight of 4.5 kg and operates on alternating current or utilises the energy of accumulators. It is supplied with an integral flow-through optical cell, a peristaltic pump, a microprocessor with push-button control and eight light filters operating at 400–750 nm. Its operation is based on the detection of changes in colour (*e.g.*, reflection with optical sensors or the optical density of the tested solution) as a result of interaction of metal ions with analytical reagents. The analytical signals are shown on a digital display as the transmission (reflection) coefficient, optical density and concentration of metal ions in the tested solution.

The potentials of OSA-TM are exemplified⁸⁷ in the determination of chromium(III) and chromium(VI) in surface waters. Chromium(III) is measured photometrically with Arsenazo III,

while the concentration of chromium(VI) is determined in a flow-through cell with anion-exchanger filled fibres using complexation with 1,5-diphenylcarbazine on the solid phase. A method was proposed for the simultaneous determination of chromium(III) and chromium (VI) in sanitary–general-purpose water up to 1 : 5 ratio at the concentration of Cr(III) > 0.2 MPC and that of Cr(VI) > 0.1 MPC. The duration of one assay is 10 to 20 min.

A procedure for sorption-spectroscopic assay utilising optical sensors is simple with this instrument. A carrier disc ($\varnothing$ 10 mm) is placed in a flow-through cell and the test solution is pumped through the disc at a rate of 10 ml min⁻¹ under optimal sorption conditions. If unmodified carriers are used, the reagent solution is pumped through under optimum assay conditions after which the diffuse reflection coefficient is measured.

The main advantage of the OSA-TM analyser is that it allows both routine photometric measurements and measurements in flow-through optical cells where the sorption of the tested ion occurs. The reaction of the ion takes place on a solid phase and is followed by measurement of the analytical signal. A combination of these three processes in a single flow-through cell not only simplifies the procedure but also increases significantly the reproducibility of experimental results owing to the omission of one step, *i.e.*, the transfer of the optical sensor from the sorption cell to the measuring cell, which excludes any fluctuations in the sensor wetness. The use of the instrument allows for rapid presentation of experimental results in units of concentration. The construction of the instrument with a flow-through optical cell became possible due to development of optical sensors in which fibrous materials filled with ion-exchange resins or fabrics containing ionogenic groups are used as carriers.

IV. Test methods

Numerous versions of test methods are being actively developed.^{88–104} The materials used as carriers for sorption-spectroscopic assays, such as reagent papers, foamed polyurethanes, silica gel, membranes, ion-exchange resins, *etc.*, are also employed in test methods. Indicator test systems, *e.g.*, from 'Merck', are currently known.

Some densitometric characteristics for express tests have been obtained which are based on the use of reactive reagent papers⁹⁶ and are designed for the determination of certain elements with the help of reflective electronic mini-photometers equipped with light-emitting diodes operating at wavelengths of 567 $\pm$ 15 and 660 $\pm$ 10 nm and a modified device for concentration of 10⁻⁷ mass %–10⁻⁵ mass % of components in aqueous media.

The main requirements for test reactions are as follows:¹⁰¹ high sensitivity (not lower than MPC); high light-transition contrast; proximity of the optimum acidity of assays to the acidity of the tested solution; stability of external effects for a sufficiently long time and upon exposure to light; the possibility to preserve the test form after positive response for subsequent quantitative assay under laboratory conditions; and selectivity.

The methodological aspects of detection and processing of analytical signals in colorimetry have been reviewed.^{48, 101} The general colour discrimination criterion (ΔE) is the main parameter in making a test scale. In order to increase the sensitivity of a test reaction, special parameters, such as whiteness (W) for colourless sorbents and yellowness (G) for blue-coloured complexes have been introduced. The calibration test scale is built up from the known dependence of the general colour discrimination on the concentration of the tested element. One unit of ΔE corresponds to one colour discrimination threshold; therefore, the concentrations of tested elements are selected in accordance with the corresponding magnitude of ΔE . A reliable sense of difference in light flux intensities is reached if this difference is at least 10%. Therefore, discrete values of colour discrimination with $\Delta E > 10$ are especially preferred in the case of diffuse reflection. If the tested sample loses its colour or is bleached in the course of an

analytical reaction, its whiteness is used for building up a test scale:

$$W = 100 - \Delta E.$$

The lower threshold of tested concentrations in any test method is defined as general colour discrimination (10 arbitrary units) between the original test sample (E_0) and the test sample following its reaction with the tested element (E):

$$E - E_0 = 10 \text{ or } W_0 - W = 10.$$

In the building up of a test scale, one should not go beyond the limits of saturability (ΔS) of the tested sample (20%–60%) which corresponds to the upper threshold of tested concentrations.

The contrast of a colour reaction is enhanced after application of optical bleaching compounds onto the matrix surface; their operation principle is fluorescence. The presence of these compounds does not influence chemical and analytical characteristics of immobilised reagents. In their presence, reagents are rapidly and evenly distributed over the matrix surface and are well retained in acid media under both static and dynamic conditions. For example, the detection limit in the determination of uranium(VI) with Arsenazo III and application of optical bleaching is $0.001 \mu\text{g ml}^{-1}$. The colour of the complex compound is bright green, whereas in the absence of the bleaching agent the complex has a grey-blue colour and has a detection limit of $0.1 \mu\text{g ml}^{-1}$ (see Ref. 102).

A portable field test system for the determination of numerous elements in water, soil and rainfall has been developed.^{103, 104} This assay includes the following steps, *viz.*, measurement of the lengths of coloured or bleached zones on reactive reagent papers cut into stripes and pasted into a polymeric film one end of which is brought into contact with the tested fluid, visualisation of colour intensity, measurement of the area of the coloured or bleached zone and visualisation of colouring of the tested fluid after application of reagent papers. The range of tested concentrations is $0.001 - 1000 \text{ mg litre}^{-1}$.

1. Reagent test papers

The majority of publications devoted to test methods deal with reagent papers.^{88–121} Heavy metals on the whole are determined with the help of a device which is similar to that used for air sampling (the detection limit is up to $10^{-7} \text{ mol litre}^{-1}$) which employs test papers impregnated with potassium tetraborate and PAN.¹⁰⁷ Rapid tests for the determination of toxic elements in water are carried out on papers, films or glasses with the detection limits of 0.05 for Cu(II), 0.2 for Fe(III), 0.5 for Co(II), 0.03 for Mn(II) and $0.03 \text{ mg litre}^{-1}$ for V(V) (see Ref. 108).

Iron ions are determined on reactive test papers with detection limits ranging from 0.02 to $0.2 \text{ mg litre}^{-1}$ depending on the method (see Refs 109–111). A tape method was proposed for the determination of Fe(III) ($0.5 - 3.5 \text{ mg litre}^{-1}$) on papers impregnated with the anion-exchange resin Amberlite IRA 400 modified with sodium ethylenediaminedi(hydroxybenzylphosphonate).¹¹²

Immobilisation of pyrazole-containing formazanes and hydrazones on the base-paper increases their sensitivity with respect to transition metals. Express tests for determining Cu(II), Ni(II) and Co(II) at the level of $10^{-7} \text{ mass \%} - 10^{-8} \text{ mass \%}$ have been developed.¹¹³ Test paper impregnated with Michler's thio-ketone, potassium dihydrogenphosphate, sodium thiosulfate (in order to reduce copper and remove active chlorine) and Triton X-100 was proposed for the determination of copper in drinking water (the detection limit is $0.05 \text{ mg litre}^{-1}$);¹¹⁴ test paper containing the nickel complex with 2-nitroso-1-naphthol, diphenylguanidine, thiourea and ammonium fluoride was used for the determination of cobalt.¹¹⁵

An express test method for the determination of manganese in drinking water is carried out on paper containing a multicomponent reagent. This analysis is based on the measurement of the time interval during which the indicator zone changes its colour as

a result of oxidation of Malachite Green with potassium periodate (KIO_4) catalysed by manganese(II) ions. The detection limit is $0.03 \text{ mg litre}^{-1}$ (see Ref. 116).

Zinc ions are determined in foodstuff using reagent test paper (FMOPF-6C) at pH 8.0. The effect of copper ions is eliminated by addition of thiourea.¹¹⁷ Reagent test paper was recommended for use as indicators for multicomponent assay of water.¹¹⁸

Ion	Concentration range /mg litre ⁻¹	Ion	Concentration range /mg litre ⁻¹
Pb(II)	0.001–0.1	Bi(III)	0.001–0.1
Cu(II)	0.001–0.1	Fe(II)	0.01–0.2
Fe(III)	0.01–0.2	Hg(II)	0.2–2
Cr(VI)	0.1–5		

Lead ions are determined using a reagent test paper (RTP) metal test after its fast separation from Cu, Fe and Zn in aqueous solutions (pH 6.0), emulsions and suspensions using the sensor filter of a pocket indicator ultrafiltration unit.¹¹⁸

Stripes of reagent paper are used for the quality control of water;¹¹⁹ paper stripes impregnated with diphenylthiocarbazone are used for test determination of trace amounts (15 ppb) of lead in drinking water,¹²⁰ while paper stripes soaked with a covalently bound multidentate chromogenic reagent of the formazane type are used for the determination of mercury with a detection limit of $0.05 \text{ mg litre}^{-1}$ (see Ref. 121).

The detection limit in enzymic determinations of mercury and organomercurials on foamed polyurethanes, paper and chitosan with immobilised peroxidase is $10^{-5} \mu\text{g ml}^{-1}$, *i.e.*, below the MPC for mercury.^{122–127} A sorption-catalytic procedure for the determination of manganese¹²⁸ is based on preliminary concentration of manganese(II) ions on cellulose filter paper with chemically bound diethylenetriaminotetraacetate groups (DETATA) and subsequent catalytic oxidation of 3,3',5,5'-tetramethylbenzidine with KIO_4 . The optimum conditions for this reaction in solution and on filter paper were found to be different. Preliminary concentration of manganese on DETATA-paper allows for a nearly 10-fold decrease in the detection limit (up to $6 \times 10^{-6} \text{ mg litre}^{-1}$) and expands the range of tested concentrations up to $5 \times 10^{-6} - 2.5 \times 10^{-3} \text{ mg litre}^{-1}$. The selectivity of the assay is higher in this case: after preliminary concentration from a 20-ml sample, determination of 1 ng of manganese is insensitive to a 1000-fold molar excess of other ions. This method is applied in the analysis of tap and river water.

An express test for the detection and determination of vanadium, which catalyses the oxidation of *p*-diethylaminoaniline with bromate, on glass or poly(methyl methacrylate) at pH 4–5 has been developed. The detection limit decreases in the presence of ferrone which potentiates the catalytic effect of vanadium. This determination is selective with respect to many metals. The interference of Fe(III) ions is eliminated with fluorides. The detection limit for vanadium is $0.09 \text{ mg litre}^{-1}$ (see Ref. 129).

The approaches used in test methods are very diverse. For example, in one of them the analyte is concentrated in a limited area on a hydrophobic surface by evaporation and the element is detected by colour reaction or fluorescence. This procedure is used to determine aluminium with Xylenol Orange in tap water at pH 8.0 or with lumogallione at pH 7.0 (the detection limit is 2.7 ppb) (see Ref. 130).

Molybdenum is determined by an ion-exchange drop reaction with azide with the detection limit of $2 \mu\text{g}$ in 0.09 ml of the sample using the anion-exchange resin Bio-Rad AG 1X8.¹³¹ In the determination of chromium(VI), five to ten beads of the anion-exchange resin Amberlite IR-120 (H-form) are placed onto a white plate and Malachite Green is added (drop reaction). The green colouring of the resin surface observed after 10 min points to the presence of chromium; the detection limit is $1.6 \mu\text{g}$.¹³²

Iron ions are determined on the anion-exchange resin AB-17X8Cl with the detection limit of $0.01 \mu\text{g ml}^{-1}$ (see Ref. 41). Polyester fabric based on poly(ethylene terephthalate)

is used as a substrate for an array of multipurpose indicators. This procedure permits complete elimination of cross contamination of reagent paper stripes with chemical reagents from adjacent stripes.¹³³

2. Silica gel

Test methods on silica gel have attracted attention in the past decade.^{8, 34, 49, 134–140} It was found⁴⁹ that the optical characteristics of Fe(III), Cr(VI), Mn(II), Ni(II), Cu(II) and Zn(II) complexes with PAN on Silochrom C-120 are very similar to those in solution. Thus sorption of 1-(2-pyridylazo)-2-naphthol and 4-(2-pyridylazo)resorcinol (PAR) from aqueous solutions of various acidities was investigated and the conditions for the preparation of modified adsorbents with predetermined capacity with respect to azo compounds were established. Sorption of PAN and PAR on Silochroms C-80 and C-120 was studied under static conditions.¹³⁴ A procedure has been developed for the determination of the reagents in the sorbent phase. The indirect assay consists in the measurement of changes in light absorption of solutions after immobilisation. Alternatively, azo compounds are determined upon oxidation with cerium(IV) in the modified sorbent phase. Maximum modification of the silica surface is observed at pH < 3. The protonated form of PAR is the most intensively adsorbed on silica hydrated to the greatest degree. The completely dissociated form of PAR is not adsorbed by the silica surface. The degree of adsorption of PAN at pH 4.0 decreases as the proportion of acetone in the tested solution increases. At an acetone concentration of 60 vol. %, PAN is not adsorbed on silica surface. Complete adsorption of PAN with Silochrom C-120 usually takes 20 minutes.

It was found that the efficiency of sorption of azo compounds depends on the structure of the silica, its porosity and specific surface. With an increase in specific surface, sorption of the reagent increases. At lower specific surface, the greater part of the reagent diffuses into the sorbent and the pore sizes thus become critical. It was found that adsorbents with a low capacity with respect to the reagent (*e.g.*, < 25 $\mu\text{mol g}^{-1}$) are more preferable for use in test methods (see Ref. 134).

The colorimetric method was used for separate determination of Cu [(0.4–22.0) $\times 10^{-6}$ mass %] and Zn [(3.8–39.0) $\times 10^{-6}$ mass %] in natural water on PAN-modified silica.⁴⁸ Cobalt was determined with PAN immobilised on silica gel¹³⁵ using a test method based on colour discrimination by luminosity (the detection limit is 0.004 $\mu\text{g ml}^{-1}$); its quantitative determination was performed using the Gourevich–Kubelka–Munk function (the detection limit is 0.03 $\mu\text{g ml}^{-1}$). It was found that on going from diffuse reflection coordinates (ΔF) to sorbate colour coordinates (ΔL) with a test reagent, the sensitivity and reproducibility of determination of cobalt increase 4- and 1.5-fold, respectively. 4-(2-Thiazolylazo)resorcinol immobilised on silica gel was recommended¹³⁶ as the test reagent for Co(II), Pd(II) and U(VI) (the detection limits are 0.02, 0.005 and 0.03 $\mu\text{g ml}^{-1}$, respectively).

Test methods for the determination of Co(II), Cu(II) and Zn(II) with 1-(2-thiazolylazo)-2-naphthol, for the determination of Ag(I), Hg(II), Pb(II) with dithizone and for the determination of Co(II), Fe(III) and Bi(III) thiocyanates with quaternary ammonium salts on silica gels and cellulose have been developed.³⁴

The optical and colorimetric characteristics of immobilised 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol and its complexes were obtained in the analysis of sorption of indium and uranium(VI) ions on Silochrom C-120. Test methods for the determination of indium with a detection limit of 0.002 $\mu\text{g ml}^{-1}$ (see Ref. 44) and uranium with a detection limit of 0.25 $\mu\text{g ml}^{-1}$ (see Ref. 137) have been developed; subsequent determination of uranium by diffuse reflectance spectroscopy in the sorbate phase reached a detection limit of 3.5 ng ml^{-1} . The optimum conditions for the formation of uranium(VI) complexes with PAR immobilised on KU-2, foamed polyurethane and Silochrom C-120 were established as pH of 5.8–8.2 and an equilibration time of 20, 20 and 15 min, respectively. An advantage of PAR immobilised on

KU-2 is that it elicits analytical signals of greater magnitude and produces a broader plateau on the optical density versus pH of the complex solution curve. This reaction is selective in the presence of cyclohexanediaminetetraacetic acid; the detection limit is 0.1 $\mu\text{g ml}^{-1}$ (see Ref. 138).

A linear-colouristic method^{141–143} is based on the linear dependence of the length of the coloured zone of the display tube on the concentration of the tested compound. In this procedure, hydrophobic carriers, such as silica gels Diasorb-C₁₆ and Diasorb-phenyl, are modified with known analytical reagents. The dimensions of the coloured zone depend on the nature of the carrier, quantity of the adsorbed reagent, internal diameter of the display tube, flow rate and pH of the sample. By varying tube diameter, one can change the concentration range of the tested element. The detection limits for various elements vary from 10^{-8} to 10^{-6} mol litre⁻¹.

Silica gel modified with lead diethyldithiocarbamate can be used as the indicator powder for the determination of copper ions with a detection limit of 1.5×10^{-8} mol litre⁻¹ in the presence of 1000-fold excess of Ni(II), Zn(II), Cd(II) and Co(II).¹⁴¹ PAN and Xylenol Orange immobilised on silica gel are used for the determination of copper and iron.¹⁴² At equal concentrations of these ions (< 5×10^{-6} mol litre⁻¹), two differently coloured zones are formed in the tube filled with silica gel Diasorb-phenyl-PAN, *viz.*, crimson (Cu) and green (Co).¹⁴² The possibility of determination of cobalt and Fe(III) in the same sample at the MPC level with the use of a tube filled with silica gel Diasorb-C₁₆ modified with 1-nitroso-2-naphthol was demonstrated.¹⁴³ This method is characterised by ease of tube preparation and rapidity of analysis.

The possibility of direct determination of trace amounts (10^{-9} – 10^{-5} mol litre⁻¹) of heavy metals in water, soil extracts and other natural subjects by the sorption-colouristic method was considered.¹⁴⁴ Coloured zones are produced upon frontal chromatographic sorption of Hg(II), Cd(II), Pb(II), Co(II), Cu(II), Bi(III), Sb(III) and Fe(III) on microcolumns packed with cellulose and polystyrene-based ion-exchange resins modified with polar residues (*e.g.*, sulfides of zinc, cadmium and manganese as well as hexacyanoferrates of calcium and lead) and organic reagents.

3. Foamed polyurethanes and membranes

The polymeric matrix of foamed polyurethanes, which have a membrane structure, contains both polar groups and hydrophobic fragments. This makes foamed polyurethanes helpful tools in test methods for the determination of metal cations, polycyclic hydrocarbons, phenols, heteropolyacids, surfactants and other compounds.^{93, 123, 138, 145}

A number of test reactions on foamed polyurethane carriers have been developed for determination of several elements (the colour scale ranges, Δc , are indicated):

Element	Cr	Ni	Co	Ti	Fe
$\Delta c / \text{mg litre}^{-1}$	0.1–1	0.1–40	0.04–6	0.01–0.5	0.004–0.6

1,5-Diphenylcarbazide and dimethylglyoxime are used for the determination of chromium and nickel, respectively; potassium thiocyanate is used for the determination of cobalt, titanium and iron.⁹³

Immobilisation of chitosan HRP on foamed polyurethane gives a more active and stable sorbent than on a polystyrene plate or on paper. Oxidation of *o*-dianizidine proved to be the most efficient indicator reaction which made it possible to decrease the detection limit for mercury to 25×10^{-3} ng ml^{-1} . The rate of the indicator reaction is monitored visually by fixing the moment of appearance of red-coloured oxidation product. Thiourea was used to enhance the inhibitory effect of mercury. This method is not only highly sensitive, but also highly selective: only 10^5 -fold excess of Cd(II), Pb(II) and Bi(III) interfere with the determination.¹²³

Optimum conditions were established for complexation of uranium(VI) with PAR immobilised on foamed polyurethane,

KU-2 and Silochrom C-120. The detection limit is $0.1 \mu\text{g ml}^{-1}$ (see Ref. 138).

Test methods employing poly(vinyl chloride) and caprone membranes were recommended for the determination of Hg(II), Ag(I), Cu(II), Au(III), Pd(II) and Pt(IV) in the presence of at least a 10-fold excess of Fe(III), Ni(II), Co(II), Zn(II), Cd(II), Be(II), Al(III) and alkaline-earth metals with detection limits from 1 to $15 \mu\text{g litre}^{-1}$. Immobilised azorhodanines and Sulfonitrophenol M were used as reagents.⁸⁵

A highly sensitive field test for the determination of chromium(VI) in water at the level of $< 1 \mu\text{g litre}^{-1}$ is based on the formation of a coloured chromium complex with 1,5-diphenylcarbazide in 0.1 M sulfuric acid and its sorption on an ion-exchanger incorporated into the membrane.¹⁴⁶ The intensity of coloration is proportional to the chromium concentration in the range from 0.05 to $50 \mu\text{g litre}^{-1}$. In 50-ml samples, chromium is determined with a detection limit of 10 ng litre^{-1} .

4. Fibrous materials filled with ion-exchange resins

Fibrous filled materials are perfect carriers for visual assays. They allow for simultaneous concentration and determination of tested elements as well as for variation in the nature of the adsorbent depending on a concrete experimental task. The tested ions may first be adsorbed on original, colourless materials and are then 'developed'. Alternatively, adsorbents with immobilised reagents can be used. Carriers can be used under both static and dynamic conditions; they are resistant to mechanical and chemical actions.

Fibrous materials filled with ion-exchange resins and fabrics with ionogenic groups are used as carriers in visual determinations of metal ions using known colour reactions with organic reagents.^{69, 74, 99, 147–151} The tested element is selectively concentrated on a solid phase; the use of highly sensitive and highly selective reagents facilitates its determination in drinking water at the MPC and lower levels.

In addition to remarkable kinetic properties (*e.g.*, ease of sorption and high filtration rates), fibrous materials endowed with

ion-exchange properties manifest high stabilities in aggressive media. Therefore they can be used for sorption and determination of metal ions under drastic conditions in the presence of large concentrations of masking substances and in highly acidic media. These materials are distinguished by handling convenience, are easily transferred with pincers and do not lose their shape upon stirring, heating in solution, drying, *etc.*

Express tests are based on colour reactions of metal ions with reagents on a solid phase. Fibrous materials filled with ion-exchange resins used as carriers and fabrics with ionogenic groups in the form of discs 1–2 cm in diameter serve not only as the reaction sites but also as sorbents for the concentration of tested ions (and thus increasing the sensitivity of the reaction) and their separation from ballast substances. The use of carriers containing specific groups allows one to lower the detection limit and to increase the selectivity. In addition, these express methods employ well-known, organic reagents that have proved to be efficient in photometric assays and are commercially available which significantly simplifies their introduction into routine analytical practice.

The analytical procedure is simple and easily accessible. Reagent solutions are added dropwise to a tested solution (10 ml) to ensure optimum sorption conditions after which the carrier disc is introduced. The solution is agitated for 5–7 min and then decanted with the disc held back by a glass rod. One to three drops of the reagent solution are dripped onto a colourless unmodified disc and the colouring of the disc is compared with the calibration colour scale obtained under identical conditions. In some cases, the scale, enclosed in a polyethylene film, is preserved for a sufficiently long period of time. Carrier discs can be regenerated with acids and re-used after washing with water. Some characteristics of modern test methods for visual assessment of metal ions utilising fibrous materials filled with ion-exchange resins and fabrics with ionogenic groups are summarised in Table 2.

Table 2. Some characteristics of test methods for the determination of metal ions which utilise fibrous materials as a solid phase.

Ion (I)	Fibre (fabric)	Sorption conditions	Detection conditions	Selectivity factor		Change in disc colour	Colour scale /mg litre ⁻¹	MPC /mg litre ⁻¹	Ref.

Co(II)	F(II)	pH 5–6, acetate buffer	PAN	Fe(III), Mn 100 Cu, Zn 10 Ni 5		orange → green	0.05–0.5	0.1	99

Studies with two or three elements or with one element in different oxidation states are being developed during the past decade. For example, both Cr(VI) and Cr(III) ions can be determined following oxidation of Cr(III) by heating with ammonium persulfate in 0.05 M H₂SO₄ followed by decomposition of the excess of the oxidant by boiling with subsequent sorption of Cr(VI) ions on discs prepared from fibres filled with an anion-exchange resin and their detection with 1,5-diphenylcarbazine, which gives a pink coloration. The solution is divided into two parts one of which is used for the determination of only Cr(VI) ions and the other one, for the determination of both Cr(III) and Cr(VI) ions after which the concentration of Cr(III) ions is determined from the difference between the two measurements.⁹⁹

If uranium(VI) and thorium(IV) are present in solution in 1 : 3 to 3 : 1 ratios, they can be determined in the same sample with Arsenazo III in the presence of a 3-fold excess of zirconium. Sorption is performed from a carbonate medium in the presence of ethylenediaminetetraacetic acid; the assay is carried out after acidification with 6–7 M HCl. The overall concentration of uranium and thorium is determined judging from the coloration of wet discs; thorium is determined judging from the coloration of dried discs. The coloration of the uranium complex with Arsenazo III disappears upon drying due to a decrease in acidity.¹⁵⁰

V. Conclusion

At present, the detection limits for metal ions attainable using sorption-spectroscopic and test methods reach 10⁻³–10⁻² mg litre⁻¹. Enzymic test methods provide an exception,

for they allow measurements of up to 10⁻⁵ mg litre⁻¹. However, by reason of high complexity of these reactions, the reproducibility of experimental results is rather low. In some cases, sorption-spectroscopic methods allow for a detection limit of 10⁻⁴ mg litre⁻¹.

As can be judged from the increasing number of publications, these methods are extensively developing along several different lines. The range of tested elements and carriers is expanding and novel procedures for the detection of analytical signals (*e.g.*, colorimetry, derived photometry, flow-injection analysis, *etc.*) evolve. New steps are having made on the road to multielement assays.

The equipment for sorption-spectroscopic assays is also being improved. The use of small-size instruments allows a more objective estimation of experimental results, on the one hand, though this increases the cost of assays on the other hand. Test methods intended for routine and versatile uses present particularly great interest in those cases where the most reliable tool is the human eye, especially because sometimes it detects differences in colour much better than any device. In this context, the simplest, easiest, highly contrasting and safe systems provide the most efficient test methods. Sometimes, the sensitivity and accuracy of sorption-spectroscopic methods is one order of magnitude higher than those of test methods. When these methods are used simultaneously, the concentration of toxic elements can be assessed by test methods; more accurate concentration measurements are accomplished by sorption-spectroscopic methods.

Modern test methods allow detections at the MPC level. Some ions, *e.g.*, mercury, selenium, cadmium, *etc.*, having detection

limits below 10^{-3} mg litre $^{-1}$ present a problem. However, the main problem involved in sorption-spectroscopic and test methods is selectivity. In order to increase selectivity, one should make the carrier resistant to aggressive media, such as acids, alkalis, masking complexing compounds, oxidants and reducing agents used to eliminate the interfering effects of ballast components. There must also be a possibility to vary the nature of the carrier in order to increase the sorption of the tested ions and to prevent the sorption of ballast components.

In our opinion, ion-exchange materials have indisputable advantages over paper, membranes, silica gel and other materials. They are characterised by high mechanical and chemical stabilities, high capacity and good kinetic properties, which allows for a significant decrease in the detection limit by increasing the volume of the tested solution in those cases where the sensitivity of a colour reaction is not high enough. The array of active ionogenic groups is rather broad.

The use of fibrous ion-exchange materials eliminates such disadvantage of ion-exchangers as friability and ensures easy drying, washing and other procedures without any detriment to the carrier surface. This increases the reproducibility of experimental results and simplifies the automation of analysis. The use of fibrous materials filled with ion-exchange resins permits one to combine selective concentration of an element with its selective determination and thus solves the problem of selectivity, lowering of the detection limit and rapidity of analysis. In this sense, too, these materials hold much promise.

Recent trends in the development of sorption-spectroscopic and test methods are towards further improvement of assay methodology and synthesis of novel reagents and updating of the existing ones aimed at their use in combination with the solid phase. Some reagents often lose their ability to form complexes upon immobilisation on the carrier. The broadening of the range of carriers and their potentials, variation of the nature and degree of dispersion and filling of carriers may help to solve numerous problems connected with the increase in the sensitivity and selectivity of analytical methods. And, finally, it is necessary to update the existing mini-instruments and to design new ones including those which utilise fibre optics, flow-through cells and mini-computers providing for rapid analysis in an automated regime. This will favour progress in the design of sorption-spectroscopic and test methods and their application in the analysis of natural and industrial materials and environmental subjects.

Naphthyridines. Structure, physicochemical properties and general methods of synthesis

V P Litvinov, S V Roman, V D Dyachenko

Contents

I. Introduction	201
II. Physicochemical properties	201
III. The reactivity of naphthyridines	202
IV. General methods for the synthesis of naphthyridines	207
V. Conclusion	218

Abstract. Data on the synthesis, chemical properties and applications of naphthyridines published mainly over the last 15 years are described systematically and analysed. The bibliography includes 238 references.

I. Introduction

Naphthyridines (pyridopyridines, diazanaphthalenes) represent a group of six isomeric heterocyclic systems containing two fused pyridine rings with different mutual arrangements of nitrogen atoms. They include two groups of compounds — N(1),N(*i*)-naphthyridines (*i* = 5, 6, 7, 8) **1–4** and N(2),N(*j*)-naphthyridines (*j* = 6, 7) **5, 6**.

1,5-naphthyridine

1,8-naphthyridine

1,6-naphthyridine

1,7-naphthyridine

2,7-naphthyridine

2,6-naphthyridine

The first derivative of the cyclic naphthyridine system was obtained in 1893 by Reissert,¹ who proposed this name for the new class of heterocyclic compounds. The first representatives of unsubstituted naphthyridines — 1,5-naphthyridine **1**² and 1,8-naphthyridine **2**³ — were described only in 1927. Naphthyridines containing nitrogen atoms at positions 1,6 (**3**),⁴ 1,7 (**4**),⁵ and 2,7 (**5**)⁶ were prepared in 1958, and 2,6-naphthyridine (**6**)^{7,8} was synthesised only in 1965. Since then, researchers have shown ever increasing interest in the chemistry of naphthyridines. Indeed, the bibliography of a review⁹ published in 1950 included 75 references, while that of a review¹⁰ which appeared in 1970

comprised 242 references. More recent reviews^{11,12} (1983) present 223 studies. Several reviews dealing with more specific aspects were also published before 1983.^{13–22} In recent years, the number of publications devoted to various aspects of naphthyridine chemistry has sharply increased. More than 1000 publications have appeared during the last 15 years, 40% of them being patents.

This interest in naphthyridine derivatives is due to the exceptionally broad spectrum of their biological activities. They are used for the diagnostics and therapy of diseases of humans including AIDS; for combating exo- and endo-parasites in agriculture and in cattle breeding; as preservatives and ingredients of cutting fluids, as ligands in analytical chemistry, etc.

This review mainly surveys the data published over the last 15 years; however, earlier fundamental studies are also invoked in the discussion of structures, physicochemical properties and reactivities of naphthyridines.

II. Physicochemical properties

1. Structure

X-Ray diffraction study was first performed for unsubstituted 1,5- (**1**) and 2,6-naphthyridines (**6**).^{10,23,24} It was found that transition from pyridine to naphthyridines is accompanied by shortening and lengthening of C–C bonds approximately equal to that observed on passing from benzene to naphthalene. In addition, the N–C bonds in naphthyridines were found to be shorter than these bonds in pyridine. X-Ray diffraction analysis was also used to determine the structures of several naphthyridine derivatives, **1**, **2**, **4** and **6**.^{25–37}

2. Quantum-chemical calculations

Since the 1950s, quantum chemistry methods have been used to elucidate structure–property relationships in the naphthyridine series.^{38–57} The intensities of bands in the UV spectra of naphthyridines have been found to be correlated with the energies of lower unoccupied molecular orbitals;^{38–40} quantum-chemical calculations have also been used in the ¹H and ¹³C NMR spectroscopy^{47–51} and for comparison of the total π -energy and delocalisation energy for naphthyridines and naphthalene.^{41,43} Other results include determination of π -electron distribution;^{43,44} elucidation of correlations of the total π -electron energy with specific features of electrophilic⁴³ and nucleophilic^{43,44} substitution and with the hyperfine splitting constants in the EPR spectra.⁴⁷

In recent years, quantitative structure–biological activity relationships for 6-[2-(4-arylpiperazino)ethyl]-5,6,7,8-tetrahydro-

Received 16 September 1999

Uspekhi Khimii 69 (3) 218–238 (2000); translated by Z P Bobkova

1,6-naphthyridines have been established⁵³ and complexes of antitumour antibiotics — naphthyridinomycins — with DNA have been studied by molecular modelling methods.⁵⁴

3. Spectroscopy

Spectroscopic techniques (UV, IR, ¹H and ¹³C NMR) are widely used not only to identify naphthyridines but also to elucidate fine points concerning their structures.^{10, 12}

Thus it has been found that the UV spectra of 1,5-, 1,6-, 1,7- and 1,8-naphthyridines **1–4** are fairly similar to one another and contain three separate groups of bands, analogous to the bands displayed in the spectra of quinoline and isoquinoline. However, the spectra of 2,7- and 2,6-naphthyridines **5** and **6** differ both from each other and from the spectra of any other naphthyridines.^{10, 58} The UV spectra of 4-hydroxy-1,5-naphthyridine⁵⁹ and of a large number of substituted 1,8-naphthyridines⁶⁰ have been analysed in detail. In order to disclose the influence of substituents on the absorption spectra, UV spectra of 1,8-naphthyridines monosubstituted at position 2 (Me, Cl, Br, OMe, OEt, SMe, NH₂, OH, SH), position 3 (Me, Cl, Br, NO₂, NH₂) and position 4 (Me, Cl, Br, OMe, OEt, OH, SH) have been studied.⁶¹

Transmission and absorption spectra of 1,8-naphthyridine **2** in the range of 50 000–20 000 cm^{−1} have been investigated in solutions and in various mixed crystals at 4.2 and 300 K.⁵² The pattern of the band corresponding to the $\pi \rightarrow \pi^*$ transition was found to be similar to that observed in the spectrum of the related naphthalene molecule with allowance for perturbations induced by the replacement of carbon by nitrogen. The position of the long-wavelength $\pi \rightarrow \pi^*$ band at about 27 000 cm^{−1} complies with the theoretical predictions based on extended Hückel calculations. The bands at about 31 600–31 900 cm^{−1} were assigned empirically to the second $n \rightarrow \pi^*$ transition.⁵²

All bands in the IR spectra of several substituted 1,5-naphthyridines have been assigned; the spectrum of 1,5-naphthyridine **1** was compared with the spectrum of 5-substituted quinoline.⁶² IR spectroscopy was used to study the keto–enol tautomerism of 4-hydroxy-1,5-naphthyridine in solution and in the solid state; it was found that the keto form predominates in polar solvents and the enol form, in nonpolar solvents.⁵⁹

Study of the IR and Raman spectra of 1,6- and 1,8-naphthyridines permitted the assignment of all 42 fundamental vibrations of these two heterocyclic systems.⁶³

Data on the ¹H NMR spectra (chemical shifts and spin–spin coupling constants) for the naphthyridines **1–4** and **6** can be found in the literature.^{7, 8, 10, 12, 42, 43, 49–51, 64–77} The chemical shifts observed in the ¹³C NMR spectra of the naphthyridines **1–6** were compared with those for quinoline and isoquinoline.^{12, 49–51} The resonance signals in the ¹H NMR spectrum of 2-(2'-pyridyl)-1,8-naphthyridine were completely assigned using homonuclear 2D NMR spectroscopy.⁷⁵

The behaviour of derivatives of the isomeric naphthyridines **1–4** under electron impact has been studied and the main fragmentation pathways have been identified.^{10, 78–80} The structures and destruction pathways of the isomeric ions [M–HCN]^{−•} and [M–2 HCN]^{−•}, resulting from fragmentation of the naphthyridines **1–4** and benzazines, were studied using collisional activation.⁸¹ It was found that the [M–2 HCN]^{−•} ions can exist as two isomers, one of them being characteristic of naphthyridines and the other being characteristic of benzazines.

High-resolution photoelectron spectra of the naphthyridines **1–6** have been described.⁸² The ionisation potentials for the n and π orbitals are listed in Table 1.

Polarised phosphorescence spectra of 1,5-naphthyridine **1**^{83–85} and the EPR spectrum of 1,6-naphthyridine **3** were recorded.⁸⁶

A number of publications deal with the capacity for ionisation (including the pK_a values) of the naphthyridines **1–4** and their derivatives.^{10, 58, 70, 87–91}

Table 1. Ionisation potentials (eV) of naphthyridines **1–6**.⁸²

III. The reactivity of naphthyridines

Reactions of naphthyridines including electrophilic substitution (bromination, nitration), nucleophilic substitution (amination, metallation), reduction, oxidation, complexation, *etc.*, have been considered fairly comprehensively in reviews.^{10, 12} In yet another review, attention is focussed on the reactivity of naphthyridines towards N-nucleophiles.¹¹ Here we survey the data on the reactivity of naphthyridines published over the last 15 years.

Electrochemical reduction of the naphthyridines **1–6** has been reported.^{92, 93} On exposure to UV radiation in the presence of sodium nitrite, 3-amino-1,6-naphthyridine-4(1*H*)-one eliminates a nitrogen molecule being thus converted into 5-azaindole-3-carboxylic acid.^{94, 95}

Nucleophilic substitution of bromine at position 4 in 3,4-dibromonaphthyridines **7a–c** on treatment with a saturated alcoholic solution of ammonia in an autoclave affords 4-amino-3-bromo-N(1),N(*i*)-naphthyridines **8a–c**.⁹⁶

$i = 5$ (**a**), 6 (**b**), 7 (**c**).

The naphthyridine derivatives **9a–c**, possessing fungicidal activity, have been synthesised using nucleophilic substitution of the halogen atoms in isomeric halo naphthyridines. These products can also be employed for combating exo- and endo-parasites in agriculture and cattle breeding, for wood protection, and as preservatives for paints, varnishes and cutting fluids during metal working.⁹⁷

$i = 5$ (**a**), 6 (**b**), 7 (**c**); X = O, S, SO, SO₂; Y is alkenyl or a single bond; R is cycloalkyl or piperidin-2-yl.

In recent years, nucleophilic addition reactions have been widely used for the synthesis of various derivatives of isomeric naphthyridines. For example, nucleophilic addition of indole to 1,5-, 1,6- and 1,8-naphthyridine derivatives in the presence of

benzoyl chloride in toluene or DMF yields, depending on the temperature and reactant ratio, hydrogenated mono- (**10**–**12**) or bis-(3-indolyl)naphthyridines **13**–**18**.^{98–100} Hetarylation includes the *in situ* formation of *N*-acyl heteroaromatic cations and the addition of nucleophiles to them. Aromatisation of the *N*-acylated hydrogenated naphthyridine derivatives **13** and **14** on treatment with tetrachloroquinone affords the same compound, naphthyridine **19**.

Refluxing of *N*(1),*N*(*i*)-naphthyridin-4(1*H*)-ones **20a–d** in DMSO gives rise to 1-methylthiomethyl naphthyridine derivatives **21a–d**, which depress microbial growth.^{100–103} Similar methylthiomethylation of naphthyridin-2(1*H*)-ones **22a–d** has resulted in *N*-substituted *N*(1),*N*(*i*)-naphthyridin-2(1*H*)-ones **23a–d**.¹⁰⁴

i = 5 (**a**), 6 (**b**), 7 (**c**), 8 (**d**); R^1 = H, Me; R^2 = H, CO₂H, CO₂Et.

Regioselective alkylation of quinuclidinopyridine-2(1*H*)-thiones **24**, containing a 1,5-naphthyridine fragment, with 3-bromocyclohexene or allyl bromide in the presence of a base affords the corresponding 2-(cyclohex-2-enylthio)- (**25**) and 2-allylthio-derivatives **26**. Halogen-induced quaternisation of these products is a synchronous process yielding salts **27** and **28** with high regio- and stereoselectivity.^{105–108}

X-Ray diffraction analysis has shown that the pyridine nitrogen atom in the compound **25** has a short non-valence contact with the C=C bond of the cyclohexene fragment. The close arrangement of these reaction sites is favourable for synchronous cyclisation in intermediate **29** involving the H^a, H^b and H^b, H^c systems of protons. The high stereoselectivity of this reaction is apparently due to the synchronism of the action of the donor (*i.e.* the lone electron pair of the naphthyridine nitrogen atom) on the π -electrons of the cyclohexene double bond and electrophilic rupture of the double bond, which are followed by quaternisation. Thus the H^b and H^c protons occupy *trans*-positions. This intramolecular electrophilic quaternisation of the compound **25** can be regarded as synchronous *trans*-quaternisation with *cis*-annulation.¹⁰⁸

2-Cyanomethylthio derivatives **30**, prepared by alkylation of the compounds **24** with chloroacetonitrile, cyclise under conditions of the Thorpe–Ziegler reaction to give the corresponding thieno[2,3-*b*]pyrido[3,2-*e*]quinuclidines **31**, containing a 1,5-naphthyridine fragment.¹⁰⁷

R = H, Ph, 4-FC₆H₄;

(a) ClCH₂CN, KOH, DMF, 25 °C, 3 h; (b) OH[−]; (c) H⁺.

Similar treatment with sodium ethoxide of thioethers **32**, prepared by the reaction of 1,2,5,6,7,8-hexahydro-1,6-naphthyridine-2-thiones with halo ketones, esters, amides or nitriles, resulted in the synthesis of thieno[2,3-*b*]-1,6-naphthyridines **34**.¹⁰⁹

R = MeCO, PhCO, EtO₂C, CONH₂, CONHPh, CN, CONHC₆H₄Me-4, CONHC₆H₄OMe-4, CONHC₆H₄COMe-4.

The reaction of 6,7,8*a*-trimethyl-1-oxo-3-thio-1,2,3,5,6,7,8,8*a*-octahydro-2,7-naphthyridine-4-carbonitrile (**35**) with 4-bromophenacyl bromide or *N*-cyanochloroacetamide in the presence of a base gives thieno[2,3-*c*]-2,7-naphthyridines **36**.¹¹⁰

Hal = Br, Z = 4-BrC₆H₄CO; Hal = Cl, Z = C(NH₂)NCN.

Cyclocondensation of 3-ethoxycarbonylmethylthio-2,7-naphthyridine **37** on heating in anhydrous ethanol in the presence of an equimolar amount of sodium ethoxide affords thienonaphthyridine **38**. The dihydrochloride of the compound **38** possesses a mutagenic activity.¹¹¹

Mor is morpholin-1-yl.

Treatment of 1-methyl-N(1),N(*i*)-naphthyridinium iodides **39a,b** with liquid ammonia in the presence of potassium permanganate gives rise to mixtures of imino (**40a,b**) and oxo (**41a,b**) derivatives of dihydronaphthyridines and vicinal methylamino-pyridinecarboxamides **42a,b**.¹¹²

X = N, Y = CH (a); X = CH, Y = N (b).

Unlike compounds **39a,b**, 7-methyl-1,7-naphthyridinium iodide **43** and 6-methyl-1,6-naphthyridinium iodide **44** react with liquid ammonia and KMnO₄ with ring contraction as the predominant reaction pathway yielding 4-azaindole derivatives **45–48** together with the oxo derivatives of the corresponding dihydronaphthyridines **49** and **50**. Study of the ¹H NMR spectra showed that on treatment with liquid ammonia in the absence of potassium permanganate, the compounds **43** and **44** are converted into amino derivatives **51** and **52**.¹¹³

(a) NH₃ (liq), KMnO₄, –33 °C; (b) OH[–]; (c) NH₃ (liq).

When 3,6-dinitro-1,8-naphthyridine **53** or 6-*R*-1-ethyl-3-nitro-1,8-naphthyridin-2(1*H*)-ones **54** are made to react with a solution of potassium permanganate in liquid ammonia at –33 °C, amination proceeds giving rise to the corresponding 4-amino derivatives **55** and **56**. The intermediate formation of σ -adducts **57** and **58** was detected by ¹H NMR spectroscopy.^{114,115} It was also shown that 1-ethyl-3-nitro-1,8-naphthyridin-4-one is not aminated under these conditions.¹¹⁵ However, treatment of 1,8-naphthyridine derivatives **59a,b** with liquid ammonia at –45 °C affords 4-amino-1,4-dihydro-3,6-dinitro-2-*R*-1,8-naphthyridines **60a,b**. The compound **59c** was converted into a mixture of the naphthyridine **60c** and isomeric 5-amino-2-ethoxy-3,6-dinitro-5,8-dihydro-1,8-naphthyridine **61**.¹¹⁶

R = H, NO₂.

$R = OH$ (a), NH_2 (b), OEt (c).

2-Nitro-N(1),N(i)-naphthyridines **62a-c** undergo replacement of the nitro group rather than amination on treatment with a solution of potassium permanganate in liquid ammonia; this gives the corresponding 2-aminonaphthyridines **63a-c**, although their yields are relatively low. These products react with DMSO and trifluoromethanesulfonic anhydride giving rise to *S,S*-dimethyl-[N(1),N(i)-naphthyridin-2-yl]sulfylimines **64a-c**.¹¹⁵

$i = 5$ (a), 6 (b), 8 (c);

(a) NH_3 (liq), $KMnO_4$, $-33^\circ C$; (b) DMSO, $(CF_3SO_2)_2O$.

The kinetics of *N*-methylation of benzonaphthyridines **65a-d** with methyl iodide in DMSO have been studied.¹¹⁷ It was shown that the salt **66**, formed from the naphthyridine **65b**, slowly dimerises in a 10% aqueous solution of DMSO to give compound **67**.

$i = 5$ (a), 6 (b), 7 (c), 8 (d);

(a) $i = 6$, MeI, $MeCO_2Et$, Δ , 0.5 h; (b) DMSO– H_2O (1:9), 10 h.

The methyl group in benzo[2,3]naphthyridines **65a-d** can be easily modified. Thus refluxing of these compounds with SeO_2 in chloro-, 1,2-dichloro- or 1,2,4-trichlorobenzene gives aldehydes **68a-d**, which serve as the starting compounds for the synthesis of diverse functional derivatives of benzonaphthyridines.^{118–120} Oxidation of the compounds **65a-d** to the aldehydes **68a-d** and further oxidation to the corresponding acids are the key stages of the synthesis of compounds **71–75**, which are the aza analogues of

the potential antitumour preparation, *N*-[2-(dimethylamino)-ethyl]acridine-4-carboxamide.^{118–120}

$i = 5$ (a), 6 (b), 7 (c), 8 (d); (a) $i = 6$, $NaClO_2$; (b) $i = 7$, Ag_2O ; (c) $i = 5$; (d) $i = 8$, $NaClO_2$.

The aldehydes **68a-d** can be oxidised using Ag_2O , $NaClO_2$, $K_2Cr_2O_7$, etc.; oxidation can proceed to different extents depending on the structure of the initial compound and the reagent employed. For instance, oxidation of the aldehyde **68b** with $NaClO_2$ involves the central ring and gives oxo acid **69b**. The oxidation of the aldehyde **68c** with Ag_2O affords acid **70c** as the only product. The aldehyde **68a** is oxidised by Ag_2O to **70a** but the reaction does not proceed to completion, up to 10% of the starting compound being recovered unchanged. The reaction of the aldehyde **68d** with $NaClO_2$ yields a mixture of acids **69d** and **70d**. The oxo acids **69a-d** are also produced upon oxidation of **68a-d** with $NaClO_2$ in Bu^iOH .

Further modification of the acids **69** and **70** includes reactions of the carboxy group with 2-(*N,N*-dimethylamino)ethylamine and nitration of the benzene ring. Thus compounds **74** and **75** were prepared by oxidation of the methyl group in nitro derivatives **76** followed by modification of the acids **77** and **78** formed (Scheme 1).

Dipolar 1,3-cycloaddition of various dienophiles to benzo[3,4]naphthyridinium ylides **79–81**, generated *in situ* by dehydrobromination of the corresponding quaternary salts, has been studied; this gives rise to benzo[*h*]pyrrolonaphthyridines **82–88** (Scheme 2).^{121–126} The compounds **82–84** exhibit bactericidal activities.^{124, 125}

The dipolar 1,3-cycloaddition of *N*-dichloromethylides **89–91**, generated *in situ* from the corresponding benzo[*h*]naphthyridines **92–94** and dichlorocarbene¹²⁷ (produced from CCl_3CO_2Na on heating or from $CHCl_3$ in the presence of a base and $Et_3BnN^+Cl^-$), to dimethyl acetylenedicarboxylate is less selective; only the ylide **89** is converted into the corresponding adduct **95** in 52% yield. In the case of **90** and **91**, the reaction gives a mixture of dipolar 1,3-addition products **96** and **97** and bisadducts **98** and **99** (Scheme 3). Quaternisation of naphthyridines **92–94**^{128–130} (the compounds **92** and **93** were prepared by the Skraup method¹²⁸ and **94** was synthesised by photocyclisation of diazastilbene¹³¹) induced by alkyl, aryl or benzyl halides gave

quaternary salts **100–102**. The salts **101**, **102** exhibit bactericidal and fungicidal activities.¹²⁸

$\text{R} = 2,4\text{-(NO}_2)_2\text{C}_6\text{H}_3$, $\text{H}_2\text{C=CHCH}_2$, Bn , $\text{Me}(\text{CH}_2)_9$; $\text{X} = \text{Cl}$, I .

In order to elucidate the influence of the structure of benzo[*h*]-naphthyridines on their reactivity, charge distributions, excitation energies, and the oscillator strengths for the molecules **92–94** and their amino derivatives have been calculated. The calculation was carried out by a semiempirical self-consistent field method in the Pariser–Parr–Pople π -electron approximation with allowance for the configurational interaction between singly excited states and by the Hückel method. The results are in satisfactory agreement with the data of the UV spectra.¹³² The populations of the atomic π -orbitals, the order of π -bonds and the frequency and oscillator strengths for three electron transitions in the molecules of the naphthyridines **92–94** and their salts **100–102** were also calculated. By comparing the calculated and experimental spectra, correlation coefficients for the relation $\nu_{\text{calc}} = a\nu_{\text{exp}} + b$ were determined.¹³³

tives. A similar mixture of reaction products is also formed when POBr_3 reacts with 1,5-naphthyridine bis(*N*-oxide).¹³⁵

$i = 5$ (a), 8 (b).

Carboxylic acid derivatives **104** of the pyrrolonaphthyridine series — potential preparations for treatment of degenerative, ischemic, and autoimmune diseases — have been synthesised using intramolecular cyclisation of ethyl (3-ethoxycarbonylnaphthyridin-4-ylamino)acetates **105** induced by potassium *tert*-butoxide in a toluene– Bu^tOH mixture.¹³⁶

(a) Bu^tOK , PhMe, Bu^tOH , 20 h.

The reaction of naphthyridinecarboxylic acids **106** with guanidine in the presence of carbonyldiimidazole in anhydrous THF results in heteroylguanidines **107**, which can be used for the therapy of heart diseases, for surgical operations and organ transplantation, for the diagnostics and treatment of hypertension and proliferative diseases.¹³⁷

$\text{R}^1, \text{R}^2 = \text{H}, \text{Hal}, \text{Alk}, \text{alkenyl}, \text{alkynyl}, \text{CN}, \text{AlkF}$;
 $\text{R}^3, \text{R}^4 = \text{H}, \text{Hal}, \text{Alk}, \text{AlkF}, \text{AlkO}, \text{Alk}_2\text{N}, \text{CON}=\text{C}(\text{NH}_2)_2$ or none;
 $\text{X} = \text{N}, \text{Y} = \text{C}; \text{X} = \text{C}, \text{Y} = \text{N}$.

IV. General methods for the synthesis of naphthyridines

General synthetic methods used to prepare various types of naphthyridine include the Skraup, Friedlander and some other name reactions; cyclisation, cyclocondensation, dimerisation reactions, *etc.*

1. The Skraup method and its modifications

The Skraup reaction was first employed to synthesise unsaturated 1,5-naphthyridine **1** from 3-aminopyridine in the late 1920s.^{2, 138, 139} Subsequently this reaction and its modifications have been successfully used to prepare other naphthyridines and their derivatives.^{9, 10, 12}

Recently 1,6-naphthyridine **3** has been prepared by the Skraup method, namely, by heating (135°C , 48 h) of 4-aminopyridine with glycerol, fuming sulfuric acid and nitrobenzene.¹⁴⁰

In recent years, a modified Skraup reaction (20% oleum, nitrobenzene, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, H_3BO_3) has been used to synthesise fused naphthyridines. Thus 3-aminobenzo[*f*]quinoline **108** was converted in this way into naphtho[2,1-*b*]-1,5-naphthyridine **109**.¹⁴¹ Similarly 2-aminobenzo[*h*]quinoline **110** was transformed into a mixture of naphthonaphthyridines **111** and **112** (yields 6.8% and 4.5%, respectively), and 3-aminobenzo[*g*]quinoline **113** gave rise to naphthonaphthyridine **114** (yield 4.2%). The naphthonaphthyridines **111** and **114** were also prepared from hydrogenated benzoquinolines **115** and **116**. Intermediates **117** and **118** were dehydrogenated by treatment with dichlorodicyanoquinone and palladium supported on carbon, respectively. In this case, the overall yields of products were substantially higher.¹⁴²

A modified Skraup method, namely, the reaction of 4-aminoisoquinoline **119** with methyl vinyl ketone in the presence of As_2O_5 and concentrated sulfuric acid, was used to prepare 4-methylbenzo[c]-1,5-naphthyridine **120** in 36% yield.¹⁴³ A similar reaction of 3-aminoquinoline **121** with crotonaldehyde or methyl vinyl ketone results in 2-methyl- (**122**) or 4-methyl-benzo[*f*]-1,7-naphthyridine **123**. Oxidation of the compounds **120**, **122** and **123** on treatment with SeO_2 in dioxane yields aldehydes **124**–**126**.

(a) $\text{CH}_2=\text{CHCOMe}$; (b) $\text{MeCH}=\text{CHCHO}$.

2. The Friedlander reaction in the synthesis of naphthyridines

The condensation of vicinal aminopyridinecarbaldehydes **127** with malononitrile in ethanol in the presence of a base (according to the Knoevenagel reaction pattern) furnished 2-amino-3-cyano- $\text{N}(1),\text{N}(i)$ -naphthyridines **128a–d**; some of them were found to be effective diuretics.^{144, 145} The condensation of the aldehydes **127** with creatinine in ethylene glycol affords imidazo[4,5-*b*]- $\text{N}(1),\text{N}(i)$ -naphthyridines **129a–d**.¹⁴⁶ The reaction of the compounds **127** with 2-methylcyclohexanone in Bu^tOH in the presence of Bu^tOK (1.5 h, refluxing) followed by dehydrogenation of the products **130a,c,d** thus formed (refluxing with Pd/C in Ph_2O) gives rise to benzo[*b*]- $\text{N}(1),\text{N}(i)$ -naphthyridines **65a,c,d**. Using the Friedlander reaction, naphthyridines **131** have been synthesised; they are active components of herbicide formulations.^{147, 148} Benzo[*b*]-1,6-naphthyridine **65b** has been prepared by condensation of the amino acid salt **132** (obtained from 7-methylisatin **133**)

i = 5 (a), 6 (b), 7 (c), 8 (d).

with *N*-benzylpiperidone (KOH, 0.5 h, < 40 °C; refluxing, 20 h) followed by dehydrogenation of the reaction product **134**.^{117–119}

3. Condensation of aminopyridines with diethyl ethoxymethylidenemalonate

As in the previous cases, the use of condensation of aminopyridines with diethyl ethoxymethylidenemalonate for the synthesis of naphthyridines attracts attention because it provides the possibility of synthesising diverse naphthyridines exhibiting a broad range of biological activities. Thus the condensation of substituted aminopyridines **135** with diethyl ethoxymethylidenemalonate **136** and subsequent cyclisation on refluxing of the resulting diesters of *N*-(pyridyl)aminomethylidenemalononic acids **137** gives derivatives of naphthyridinecarboxylic acids **138**, possessing antibacterial activity or serving as intermediates in the synthesis of compounds with this type of activity.^{130, 149–161}

$n = 1, 2$; $R^1 = \text{Me, EtO, EtS, F, 4-pyridyl}$; $R^2 = \text{H, cyclopropyl}$.

Naphthyridines **138** ($R^2 = \text{H}$) without substituents at nitro- gen have served as the starting compounds *en route* to pyrazolo[3,4-*c*]naphthyridines **139**, which act as modulators of benzodiazepine receptors and possess sedative and antispasmodic activities.^{162–164} The reactions of chloronaphthyridines **140** with amino acid amides afford compounds **141**, which possess anxiolytic, anticonvulsive, sedative and hypnotic activities, antimicrobial and analgesic properties; they are capable of reducing blood pressure and are used as pharmaceuticals.^{165–167}

$n = 1, 2$; $R^1 = \text{Me, MeO}$; $R^2 = \text{Ph, pyridyl, quinolyl, isoquinolyl, pyrimidyl, thiazolyl}$; (a) $(\text{COCl})_2$, MeCN, DMF, from -30 to 20 °C; (b) $R^3\text{NHNH}_2$, xylene, Δ .

(a) $R^2R^3\text{NC(O)(CH}_2)_m\text{CH(R}^4\text{)NHR}^5$; $n = 1, 2$; $m = 0-2$; $R^1 = \text{Hal, Alk, AlkO, NO}_2, \text{CF}_3$; $R^2, R^3 = \text{H, Alk, Ph, Bn}$; $R^2-R^3 = (\text{CH}_2)_x$ ($x = 4-8$); $R^4 = \text{H, Alk, Bn}$; $R^5 = \text{H, Alk}$.

The condensation of diethyl ethoxymethylidenemalonate **136** with 5-amino-2,3-dihydrofuro[3,2-*b*]pyridine **142**¹⁵⁴ or 7-amino-oxazolo[4,5-*b*]pyridine **143**¹⁶⁸ results in annulated naphthyridines **144** and **145**. 2,3-Dihydrofuro[3,2-*b*]-1,8-naphthyridine **144** shows antibacterial activity.¹⁵⁴

4. Condensation of aminopyridinecarboxylic acids and their derivatives with compounds containing an active methylene group

The condensation of vicinal aminopyridinecarboxylic acids or esters with ethyl hexanoate **146** in the presence of Bu^tOK under a nitrogen atmosphere gave *N*(1),*N*(*i*)-naphthyridin-2(1*H*)-ones **147a–c**, exhibiting antiallergic activities.¹⁶⁹

$R = \text{H, Me, Et}$; $i = 5$ (a), 7 (b), 8 (c).

Naphthyridones **148**, which are of interest as pharmacological preparations, have been synthesised by the reaction of vicinal aminopyridinecarbonitriles **149** with diethyl malonate. Alkylation of these products with ethyl monobromoacetate results in *N*-substituted compounds **150**.¹⁷⁰

(a) $\text{CH}_2(\text{CO}_2\text{Et})_2$, EtONa; (b) $\text{BrCH}_2\text{CO}_2\text{Et}$, BuOH, K_2CO_3 ; $i = 5-8$.

When diethyl malonate is made to react with ethyl 3-aminopicolinate, substituted 1,5-naphthyridine **151** is formed; it is used in the synthesis of potential antimalarial remedies.¹⁷¹

1,8-Naphthyridine-3-carboxamides **152** — starting compounds for the preparation of products with antihypertensive, antiphlogistic and antiaggressive activities — have been synthesised from 2-aminonicotinic acid and amido esters **153**. The synthesis includes the formation of the chloride and a salt of 2-aminonicotinic acid upon the reaction of **153** with POCl_3 . The subsequent reaction of these intermediates results in the C-acylated product, the condensation of which gives the compound **152**.¹⁷²

$\text{R}_2 = \text{Me}_2, \text{Et}_2, \text{Pr}_2^i, (\text{CH}_2)_5$.

5. Acylation of α -hetarylacetonitriles with halo-substituted nicotinic and isonicotinic acid chlorides

Fused azahetareno-1,7-naphthyridines **154a–158a**, containing a nitrogen atom in the bridgehead position, were obtained by the reaction of 3-bromoisonicotinic acid chloride **159** with 2-cyanomethyl derivatives of pyridine, 1-methylbenzimidazole, benzo-1,3-thiazole, quinoline or 4-methyl-1,3-thiazole followed by cyclisation of the resulting C-acylated derivatives on heating to the melting point or on refluxing in *N*-methyl-2-pyrrolidone (as shown for compound **154a** taken as an example).¹⁷³

$i = 7$ (a), 6 (b).

A similar reaction of 2-cyanomethyl derivatives of hetarenes with 4-chloronicotinoyl chloride yielded annelated azahetareno-1,6-naphthyridines **154b–158b**.¹⁷³ In this case, the intermediate C-acylated derivatives were not isolated because they easily cyclised to give **154b–158b**. 4,6-Dichloronicotinoyl chloride was used as the initial compound in this synthesis.¹⁷⁴

The product of interaction of 2-cyanomethylbenzo-1,3-thiazole with 2-chloronicotinoyl chloride cyclises on refluxing in DMF to give benzothiazolo[3,2-*a*]-1,8-naphthyridin-4-one derivative **156c**.¹⁷³

6. Photocyclisation of aminopyridines with chlorides of *ortho*-chlorinated hetarencarboxylic acids

The reaction of 3-chlorobenzo[*b*]thiophene-2-carboxylic acid chloride **160** with 2-, 3- or 4-aminopyridine **161** in benzene in the presence of triethylamine has resulted in the synthesis of amides **162**, which undergo photocyclisation (UV irradiation by a medium-pressure mercury lamp, 450 W), giving rise to naphthyridines **163**.¹⁷⁵ Deoxygenation of these products on treatment with POCl_3 followed by dechlorination of compounds **164** results in [1]benzothieno-*N*(1),*N*(*i*)-naphthyridines **165a–d**.

$i = 5$ (a), 6 (b), 7 (c), 8 (d).

Similarly, the reaction of chloride **160** with 4-amino-2-methylquinoline gave 1-methylbenzo[*h*][1]benzothieno[2,3-*c*]-1,6-naphthyridine **166**.¹⁷⁶

(a) Et₃N; (b) *hν*; (c) POCl₃; (d) Pd/C.

Photocyclisation is also one of the stages in the synthesis of naphtho[2,3-*b*]thieno-*N*(1),*N*(*i*)-naphthyridines **167a–c** and **168** from the chlorides of vicinal chloronaphtho[2,3-*b*]thiophenecarboxylic acids **169a–c** and **170**.¹⁷⁷

$i = 5$ (a), 6 (b), 7 (c).

(a) PhH, Δ, 4 h; (b) *hν* (Hg lamp, 450 W), 1% MeOH in PhH, 3 h; (c) POCl₃, Δ, 4 h; (d) 10% Pd/C, KOH, MeOH–PhH (1 : 1), 20 °C, 24 h.

7. Synthesis of naphthyridines fused to a thiophene ring

A one-stage procedure has been proposed^{178–181} for the preparation of isomeric *N*(1),*N*(*i*)-naphthyridines; the procedure includes Pd(PPh₃)₄-catalysed cross-coupling of thiopheneboronic acids **171**, **172** or **173** containing an *ortho*-formyl group with *o*-amino-hetaryl halides **174–176**. The cross-coupling products cyclise spontaneously during the reaction to give thiophenonaphthyridines **177–185** with all possible types of ring fusion. The effects of the amount of the catalyst, the nature of the base and the reaction time on the yield of the naphthyridines **178** and **181** have been studied.¹⁸⁰

R = H: X = Cl (a), Br (b); R = Ac, X = Br (c);
(a) Pd(PPh₃)₄, Na₂CO₃, DME or DMF.

(a) Pd(PPh₃)₄, Na₂CO₃, DME or DMF.

When 2-bromo-3-nitropyridine **186** is employed in the cross-coupling with formylthiopheneboronic acids **171–173**, thieno-1,5-naphthyridine 5-oxides **188–190** are produced. However, in this case, cyclisation of the cross-coupling products **191–193** proceeds on treatment with FeSO₄ in NH₄OH. Isomeric thieno-1,5-naphthyridine 9-oxides **194–196** are formed upon cross-coupling of the formylboronic acids **171–173** with 3-acetyl-amino-2-bromopyridine oxide **187**. 2-Tributylstannyl-3-formylthiophene **197** can be used in the cross-coupling with aryl halides **186** and **187** instead of arylboronic acids. A mixture of *N*-oxide isomers **190** and **196** is also formed upon oxidation of thienonaphthyridine **179** with *m*-chloroperbenzoic acid.¹⁸¹

(a) Pd(0), Na₂CO₃, DME or DMF; (b) FeSO₄, NH₄OH.

The reaction of vicinal trimethylstannyl derivatives of *tert*-butoxycarbonylaminothiophenes **198** and **199** with halo-substituted pyridinecarbaldehydes **200**–**203** in the presence of PdCl₂, CuO and bis(diphenylphosphino)butane results in fused thienonaphthyridines of all the possible types.¹⁸²

(a) PdCl₂, CuO, Ph₂P(CH₂)₄PPh₂.

The photoelectron spectra of all the thienonaphthyridine isomers have been analysed using semiempirical methods for the calculation of the ionisation energies of molecular orbitals.^{183, 184}

Cross-coupling catalysed by zerovalent palladium complexes has been employed to obtain other annelated naphthyridines. Thus the reaction of bromoaminopyridine **176** with 2-formylphenylboronic acid provided 9-methylbenzo[*c*]-1,8-naphthyridine **204**.¹⁷⁸

Cross-coupling of *o*-bromoacetanilides **205** with trimethylstannylpyridyl ketones **206** in the presence of PdCl₂ and CuO in DMF affords benzo[*c*]-2,7-naphthyridines **207**.¹⁸⁵ Benzo[*c*]-2,7-naphthyridines **208** were prepared by refluxing 2-*tert*-butoxycarbonylaminothiophenylboronic acid **209** with substituted iodonicotin-aldehydes **210** in the presence of Pd(PPh₃)₄ and K₂CO₃ in a mixture of ethanol and toluene.¹⁸⁶

R¹ = H, Me, OMe; R² = H, Me; R³ = H, OMe.

R = F, Cl, CONPr₂.

8. β -Enaminocarbonyl compounds in the synthesis of naphthyridines

β -Enaminocarbonyl compounds have long been used successfully in the synthesis of isomeric naphthyridines. Thus pyridone **211**, prepared by the reaction of β -enamino ketone **212** with 4,4-dicyano-3-aminobut-2-enitrile **213**, cyclises to give substituted 1,2,7,8-tetrahydro-1,8-naphthyridin-2-one **214**. On treatment with concentrated hydrochloric acid at 100 °C, compound **214** undergoes disproportionation giving rise to a mixture of hexahydro (**215**) and dihydro derivatives of 1,8-naphthyridin-2-ones **216**.^{187, 188}

The reaction of 4-dialkylaminopyridones **217**, containing a β -enaminoamide fragment, with *N*-methylcyanoacetamide (**218**) is accompanied by replacement of the endocyclic amino group followed by cyclisation to give 2,7-naphthyridine **219**.¹⁸⁹

$\text{R}^1 = \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$; $\text{R}^2 = \text{Et}, \text{Ph}, \text{CH}_2\text{Ph}, \text{CH}_2\text{CH}(\text{OEt})_2$; $\text{R}^3 = \text{H}, \text{CH}_2\text{CH}_2\text{OCH}_2\text{CH}_2$.

One approach to the construction of fused 1,6-naphthyridines **220** includes the reaction of 4-amino-2,6-dioxo-1,2,5,6-tetrahydro-3-pyridinecarbonitrile **221** with cyclic β -enamino ketones **222**. The pyridinedione **221** reacts with 3-dimethylamino-1-phenylpropan-1-one to give 1,5,6,7-tetrahydro-1,6-naphthyridine-5,7-dione **223**.^{190–192}

$n = 1–3$.

Enamino amides **226** and **227**, containing a β -enaminocarbonyl fragment, are promising starting compounds in the synthesis of hydrogenated naphthyridines **224** and **225**.^{193–204}

Study of the kinetics of these reactions demonstrated that the rate of cyclisation of the compounds **226** is much higher than that for the amidine **227**, due to the more pronounced delocalisation of the positive charge in the amidine system compared to the enamine system.^{195, 203, 204}

9. Cyclisation of 1,5-dinitriles and 1,5-amino(amido)nitriles of the pyridine series

Acid hydrolysis of 3- or 4-cyanopyridylacetoneitriles or their reaction with sodium ethoxide affords isomeric amino derivatives of naphthyridines **228a–c** and **229a–c**. The 1,6-naphthyridines **228d,e** have been prepared by hydrolysis of 2-cyanomethylnicotinonitriles.^{144, 205}

$\text{R} = \text{H}$: $i = 6, 7$; $\text{R} = \text{Me}$, $i = 6$; (a) HBr ; (b) EtONa .

$\text{R} = \text{H}, 4\text{-FC}_6\text{H}_4$; (a) 30% HBr – AcOH .

2-Cyanophenyl- (**230a**) or 2-cyano-3-pyridylacetoneitriles **230b** react with methyl crotonate to give adducts **231a,b**. Subsequent acid-catalysed cyclisation of compounds **231a,b** gives rise to the corresponding pyrido- and benzo[*c*]-1,8-naphthyridines **232a,b**—potential means for treating heart weakness, stenocardia and hypertension.^{206, 207}

$\text{X} = \text{CH}$ (a), N (b).

Scheme 4

$\text{R}^1, \text{R}^2 = \text{H, Me, Ph}$; (a) $\text{CH}_2(\text{CN})_2$; (b) $\text{NCCH}_2\text{CO}_2\text{Me}$; (c) $\text{NCCH}_2\text{CONH}_2$; (d) HX , $\text{X} = \text{Cl, Br}$; (e) MeONa, MeOH , $\text{X} = \text{OMe}$; (f) HBr ; (g) OH^- , H_2O or RO^- , ROH .

The methoxy group in 5-cyano-6-methoxy-3,4-dihydro-2(1H)-pyridones **233** is replaced by malononitrile, methyl cyanoacetate or cyanoacetamide. The intermediates **234**–**236** cyclise in acid or basic media to give 3,4-dihydro-1,6-naphthyridine-2(1H)-ones **237**–**239** (Scheme 4).^{208, 209}

Cyclisation of piperidine **240** yields 1,6-naphthyridine monohydrate **241**. An X-ray diffraction study showed that the $\text{C}(2)–\text{N}(1)$ bond (1.362 Å) is longer than these bonds in other cyclic amides due to less efficient conjugation with the carbonyl group.²¹⁰

Dinitriles **242** have been used to perform regioselective synthesis of 7-amino-8-cyano-1,6-naphthyridines **243**.^{144, 211, 212}

$\text{R}^1, \text{R}^2 = \text{Me, Et}$; $\text{X} = \text{Br, OMe}$.

Naphthyridinediones **244** and **245** have been synthesised using reactions of 3-amino-4,4-dicyanobut-2-enenitrile (**213**) with α -diketone monophenylhydrazones. Cyclisation of intermediate dinitriles **246** and **247** was performed on treatment with a mixture of AcOH and HCl .²¹³

(a) $\text{PhNHN}=\text{C}(\text{Ac})\text{CO}_2\text{Et}$; (b) $\text{PhNHN}=\text{C}(\text{Ac})\text{CN}$; (c) AcOH, HCl .

Enamino nitriles of 2,7-naphthyridinone(or -thione) **248** have been synthesised by cyclisation of amido(or thioamido) nitriles **249**, which are prepared from enamine **250** or substituted malononitrile **251**.^{214, 215}

X = O, S.

On treatment with sodium ethoxide in ethanol, 1-methyl-2-dicyanomethylidenepiperidine-3-carbanilides **252** cyclise to give partially hydrogenated 1,6-naphthyridin-5(6*H*)-ones **253**.²¹⁶

Ar = Ph, 4-ClC₆H₄, 3-MeC₆H₄.

Ammonolysis of enamines **254**, obtained from 1-aryl-3-(2,2-dicyanovinyl)-4-piperidones affords 2-amino-6-aryl-3-cyano-5,6,7,8-tetrahydro-1,6-naphthyridines **255**, employed in the synthesis of pteridines **256**.²¹¹

R¹ = Me, Et; R₂² = (CH₂)₄.

10. Thorpe dimerisation of cyanopicolines

Dimerisation of 2-methylnicotinonitrile (**257**) induced by potassium *tert*-butoxide and including intramolecular addition of the imine to the nitrile at the cyclisation stage gives rise to 5-amino-7-(2-methyl-3-pyridyl)-1,6-naphthyridine (**258**).¹³⁰

8-Amino-1,7-, 1-amino-2,6- and 1-amino-2,7-naphthyridines **259–261**, possessing efficient bactericidal and fungicidal activities, were prepared from the corresponding cyanopicolines in a similar way.¹⁴⁴

i = 6, 7.

11. Condensation of piperidones with cyanoacet(or thioacet)amides

The condensation of cyanothioacetamide **262** with the sodium salt of 2-formyl-3-quinuclidone **263** in ethanol in the presence of AcOH has resulted in the synthesis of 1,5-naphthyridine-2(1*H*)-thione **24a**.¹⁰⁶

Cyanothioacetamide **262** condenses with 2-arylmethylidene-3-oxoquinuclidines **264** in the presence of piperidine to yield relatively stable salts **265**; in an acid medium, these products are converted into 3,4-dihydro-1,5-naphthyridinethiones **266**. Upon refluxing in an HCl–EtOH mixture, the compounds **266** are transformed into naphthyridinethiones **24**, which are also formed directly on refluxing the salts **265** in an ethanolic solution of HCl.

R = H, Ph, 4-FC₆H₄; Pi is piperidine.

The partially hydrogenated 1,6-naphthyridinethione **33** has been synthesised by the reaction of 3,5-bis(phenylmethylidene)-1-isopropyl-4-piperidone **267** and the amide **262**.¹⁰⁷

The reaction of the salt **268** with the amide **262** in ethanol in the presence of AcOH follows the Knoevenagel reaction route and affords adduct **269**, which recycles when refluxed in ethanol in the presence of a catalytic amount of piperidine, giving rise to the 2,7-naphthyridine **35**. The compound **35** is the product of a cascade type reaction comprising acidic cleavage according to Claisen, the Michael intramolecular addition, the interaction between the thioamide and ester groups and dehydrogenation.¹¹⁰

The cyclocondensation of piperidone **270** with cyanoacetamide in the presence of diethylamine gives 1,6-naphthyridinone **271**, which reacts with POCl₃ to give chloro derivative **272**.²¹⁷ The compound **272** was also prepared by condensation of enamine **273** with ethoxymethylidenemalononitrile followed by cyclisation of intermediate **274**.²¹⁷

Refluxing of 1,3-dicarbonyl compounds **275** with cyanoacetamide in ethanol in the presence of piperidine gives 2,7-naphthyridine derivatives **276**, used as components of formulations for treatment of diseases of blood circulation organs.²¹⁸

R = H, Alk, Ph, Ac, Bn, 4-pyridyl.

12. Cyclocondensation of piperidones with aminopyrimidines

When aminopyrimidines **277** are heated (100 °C, 3 h) with the salts of isomeric hydroxymethylidenepiperidones **278** and **279** in 85% orthophosphoric acid, substituted tetrahydropyrimido[4,5-*b*]-1,6- (**280a,b**)²¹⁹ and -1,7-naphthyridines **281a,b** are formed;²²⁰ they are potential antitumour remedies.

R = NH₂ (a), OH (b).

Refluxing of aminopyrimidines **277a,b** and **282** with methyl 1-benzyl-4-oxopiperidine-3-carboxylate hydrochloride **283** in glacial acetic acid provided the synthesis of pyrimido[4,5-*c*]-2,7-naphthyridin-6-ones **284a,b** and **285**. The compounds **284b** and **285** present in concentrations of 10⁻⁵ and 2 × 10⁻⁶ mol litre⁻¹, respectively, inhibit *in vitro* the growth of malignant leukemia cells by 50%.²²¹

A similar condensation of the aminopyridine **277a** with hydrogenated 3-formylpyridine **286** in the presence of HCl in ethanol results in tetrahydropyrimido[4,5-*c*]-2,7-naphthyridine **287** mixed with its 7-benzoyl derivative.^{219, 222}

13. Other general methods for the synthesis of naphthyridines

Below we present the syntheses of naphthyridines starting from pyridine derivatives containing an amino (or protected amino) group and a carbonyl group or its synthetic equivalent in vicinal positions. Cyclisation is accomplished by treatment with basic or acidic reagents.

R = H, Me; *i* = 5–8.

$i = 6-8$; $R^1 = \text{H, Me, Cl}$; $R^2 = \text{Alk}$; $X = \text{O, S}$; (a) 3 M HCl; (b) POCl_3 , Δ ; (c) $4\text{-HXC}_6\text{H}_4\text{OCH}(\text{Me})\text{CO}_2\text{R}^2$, K_2CO_3 or NaH , DMSO.

(a) Bu^nLi ; (b) $(\text{EtO})_2\text{CHCOPh}$; (c) HCl; (d) H_2SO_4 ; (e) MeOH, H_3PO_4 ; (f) diazabicycloundecene, dioxane, Δ .

Cyclisation of ethyl aminopyridineacrylates **288** in ethanol in the presence of sodium ethoxide has served as a route to $\text{N}(1),\text{N}(i)$ -naphthyridin-2(1H)-ones **289**.²²³ Cyclisation of ethynylpyridinecarboxamides **290** under similar conditions yields 1,6-, 1,7-, 2,6- and 2,7-naphthyridones **291**.²²⁴ Naphthyridones **292** were prepared by refluxing vicinal (2,2-dimethoxyethyl)pyridinecarboxamides **293** with toluene-*p*-sulfonic acid in benzene.²²⁴ $\text{N}(1),\text{N}(i)$ -Naphthyridin-2(1H)-ones **294**, prepared by refluxing vicinal 2-*tert*-butoxycarbonyl-1-hydroxyaminopyridines **295** in dioxane in the presence of 3 M HCl, have been used to obtain naphthyridine derivatives **296**, which possess herbicidal and fungicidal properties and are efficient for the protection of cotton, soy-bean and sugar-cane crops.^{225, 226} Intramolecular cyclisation of substituted *tert*-butoxycarbonylaminopyridines **297** and **298**, synthesised from compounds **299** and **300** via a two-stage procedure, gives 1,7- (**301**) and 1,6-naphthyridines **302**.²²⁷

2-(3-Cyanopropyl-oxy or -thio)pyridine-3-carbonitriles **303** undergo an intramolecular nucleophilic rearrangement, similar to the Smiles rearrangement, being thus converted into fused 1,6-naphthyridines **304**.²²⁸⁻²³⁰ A similar cyclisation of 2-pyridinecar-

bonitrile **305** gives rise to dihydrofuro[3,2-*f*]-1,7-naphthyridine **306**.²³¹

$X = \text{S}$, $R = \text{H}$; $X = \text{O}$, $R = \text{Me}$.

Substituted 1,2,4-triazines decompose on thermolysis with nitrogen evolution. Thermolysis of compounds **307** and **308**, having an ethynyl substituent in the side chain, yields substituted naphthyridines **309**²³² and **310**.²³³

N-Hydroxyethyl-substituted 1,6- (**311**) and 2,7-naphthyridones **312** were prepared by refluxing the pyranopyridine isomers **313** and **314** with ethanolamine.²³⁴

The synthetic routes to 1,8- (**315**) and 1,6-naphthyridones **316** and **317** and annelated systems **318** and **319** make use of the reactions of pyrans **320** and **321** with malononitrile or its derivatives. The reactions are carried out in ethanol in the presence of piperidine (Scheme 5).²³⁵⁻²³⁷

Scheme 5

$R^1 = 2\text{-ClC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4;$

(a) $\text{NCCH}_2\text{CONH}_2$; (b) $\text{CH}_2(\text{CN})_2$; (c) $\text{R}^2\text{CH}=\text{C}(\text{CN})_2$; $\text{R}^2 = \text{Alk, Ar.}$

(a) $\text{NCCH}_2\text{CONH}_2$.

3-Acetyl-2-cyanomethylidenepyridine **322** and 3-acetyl-4-cyanomethylidenepyridine **323** cyclise on heating (130 °C, 30–45 min) in 85% orthophosphoric acid to give 1,6- (**324**) and 2,7-naphthyridinone derivatives **325** (Scheme 6).²³⁸

Scheme 6

$R^1 = \text{CN, CO}_2\text{Et}; R^2 = \text{Ph, 4-MeOC}_6\text{H}_4.$

V. Conclusion

The data surveyed here demonstrate that general and facile methods for the synthesis of diverse substituted naphthyridines are now available. Various naphthyridines can be synthesised

under the same conditions using similar equipment. Various types of biological activity exhibited by many naphthyridine derivatives together with the ease of their preparation make these products attractive objects for the search for new highly effective medicinal preparations, which can be done using combinatorial synthesis.

Sulfamides in the synthesis of heterocyclic compounds

G A Gazieva, A N Kravchenko, O V Lebedev

Contents

I. Introduction	221
II. Structure and physicochemical properties of sulfamide	221
III. Synthesis of heterocyclic compounds containing the sulfamide fragment	222
IV. Properties of cyclic sulfamides	227

Abstract. A comparative analysis of the structures and physicochemical properties of sulfamides and ureas has been performed. New procedures for the synthesis of heterocyclic compounds containing the sulfamide fragment are surveyed and the properties of the resulting compounds are described. The bibliography includes 112 references.

I. Introduction

The chemistry of sulfamides has received sufficient attention in the literature. The synthesis, physicochemical properties and reactions of these compounds have been considered many times in reviews which were partially or completely devoted to sulfamides.^{1–13} However, the latest review¹³ was published more than 10 years ago. During the last decade, abundant experimental data have accumulated, which call for further generalisation.

Sulfamides attract permanent interest because acyclic and cyclic products containing sulfamide fragments exhibit a broad spectrum of physiological activities. Thus sulfamoylamidines possess antiulcerous¹⁴ and diuretic¹⁵ activities, 4-phenyl-1,2,5-thiadiazolidin-3-one 1,1-dioxide exhibits antispasmodic activity,¹⁶ 5-alkyl-2-phosphinyloxymethyl-1,2,5-thiadiazolidin-3-one 1,1-dioxides are proposed for the treatment of rheumatoid arthritis,¹⁷ and 1,2,5-thiadiazolidine 1,1-dioxides containing an indole substituent at position 2 are used for the treatment of migraine.^{18,19} 5-Alkyl-2-fluoromethyl-1,2,5-thiadiazolidin-3-one 1,1-dioxides inhibit enzymes, *viz.*, human leucocyte elastase and cathepsin G.²⁰ 6,7-Dihydro-5*H*-cyclopenta[*c*]- and 5,6,7,8-tetrahydrobenzo[*c*]-2,1,3-thiadiazine 2,2-dioxides act as myorelaxants,²¹ and 3,5-dioxo-1,2,6-thiadiazine 1,1-dioxides are used as antiinflammatory agents.²² Aryl-substituted seven- and eight-membered cyclic sulfamides inhibit HIV-1 protease.^{23,24} Many sulfamides possess antibacterial properties.^{25,26}

Sulfamides are also used in photography,²⁷ they are components of fungicide²⁸ and insecticide²⁹ mixtures and are employed as detergents.³⁰ 3,5-Dioxo- and 3,5-diimino-1,2,6-thiadiazine 1,1-dioxides are used for the preparation of azo dyes.³¹ 3-Amino-1,2,6-thiadiazine 1,1-dioxides exhibit fungistatic activities.³²

S,S-Dioxides of benzothiadiazine, thiadiazine, and thiatriazine as well as some acyclic sulfamides can serve as herbicides.^{33–35}

In the 1980s, a new class of chiral oxidising agents based on sulfamides was found. These are 2-sulfamoyloxaziridines which exhibit high enantioselectivity (40%–91%) in asymmetric oxidation of sulfides to sulfoxides.^{36–38}

It is believed^{1,7,14,39–42} that the increased interest in sulfamide derivatives stems from the fact that these compounds are structurally similar to ureas. In this connection, we thought that it was worthwhile performing a comparative analysis of the structures and physicochemical properties of sulfamide and urea. However, the major aim of the present review is to systematise procedures for the synthesis of heterocyclic compounds based on sulfamide. Wherever possible, a comparative analysis of the properties of cyclic sulfamides and of the corresponding cyclic ureas was carried out.

II. Structure and physicochemical properties of sulfamide

Whereas the electronic structure of the carbonyl group has been studied comprehensively and described in detail, the data on the electronic structure of the sulfonyl group are ambiguous. The character of the S–O bond remains unclear, and the question of whether this bond is purely polar, semipolar, covalent or ‘intermediate’ is still open.

The question about the nature of the sulfonyl groups is closely related to the question about the participation of the *d* orbitals of the sulfur atom in bonding with other elements and to the question of whether the sulfur atom can exhibit ‘hypervalence’ thus violating the Lewis octet rule.⁴³

Quantum-chemical calculations with the 3-21G* and 6-31G* basis sets (*i.e.*, taking into account the contribution of the *d* orbitals) for a series of model compounds containing the SO and SO₂ groups demonstrated that the contribution of the *d* orbitals to the formation of the S–O bond is insignificant.^{44,45} Thus Reed and von Ragué Schleyer⁴⁴ concluded that the character of the S–O bond is determined primarily by the partially ionic σ bond and the π – σ^* ‘negative hyperconjugation’. However, studies of the electronic structures of sulfamides and heterocyclic compounds containing the SO₂ group by calculation methods demonstrated that p_π – d_π interaction with the participation of the *d* orbitals of the sulfur atom contributes to the formation of the multiple S–O bond.^{45–50} According to these calculations, the S–O bond has two components of the σ and π types, *viz.*, the σ bond between the corresponding atomic orbitals of the oxygen and sulfur atoms and the π bond between, on the one hand, three lone electron pairs of the oxygen atom polarised toward the sulfur

atom, and, on the other hand, the p and d orbitals of the sulfur atom. However, the S–O bond is not, strictly speaking, a double bond because the π type of interaction is $p_\pi-d_\pi$ bonding with the participation of all three electron pairs of the oxygen atom. Nevertheless, as in Ref. 43, we shall arbitrarily denote these bonds as O=S=O. It should be remembered that these ‘double’ bonds differ substantially from true double bonds formed by elements of the second row (for example, from C=O bonds) and are characterised by a substantial contribution of the ionic state.^{43–50}

The specificity of the structure of the sulfo group is reflected in the spatial configuration of the atoms in the sulfamide molecule as well as in the electron density distribution. Recently, the crystal structure of sulfamide has been studied by X-ray and neutron diffraction analysis (Table 1).^{49, 51, 52} According to the results of these studies, the S and N atoms in the sulfamide molecule have tetrahedral and pyramidal bond configurations, respectively, whereas the nitrogen atom in amides and urea is characterised by sp^2 hybridisation and a planar bond configuration.⁵² The urea molecule is planar and symmetrical. The bond angles in this molecule differ little from 120°. This structure is consistent with the notion of conjugation between the π electrons of the C=O double bond and the lone electron pairs of the nitrogen atoms. This conjugation cannot occur in the sulfamide molecule because the sulfur atom does not possess unoccupied orbitals for participation in electron delocalisation. It has been demonstrated^{45, 47} that the d orbitals of the sulfur atom are not involved in bonding with the S and N atoms in sulfamides. It was also found that sulfonamides cannot adopt the limiting resonance structure 2 analogous to the structure 4 for carboxamides.⁵⁷

The electron-withdrawing effect of the SO₂ group is stronger than that of the carbonyl group, and hence the acidity of the amino groups in sulfamide is higher than that in urea. Thus the amino groups in urea exhibit a weakly basic character, whereas

Table 1. Comparative characteristics of the sulfamide and urea molecules.

Parameter	Sulfamide	Urea
Bond lengths / Å		
S–O	1.434	C–O 1.276
S–N	1.614	C–N 1.356
N–H	1.034	N–H 1.046
N–H'	1.038	N–H' 1.070
Bond angles / deg		
O–S–O'	118.0	O–C–N 120.9
O–S–N	106.2	N–C–N' 118.2
O'–S–N	107.0	C–N–H 122.5
N–S–N'	111.7	C–N–H' 120.5
H–N–H'	112.5	H–N–H' 117.0
Dihedral angle / deg	OSO/NSN 89.39	
Stretching vibrations / cm ^{–1}		
N–H	3210–3372	N–H 3342–3449
SO ₂	1315–1369, 1145–1155	C=O 1681
SN ₂	870–955	CN 1004, 1466

Note. The geometric parameters for the sulfamide molecule were taken from Refs 51 and 52, the parameters for the urea molecule were taken from Ref. 53, and the stretching vibration frequencies were published in Refs 53–56.

these groups in sulfamide are weakly acidic. Urea forms salts with acids⁵⁸ and sulfamide gives salts with heavy metals (for example, AgNHSO₂NHAg) and alkali metals.^{1, 12, 59} These data agree with the Taft induction constants σ_1 for the electron-withdrawing substituents in dioxane (σ'_1) and in weakly acidic solvents (σ''_1).⁶⁰

Group	σ'_1	σ''_1
CONH ₂	0.11	0.21 ± 0.02
SO ₂ NH ₂	0.38	0.46 ± 0.03

Therefore, sulfamide can be considered as an analogue of carbamide only bearing in mind that the N–SO₂ conjugation is actually not realised in sulfamide by virtue of electronic and steric factors and that, in addition, the NH bond in sulfamide is substantially more acidic, and, correspondingly, the nitrogen atom is less basic than those in urea.

The results of *ab initio* calculations^{45–50} of the geometry, dipole moments, atomic charges and bond orders in sulfamides and heterocyclic compounds containing the NSO₂N fragment agree well with the experimental data.

In the crystal, the sulfamide molecules, like the urea molecules, are linked together through strong hydrogen bonds,^{51, 52, 54, 58} which may be responsible for the rather high melting points of these compounds. In solutions of sulfamides, these hydrogen bonds are substantially weaker and are observed only in water, which is confirmed by the data from IR and Raman spectroscopy.⁵⁵

The ¹⁵N, ¹⁴N and ³³S NMR spectra of sulfamide have also been reported.^{61, 62}

III. Synthesis of heterocyclic compounds containing the sulfamide fragment

Since heterocyclic systems containing the NSO₂N fragment are highly diversified, we believe that it is more convenient to classify procedures for their synthesis according to the initial compounds, as in Ref. 12, rather than according to the resulting products, as in Ref. 13.

Sulfamide and urea are not as strong nucleophiles as ammonia or amines; nevertheless, they can also react with electrophilic reagents. Reactions of sulfamides with carbonyl compounds, diamines, dinitriles and other bifunctional reagents are considered in this Section.

1. Reactions of sulfamides with carbonyl compounds

One of the most general procedures for the synthesis of heterocyclic compounds based on sulfamides involves their condensation with carbonyl compounds^{39, 63–72} or with their acetals.^{41, 42, 73}

Formaldehyde,^{7, 12, 13, 63, 65} paraformaldehyde⁶⁴ and trioxane⁶³ are most commonly used in the synthesis of heterocyclic compounds containing methylene groups.

Reactions of alkylsulfamides with paraformaldehyde in trifluoroacetic acid occur through the intermediate formation of 1,5-dithia-2,4,6,8-tetraazocine 1,1,5,5-tetroxides **8** to yield 2,6-dithia-1,3,5,7-tetraazabicyclo[3.3.1]nonane 2,2,6,6-tetroxides **9**.⁶⁴

Condensation of sulfamides with formaldehyde and primary amines afforded tetrahydro-1,2,4,6-thiatriazine 1,1-dioxides **10** in 60%–86% yields.⁶⁵

R¹ = H, OAlk, OAr; R² = Alk, Ar.

Ureas also react with formaldehyde to form a wide variety of products (both polymeric and heterocyclic) including compounds analogous to compounds **8** and **10**.^{7, 74, 75}

3,7-Bis(ethoxycarbonyl)perhydro-1,5-dithia-2,4,6,8-tetraazocine 1,1,5,5-tetroxide (**11**) was prepared from sulfamide and glyoxylic acid followed by esterification.⁶⁶

3-Imino-4-substituted 1,2,5-thiadiazolidine 1,1-dioxides (**12**) were formed upon boiling of solutions of aldehydes, sodium (or potassium) cyanide and sulfamide in aqueous ethanol.³⁹ Presumably, the reaction proceeds as follows:

R = *n*-C₆H₁₃, PhCH₂CH₂, Ph, 4-MeOC₆H₄, 3,4,5-(MeO)₃C₆H₂,

This reaction did not take place with paraformaldehyde, trioxane, acetone and acetophenone.

3-Oxo derivatives **13** are prepared from the corresponding 3-imino-1,2,5-thiadiazolidine 1,1-dioxides.

Unlike sulfamide derivatives **13**, 2,4-dioxoimidazolidines **14** are readily formed from ureas and α-dicarbonyl compounds in an acidic medium.^{7, 76}

Over many years, the reactions of sulfamides with α- and β-dicarbonyl compounds have also been widely used in the synthesis of heterocyclic compounds.^{5, 12, 13, 67–71} Thus the reaction of *N,N'*-dimethylsulfamide with glyoxal in an acidic medium (pH 3–4) afforded the first representative of bis(sulfamides) of the bicyclooctane series, *viz.*, 2,4,6,8-tetramethyl-3,7-dithia-2,4,6,8-tetraazabicyclo[3.3.0]octane 3,3,7,7-tetroxide (**15**), (the yield was 23%).⁶⁷

It should be noted that analogous bicyclic bisureas **16** have been prepared long ago from ureas and α-dicarbonyl compounds in 91% yield. Over the past century, tens of representatives of this class of compounds have been synthesised,^{7, 77} whereas sulfamide analogues have been previously unknown.

With the aim of increasing the yield of compound **15**, we performed the reactions of *N,N'*-dialkylsulfamides with glyoxal monohydrate in 36.7% hydrochloric acid. However, new heterocyclic compounds, *viz.*, 3,3'-bis(6,8-dialkyl-2,4-dioxo-7-thia-6,8-diazabicyclo[3.3.0]octane 7,7-dioxides) (**17**, the yields were 54%–85%), were obtained instead of the expected products **15**. The structures of the products **17** were confirmed by X-ray diffraction analysis.

R = Me, Et, Pr, Bu.

The reaction of *N,N'*-dimethylurea with glyoxal afforded another product, *viz.*, 4,6,12,14-tetramethyl-2,8,10,16-tetraoxa-4,6,12,14-tetraazatetracyclo-[7.7.0.0^{3,7}0^{11,15}]hexadecane-5,1-3-dione (**18**).⁷⁸

Reactions of sulfamide with β-diketones yielded various 1,2,6-thiadiazine 1,1-dioxide derivatives.^{70, 71}

$\text{R}^1 = \text{H}, \text{CH}_2\text{CONH}_2, \text{C}(\text{NH}_2)=\text{NH}, \text{Ar}; \text{R}^2 = \text{Me}, \text{Ph}; \text{R}^3 = \text{Me}, \text{Ph}.$

$\text{R} = \text{H}, \text{Me}; n = 1 \text{ (20, 21)}, 2 \text{ (22, 23)}.$

Reactions of sulfamide with symmetrical β -diketones afforded one type of products (**19**, $\text{R}^2 = \text{R}^3$); however, the reactions with unsymmetrically substituted β -diketones gave mixtures of tautomers (**20–23**, $\text{R} = \text{H}$). Moreover, the reactions of unsymmetrically substituted β -diketones with monosubstituted sulfamides afforded mixtures of regioisomers (**20–23**, $\text{R} = \text{Me}$).^{70–72}

The reactivity of β -diketones with respect to sulfamide depends on both the electronic and steric characteristics of the substituents in the diketones. Thus 3,5-diphenyl-2*H*-1,2,6-thiadiazine 1,1-dioxide and its 2-butyl derivative were prepared in 45% and 39% yields, respectively, whereas 3,5-di-*tert*-butyl-2*H*-1,2,6-thiadiazine 1,1-dioxide has not been synthesised yet.⁷²

It was demonstrated⁷² that the reactions of β -amino- and β -chloro- α,β -unsaturated ketones with sulfamide occurred regio-specifically under milder conditions than the reactions with the corresponding β -diketones. In anhydrous ethanol in the presence of HCl, these compounds gave a series of 2*H*-1,2,6-thiadiazine 1,1-dioxides **24** and **25**.

$\text{R} = \text{Me}, \text{Ph}, \text{Bu}^t.$

$\text{R}^1 = \text{Alk}, \text{Ar}; \text{R}^2 = \text{H}, \text{Me}.$

In the reactions of ureas with β -dicarbonyl compounds, bicyclic products **26** were formed more readily than 2-oxodihydropyrimidines **27**, whereas the reactions with β -chloro- α,β -unsaturated aldehydes afforded only derivatives **27**.^{7,79}

The use of acetals of carbonyl compounds instead of these compounds as such in the reactions with sulfamides resulted in the formation of six- and eight-membered *N,S*-containing heterocyclic compounds analogous to those described above along with new unexpected intramolecular α -sulfamidoalkylation products.^{41,42,73} Presumably,^{42,73} the mechanism of these reactions is analogous to the mechanism of α -ureidoalkylation.⁷ Reactions of sulfamides with acetals in an acidic medium afforded iminium ions **28** and **29**,

$\text{R}^1 = \text{H}; \text{R}^2 = \text{H}, (\text{CH}_2)_n\text{Ph}, \text{CH}_2\text{C}_6\text{H}_4\text{OMe-3};$

$\text{R}^1 = \text{R}^2 = (\text{CH}_2)_n\text{Ph} (n = 0-4);$

$\text{R}^3 = \text{Me}, \text{R}^4 = \text{H}; \text{R}^3 = \text{Et}; \text{R}^4 = \text{H}, \text{CO}_2\text{Et}, \text{CH}_2\text{CO}_2\text{Et};$

which underwent intramolecular or intermolecular α -sulfamidoalkylation depending on the nature of the substituent in the sulfamides and the reaction conditions.

In the case of α -sulfamidoalkylation of the aromatic rings in the iminium ions, annelation products **30**, **35–38** and **41** were formed. If the aromatic substituent in sulfamide is either remote from the generated iminium ion or absent, intermolecular dimerisation occurs to form eight-membered heterocyclic compounds **11**, **34** and **40**. Under certain conditions, these products can react with acetals to form compounds **5** and **31–33**. Symmetrical diarylsulfamides react with acetals $(\text{EtO})_2\text{CH}(\text{CH}_2)_m\text{COOEt}$ ($m = 0$ or 1) to form new sulfamide **39** as a result of intramolecular α -sulfamidoalkylation.

Compound	R^1	Yield (%)
31	Ph	46
32	CH_2Ph	72
33	$(\text{CH}_2)_4\text{Ph}$	56
11	H	75
34	CH_2Ph	74

Compound	<i>n</i>	R ⁴	Yield (%)
35	2	H	88
36	2	CO ₂ Et	80
37	3	H	85
38	3	CO ₂ Et	11
39	3	CO ₂ Et	68

The reactions of unsubstituted sulfamide and arylsulfamides with two equivalents of an acetal in an acidic medium afforded 1,2,6-thiadiazines **42–46**, while the reaction with one equivalent of an acetal yielded 1,2,6-thiadiazine **47**.

Compound	R	Yield (%)
42	H	38
43	Ph	42
44	CH ₂ Ph	68
45	(CH ₂) ₂ Ph	37
46	(CH ₂) ₃ Ph	79

2. Reactions of sulfamides with diamines

An efficient procedure for the synthesis of heterocyclic compounds containing the sulfamide fragment involves condensation of sulfamide with diamines.^{12, 13, 23, 24, 80} This procedure allows one to prepare heterocyclic compounds with five, six or more atoms in the ring. Note that this procedure is the most convenient method for the synthesis of the latter compounds.

B is an organic base.

Heating of ureas with diamines is also used in the synthesis of heterocyclic compounds.⁸¹

3. Reactions of sulfamides with dinitriles

The reactions of sulfamides with dicyan and malonodinitriles find wide application.^{13, 82–86} Numerous examples of the preparation of diamino and diimino derivatives of 1,2,5-thiadiazole 1,1-dioxides and 1,2,6-thiadiazine 1,1-dioxides (**52–55**) are documented (Scheme 1).

Acid hydrolysis of compounds **52** and **54** afforded the corresponding 3-oxo derivatives.^{85, 86}

4. Condensation of sulfamides with diols and other bifunctional reagents

Until recently, condensation of dihydroxy compounds with sulfamides have not found wide use, whereas these reactions with ureas have long been known⁷ and they are successfully used, for example, in the synthesis of bicyclo[3.3.0]octanediones (**16**).

Procedures for the preparation of bi-, tri- and tetracyclic compounds (**57**, **59** and **61**, respectively) containing sulfamide fragments from sulfamides and the corresponding dihydroxy compounds **56**, **58** and **60**, respectively, have been developed in recent years.^{67, 87}

R¹ = Alk; R² = H, Alk.

Scheme 1

A method for the synthesis of tetrahydro-3,5-dioxo-1,2,6-thiadiazine 1,1-dioxides (**62**) from malonyl chloride and *N*-substituted sulfamides was also proposed.^{35, 88}

$\text{R}^1 = (\text{CH}_2)_n\text{Ph} (n = 0-2), \text{C}_6\text{H}_{11}; \text{R}^2 = \text{H, CH}_2\text{Ph}$.

An interesting procedure for the preparation of 5-methyl-3-oxo-3,6-dihydro-2*H*-1,2,6-thiadiazine 1,1-dioxide (**63**) was described.^{89, 90}

A method for the synthesis of 3-oxo-3,6-dihydro-2*H*-1,2,6-thiadiazine 1,1-dioxides (**64**) from sulfamides and 5-alkanoyl-1,3-dioxane-4,6-diones was covered by a patent.⁹¹

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{Alk}; \text{R}^4 = \text{H, Alk, Ar}$.

The reactions of derivatives of 1,3-dioxane-4,6-diones with urea and thiourea proceed analogously.⁹²

The use of a new synthon, viz., diphenyl *N*-sulfamoyl-carboimidate, which was prepared from sulfamide and dichlorodiphenoxymethane, opens a new way to the synthesis of 1,2,6-thiadiazine 1,1-dioxide (**65**) and 1,2,4,6-thiadiazine 1,1-dioxide (**66**).⁹³

Of the currently available approaches to the construction of cyclic sulfamides, the reactions of sulfonyl halides^{94–98} and chlorosulfonyl isocyanate^{20,99} with amino compounds should also be mentioned. The preparation of 3-oxo-1,2,5-thiadiazolidine 1,1-dioxides (**13**) from chlorosulfonyl isocyanate and amino acids is an example.⁹⁹

The above-considered experimental data demonstrate that sulfamides are rather often similar in their chemical behaviour to ureas. Sulfo-analogues of many urea-containing compounds have been prepared.

IV. Properties of cyclic sulfamides

Recently, the aromaticity of heterocyclic compounds has been the subject of many theoretical studies.^{47,49,50} The results of *ab initio* quantum-chemical calculations of the electronic properties and the geometry of these molecules, which were confirmed by X-ray diffraction analysis,^{47,49,50,100,101} demonstrated that the rings in 1,2,5-thiadiazole 1,1-dioxide and 1,2,6-thiadiazine 1,1-dioxide, unlike those in 2-pyrimidinones, are nonaromatic.⁴⁷ The lack of the aromaticity results from the specificity of the structure of the SO₂ group (see Section II). The sulfur atom cannot be involved in π delocalisation because the oxygen and sulfur atoms in thiadiazines (**67**) deviate from the plane passing through the remaining atoms.

The tautomerism^{39,47,71} and rotational isomerism^{40,102} of cyclic sulfamides attract considerable interest. The difference in the stability of the tautomers of 1,2,6-thiadiazine 1,1-dioxide (**67**) and 2-pyrimidinone (**68**) results from the aromaticity of the compound **68** and nonaromaticity of the compound **67**.⁴⁷

According to the data from X-ray diffraction studies and NMR spectroscopy, 3,5-dialkyl- and 3,5-diaryl-substituted 1,2,6-thiadiazine 1,1-dioxides exist in solutions predominantly as the isomers **A**, whereas the tautomers **B** of 3(5)-hydroxy- and 3(5)-amino-substituted derivatives are more stable.⁴⁷ In no case was

the tautomer **C** experimentally observed. In the case of substituted 2-pyrimidines, the stabilities of tautomers **A'**–**C'** are related in a different way.

Tautomeric forms of 3-oxo- (**13**) and 3-imino-1,2,5-thiadiazolidine 1,1-dioxides (**12**)³⁹ as well as those of 6,7-dihydro-5*H*-cyclopenta[*c*]- (**20** and **21**) and 5,6,7,8-tetrahydrobenzo[*c*]-2,1,3-thiadiazine 2,2-dioxides (**22** and **23**)⁷¹ were studied.

In solution, 3-oxo- and 3-imino-1,2,5-thiadiazoles occur as equilibrium mixtures of the tautomers **12** and **12'** and the tautomers **13** and **13'**, respectively, whereas 6,7-dihydro-5*H*-cyclopenta[*c*]-2,1,3-thiadiazine 2,2-dioxide and 5,6,7,8-tetrahydrobenzo[*c*]-2,1,3-thiadiazine 2,2-dioxide exist predominantly in the forms **21** and **22**, respectively.

The rotational isomerism of glycosylated derivatives of 1,2,6-thiadiazine 1,1-dioxides at the N-glycosidic bond was studied by NMR spectroscopy. Thus 6- β -D-glucopyranosyl-2-methyl-3-oxo-3,6-dihydro-2*H*-1,2,6-thiadiazine 1,1-dioxides (**69**) exist in solutions as mixtures of *syn* and *anti* rotamers.⁴⁰

It was found that the energy barriers to rotation about the glycosidic bond for glycosylated thiadiazine derivatives are lower than those for the corresponding uracils and pteridines.^{40,102} This is attributed to the fact that the SO₂ group deviates from the plane of the heterocycle and hinders the rotation about the C–N bond to a lesser extent.

Under the action of various reagents, six- and seven-membered cyclic sulfamides are transformed with elimination of the NSO_2N ,^{103, 104} SO_2 (see Ref. 105) or CO fragments.⁸⁸ Thus derivatives of 1,2,6-thiadiazine 1,1-dioxides were converted under the action of nucleophiles into pyrazoles **70**¹⁰³ and 2-pyridones **71**.¹⁰⁴

Under the action of oxidising agents, seven-membered cyclic sulfamides, which do not contain substituents at the nitrogen atoms were converted into pyridazine derivatives **72** with elimination of the SO_2 fragment.¹⁰⁵

whereas successive nitrosation and acidification of *N*-substituted tetrahydro-3,5-dioxo-1,2,6-thiadiazine 1,1-dioxides afforded 2-substituted 4-amino-2,3-dihydro-3-oxo-1,2,5-thiadiazole 1,1-dioxides (**73**) with elimination of the CO group.⁸⁸

$\text{R} = \text{Ar}, \text{cyclo-C}_6\text{H}_{11}$.

Substitution at the nitrogen atoms is typical of cyclic sulfamides. It was demonstrated that heterocyclic sulfamides undergo alkylation,^{20, 24, 41, 69, 73, 93, 106, 107} acylation,⁶⁹ nitration,⁹⁴ hydroxymethylation,²⁰ silylation^{40, 41, 102} and glycosylation.^{40, 41, 102}

Diazomethane,¹⁰⁶ dimethyl sulfate¹⁰⁷ and alkyl and aryl halides^{20, 24, 41, 69, 73, 93, 107} are used as alkylating agents. Procedures for alkylation with methyl iodide in acetone in the presence of K_2CO_3 or with benzyl chlorides and bromides in the presence of sodium hydride are most generally used.

$\text{R} = 4\text{-MeOC}_6\text{H}_4\text{CH}_2$.

1,2,5-Thiadiazolidine 1,1-dioxides were acylated with acyl chloride or dimethylcarbamoyl chloride in an alkaline media,⁶⁹ nitrated with nitric acid⁹⁴ and hydroxymethylated with a methanolic solution of formaldehyde.²⁰

1,2,6-Thiadiazine 1,1-dioxides were silylated with hexamethyldisilazane. Their silyl derivatives underwent glycosylation under the action of penta-*O*-acetyl- β -D-glucopyranose and 1,3-oxathiolane.^{40, 41, 102}

Halogenation and arylation of 1,2,6-thiadiazine 1,1-dioxides **25** ($\text{R}^1 = \text{R}^2 = \text{H}$) at the carbon atom using organometallic reagents have been reported.¹⁰⁸ Amine exchange in 3,4-diamino-1,2,5-thiadiazole 1,1-dioxides **53** has been described.⁸³

The sulfo group is stable to reducing agents.^{5, 43} The SO_2 group also remains intact upon electroreduction. Thus electroreduction of 3,4-diphenyl-1,2,5-thiadiazole 1,1-dioxide in acetonitrile afforded the corresponding dihydrothiadiazole 1,1-dioxide (**74**),¹⁰⁹ i.e., only the $\text{C}=\text{N}$ bond was reduced.

All the above-described reactions are also typical of cyclic ureas. The latter are alkylated with alkyl halides and alkyl sulfates

and undergo acylation, hydroxymethylation, nitration and glycosylation at the nitrogen atoms.^{7, 110–112}

* * *

The examples considered in this review demonstrate that the chemistry of cyclic sulfamides is progressing successfully. Procedures for the preparation of heterocyclic compounds which contain different numbers of carbon atoms in the ring and bear different substituents at the nitrogen and carbon atoms have been developed. One would expect further progress in this field of chemistry. New possibilities of the reactions of sulfamides with carbonyl compounds yielding bi- and polycyclic sulfamides would be expected to be opened. Various useful properties of sulfamides give promise that new approaches to their directed synthesis will be developed.

Abstract. Based on the results of kinetic analysis of numerous experimental data, advantages of heterogeneous and heterophase mechanisms of autooxidation of non-crystalline polymers over homogeneous liquid-phase mechanisms are demonstrated. The supermolecular organisation of polymer chains according to the pattern of spongy micelles incorporating non-uniform porous areas is chosen as the model structure. It is established that, depending on the physical state of the polymer, the oxidation kinetics correspond either to a mechanism in which reaction chains are distributed over non-uniform nanophases or to a mechanism in which they are mainly located in one nanophase. The kinetic equations obtained for the macroscopic stages of oxidation take into account the dependence of the chemical reactivity of reactants on the thermomechanical mobility of the molecular sponge. It is demonstrated that the fine structure of molecular spongy micelles plays a crucial role in the chemical physics of polymers. The bibliography includes 94 references.

I. Introduction

Oxidation of block polymers is often considered within the framework of homogeneous oxidation schemes designed for liquid hydrocarbons.^{1–13} This is formally based on the view, accepted long ago, that a non-crystalline polymer is an amorphous homogeneous material. The evident physical difference between polymeric and liquid phases is attributed in its simplified form to the functioning of unstable structures continuously formed and degraded and having rather long lifetimes and low rates of the relaxation response to an external action.

Meanwhile, the kinetics of polymer oxidation usually do not fit in the framework of homogeneous reactions. In fact, when analysing the mechanisms of several macroscopic stages (for

example, induction period⁵ and self-accelerated stage^{4–6,8–15}) in terms of homogeneous schemes, researchers were forced either to change the essence of these schemes or to use mathematical simplifications.^{1–17} The results were often at variance with experimental data.

The contradictions caused by the use of the homogeneous reaction model could not fail to cast doubt¹⁶ upon the validity of the mechanisms of inhibited oxidation and ‘critical’ concentrations of antioxidants discussed in the literature.^{4,6–8} Nevertheless, the generally accepted view of the liquid-phase homogeneous structure of a non-crystalline polymeric matrix delayed for a long period the development of an adequate oxidation mechanism, even after the dependence of the reaction rate on the thermomechanical state of the polymeric matrix had been established.^{4–6,18–26} Instead of diverging from the old-fashioned homogeneous model, the researchers spent effort on the improvement of this model. This was done by invoking ideas of polychromatism of kinetic parameters^{5–7} and by assuming the presence of so-called ‘disordered areas’^{4,5} and ‘rigid cages’⁸ in the matrix being oxidised.

The kinetic ‘polychromatism’ assumes that reactions which are elementary in homogeneous media cannot be characterised by a single rate constant when they occur in polymers. It is postulated that the reactivity of particles depends on their closest environment. However, the physical grounds for this dependence usually remain unknown.

The ideas of the molecular-segment ‘disordered areas’ and ‘rigid cages’ make the views on a polymer process somewhat more detailed. It cannot be ruled out that the schemes based on each concept would describe different particular situations. They are unable to serve as the common ground for the simulation of reactions in a non-crystalline polymeric matrix because they assume *a priori* that the ‘areas’ and ‘cages’ arise in an essentially homogeneous medium.

The same is true for the known theoretical approach resorting to the model of propagation of infectious diseases.¹⁴ This approach is based on the statements that oxidation of a partially crystalline polymer develops through multiplication of ‘pest-holes’, which successively involves amorphous regions dispersed inside the crystalline phase, and that the ‘infection’ is transmitted by monomeric oxidation products acting as initiators.

Uspekhi Khimii 69 (3) 249–282 (2000); translated by Z P Bobkova

Since the above approaches are modifications of the same homogeneous reaction model, none of them discloses the physical reasons for, for example, the fact that oxidation of polymer samples in different physical states often follows the same kinetics. Thus the temperature dependence of the rate constant of non-inhibited oxidation of low-density polyethylene (LDPE) in the induction period is described by an Arrhenius equation in the temperature range of 40–200 °C; this implies the absence of changes in the oxidation mechanism on passing from the solid state to the molten state ($T_m \sim 115$ °C).²⁷

The inapplicability of homogeneous schemes (both the classical and modified ones) to the description of the oxidation of polymers is also indicated by the fact that the same polymer often behaves (in the reaction) in different ways depending on the method used to prepare the sample. In addition, the macroscopic stages of polymer oxidation are described by kinetic laws different in kind.

The reasons for these specific kinetic features are hidden in the supermolecular organisation of polymer chains in spongy micelles incorporating non-homogeneous porous areas, *i.e.* in the real heterogeneity of the ‘amorphous’ polymer phase.^{15, 16, 28, 29} The molecular-chain sponge is actually a system of connected pendula (oscillators), the oscillations of which can become cooperated; this makes the units of macromolecules move apart to form nanopores with different widths.

It was emphasised in a series of studies^{15, 16, 18–22} that the initiating activity of admixed initiators and polymeric hydroperoxides and the routes of transformation of free radicals depend on which particular site in the nanoporous structural zone of the molecular spongy matrix contains the reactants. Due to the high degree of heterogeneity and the high elasticity with respect to mechanical treatment, typical of this matrix, stretching of polymer chains and the amplitudes of beating of nanopores of each size can vary over wide limits.

Therefore, the kinetics of oxidation of samples existing in different thermomechanical states, depending on the preparation method, can be different in kind, although the chemical structure of the polymeric molecules remains the same.

II. The influence of the thermomechanical state of a polymer on the oxidation kinetics

1. Characteristic features of the process under structural relaxation conditions

The thermomechanical state of a polymer subjected to oxidation largely depends on the character of thermal and mechanical treatment of the polymer sample prior to the reaction. Oxidation of polymer samples can be described by qualitatively different kinetics depending on the previous history of the samples.

This refers, for example, to samples of isotactic polypropylene (IPP), studied by Pudov *et al.*^{1, 2, 30} and Monakhova *et al.*^{24, 31}

The data on accumulation of polymeric hydroperoxide (POOH) in IPP samples obtained by Pudov *et al.*^{1, 2, 30} (Fig. 1) differ from the results of Monakhova *et al.*^{24, 31} (Fig. 2) by a longer period of accumulation and a lower rate of decomposition of POOH.

The plots for the oxygen absorption rate *vs.* the concentration of accumulated POOH also follow different patterns in these two cases. Pudov *et al.*^{1, 2, 30} attribute this plot to one macroscopic stage and describe it as a sum of two terms close in magnitude

$$v = a [\text{POOH}]^{0.5} + b [\text{POOH}],$$

where a and b are constants. On the contrary, the curves shown in Fig. 2^{24, 31} actually represent three macroscopic stages of oxidation, characterised by different types of variation of v *vs.* $[\text{POOH}]$. In fact, successive transitions from a more or less extensive induction period to a short self-accelerated process and then to a stage with a virtually constant rate of oxygen absorption can be distinguished in curves 3 and 4. At the third stage of oxidation, the concentration of POOH first increases and then starts to decrease.

Figure 1. Variation in the concentration of hydroperoxide in films pressed from non-melted IPP powder during oxidation at 130 °C and oxygen pressures of 26.7 (1) and 53.3 kPa (2).^{1, 2, 30}

Figure 2. Calculated curves for hydroperoxide accumulation (1, 2) and experimental (3, 4) and calculated (5, 6) curves for the oxygen absorption during oxidation at 130 °C and $P_{O_2} = 40$ kPa of IPP films prepared from the melt and containing small (1, 3, 5) and large (2, 4, 6) spherulites.^{24, 31} The dots correspond to experimental concentrations of POOH.

These kinetic differences are apparently due to nonequivalent methods used to prepare the samples in question. In one study³⁰ films were prepared by short-term (2–3 min) pressing of the IPP powder at 125–130 °C without bringing the crystals to melting, while in the other studies^{24, 31} the initial IPP was first melted at 220 °C and then the melt was cooled to give films with small spherulites. On additional heating, large spherulites were formed but the degree of crystallinity did not change.

It is obvious that pressed films employed by Pudov *et al.*^{1, 2, 30} were characterised by enhanced internal mechanical stress, caused by deformation of the framework of non-melted crystallites and by biaxial orientational stretching of polymer chains which fill the space between the crystallites. Comparison of curves 1, 2 in Fig. 1 with the corresponding curves in Fig. 2 leads to the conclusion that in the concentration range of 0–0.2 mol kg^{−1}, accumulation of POOH in the films prepared by pressing occurs at almost the same rate as in the films with small spherulites. However, the yield of POOH in the subsequent oxidation stages is much higher in the former type of films. This indicates that the reaction rate increases in samples with internal stresses. Apparently, at a certain stage of the process, efficient stress relaxation occurs in ‘stressed’ films, which is accompanied by the appearance of local centres of thixotropic excitation of the matrix.³² In these centres, the frequency and amplitude of beats of macromolecular units increase; this changes the dimensions of nanopores and, consequently, increases the rate of generation of free radicals.^{15–22, 33, 34}

The IPP films prepared by cooling a melt^{24, 31} differed from those made of a pressed conglomerate of non-melted particles by the presence of a much more equilibrated (as regards the thermomechanical state) framework of crystallites. The residual internal

stress in the crystallites is much lower. They are distributed more uniformly in the material and do not bring about any thermomechanical excitation of the matrix or substantial shear deformations during oxidation.

The increase in the induction period associated with enlargement of spherulites due to recrystallisation (see Fig. 2, curve 2) can be explained by assuming that some of the units of macromolecules are incorporated into crystallites and thus induce orientational drawing of the polymer chains in the intercrystallite regions. The stretched polymer chains are fixed rather firmly on the crystallite framework; this accounts for the extension of the induction period.

A similar effect is involved in the oxidation of highly crystalline films of IPP, high-density polyethylene (HDPE) and polymethylpentene subjected to uniaxial orientational drawing. The greater the degree of drawing, the greater the increase in the induction period of oxidation.^{5,35}

The rate of oxidation of LDPE is affected by orientational drawing in a different way. The low degree of crystallinity of this polymer does not ensure sufficient resistance to the internal stress and the fast relaxation increases the oxidation rate from the very beginning of the process.³⁵

Thus, despite the identical treatment of the polyolefin films (orientational drawing), the rates of the initial stage of their oxidation differ depending on the strength of the supermolecular framework.

Yet another specific feature of oxidation of uniaxially stretched IPP films is that the molecular mass of the polymer increases substantially at the initial oxidation stages, whereas in the case of isotropic films, fast destruction of macromolecules is observed.⁵ Calculations have shown³⁵ that the influence of drawing is due to the change in the physical structure of the IPP matrix subjected to oxidation rather than to the change in the solubility and the oxygen diffusion coefficient.

It should be noted that the draw ratio also influences the parameters of the self-accelerated stage of oxidation. This stage becomes longer for high draw ratios;^{5,26,35} in some cases, the rate of oxygen absorption increases according to the law $v \sim \exp(\Phi t)$ rather than in proportion with time.²⁶

The state of the spongy molecular matrix can change due to different types of treatment and thus influence the oxidation kinetics. Thus, it has been reported²⁰ that previous heat treatment of a non-stabilised commercial sample of IPP *in vacuo* decreases the rate of its high-temperature oxidation by increasing the induction period; however, the rate of low-temperature (20 °C) oxidation substantially increases (possibly, due to the structural relaxation under the influence of absorbed moisture²⁹).

Simultaneously, a new specific feature appears which cannot be interpreted within the framework of the homogeneous reaction model, namely, different induction periods are observed for identical contents of POOH in the polymer and, conversely, identical induction periods correspond to hydroperoxide concentrations that differ by an order of magnitude.²⁰

Note that these regularities (observed in the kinetic regime of oxygen absorption) reflect a general feature of heterogeneous micro- and nanoporous materials associated with the lability of their physical structure. In many cases, this lability is undesirable because it accounts for the poor reproducibility of the useful properties of materials.³⁶ The molecular sponge, which is an important structural material of a non-crystalline polymer matrix, exhibits clear-cut susceptibility to thermomechanical treatment and has a fairly labile structure. Owing to these properties of the molecular sponge, non-crystalline polymers differ fundamentally from homogeneous fluids, in which reaction rates do not change upon shear mechanical treatment (stirring). Moreover, parameters of elementary chemical steps proceeding in homogeneous media are usually unambiguous.

2. Specific features of oxidation in the steady state of the polymer matrix

The notion of structural steady state as applied to a polymer being oxidised is somewhat arbitrary. Oxidation is inevitably associated with the formation of oxygen-containing groups in macromolecules and with rupture or cross-linking of polymer chains. These processes change the initial balance of elastic forces in the spongy molecular matrix and cause more or less fast structural evolution. However, if the chemico-mechanical perturbation is relatively slight and the matrix quickly returns to the thermomechanical equilibrium, this process can be regarded as being structurally stationary.

The structurally steady-state oxidation includes several macroscopic stages which obey different kinetic laws. Thus the induction period is characterised by a low rate of oxygen consumption (v_1). This period ends after a small amount of oxygen, usually less than 0.1 mol kg⁻¹, has been absorbed. The v_1 value does not depend on the concentration of hydroperoxide accumulated during the induction period but increases with an increase in the pressure of oxygen without, however, reaching a limiting value²⁰

$$v_1 = \frac{a_1 P_{O_2}}{(b + P_{O_2})^{1/2}},$$

where a_1 and b are constants.

The induction period is followed by a short stage of self-accelerated oxygen absorption. The reaction rate at this stage (v_2) is most often proportional to the oxidation time. In this case, reaction chains are initiated upon dissociation of POOH and are terminated upon recombination of macropoxylys.

As oxidation develops, the increase in the rate of oxygen absorption becomes less pronounced. After some period, the rate reaches a maximum and no longer depends on the POOH concentration. Whereas in the first stage (v_1), the rate of oxygen absorption does not reach any limiting value upon an increase in the pressure of oxygen, in the third stage (v_3) this rate does have a limit. It is significant that the third stage of oxidation is established earlier than the maximum hydroperoxide concentration has been attained and continues even after the POOH concentration has considerably diminished. This pattern (which can be seen, for example, in Fig. 2) is typical of reactions having the zero order with respect to hydroperoxide.^{20–22} This distinguishes high-molecular-mass block polymers from their solutions.

The difference between the kinetics of oxidation of block and dissolved LDPE is demonstrated in Fig. 3 (data of Ref. 37). Although curves 1'–3' are qualitatively similar, the kinetics of accumulation of POOH in the two systems are substantially different. It can be seen that the variation of the hydroperoxide concentration in the melt is described by a curve with a sharp maximum (curve 1'), while that in solution is described by monotonic curves with relatively low limiting values (curves 2', 3').

According to a study by Iring *et al.*,³⁷ oxidation of LDPE in solutions can be described by a kinetic equation for liquid-phase oxidation

$$\frac{d[\text{POOH}]}{dt} = \alpha v - k[\text{POOH}], \quad (1)$$

where α is the yield of POOH, v is the rate of oxygen absorption and k is the rate constant for the decomposition of POOH. The reaction reaches a steady-state regime at those degrees of conversion at which the consumption of the CH groups is still insignificant and the following conditions hold:

$$\left(\frac{d[\text{POOH}]}{dt} \right)_{\text{lim}} = 0, \quad \alpha v_{\text{lim}} = k[\text{POOH}]_{\text{lim}} \rightarrow \text{const.}$$

Figure 3. Amount of absorbed oxygen (Z , moles of O_2 per mole of molecular units) vs. oxidation time (a) and amount of accumulated hydroperoxide (Y , moles of POOH per mole of molecular units) vs. amount of absorbed oxygen (b) during the oxidation of a melt ($1, 1'$) and a solution of LDPE (the LDPE concentration is $0.56 \text{ mol litre}^{-1}$) in trichlorobenzene ($2, 2', 3, 3'$).³⁷ Temperature/ $^{\circ}\text{C}$: $1, 1', 2, 2'—160, 3, 3'—170$. Pressure of O_2 /kPa: $1, 1'—100; 2, 2', 3, 3'—75$.

Oxidation in the melt also reaches a steady-state regime at a relatively low consumption of CH groups (Fig. 3, curve 1); however, the pattern of variation of the POOH concentration (Fig. 3, curve $1'$) differs from that for the liquid-phase reaction.

Oxidation of high-molecular-mass block polyolefins in the steady-state regime is characterised by the following features.^{15, 20–22}

- (1) hydroperoxide is not the only molecular product of the reaction (other oxygen-containing compounds are also formed);
- (2) decomposition of POOH is due to its reaction with an oxidation product and is not accompanied by the formation of free radicals;
- (3) oxidation has the zero order with respect to hydroperoxide.

It should be emphasised that the zero order with respect to hydroperoxide in the steady state has been repeatedly found by numerous researchers; however, this fact has not received adequate attention (apparently, in the heyday of the theory of liquid-phase oxidation of hydrocarbons, researchers have not yet faced the problem of structure-kinetic modelling). Since this finding was undoubtedly significant, it was specially verified in relation to the oxidation of molten polyethylene oxide (PEO),^{15, 18, 19} a high-elasticity copolymer of ethylene with propylene and solid-like IPP.²¹ These experiments confirmed simultaneously yet another fact which had been repeatedly described previously — admixed initiators present in polymers accelerate the attainment of the highest reaction rate but do not influence the rate itself over a broad range of concentrations.

Figure 4 presents experimental results on the oxidation of a PEO melt in air.¹⁵ It can be seen that the constant rate v_3 is established earlier (curve 1) than the maximum POOH concentration is attained (curve 2). The curves for the consumption of the polymer CH groups (curve $1'$) and for the accumulation of aldehyde reaction products (curve $2'$) also indicate that constant

Figure 4. Curves for oxidation of molten poly(ethylene oxide) at 90 ($1, 2, 1'–3'$) and 80 $^{\circ}\text{C}$ ($3–6$); (a) oxygen absorption (1) and hydroperoxide accumulation ($2–6$); (b) variation of the optical density of the CH ($1'$) and CO ($2', 3'$) absorption bands in the IR spectra. Concentration of dibenzoyl peroxide/ mol kg^{-1} : 0 ($1–3, 1', 2'$), 0.06 ($3'$), 0.0165 (4), 0.039 (5) and 0.12 (6). The IR spectra were recorded using chloroform solutions of the polymer (10 mg ml^{-1}) (data from Refs 15, 18).

oxidation rates are rapidly attained and that they do not depend on the content of POOH in the melt.

The introduction of a foreign initiator, dibenzoyl peroxide (BP) in concentrations of up to 0.12 mol kg^{-1} , into the PEO melt eliminates the self-accelerated stage but does not influence the steady-state rates of accumulation of aldehyde (curve $3'$ in Fig. 4 is parallel to the straight section in curve $2'$) and hydroperoxide (curves $4–6$ are parallel to the straight section in curve 3).

The fact that the steady-state rate of oxidation does not depend on the content of a foreign initiator indicates that the polymeric matrix has some structural filter ('bottle-neck'), which restricts the transfer of free radicals from areas in which the initiator dissociates to other areas in which chain oxidation occurs.

It is noteworthy that dibenzoyl peroxide present in a relatively high amount in a PEO melt depresses the reaction; as its concentration increases from 0.12 to 0.38 mol kg^{-1} , the rate v_3 diminishes 1.4 fold at 90 $^{\circ}\text{C}$,¹⁹ which is inconsistent with the homogeneous model.

The 'bottle-neck' effect is clearly manifested in the experiments on oxidation of solid-like IPP in the presence of dibenzoyl peroxide.²¹ Figure 5 shows how the total concentrations of BP being consumed and POOH being accumulated vary during the

Figure 5. Variation of the total concentration of hydroperoxide and dibenzoyl peroxide ($1, 2$) and the concentration of only dibenzoyl peroxide (3) during oxidation of IPP films in air at 100 $^{\circ}\text{C}$.²¹ $[\text{BP}]_0/\text{mol litre}^{-1}$: (1) 0.025 , ($2, 3$) ~ 0.8 .

Figure 6. Amount of the absorbed oxygen (1, 3) and accumulated hydroperoxide (2, 4) vs. time of oxidation of low-molecular-mass APP with $M_n = 4500$ (1, 2) and 5-fold orientationally drawn IPP films (3, 4) at $T = 120^\circ\text{C}$ and $P_{\text{O}_2} = 10^3\text{ kPa}$.²⁶

oxidation of IPP films in air at 100°C . In this particular case, the presence of a structural filter for the radicals arising is quite obvious: the higher the content of BP in the polymer, the greater fraction of BP decomposes unproductively with respect to the accumulation of POOH. In addition, the steady-state rate of the process does not depend on the initial concentration of BP or on the current concentration of POOH.

Yet another result obtained in a study of oxidation of a low-viscosity melt of atactic polypropylene (APP) with the molecular mass $M_n = 4500$ and orientationally drawn IPP films (Fig. 6) is worth noting.²⁶ The rate of oxidation at 120°C increases for a long period in direct proportion to the concentration of the accumulating POOH; simultaneously, the amount of absorbed oxygen increases with time according to an exponential law and $v \sim \exp(\Phi t)$. The same pattern is followed at 110 and 130°C . Meanwhile, oxidation of solutions of these polymers in inert trichlorobenzene (concentration 0.56 mol kg^{-1} per monomer unit) obeys kinetic laws of homogeneous reactions, *i.e.* the dependences $v \sim t$ and $v \sim [\text{POOH}]^{0.5}$ hold. Thus, the kinetics of oxidation of polymer samples in which the molecular sponge exists in the state of enhanced thermal fluctuation mobility differ from the kinetics of oxidation of liquid hydrocarbons or high-molecular-mass polyolefins in the structural steady state.

To summarise, it can be noted that oxidation of the same (from the chemical viewpoint) polymer is described, depending on its thermomechanical state, by a whole range of kinetic laws different in kind, which is inconsistent with the model of homogeneous reactions. Thus a new model taking into account the nanosize heterogeneity of the non-crystalline polymeric phase needs to be developed.

III. The microreactor model and kinetic regimes of oxidation

In several studies,^{15, 16, 18–22, 28, 29, 33, 34, 38, 39} non-crystalline polymers are considered as systems of molecular-chain spongy micelles which fill the cells of an infinite three-dimensional framework (Fig. 7a). This framework is an open-work lattice of paracrystalline domains, each of them containing up to a dozen parallel segments. The size of spongy micelles is of the order of tens of nanometers. The three-dimensional framework in the matrix of partially crystalline polymers incorporates a more or less shaped carcass of lamellar crystallites (Fig. 7b).

The molecular spongy micelle, which acts as a chemical microreactor, is a heterophase aggregate, the chains of which enter the paracrystalline domains at one end and enter the spongy grains at the other end. The chains within the grain are tightened by cohesion forces but are not completely collapsed, being

Figure 7. Scheme of the molecular spongy-micellar nanosized reactor for non-crystalline (a) and partially crystalline (b) polymers.

stabilised as a sponge filled with fairly narrow micropores (more precisely, nanopores). The sizes of the micropores range from a chemical bond length to a polymer chain thickness ($0.1–0.5\text{ nm}$).

Under conditions of balanced elastic forces between the spongy grain and the domains of the continuous framework, a layer is formed consisting of radially arranged chain segments, which constitute the walls of relatively wide nanopores (supernanopores). As a consequence, two types of nanosized zones arise in the micelle, namely, s-zones consisting of radial chain segments (the size of a thermodynamic segment is $2–3\text{ nm}$), which form supernanopores, and v-zones consisting of grains with narrow nanopores.

The chain segments of these two zones are characterised by different motion dynamics. The segments in the s-zones play a role of mechanical strings fixing the micellar grain; the s-zones themselves can be compared to a porous adsorbent with a rigid framework. A v-grain is close in thermomechanical properties to a mobile drop of a liquid. Such a drop hanging from a domain of the continuous three-dimensional framework can execute, to a certain extent, its own vibrational or rotational motions and volume beats, thus transferring the kinetic momentum to more or less flexible polymer chains composing the drop.

Due to their spongy structure, the micelles can rapidly rearrange and capture even those admixtures where the molecules are larger than the diameter of empty nanopores. In addition, since the molecular sponge is, in essence, a set of coupled pendula, it is subject to interference, *i.e.*, damping or synchronisation of oscillations; this creates conditions for a fluctuation increase in the size of v-nanopores or, correspondingly, for more or less fast migration of admixtures over the sponge bulk.

The nanosized heterogeneity of the molecular spongy micelles influences the chemistry of chain reactions. Firstly, foreign compounds (oxygen, initiators, inhibitors) are distributed non-uniformly between the zones, being mainly accumulated in the v-grains. Secondly, due to different sizes of the s- and v-nanopores, the reactivities of macromolecules and admixtures absorbed in them are appreciably dissimilar. Indeed, a reacting species in a narrow v-micropore resides most of the time under constrained conditions — either on a nanopore wall (if it belongs to the macromolecule) or in the pore bulk (if it is a foreign species). A foreign molecule is expelled to the pore bulk under the influence of dispersion electromagnetic forces.^{28, 29} The situation in an s-nanopore is different: most of the time, a foreign molecule is adsorbed on the walls of a pore.

The difference between the chemical reactivities of a species caused by the steric and energetic nonequivalence of s- and v-nanopores affects all the intermediates of a chain reaction. The quantitative changes in the reactivity of the same reactant can be very pronounced; the pathways of transformations in the two zones can differ even qualitatively.

Chain reactions in spongy micelles can proceed in different modes; kinetic modelling can be performed most easily for the steady-state heterophase and homophase modes, which are realised in the pure form when the rate of structural evolution is negligibly low, *i.e.* when the volumes and the properties of the zones are virtually invariant.

By definition, the scheme of a heterophase process should include separate charts for the reactions in each zone and the chart for the transfer of the reacting species from one zone to another. The primary reactions occur usually in s-zones because these zones provide more favourable conditions for the dissociative generation of free radicals, which subsequently migrate to v-zones.

If a chemical reaction is localised in one zone, it can formally be referred to as a homophase reaction. This situation is observed, for example, when free radicals are generated in v-zones when v-nanopores undergo high-frequency fluctuations and thus reach the size of s-nanopores. In this case, the initiating activity of the POOH groups captured by v-nanopores increases and the fluctuation initiation of a chain reaction starts to prevail.

The heterophase mode, involving coupling of non-uniform reaction chains, is more frequently encountered in the absence of clear-cut structural evolution of high-molecular-mass polyolefins. Oxidation of a polymer without an admixed initiator starts upon direct reaction of oxygen adsorbed on s-nanopore walls with the CH groups of the polymer s-segments. The greater part of the generated free radicals enter into subsequent reactions and decay without leaving the s-nanopore. When a small portion of radicals has passed from s-zones to the bulk of v-grains and has induced there reaction v-chains, the process acquires a heterophase character.

The sequence of s,v-transitions (s,v-translations) of free radicals described by the corresponding chart means physically the passage of free valences through the structural 'bottle-neck'. The 'bottle-neck' capacity depends on the thermomechanical state of the polymer sample and on the presence of impurities able to promote or, conversely, suppress the s,v-translation of free valences.

The secondary reaction chains induced by this transfer (in v-zones) differ fundamentally from the primary chains (in s-zones) in the character of transformations. In particular, oxygen is mainly accumulated in v-zones. In addition, the rate of rupture of polymer chains with participation of alkyl macroradicals and the rate of termination of oxidation chains in v-zones are lower than those in s-zones. Consequently, the reaction v-chains are longer. Thus, the amount and composition of the oxidation products are mainly determined by the transformations of polymer units of v-zones, which constitute the main bulk of the molecular spongy micelles.

The steady-state oxidation mode includes the steps of transfer of hydroperoxide groups from v-zones to s-zones. The hydroperoxide formed in narrow v-nanopores dissociates into radicals very slowly due to unfavourable steric and energetic conditions. However, as hydroperoxide is accumulated, it starts to occupy the stationary s-zones, which have supernanopores favourable for dissociation. Thus the process passes from the induction period to the self-accelerated stage.

IV. Kinetic model of oxidation of polyolefins

1. Induction period

In accordance with the foregoing, the overall scheme of an initial period of autooxidation of polyolefins includes two charts for reactions in s- and v-zones and a chart for the inter-zone chemical induction, responsible for coupling of inhomogeneous reaction chains.

In the absence of a foreign initiator, free radicals are generated in s-nanopores upon the reaction of oxygen with the CH groups of the polymer.

The scheme of the primary reaction chain (in the s-zone) can be written in the following general form:

where PH_s is a polymer unit in zone s, which includes reactive hydrogen atoms, $\text{P}_s^\bullet$ is the macroradical with a free valence on an internal unit of the macromolecule [for polyethylene (PE), this is $\sim\text{CH}_2\dot{\text{C}}\text{H}\sim$ and for polypropylene (PP), these are $\sim\text{CH}_2\dot{\text{C}}(\text{CH}_3)\sim$ and $\sim\dot{\text{C}}\text{HCH}(\text{CH}_3)\sim$], δ_1 is a factor characterising the yield of free radicals, $\text{R}_s^\bullet$ and $\text{R}^\bullet$ are a terminal radical and a terminal unsaturated group, respectively, and $\text{R}_{1s}^\bullet$ is the product of isomerisation of the terminal radical $\text{R}_s^\bullet$ (the structures of $\text{R}_s^\bullet$ and $\text{R}_{1s}^\bullet$ for PP have been considered previously²¹).

The pattern of the inter-zone transfer of free valence includes migration of the radical $\text{R}_s^\bullet$ from the supermolecular framework structure to the s-nanopore bulk (with transition to the $\text{R}_m^\bullet$ state) and subsequent oxidation of $\text{R}_m^\bullet$:

The subscript 'm' implies belonging to the nanopore bulk and 'tr' stands for belonging to the inter-zone chain transfer process.

As noted above, the rate of the s,v-transfer is negligibly low compared to the rate of radical transformations in the s-zone. It is determined by the thermomechanical ability of the radicals $\text{R}_s^\bullet$ to oscillate with some frequency between the rigid framework of s-segments and the s-nanopore bulk and to pass to the state $\text{R}_m^\bullet$, more convenient for the reaction with oxygen. The terminal radical $\text{R}_m\text{OO}^\bullet$ thus formed undergoes α -isomerisation⁴⁰ to a hydroperoxyalkyl radical, which decomposes with elimination of free hydroxyl $\text{HO}_m^\bullet$.

The free hydroxyl migrates to the v-zone and induces there a chain reaction

The $\text{POO}_v^\bullet$ radical thus formed can be converted according to three pathways to give hydroperoxides, epoxides, or chain termination products.

Epoxides **E**, which are highly reactive towards free radicals, undergo subsequent transformations giving rise to carbonyl compounds (the corresponding reactions are considered below).

When calculating the s-scheme, we employed the condition of steady-state concentration of free radicals and did not take into account the loss of s-radicals by the inter-zone transfer; however, this transfer needs to be taken into account (as an initiation step) in the calculation of the v-scheme. The concentration of macroradicals responsible for the inter-zone chemical induction can be described by the expression

The presence of some compounds such as methyl ethyl ketone, methyl propyl ketone, butyraldehyde, pentanone, hexanone, *etc.* among the products of oxidation of polyolefins proves the occurrence of the above reactions.^{41–43}

The transformations of the terminal radical **B**[•] are shown in Scheme 2.

This set of reactions, which is far from being complete, is still sufficient to demonstrate the pathways to the final products of polyolefin oxidation and to state the fact that transformations of radicals **A**[•] and **B**[•] and carbonyl compounds have no influence on the steady-state concentration of peroxy radicals [Eqn (2)]. The concentration of carbonyl compounds, which are oxidised and formed again in the chain process, continuously increases.

In view of the foregoing, one can write the following condition for the steady-state concentration of epoxide

$$\frac{d[\text{E}]}{dt} = k_3[\text{POO}^{\cdot}]_1 - k_4[\text{E}][\text{POO}^{\cdot}]_1 = 0, \quad (4)$$

where $k_4 = (k'_4 + k''_4)$. It follows from Eqn (4) that $[\text{E}] = k_3/k_4 = \text{const}$. The total rate of accumulation of carbonyl compounds (CO) in the epoxide branch of the reaction is equal to

$$v_{\text{CO},1} = \left(\frac{d[\text{CO}]}{dt}\right)_1 = (\alpha_1 + \alpha_2)k_4[\text{E}][\text{POO}^{\cdot}]_1 = \alpha k_3[\text{POO}^{\cdot}]_1,$$

where α_1 and α_2 are the yields of polymeric and volatile compounds, respectively, and α is their sum. Thus, after condition (4) has been reached, the rate $v_{\text{CO},1}$ depends on the pressure of oxygen in the same way as the rates v_1 and $v_{[\text{POOH}]_1}$ and the content of CO groups increases with time in accordance with the equation

$$[\text{CO}]_1 = v_{\text{CO},1} t. \quad (5)$$

The same is true for the growth of the concentration of broken polymer chains (n) in the v-zones of spongy micelles detected by viscometry. The total rate of chain rupture is composed of two fractions proportional to the constants k'_4 and k''_4 :

$$v_{n,1} = \left(\frac{dn}{dt}\right)_1 = (v_1 k'_4 + v_2 k''_4)[\text{E}][\text{POO}^{\cdot}]_1 = \text{const}[\text{POO}^{\cdot}]_1, \quad (6)$$

where v_1 and v_2 are coefficients.

The direct proportionality between the amount of oxidation products and the amount of oxygen absorbed in the induction

period, which follows from the scheme in question, is also retained for some time after the induction period has been completed, this time being much longer for the processes of accumulation of carbonyl compounds and destruction of macromolecules than for accumulation of POOH.^{41–43}

It should be emphasised that Eqn (5) refers to the overall process of formation of carbonyl compounds accompanied by abstraction of monomeric fragments. These destruction steps change the viscosity of the polymer solution only slightly compared to the primary scission steps in the epoxide branches, the rates of which are described by Eqn (6).

2. Hydroperoxide-initiated process

The induction period in the autooxidation of polyolefins usually ends when 10^{-2} mol kg⁻¹ of oxygen has been absorbed due to the occupation of the s-zones of the spongy matrix by the hydroperoxide from v-zones. This occupation is provided by the transfer of free valence and migration of OOH groups along the polymer chain and by the fluctuation steps of rearrangement of the molecular sponge units.^{15, 20, 21, 33}

By expressing the total frequency of the v,s-transfer of the OOH groups in terms of the effective constant k_{vs} , taking into account the fact that activation of these processes requires a fluctuation of the sponge with opening of narrow v-micropores, we can express the scheme of the hydroperoxide v,s-transfer as

where the subscript 'f' refers to a fluctuationally excited v-nanopore with a trapped OOH group.

Having got into the s-nanopores, the OOH groups become able to dissociate to give free radicals

and, as their concentration increases, to enter into the bimolecular reaction

giving no free radicals. This scheme of the chemical inter-zone feedback permits us to express the steady-state concentrations of the OOH groups in the fluctuationally active and s-states by the equation

$$\begin{aligned}
 \frac{d[\text{POOH}]_f}{dt} &= k_f[\text{POOH}]_v - k_{-f}[\text{POOH}]_f - \\
 &- k_{vs}[\text{POOH}]_f - k^f[\text{POOH}]_s[\text{POOH}]_f = 0.
 \end{aligned}$$

Scheme 2

In view of the high rate of deactivation of fluctuations, the last two terms can be neglected and the resulting expression

$$[\text{POOH}]_f = \frac{k_f[\text{POOH}]_v}{k_{-f}}$$

can be used in the equation for the rate of the reaction involving s-hydroperoxide

$$\frac{d[\text{POOH}]_s}{dt} = k_{vs}[\text{POOH}]_f - k_f[\text{POOH}]_s[\text{POOH}]_f - k_{os}[\text{POOH}]_s = 0.$$

The concentration $[\text{POOH}]_s$ found in this way,

$$[\text{POOH}]_s = \frac{k_{vs}k_f[\text{POOH}]_v}{k_{-f}k_{os} + k_fk_f[\text{POOH}]_v}, \quad (7)$$

can be used to express the overall rate of radical generation in s-zones by the equation

$$v_{is} = k_0''[\text{O}_{2,s}] + \delta k_{os}[\text{POOH}]_s \approx \delta k_{os}[\text{POOH}]_s.$$

The contribution of the direct reaction between CH bonds and oxygen soon becomes negligibly small and the expression for $v_{tr,1}$ derived previously is replaced by the equation

$$v_{tr,2} = \frac{k_{tr}k_m\delta k_{os}[\text{POOH}]_s[\text{O}_{2,s}]}{2k_{1s}(k_{-m} + k_{tr}[\text{O}_{2,s}])}$$

(the subscript 2 denotes the second stage of the oxidation process).

The equation describing the concentration of peroxy radicals also changes

$$[\text{POO}^*]_2 = \frac{(k_{tr}k_m\delta k_{os}[\text{POOH}]_s[\text{O}_{2,s}])^{0.5}}{[4k_1k_{1s}(k_{-m} + k_{tr}[\text{O}_{2,s}])^{0.5}]}. \quad (8)$$

During an initial period of the accelerated stage of autooxidation, the final reaction products are accumulated synchronously with the hydroperoxide. Being unable to dissociate in the v-zones of the spongy matrix, hydroperoxide is accumulated for some period almost without reacting with other oxidation products because their concentrations are too low. The rate of hydroperoxide accumulation during this period is described by the equation

$$v_{[\text{POOH}]_2} = k_2[\text{POO}^*] = A(\delta k_{os}[\text{POOH}]_s)^{0.5},$$

where

$$A = k_2 \left\{ \frac{k_{tr}k_m[\text{O}_{2,s}]}{4k_1k_{1s}(k_{-m} + k_{tr}[\text{O}_{2,s}])} \right\}^{0.5},$$

or, with allowance for Eqn (7) and the relation $[\text{POOH}]_v \approx [\text{POOH}]$, which means that the major portion of OOH groups of the non-crystalline polymer phase is concentrated in the v-zones, by the equation

$$v_{[\text{POOH}]_2} = A \left\{ \frac{\delta k_{os}k_{vs}}{k_f[1 + k_{os}k_{-f}/(k_fk_f[\text{POOH}]_v)]} \right\}^{0.5} = \frac{v_{[\text{POOH}]_3}}{(1 + C/[\text{POOH}])^{0.5}}, \quad (9)$$

where $v_{[\text{POOH}]_3} = A(\delta k_{os}k_{vs}/k_f)^{0.5}$, $C = k_{os}k_{-f}/(k_fk_f)$.

The expressions for the rates of the other macroscopic processes have the following form:

$$\begin{aligned} v_{CO} &= \alpha k_4[E][\text{POO}^*] = \frac{v_{CO,3}}{(1 + C/[\text{POOH}])^{0.5}} = \\ &= \frac{\gamma v_{[\text{POOH}]_3}}{(1 + C/[\text{POOH}])^{0.5}}, \\ v_{aq} &= k'_1[\text{HO}^*][\text{PH}] = \beta k_3[\text{POO}^*] = \frac{v_{aq,3}}{(1 + C/[\text{POOH}])^{0.5}}, \end{aligned} \quad (10)$$

$$\begin{aligned} v &= v_{CO} + v_{[\text{POOH}]_2} = \frac{v_3}{(1 + C/[\text{POOH}])^{0.5}} = \\ &= \frac{v_{[\text{POOH}]_3}}{\varphi(1 + C/[\text{POOH}])^{0.5}}, \end{aligned} \quad (11)$$

$$v_n = (v_1k'_4 + v_2k''_4)[E][\text{POO}^*] = \frac{v_{n,3}}{(1 + C/[\text{POOH}])^{0.5}}, \quad (12)$$

where $\gamma = \alpha k_3 k_2^{-1}$, β is the yield of water, φ is the yield of the hydroperoxide, $v_{[\text{POOH}]_3}$, $v_{CO,3}$, $v_{aq,3}$, v_3 and $v_{n,3}$ are the maximum rates at the third macroscopic stage of autooxidation, attained when $C/[\text{POOH}] < 1$. This inequality transforms Eqn (7) to the form

$$[\text{POOH}]_s = \frac{k_{vs}}{k_f} = \text{const}. \quad (13)$$

It follows from Eqn (13) that the self-accelerated stage of oxidation should sooner or later come to an end because the s-zone is the structural boundary of the micellar reactor, which terminates the chemical relay of the OOH groups and thus favours the bimolecular reaction giving no free radicals.

Since a hydroperoxide-involving reaction takes place in the s-zone, oxidation takes place again in a regime which obeys a zero order with respect to hydroperoxide. In this case, hydroperoxide still acts as an initiator and simultaneously plays the role of a specific buffer because it maintains a constant rate of initiation of the reaction v-chains and a certain time-independent concentration of free peroxy radicals [Eqn (8)].

Equations (9)–(11) and (13) derived theoretically have been confirmed experimentally in a number of studies^{15, 18, 20–22} in which the third macrokinetic stage of autooxidation with the zero order with respect to hydroperoxide was defined for the first time.

When oxidation follows the zero order with respect to POOH, the maximum rate of oxygen absorption in the third steady-state stage (v_3) depends on the oxygen pressure and tends to a limit at high P_{O_2} :

$$v_3 \sim \left(\frac{P_{O_2}}{b + P_{O_2}} \right)^{0.5}.$$

Unlike v_3 , the rate v_1 (in the induction period) does not reach a constant value as P_{O_2} increases; according to Eqn (3), $v_1 \rightarrow P_{O_2}^{0.5}$. These differences, which have not been interpreted in terms of the homogeneous model, are explained in the heterophase model by assuming that oxygen acts twice as an initiator of oxidation chains during the induction period — first, in the generation of s-radicals and, second, in the s,v-transfer of the free valence. In the steady-state stage of the process, oxygen no longer acts as the main initiator but still promotes the passage of radicals through the structural ‘bottle-neck’.

3. The mechanism of decomposition of POOH by oxidation products

As has already been noted, the synchronism of the absorption of oxygen and accumulation of the hydroperoxide is violated starting from some point due to the reaction of POOH with reaction products (note that decomposition of POOH in oxidised polyolefin in the absence of oxygen follows a chain mechanism,^{16, 34} as opposed to the non-chain decomposition of POOH during polymer oxidation).

Carboxylic acids are known to accelerate hydroperoxide decomposition.^{3, 44, 45} Study of reactions in mixtures of cumene hydroperoxide with acetophenone, dimethylphenylcarbinol, and benzoic acid showed that only the acid can markedly accelerate hydroperoxide decomposition (giving free radicals).⁴⁵ Acids are among the major products of oxidation of polyolefins; they are characterised by a broad molecular-mass distribution. It should be expected that acids with long molecular tails incorporated in the micellar sponge would not affect much the decomposition of POOH because they cannot freely migrate over the matrix. The decomposition is catalysed, most probably, by the mobile frag-

ment acids formed upon oxidative abstraction of terminal ketone groups.

The equation for the rate of formation of terminal ketones

$$\begin{aligned} v_{\text{CO},t} &= \alpha_t k_4 [\text{E}] [\text{POO}^*] = \alpha_t k_3 [\text{POO}^*] = \\ &= \frac{\gamma_t v_{[\text{POOH}],3}}{(1 + C/[\text{POOH}])^{0.5}} \end{aligned}$$

$[\alpha_t]$ is the yield of $(\text{CO})_t$ and $\gamma_t = \alpha_t k_3 k_2^{-1}$ can be simplified taking into account the fact that the accelerated stage on the curves of absorption of O_2 (and accumulation of CO groups) is substantially shorter than the steady-state stage (see Fig. 2)^{15, 21, 41–43, 46, 47}

$$v_{\text{CO},t} = \gamma_t v_{[\text{POOH}],3} = \text{const},$$

$$[\text{CO}]_t = \gamma_t v_{[\text{POOH}],3} t.$$

Then the rate of the formation of mobile acids (AH) can be written as

$$\frac{d[\text{AH}]}{dt} = k_5 [\text{CO}]_t [\text{POO}^*] = k_5 \gamma_t v_{[\text{POOH}],3} t$$

and their amount is equal to

$$[\text{AH}] = B t^2, \quad (14)$$

where $B = 0.5 k_5 \gamma_t v_{[\text{POOH}],3} = \text{const}$. Equation (14) is quadratic with respect to time. This accounts for the accelerated accumulation of acids observed at high levels of polyolefin oxidation, despite the substantial decrease in the concentration of POOH after the $[\text{POOH}]_{\text{max}}$ has been attained.^{48, 49}

It should be noted that the consumption of POOH, which accelerates with time, does not influence the invariant rate v_3 of the third macrokinetic stage of autooxidation; this indicates that the yield of radicals in the catalysed reaction is negligibly low.

An adequate scheme of the catalysed process should include condensation of POOH with the acid migrating in the sponge

The peroxy ester thus formed dissociates when the v-nanopore containing it undergoes fluctuation expansion to the volume of an s-nanopore; dissociation gives radicals, which disproportionate with regeneration of the acid without having time to depart from the expanded 'rigid cage'

This scheme is equivalent to the scheme of an intra-cage reaction in which radicals do not migrate to the bulk of the reacting material.¹⁶

Taking account of these considerations, we obtain a fuller kinetic equation for the rate of accumulation of hydroperoxide

$$\frac{d[\text{POOH}]}{dt} = \frac{v_{[\text{POOH}],3}}{(1 + C/[\text{POOH}])^{0.5}} - k_6 [\text{AH}] [\text{POOH}];$$

with allowance for Eqn (14), it acquires the form

$$\frac{d[\text{POOH}]}{dt} = \frac{v_{[\text{POOH}],3}}{(1 + C/[\text{POOH}])^{0.5}} - K [\text{POOH}] t^2, \quad (15)$$

where $K = 0.5 k_6 k_5 \gamma_t v_{[\text{POOH}],3}$, and the rate $v_{[\text{POOH}],3}$ at a saturating pressure of oxygen is

Figure 8. Calculated curves for accumulation of hydroperoxide during the oxidation of APP in air at temperatures of 90 (1), 100 (2), 110 (3) and 120 °C (4) (dots correspond to experimental results from Ref. 50).

$$v_{[\text{POOH}],3} = k_2 \left(\frac{\delta k_{0s} k_{vs} k_m}{4 k_t^f k_t k_{1s}} \right)^{0.5}. \quad (16)$$

The equation describing the rate of oxygen absorption remains the same in the steady-state period [see Eqn (11)]

$$\begin{aligned} v &= k_1 [\text{P}^*] [\text{O}_2] = (k_2 + \eta k_3) [\text{POO}^*] = v_{\text{CO}} + v_{[\text{POOH}],2} = \\ &= \frac{v_3}{(1 + C/[\text{POOH}])^{0.5}} = \frac{v_{[\text{POOH}],3}}{\varphi (1 + C/[\text{POOH}])^{0.5}}, \end{aligned}$$

where η is the multiplicity of oxygen absorption steps in the epoxide branches of oxidation and φ is the yield of POOH after absorption of 1 mol kg⁻¹ of oxygen.

The data obtained using differential kinetic equations (11) and (15) were compared with experimental data on the oxidation of molten APP (Fig. 8),⁵⁰ LDPE (Fig. 9),⁹ ethylene-propylene copolymers (EPC) (Fig. 10),⁵¹ solid-like IPP-1 and IPP-2 films differing in the size of spherulites (Fig. 2),^{24, 31} and home-manufactured polypropylene (IPP-3) (Fig. 11).[†] The theoretical curves presented in Figs 2 and 8–11, were calculated by the Runge–

[†] Data on the oxidation of polypropylene were provided by L N Guseva.

Figure 9. Calculated curves for the absorption of oxygen (I, I') and accumulation of hydroperoxide (2, 2') during oxidation of a LDPE melt at temperatures of 130 (a) and 160 °C (b) and $P_{\text{O}_2} = 100$ kPa (dots correspond to the experimental data from Ref. 9).

Figure 10. Calculated curves for the absorption of oxygen (*a*) and accumulation of hydroperoxide (*b*) in EPC-1 (*I*, *I'*) and EPC-2 (*2*, *2'*) melts at 130 °C and $P_{O_2} = 40$ kPa (dots correspond to the experimental data from Ref. 51).

Figure 11. Experimental points and calculated curves for the accumulation of hydroperoxide during oxidation of IPP-3 in air at temperatures of 120 (*I*), 130 (*2*) and 140 °C (*3*).

Kutta method using a simplified version in which Eqns (11) and (15) were integrated separately.⁵² This simplification, used instead of solving the set of two equations, restricts the scope of calculations at high degrees of oxidation by the condition $C/[POOH] < 1$, which is still quite sufficient to perform the given task.

The v_3 and $v_{[POOH],3}$ values were found by drawing tangents to the ascending branches of the curves shown in Figs 2 and 8–11. The coefficients C and K were determined using Eqns (11) and (15). Due to the scatter of experimental points and the values for the induction periods (τ) and the accumulated hydroperoxide concentrations $[POOH]_1$ corresponding to these periods, all the above-listed parameters had to be refined by performing series of calculations in order to attain the best agreement between the calculated curves and experimental points.

The curves for the variation of the concentration of POOH in APP being oxidised in air at temperatures of 90, 100, 110 and 120 °C are presented in Fig. 8.⁵⁰ These curves are matched by the following kinetic characteristics:

$T/^\circ\text{C}$	τ/h	$v_{[POOH],3}/\text{mol kg}^{-1}\text{h}^{-1}$	K/h^{-3}
90	33	0.0129	6.3×10^{-6}
100	10	0.0255	5.6×10^{-5}
110	2	0.0400	3.0×10^{-4}
120	0–1	0.0700	2.0×10^{-3}

In all cases, the equality $C = [POOH]_1 = 0.02$ mol litre⁻¹ holds. The relevant general equations have the following form on the minute time scale

$$\tau = 5.25 \times 10^{-19} \exp(E_\tau/RT) \text{ min},$$

$$v_{[POOH],3} = 2.1 \times 10^6 \exp(-E_{[POOH]}/RT) \text{ mol litre}^{-1} \text{ min}^{-1},$$

$$K = 3.9 \times 10^{22} \exp(-E_K/RT) \text{ min}^{-3},$$

where $E_\tau = 150$, $E_{[POOH]} = 69.5$, $E_K = 230$ kJ mol⁻¹.

Figure 9 presents the calculated curves for the absorption of oxygen and for the accumulation of POOH in a melt of LDPE subjected to oxidation at an oxygen pressure of 100 kPa and temperatures of 130 and 160 °C. These curves are matched by the following kinetic characteristics:

$T/^\circ\text{C}$	τ/min	$v_3/\text{mol kg}^{-1}\text{min}^{-1}$	$v_{[POOH],3}/\text{mol kg}^{-1}\text{min}^{-1}$	K/min^{-3}
130	160	0.006	1.05×10^{-3}	1.7×10^{-8}
160	12	0.076	1.45×10^{-2}	1.6×10^{-5}

The curves for LDPE obtained in another publication⁹ at 150 °C ($P_{O_2} = 100$ kPa), which are not given in Fig. 9, are in good agreement with experimental data for $\tau = 35$ min, $v_3 = 0.036$, $v_{[POOH],3} = 0.005$ mol kg⁻¹ min⁻¹ and $K = 1.0 \times 10^{-6}$ min⁻³. In the case of LDPE, the equality $C = [POOH]_1 = 0.02$ mol kg⁻¹ also holds. The corresponding general equations have the following form:

$$\tau = 4.34 \times 10^{-15} \exp(E_\tau/RT) \text{ min},$$

$$v_3 = 8.86 \times 10^{13} \exp(-E/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

$$v_{[POOH],3} = 1.48 \times 10^{13} \exp(-E_{[POOH]}/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

$$K = 1.86 \times 10^{31} \exp(-E_K/RT) \text{ min}^{-3},$$

where $E_\tau = 128.4$, $E = 124.4$, $E_{[POOH]} = 124.4$, $E_K = 300$ kJ mol⁻¹. The average yield of hydroperoxide is $\phi = 0.167$.

Figure 10 shows the calculated curves for the absorption of oxygen and accumulation of POOH in the EPC-1 and EPC-2 samples, the macromolecules of which contain 1.5 mass % and 24 mass % of propylene units, respectively.⁵¹ In this case, the results of calculations are in good agreement with experimental data for the following kinetic parameters:

for EPC-1 — $C = [POOH]_1 = 0.01$ mol kg⁻¹, $\tau = 180$ min, $v_3 = 0.004$, $v_{[POOH],3} = 6.2 \times 10^{-4}$ mol kg⁻¹ min⁻¹, $K = 1.0 \times 10^{-8}$ min⁻³, $\phi = 0.15$;

for EPC-2 — $C = [POOH]_1 = 0.02$ mol kg⁻¹, $\tau = 100$ min, $v_3 = 0.005$, $v_{[POOH],3} = 1.1 \times 10^{-3}$ mol kg⁻¹ min⁻¹, $K = 2.8 \times 10^{-8}$ min⁻³, $\phi = 0.22$.

Similar calculated curves for samples of IPP-1 (with small spherulites) and IPP-2 (with large spherulites) subjected to oxidation at 130 °C and $P_{O_2} = 40$ kPa are presented in Fig. 2. Satisfactory agreement between theoretical and experimental results is attained with the following parameters:

for IPP-1 — $C = 0.025$ mol kg⁻¹, $[POOH]_1 = 0.01$ mol kg⁻¹, $\tau = 10$ min, $v_3 = 0.0365$, $v_{[POOH],3} = 0.005$ mol kg⁻¹ min⁻¹, $K = 3.0 \times 10^{-6}$ min⁻³, $\phi = 0.14$;

for IPP-2 — $C = 0.025$ mol kg⁻¹, $[POOH]_1 = 0.01$ mol kg⁻¹, $\tau = 40$ min, $v_3 = 0.022$, $v_{[POOH],3} = 0.004$ mol kg⁻¹ min⁻¹, $K = 1.7 \times 10^{-6}$ min⁻³, $\phi = 0.18$.

The theoretical curves for the accumulation of POOH in IPP-3 samples being oxidised in air (Fig. 11) were constructed for $C = [\text{POOH}]_1 = 0.01 \text{ mol kg}^{-1}$. These curves are matched by the parameters presented below

$T/^\circ\text{C}$	τ/h	$v_{[\text{POOH}]_3}/\text{mol kg}^{-1} \text{ h}^{-1}$	K/h^{-3}
120	1	0.056	0.003
130	0.4	0.115	0.026
140	0	0.190	0.110

The general equations for the parameters τ , $v_{[\text{POOH}]_3}$ and K on the minute time scale have the form

$$\tau = 6.66 \times 10^{-15} \exp(E_\tau/RT) \text{ min},$$

$$v_{[\text{POOH}]_3} = 7.72 \times 10^8 \exp(-E_{[\text{POOH}]/RT}) \text{ mol kg}^{-1} \text{ min}^{-1},$$

$$K = 1.94 \times 10^{23} \exp(-E_K/RT) \text{ min}^{-3},$$

where $E_\tau = 120$, $E_{[\text{POOH}]} = 90$, $E_K = 234 \text{ kJ mol}^{-1}$.

Calculations show that the theoretical equations (11) and (15) for a heterophase process describe correctly the relationship between the curves for the absorption of oxygen and accumulation of POOH and account for their non-synchronism over a long time interval and for the succession of induction and self-acceleration periods and a steady-state period characterised by a constant rate of oxygen absorption. During these periods, the yield of POOH per mole of absorbed oxygen does not change, although the concentration of POOH passes through a maximum. This indicates that the process is mainly due to the reaction of POOH with the accumulating reaction products and that the contribution of the chain reaction of POOH is negligibly small.

Catalytic decomposition of polymeric hydroperoxides is characterised by a high effective activation energy E_K . In accordance with the heterogeneous scheme, the rate of catalytic reaction is determined by the rate of interaction of peroxy radicals with the terminal ketone groups and of the condensation of POOH with acids (the activation energies of these reactions are E_5 and E_6 , respectively). The occurrence of these reactions might require strong thermomechanical fluctuations able to extend a v-nanopore of the micellar sponge to the appropriate size. Thus for a LDPE melt, $E_K = 300 \text{ kJ mol}^{-1}$, i.e. it is greater than the corresponding values for APP and IPP melts in which the activation energies are 230 and 234 kJ mol^{-1} , respectively; this can be due to the more ordered arrangement of the chain segments in LDPE^{32,53} (or to a smaller size of steady-state v-nanopores and greater relative increase in the volume during fluctuation beats).

When the degree of oxidation is high, the theoretical curves for the variation of the concentration of POOH presented in Figs 8–11 can markedly deflect downwards from the experimental points. This can be explained by assuming that the acids (catalysing decomposition of POOH) are lost due to evaporation and to side reactions which are not taken into account in the scheme. Evaporation of monomeric fragments from a polymer being oxidised is limited, unlike the transfer of oxygen,⁵⁴ by physical diffusion at any sample thickness admissible from the experimental standpoint; therefore, the average concentration of volatile acids depends on the thickness of polymer films, which substantially influences $[\text{POOH}]_{\text{max}}$.

It is also noteworthy that experimental curves 3, 4 in Fig. 2 deviate at high degrees of oxidation from the theoretical curves 5, 6 (when the concentration of POOH markedly decreases having passed through a maximum). Among other reasons, this may be due to the distortion of the amount of absorbed oxygen measured by a pressure gauge, caused by the accumulation of gaseous oxidation products, namely, CH_4 , CO and H_2 , which are not absorbed by sorbents meant for H_2O and CO_2 and do not freeze out at the liquid nitrogen temperature. These gases are not only evolved during polymer oxidation but are also formed in the gas-phase oxidation of the volatile oxidation products.

4. Phenomenological consequences

The sequential replacement of macroscopic stages of the reaction is a general feature of the oxidation of high-molecular-mass hydrocarbons (Fig. 12).

The whole set of experimental data presented in Fig. 12 can be described by only one curve, characterised by a rather long self-acceleration period.^{4,27} However, this masks the real patterns of individual curves for each particular polymer. Meanwhile, by distinguishing a series of points for each polymer (see Fig. 12), one can easily make sure that the self-accelerated stage, which follows the induction period, is actually much shorter and is soon replaced by a prolonged steady-state period, which obeys zero-order kinetics with respect to hydroperoxide, i.e. the pattern described above is represented in this case.

The above relation giving the induction period of the oxidation of LDPE [$\tau = 4.34 \times 10^{-15} \exp(128000/RT) \text{ min}$] can be supplemented by two other relations, which were derived from the plots taken from two publications:^{27,55} $\tau = 3.93 \times 10^{-12} \exp(107000/RT) \text{ min}$ (see Ref. 27) and $\tau = 2.5 \times 10^{-9} \exp(85700/RT) \text{ min}$ (Ref. 55). The presence of three different expressions for one polymer (LDPE) implies, on the one hand, that the activation energies E_τ vary over wide limits and, on the other hand, that the pre-exponential factor (τ_0) varies simultaneously with E_τ , i.e. the so-called compensation effect (CEF) is observed.⁶

For each of the above-mentioned polymers, the following relation holds:

$$\ln \frac{1}{\tau_0} = -12.0 + 3.6 \times 10^{-4} E_\tau.$$

The compensation effect is also displayed in the description of the steady-state rates of the accumulation of hydroperoxide in APP, IPP-3 and LDPE (in $\text{mol kg}^{-1} \text{ min}^{-1}$):

$$\text{for APP} — v_{[\text{POOH}]_3} = 2.1 \times 10^6 \exp(-69500/RT),$$

$$\text{for IPP-3} — v_{[\text{POOH}]_3} = 1.93 \times 10^9 \exp(-90000/RT) \text{ (recalculated in relation to the non-crystalline phase of the polymer),}$$

$$\text{for LDPE} — v_{[\text{POOH}]_3} = 1.48 \times 10^{13} \exp(-124700/RT).$$

These formulae can be supplemented by the results of calculations performed using the plots given in the study by Iring *et*

Figure 12. Amount of absorbed oxygen vs. the $a^{0.5}(t - \tau)$ value in the oxidation of several polymers:

(1) polyethylene (90°C); (2) polypropylene (130°C); (3) ethylene copolymer with 13.5% of propylene (130°C); (4) poly-4-methylpent-1-ene (130°C); (5) a vulcanised synthetic rubber (110°C); (6) polystyrene (160°C); (7) polyhept-1-ene (100°C); (8) polynon-1-ene (100°C); (9) epoxy rubber (200°C).^{4,27}

Curves B, C and D are shifted relative to curve A along the abscissa axis by one (B) or two (C, D) scale units (one scale unit is equal to 0.5). The $a^{0.5}$ values, induction periods and oxygen pressures are given in a monograph⁴.

al.⁵⁵ for the oxidation of LDPE (the value $\varphi = 0.17$ found for LDPE was employed in the calculations):

in the region of $T < T_m$,

$$v_{[\text{POOH}]_3} = 1.87 \times 10^6 \exp(-76\,000/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

in the region of $T > T_m$

$$v_{[\text{POOH}]_3} = 4.25 \times 10^{15} \exp(-145\,000/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

where T_m is the melting point of crystallites.

In this case, the relationship between the $E_{[\text{POOH}]}$ values and the pre-exponential factors ($v_{[\text{POOH}]_3}^0$) is described by a common equation

$$\ln(v_{[\text{POOH}]_3}^0) = -7.0 + 3 \times 10^{-4} E_{[\text{POOH}]},$$

which does not depend on the presence of substituents in macromolecules or on the change in $E_{[\text{POOH}]}$ following the transition of LDPE from the solid-like state to the molten state.

Attention is drawn to a peculiar inversion of the position of APP on the CEF plots; the point corresponding to this polymer is located right at the top of the straight section in the dependence of $\ln(1/\tau_0)$ on E_τ but it moves to the very bottom of the straight section in the dependence of $\ln(v_{[\text{POOH}]_3}^0)$ on $E_{[\text{POOH}]}$. Isotactic polypropylene behaves in a similar way.

The heterophase model of oxidation of polymers is at an early stage of development when structural-kinetic reaction models are tested; it still cannot provide a theoretical interpretation of the presence of CEF. However, even now, it is clear that the widely held opinion that the reaction rate should necessarily increase upon an increase in the molecular-segment mobility of macromolecules is unfounded.

Indeed, the rates of accumulation of the hydroperoxide groups at the third macroscopic stage of oxidation of molten APP and LDPE at 130 °C are 2.0×10^{-3} and 1.0×10^{-3} mol kg⁻¹ min⁻¹, respectively; however, in solid IPP-3, this rate is 4.0×10^{-3} mol kg⁻¹ min⁻¹.

It is noteworthy that, although IPP is oxidised faster than LDPE at 130 and 150 °C, the rate of the rupture of the IPP macromolecules determined by viscometry is 6 times as low.⁴² According to our heterophase scheme, this fact, which had not been interpreted previously,⁴² is associated with the existence of a competing pathway for the decomposition of the polymeric alkoxyl arising in the epoxide oxidation of IPP, accompanied by liberation of a methyl radical. No route of this type exists for LDPE; thus, the internal alkoxyl radicals formed in LDPE are mainly converted with the rupture of macromolecules.

We are reminded that statistical rupture of macromolecules (not related to the elimination of terminal fragments) can also take place in the s-zones of spongy micelles. The contribution of these events to the overall oxidative degradation is rather low due to the low mass fraction of polymeric s-segments. Meanwhile, in some cases, they can determine the physical essence of the process, for example, by ensuring the observance of the first kinetic order with respect to the initiator under conditions of chemically initiated relaxation of stress applied to cross-linked polymers.⁵⁶ The first order with respect to the initiator means that the mechanical strength of polymer samples under the experimental conditions is determined, first of all, by the degree of damage of the continuous three-dimensional paracrystalline framework, *i.e.* by the degree of development of the process that occurs directly in the s-zones of the spongy micelles.²¹

Yet another important remark concerns the coefficient C [see Eqns (9)–(12)], found for the IPP-1 and IPP-2 films ($C = 0.025$ mol kg⁻¹).^{24,31} This coefficient is exactly equal to the constant C determined previously in the experiments on anaerobic decomposition of hydroperoxide in films of previously oxidised IPP-1.³⁴ The point is that decomposition of POOH in this polymer in the absence of oxygen is due to a chain heterophase reaction, whose rate depends not only on the POOH concentration in the v-zones of spongy micelles but also on the POOH

concentration in s-zones and is proportional to $[\text{POOH}]_s^{0.5}$. The initial concentration $[\text{POOH}]_s$ in an anaerobic reaction is determined using Eqn (7); therefore, the constant C characterises both the oxidation and the anaerobic process. Thus, the value $C = 0.025$ mol kg⁻¹ reflects the real relationship between the rates of two heterophase processes which occur in the IPP-1 samples under conditions different in kind, namely, in the absence of oxygen and with active participation of oxygen.

It should be emphasised that the third macroscopic stage of the oxidation of a hydrocarbon polymer is not the last stage because the content of CH and OOH groups in the s-zones should sooner or later substantially decrease. This fact, together with the simultaneous change in the structure of molecular spongy micelles would inevitably produce a situation where Eqn (7) no longer holds and the reaction kinetics have changed. Nevertheless, the heterogeneous-heterophase model appreciably extends the capacities of the kinetic description of the oxidative transformation of hydrocarbon polymers.

V. Oxidation of molten polystyrene

The kinetic curves for the absorption of oxygen and accumulation of POOH in the oxidation of molten polystyrene (PS) (Figs. 13, 14), presented in a publication,⁵⁷ are qualitatively similar to those characterising oxidation of polyolefins. This is quite natural for a carbochain polymer with reactive CH bonds like PS, which is characterised by the same micellar spongy organisation of polymer chains as any non-crystalline polymer.³⁸ Meanwhile, the concentration of the POOH groups formed in PS is 100 times lower (Fig. 14).

Our calculations showed that the experimental data found in the study cited⁵⁷ are adequately described by theoretical equations (11) and (15). Using these equations, the following values were found for the parameters τ , K , and φ

T /°C	τ /h	v_3 /mol kg ⁻¹ h ⁻¹	$10^3 v_{[\text{POOH}]_3}$ /mol kg ⁻¹ h ⁻¹	K /h ⁻³	$10^2 \varphi$
180	0.4	0.06	1.35	0.07	2.25
190	0.05	0.14	2.35	0.44	1.68
200	~0.00	0.30	3.8	2.8	1.27
210	~0.00	0.61	—	—	—

The coefficient C (2.0×10^{-4} mol kg⁻¹) and the concentration of $[\text{POOH}]_1$ (1.5×10^{-4} mol kg⁻¹) are constant in the temperature range of 180–210 °C.

The relevant generalised expressions used to calculate v_3 , $v_{[\text{POOH}]_3}$, and K have the form (on the minute time scale)

$$v_3 = 9.7 \times 10^{12} \exp(-138\,500/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

$$v_{[\text{POOH}]_3} = 3.6 \times 10^5 \exp(-88\,300/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

Figure 13. Oxygen absorption during oxidation of a PS melt at 180 (1), 190 (2), 200 (3) and 210 °C (4) and $P_{O_2} = 26.7$ kPa.⁵⁷

Figure 14. Calculated curves for hydroperoxide accumulation during oxidation of a PS melt at 180 (1), 190 (2) and 200 °C (3) (the dots correspond to experimental data from Ref. 57).

$$K = 7.6 \times 10^{10} \exp(-151\,000/RT) \text{ min}^{-3}.$$

Polystyrene is much less reactive in oxidation than polyolefins. When comparing characteristics of oxidation of PS with the corresponding characteristics of polyolefin oxidation, one can note lower C and $[\text{POOH}]_1$ values.

The low C and hydroperoxide concentrations $[\text{POOH}]_1$ at the end of the induction period are due to high fluctuation mobility of the molecular sponge in a PS melt. This is indicated by the expression $C = k_{0s}k_{-f}(k^f k_f)^{-1}$, the denominator of which is the product of the fluctuation rate constants. In this particular case, it is 100 times as great as that for an LDPE melt. Presumably, the much higher frequency of beats of the nanopores in the PS sponge ensures a higher rate of migration of the OOH groups from the v-zones of spongy micelles to s-zones

and a higher rate of the radical-free bimolecular reaction,

which manifests itself as the fulfillment of Eqns (7), (8), (11) and (13).

In view of the high flickering activity of nanopores in the molecular sponge of PS, a simultaneous increase in the rate of the quadratic termination of reaction v-chains should be expected. However, the notation chosen previously for this step of the oxidation of polyolefins,

does not reflect in an explicit form the influence of the structural factor and formally corresponds to a homogeneous reaction. This simplified approach does not change much the kinetic description of the oxidation of high-molecular-mass polyolefins; however, when considering a wider range of objects, it is necessary to define the chain termination mechanism in more detail.

A more precise scheme of reactions of polymeric peroxy radicals in the molecular sponge should include the steps of fluctuation excitation and deactivation of the nanopores in which the peroxy radicals are located and the step of peroxy migration into a common nanopore and should also reflect the competition between the reaction steps and the departure of the peroxy radicals from the common nanopore

By applying the steady-state concentration condition to fluctuationally excited peroxy radicals and radical pairs, one can easily derive an expression for the chain termination rate

$$v_t = -\frac{d[\text{POO}^\bullet]}{dt} = \frac{2k_{t,1}k_{t,2}k_{t,3}[\text{POO}^\bullet]^2}{(k_{-t,1} + k_{t,2}[\text{POO}^\bullet])(k_{t,3} + k_{t,4})}.$$

When the probability of deactivation of the fluctuationally excited peroxy radicals is high, i.e. $k_{-t,1} > k_{t,2}[\text{POO}^\bullet]$, this expression acquires the form

$$v_t'' = \frac{2k_{t,1}k_{t,2}k_{t,3}}{k_{-t,1}(k_{t,3} + k_{t,4})}[\text{POO}^\bullet]^2 = k_t''[\text{POO}^\bullet]^2, \quad (17)$$

and when the frequency of encounter of two peroxy radicals in one nanopore is high, i.e. $k_{-t,1} < k_{t,2}[\text{POO}^\bullet]$, it has the form

$$v_t' = \frac{2k_{t,1}k_{t,3}}{k_{t,3} + k_{t,4}}[\text{POO}^\bullet] = k_t'[\text{POO}^\bullet]. \quad (18)$$

Although Eqn (17) implies a quadratic dependence of the termination rate on the peroxy radical concentration, it actually refers to a heterogeneous process. Equation (18) describes heterogeneous linear termination of reaction chains, which would be impossible if equivalent peroxy radicals reacted in a homogeneous medium.

The fact that the kinetics of oxidation of PS are described by Eqns (11) and (15) implies the quadratic chain termination in accordance with Eqn (17). Thus, the low rate of oxidation of PS (compared to polyolefins) can be attributed to the great value of the termination rate constant $k_t'' = 2k_{t,1}k_{t,2}k_{t,3}/k_{-t,1}(k_{t,3} + k_{t,4})$; this is due to the fact that the rate constant for the fluctuations ($k_{t,1}$) is high and the rate constant for the 'collapse' of the v-nanopores with an increased size to the initial size ($k_{-t,1}$) is low. The benzene rings present in PS occupy room in nanopores and thus decrease the probability of their 'collapse'. As a consequence, the fluctuation oscillations of the surrounding sponge units become cooperative. The constant $k_{t,2}$ for the capture of the OOH groups by flickering nanopores can increase for the same reason.

The mechanisms of heterophase initiation and termination of reaction chains in the zones of the PS matrix do not change due to the presence of the benzene rings; therefore, expressions (7) and (13) for the steady-state concentrations of peroxy radicals remain valid. The qualitative similarity of the oxidation kinetics of PS and polyolefins implies that the chemical reactions involved in these two processes are the same. In particular, in PS, the terminal ketone groups are formed *via* the following route

In turn, the terminal ketone groups serve as the source of formation of benzaldehyde and benzoic acid (Scheme 3).

Figure 15. Calculated curves for hydroperoxide accumulation during oxidation of molten PEO in air at 80 (1), 90 (2), 95 (3) and 99 °C (4) (the dots correspond to experimental data from Ref. 18).

(0.2 mol kg⁻¹ h⁻¹) and ester groups in the polymer (0.35 mol kg⁻¹ h⁻¹). Accumulation of polymeric aldehydes proceeds at a high rate (5 mol kg⁻¹ h⁻¹) without the addition of gas-phase oxygen to macromolecules.

It is worth noting that oxidation of PEO in chlorobenzene and dichlorobenzene (75–95 °C) follows a mechanism of homogeneous chain reaction with the quadratic termination of reaction chains;⁶⁰ this was demonstrated using an initiator — azobisisobutyronitrile. For low degrees of the initiated reaction, the amount of POOH formed coincides almost entirely with the amount of absorbed oxygen. This indicates that the contribution of reactions of alkyl and peroxy macroradicals resulting in the rupture of polymer chains is insignificant.

The initiated oxidation of PEO in solution gives rise to ester groups. The initial rate of formation of these groups is close to zero but it increases to reach a constant value as POOH groups are accumulated.⁶¹ This finding points to the occurrence of induced decomposition of hydroperoxide

(ROO[•] is a peroxy radical of the initiator). In addition, this means that the probability of α- and β-isomerisation is relatively low. The β-isomerisation steps still do occur, although at a low rate, and thus ensure rupture of internal bonds in macromolecules

We would like to emphasise that the rate of scission of PEO macromolecules in solutions is relatively low and decreases during the reaction.⁶¹

Oxidation of low-molecular-mass molten PEO ($M_n = 6000$), unlike oxidation of PEO in solution, is accompanied, even at high temperature (145 °C), by vigorous formation of water and ester groups (at low concentrations of POOH). Apparently, under these conditions, the macromolecules are not split at the internal bonds.⁶² The same is true for oxidation of molten low-molecular-mass tetraethylene glycol, which is a homologue of PEO.⁶³ The difference between the oxidation processes in solutions and in melts is apparently due to the high concentration of CH₂ groups in the melts and to the predominant role of intermolecular propagation of oxidation chains. The frequency of contacts between macromolecules in solutions of PEO is much lower than in the melts; therefore, the role of intramolecular oxidation increases.

High-molecular-mass molten PEO, unlike the low-molecular-mass homologue, tends to undergo rather vigorous rupture of polymer chains under oxidation conditions. What is significant is that this process does not involve chemical binding of molecular oxygen. This specific feature can be interpreted by assuming that in the melt, long PEO molecules form heterophase spongy micelles, which contain zones with relatively large supernanopores. In these zones, oxygen molecules reside most of the time in the adsorbed state on the pore walls; hence, the alkyl macroradicals formed in the polymer s-segments can react without being oxidised. In view of the foregoing, by analogy with the mechanism of oxidation of polyolefins, the following scheme of reactions in the s-zone can be proposed:

This scheme, unlike that considered above, takes into account the participation of the terminal R_s radicals in the chain propagation steps giving rise to the $\sim\text{CH}_2\dot{\text{C}}\text{HO}\sim$ radicals, which then dissociate to yield aldehydes.

Full scheme of the oxidation process covers also the inter-zone chemical induction

the oxidation chains in v-zones

and the steps of occupation of s-zones by hydroperoxide

The main differences between the oxidation mechanisms of PEO and polyolefins are associated with the formation of aldehydes *via* a chain reaction in s-zones and with the decomposition of hydroperoxide *via* the intermediate condensation of aldehydes with POOH considered below

According to this scheme, simultaneously with regeneration of aldehydes, carboxylic acids, which also catalyse decomposition of POOH, can be accumulated in a PEO melt. However, the amount of carboxylic acids is much smaller than that of aldehydes and their role as catalysts must be insignificant.

This heterophase scheme accounts for the existence in the oxidation of PEO of macroscopic induction and self-accelerated periods and a period of steady-state oxidation with a zero order with respect to hydroperoxide. However, the differential kinetic equation describing the variation of the concentration of POOH differs somewhat from the corresponding equation for polyolefins.

By applying the condition of steady-state concentrations to the free radicals appearing in the s-scheme, one can easily derive an expression for the rate of accumulation of aldehydes (A):

$$v_A = \frac{d[A]}{dt} = k_d[P'_s] = \frac{k_{3s}[PH_s]v_i}{2k_{1s}},$$

where v_i is the rate of generation of free radicals in s-zones.

Since the CH bonds are highly reactive, oxidation of PEO soon passes from the induction period to the self-accelerated stage in which the relation

$$v_i = \delta k_{os}[POOH]_s = \frac{\delta k_{os}k_{vs}k_f[POOH]_v}{k_{-f}k_{os} + k_fk_f[POOH]_v}.$$

starts to be obeyed.

Substitution of this relation to the expression for v_A and taking into account that $k_{-f}k_{os} < k_fk_f[POOH]_v$ (the self-accelerated stage is much shorter than the subsequent stages of the process) gives a simplified equation for the rate of accumulation of aldehydes

$$v_A = k_{3s}[PH_s] \frac{\delta k_{os}k_{vs}}{2k_{1s}k_f} = v_{A,3},$$

where $v_{A,3}$ is the maximum constant rate of accumulation of aldehydes in the third stage of oxidation.

The equation for the overall rate of variation of the POOH concentration in the oxidation of PEO has the form

$$\frac{d[POOH]}{dt} = \frac{v_{[POOH],3}}{(1 + C/[POOH])^{0.5}} - k_A[POOH][A], \quad (19)$$

where k_A is the effective rate constant for the condensation. Substitution into relation (19) of the concentration of aldehyde

$$[A] = v_{A,3}t = k_{3s}[PH_s] \frac{\delta k_{os}k_{vs}}{2k_{1s}k_f} t,$$

gives the final equation for the rate of accumulation of POOH

$$\frac{d[POOH]}{dt} = \frac{v_{[POOH],3}}{(1 + C/[POOH])^{0.5}} - K[POOH]t,$$

where

$$K = k_A k_{3s}[PH_s] \frac{\delta k_{os}k_{vs}}{2k_{1s}k_f}. \quad (20)$$

The points determined from the experimental data obtained in Ref. 18 fit well in the integral curves calculated from Eqn (20) using the Runge–Kutta method (Fig. 15). The curves shown in Fig. 15 were constructed using the values $C = 0.08 \text{ mol kg}^{-1}$ and $[POOH]_i = 0.02 \text{ mol kg}^{-1}$ (the concentration of POOH at the end of the induction period) and the following kinetic parameters:

$T/^\circ\text{C}$	τ/h	$v_{[POOH],3}/\text{mol kg}^{-1} \text{ h}^{-1}$	K/h^{-2}
80	1.5	0.184	0.0105
90	0.7	0.40	0.0504
95	0.4	0.60	0.122
99	0.25	0.90	0.263

These parameters match the general formulae of the form

$$\tau = 3.7 \times 10^{-13} \exp(-97400/RT) \text{ min},$$

$$v_{[POOH],3} = 1.0 \times 10^{11} \exp(-91400/RT) \text{ mol kg}^{-1} \text{ min}^{-1},$$

$$K = 1.42 \times 10^{21} \exp(-180600/RT) \text{ min}^{-2}.$$

The experimental dependence of the rate of oxygen absorption v_3 on the pressure of oxygen P_{O_2} at 95°C found by Mikhnev *et al.*¹⁹ is described by the theoretical equation for the heterophase process (see Section IV)

$$v_3 = - \frac{aP_{O_2}^{0.5}}{(b + P_{O_2})^{0.5}},$$

where $a = 0.79 \text{ mol kg}^{-1} \text{ h}^{-1}$, $b = 1.0 \times 10^{-4} \text{ Pa}$.

As regards the mechanism of the catalytic decomposition of POOH, it can be assumed that the terminal aldehyde groups, which differ from internal units by a higher fluctuation mobility, are more efficient in approaching the OOH groups, which are mainly localised in the internal units of macromolecules. In this case, the effective rate constant for the condensation

has the form

$$k_A = \frac{k'_A k_{fA}}{k_{-fA}}, \quad (21)$$

where k_{fA} and k_{-fA} are the frequencies of the fluctuation excitation and deactivation, respectively, of v-nanopores containing aldehyde groups and k'_A is a quasi-elementary constant, which corresponds to the activation energy E'_A .

The activation energy E'_A can be estimated by using the above expression for the constant k_A , appearing in the relation for K . For this purpose, we multiply the numerator and denominator of this expression by k_f and replace k_A by the value from Eqn (21)

$$K = \frac{k'_A k_{fA} k_{3s} [\text{PH}_s] \delta k_{0s} k_{vs} k_f}{2 k_{-fA} k_{1s} k^f k_f}.$$

Let us assume that the reactions with the abstraction of hydrogen atoms (they are characterised by the constants k_{1s} and k_{3s} in the scheme) have virtually equal activation energies ($E_{1s} \approx E_{3s}$). Keeping in mind that the constant C does not depend on the temperature and assuming that the activation energy of the 'collapse' of the excited nanopores is equal to zero ($E_{-f} = E_{-fA} \approx 0$), we obtain the equality $E_{0s} = E^f + E_f$. By examining the expression for the constant K , we can find that the effective activation energy related to K ($E_K = 180.6 \text{ kJ mol}^{-1}$) is the sum

$$E_K = E'_A + E_{fA} + E_{vs} + E_f.$$

Hence,

$$E'_A = 180.6 - E_{fA} - E_{vs} - E_f.$$

Since the fluctuation excitation of nanopores and the migration of OOH groups (with the constants k_f , k_{fA} and k_{vs}) are limited³³ by kinetic jumps of the PEO chain segments and the activation energy of this process is $\sim 40 \text{ kJ mol}^{-1}$, the E'_A value is found to be equal to $\sim 60 \text{ kJ mol}^{-1}$; this fits in the series of values for the effective activation energy of the corresponding liquid-phase transformation.⁶⁴

The results of calculations lead to the following conclusions.

1. The fact that the kinetics of accumulation of POOH in a PEO melt at 80–100 °C are described by the single kinetic equation (20) of the heterophase process indicates that the structure of the micellar framework of s-zones is rapidly restored during oxidation, despite the destruction of s-units of macromolecules to give aldehydes.

2. Poly(ethylene oxide) is oxidised much faster than polypropylene, although the effective activation energies ($E_{[\text{POOH}]}$) in these two cases are close (90 and 91.4 kJ mol^{-1} for IPP-3 and PEO, respectively). This is due to the large difference between the pre-exponential factors in the expressions for the oxidation rate $v_{[\text{POOH}]}$,³ (the corresponding factors are 1.93×10^9 and $1.0 \times 10^{11} \text{ mol kg}^{-1} \text{ min}^{-1}$); in all probability, this is a consequence of the specific features of the heterogeneous mechanism of the oxidation chain termination.

According to Eqn (17), the rate constant for the heterogeneous chain termination k_t comprises several partial structure-mechanical constants, which are directly related to the fluctuation activity of the sponge units in the micellar grains of the polymeric matrix. In the case of PEO, which differs from IPP-3 by the absence of substituents and the presence of a large number of polar ether bonds and, hence, by a high density of intermolecular contacts, restructuring of the sponge during the volume beats of nanopores is apparently hampered. This should either decrease the probability of formation of a pair of peroxy radicals in one nanopore or increase the probability of the escape of peroxy radicals from the intermediate radical pairs.

It should also be emphasised that the activation energy of oxidation of molten PEO is lower than the activation energy of oxidation of a solution of PEO in trichlorobenzene,⁶² which is equal to 147 kJ mol^{-1} . This attests that the molecular-sponge structure, typical of a block polymer, is not formed in solution.

VII. Characteristic features of initiated oxidation of polymers

Initiators are finding extensive practical application in the studies of the kinetics of polymer oxidation. It is believed that they can stabilise for some period the rate of initiation of the transformations (v_{i0}) and thus ensure the non-branching-chain reaction mode. The researchers relying on the theory of homogeneous liquid-phase oxidation often restrict the measurements to the oxygen absorption rate.⁸ By calculations carried out in terms of homogeneous schemes, researchers find the apparent length of the oxidation chains and other kinetic parameters, which allow theoretical construction of the initial sections of kinetic curves for the absorption of oxygen; the results obtained by different authors can be compared more or less successfully.

When oxidation of polymers is treated as a homogeneous process, the scope of the use of the initiation method in kinetic investigations is restricted by several conditions.⁸ In particular, it is required that the initiator be the main source of radicals throughout the experiment (t) {i.e. the condition $v_{i0} > k_i[\text{POOH}]$ should hold}; the admissible working time interval estimated from the inequality $k_i t < 1$ should be $\sim 1000 \text{ s}$. The restrictions imposed on the parameters of initiated processes actually result in a purely formal mathematical description of the short stage of the process. This description is in fact adjusted to the known schemes of homogeneous reactions.

Meanwhile, as shown above, the kinetic features of the polymer process do not fit into the framework of the homogeneous reaction model. In the preceding Sections, we disclosed the mechanism of successive macroscopic stages of oxidation, caused by functioning in polymers of a 'structural-kinetic filter,' restricting the migration of free radicals and hydroperoxide between the structural zones of the matrix. This structural filter is also effective in the case of initiated oxidation of PEO and polyolefins.^{15, 19, 20} This is why the introduction of initiators, which reduce the time it takes to reach the maximum rate of the chain reaction, does not increase the maximum rate; excess initiator is either wasted (Fig. 4, 5) or even decreases the oxidation rate.¹⁹

It should be noted that kinetic features of the initiated oxidation of polymers can be elucidated much more comprehensively by analysing them in terms of heterophase models.

1. Structural filter effects

The presence of a structural filter, restricting transfer of the radicals formed upon decomposition of the initiator, is indicated, for example, by the kinetic curves for the variation of the total concentration of peroxides in IPP samples being oxidised in air at 100 °C in the presence of dibenzoyl peroxide²¹ (see Fig. 5). In the absence of BP, oxidation of IPP at 100 °C has an extended induction period ($\sim 35 \text{ h}$). In the presence of BP, the induction period vanishes; however, dibenzoyl peroxide, which readily dissociates and ensures an appreciably higher rate of initiation in homogeneous solutions than POOH, does not realise in full measure its potential as a source of free radicals. Curves 1 and 2 in Fig. 5 indicate that BP substantially accelerates oxidation of IPP; however, when its content is fairly high, the role of the leading initiator rapidly passes to hydroperoxide, while the BP itself becomes an inefficient ballast.

The unproductive loss of the initiator seems to be due to the 'cage effect,' which is considered in the literature as an analogue of the Franck–Rabinovich homogeneous liquid-phase effect.⁸ However, this approach does not provide interpretation of the curves in Fig. 5. In particular, curve 2 shows that accumulation of POOH proceeds at a constant rate from the very first moment when decomposition of BP has just begun (curve 3).

On the one hand, it can be suggested that only the first, minor portion of the initiator is active in the oxidation of IPP; after this portion has decomposed, the process is initiated only by hydroperoxide. In this case, the main bulk of BP should be located as if inside exceptionally rigid 'cages,' which do not let free radicals

migrate to the bulk of the polymeric matrix. In this case, BP is consumed for no result.

On the other hand, one can suggest with equal success that the free radicals formed from BP migrate to the matrix bulk throughout the whole period of BP decomposition, *i.e.* BP does not lose the initiating activity at the beginning. In this case, the invariance of the rate of POOH accumulation observed from the beginning (curve 2) under conditions of continuous decomposition of BP (curve 3) can be interpreted as pointing to the migration of the free radicals derived from BP from the 'homogeneous liquid-phase cages' to the matrix bulk, which is first insignificant and then permanently increases during the process. It can be easily seen that these two 'cage' models are mutually exclusive.

In addition, the homogeneous model of oxidation does not answer the following questions: why does the rate of accumulation of POOH at a relatively high initial concentration of BP (curve 2) remain constant even when BP has completely decomposed? and why do the rates of accumulation of POOH corresponding to the straight sections of curves 1, 2 remain equal and not increase as its concentration grows?

Such 'abnormal features' of the kinetic curves shown in Fig. 5 can be interpreted within the framework of the model of coupled heterophase s- and v-reaction chains. It should be borne in mind that the initiator molecules decompose mainly in the s-zones of the molecular spongy micelles,^{16, 38, 65} into which they get *via* inter-zone exchange. The BP concentration in the s-zones is

$$c_s = \frac{K_e c}{\beta},$$

where K_e is the equilibrium constant for the migration of BP molecules between the zones, c is the overall BP concentration calculated for the whole sample, and β is the fraction of non-crystalline polymeric phase.

When the polymer contains no POOH in the beginning of the process, the following reactions proceed in the s-zone:

According to this scheme, half the BP radicals add to polypropylene macromolecules to give the compounds PhC(O)OR and PhC(O)OR_1 .⁶⁵

Thus, the concentration of the $\text{R}_s^{\bullet}$ radicals

$$[\text{R}_s^{\bullet}] = \frac{k_{BP,s} c_s}{(k_{1s} + k_{2s} k_{BP,s} c_s / k_{1,BP})},$$

responsible for the induction of the oxidation chains in v-zones, increases as the BP concentration in the polymer grows and at high concentration c , it reaches a limiting value,

$$[\text{R}_s^{\bullet}]_{\text{lim}} = \frac{k_{1,BP}}{k_{2s}}.$$

For this reason, the rate of initiation of the oxidation chains in v-zones also reaches a limiting value for a high concentration of BP; therefore, the 'bottle-neck' effect manifests itself quite clearly in the inter-zone transfer of free valence as the unproductive loss of a great amount of the initiator.

The radical s,v-translation steps are known to be related to the oscillations of the terminal $\text{R}_s^{\bullet}$ radicals between the framework s-domains and the nanopore cavities. In the absence of BP, the

s,v-transfer is due to the interaction of the $\text{R}_m^{\bullet}$ radicals with oxygen (see Section IV). However, the $\text{R}_m^{\bullet}$ radicals are highly reactive towards the benzene rings of BP.^{16, 38, 65} The σ -complexes formed in this reaction are readily oxidised with oxygen with the evolution of free hydroperoxyl radicals $\text{HOO}^{\bullet}$, which participate in the decay of s-radicals

Thus, when no POOH is initially present and the content of BP in the polymer is high, one should expect that not only the limiting rate of the inter-zone chemical induction would be attained but also that the oxidation rate would diminish due to the competing trapping of free valences by dibenzoyl peroxide during the s,v-transfer (in the 'bottle-neck').

In view of the above consideration and with allowance for the scheme of oxidation v-chains, considered in Section IV, we obtain the following expressions for the initial rates of the initiated hydroperoxide accumulation ($v_{[\text{POOH}],BP}$) and oxygen absorption (v_{BP}):

$$\begin{aligned} v_{[\text{POOH}],BP} &= k_2 [\text{POO}^{\bullet}] = k_2 \left(\frac{v_{tr,BP}}{k_t'} \right)^{0.5}, \\ v_{BP} &= (k_2 + \eta k_3) [\text{POO}^{\bullet}] = \frac{k_2 v_{tr,BP}}{\phi k_t'^{0.5}}, \end{aligned}$$

where

$$v_{tr,BP} = k_{tr} [\text{R}_m^{\bullet}] [\text{O}_{2,s}] = \frac{k_m k_{BP,s} c_s P_{O_2}}{(b + b_1 c_s + P_{O_2})(k_{1s} + b_2 c_s)} \quad (22)$$

[$b_1 = k_m(\gamma_s k_{tr})^{-1}$, $b_2 = k_{2s} k_{BP,s} k_{1,BP}^{-1}$]. Equation (22) implies that the relation

$$v_{BP} \sim \frac{v_{tr,BP}^{0.5}}{k_t'^{0.5}} \sim (k_i c)^{0.5},$$

where $k_i = k_{BP,s} K_e \beta^{-1}$, should hold at a relatively low BP concentration in the polymer. It actually does hold, as has been confirmed experimentally. The relation $v_{BP} \sim (k_i c)^{0.5}$ is usually discussed in terms of homogeneous reaction schemes,⁸ although it basically refers to a special case of a heterophase process.

It follows from Eqn (22) that, at low concentrations of the initiator (c_s), the initial rate of oxygen absorption v_{BP} should increase with an increase in pressure P_{O_2} as long as the condition $(b + b_1 c_s) \leq P_{O_2}$ is fulfilled and until the limiting value $v_{BP,lim}$ is attained. As the BP concentration increases, the pattern of the curve $v_{BP} = f(P_{O_2})$ should change in a fairly complex manner. Over some range of the initiator concentration c , the limiting rate $v_{BP,lim}$ would increase but, simultaneously, the range of variation of v_{BP} in the pressure range from 0 to $P_{O_2,lim}$ would become wider. The oxidation of polypropylene at relatively low concentrations of BP has displayed exactly this type of behaviour.^{8, 66} In addition, when the BP concentration is very high, even a decrease in $v_{BP,lim}$ can be expected in conformity with Eqn (22).

Note that the logic of reasoning accepted in the studies by Denisov^{8, 66} was based on the homogeneous reaction model; the observed transformation of the curves for the variation of the oxidation rate *vs.* pressure of O_2 was explained by the existence of diffusion restrictions on the absorption of oxygen. Meanwhile, the heterophase model treats this fact as being due to the 'bottle-neck' effect, which exists even in the absence of diffusion restrictions.

A method for determining kinetic parameters of the processes discussed here borrowed from the homogeneous oxidation practice has been described in a monograph;⁸ this is the method of mixed initiation, which assumes the additivity of the rates of reactions initiated by the hydroperoxide and by an admixed initiator. Within the framework of the heterogeneous scheme, the overall rate of the process can be represented as the sum of the

rates of transfer of free valences through the structural 'bottle-neck', $v_{\Sigma} \sim (v_{tr,BP} + v_{tr,2})^{0.5}$. The kinetics of the oxygen absorption would formally comply with the laws of a homogeneous reaction. However, this additivity is often disturbed because POOH groups react with the initiator in the s-zones of the spongy micelles. The mechanisms of these reactions and the specific features of the kinetics of the initiated oxidation of polymers brought about by these reactions are considered below.

2. Suppression of the initiator by the hydroperoxide

We have considered above the decrease in the initiation efficiency according to the 'self-locking' mechanism at relatively high initiator (BP) concentrations. This mechanism implies capture of the $R_s^{\bullet}$ radicals, responsible for the inter-zone chemical induction, by the primary $PhC(O)O_s^{\bullet}$ radicals and by the dibenzoyl peroxide itself. However, this does not exhaust the specific features of the initiated process. Indeed, it can be seen from Fig. 5 (curve 2) that the oxidation rate in the presence of a high concentration of BP not only reaches the maximum possible value at the very beginning but also does not change subsequently during decomposition of BP and accumulation of POOH. In other words, POOH soon becomes the main initiator (note that the role of the hydroperoxide in restricting the initiator efficiency can also be clearly followed in experiments with initiators that dissociate with difficulty^{15, 19, 21}).

After POOH groups have appeared in the s-zones, in addition to the reactions described above (see Section VII.1), trapping of the initiator free radicals by hydroperoxide occurs followed by recombination and disproportionation steps

Peroxobenzoic acid reacts with hydroperoxide giving no free radicals

Taking into account the schemes for the s,v-transfer of radicals and for the oxidation chains in the v-zones and the steps of hydroperoxide migration and transformations, the rate of oxygen absorption can be expressed as follows:

$$v_{\Sigma} = (k_2 + \eta k_3)[POO^{\bullet}] = \frac{k_2}{\varphi} \left(\frac{v_{tr,\Sigma}}{k_t''} \right)^{0.5},$$

where the value

$$\begin{aligned} v_{tr,\Sigma} &= \frac{k_m P_{O_2}}{k_{1s}(b + P_{O_2})} \left(\frac{k_{1,BP} k_{BP,s} c_s}{k_{1,BP} + k_s [POOH]_s} + \delta k_{0s} [POOH]_s \right) = \\ &= k_t'' [POO^{\bullet}]^2 \end{aligned} \quad (23)$$

corresponds to the condition of a low concentration of BP ($b_1 c_s < b$, $b_2 c_s < k_{1s}$).

At the very beginning of oxidation when $[POOH]_s$ is close to zero and the relations $k_{1,BP} > k_s [POOH]_s$ and $k_{BP,s} c_s > \delta k_{0s} [POOH]_s$ are obeyed, Eqn (23) becomes simpler and assumes the form

$$v_{tr,BP} = \frac{k_m P_{O_2} k_{BP,s} c_s}{(b + P_{O_2}) k_{1s}} = k_t'' [POO^{\bullet}]^2,$$

and the rate of oxygen absorption is determined by the equation

$$v_{BP} = A(k_{BP,s} c_s)^{0.5} \sim (k_1 c)^{0.5},$$

where

$$A = \frac{k_2}{\varphi} \left[\frac{k_m P_{O_2}}{(b + P_{O_2}) k_{1s} k_t''} \right]^{0.5}.$$

This equation is consistent with the experimental data obtained with relatively low rates of decomposition of the initiator.^{8, 19}

Having occupied s-zones, the hydroperoxide becomes the main initiator. Since benzoyloxy radicals detach hydrogen from the OOH groups hundreds times as fast as from the CH groups,¹⁶ which ensures the fulfillment of the inequality $k_{1,BP}(k_s [POOH]_s)^{-1} \ll 1$, Eqn (23) can be transformed to the form

$$v_{tr,\Sigma} = \frac{k_m P_{O_2} \delta k_{0s} [POOH]_s}{k_{1s}(b + P_{O_2})}.$$

Thus, the oxidation rate is described by the relation

$$v_{\Sigma} = A(\delta k_{0s} [POOH]_s)^{0.5}. \quad (24)$$

To determine the concentration $[POOH]_s$, which appears in Eqn (24), the above reactions involving POOH need to be supplemented by the reactions of the proper transformations of the hydroperoxide (see Section IV.2). This gives the expression

$$[POOH]_s = \frac{k_{vf} [POOH]}{k_{0s} + k^{ff} [POOH] + 2k_s k_{BP,s} c_s / (k_{1,BP} + k_s [POOH]_s)},$$

which can be simplified. An identical transformation with the assumption that $k_{1,BP} \ll k_s [POOH]_s$ (this means that the hydroperoxide located in s-zones traps almost all radicals of the admixed initiator) gives

$$[POOH]_s = \frac{k_{vf} [POOH] - 2k_{BP,s} c_s}{k_{0s} + k^{ff} [POOH]}.$$

Here k_{vf} and k^{ff} are constants corresponding to the $POOH_v \longrightarrow POOH_s$ transfer and the $POOH_v + POOH_s$ reaction, respectively (accomplished through an excited v-nanopore; the detailed mechanism is described in Section IV.2), $[POOH] \approx \beta [POOH]_v$.

By substituting the concentration $[POOH]_s$ into Eqn (24), one can determine the rate of the oxygen absorption in the stage in which two sources of free radicals are effective

$$v_{\Sigma} = A \left(\delta k_{0s} \frac{k_{vf} [POOH] - 2k_{BP,s} c_s}{k_{0s} + k^{ff} [POOH]} \right)^{0.5}.$$

It follows from the above relation that, during the accumulation of the hydroperoxide, the oxidation rate increases to a certain limit, which is attained when $k_{0s} < k^{ff} [POOH]$

$$v_{max} = A \left(\delta k_{0s} \frac{k_{vf} [POOH] - 2k_{BP,s} c_s}{k^{ff} [POOH]} \right)^{0.5}. \quad (25)$$

If the subtrahend in Eqn (25) is sufficiently small, the reaction acquires the zero order with respect to both the initiator and hydroperoxide. Then

$$v_{max} = A \left(\frac{\delta k_{0s} k_{vf}}{k^{ff}} \right)^{0.5}.$$

This conclusion has been confirmed experimentally.^{15, 19, 21}

If the subtrahend in Eqn (25) is great, which is the case for a relatively high rate of dissociation of the initiator ($k_{BP,s} c_s \sim k_i c$), this term makes a contribution to the decrease in the steady-state oxidation rate. This has been observed in experiments with samples of readily oxidisable PEO; an increase in the BP concentration from 0.12 to 0.38 mol kg⁻¹ decreases the oxygen absorption rate by a factor of 1.4.¹⁹ This outcome appears as a paradox but it has a clear physical meaning in terms of the heterophase scheme, pointing to the interaction between two sources of free radicals, which is unproductive for oxidation.

In the scheme that we propose, the formation of peroxobenzoic acid in disproportionation steps and the radical-free reaction of peroxobenzoic acid with POOH can be classified as unproductive consumption of radicals. The possibility of radical-free bimolecular decomposition of peroxobenzoic acid can also be

assumed, by analogy with the heterogeneous reaction $\text{POOH}_f + \text{POOH}_s$ or, for example, with the known decomposition of *tert*-butyl hydroperoxide⁶⁷ and aromatic dihydroperoxide⁶⁸ in liquid solutions.

In this connection, the known fact of retardation of the initiated oxidation of polypropylene and polyethylene by the addition of cumene hydroperoxide⁸ (with BP as the initiator) can be considered from a new standpoint. In all probability, this fact is due to the decrease in the rate of initiation ($v_{tr,\Sigma}$) of oxidation v -chains caused by the unproductive loss of the radicals generated in s -zones. Anyway, the idea of acceleration of the oxidation chain termination upon the involvement of mobile cumene peroxy radicals⁸ does not seem quite convincing because the rate of injection of free valences into v -zones is extremely low. In our opinion, the conditions in s -zones are much more favourable for trapping of the BP free radicals by the admixed cumene hydroperoxide molecules and for unproductive (with respect to the oxidation chains) interaction between these components.

3. Synergism of the action of hydroperoxide and an initiator

In some cases, the hydroperoxide accumulated in the polymer enhances the efficiency of an admixed initiator. This is indicated by the fact that hydroperoxide has a promotory influence on azobisisobutyronitrile (AIBN),⁶⁹ although the researchers themselves did not interpret this effect. It was found that the rate of oxygen absorption by solid IPP at 82 °C in the presence of 7.5×10^{-2} mol kg⁻¹ of AIBN increases from the very beginning until it reaches a constant level, 4 to 7 times as high as the initial level. This increase is at variance with the view⁸ that the oxidation rate always remains constant as long as the initiation rate is constant. Meanwhile, the rate of oxidation of pre-oxidised IPP samples containing 5×10^{-3} mol kg⁻¹ of POOH and 7.5×10^{-2} mol kg⁻¹ of AIBN is equal from the beginning to the steady-state rate of oxidation of non-oxidised IPP.

The rates of radical generation upon dissociation of POOH and AIBN, found by the inhibitor method (based on the consumption of stable nitroxides) are 7.5×10^{-9} and 7.5×10^{-7} mol kg⁻¹ s⁻¹, respectively. Proceeding from these values and relying on the homogeneous reaction model, the researchers⁶⁹ concluded that AIBN is responsible for the initiation virtually alone, whereas the hydroperoxide ensures branching of the oxidation chains and efficiently decreases the rate constant for the termination of these chains by increasing their length. The last-mentioned conclusion was criticised in a monograph by Popov *et al.*,⁵ who proved that the rate constant for the termination of oxidation chains in IPP does not depend on the content of POOH. This result is confirmed, in particular, by the fact that the radiation-induced oxidation of IPP proceeds at a constant rate. When other initiators are employed (for example, BP and dicumene peroxide), no noticeable change in the rate constant for chain termination upon accumulation of POOH has been identified either.⁸

The discussion around the 'AIBN effect'^{5,8} precluded elucidation of its mechanism because the effect was discussed within the framework of the homogeneous model, which is not valid for this particular case. However, if the mechanism of AIBN initiation is considered in terms of the heterophase model, two initiation rates should be distinguished: (1) the rate of generation of free radicals found by the inhibitor method and corresponding to the process localised in the s -zones of the micellar sponge and (2) the much lower rate of initiation (and termination) of the proper oxidation chains which are continued in v -zones. In this case, the essence of the AIBN effect in question can be explained as follows. Azobisisobutyronitrile decomposes in the s -zones of spongy micelles and generates alkyl cyanoisopropyl radicals, $R_j^\bullet$, which readily react with nitroxides but virtually do not react with macromolecules. The primary $R_j^\bullet$ radicals partially decay without leaving a radical pair, while some of the radicals are oxidised to give reactive peroxy radicals, which do react with macroradicals.

In accordance with the experimental data, the ratio of the rate of formation of the $R_j^\bullet$ radicals to the rate of AIBN decomposition in the IPP matrix at 82 °C amounts to $2k_{ij}/(k_{oj} + k_{ij}) = 0.054$.⁸ Thus, a substantial portion of AIBN radicals decay at the beginning of the process and do not participate in the oxidation.

The situation changes as POOH groups are accumulated in s -zones. Since alkyl radicals are highly reactive towards the abstraction of hydrogen from the OOH groups,^{70,71} they provide an additional opportunity for the formation of the terminal $R_s^\bullet$ macroradicals, which are responsible for the transfer of free valences to the v -zones. In this case, all the generated $R_j^\bullet$ radicals are consumed for the oxidation reaction and thus ensure a hundred percent initiating efficiency of AIBN.

The above considerations can be summarised by the following simplified scheme of transformations (Scheme 4):

Scheme 4

Here we neglect the contribution of POOH to the generation of free radicals, in compliance with the results obtained by the inhibitor method.⁶⁹

According to Scheme 4, the quasi-steady-state concentration of the $[R_s^\bullet]$ radicals, responsible for the chemical s,v -induction,

$$[R_s^\bullet] = \frac{2k_{sj}c_j(k_{1j} + k_{4j}[\text{POOH}]_s)}{k_{1s}(k_{oj} + k_{1j} + k_{4j}[\text{POOH}]_s)}$$

(c_j is the concentration of AIBN in s -zones) increases during the accumulation of POOH from the initial value

$$[R_s^\bullet]_0 = \frac{2k_{1j}k_{sj}c_j}{k_{1s}(k_{oj} + k_{1j})} \text{ for } k_{4j}[\text{POOH}]_s \ll k_{1j}$$

to the limiting value

$$[R_s^\bullet]_{\text{lim}} = \frac{2k_{sj}c_j}{k_{1s}} \text{ for } k_{4j}[\text{POOH}]_s \gg (k_{oj} + k_{1j}).$$

Under these conditions, the rate of oxygen absorption

$$v = \frac{k_2[\text{POO}^\bullet]}{\varphi} = \frac{k_2}{\varphi} \left(\frac{v_{tr}}{k_t'} \right)^{0.5}$$

increases from the initial value v_0 to the limiting value v_{lim} in conformity with the equation

$$\frac{v_{\text{lim}}}{v_0} = \left(\frac{v_{tr,\text{lim}}}{v_{tr,0}} \right)^{0.5} = \left(\frac{[R_s^\bullet]_{\text{lim}}}{[R_s^\bullet]_0} \right)^{0.5} = \left(\frac{k_{oj} + k_{1j}}{k_{1j}} \right)^{0.5}.$$

Substitution into this equation of the $k_{1j}(k_{oj} + k_{1j})^{-1} \approx 0.027$ determined experimentally⁸ gives the equality $v_{\text{lim}} = 6v_0$, which is consistent with the value found in another study.⁶⁹

Thus, within the framework of the heterophase reaction model, the specific kinetic feature observed in the initial stage of oxidation of polymers in the presence of AIBN is interpreted as being due to the increase in the initiating efficiency of AIBN,

This means that the main reaction involving free radicals in the oxidation of non-crystalline PCH is abstraction of hydrogen atoms giving rise to allyl type radicals. The subsequent transformations of these radicals in the s- and v-zones of the PCH matrix differ in kind. Indeed, due to the substantial steric restrictions hampering opening of the six-membered carbon rings and epoxidation in narrow v-zones, an intermolecular mechanism of the propagation of oxidation chains comes to the fore.

Now we return to the s-scheme of reactions involving AIBN (see Scheme 4), eliminate the reaction of radical pairs with the hydroperoxide POOH (k_{4j}) (which is unlikely in a vitreous polymer), add reactions involving the $Me_2C(CN)OO^*$, POO^*_s and $\cdot OH_s$ radicals

and write the algebraic condition for the steady-state concentrations of radicals participating in the inter-zone s,v-chemical induction,

$$\begin{aligned} \frac{d[R_s^*]}{dt} &= k_{3j}[Me_2C(CN)OO^*][PH_s] \\ &+ k_{6j}[Me_2C(CN)OO^*][POOH_s] \\ &- k_{5j}[Me_2C(CN)OO^*][R_s^*] = 0. \end{aligned}$$

By solving this equation, we make sure that the concentration

$$[R_s^*] = \frac{k_{3j}[PH_s] + k_{6j}[POOH_s]}{k_{5j}}$$

does not depend on the concentration of the initiator.

The s-scheme for the reactions involving LP is qualitatively the same.

Now we employ the scheme of the s,v-translation of free valences, which is similar in kind to the corresponding scheme for polyolefins, and express the balance of the rates of initiation and termination of oxidation v-chains by the equation

$$v_{tr} = \frac{k_m P_{O_2} [R_s^*]}{b + P_{O_2}} = k_t'' [POO^*]^2,$$

and the rate of oxygen absorption by the equation

$$\begin{aligned} v_1 &= \frac{k_2 [POO^*]}{\varphi} = \\ &= \frac{k_2}{\varphi} \left(\frac{P_{O_2}}{b + P_{O_2}} \right)^{0.5} \left(\frac{k_m k_{3j} [PH_s] + k_m k_{6j} [POOH_s]}{k_{5j} k_t''} \right)^{0.5}. \end{aligned}$$

It can be seen from the latter equation that v_1 does not depend on the concentration of an admixed initiator.

In the absence of an admixed initiator, the steady-state rate of the absorption of oxygen by PCH does not depend on the content of POOH either [Eqn (9)]

$$v_3 = \frac{k_2}{\varphi} \left(\frac{P_{O_2}}{b + P_{O_2}} \right)^{0.5} \left(\frac{\delta k_{0s} k_m k_{vs}}{2 k_t'' k_{1s} k_t''} \right)^{0.5},$$

and the relatively low value of this rate is stipulated by the small value of the product $\delta k_{0s} k_{vs}$.

It is worth noting that, in accordance with the mechanism in question, the constant values of $[R_s^*]$ and v_1 correspond to a relatively high content of the initiator, which provides the 'self-locking' effect in the passage of free valences through the 'bottle-

neck'. It is evident that at low concentrations of the initiator, the 'self-locking' condition is not met; however it is met in the range of AIBN and PL concentrations studied by Chaplanova *et al.*^{72–74} In terms of this mechanism, the dissimilarity between the v_1 values observed in the AIBN- and LP-involving processes is due to the different values of the complex constant

$$\frac{k_{3j}[PH_s] + k_{6j}[POOH_s]}{k_{5j}},$$

characterising the reactions of peroxy radicals derived from AIBN and LP with the CH bonds of the oxidised PCH (POOH) and the macroradicals R_s^* . According to experimental data, this complex constant is greater for the LP radicals.

Thus, the heterophase reaction model interprets the initiated 'jumps' in the oxygen absorption rate, observed in the oxidation of PCH samples, without violating the logical link between this partial model and those describing oxidation of other polymers.

VIII. The model of oxidation of thermofluctuationally active objects

In the preceding Sections, we considered oxidation processes that occur in the mode of heterophase injection of free valences from the zones in which they are generated to the zones in which chain reaction of macroradicals with oxygen takes place. This mode is typical of specimens with relatively low molecular-segment mobility.

Meanwhile, the mobility of units of the molecular sponge can increase appreciably under certain conditions. This is accompanied by an increase in the frequency of formation of fluctuationally excited nanopores (f-nanopores) directly in the grains of spongy micelles. These conditions are fulfilled, for example, in polymers with relatively low molecular masses and, correspondingly, with low macroscopic viscosity (for example, for low-molecular-mass APP) and in a polymer matrix in the state of thixotropic excitation, caused by structural and mechanical relaxation (for example, in oriented IPP).²⁶

Due to excitation in a dynamically active molecular sponge, f-nanopores reach the size of s-nanopores and their lifetime increases because relaxation requires spatial redistribution of numerous units of the sponge in the vicinity of the f-nanopore formed. Since the frequency of formation of f-nanopores is relatively high, they increase the rate of dissociation of the POOH groups in the v-zones of spongy micelles¹⁶ and also trigger off the mechanism of quasi-linear termination of reaction chains according to Eqn (18).

The new steps of initiation and termination of oxidation chains, which are added to the heterogeneous initiation and quadratic termination steps or even prevail in the oxidation, should necessarily change qualitatively the reaction kinetics.

The kinetics of oxidation of low-molecular-mass APP and oriented IPP provide an example of such a change (see Fig. 6). This process displays a fairly prolonged exponential increase in the amounts of oxygen absorbed (curves 1, 3) and the POOH formed (curves 2, 4).²⁶ The amount of oxygen absorbed in the exponential stage reaches 1.5–2.0 mol kg^{−1}, which markedly differentiates this process from the oxidation of high-molecular-mass polyolefins, which includes a short-term 'parabolic' self-accelerated stage and, after 0.1–0.2 mol kg^{−1} of oxygen has been absorbed, switches to the mode characterised by zero-order kinetics with respect to hydroperoxide.

The long-term exponential acceleration of the reaction has also been found in experiments with a model analogue of polyolefins, cetane (oxidation was carried out with the removal of the resulting aqueous phase containing acidic products),⁴⁴ and in experiments with low-molecular-mass APP ($M_n = 2250$) in the temperature range of 120–160 °C⁷⁵ (Fig. 16).

The change in the kinetics of the absorption of oxygen upon orientational drawing has been observed in experiments with IPP (Fig. 6), polyethylene and polymethylpentene films (Fig. 17).^{5, 76}

Figure 16. Variation of the amount of oxygen absorbed (*a*) and the number of breaks in macromolecules (*b*)⁷⁵ during oxidation of molten APP ($M_n = 2250$) at an oxygen pressure of 97.3 kPa and temperatures of 120 (1), 130 (2), 140 (3), 150 (4) and 160 °C (5) (the dots correspond to experimental data from Ref. 75).

It can be clearly seen in Fig. 17 how curve 1 for isotropic films (with short self-acceleration and then zero-order kinetics with respect to POOH) is replaced upon film drawing by curves 2–5, characterised by continuous variation of the oxygen absorption rate.

The presence of a long period in which the kinetic law $\exp(\Phi t)$ is fulfilled does not exhaust the specific features of the oxidation of polymers with enhanced thermofluctuation mobility of the molecular sponge. Yet another feature is the substantial dependence of the reaction rate on the pressure of oxygen in the 26–100 kPa range⁷⁵ (the rate of oxidation of liquid hydrocarbons in this range is close to the limiting value).

In addition, it can be seen from Fig. 6 (curves 2, 4) that this oxidation mode is characterised by a high limiting concentration of POOH, which barely changes for a long period of time. Unlike this situation, in the oxidation of high-molecular-mass polyolefins (and quite often, of low-molecular-mass liquid hydrocarbons), the

Figure 17. Variation of the amount of oxygen absorbed (*a*) and hydroperoxide accumulated (*b*) in the initial (non-oriented) polymethylpentene film (1, 1') and in films stretched to a ratio of 4 (2), 6 (3, 3'), 9 (4) and 12 (5) during oxidation at 130 °C and an oxygen pressure of 80 kPa.⁷⁶

POOH concentration passes through a relatively sharp maximum, which appears due to the decomposition of hydroperoxide induced by organic acids, which accelerates with time. The carboxylic acids formed in large amounts in the oxidation of liquid cyclohexane, *n*-decane⁷⁷ and nonene⁷⁸ destroy another oxidation product, hydroperoxide, its maximum concentration being thus limited to ~0.3, 0.2 and 0.4–0.5 mol kg⁻¹, respectively.

However, oxidation of a melt of low-molecular-mass APP and orientationally drawn IPP films gives POOH and polymeric ketones as the major products, whereas the yield of acids is insignificant.²⁶ It is the low concentration of acids that accounts, in all probability, for the absence of sharp maxima in curves 2, 4 in Fig. 6. The presence of a concentration limit in these curves can be regarded as evidence for the occurrence of chain decomposition of POOH under the action of free radicals. The rate of chain decomposition of POOH corresponding to this limiting concentration should be equal to the rate of its chain formation, the quasi-steady-state concentration of radicals that induce the decomposition remaining virtually constant for a long period.

Yet another important feature of the oxidation of low-molecular-mass APP is the fact that the kinetic laws of the cleavage of the macromolecules established by Iring *et al.*²⁶ using the gel-chromatographic method for the determination of the molecular mass distribution do not coincide with the kinetic laws established by Ivanov *et al.*,⁷⁵ who used a variant of osmometry.

For example, in the former study,²⁶ in which the oxidation of APP was carried out at a high pressure of oxygen (10³ kPa), the number of breaks in the polymer chains increased according to the same law as the amount of absorbed oxygen and was equal to 0.01 mol litre⁻¹ at 120 °C over a period of 50 min, while in the latter study,⁷⁵ in which APP was oxidised at $P_{O_2} \leq 100$ kPa, the number of breaks was 0.033 mol litre⁻¹ over the same period of time. The rate of polymer chain scission remained constant during the whole process (Fig. 16 *b*), although it was directly proportional to the pressure of oxygen. In this particular case (when the pressure of oxygen is low) more intense degradation takes place due to the cleavage of those macroradicals the concentrations of which do not depend on the oxidation time or on the concentration of POOH formed.

The factors listed above give grounds for claiming that neither the model of homogeneous oxidation of hydrocarbons nor the models of heterophase oxidation of high-molecular-mass polymers, considered in the preceding Sections, are suitable for describing the oxidation of molten low-molecular-mass APP. The law $\exp(\Phi t)$ characterising the self-accelerated stage coincides only formally with the regularity established for gas-phase reactions with avalanche-like branching of reaction chains. In the condensed phase, the avalanche-like chain branching is impossible for several reasons reported in the literature.⁷⁹

Thus, a kinetic model for the oxidation of polymers distinguished by high thermofluctuation mobility of the molecular sponge should take into account the structural and physical changes of the chemical quasi-elementary steps, specific for the given state, which are actually heterogeneous.

The high frequency of excitation of f-nanopores in a spongy matrix makes it possible to propose the following scheme of the frequency-modulated oxidation process

By applying the condition of steady-state concentrations of free radicals, one can easily find the concentration of peroxy radicals $\text{POO}^\bullet$, involved in the oxidation chains, which will be referred to as linear chains

$$[\text{POO}^\bullet] = \frac{\delta k_f [\text{POOH}]}{2k_{t,1}}$$

(δ is the yield of macroradicals in the decomposition of POOH_t), the concentration of alkyl macroradicals

$$[\text{P}^\bullet] = \frac{0.5\delta k_f [\text{POOH}](k_2 + k_3)}{k_{t,1}(k_1[\text{O}_2] + k_{-2}[\text{POOH}])},$$

the rate of accumulation of POOH , which is made up of the rates of chain formation, chain decomposition and spontaneous decomposition

$$\begin{aligned} \frac{d[\text{POOH}]}{dt} &= \frac{0.5\delta k_f [\text{POOH}]}{k_{t,1}} - \frac{0.5k_{-2}(k_2 + k_3)\delta k_f [\text{POOH}]^2}{k_{t,1}(k_1[\text{O}_2] + k_{-2}[\text{POOH}])} \\ &\quad - k_f [\text{POOH}] = \Phi [\text{POOH}] - \frac{\Phi [\text{POOH}]^2}{\varphi(\chi + [\text{POOH}])}, \end{aligned} \quad (26)$$

and the rate of oxygen absorption (the contribution of the spontaneous decomposition of POOH can be neglected)

$$-\frac{d[\text{O}_2]}{dt} = \frac{d\Delta[\text{O}_2]}{dt} = k_1[\text{P}^\bullet][\text{O}_2] = \frac{\Phi \chi [\text{POOH}]}{\varphi(\chi + [\text{POOH}])}, \quad (27)$$

where $\Phi = k_f(0.5\delta k_f k_{t,1}^{-1} - 1) \approx 0.5k_2\delta k_f k_{t,1}^{-1}$, $\varphi = k_2(k_2 + k_3)^{-1}$, $\chi = k_1[\text{O}_2]k_{-2}^{-1}$.

It follows from Eqn (26) that at the beginning of the self-accelerated oxidation stage, when $d[\text{POOH}]/dt = \Phi[\text{POOH}]$, the content of POOH increases with time by an exponential law

$$[\text{POOH}] = [\text{POOH}]_t \exp(\Phi t),$$

where $[\text{POOH}]_t$ is the concentration of POOH at the end of the induction period.

During this period, the rate of oxygen absorption also increases according to an exponential law in view of the relation $[\text{POOH}] < \chi$:

$$\frac{d\Delta[\text{O}_2]}{dt} = \frac{\Phi [\text{POOH}]}{\varphi} = \frac{\Phi [\text{POOH}]_0}{\varphi} \exp(\Phi t). \quad (28)$$

The Φ , φ , and χ values were found by solving the set of differential equations (26) and (27) using the simple Euler method.⁵² The results of calculations were compared with experimental data presented in Figs 6, 16 and 17.

The theoretical curves 1 and 2 in Fig. 6, corresponding to low-molecular-mass APP, are in agreement with experimental data obtained by Iring *et al.*²⁶ The Φ , φ , χ and $[\text{POOH}]_t$ values corresponding to these curves are

$$\Phi = 0.034 \text{ min}^{-1}, \varphi = 0.5, \chi = 1.1 \text{ mol litre}^{-1}, \\ [\text{POOH}]_t = 0.02 \text{ mol litre}^{-1}.$$

The theoretical curves 3 and 4 in Fig. 6, which refer to IPP films stretched orientationally by a factor of 5, are also in good agreement with experimental points. The corresponding coefficients are

$$\Phi = 0.027 \text{ min}^{-1}, \varphi = 0.4, \chi = 1.05 \text{ mol litre}^{-1}, \\ [\text{POOH}]_t = 0.02 \text{ mol litre}^{-1}.$$

The qualitative difference between curves 3, 4 and curves 1, 2 is associated with the appearance of an induction period with $\tau = 200$ min in the oxidation of oriented films (in the case of a melt, $\tau \approx 0$ min).

Figure 16 shows the theoretical curves corresponding to the oxidation of an APP melt at a lower pressure $P_{\text{O}_2} = 100$ kPa. They are also in good agreement with experimental data⁷⁵ with the following coefficients Φ , φ and χ :

$T/^\circ\text{C}$	Φ/s^{-1}	φ	$\chi/\text{mol litre}^{-1}$
120	1.0×10^{-3}	0.5	0.4
130	1.8×10^{-3}	0.5	0.4
140	3.6×10^{-3}	0.5	0.4

The calculations were performed with the assumption that the yield of POOH per mole of oxygen absorbed in linear chains does not depend on temperature and corresponds to the φ value taken from a study by Iring *et al.*,²⁶ the $[\text{POOH}]_t$ value remains equal to $0.02 \text{ mol litre}^{-1}$, and the limiting concentration of the hydroperoxide, needed to estimate the coefficient χ , is $[\text{POOH}]_{\text{lim}} = 0.4 \text{ mol litre}^{-1}$.

Taking into account the variation of the coefficient Φ vs. temperature and using the Arrhenius equation, one can calculate the effective activation energy $E_\Phi = 86.0 \text{ kJ mol}^{-1}$. This value differs from the effective activation energy of scission found from Fig. 16 b ($E_n = 106.0 \text{ kJ mol}^{-1}$).

The thermomechanical modulation of the chemical events is also manifested in the experiments with oriented polymethylpentene films (Fig. 17). As in the case of oriented IPP films, the modulation is due to the enhancement of the molecular-segment mobility as a result of relaxation of internal stress. The qualitative difference between curves 1, 1', describing the oxidation of isotropic films, and curves 3, 3', which refer to oriented films can be clearly seen in Fig. 17. Curves 3 (Fig. 17 a, oxygen absorption) and 3' (Fig. 17 b, POOH accumulation) were constructed by solving the set of equations (26) and (27). For $\Phi = 0.03 \text{ min}^{-1}$, $\varphi = 0.13$, $\chi = 2.4 \text{ mol kg}^{-1}$, $[\text{POOH}]_t = 0.01 \text{ mol kg}^{-1}$ and $\tau = 160$ min, they are in good agreement with experimental data reported by Rapoport *et al.*⁷⁶ (130°C , $P_{\text{O}_2} = 80$ kPa).

It should be noted that the yield of hydroperoxide φ in oriented films permanently varies during oxidation. Indeed, it can be seen in Fig. 17 b, which shows the curves for 0.5 (curve I) and 1.4 mol kg^{-1} (curve II) of absorbed oxygen, that $\varphi = 0.1$ at the point of intersection of curves I and 3' and $\varphi = 0.16$ at the point of intersection of curves II and 3'. The value $\varphi = 0.13$ assumed in our calculations is the average of these two values.

The fact that the parameter φ (and, hence, χ) depends on the draw ratio and on the degree of oxidation suggests that the good agreement between the calculated and experimental data for oriented films results, most likely, from a favourable superposition of the chemical reaction and structural relaxation. In other cases, this agreement may be missing and the process kinetics would undergo substantial changes.¹⁴ Nevertheless, the results indicate that the principle of structure-mechanical modulation of chemical steps is correct at the qualitative level.

The scheme of chemical transformations analysed in this Section differs from the heterophase schemes considered previously not only by the fact that it includes the steps of free radical generation in enlarged f-nanopores but also by the fact that it assumes decomposition of POOH induced by alkyl macroradicals (characterised by the constant k_{-2}) and quasi-linear termination of oxidation chains in f-nanopores [Eqn (18)].

The induced decomposition of POOH can also account for both the presence of the concentration limit in the accumulation of the hydroperoxide and the influence of the pressure of oxygen on the oxidation rate. The latter is due to the competition between oxygen and hydroperoxide for the alkyl macroradicals, which are converted in linear oxidation chains (see above).

According to published data, in liquid-phase systems under conditions of oxygen deficiency, the contribution of the reaction of alkyl radicals with hydroperoxide to the overall scheme is fairly high. This has been explained by the 'abnormally' high rate of the abstraction of hydrogen atoms from hydroperoxide groups by the attacking alkyl radicals.^{70, 71} Previously, based on the idea of

competition between the process acceleration due to the increase in the oxygen concentration and the process retardation due to the increase in the mechanical pressure of the gas phase.

Thus, the mechanical pressure of the gas atmosphere on the chain-segment sponge of the polymers being oxidised should be taken into account as necessarily as is the structural and mechanical previous history of samples and the internal stress relaxation.

IX. Cross-linking of polyolefin macromolecules

Oxidation of polyolefins is accompanied not only by chain scission according to one of the mechanisms considered above but also by the formation of chain cross-links. Cross-linking increases the molecular mass of the polymer and the number of points of branching on individual chains and creates a three-dimensional network, which, under certain conditions, can produce a gel fraction insoluble in liquids. Experimental data available from the literature make it possible to consider the oxidative cross-linking of polyolefins in terms of the micellar-sponge model of the polymeric matrix.

The redistribution of the molecular masses of molecules in an LDPE melt and solid-like IPP films during their oxidation at 130–160 °C has been studied.^{5,82,83} Analysis of the molecular-mass distribution (MMD) by gel permeation chromatography showed that even absorption of a slight amount of oxygen changes the molecular masses of IPP and LDPE, the patterns of these changes being different for these two polymers.

During the oxidation of molten LDPE, rupture of macromolecules predominates in the induction period over a broad range of oxygen pressures; a slightly pronounced tendency for the enlargement of macromolecules is detected only for very low pressures ($P_{O_2} \leq 2.6$ kPa).⁸²

However, in the case of IPP at $P_{O_2} = 10.6, 80.0$ and 101.3 kPa, scission and cross-linking of molecules proceed in the induction period at comparable rates. This gives a bimodal MMD (having two peaks, one at higher and one at lower molecular masses); the yield of the higher-molecular-mass fraction increases as the pressure of oxygen diminishes. As oxidation advances, the high-molecular-mass fraction of IPP becomes involved in the degradation process and an unimodal distribution is established, the MMD maximum being shifted towards lower molecular masses.^{5,82,83} In this case, the enlargement of molecules is transient.

No clear view on the mechanism of transient cross-linking can be found in the literature. It has been suggested^{5,83} that it is due to the termolecular reaction

yielding two macroradicals, which recombine in a 'cage'. In the opinion of the researchers cited,^{5,83} this assumption is supported by the fact that the yield of cross-linked macromolecules increases upon orientational drawing, which prevents radicals from leaving the cage.

For instance, when isotropic and oriented IPP samples absorb equal amounts of oxygen (0.14 mol kg⁻¹, 130 °C, $P_{O_2} = 78$ kPa), the average molecular mass of isotropic IPP decreases from 3.0×10^5 to 0.6×10^5 , while the molecular mass of IPP films stretched 10-fold, conversely, increases from 3.0×10^5 to 6.3×10^5 . However, during further oxidation of the stretched films degradation becomes the predominant process. It will be shown below that the transient cross-linking of IPP molecules occurs in s-zones and involves the alkyl macroradicals and the C=C bonds formed in these zones. This is facilitated by the deficiency of free oxygen molecules, typical of s-zones.

The transient cross-linking of molten polyethylene in the beginning of oxidation barely influences the molecular mass of the polymer; however, the formation of the macromolecular network is manifested in full measure in the macroscopic kinetic stage that comes after fairly extensive destruction.^{84,85} The process of destruction preceding the formation of the molecular

network involves a 200- to 600-μm thick layer of the melt, depending on the temperature (230–150 °C, respectively). This results in a substantial (5–15-fold) decrease in the molecular mass of the polymer; as a consequence, the oxidised polymer becomes waxy.⁸⁵ The cross-linking of molecules during further oxidation of the destroyed material proceeds in an autocatalytic mode and yields a 30–160-μm cross-linked shell.

It has been emphasised⁸⁵ that cross-linking of the oxidised material starts simultaneously throughout the whole relatively thick near-surface layer (80 μm at 150 °C), although the sources of free radicals, POOH groups, are distributed in this layer non-uniformly, their concentration decreasing on moving away from the surface. The amount of the gel fraction in the oxidised polyethylene increases over some period of time. During this period, a densely cross-linked crust is formed. The process continues until almost all macromolecules are incorporated in the molecular network structure. The density of the gel fraction at the end of the process reaches 1 g cm⁻¹.

No clear views on the mechanism of this process can be found in the literature. A rather obvious reaction is condensation of carboxylic acids with secondary alcohols.⁸⁶ However, the mechanisms of formation of the acids and the alcohols are not discussed.

Meanwhile, the fact that cross-linking starts only after accumulation of a particular amount of the oxidised fragments of polyethylene molecules suggests that this process can be associated with the condensation of carboxylic acids with epoxides, formed as intermediate oxidation products (see Section IV), the concentration of which does not depend on the content of POOH:

In accordance with the heterophase structure of the polymeric molecular-sponge microreactors (see Fig. 7), the condensation cross-linking should occur in the v-zones of the micelles, which accumulate the main bulk of oxygen-containing oxidation products, as opposed to the transient cross-linking, which occurs in s-zones.

The condensation, considered in terms of the heterophase model, becomes possible only at a substantial degree of oxidative degradation (after a required amount of acid residues has been accumulated). The condensation can account for the self-accelerated character of cross-linking, which is due to the permanent increase in the acid concentration and for the fact that this process virtually does not depend on the distribution of POOH over the layer depth. This is confirmed by the appearance of ester groups at high degrees of oxidation of molten polyethylene and by their subsequent self-accelerated accumulation (which was demonstrated by NMR⁴⁹ and IR spectroscopy⁸⁴). The complete solubility of the gel fraction in strong alkalis and acids proves that the cross-links in the molecular network are actually formed by ester groups.⁸⁴

Let us consider once again the transient cross-linking, which manifests itself most clearly for IPP films stretched 10-fold. It should be noted that the number of cross-links observed in practice under conditions most favourable for the termolecular reaction is 1000 times greater than the value calculated theoretically.⁸ Therefore, Denisov⁸ proposed that the addition of alkyl and peroxy macroradicals to the C=C bonds, always present in polyolefins in small amounts, should also be included in the consideration.

However, this assumption does not agree with the kinetics of cross-linking of polymer chains in oriented IPP films. Indeed, in the oxidation of 10-fold stretched films, the cross-linking starts only 75 min after the reaction has begun but before the induction period has been over ($\tau = 100$ min at 130 °C and $P_{O_2} = 78$ kPa). During these 75 min, the mean mass of molecules remains

constant.^{5, 83} Thus, cross-linking involves only unsaturated C=C bonds, which accumulate during oxidation.

The transient cross-linking of the IPP molecules might occur by a chain mechanism,⁸⁷ which has been established previously for the cross-linking of polyethylene molecules initiated by dibenzoyl peroxide. According to this mechanism, cross-links are formed due to the addition of macromolecule fragments having terminal C=C bonds ($R^{\cdot}$) to internal macroradicals ($P_s^{\cdot}$):

By adding these reactions to the overall scheme of the process occurring in the s-zones of the matrix in the induction period (see Section IV.1) and by using the steady-state concentration conditions for free radicals, one can easily see that these reactions do not change the form of the equation describing the concentration of the $R_s^{\cdot}$ radicals, responsible for the s,v-translation of free valence

$$[R_s^{\cdot}] = \frac{\delta k'_{0s}[PH_s][O_{2s}]}{2k_{1s}}.$$

The rate of initiation of the oxidation chains in the v-zones of matrix micelles does not change either.

The validity of the above scheme for the transient chain cross-linking of the IPP molecules is supported by the fact that the rate of this process increases upon orientational drawing of films. Drawing is known to be accompanied by fibrillation of polymer chains, which are reorganised to give bundles (about tens of angstroms in diameter) and acquire enhanced highly elastic tension.^{5, 88} Despite dense packing, the fibrillar units are separated from one another by clear-cut interfaces, which can be clearly seen in the micrographs taken by an electron microscope.

Judging by the structure of spongy micelles (Fig. 7), one can expect that uniaxial drawing of a polymer film would result in the transformation of spherical grains into ellipsoids filled with fibrils of stretched chains. The mobility of chain units inside the fibrils would decrease and the nanopores in them would become even narrower. However, the interfaces between the fibrils would actually represent newly formed zones of s-nanopores. The increase in the number and the volume of zones filled with s-nanopores should naturally increase the contribution of reactions which occur in these zones including chain cross-linking.

It has been noted that cross-linking lags somewhat behind the rupture of IPP macromolecules. This is due to the fact that the structure-mechanical stabilisation of fibrils in the supermolecular framework depresses for some period the mobility of the fragments of macromolecules with terminal C=C bonds. A definite number of polymer chain scissions is required in order to weaken the rigid mechanical fixing of fragments in the framework structure. During this period, some C=C bonds are accumulated in the interfibrillar layers, and, as the chemically induced relaxation of internal stress goes on, rapid formation of the cross-linked network starts by the radical chain mechanism described above

X. Oxidation of fibrillised polyolefins

The change in the structure of the spongy micellar matrix induced by fibrillation influences the dynamic characteristics of a paramagnetic probe — stable free radical, 2,2,6,6-tetramethylpiperidin-1-oxyl — introduced in a polymer. The behaviour of the nitroxide depends on when it is introduced into the sample.^{5, 89} If the radical probe is introduced initially and then the sample is drawn, the probe is fixed in a low-mobility state with appreciably hindered rotational and translational motion. However, if the radical probe is introduced into the films after drawing, it populates the accessible areas of the matrix and displays high frequency of rotation and high rate of migration through the matrix.

Owing to the spongy micellar structure of the matrix, the radical probe added before the film drawing is absorbed during

drawing in fairly narrow nanopores of the fibrils being formed and is not displaced into the interfibrillar layers. Conversely, the radical probe added after fibrillation is unable to penetrate inside the fibrils and mainly occupies s-nanopores in the interfibrillar layers.

It is obvious that the structural rearrangement induced by drawing should necessarily change the kinetics of oxidation. Indeed, the fairly strong fixing of fibrils due to restructurisation of the crystallite framework can substantially extend the induction period of oxidation by decreasing the frequency of the steps of s,v-transfer of free valence and migration of hydroperoxide groups from the inner space of fibrils to interfibrillar s-nanopores. This situation is observed in the oxidation of highly crystalline IPP, HDPE and polymethylpentene.^{5, 35, 76}

It is typical that the induction period disappears if IPP films have been subjected to non-extensive oxidation (up to the accumulation of $\sim 0.02 \text{ mol kg}^{-1}$ of POOH) prior to drawing.⁵ This fact contradicts the assumption, made in the same study,⁵ that drawing enhances the cage effect (*i.e.* decreases the yield of radicals in the dissociation of POOH) but it is in line with the 'bottle-neck' effect in both the forward and backward phase transfer chemical induction processes.

In fact, orientational drawing of non-oxidised films increases the induction period for the structural and mechanical reasons indicated above, whereas drawing of pre-oxidised films, without changing the content of POOH in the previously oxidised s-zones, increases the number of new interfibrillar s-zones, to which hydroperoxide is displaced from the inner bulk of fibrils during their formation. With this type of sample processing, oxidation is effected from the very beginning by vigorous scission of macromolecules and by chemically induced relaxation of internal stresses; this accounts for the absence of a noticeable induction period.

Study of IPP and HDPE films by local IR spectroscopy (by scanning samples by a beam with a 1-mm^2 cross-section) showed that oxidation of oriented films with mechanically fixed ends occurs non-uniformly over the area of the sample and has different rates in different local zones. The ratio of the carbonyl products of oxidation changes.⁵ Note that in conventional IR spectra of oxidised fibrillised samples, the intensities of the absorption bands at about $1740\text{--}1745$ and $1770\text{--}1780 \text{ cm}^{-1}$, which correspond to ester and lactone groups,^{86, 90} are greater³⁵ than the intensities of the absorption bands at $1710\text{--}1720 \text{ cm}^{-1}$, due to acids and ketones.

Qualitatively, the process can be represented as follows. The primary reaction chains are originated in the interfibrillar s-zones. They include the steps of scission and cross-linking of s-units, which ensure restructurisation of interfibrillar layers and thus increase the elastic load on the fibrils. These processes result in the appearance of free valences, translated with a low frequency to the narrow internal nanopores of the fibrils. Due to the narrowness of the pores and the high-elasticity tension of the polymer molecules in the fibrils, the peroxy radicals formed under these conditions undergo mainly β -isomerisation to give epoxide rings and free hydroxyls. The hydroxyl and the epoxide, which are unable to separate widely in a narrow nanopore, react with each other; this gives rise to the non-hydroperoxide oxidation pathway leading to ketones (aldehydes) and acids

Rupture of an individual polymer molecule in the structure of an elastically stretched fibril affords fragments which relax independently to the most equilibrium conformation by transferring the mechanical load to the surrounding molecules and enhancing their tension. Thus, narrow nanopores having an increased length appear inside the fibrils; they serve simultaneously as the sites of accumulation of the oxygen molecules expelled from the neighbouring layers of the intrafibril sponge.

The subsequent reactions inside the newly arisen relaxation site of oxidation include the transfer of free valence over its surface in accordance with the above scheme. Under these conditions, carboxy and epoxy groups are formed in the vicinity of each other; they react to give ester groups. Thus, orientational drawing of IPP and HDPE creates conditions for the formation of esters in the relaxation intrafibril sites even at early oxidation stages, whereas in the case of isotropic polyethylene melts, esters are formed only after fairly extensive oxidative destruction has taken place (see Section IX).

An important feature of oxidation in the relaxation sites inside the fibrils is that the removal of fragments of macromolecules from these sites facilitates the arrival of free radicals at the intact polymer chains, which remain in the stretched state. As a consequence, the process propagates predominantly across the fibril, and the intermediate polymeric peroxy radicals participating in the process are rigidly fixed at the elastically stretched macromolecules; thus, they are mainly converted without the formation of POOH.

The continuous accumulation of structural damages inside the fibril and enhancement of the load on the remaining oriented chains should result sooner or later in the rupture of the fibril and in the abrupt relief of the elastic strain. The sharp increase in the beating mobility of a nanopore in the fibril fragments substantially increases the probability of intermolecular propagation of oxidation chains accompanied by the formation and simultaneous dissociation of POOH. In other words, upon the relief of mechanical stress, oxidation sharply accelerates becoming a local chemical outburst and efficiently influences the surrounding matrix both by transferring mechanical load and injecting chemically reactive species therein.

During further oxidation, fragmentation involves initially the separate macroscopic areas and then the whole oriented sample, whose ends are mechanically fixed. As a consequence, a backbone crack grows through the sample cross-section, which fractures the sample, and oxidation passes to the self-accelerated stage.⁵

The kinetic, structural and mechanical features of oxidation listed above have been observed in experiments with polyolefin films subjected to uniaxial orientational drawing. Commercial polymeric articles produced by extrusion, moulding and hose blowing have micellar structures. The structural lability of molecular spongy micelles and the ability of the crystalline framework to be reorganised account for the appearance of uncontrolled internal stresses and local deformations accompanied by fibrillation, taking place in these articles to one or another extent.

The structural and mechanical inhomogeneities introduced into the articles at the stage of processing of polymer ingredients are the reason for the change of the physical properties of articles during performance and storage.⁹¹ Even minor external mechanical action (during cooling of the melt) induces the layer structural inhomogeneity of the material, caused by the relaxation mechanism of heat removal and non-uniform temperature distribution over the material thickness.⁹²

This should lead to non-reproducibility of the quantitative results of kinetic studies, which is typical of these materials. This is illustrated by numerous experimental data (see Ref. 93 and references therein), which show that the durations of the induction

periods and the amounts of accumulated products in the oxidation of IPP and LDPE vary over wide limits, depending on the previous history and thickness of samples manufactured by industrial technologies.

The diversity of factors which influence in one or another way the internal structure of polymeric articles makes very difficult the task of constructing a unified kinetic model of oxidation, which would provide a quantitative description for both laboratory specimens and commercial materials. However, we hope that the oxidation models proposed here would lay a more reliable foundation for the analysis of particular processes of ageing and stabilisation of polymers than liquid-phase models, which are not quite applicable to polymers.

XI. Conclusion

The purpose of this review is to demonstrate the principles of structure-kinetic modelling of chain oxidation reactions occurring in a non-crystalline polymeric matrix. A molecular spongy micelle, an important element in the framework structure of a noncrystalline polymer, was chosen as the morphological basis for modelling.

The kinetic model developed with allowance for the nanoscale micellar heterophase structure has already explained a series of specific features of free radical chain transformations which cannot be explained in terms of homogeneous reaction models.^{15, 16, 18–22, 38, 94} This model was used to interpret the mechanisms of separate stages of the oxidation of polymers described by kinetic laws different in kind. These stages either replace one another during the process or are changed themselves due to the change in the thermomechanical state of the polymeric object.

The structure-mechanical reasons for the curious features of initiated oxidation, which do not fit in the homogeneous reaction models, were identified. The morphological and structure-kinetic models used here impart definite meaning to the concept of structure-mechanical modification of the chemical reactivity of species reacting in a molecular spongy matrix, which is considered as a process directly related to the molecular-segment lability and flickering mobility of nanopores.

It should be emphasised that the heterophase models considered here not only disclose the physical essence of each oxidation stage but also identify the relationship between the chemistry of transformations and the most important structural properties of the molecular spongy matrix, thus extending the morphological basis of the chemical physics of polymers.

Abstract. The role of the physical network in the dynamics of macromolecules is considered. It is shown that experimental data are often inconsistent not only quantitatively but also qualitatively with the results obtained in terms of the widespread reptation model based on the concept of network entanglement. Evidence is given indicating that the network of physical bonds is the governing factor in the dynamics of macromolecules. The bibliography includes 218 references.

I. Introduction

The condensed state of substances is determined by the nature of intermolecular interactions. This statement appears trivial; however, in the case of polymers the situation is not that simple. Indeed, below the glass transition temperature, the properties of a high-molecular body virtually do not differ from those of a low-molecular body (the latter may be brittle), whereas in the high-temperature range they differ rather substantially. This is primarily due to the chain nature of the molecules owing to which polymers display properties which allow one to speak about their specific (highly elastic) state; network structures are only possible in polymeric bodies; it is in the polymers that such a structural level as the topological one is the most important. Thus, intermolecular interactions in high-molecular-mass compounds cannot be reduced only to the formation of more or less strong bonds of an energetic nature. In order to understand and describe properties of polymeric substances, it is necessary to take into consideration topological features of their structures.

The use of the concept of physical networks¹ allows a more adequate description of polymers: energetic interactions are assumed to be localised at certain points regarded as nodes, whereas the topological aspects of the structure are interpreted

with the aid of terminology used to describe covalent networks (*e.g.*, internodal chains, tails, gel and sol fractions, *etc.*).^{2,3} Any polymeric system can be described as a network whose nodes have a finite lifetime. The concentration of nodes depends on external conditions: temperature, strain, the presence of a solvent.

Physical networks, usually called gels, are fairly well studied subjects.^{4–7} According to Flory,⁸ they can be classified as follows: well-ordered lamellar structures, including gel-like mesophases; totally disordered polymeric networks; polymeric networks formed by physical aggregation which are mostly disordered but comprise some ordered regions; and specific disordered structures.

This classification comprises covalent network polymers but does not include non-crosslinked polymers. This is due to the fact that in the cases under consideration the nodes of physical networks are represented by certain microphase structures. Common linear or branched polymers devoid of such structures, though not being called gels, exhibit, in definite temperature and time intervals, properties of gels, which are in particular exhibited in the relaxation of the elasticity modulus. Consequently, when considering all polymers, one can make recourse to the above-mentioned Flory classification complemented with disordered polymeric systems comprising the nodes whose nature differs from that of microphases.

At present, the most popular viewpoint is that the nodes of a physical network are entanglements, *i.e.*, units of topological and entropic rather than energetic origin.^{9–13} However, it should be noted that in this case too, the concentration of nodes depends on temperature, although the heat of node formation is rather small, $\sim 9 \text{ kJ mol}^{-1}$.¹⁴

The polymers containing functional groups capable of forming sufficiently strong energetic bonds (of the hydrogen bond type) can be regarded as an intermediate case, if these groups are distributed along the chain in a manner, which prevents the formation of ‘zones of physical bonds’.¹⁵ According to the Flory classification, the first group of physical networks is macromolecular in essence. Therefore, if the network polymers are excluded, then all the polymeric systems regarded as physical networks may be classified as follows:

(1) networks with nodes of a microphase type which have ordered or disordered structures;

Received 17 September 1999

Uspekhi Khimii 69 (3) 283–301 (2000); translated by V D Gorokhov

(2) networks with nodes formed by strong intermolecular bonding of the hydrogen bond type;

(3) networks with nodes of entropic (topological) nature.

The first group comprises systems which are commonly regarded as physical gels. Numerous papers and reviews have been devoted to the thermodynamic aspects of such systems and their phase structure.^{4–8, 15} The role of energetic intermolecular interactions in these systems has been established.

All other polymers may be included into the second and mostly the third groups. An important point here consists in estimating the contribution of the energetic component and intermolecular interactions to the properties of polymeric systems of these types.

II. The role of topological factors. The reptation model

A distinctive feature of polymeric systems consists in the existence of the highly elastic state which is manifested in that they exhibit properties of an elastic body over definite time and temperature intervals: above the glass transition temperature and below the flow temperature, one observes a high-elasticity plateau in the relaxation curves. In this range, the real part of the elasticity modulus is slightly dependent on the temperature and time (frequency of measurements) of the experiment; consequently, the plateau is of the entropic rather than energetic origin. It is noteworthy that the above-mentioned weak dependence is relative, because in the interval of low temperatures and high frequencies (short times) the high-elasticity plateau is superimposed on the glass transition region. For this reason, it is sometimes difficult to establish whether the changes in the elasticity modulus are associated with this circumstance, or this parameter depends *per se* on the temperature and time of the experiment in the plateau region.

Evidence in favour of the entropic nature of intermolecular interactions which determine properties of the polymeric systems is provided by the dependences of the range of the high-elasticity plateau and the viscosity of melts and concentrated solutions of polymers on their molecular masses (MM).

The theories which substantiate the above dependences (see, e.g., Refs 10, 13, 16–18) are based on the concepts of crucial role of the network of physical (topological) nodes, while the network connectivity (critical conditions of the network appearance) depends on the length of the chains that are cross-linked the correlation between theoretical predictions of basic regularities of diffusion and relaxation in such systems and experimental results requires that some refinements of the type of ‘constrain release’ and ‘tube relaxation or tube renewal’ are introduced.^{19, 20}

The simplest version¹³ of the reptation model describes the dynamic properties of a polymer melt in terms of the Rouse theory (R) if MM is smaller than a certain critical value M_c . In this case, the viscosity η should be proportional and the diffusion coefficient D inversely proportional to MM; hence, the product ηD is independent of MM. The dynamics of a macromolecule is determined by two characteristic scaling parameters: the segment length l and the mean square radius of the macromolecule coil $\langle R^2 \rangle^{1/2}$. The dependence of the squared displacement of the central segment of the chain on time $g_m(t)$ obeys the following relations:

$$g_m(t) \propto \begin{cases} t & \text{if } g_m < l^2, \\ t^{1/2} & \text{if } l^2 < g_m < \langle R^2 \rangle, \\ t & \text{if } g_m > \langle R^2 \rangle. \end{cases} \quad (1)$$

At $MM > M_c$, the crucial role is played by the third scaling parameter, i.e., the mean square radius of the chain between entanglements or the ‘tube’ radius $\langle R_e^2 \rangle^{1/2}$. The dependence of viscosity and maximum relaxation time on MM should be exponential with the exponent equal to 3. The diffusion coefficient decreases proportionally to the squared MM; consequently, the product ηD is proportional to MM. The squared displacement of

the central segment of the chain as a function of time $g_m(t)$ is determined by the following relations:

$$g_m(t) \propto \begin{cases} t & \text{if } g_m < l^2, \\ t^{1/2} & \text{if } l^2 < g_m < \langle R_e^2 \rangle, \\ t^{1/4} & \text{if } \langle R_e^2 \rangle < g_m < \langle R^2 \rangle, \\ t^{1/2} & \text{if } \langle R^2 \rangle \frac{N}{N_e} > g_m > \langle R^2 \rangle, \\ t & \text{if } g_m > \langle R^2 \rangle \frac{N}{N_e}. \end{cases} \quad (2)$$

where N is the chain length and N_e is the chain length between entanglements.

Predictions of the dynamics of macromolecules have been the subject of both numerous experimental studies^{10, 14–23} and computer simulations.^{24–38} In the latter case, the energy factor was not, as a rule, taken into account, since it was believed that only the excluded volume (the ‘repulsive’ part of the interaction potential) and impermeability of chains are significant. Unfortunately, there are virtually no studies (except for the investigations^{29–32} on the behaviour of low-molecular chains of the type of paraffin oligomeric chains) in which the ‘attractive’ part of the interaction potential has been estimated. In short, ‘...the reptation hypothesis and models built thereon give an extremely good qualitative description of a broad range of experimental observations; in many cases, the agreement is quantitative. ...If it is more important for a good model to explain a wide variety of phenomena reasonably well than to be in precise agreement with a restricted set of observations, then reptation-based models must be viewed as extremely successful’.¹⁹

The existence of topological nodes in the structure of polymers is proved by their fixation upon cross-linking of linear polymers.³³ At a sufficiently high degree of cross-linking, the total number of nodes as determined from physical measurements exceeds the number of nodes calculated from the conditions of a chemical experiment by an amount which presumably corresponds to the number of entanglements (topological nodes) in a non-cross-linked system.²

For a number of polymeric systems^{2, 39, 40} this finding was confirmed experimentally and by computer simulation.^{41–44} However, there are data (see, e.g., Ref. 45) which disprove this view.

Thus, it would seem that there are no reasons for casting doubts on the existence of entanglements as structural units and their role in the formation of relaxation properties of polymers. However, a detailed analysis of experimental results shows that such reasons exist.

III. Correlation between viscosity and viscoelasticity

It is usually assumed that the character of the dependence of viscosity on MM, a kink in the curve in the vicinity of certain ‘critical’ value of M_c ⁴⁶ and the appearance of a high-elasticity plateau[†] are determined by the same factor, viz., by the presence of topological nodes or entanglements of polymeric chains.¹⁴ Therefore, it is natural to suggest if not equality, at least a correlation between the parameters M_e and M_c . However, back in 1974, Graessley¹⁷ noticed that such a correlation does not exist and, what is more, the M_e values found from the results of viscosity and compliance measurements are conflicting. Having analysed 70 polymers, Aharoni⁴⁹ showed that despite the absence of a correlation between M_c and M_e definite correspondence can be revealed for small groups of similar polymers.^{50, 51} However, it should be noted that the values of both viscosity at finite concentrations of polymers and their MM exceed critical values and the elasticity moduli in the high-elasticity plateau region

[†] Based on the concepts of classical theory of network elasticity, the chain length between the network entanglements (M_e) may be calculated from the magnitude of the elasticity modulus in this region.^{9, 47, 48}

depend on the size of the polymeric coil. This circumstance was apparently first brought to light by Fox⁵² and this fact was repeatedly confirmed in later studies.^{48, 53, 54} It has been shown that the M_c values for many polymers approximately correspond to one size of the macromolecular coil: the characteristic viscosity $[\eta]_c$ corresponding to the M_c value of different polymers amounts to $\sim 13 \text{ dl g}^{-1}$ (26 polymers were analysed). This conclusion was confirmed by Chee⁵³ (35 polymers) and He and Porter⁵⁴ (37 polymers). The latter study has shown that the mean square radius of the coil of the critical size of a macromolecule $\langle R_c^2 \rangle^{1/2}$ is constant

and equal to about 4 nm (the spread of values from 1.3 nm for poly(oxy-2,6-dimethyl-1,4-phenylene) to 5.9 nm for poly(dodecyl methacrylate).

An illustrative example of the invariance of the coil critical size was given in a study of Baird and Ballman.⁵⁵ The dependence of viscosities of the rigid-chain poly(*p*-phenylene terephthalate) (the persistence length $A = 130 \text{ nm}$, $M_c = 1180$) and the flexible-chain nylon-6,6 ($A = 9.4 \text{ nm}$, $M_c = 5300$) on MM is the same, if not the MM proper but the polymer coil size (characteristic viscosity) is used as the argument. Table 1 contains the values of characteristic

viscosity $[\eta]_c$ for different polymers. The coil radius was calculated by the Flory–Fox formula⁵⁶

$$\langle R_c^2 \rangle^{1/2} = \frac{([\eta]_0 M_c)^{1/3}}{\Phi},$$

where $[\eta]_c$ is the characteristic viscosity of the θ -coil and $\Phi = 2.87 \times 10^{21}$. It is seen that the values of the critical radii of the coils of different polymers are close.

Antonietti *et al.*⁵⁹ have shown that macromolecules of polystyrene with different topologies (linear, cyclic and star-like with different numbers of branches and microgel spheres) also exhibit the same dependence of viscosity on MM if the argument is the polymer coil size. An analogous result was also obtained for other types of polymers, *viz.*, rigid-chain,⁶⁰ liquid-crystalline,⁶¹ comb-shaped,⁶² and branched^{63,64} ones. The use of characteristic viscosity allows unification of the data on viscosity of different polymer systems over a wide concentration range.⁶⁵

Such a similarity of the behaviour of macromolecules (including highly cross-linked globules) which differ greatly in their nature and topological type is often interpreted from a purely geometrical viewpoint: entanglements can arise only when the coils overlap, *i.e.*, when the total volume of coils (the product of the coils concentration by the macromolecular coil volume) is larger than the system's volume. The criterion ratios proposed by different authors^{49, 52–54, 66, 67} differ in minor details. However, the fact that dense globules⁵⁹ and rigid rods⁶⁰ obey the same regularity casts doubts on the validity of the topological approach.

The data on the correlation between the elasticity moduli G_e in the high-elasticity plateau region and the molecular characteristics of block polymers have been analysed.^{13, 49, 54, 57, 68} The value of

the effective volume of the network of entanglements $([\eta]_0)^\ddagger$ was found to be constant irrespective of the magnitude of M_c , which is determined by the nature (rigidity) of a polymeric chain (Table 2). However, the product $[\eta]_0 \rho$ is somewhat smaller ($\sim 8 \text{ cm}^3 \text{ g}^{-1}$, on the average, for the polymers studied) than that derived from viscosimetric measurements ($13 \text{ cm}^3 \text{ g}^{-1}$). At the first glance, this result does not contradict the simple network model according to which

$$M_c = 2M_e.$$

However, it should be noted that the same regularities are characteristic of both rigid rods⁶⁰ and dense highly cross-linked globules⁵⁹ as well as latex dispersions,⁶⁹ *viz.*, at definite concentrations and/or MM of polymers, the polymeric systems exhibit viscoelastic properties. Evidently, the elastic properties are determined by the network structure resulting from intermolecular interactions which are apparently of an energetic nature.^{61, 70} The viscoelastic properties of comb-like polymers are presumed to be also determined by intermolecular interactions due to the side groups.

IV. Regularities of viscous flow

It is believed that the viscosities of polymers strongly depend on MM ($MM > M_c$) and concentration of the polymers (exponents of 3.4 and ~ 5 , respectively) and are determined by the formation of interchain topological nodes called entanglements (*see, e.g.*, Refs 9, 10, 12–14, 16–19, 46, 71). The entanglements arise in the concentration region where mutual penetration of polymer coils resulting in a cooperative flow of polymer chains occurs. It is presumed^{10, 12, 13} that in the frame of the reptation model, the translation diffusion of polymer chains during such a flow is restricted by the 'tube', *i.e.*, it becomes substantially anisotropic.

Changes in the size of a macromolecular coil upon concentration of a solution are highly important in the studies of the dependence of the viscosity of a polymer solution on the concentration and MM of this polymer. The dependence of the size of a macromolecular coil on the polymer concentration in the range of semidilute and concentrated solutions was investigated both theoretically^{10, 13, 72, 73} and experimentally.^{74–76} Flory⁷⁷ was the first to notice that the coil changes its dimensions upon transition from dilute to concentrated solutions. In the isolated state (in a dilute solution), the conformation of macromolecules is determined by the competition of two factors, *viz.*, the effect of excluded volume and the energy of interaction of monomeric units with the medium (in an athermal solution where the interaction energy does not play any role and the coil swells owing to the effect of excluded volume), while, according to Flory, the coil should have the θ -dimensions in the bulk.

Edwards *et al.*^{13, 73} proposed a theory based on the idea of screening of the energy of repulsion of monomeric units of the same chain by the units of the neighbouring chains. With such a screening, the effect of excluded volume is neutralised: as in the case of dilute solutions, the energy of repulsion of monomers of the same chain is compensated by the energy of their attraction owing to the interaction with the monomeric units of the neighbouring chains. In this case, the principal role is played by the entropy factor the nature of which has been clearly explained by de Gennes in a simple example.¹⁰ The entropic nature of this factor is manifested in that the temperature factor influences the size of the θ -coil in a melt to a substantially lesser extent than in a dilute solution.⁷⁸

For the same reason, the concentration dependences of the swelling coefficient shown in Fig. 1 comprise two regions: in the first region, the shape of the curve is substantially dependent on the nature of the solvent and the curve may be monotonic or have

extrema (the region of dilute solutions); in the second region, the shape of the curve is the same for solvents of any type.

Variation of the size of a macromolecular coil as a function of the polymer solution concentration is described by power dependences, for example:¹³

$$\frac{\langle R^2 \rangle}{\langle R^2 \rangle_0} - 1 \propto c^{1/2} \text{ or } R_g = R_g^0 \left(\frac{c}{c^*} \right)^{2\nu-1/2(1-3\nu)},$$

where R_g is the hydrodynamic radius of the polymer coil, c^* is the critical concentration (the boundary between dilute and semidilute solutions), ν is the power index in the relation

$$\langle R^2 \rangle^{1/2} \propto M^\nu,$$

where M is the molecular mass of a polymer.

Usually, experimental data are also presented in the form of power dependences.^{74, 79}

It should be noted that the above dependences can serve as estimates. As is mentioned in the monograph of Doi and Edwards,¹³ 'the scaling argumentation gives only a qualitative picture of the dependence on basic parameters'.

The sought dependence of the macromolecular coil size on the polymer concentration may be derived by analysing computer simulation models.^{79–81} As a rule, these models take into consideration only the factor of the excluded volume, *i.e.*, the repulsive part of the interaction potential. This means that the computer simulation techniques investigate athermal systems.

The results of such simulations indicate^{79, 80–82} that the following simple relation is obeyed over the entire concentration range (Fig. 2a).

$$\frac{V_c}{V_0} = \frac{1}{1 + \gamma c}, \quad (3)$$

where V_c and V_0 are the coil volumes at the concentration c and in an extremely dilute solution, respectively; γ is a coefficient.

The coefficient γ depends on the chain length N (Fig. 3)

$$\gamma = N^a,$$

where the exponent a is equal to 1 for short chains and $a \simeq 0.34$ for long chains. Such a character of the dependence may be explained qualitatively by the relationship between the coil size and the length of the chain contour: the linear dependence in the first case and the exponential dependence with the exponent $1/2$ in the second case.

The validity of relation (3) is illustrated in the experiments showing the effect of 'thickening' (increase in concentration) of a polymer solution on the diffusion of macromolecular coils,⁸³ viscosity^{2, 84, 85} and characteristic viscosity of the polymer.^{86–90} For corresponding analysis of the experimental results, see Ref. 82.

Figure 2. Dependence of the size of a macromolecular coil on the polymer concentration in the coordinates of Eqn (3); (a), data from computer simulation,⁸¹ the numerals at the straight lines indicate the chain length; (b), system PS – carbon disulfide.⁷⁴

Figure 3. Dependence of the coefficient γ from Eqn (3) on the chain length according to the data reported by de Vos and Bellemans⁷⁹ (1) and Paul *et al.*⁸¹ (2).

By comparing changes in the diffusion coefficients of a rigid sphere (chloroform as the solvent) and a macromolecular PS coil (toluene as the solvent) upon concentration of solutions in the PMMA concentration range from 0% to 5%, Brown and Rymden⁸³ have concluded that the size of the coil of the PS macromolecule depends on the 'thickener' concentration. As the molecular masses of PS and PMMA are high (ranging from 1.26×10^6 to 15×10^6 for the former and from 1.01×10^5 to 4.45×10^5 for the latter), the solutions in the above-mentioned concentration range are regarded, if not as concentrated, at least as semidilute ones for which the entropy factor is decisive.

In the experiments⁸⁶ on measuring the characteristic viscosity of PS ($MM = 3.5 \times 10^6$) in a mixture of bromoform with PS with $MM = 0.46 \times 10^5$ or PS with $MM = 1.1 \times 10^6$ as the 'thickener', the interval of the system's volume 'packing' {parameter $[\eta]c$ } is overlapped almost 10 times which is undoubtedly indicative of the transition to the region of concentrated solutions.

The results of the studies on the variation of the coil size as a function of concentration of polymers obtained by the neutron scattering method (Fig. 2b)⁷⁴ are not described by relation (3). Possibly, in this system the break in the straight line corresponds to the critical concentration of transition from a dilute solution to semidilute one, *i.e.*, the energy factor plays the decisive role in the initial stage. Daud *et al.*⁷⁴ used carbon disulfide which is a good

solvent. There are no accurate data on the characteristic viscosity of PS in this solvent, although it may be assessed using the Mark–Kuhn equation

$$[\eta] = KM^a;$$

if it is assumed that $K = 1 \times 10^{-4} \text{ dl g}^{-1}$ and $a = 0.72$,⁵⁸ then $[\eta] = 0.44 \text{ dl g}^{-1}$, while the critical concentration is $\sim 0.02 \text{ g ml}^{-1}$. Of course, these values are lower than the value of characteristic viscosity corresponding to the inflection point on the graph, though they are close in their orders of magnitude.

It is also possible that a definite role in the above discrepancy is played by some additional factors, *e.g.*, the sample prehistory.⁹¹

Thus, the analysis of experimental data and results of computer simulation make it possible to conclude that formula (3) may be used for the description of the concentration dependence of the coil size in the range of semidilute and concentrated solutions of polymers.

It is noteworthy that relation (3) is a consequence of the dependence established for dilute solutions^{84,85}

$$V_c = V_0(1 - \gamma[\eta]c + \dots). \quad (4)$$

For low concentrations of polymers

$$V_c - V_0 = -kV_0^2c, \quad (5)$$

since

$$[\eta] \propto V_0.$$

If the latter expression is assumed to hold for finite values of concentration c , then Eqn (5) may be presented in form of the differential equation

$$dV = -kV^2dc, \quad (6)$$

from which Eqn (3) is derived by integration. It is seen that the coefficient

$$\gamma = kV_0$$

is a function of MM.

The fact that the principal quantity in Eqn (3) is the product $[\eta]c$ means that the scaling relations are virtually fulfilled,^{10,13} *i.e.*, the macromolecular coil size depends on the dimensionless parameter c/c^* .

Equation (6) is valid over the entire range of concentrations for both dilute and concentrated solutions of polymers (the differing k values, see Fig. 2*b*). This means that a polymeric solution of any concentration acts as a continuous medium for a macromolecular coil and that there is no difference in principle between the solvent and the polymer solution: the difference is purely quantitative due to different energetic interaction of the polymer chain with the medium and viscosity, which is confirmed by diffusion experiments.⁸³

This may also mean that macromolecular coils behave independently during the flow of a polymeric solution and/or a melt *viz.*, interactions of the entanglement type do not affect the viscosity. In other words, Eqn (3) holds over the entire range of polymer concentrations (up to its melt).

This hypothesis formed the basis for the analysis of the viscosity dependence on the concentration and MM of a polymer.^{2,92–95} It turned out that over a certain concentration interval depending on the glass transition temperature of a system, all polymers obey the following law:

$$\ln \eta_{\text{rel}} = K^{-1} \ln[1 + K[\eta]_c(c - c^*)], \quad (7)$$

where $\eta_{\text{rel}} = \eta/\eta_c$, η_c is the viscosity of a polymer solution at the critical point, $[\eta]_c$ is the characteristic viscosity of a polymer at the critical point, $K = 0.125$ for all the polymers studied.

As an example, Fig. 4 shows the data on the viscosity of polydimethylsiloxane solutions in siloxane pentamer.⁹⁶ The curves plotted in the coordinates of Eqn (7) are straightened over the entire range of concentrations and MM, the straight line slope {the product $K[\eta]_c$ } being dependent on MM in conformity with

Figure 4. Dependence of the viscosity of polymethylsiloxane on its MM and concentration in the siloxane oligomer with the chain length equal to 5 plotted in the logarithmic coordinates (*a*) and the coordinates of Eqn (7) (*b*);⁹⁶ $10^3 M_w$: (1) 490; (2) 152; (3) 88; (4) 36; (5) 11.2; (6) 2.9.

the Mark–Kuhn equation. In this case, the exponent a is equal to 0.54, which is somewhat larger than under θ -conditions but smaller than in an athermal solution. Analogous conclusions have been drawn from other studies.^{89,94} The corresponding data are listed in Table 3.

According to the data reported by Kataoka and Ueda,⁹⁶ the M_c of the bulk polymer is 27 000 (30 000, according to Ref. 48). However, there is no kink in the dependence of viscosity on MM plotted in the coordinates of Eqn (7) (Fig. 5*a*). Naturally, such a kink will certainly be absent at lower polymer concentrations.

The results obtained may be suggested to be due to that the polysiloxane fractions had a broad molecular-mass distribution ($\overline{M}_w/\overline{M}_n \approx 2$). However, the data on the viscosity of PS⁵⁹ with a rather narrow molecular-mass distribution ($\overline{M}_w/\overline{M}_n \geq 1.1$) and of polybutadienes¹⁰² also with a narrow molecular-mass distribution over a very wide MM range (from 10^3 to 10^7) point to the preservation of the above regularity (Fig. 5*b*). The linear law

holds up to MM of the order of 10^6 . Deviation from the linearity observed for samples with larger MM may be due to their higher polydispersity. It should be noted that an analogous deviation from linearity is observed in double logarithmic coordinates.

The conclusion about the independence of macromolecular coils in concentrated solutions was confirmed by the data on the relationship between the solution viscosity and the longest relaxation time (τ) determined from the critical gradient rate in the longitudinal flow of solution between two coaxial capillaries.⁸⁷ It was shown that the following relation holds over a wide range of polymer concentrations

$$\tau = A \frac{M[\eta]\eta_0}{RT},$$

where A is a coefficient and η_0 is the solvent viscosity. In this equation which is valid for dilute solutions,⁵⁶ the role of the solvent viscosity is played by the solution viscosity.

The above results make it possible to conclude that the critical conditions under which a kink in the plot of the viscosity dependence on MM and concentration of a polymer is observed, are not associated with the transition of the individual flow of coils into a cooperative one. This artefact is determined by the representation of the sum of two magnitudes in logarithmic coordinates [see Eqn (7)].

Apparently, the reptative character of the displacement of chains in the flow of polymer solutions is manifested at the MM and concentrations of polymers which are appreciably larger than the critical ones. Thus it was suggested that¹³ the true reptation manifests itself in the range of MM of about $800 M_c$, i.e., the values of the order of tens of millions.

V. Diffusion of macromolecules

Various aspects of the translational diffusion of polymers have been reviewed by Green.²⁰ In experiments, the criterion of transition from the R-dynamics to the reptation dynamics was the dependence of the diffusion coefficient on the molecular mass of the chain, which is linear in the R-model and quadratic in the reptation model. Various methods (ranging from radioactive labelling NMR spectroscopy) and different polymers (PS, PE, PDMS, etc.) were used for deriving quantitative data. Having analysed the available experimental results concerning the diffusion of polymers in bulk and in mixtures, Green²⁰ concluded that the diffusion coefficient depends on the mixture composition, the dependence being often non-monotonic.

In many cases, the validity of the dependence characteristic of the reptation mechanism was revealed.

$$D \propto M^{-a},$$

where $a = 2$. It should however be emphasised that in the graphs plotted from the results of Green's study²⁰ all the points fall onto the same straight line for both $MM > M_c$ and $MM < M_c$. At the same time, this author points to numerous data which show that

the exponent a for the polymers with MM substantially higher than M_c is markedly smaller than 2 (e.g., for PDMS¹⁰³). In the case of polyisoprene,²⁰ this exponent is, on the contrary, close to 3, while in the 60% solution of PS in dibutyl phthalate¹⁰⁴ $a = 2.6 \pm 0.2$. Comparative investigation of the dependences of viscosity and diffusion of hydrogenated polybutadiene has been carried out by Pearson *et al.*,¹⁰⁵ who have shown that at the MM much higher than M_e ($MM > 9M_e$) the following relation is respected

$$(D\eta)_{\text{rep}} = (D\eta)_R \left(\frac{M}{M_e} \right),$$

where the subscripts 'rep' and 'R' denote the reptation and Rouse models, respectively.

Similar results were obtained for PS and hydrogenated polyisoprene. It was proposed to describe diffusion in the general form using the expression

$$D\eta = (D\eta)_{\text{rep}} + (D\eta)_R = (D\eta)_R \left[1 + \left(\frac{M}{M^*} \right)^d \right],$$

where $M^* = (9.5 \pm 1.1)M_e$ and $d = 1.5 \pm 0.1$.

In order to describe the dependence of diffusion coefficient on MM and concentration of a polymer, more complex expressions are used, in particular the 'stretched' exponent:^{106, 107}

$$D \propto \exp(-kM^b),$$

where $b = 1$ for low MM and $b < 1$ for high MM. Such a character of the dependence is related¹⁰⁸ to the Kohlrausch–Williams–Watts law.¹⁰⁹ This expression is empirical but this does not prevent its use because the power dependences fit experimental results poorly. Indeed, the results reported by Pahl *et al.*¹¹⁰ indicate that the dependence of the diffusion coefficient of PDMS (with MM ranging from 118 000 to 716 000) on MM is an exponential function rather than a power one. These investigators revealed a trend towards the transition of the translational diffusion to the reptation regime; however, the reptation regime was not achieved because of the time limit (~ 1 s, with the use of NMR in a gradient field).¹¹⁰

Experimental studies of diffusion were carried out in dilute and semidilute solutions of polymers using different methods, in particular NMR spectroscopy in a gradient field,^{22, 29, 111, 112} dynamic light scattering¹¹³ and neutron spin echo.^{23, 114}

The dependence of dynamic (including also diffusive) characteristics of macromolecules on the solution concentration is determined by the characteristic parameter ξ , viz., the correlational length of the excluded volume.^{10, 13} The dependence of this parameter on concentration, for example, for a semidilute solution is as follows:

$$\xi \propto c^{-v/(3v-1)} \propto c^{-3/4}.$$

With the consideration of this formula, the diffusion coefficient of a polymeric chain in the range of concentrations corresponding to semidilute solutions is expressed as

$$D \propto N^{-2} c^{-1.75}.$$

As noted above, experimental results are more likely to indicate an exponential function.^{106, 107, 115} Thus depending on the nature of the solvent and the polymer, the value of power v in the 'stretched' exponent varied from 0.42 to 2.21.¹¹⁵ In addition, v depends on MM

$$v \propto M^{-0.25}$$

as results from the analysis of more than 40 systems show.

The validity of specific models is confirmed by the results of computer simulation of the dynamics of polymers^{116, 117} using molecular dynamics^{30, 32} and Monte Carlo methods.^{118–124}

Despite its somewhat artificial character, the Monte Carlo method is often used in studies of physical properties of polymers,³¹ and it was this method that provided basic information on the dynamics of macromolecules. As the investigation of dense

(bulk) systems by computer simulation techniques is a rather complex problem, the concentration factor was found to play a substantial role: basic results were obtained for the systems in which the polymer concentrations did not exceed 50%.

With the Monte Carlo method, the main attention is paid to the investigation of the dependence of the chain diffusion coefficient on the concentration and MM.¹¹⁸ In this context, the following trends have been brought to light:

(i) as the concentration increases, the power index a in the dependence of maximum relaxation time τ on MM

$$\tau \propto N^a$$

varies from 2 to 3, which corresponds to the change in the conditions of chain displacement, *i.e.*, from the R-regime to the reptation regime;

(ii) at low concentrations, the temporal dependence of the displacement of the macromolecule mass-centre obeys the relation

$$g_m \propto t^{0.54};$$

(iii) as the concentration increases, the power index approaches 0.50, which is related to the above-discussed compression of the polymer coil to the θ -dimensions;

(iv) the squared shear of the inner monomeric chain depends over some time interval on the current time (t)

$$g_m \propto t^{0.3},$$

which is interpreted as manifestation of the reptation mechanism in which the power index should be equal to 0.25.

It should be noted that the extension of the results obtained to the range of polymer concentrations close to 100% leads to a paradoxical conclusion that the dependences of diffusion coefficient and maximum relaxation time on MM become stronger than those predicted by the reptation model: the power indexes increase to 2.4 and 3.6, respectively.¹²⁰ Furthermore, restriction of the lateral shift of the segregated chain was revealed solely in the case on 'frozen' environments. If in a mobile system, all chains are equally mobile, the 'tube' effect, expressed in the anisotropy of the differentiated chain motion, is not manifested.

Figure 6. Dependence of the minimum time of R-relaxation τ/N^2 on the macromolecule size:^{81, 119} (a) in the Stokes equation coordinates; (b) concentration dependence.

On the other hand, the analysis of the dependences of the diffusion coefficient D and maximum relaxation time τ reported by Paul *et al.*^{81, 119} shows that the relationship between τ and D^{-1} is linear over the entire range of concentrations studied for all lengths of chains and for all lengths of chains except for 20 (*i.e.*, 50, 80, 100, 200), a single dependence has been established (Fig. 6 a)

$$\frac{\tau}{N^2} = \frac{2.6 + 0.027}{D\langle R^2 \rangle^{1/2}}.$$

This formula expresses essentially the Stokes law in which the minimum time of R-relaxation τ/N^2 plays the role of viscosity, whereas the concentration is implicitly accounted for in the values of τ and $\langle R^2 \rangle$. Here, the minimum relaxation time⁸ should not depend on the concentration and MM of a polymer due to the effect of hydrodynamic screening.¹³ However, as one can see from the data shown in Fig. 6 b, such a dependence does exist: the minimum relaxation time is functionally related to the length of the polymeric chain and its solution concentration. It should be emphasised that the dependences observed are linear in the corresponding coordinates and that they have no kinks, which could suggest the transition from the R-mode of relaxation to the reptation regime. Consequently, as in the case of maximum viscosity, cooperativity is not manifested in slow processes of macromolecular diffusion.

VI. Stress relaxation

In the curves of the stress relaxation of linear polymers with a narrow molecular-mass distribution, one can differentiate several zones corresponding to different states of the system:¹²⁵ glassy, transient, highly elastic (plateau of high elasticity) and terminal states (see, *e.g.*, Fig. 7 a). It is seen that MM has no effect on the shape of relaxation curves in the glassy and transient states, this effect being manifested only at the end of the high-elasticity plateau, *viz.*, in the terminal zone. This fact is well known. The high-elasticity modulus exhibits rather small variation in the plateau region. A drastic drop of this modulus (by 90% and

§ This magnitude corresponds to the friction coefficient of a bead of the R-chain. According to the R-model, the polymeric chain is a system of beads (friction elements) connected by elastic elements.

Figure 7. Curves of relaxation of the stress of PS with a narrow molecular-mass distribution;¹²⁶ (a) elasticity modulus; (b) effective time of relaxation; $10^{-3}M$: (1) 80; (2) 125; (3) 193; (4) 239; (5) 267.

more) occurs in the terminal zone, and the kinetics of its decrease strictly obeys the exponential law.

All the zones corresponding to the above-listed ranges are clearly seen in the curves of the dependence of effective relaxation time τ_{ef} on the current time (Fig. 7b)¹²⁶

$$\tau_{\text{ef}} = - \left(\frac{d \ln G(t)}{dt} \right)^{-1}. \quad (8)$$

The relaxation time is approximately proportional to the square root of the time in the region of the transient state, this dependence is almost linear (the power index is slightly larger than 1) in the high-viscosity region, then it weakens in the region where MM begins to have its effect and, finally, the relaxation time becomes invariant with time, *i.e.*, $\tau_{\text{ef}} = \tau_{\text{max}}$.

The data reported by other investigators^{127–129} confirm the above-noted regularities of changes in the stress relaxation. The maximum time of relaxation is MM-dependent (Fig. 8)

$$\tau_{\text{max}} \propto M^4.$$

However, this law cannot always be revealed. Indeed, as is seen from the data shown, on the one hand, if the MM interval is not too large, the regularity may be distorted. On the other hand, relaxation measurements of polymers in a wide MM range are usually performed at strongly differing temperatures, and the use of the temperature–time superposition principle reduces them to a certain selected temperature. Minor inaccuracies in such normalisation may lead to some errors (Fig. 8). The analysis of the whole body of available data provides evidence that it is the above-mentioned law that is observed.

Let us emphasise that the data shown in Figs 7 and 8 refer to polymers with a narrow molecular-mass distribution; therefore, the peculiarities of the stress relaxation noted above are characterised namely by the dependence on the chain length.

It is presumed that the relaxation of relatively short chains is well described by the R-model, while the relaxation of fairly long chains is fitted by the Doi–Edwards (DE) model. Herewith, the R-relaxation occurs in a small segment of the transient zone, which adjoins the high-elasticity plateau and is characterised by the exponential dependence of relaxation on the current time with the exponent 1/2.¹³ However, a thorough analysis¹³⁰ of the shape of the relaxation curves corresponding to the R- and DE-models has shown (Figs 9 and 10) that one can differentiate three segments (in the logarithmic coordinates) in the dependence of the elasticity modulus relaxation on time

$$\frac{G(t)}{G(0)} = \frac{1}{n} \sum_{p=1}^n \exp \left(- \frac{p^2 t}{\tau_{\text{max}}} \right), \quad (9)$$

where

$$G(0) = \frac{6n}{\pi^2 \tau_{\text{max}}} \left(\int_0^\infty G(t) dt \right)^{-1} \quad (10)$$

Figure 8. Dependence of the maximum relaxation time on MM of PE according to the data of Akovali¹²⁷ (1), McGrory and Tuminello¹²⁸ (2), Lin¹²⁹ (3) and Aklonis and Tobolsky¹²⁶ (4). Normalised temperature/°C: (1 and 4) 129; (2) 160; (3) 127.5.

Figure 9. Curves of the stress relaxation (a) and the temporal dependence of the effective time of R-relaxation (b) according to Eqns (8)–(10). The chain length: (1) 11; (2) 21; (3) 51; (4) 101; (5) 201; (6) 501.

where τ_{max} is the maximum relaxation time and n is the R-chain length.

These are

(i) the linear segment for the interval of relative relaxation $\sim 0.9 < G(t)/G(0) < 1$ and $t/\tau_0 \leq 1$ (τ_0 is the minimum time of R-relaxation);

(ii) the segment of the power dependence with the power index 1/2 for the interval $0.1 < G(t)/G(0) < 0.9$ (depending on the chain length, the left limit may be smaller)

$$\frac{G(t)}{G(0)} \propto \left(\frac{t}{\tau_0} \right)^{-1/2},$$

this relaxation interval corresponds to the time t of variation of the relaxation time from its minimum to maximum value;

(iii) the segment of the exponential decay of the relaxation modulus

$$\frac{G(t)}{G(0)} \cong \frac{1}{n} e^{-t/\tau}.$$

This segment of the curve corresponds to the region in which the elasticity modulus amounts to fractions of a percent of the initial value, while the time t is longer than the maximum relaxation time: $t/\tau_{\text{max}} > 1$.

Figure 10. Curves of the stress relaxation (a) and the temporal dependence of the effective time of DE-relaxation (b) according to Eqns (8), (11) and (12). The chain length: (1) 11; (2) 21; (3) 51; (4) 101; (5) 201; (6) 501.

Characteristically, regardless of the time, each of the relaxation curve segments refers to a strictly definite range of values of the relaxation degree $G(t)/G(0)$. Thus the criterion of R-relaxation may be the observance of the power law with the power index equal to 1/2 in the region of the degree of relaxation 0.8–0.1. The interval corresponding to this relaxation is the longer the higher is the MM of a polymer, which is also inherent in the R-model.

It is also typical that the dependence of the effective time of R-relaxation on time τ_{ef} proves to be proportional to time, namely, in the wide range (where the elasticity modulus decreases proportionally to the square root of the time) (see Fig. 9b). According to the R-model,

$$\tau_{\text{max}} \propto M^2.$$

According to the DE-model, temporal changes in the relaxation modulus obeying the relations

$$\frac{G(t)}{G(0)} = \frac{8}{\pi^2} \sum_{p=1,3,\dots}^n p^{-2} \exp\left(-\frac{p^2 t}{\tau}\right), \quad (11)$$

$$G(0) = \frac{12}{\pi^2 \tau} \left(\int_0^\infty G(t) dt \right)^{-1}, \quad (12)$$

are characterised by substantially farther extension of the region of high-elasticity plateau than in the R-model (Fig. 10). In this case, the drop of the modulus in the plateau region is insignificant (see Fig. 10a). The plateau passes smoothly to the exponential decay; the transition interval is rather narrow, while its position in the time scale depends on MM.

The temporal dependence of the effective time of DE-relaxation has its characteristic features, too (Fig. 10b). In the R-model, the minimum value of τ_{ef} is independent of MM and its maximum value is proportional to the square of MM, whereas in the DE-model the minimum and maximum values of τ_{ef} are proportional to the square and the cube of MM, respectively.

The temporal dependence of the effective relaxation time in the transient range obeys the law

$$\tau_{\text{ef}} \propto t^{1/2}.$$

Comparison of the features of the relaxation curves corresponding to the models considered with experimental results shows that none of these models fit the experimental results.

According to the experimental data, the elasticity modulus decreases by $\sim 30\%$ in the region of high-elasticity plateau, whereas the models studied suggest a substantially smaller drop, particularly in the case of the DE-model.

The experimental curves of relaxation comprise no segment corresponding to the exponential dependence with the power index 1/2, which contradicts the R-model. A segment of the exponential dependence of τ_{ef} on t , which may be ascribed to the DE-relaxation, can be found only in individual curves in the transient range (transition from the plateau to the exponential drop) (see, e.g., curve 5 in Fig. 7b). Though, such a segment is virtually absent on the curves describing the relaxation of PS over a wider MM interval. However, one cannot assume that the high-elasticity plateau corresponds totally to the R-relaxation for the following reasons. Firstly, the dependence of τ_{ef} on t is non-linear: in the logarithmic coordinates, $\tan \alpha > 1$ (~ 1.3) in the maximum dependence region. Secondly, as noted above, in the R-relaxation the segment corresponding to the transient state covers a considerable interval of the relaxation degree which is the longer the larger is the MM. In the experimental curves, this segment is little dependent on the chain length and covers the range of $\sim 90\%$ relaxation, which, of course, is substantially more than follows from the DE-model. Finally, the dependence of the maximum relaxation time on MM is a function with the exponent 4 and is not a quadratic function as in the case of R-relaxation, nor is it a cubic function as in the case of reptation model.

The frequency (ω is the frequency of impact) dependence of the relaxation of the real and imaginary parts of the elasticity modulus for narrow PS fractions is shown in Fig. 11.¹³¹ The corresponding dependences for the R- and DE-models are presented in Figs 12 and 13. It is seen that the relaxation curves cannot be described by any of the models discussed. Thus the curve reflecting the frequency dependence of the relaxation of the real part of the elasticity modulus has virtually no segment of exponential dependence with the exponent 1/2 characteristic of the R-model. However, in contrast to the curves typical of the DE-model, the experimental curves exhibit a substantial decay (by almost one order of magnitude) of the elasticity modulus in the region of the high-elasticity plateau.

The decrease in the imaginary part of the elasticity modulus in the high-frequency region occurs much more slowly than those predicted by the R- and DE-models: the power index in the dependence of elasticity modulus relaxation is equal to 1 for the

Figure 11. Frequency dependences of the real (a) and imaginary (b) parts of the elasticity modulus and of the effective time of PS relaxation (c).¹³¹ $10^{-3}M$: (1) 3000; (2) 770; (3) 275; (4) 128; (5) 70; (6) 39.

Figure 13. Frequency dependences of the real (a) and imaginary (b) parts of the elasticity modulus and of the effective relaxation time (c) in terms of the DE-model equations. The chain length: (1) 501; (2) 201; (3) 101; (4) 51; (5) 21; (6) 11.

R-model and to 1/2 for the DE-model, whereas according to experimental data, it makes up 0.2–0.3, the latter dependence being the more clear-cut the larger is the MM of polymers. The position of the maximum on the curves reflecting the frequency dependence of the imaginary part of the elasticity modulus depends on MM, though it is not cubic, as follows from the DE-model, but has the exponent 4, *i.e.*, it is analogous to the maximum relaxation time dependence.

Variation of the effective time of relaxation

$$\tau_{\text{ef}} = \frac{G'(\omega)}{\omega G''(\omega)} \quad (13)$$

also points to an appreciable distinction from the R- and DE-models, on the one hand, and to a discrepancy between the predictions based on these models and the experimental results, on the other: as in the case of the temporal dependence, on the curve reflecting the frequency dependence of the effective relaxation time one can differentiate two segments with constant values of minimal and maximal times and a transition region where τ_{ef} is proportional to the frequency (R-model) or to the square root of the frequency (DE-model). According to the experimental data, this dependence is expressed by the relation

$$\tau_{\text{ef}} \propto \omega^a,$$

where $0.5 < a < 1$.

Hence, the analysis of experimental data shows that the regularities of relaxation of such narrow fractions of linear polymers cannot be described even qualitatively by either the R-model or the DE-model.

The quantitative description of the relaxation of polymers based on the models considered faces serious difficulties; therefore, numerous semi-empirical and empirical approaches which recommend the use of exponential laws or dependences of the ‘stretched’ exponent type have appeared. For example, it is proposed^{125,132,133} to express the elasticity modulus relaxation with sums [see, *e.g.*, Eqns (9) and (11)] by analogy with the R-model, though with a different spectrum of relaxation times and a small number of the sum members. The physical meaning of such presentation is unclear.

There are equations of the type¹³⁴

$$G(t) \approx t^a e^{-\beta t},$$

which can be used for deriving the dependences of the elasticity modulus relaxation on the frequency of measurements of the type of the Havriliak–Negami dependence¹³⁵

$$G(\omega) \approx [1 + (\omega\tau)^2]^{-\alpha},$$

as well as the Kohlrausch–Williams–Watts equation

$$G(t) = a_1 \exp(-k_1 t^{\beta_1}) + a_2 \exp(-k_2 t^{\beta_2}).$$

Equations of this type often give a satisfactory description of the regularities of relaxation processes over a certain time or frequency interval. Attempts are being made to provide them with a theoretical base (*e.g.*, some studies^{122,136,137} were devoted to the development of coupling theory). It should however be noted that

no substantial progress concerning the region of highly elastic state has been achieved.

VII. Relaxation of chain orientation

The adequacy of a specific model is judged from the results of experimental studies on the orientation of non-cross-linked polymer chains in a concentrated solution, melt or a network polymer.^{10,13} According to current theoretical concepts, the orientation of chains in a non-cross-linked polymer is possible if the chain length exceeds the magnitude of M_e , *i.e.*, if in a given time interval the polymer chain is a network with its nodes formed by entanglements. However, many experimental studies^{138–145} have shown that oligomeric and short chains with the MM much lower than M_e can also be oriented in a polymeric matrix composed of the chains the MM of which is substantially larger than M_e or which form a network polymer. In this case, the motive force of the orientation is the so-called nematic interaction, *i.e.*, the manifestation of intermolecular forces of non-topological character.^{140,141} The nature of this interaction remains the subject of discussions (see, *e.g.*, Refs 142, 143). It was speculated that the important role is played by the free volume⁹ or configurational entropy in the implementation orientation.^{146–148}

It has been proposed^{142,143,149} that the coefficient ε determined by the relation

$$\langle \mathbf{u}_i \times \mathbf{u}_j \rangle_{\text{probe}} = \varepsilon \langle \mathbf{u}_i \times \mathbf{u}_j \rangle_{\text{matrix}}, \quad (14)$$

be used as the measure of nematic interaction where $\mathbf{u}_i$ and $\mathbf{u}_j$ are the components of the vector of orientation of monomeric chains.

The value of ε depends on the concentration and MM of short chains: as the concentration of long chains increases, the relaxation of the orientation of short chains is decelerated.¹⁴⁰ For example, the value of coefficient ε reaches 0.9 for short polybutadiene chains ($\text{MM} \leq 1000$) and decreases to 0.4 as the chain length increases (see Ref. 142). Approximately the same value of ε is characteristic of the nematic interaction in polybutadiene, ethylene–propylene^{140,150} and polystyrene¹⁵¹ block copolymers, as well as of the orientation of short molecules in the polydimethylstyrene¹⁵² and polyisoprene^{153,154} matrices. The value of ε equal to 1 was found for the polydimethylsiloxane matrix–oligomer system (see Refs 155, 156). Most studies have not revealed any temperature dependence of ε , though the opposite data are also available (see, *e.g.*, Refs 157–159).

Sotta¹⁶⁰ studied the phenomenon of a free segment orientation in a polymer network by the Monte Carlo method and found that $\varepsilon = 0.397$. The only factor whose action can explain the occurrence of orientation is the effect of excluded volume.

The theoretical approach to the estimation of ε magnitude developed by Merrill *et al.*¹⁶¹ consists in a modification of the DE-model and bears a semi-empirical character. This approach proposes the use of the notion of ‘nematic interaction’ of the end unit of a test chain with the matrix, though its physical meaning is not explained.

Upon introduction of groups capable of strong intermolecular interaction, *e.g.*, formation of hydrogen bonds, into polymeric chains, the coefficient ε increases substantially and becomes temperature-dependent.¹⁴⁹ This points to an important role

played in this phenomenon by the intermolecular interaction of energetic origin. However, an attempt at theoretical consideration of this factor¹⁶² did not go beyond the frame of empirical increment to the diffusion coefficient which takes into account the lifetime of the arising hydrogen bond.

It should be noted that the temperature dependence of the equilibrium constant of the reaction of hydrogen bond formation in macromolecular systems (polybutadienes with the MM ranging from 26 000 to 48 500) is markedly weaker than that in low-molecular systems (squalene):¹⁶³ as the temperature is increased from 20 to 100 °C, the equilibrium constant is changed 4-fold in the polymer and more than 10-fold in squalene. In contrast with the low-molecular model, the entropy of hydrogen bond formation decreases with temperature (provided the enthalpy remains constant, 28.6 kJ mol⁻¹). It may be presumed that weak intermolecular bonds (of the van der Waals type) will exhibit a still weaker temperature dependence. The effect of groups capable of forming hydrogen bonds that have been specially introduced in the polymeric chains on the relaxation properties of polymers is significant:^{163–169} the region of high-elasticity plateau is widened by several orders of magnitude with regard to frequency, the maximum of the $G''(\omega)$ is shifted to the low-frequency region also by a few orders; in addition, a shoulder appears on the low-frequency branch.^{163, 164, 167} Such changes occur upon addition of as little as 1%–4% of phenylurazole groups modifying polybutadiene. The observed effect of hydrogen bonds proves to be significantly stronger than the repetitive deceleration of the relaxation of polymeric chains.¹⁶⁵

VIII. The network of physical bonds as a dynamic factor

The effect of fluctuating physical entanglements on the dynamics of a macromolecule was studied by the Monte Carlo method¹⁷⁰ using a classical chain model on the Verdier–Stockmayer cubic lattice with two types of kinetic units.^{116, 117} The chain length was varied from 5 to 1000 monomeric units within the observation time intervals which made it possible to follow the motion of the chain as of an integral system. The behaviour of the chain was typical of the R-model, *i.e.*, the displacement of a random monomeric unit $g_m(t)$ obeyed the law expressed by relations (1).

If the chain was fixed on the lattice by a virtual network of physical bonds, the number of bonds and their lifetimes being set randomly, the dynamic behaviour of the chain had the features characteristic of the reptation diffusion, *i.e.*, at certain lifetimes and concentrations of nodes, at the distance equal to the medium-length chain scale a regime appeared determined by the relation (Fig. 14)

$$g_m(t) \propto t^\alpha,$$

where α was 0.25 (the value characteristic of the reptation regime) or even smaller. The motion of the chain mass-centre is characterised by the same dependence [see also relation (2)].

Consequently, the long-living fluctuating physical nodes can provide a polymer system with dynamic properties the manifestation of which is usually related to the availability of a network of topological nodes.

However, it is unclear whether the appearance of such type of fluctuating long-lived nodes in polymeric systems is possible above the glass transition temperature.

IX. On the nature of a physical network nodes

It is known that polymeric systems are characterised by rather strong intermolecular interactions of energetic origin above the glass transition temperature.¹ This is manifested, for instance, as the II-transition in their melts.¹⁷¹ This transition temperature is related to the glass transition temperature by the simple expression

$$T_{II} \approx (1.2 \pm 0.05)T_g.$$

In other words, supramolecular structural units are preserved up to the temperatures 20–60 °C higher than the glass transition temperature: in the opinion of Bershtein and Egorov,¹⁷¹ the liquid–liquid transition temperature T_{II} represents the upper temperature limit of the cooperative segmental motion.

Bartenev and Barteneva¹⁷² developed concepts of the λ -transition, *viz.*, the relaxation process characteristic of the highly elastic and liquid state of polymers. They argue that the λ -relaxation is determined by the existence, at temperatures above the glass transition temperature, of microvolume physical entanglements which have linear sizes ranging from 10 to 100 nm and

Figure 14. Dependence of displacements of a random monomeric unit and of the chain mass-centre (dashed lines) on time¹⁷⁰ for chains with the unit number $N = 100$ for different quantities of fixed monomeric units (p_f) with a lifetime (τ_f) of 6×10^3 (a) and 5% of fixed monomeric units (b) with different lifetimes; (a): $p_f = 0\%$ (I), 5% (2), 10% (3), 20% (4), 30% (5) and 60% (6); (b): $\tau_f = 0$ (I), 3×10^3 (2), 6×10^3 (3), 3×10^4 (4), 10^5 (5). For comparison, the Roman numerals I–III designate the lines with the slopes corresponding to t , $t^{1/2}$, $t^{1/4}$.

represent long-lived ($\sim 10^4 - 10^5$ s) fluctuations of the local orientation of segments.

Numerous data point to the formation of structural (including microphase) long-lived fluctuations. Thus the application of the techniques of static and dynamic light scattering has shown that¹⁷³ that large-scale density fluctuations occur in poly-(methyl-*p*-toluylsiloxane ($T_g = -17^\circ\text{C}$) up to 90°C . Poly-(methyl methacrylate) was found to preserve its ‘memory’ about the glass structure ($T_g = 65^\circ\text{C}$)¹⁷⁴ up to 132°C (^{13}C NMR). The use of EPR and NMR revealed¹⁷⁵ structural heterogeneities in a number of linear and network polyurethanes at temperatures $30 - 70^\circ\text{C}$ higher than the glass transition temperatures. The characteristic sizes of heterogeneities are ~ 10 nm, while their lifetimes are longer than 100 ms. The use of double-quantum NMR spectroscopy¹⁷⁶ revealed an anomalously high degree of orientation of monomeric units in the PB melt. It should be emphasised that the stability of heterogeneities (associates) is strongly dependent on the MM of polymers.^{176,177} Naturally, the trend towards the increase in the concentration of long-lived associates in polymeric systems is enhanced as the temperature is decreased and the solvent concentration is increased.¹⁷⁸

Simulation of properties of polymer solutions by the Monte Carlo method has shown¹⁷⁹ that there is a trend towards formation of dynamically fluctuating local domain structures with a parallel arrangement of segments if a polymeric chain is locally rigid. Mutual attraction of monomeric units enhances this effect.

Analogous results were obtained in a study of polymeric liquids of the *n*-alkane type by the method of molecular-dynamic simulation.¹⁸⁰ In this case, use was made of the Lennard–Jones potential with the energy of attractive interaction of non-bound monomeric units equal to 500 J mol^{-1} . The extent of ordering decreases with the increase in temperature, although its total collapse is observed at a temperature approximately twice as high as T_g .

Experimental studies^{181,182} indicate that associates of reactive oligomers substantially influence the kinetics of their polymerisation and the rate of relaxation processes in oligomer–polymer systems.¹⁸¹

We considered several clear examples of the existence of long-lived structures in polymeric melts, and numerous other examples can be found in recent reviews.^{1,182,183}

The role of intermolecular bonds in the manifestation of relaxation properties of polymers is great. It has been shown^{163,165} that even a small number of hydrogen bonds formed in a polymeric chain lead to an appreciable extension of the high-elasticity plateau. The presence of functional groups capable of association substantially influences the rheological properties of polymer systems.^{184,185}

A characteristic property of polymers is their ability to fix multicentre entanglements.^{186,187} Relevant computations¹⁸⁷ indicate that the lifetime of a complex formed by several bonds, with the energy of each bond reaching a value of the order of kT , increases exponentially as a function of the number of bonds, the exponent growing substantially as the energy increases (Fig. 15). In this case, the lifetime of the complex exceeds by many orders of magnitude the lifetime of a single bond. For example, the lifetime of a complex formed by three bonds ($10RT$) at 27°C is 1 s, whereas the lifetime of each bond is $\sim 10^{-9}$ s.¹⁸⁹ Such is the effect of connectivity! Even in the absence of energetically strong physical bonds, the monomeric units localised within the same volume element can remain in contact for a long time (which is at least twice as long as the time of release from the ‘tube’).^{32,190} In this situation, the number of such ‘contacting’ units is fairly large: it can amount to a half of the total number of units.¹⁹⁰ These results were obtained by the methods of molecular dynamics applied to systems in which only the impermeability of chains and the effect of excluded volume were taken into consideration. Ben-Naim *et al.*¹⁹⁰ believe that such long-lived contacts are formed due to the presence of entanglements, *viz.*, topological

Figure 15. Dependence of the lifetime of associates t_a on the chain length N at different values of the bond energy;¹⁸⁸ E/kT : (1) 0; (2) 0.5; (3) 1.0; (4) 1.5; (5) 2.0.

nodes. However, in our opinion, in this case the nature of the nodes is not significant: the presence of some long-lived nodes leads to the appearance of others in long chains, and it is their ensemble that determines the dynamics of chains in concentrated systems.

X. Theoretical approaches other than the reptation model

Most theoretical approaches proposed for the description of dynamic properties of polymeric systems take into consideration the existence of a network of topological nodes.^{10,13,17–20,117} For this reason, there is no need to discuss them here. Instead, let us dwell briefly upon some new ideas.

1. The coupling theory

A series of reports (see the bibliography in Ref. 137) discuss various aspects of the coupling theory, the fundamentals of which were formulated by Ngai and Plazek.¹⁹¹ A modification of the R-model is used for describing the dynamics of low-molecular polymeric systems with the MM of a test chain exceeding certain critical MM which corresponds to the chain length between entanglements. The relaxation times τ_p of all modes increase proportionally to the magnitude $(t/t_c)^{n_p}$, where n_p is the coupling parameter, t_c is the time of transition of the test chain from the R-motion to a decelerated motion due to its interaction with the surrounding macromolecules. As a result, a simple exponent describing relaxation at short time intervals ($t < t_c$) is transformed into the ‘stretched’ exponent

$$\phi(t) = \exp \left[- \left(\frac{t}{\tau^*} \right)^{1-n} \right],$$

where τ^* is the effective relaxation time

$$\tau^* = \left(\frac{\tau_0}{t_c^n} \right)^{1/(1-n)}.$$

The latter relation takes into account the cooperative motion of the ‘test’ chain and the surrounding chains with a relaxation time characterising the motion of the non-interacting chain (τ_0).

The coupling parameter n varies from 0 to 1; it is dependent on the character of intermolecular interaction, and in many cases $n = 0.4$.

The proposed approach made it possible to describe to a good approximation a broad spectrum of dynamic experiments (see, *e.g.*, Ref. 137).

To our mind, the coupling theory is of a semi-empirical character, though its authors argue that this theory is based on fundamental ideas of classical mechanics with a chaotic structure determined by the non-harmonic (non-linear) nature of the interaction between molecules.¹³⁷ The authors do not provide any clear-cut physical justification of the relations used and confine themselves solely to claiming that any cooperative process

(be it segmental motion or motion of a polymeric chain) is described by the 'stretched' exponent.

2. The model of lateral diffusion

Some studies^{192–196} consider diffusion of contacts of a given chain with surrounding chains instead of the diffusive motion of the chain along the 'tube'. Since the diffusion occurs over the chain contour, the friction coefficient determined by the presence of contacts is time-dependent. Taking into account this fact and also the lifetimes of contacts measured by Herman^{192, 193} the following expression for the relaxation modulus was proposed:

$$G(t) = G_N \left[\sum_{j=1,3,\dots} \frac{8}{\pi^2 j^2} \exp\left(-\frac{j^2 A t^{2/3}}{N^2}\right) \right]^2,$$

where A and N are constants.

This model describes well the dependence of self-diffusion coefficient on MM in melts of PE, PEO and PDMS.¹⁹⁵ A characteristic feature of the model is the isotropic character of the motion of macromolecules in space, despite the fact that the coefficients of lateral and longitudinal (along the chain) diffusion differ, though not as substantially as predicted by the reptation model, which prohibits the lateral displacement of the chain.

The physical meaning of the approach proposed consists in that the friction elements (beads) of the R-model interact with the medium in a more complex manner; in such interactions, the friction coefficient depends on time and the composition of the system (concentration and MM of the matrix).

3. The monomolecular model

A generalised linear form of the equation of macromolecule dynamics in the monomolecular approximation has been proposed (see the bibliography in Refs 197, 198)

$$m \frac{d^2 r_i^a}{dt^2} = \int_0^\infty \beta(s) (\dot{r}_i^a - v_{ij} r_j^a)_{t-s} ds - \int_0^\infty \varphi(s) (\dot{r}_i^a - \omega_{ij} r_j^a)_{t-s} ds - 2\mu T A_{\alpha\gamma} r_i^\gamma + \phi_i^a(t), \quad (15)$$

where m is the mass of a Brownian particle which is associated with a segment of the macromolecule; r_{ij}^a is the coordinate of the point in which the particle having the number i, j and belonging to the macromolecule 'a' is located; $\beta(s)$ and $\varphi(s)$ are the memory functions; v_{ij} and ω_{ij} are the symmetrised and antisymmetrised components of the velocity gradient; μ and A are the coefficient and the matrix characterising the equilibrium form of the macromolecular coil; $t-s$ is the time interval; T is temperature and ϕ is the random force.

This approach allowed consideration of various hypotheses relative to the form of the memory functions $\beta(s)$ and $\varphi(s)$ and comparison of computational and experimental results. In particular, in a simple case of the single relaxation time τ :

$$\beta(s) = 2\xi\delta(s) + \frac{\xi}{\tau} B e^{-s/\tau},$$

where ξ is the liquid viscosity and $\delta(s)$ is the delta-function. In this expression, the relaxation time of the environment proves to be the characteristic relaxation time of the macromolecular coil. The increase in the parameter B , which is the measure in the increase of the particle friction coefficient due to the fact that during slow motions the probe chain pulls the tail from the surrounding macromolecules, obeys the exponential law:¹⁹⁷

$$B \propto M^b,$$

where $b > 2$.

The first term in the right hand part of Eqn (15) reflects the strength of the interchain interaction, while the second term expresses the strength of the internal resistance associated with changes in the macromolecular coil shape and determined by the

presence of surrounding molecules bound to the chain under consideration.

Equation (15) describes essentially the motion of an isolated macromolecule in a continuous medium possessing viscoelastic properties. Thus, the approach proposed takes into consideration the effect of the environment, *i.e.*, the theory does not go beyond the semi-empirical framework.

4. The mode-coupling theory

Over the last decade, following the publication of Schweizer's paper,¹⁹⁹ many studies have been reported which develop the model of local interaction of monomeric units of polymeric chains.

The theory of polymer mode-coupling makes an attempt to describe the chain motion at the microlevel under the action of fluctuating intermolecular forces.²⁰⁰

Microscopic description of the dynamics of a single polymeric chain in a condensed medium is performed using a non-Markovian generalisation of the Langevin equation with consideration of the fluctuating force of the intermolecular interaction. The central point of this theory is the conclusion about the memory function, which takes into account the local four-particle (two particles belonging to the probe chain and two others, to the neighbouring chains) contact; in this case, the effect of excluded volume, *i.e.*, the repulsion energy, is regarded as essential. The cell (contact) in which the above-mentioned interaction occurs behaves as an entanglement. These long-lived contacts are presumed to be distributed along the probe chain and their concentration to be proportional to the square root of the chain length (see the theory of local diffusion). It is also assumed that the existence of these contacts ensures high cooperativity of the motion of all segments of the probe chain, contrary to what is predicted by the simple R-model.

Thus, according to the mode-coupling theory, the relaxation of a polymeric system results from the highly cooperative but isotropic motion of the probe chain and the surrounding chains. It is still unclear whether this picture is realistic or the provided averagings overestimate the 'cellular' effect.²⁰¹

Schweizer *et al.*^{202, 203} have thoroughly reviewed and generalised the theoretical studies and the results of their comparison with the experimental data. It was shown that the conclusions drawn from the theory of polymer mode-coupling and the reptation theory are qualitatively analogous. The mode-coupling theory makes it possible to reveal the sensitivity of diffusion constants to various factors, such as fluctuation of concentrations, degree of polymerisation, composition of a mixture, temperature, concentration of a solution and proximity to the interface.²⁰¹

A disadvantage of this theory consists in a definite arbitrariness of the choice of the memory function mode (*cf.* the monomolecular model). Furthermore, a detailed analysis has shown²⁰⁴ that the renormalised procedure does not result in the convergence of results and, consequently, is physically incorrect.

5. The physical network model: relaxation of stress

A new approach has been proposed recently for considering the extent and character of the intermolecular interaction in polymeric systems within the frame of the physical network model.¹³⁰

Sufficiently long chains of networks with both covalent nodes and entanglements, as well as suspended 'tails' were found to exhibit some features of the R-relaxation (see, *e.g.*, Refs 205–207). It is therefore natural to represent a macromolecule as if it contained k R-subchains of length m connected by physical nodes. In this case, relaxation may be described in the frame of the R-model taking into account that the relaxation of the rigidity of the 'springs' connecting the nodes follows the R-mechanism, whereas the nodes themselves are characterised by a friction coefficient, which is determined by the interchain interaction and hence depends on the concentration and MM of a polymer.

The initial system of differential equations which describes the relaxation of the R-chain is expressed as⁷¹

$$\eta \frac{dy_i}{dt} = G(2y_i - y_{i+1} - y_{i-1}), \quad (16)$$

where y_i is the coordinate of the i th bead and G is the elasticity modulus of the spring connecting the friction nodes.

Solution of this system provides an expression for the temporal dependence of the elasticity modulus relaxation [see Eqn (9)].

The physical network model assumes that G is time-dependent. Introduction of the time function φ into Eqn (16):

$$\varphi(t) = \int_0^t G(\xi) d\xi,$$

and its solution yield the equation analogous to that for the R-model, though the expression of time in it is more complex:

$$G(t) = \frac{1}{k} \sum_{p=1}^k \exp\left(-p^2 \varphi \frac{t}{\tau}\right),$$

where

$$\varphi(t) = gt + \frac{\psi}{m} \sum_{q=1}^m q^{-2} \left[1 - \exp\left(-q^2 \frac{t}{\psi}\right)\right], \quad (17)$$

g is the elasticity modulus of the R-springs, $\psi = \psi_0 m^2$ is the maximum time of R-subchain relaxation and ψ_0 is the minimum relaxation time.

Evidently, the total chain length is

$$n = mk,$$

where k is proportional to the chain length. According to the R-model, the relaxation time τ is proportional to the squared chain length and to the friction coefficient. But the latter parameter *per se* should depend on n . This dependence is rather complex and its determination is a separate problem, though it may be presumed that the second power is a fairly reasonable magnitude. Thus, in conformity with the experimental results, we derive the general dependence $\tau \propto n^4$.

The relaxation curves calculated from Eqn (17) are qualitatively similar to the experimental curves.¹³⁰ Thus changes in the relaxation of elasticity modulus in the region of high-elasticity plateau are rather significant, and the dependence $G(t) \propto t^{-a}$, where $a \simeq 0.25$, is observed to hold over a certain interval. The segment of the exponential dependence with the exponent $1/2$ is absent if the number of nodes k is not too large. At longer times, the exponential decay is determined by the relaxation time which is proportional to the chain length raised to the fourth power (more precisely, to k^4); extrapolation of the curve to the ordinate axis gives a segment whose magnitude is dependent on the total length of the chain and the number of physical nodes:

$$\ln G(0) = -\ln k - \frac{\psi_0 n}{\tau_0 k^5} b - \frac{g}{\tau_0 k^4} t,$$

where $b = \sum_{p=1}^m p^{-2} \approx 1.6$ for sufficiently large m ; at $m \rightarrow \infty$,

$$b = \pi^2/6 = 1.645.$$

A detailed analysis of experimental results (including studies of diffusion of macromolecules, rheology of solutions and melts, frequency dependence of relaxation modulus, *etc.*) with consideration of physical bonds is a matter for the future, but even now one can discern good prospects for this approach for studying the dynamics of polymeric systems. For example, Walkenhorst²⁰⁸ showed that the process of physical network rearrangement is responsible for the long-term relaxation.

The concept of the network of physical nodes was used by Soloviev *et al.*^{209–211} for the description of the relaxation properties of elastomers. In these studies, analysis of the deformation curves differentiated two types of processes differing in their relaxation times: fast diffusive displacements of ‘free’ segments

which are not involved in the formation of intermolecular nodes of the physical network and a slow diffusive process of rearrangement of the network itself. Using basic postulates of non-equilibrium thermodynamics and considering the destruction of physical nodes as a reversible chemical reaction, these authors derived a system of equations which describe viscoelastic properties of elastomers over a wide range of deformation rates. Investigation of the stretching of copolymers of acrylamide with nonyl acrylate at the rates ranging from 1 to 0.01 s^{−1} and in the temperature range 20–120 °C has demonstrated that experimental data correlate with theoretical predictions. The approach of Soloviev *et al.* represents, in its essence, the development of Bartenev’s idea¹⁷² about the occurrence of a fast (α -process) a slow (λ -process) stages of the relaxation of elastomers.

Wientjes *et al.*²¹² made an attempt to employ the physical network model for describing rheological properties of polymers.

XI. Conclusion

This review has analysed the available experimental data on the dynamics of polymers with consideration of the network of physical bonds. It has been found that these data are at variance with the reptation model and that this model is insufficient for understanding the relaxation behaviour of polymers. The authors of this theory agree that the classical variant of the reptation theory yields results which are inconsistent in many respects with the experimental data.¹³ The attempts to refine the reptation model through consideration of the ‘tube’ relaxation and the disappearance of restricting entanglements^{13, 18} have resulted in a certain enhancement of the dependence of maximum relaxation time and viscosity on MM. These and analogous amendments ‘facilitate’ the relaxation process and decrease the relaxation times compared to those given by the simple non-modified theory. At the same time, the review demonstrates that the theoretical relaxation times are underestimated compared to those obtained experimentally, whereas the reptative behaviour is characteristic of the chains with the MM substantially larger than M_e .

The existence of a network of physical bonds confirmed experimentally is indisputable. However, its role in determining a broad spectrum of dynamic phenomena has not yet been elucidated. Unfortunately, the physical network model has not been developed to the extent reached, *e.g.*, by the reptation model. The investigators have still to clarify whether the intermolecular interactions play a role in the formation of relaxation properties of polymeric systems or these interactions merely make some contribution to the network of entanglements.^{213, 214}

The existence of the network of physical bonds is taken into account explicitly or implicitly in the consideration of dynamic properties of polymers. It underlies many approaches: for instance, some aspects of the problem of physical nodes and their effect on relaxation processes in polymers were discussed by Bartenev and Barteneva.¹⁷² As a matter of fact, the theory of polymer mode coupling also uses the physical network model (the network nodes are assumed to be areas with high local packing). The results reported by Sotta¹⁶⁰ point to an important role played by the network: orientation of a ‘free’ segment is brought about under the action of the oriented matrix without introduction of some energetic factors due only to the excluded volume effect.

Apparently, the fact that the temperature position of the beginning of the high-elasticity plateau (T_g) corresponds not to MM but rather to M_e , which is much smaller in order of magnitude than the corresponding size of the kinetic segment,²¹⁵ should be interpreted from the same viewpoint. This may imply that an important, if not decisive, significance in the physical network formation belongs to the high-density fluctuations, which seem to play the role of nuclei of the glassy state²¹⁶ or of the regions of local order in terms of the cluster model of the structure of amorphous polymers.²¹⁷

Only the existence of long-lived nodes of the network, and not their nature, is important for the manifestation of ‘reptative’

properties; therefore, the physical network model may be used for describing dynamic properties of a large number of systems ranging from physical gels to polymers with intermolecular interactions of the dispersive type.

It should be mentioned in conclusion that about three decades ago a vivid discussion was underway on whether or not such a structural formation as topological entanglements exists in polymeric systems. The discussion was initiated by the appearance of the 'packet' model of the structure of polymers²¹⁸ which was the antithesis of the 'felt' structure of Flory.⁷⁷ This discussion resulted in the triumph of the idea of entanglements not only in the structural respect; it also laid the foundation for the subsequent models of the dynamics of macromolecules. Now, the time has come for a new discussion on whether the entanglements do play the role ascribed to them in the dynamics of polymers or this role is at least overestimated.

Preparation of this review was supported by the Russian Foundation for Basic Research (Project No. 98-03-33358a).

Abstract. Data on the effect of adsorption and intercalation of foreign molecules on the properties of high-temperature superconducting materials and on the reciprocal effect of superconductivity on the electronic state of adsorbed molecules are considered. Particular attention is given to the analysis of experimental conditions and interpretation of the results obtained. An effect of adsorbed molecules on the electrophysical state and the critical parameters of superconductors is noted. Specific features of the interaction between the phases in the superconducting state and the external molecules are discussed. The bibliography includes 280 references.

I. Introduction

The discovery of oxide materials which become superconductors at the liquid nitrogen temperature^{1,2} has resulted in a rapid development of studies of their physicochemical properties. These studies showed that the high-temperature superconductivity (HTSC) is extremely sensitive to the effect of the environment.

An opinion exists that superconductors are thermodynamically unstable systems.³ On the other hand, it was shown in one of the first reviews on the thermodynamic properties and stability of yttrium-containing superconducting ceramics⁴ that, although the $\text{YBa}_2\text{Cu}_3\text{O}_7$ phase is somewhat unstable thermodynamically, it can exist almost infinitely in this state. As a result of interaction of oxide ceramics with foreign molecules, superconductivity can both disappear and appear. Both of these phenomena have been observed experimentally in a study of the effect of the external molecules on the properties of HTSC oxides. Systematic analysis of the effect of foreign molecules on HTSC materials can help to reveal new ways for reaching high superconducting transition temperatures.

From the applied viewpoint, an important task is to obtain HTSC materials with high critical superconductivity parameters,

viz., temperature (T_c), current (I_c) and current density (J_c). Research on both classical low-temperature superconductors and HTSC materials has shown that high critical currents can be obtained if the superconductor structure incorporates an optimum number of defects acting as pinning centres for the Abrikosov vortices. Systematic studies of processes for the controlled formation of defects in superconducting materials has led to the conclusion that the intercalation of various chemical admixtures produces additional pinning centres, and hence increases the critical current density.

Recently, great interest arose in new electronic sensors which contain layers of organic molecules or polymeric films deposited on the surfaces of semiconductors or metals.^{5–7} Such elements have a significant advantage over the usual inorganic solid-state sensors, *i.e.*, enhanced sensitivity and selectivity with respect to environment.^{8–10} A novel class of oxide materials, *viz.*, high-temperature superconductors that possess a combination of unique physical properties at relatively high temperatures, has also become the subject of intense studies aimed at their application in similar electronic elements. For instance, it was found that molecular dye layers deposited on a Josephson junction made of superconductors increase considerably the sensitivities and selectivities of light sensors with respect to visible light.^{11–13} This was the first documented example of the effect of the properties of an HTSC material on the electron state of adsorbed organic molecules.

In this review, we have analysed the reported data on the effect of adsorption and intercalation of molecules on the physicochemical properties of ceramic and film HTSC materials and on the effect of the superconducting state on the low-temperature adsorption, catalysis and the electronic state of the molecules adsorbed on the HTSC material surfaces. Intensive studies are now being carried out along these lines, hence our review cannot claim to be comprehensive. In some cases, the interpretation of certain experimental results can be debatable. Nevertheless, the possibility of the reciprocal influence of the superconducting state and the molecular processes on the surface of HTSC materials is an established fact, which however requires detailed studies.

II. Some specific features of the physicochemical properties of high-temperature superconductors

All high-temperature superconductors are copper-containing oxides of complex chemical composition. As a rule, each unit cell of an HTSC phase incorporates from four to six chemical elements.¹⁴

The data from small angle neutron scattering indicate that polycrystalline HTSC materials contain rather branched systems of pores connected to the surfaces of samples.¹⁵ Hence, molecules from the environment can readily penetrate into the specimen and react with the superconducting phase. The specific surface of such specimens measured by the Brunauer–Emmett–Teller (BET) method on the basis of the low-temperature nitrogen adsorption is from 0.2 to 1.5 m² g⁻¹, which is rather high for compact ceramic materials. The thermodynamic instabilities of HTSC materials can manifest themselves in their smaller stabilities in comparison with those of simpler low-temperature superconductors, *viz.*, metals and alloys.

Obviously, the effect of foreign molecules on HTSC materials can be rather complex. In addition, the study of these effects and particularly their interpretation can be complicated considerably because the surface chemical composition of an HTSC material differs significantly from its bulk composition.

In order to classify possible mechanisms of the interaction between the HTSC materials and the external molecules, it is worthwhile to consider some characteristic features of the structure of these materials and the mechanism of the initiation of the superconducting state.

1. Specific features of the structure of high-temperature superconducting oxides

Such multi-component oxide systems as La–Ba(Sr)–Cu–O, Y–Ba–Cu–O, Bi–Sr–Ca–Cu–O with perovskite-like or defective perovskite-like structures (Fig. 1) represent typical HTSC materials.^{16,17}

Virtually all HTSC materials are characterised by the existence of copper–oxygen layers and chains. The first and most important factor enabling superconductivity to appear is the existence of at least two types of copper coordination in the structural cell of the material; this results from the ability of the lattice copper ions to exist in several oxidation states, namely Cu(I), Cu(II) and Cu(III). Overlapping of the 3*d* orbitals of copper with the 2*p* orbital of oxygen results in the formation of a valence band and strong delocalisation of the holes.¹⁸ In the structure of CuO₂ (the copper–oxygen layers), the holes migrate along the oxygen anions, which makes the 3*d*⁹L-type electron configuration much more probable than 3*d*¹⁰L (where L is the oxygen vacancy).¹⁹ This specific behaviour of copper ions (in particular, the possibility of existence in several different coordinations) is

closely related to a manifestation of the Jahn–Teller effect by these ions.

The second factor responsible for the superconductivity of oxide systems is the low spatial dimensionality of the electronic structure, which is nearly two-dimensional. The low effective dimensionality of the electronic structure of HTSC materials results from the presence of the copper–oxygen layers (see Fig. 1). It is in these layers that the electrons providing the superconductivity are localised. The low structural dimensionality of an HTSC material is directly proved by strong anisotropy of superconductivity: the critical current along the crystallographic axes *a* and *b* is by an order of magnitude higher than that along the *c* axis.^{20,21}

The low dimensionality of the electronic structure is not the only factor which enables the possibility of existence of the superconducting state. For example, it has been shown²² that the superconductivity of La₂CuO₄ is much more strongly affected by violation of the stoichiometry of this oxide with respect to oxygen than by structural changes. The non-stoichiometry effect becomes more pronounced as the La : Cu atomic ratio decreases. The excess of copper favours the formation of additional oxygen vacancies; this facilitates the incorporation of oxygen during synthesis, resulting in partial oxidation of Cu²⁺ into Cu³⁺. Unlike La_{2–x}Cu^{II}O₄, the La_{2–x}Cu^{II/III}O₄ compound is a superconductor.

In YBa₂Cu₃O_{7–x}, violation of stoichiometry occurs due to the filling of the oxygen rows at the O(4) position (see Fig. 1*b*).^{23–25} The superconducting orthorhombic structure of YBa₂Cu₃O_{7–x} exists at the oxygen index *x* ≤ 0.6. For *x* > 0.6, the unit cell of this oxide is characterised by a non-superconducting tetragonal structure. Figure 2 shows the dependence of the superconducting transition temperature on the oxygen index *x*.²⁴ One can see that the quantity of the excess (or mobile) oxygen affects substantially the ceramics superconductivity.

The role of oxygen in HTSC materials has been discussed in several publications (see, *e.g.*, Refs 23, 24, 26–28). In the orthorhombic phase of YBa₂Cu₃O_{7–x}, oxygen can occupy different crystallographic positions:²⁷ the O(2) and O(3) positions in the [CuO₂] plane and two positions, O(1) and O(4), in the Cu–O chains (see Fig. 1*b*). The oxygen states O^{2–}, O[–] and O₂^{2–}, which exist in dynamic equilibrium and affect the superconducting and chemical properties of the majority of HTSC materials, have been predicted theoretically and found experimentally.²⁸ The high oxygen mobility in the material bulk is provided by the oxygen

forms which have the smallest charge or even no charge at all, whereas electron migration is provided by the O^{2-} ions.

2. Structures of polycrystalline specimens

Ceramic polycrystalline HTSC materials are of the greatest interest. This is due to their accessibility and relative simplicity of their preparation, which enables the synthesis of single-phase specimens with high superconducting transition temperatures. The main obstacles to the wide practical application of polycrystalline superconductors include the low critical currents and their rapid decrease as the field increases. In addition, ceramic HTSC materials have low corrosion resistance.

A polycrystalline HTSC material (ceramic) is a system of anisotropic superconducting granules with sizes ranging from 1 to 100 μm ; they are linked in a three-dimensional network of weak Josephson junctions.^{27,28} In a general case, a sandwich-like structure of the SNISN type appears on the boundaries between the granules (where S is a superconductor; N is a layer with normal metallic conductivity or a superconductor layer with a lower critical temperature; I is a dielectric or semiconductor layer). The thickness of the boundary layer allowing superconductivity current to flow between the granules should not exceed the coherence length along the crystallographic axis c [$\xi_c(0 \text{ K}) = 0.2 \text{ nm}$] and in the ab plane [$\xi_{ab}(0 \text{ K}) = 1.64 \text{ nm}$].²⁹

Weak bonds between the granules of ceramic HTSC materials differ in nature. In this review, we shall consider only those typical features of the structure and properties of inter-granule layers that can be affected by molecules foreign to the given material, namely: (1) non-stoichiometry of granules with respect to oxygen in the near-boundary layers; (2) high probability of admixture segregation at the inter-granule boundaries; (3) possibility of defective packing; (4) presence of 'foreign' or amorphous phases at the inter-granule boundaries.

The oxygen non-stoichiometry is due to surface rearrangement because of a decrease in the surface energy at the granule boundaries. The boundary layers with a high fraction of the lattice sites belonging to both contacting microcrystals are also energetically favourable.

Studies of admixture-free boundary granule layers of single-phase ceramic with composition $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (Refs 30–33) showed that enrichment of granules with copper and their depletion of oxygen occurs in a boundary layer no thicker than 5 nm. The phase formed at the granule boundaries has a orthorhombic structure.

Within the percolation theory based on the random distribution of oxygen defects, the critical oxygen deficiency (the oxygen index x) was determined; above this value, the oxygen-enriched structures (superconducting granules) are separated with insulating layers and the inter-granule superconductivity transport current is absent.³⁴ The value of x for the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ HTSC ceramic found by the Monte Carlo method for a square lattice (two-dimensional superconductivity) was 0.26.³⁴

Segregation of admixture atoms and phases at granule boundaries seems to be the simplest and most natural reason for the formation of inter-granular layers possessing metallic conductiv-

ity and/or dielectric properties. In most cases, carbon and/or carbon-containing compounds constitute one of the main admixtures on the granule surfaces. Carbon can originate not only from the starting compounds used for the material synthesis, *e.g.*, barium carbonate, but also from atmospheric carbon dioxide.^{35–37} If excess BaCO_3 is present in the starting mixture for the ceramics synthesis, carbon is segregated on the granule boundaries and forms a coating 1–4 monolayers thick.³⁸ It is of note that carbon is not present on intergranule fractures.

In addition to carbon and its compounds, non-superconducting phases formed from the starting compounds due to incomplete synthesis were found on granule boundaries.^{39,40} For example, local melting at granule boundaries in copper–barium–yttrium HTSC materials at synthesis temperatures above 930 °C results in the formation of regions enriched with barium (the BaCuO_2 phase), yttrium (the BaY_2CuO_5 phase) or copper (the liquid phase).⁴¹

The formation of defective packing in the crystal structure at inter-granule boundaries and the formation of a twinning structure in the ceramic microcrystals are accompanied by relaxation of elastic stresses that appear upon structural phase transitions in the temperature range from 873 to 973 K. For example, the absolute majority of the granule boundaries of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramics contain inter-layers consisting of blocks of atomic planes CuO_2 – BaO – (CuO_2) – BaO_x *ca.* 1.5 nm thick; this is explained by the breaking of the layered structure in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$. This process is similar to the formation of the $\text{YBa}_2\text{Cu}_4\text{O}_{7-x}$ phase with a critical temperature of 80 K.^{42–44} Since the coherence length along the axis c is 0.7 nm, the presence of such inter-layers on the boundaries of the majority of granules should have a strong adverse effect on the ability of the ceramics to conduct electric current.

The presence of the twinning structure inside the microcrystalline granules favours the formation of domains shaped as long (up to 1 nm) narrow 'bands' parallel to the (110) or ($\bar{1}\bar{1}0$) axes. The width of these domains varies from 5 to 300 nm and depends on the technique for the ceramic's synthesis and on the granule size.⁴⁵ These structures also deteriorate the current-carrying ability of HTSC materials.

3. Properties and structures of real high-temperature superconducting oxide surfaces

The interaction of the external molecules with an HTSC material starts at its surface. It has been noted above that, generally, the chemical composition, state, and structure at the surface and in the bulk of a superconductor differ considerably. However, the properties of the surface layer of an HTSC material affect directly the electronic properties and superconductivity parameters of the bulk phase.⁴⁶

The surfaces of the specimens are highly non-uniform. They contain macroscopic defects, such as growth steps, cracks, pores, dislocation exits, *etc.* Due to the interaction of coordination- and/or valence-unsaturated surface atoms with the external molecules, various chemical components are invariably present at the surface.

The adsorption of molecules and atoms often changes the properties of the surface itself, particularly the electron state of the surface atoms. The study of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic by photoemission spectroscopy revealed a difference in the state of the 'pure' and 'contaminated' surfaces.⁴⁷ Typical contaminations appear due to the chemisorption of the H_2O , CO, and CO_2 molecules. The content of surface carbonates on 'contaminated' specimens is 10 at.%–15 at.%, while that on a 'pure' specimen is 1 at.%. The surface also contains barium hydroxide, copper oxides, various yttrium compounds and the so-called 'green' phase, *i.e.*, Y_2BaCuO_5 . The surface copper exists in the Cu^+ and Cu^{2+} states;⁴⁸ the near-surface layer does not possess superconductivity.⁴⁹ It is therefore obvious that controlled surface cleaning is an important problem in studies on the effect of the surface states on the material superconductivity.

It is well known that chemical etching of polycrystalline films of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with solutions of halogens and hydrogen halides in alcohols improves the stoichiometric composition of the surface and decreases considerably its contamination with carbonates and hydroxides.⁵⁰ For example, it was shown⁵¹ that the electric characteristics of the tunnel contact between the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film and metallic niobium are improved considerably after chemical etching of the film. In this case, an inter-layer of the SNS type is formed in which the surface resistance is almost 30 times smaller and the critical current is 40 times greater than those in contact *via* a non-cleaned surface. An inter-layer between the superconductors can be fabricated by chemical etching. Probably, this type of treatment of superconducting ceramics not only decreases considerably the surface contamination but also brings about certain chemical modification of the surface layer of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ system due to reactions of halogens and hydrogen halides with metal oxides on the surface. In fact, treatment of an $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film surface with a 1%–2% solution of Br_2 or HBr in ethanol results in the following surface compounds: YBr_3 , BaBr_2 and CuBr .⁵² Scanning electron microscopy did not reveal any significant changes in the surface morphology after chemical etching. It is important that surface treatment of this type increases its resistance against atmospheric gases.

Interesting results were obtained by bombardment of HTSC film surfaces with argon and oxygen ions. Bombardment with argon ions with an energy of 500 eV results in strong damage of the surface layer.^{23, 53} Oxygen atoms are preferentially removed from the surface and hence copper is reduced (while electroneutrality is maintained). This damage affects directly the oxygen vacancies and causes disordering of the near-surface layer atoms. As a result, the superconductivity characteristics of the films become much worse. However, the original properties of the films are completely restored after annealing in pure oxygen.

Quite a different picture is observed if the surface of an HTSC material is bombarded with oxygen ions.⁵⁴ In this case the surface etching rate is higher than that in the case of argon bombardment. After a brief bombardment, the dependence of the superconducting transition temperature for the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film on the etching time passes through a maximum with $\Delta T = 2$ K and then tends to the original value.

Hence, cleansing of the surface of an HTSC material by bombardment with oxygen ions is preferable to cleansing with argon ions. The mechanism of the effect of high-energy oxygen ions on the superconductivity transition temperature is not quite clear yet. However, it can be assumed that during bombardment with O^- ions, the surface layer, which is originally depleted of oxygen, is forcibly saturated with it, which favours the formation of the superconducting phase.

Although scribing (mechanical surface cleaning) of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic decreases the contamination with foreign molecules, it damages the surface considerably.⁵⁵ Studies of the surface by characteristic electron energy loss reflection spectroscopy showed that the near-surface layer contains an excess of barium and oxygen atoms, while the surface concentration of the copper–oxygen planes is insignificant. This is explained by the fact that scribing mostly results in microcrystal breaking along the inter-granule boundaries or at the Ba–O planes. In addition, preferential diffusion of the Ba–O complexes over the surface occurs.

One should pay attention to the nature and structure of the adsorption-active sites capable of adsorbing foreign molecules on the surfaces of HTSC materials. As shown in earlier studies,⁵⁶ the structures of real surfaces of oxide semiconductors and dielectrics are rather complex. The nature of the adsorption-active sites is determined by the state of oxygen in the near-surface region: deficiency or excess of oxygen give rise to electron-donating or electron-withdrawing active sites, respectively.

Studies of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic surface revealed active sites consisting of Cu^+ cations and an oxygen vacancy ($\square$, hole), which is an electron acceptor.⁵⁷ At room temperature, an active

site of the $[\text{Cu}^+, \square]$ type is stabilised by the elastic strain field of dislocations or by boundaries of twinning structures.⁵⁸ At 400 K, diffusion of the interstitial O^- ions begins to the sinks on the surface (holes or dislocation exits). Trapping of the O^- ion by the oxygen vacancy results in electrically neutral oxygen and a free electron. A fraction of the O^- ions reaching the Cu^{2+} surface ions can transfer a hole to them; this probably results in Cu^{3+} . Subsequent evolution of the active site at 580 K involves migration of neutral oxygen from the bulk; it ‘catalyses’ the decay of the $[\text{2Cu}^{3+}, \text{2O}^{2-}]$ site accompanied by the emission of the O^{2-} and Cu^{2+} ions to the surface.⁵⁹ The disappearance of the O_2^- bipolarons (local hole pairs) after the first heating *in vacuo* at 623 K makes the transition of this ceramic to the superconducting state at $T > 77.4$ K impossible.

The evolution of the state of oxygen on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface at low temperatures was studied⁵⁹ by recording the transformation of the $\text{O}(1s)$ X-ray photoemission spectrum upon temperature decrease from 300 to 110 K. At 110 K, the O^- ions in the near-surface region are dimerised to give the O_2^- dimer, but the oxidation state of the copper ions remains unchanged. Simultaneously, the surface electric conductivity increases.

III. The effects of adsorption and intercalation of simple compounds on the properties of high-temperature superconductors

Intercalation of simple molecules into HTSC ceramics is accompanied by various physicochemical transformations: replacement of nodal atoms in the crystal lattice, intrusion of foreign molecules into the interstitial space, diffusion of molecules along the ceramic granule boundaries and formation of strong chemical bonds at the surface.

Unfortunately, the available experimental data do not allow yet an unambiguous conclusion regarding the nature of the interaction between small molecules and the superconductor material to be made.

For example, it is believed that the low-temperature adsorption of molecules on oxides is generally of physical character, hence it is non-specific and its dependence on the availability of adsorption sites and the electron state of the surface is insignificant. Physical adsorption can result in only small changes in the surface charge and the vibration modes of the surface atoms. However, in reality the adsorption of certain molecules on HTSC materials at $T < 300$ K affects their superconductivity; this cannot be explained by simple physical adsorption. As a rule, the changes in the superconductivity characteristics observed in these cases are related to intercalation or inclusion phenomena of molecules into the structure. The possibility of intercalation and chemical interaction of simple gases with HTSC materials at high temperatures (> 473 K) has been established reliably and does not raise doubts (see below).

1. The effect of oxygen

Oxygen plays a particularly important role in the formation of the structure of perovskite-like complex oxide materials and in their transition to the superconducting state. In addition, the oxygen molecule is a paramagnetic species, its adsorption on a superconductor surface can affect directly the superconducting properties. The techniques for obtaining HTSC materials and the role of oxygen in the formation of superconducting phases have been well covered in the literature. The reaction pathways of oxygen with HTSC materials during the synthesis and high-temperature treatment are so diverse that, despite a great number of publications, this phenomenon still remains insufficiently studied because the problem of non-stoichiometry with respect to oxygen and the related phenomena for the $\text{RBa}_3\text{Cu}_3\text{O}_z + \text{O}_2$ systems (where R is a rare-earth element) are excessively complex.⁶⁰ We shall only discuss the main aspects of such interactions.

One of the first Russian reviews devoted to the role of oxygen in HTSC materials was published in 1989.⁶¹ In the final stage of the synthesis, the oxide $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ is saturated with oxygen. When compact ceramics are being obtained, this process is rather complicated, particularly in the synthesis of highly oxidised specimens ($x \rightarrow 0$). It was shown in a study of the oxidation kinetics of ceramic specimens of various densities at 773 K that slow oxygen absorption by compact ceramics results from transition of the reaction from the diffusion mode to the kinetic mode due to accumulation of considerable elastic strain in the material.⁶² Thermodynamic estimates showed that the elastic strain energy upon oxygen absorption by compact ceramics can affect the oxidation kinetics only in the case where the base planes contain oxygen ions of two types, namely, those strongly and weakly bound to the lattice.

The diffusion of oxygen into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was described⁶³ within a one-dimensional diffusion model. The equations obtained provide a good description of the experimental results on the oxygen exchange kinetics. The transformation of the specimens during oxygen diffusion in the temperature range of 423–973 K and at oxygen pressures of 1.4–10.7 atm involves three stages. A solid solution of oxygen in the tetragonal phase $\text{YBa}_2\text{Cu}_3\text{O}_6$ is formed in the first stage.⁶⁴ In this case, the diffusion factor is described by an Arrhenius dependence with the activation energy of 0.14 eV, while the pre-exponential factor depends on the oxygen pressure. In the second stage, oxygen starts to diffuse along unordered CuO chains in the tetragonal phase. The diffusion factor is also described by an Arrhenius dependence, but the activation energy is 0.6 eV and the pre-exponential factor no longer depends on the oxygen pressure. In the third (final) stage where the tetragonal phase is transformed to the orthorhombic one the diffusion factor becomes smaller than that in the tetragonal phase and gradually decreases to zero as the transition to the ideal orthorhombic phase of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ occurs.

Subsequent systematic studies of oxygen desorption from the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic at high temperatures showed^{65,66} that this process probably occurs according to a different mechanism. The main features of this process will be described in more detail below; for now, let us note that the adsorption of molecular oxygen on the surface of an HTSC material occurs according to the dissociation mechanism, whereas desorption occurs according to the association mechanism. The oxygen atoms occupy the vacant positions, *i.e.*, $\text{O}(1)$ or $\text{O}(5)$, in the near-surface layer of the crystal lattice. The exchange and transport of oxygen during the adsorption–desorption processes on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic probably involves oxygen vacancies according to the relay-race mechanism.

The kinetics of oxygen evolution from the $\text{YBa}_2\text{Cu}_3\text{O}_{6.92-x}$ ceramic with $x < 0.54$ was studied in the temperature range of 600–950 K using the thermo-programmed desorption method.⁶⁵ At $T < T_m$ (where T_m is the temperature corresponding to the desorption peak maximum), the desorption rate is described fairly well by a second-order kinetic equation which is formally consistent with associative desorption. Oxygen-deficient specimens with $x < 0.25$ are characterised by a noticeable increase in the activation energy accompanied by an increase in the pre-exponential factor; this implies the presence of a compensation effect.

Many authors (see, *e.g.*, Refs 26, 67–69) consider the surface potential barrier as the main obstacle to the release of oxygen from HTSC materials. It was shown convincingly that the nature of this barrier is determined by the surface energy parameters.⁶⁹ For example, the oxygen desorption rate increased, whereas the desorption activation energy decreased by 0.2 ± 0.03 eV after vapour phase deposition of several monolayers of silver on the surface of a sample of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic. Changes in the surface properties should not affect the oxygen desorption rate if oxygen diffusion in the granules is the limiting step of this process. UV photoelectron spectroscopy data suggest that the electron work function for the yttrium ceramic's surface decreases by 0.3 eV upon vapour deposition of silver. It is thought that this

decreases the surface energy barrier.⁶⁹ The results of this experiment also indicate that the barrier is in fact energy-related rather than resulting from the formation of a particular surface structure. The temperature where oxygen starts to enter the ceramic was observed to decrease upon 'mild' treatment of the ceramic with molecular hydrogen.^{70,71} This is also evidence of the importance of surface barriers. The temperature of oxygen penetration into HTSC ceramics also decreased upon thermal vacuum treatment⁷² and after plasma treatment.⁷³

Several parameters characterising the surface potential barrier for the release of oxygen atoms were determined.⁷⁴ It was found by isotope exchange between the gas phase and the surface of a $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ single crystal under the conditions of isochronous and isothermal annealing of the specimens that the activation energy for oxygen desorption is 1.08 eV. In the authors' opinion, this indicates that the sorption mechanism of the formation of the surface barrier upon isotope exchange is somewhat preferable. However, an unambiguous conclusion on the surface barrier nature could not be made within the scope of this study. The use of polycrystalline specimens instead of single crystals does not affect the main results.

Degradation of HTSC materials at room temperature in the presence of water vapour is accompanied by the loss of oxygen from the HTSC phase. The water layer adsorbed on the superconductor surface probably favours the acceleration of oxygen exchange between the HTSC material and the gaseous environment.^{75,76} It was confirmed⁷⁵ that oxygen is desorbed at room temperature from the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic covered with an adsorbed water layer. In this case, the basic orthorhombic phase O_I is coated with a modified orthorhombic O_{II} phase with $T_c = 60$ K. The proportion of the O_{II} phase increases with an increase in the degree of hydration of the material and decreases upon annealing the specimen at 913 K.

The low-temperature oxygen exchange between the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic and the gas phase is limited by the surface potential barrier. Probably, the adsorbed layer of water molecules lowers this barrier significantly. On the other hand, it was shown theoretically⁷⁷ that the diffusion of O^{n-} oxygen ions inside the crystal lattice 'channels' $[1/2, b, 0]$, which can be regarded as the oxygen sublattice, occurs without activation and does not limit the redox processes. The hypothesis on the high mobility of oxygen in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ lattice at low temperatures was confirmed.⁷⁶ It should be noted that the high mobility can also involve a different mechanism. Based on thermogravimetric and X-ray diffraction analyses and electric conductivity measurements, a scheme for $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ reduction at room temperature was suggested. According to this scheme, the oxygen diffusion is considered as an activationless process. Depending on the water vapour pressure, the stage limiting the oxygen exchange rate also changes. The oxygen exchange between $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and the gas phase at $p_{\text{H}_2\text{O}} \geq 760$ Pa is limited due to the presence of a chemisorbed water surface barrier. In the pressure range $250 < p_{\text{H}_2\text{O}} < 760$ Pa, the rate of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ reduction is limited by the step of O^{n-} anion diffusion through the layer of physically adsorbed H_2O molecules, while at $80 < p_{\text{H}_2\text{O}} < 250$ Pa, the movement of the O^{n-} anions is hindered by the twinning boundaries. At the lowest humidities ($p_{\text{H}_2\text{O}} < 80$ Pa), all the above factors no longer operate, and the reduction rate exceeds $0.15 \text{ mass } \% \text{ min}^{-1}$. However, a layer of the tetragonal phase is formed after some time on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface; this layer does not conduct oxygen ions at low temperatures.

A study⁶⁶ of the oxygen isotope exchange between ^{18}O from the gas phase and ^{16}O from the $\text{YBa}_2\text{Cu}_3\text{O}_{6.92}$ ceramic in the temperature range of 293–923 K aimed at the elucidation of the nature of labile oxygen, which plays an important role in heterogeneous oxidation. The maximum oxygen isotope substitution at 923 K was 3.8 ± 0.3 a.u. per formula unit of the cuprate. It was assumed that the chain $[\text{O}(4)]$ and bridging $[\text{O}(1)]$ oxygen atoms in the cuprate crystal lattice are replaced almost completely. Hence, it is in these positions that labile oxygen, which probably partic-

ipates in catalytic oxidation on the surface of these ceramics at $T > 800$ K, is localised.

The inequality of the oxygen atom positions in the CuO_2 and ab planes results from the orthorhombic structure of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ crystal. According to the experimental data^{78–81} and theoretical calculations,⁸² the activation energies $E_a^{\text{O}(3)}$ and $E_a^{\text{O}(2)}$ for oxygen exchange between the O(3) and O(2) positions (see Fig. 1 b) are equal to 1.02 eV and 1.18 eV, respectively. The transition from the O(3) to the O(2) position occurs with an activation energy of

$$E_a^{\text{O}(3)} = E_0 - \Delta E,$$

and the transition from the O(2) to the O(3) position occurs with an activation energy of

$$E_a^{\text{O}(2)} = E_0 + \Delta E.$$

The difference between these energies, $2\Delta E = 0.16$ eV, is explained by the unequal O(3) and O(2) oxygen positions in the orthorhombic lattice, where the oxygen–copper bond along the a axis is longer than that along the b axis. To the first approximation, the ratio of the occupancies of these positions with oxygen is described by the Boltzmann equation

$$\frac{N_0^{\text{O}(3)}}{N_0^{\text{O}(2)}} = \exp\left(-\frac{2\Delta E}{kT}\right),$$

while the oxygen index is described by the expression

$$x = N_0^{\text{O}(3)} + N_0^{\text{O}(2)} - 1.$$

The features of oxygen ordering in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ($x \approx 0.1$) were studied by transmittance electron spectroscopy and electron microdiffraction.⁸³ Near the superconducting transition point, oxygen ordering occurs in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ crystal; this is accompanied by an increase in the orthorhombic parameter

$$R = \frac{|a - b|}{a + b}.$$

These results suggest that oxygen atoms can diffuse in the crystal even at liquid nitrogen temperature.

Based on elastic relaxation measurements in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic in the temperature range of 283–1073 K, the activation energy of oxygen exchange between the O(4) and O(5) positions (see Fig. 1 b)

$$E_a = 1.07 \text{ eV}$$

and the pre-exponential factor in the Arrhenius equation for the self-diffusion factor

$$D_0 = 1.8 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$$

were found for various oxygen partial pressures.⁷⁸ The activation energy decreases with an increase in the oxygen content in the ceramics. More detailed data on E_a and D_0 can be found elsewhere.⁶⁰

The phase stability of copper cuprates is directly related to the diffusion of labile oxygen. A novel technique based on direct coulometric titration was developed for the study of the redox kinetics of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and for the measurement of the oxygen diffusion factor under various conditions.⁸⁴ It was found experimentally that the oxygen diffusion factor in the specimens decreased monotonically with a decrease in x from 0.8 to 0.1. In the authors' opinion, this phenomenon can be explained by the vacancy-related oxygen diffusion mechanism. The temperature dependences of the measured diffusion factors obey the Arrhenius equation; these are in good agreement with previous results (see, e.g., the review²⁶). In continuation of these studies,⁸⁵ the phase stability limits of the compounds $\text{RBa}_2\text{Cu}_3\text{O}_{7-x}$ ($R = \text{Y}, \text{Nd}$) were determined over a broad range of oxygen partial pressures. For $R = \text{Nd}$, the stability limit lies at higher temperatures than for $R = \text{Y}$. This is explained by a decrease in the energy of repulsion between the oxygen ions due to the larger distance between them

because of the larger ionic radius of Nd^{3+} . The dependences of the diffusion parameters (D_0 , E_a) on the oxygen non-stoichiometry index (x) and on the oxygen partial pressure were found. The diffusion of oxygen in the orthorhombic phase occurs faster than in the tetragonal phase. Practical recommendations were given for reducing the probability of microcrack formation, improving the contacts between the crystallites and shortening the low-temperature annealing when the HTSC ceramics are oxidised in the final stage of synthesis.

Studies on oxidation of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic under polythermal conditions showed that the temperature dependence of oxidation obeys the Arrhenius function, while the activation energy of this process changes monotonically as x increases.⁸⁶ In the ranges $0.2 < x < 0.3$ and $0.6 < x < 0.7$, the $E_a(x)$ dependence displays characteristic breaks. The authors suggest that this is closely related to a change in the mechanism of oxygen ion ordering in the CuO_2 planes. In the first case, a change in the oxidation mechanism results from the fact that 1/9 of the oxygen vacancies residing in the planar planes are occupied and their subsequent chaotic occupation is no longer possible. The second break most probably corresponds to the transformation of the tetragonal phase to the orthorhombic phase.

The diffusion of oxygen in $\text{Y}_{1-y}\text{Pr}_y\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ was studied⁸⁷ by measuring the electric conductivity of a sample in the temperature range of 300–1000 K. The desorption of oxygen from $\text{Y}_{1-y}\text{Pr}_y\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ was much slower than that from the pure $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ phase and decreased with an increase in y . The number of charge carriers in the ceramics studied was controlled by the oxygen content and did not depend on the Pr concentration.

The specific features of the thermal destruction of HTSC materials were analysed.⁸⁸ Analytical expressions for the dependence of the extent of oxygen non-stoichiometry on temperature and pressure were suggested on the basis of pseudo-chemical reaction models with consideration of the formation of point defects on copper ions and oxygen vacancies. It was found that the thermal destruction kinetics of high-temperature superconductors are described by chain nucleation equations.

A study of the processes of oxygen evolution from the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic upon thermal desorption *in vacuo* (10^{-5} Pa) revealed three characteristic temperature regions of oxygen evolution with maxima at 517, 673 and 932 K.⁸⁹ The first region corresponds to the loss of the chemisorbed, weakly bound oxygen; the second region, to the transformation of the ceramic from the orthorhombic phase to the tetragonal phase involving cleavage of the O–Cu(III) bonds; the third region, to the decomposition of this phase to give yttrium and barium cuprates as well as copper oxides with cleavage of the O–Cu(II) bonds. Thermogravimetric analysis of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic *in vacuo* at temperatures up to 1273 K revealed two temperature regions (673–873 and 1173–1233 K) where mass loss occurred due to the loss of oxygen.⁹⁰ The first region corresponds to the reversible oxygen loss related to a change in the copper oxidation state, $\text{Cu}^{2+} \rightarrow \text{Cu}^+$, whereas the second region corresponds to the irreversible oxygen loss accompanied by the destruction of the perovskite structure of the ceramics and formation of barium and yttrium cuprates.

Annealing of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic *in vacuo* at 10^{-3} Pa and 1073 K results in the destruction of the orthorhombic structure.⁹¹ On average, up to two oxygen atoms are removed from each unit cell, and the ceramic acquires a composition described by the formula $\text{YBa}_2\text{Cu}_3\text{O}_6$. Oxygen is completely removed from the O(4) positions (one atom per cell) and partially from other positions (see Fig. 1 b). The oxidation state of one-third of all copper ions becomes equal to unity. Annealing of the sample in air at 773 K results in the intercalation of oxygen into the material crystal structure; the overall number of oxygen atoms per unit cell reaches six.

The isothermal oxidation of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic comprises two stages, *viz.*, a diffusion-controlled stage and a 'slow' one

where the oxide is in equilibrium with the gas phase. The stepwise increase in the parameter x over time during the 'slow' stage was studied.^{92,93} This stepwise change in x is due to the structural transformation of the tetragonal phase to the orthorhombic one; as a result, mechanical stress is generated in the crystal, which is followed by its relaxation. This effect is described fairly well within the framework of a model which takes not only the T and p_{O_2} parameters but also the elastic intercrystallite interaction energy into account. The kinetics of oxidation of the $YBa_2Cu_3O_{7-x}$ ceramic in the temperature range of 748–873 K was explained⁹⁴ using a concept according to which the oxygen diffusion in the tetragonal cuprate phase occurs at the O(4) and O(5) vacancies and is thermally activated, while in the orthorhombic phase it occurs along specific structure 'channels' and does not require thermal activation. The oxygen migration in the orthorhombic phase is controlled by the interaction of the oxidant with the domain boundaries.

A study of the thermal stability of the orthorhombic phase of $YBa_2Cu_3O_{7-x}$ *in vacuo* and in oxygen showed that transformation of the orthorhombic phase to the tetragonal phase *in vacuo* (10^{-3} Pa) occurs at 973 K.⁹⁵ An increase in the oxygen pressure to 1 Pa increases the transformation temperature to 1073 K, while in pure oxygen, at a pressure of 10^5 Pa, this value is as high as 1173 K. A phase diagram that characterises the dependence of the temperature of transformation of the orthorhombic phase to the tetragonal phase on the oxygen pressure has been published.⁹⁶

Diffusion processes in thin superconducting films differ from those in bulk ceramic materials and single crystals. The diffusion of oxygen in thin epitaxial films of $GdBa_2Cu_3O_{7-x}$ was studied by measuring the electric resistance under isobaric and isothermal conditions in the temperature range of 650–1050 K.⁹⁷ Fast oxygen diffusion occurs preferentially at defects located along the c axis and with low activation energies. Chemical diffusion at vacancies occurs in the ab plane. The diffusion factor D in films thicker than 10 nm is $\sim 10^{-13}$ cm² s⁻¹. The thermal activation of diffusion is well described by an Arrhenius-type dependence and does not depend on the film thickness. At oxygen pressures around 10^2 Pa, the activation energy is 1.5 eV. However, if the film is thinner than 10 nm, the oxygen diffusion along the c axis is hindered due to the effect of the intermediate layer at the superconducting film–support interface.

It is important to establish the mechanism of the oxygen effect on the superconductivity parameters because it is necessary to solve the problem of the nature of the superconducting state.

Methods for the determination of the ΔH_{298}° , S_{298}° , and C_{p298} values and for the evaluation of the upper temperature threshold of superconducting transition of Y–Ba–Cu–O HTSC systems were developed with the use of thermodynamic simulation.⁹⁸ The oxygen content decreases abruptly in the temperature range of 200–500 K in complete agreement with the temperature dependences of Cu^{3+} concentration in the solutions studied. The Cu^{3+} concentration (at.%) as a function of the x index is described by linear equations for all solutions in the range of 100–900 K. For example, the equation for $YBa_2Cu_3O_z$ is

$$[Cu^{3+}] = -433.866 + 66.71538z, \quad (1)$$

where $z \geq 6.5$.

Direct comparison of the resulting Cu^{3+} concentrations with the z values for real superconductors is incorrect, since the structures of a superconductor and a model solution should be different, in accordance with the calculation conditions. However, the authors give certain recommendations regarding the applicability of the results obtained to the study of real superconductors. An equation was suggested for the superconducting Y–Ba–Cu–O system relating the Cu^{3+} concentration to the superconducting transition temperature (in K):

$$T_c = 45.32265 + 1.4333[Cu^{3+}]. \quad (2)$$

The inaccuracy of T_c calculation using Eqn (2) is considerable, since the phases obtained are usually thermodynamically unstable

under the conditions of synthesis. The correlation Eqns (1) and (2) can apparently be useful for rough estimates of T_c if the z index is known.

The application of the Langmuir–Maclin model made it possible to determine more accurately the oxygen diffusion factors in $YBa_2Cu_3O_{7-x}$ powdered superconducting ceramics at various temperatures.⁹⁹ The overestimated values for powders with particle sizes of 100 μ m were explained by the existence of 'easy pathways' for diffusion such as cracks, grain boundaries, etc., the role of which is particularly great for particles larger than separate superconductor crystallites.

A study of the physicochemical nature of oxygen dissolution and ordering of oxygen vacancies determining the superconducting properties of the $YBa_2Cu_3O_{7-x}$ ceramic¹⁰⁰ showed that an oxygen solution in the ceramic is somewhat comparable with an ideal gas (*i.e.*, obeys the Fermi–Dirac distribution), which is an important disagreement with the widespread concept of the 'regular' character of solid solution. The authors believe that the ordering of oxygen vacancies in the $YBa_2Cu_3O_{7-x}$ ceramic, which provides high-temperature superconductivity, results from structure transformations according to a mechanism related to the Jahn–Teller effect rather than from the interaction (repulsion) between the dissolved oxygen atoms.

The evolution of oxygen from the $YBa_2Cu_3O_{7-x}$, $La_{2-y}Ba_yCuO_x$, $Bi_4Ca_3Sr_3Cu_4O_x$, $Bi_{2-y}Pb_yCa_2Ba_2Cu_3O_x$ and $Tl_2Ca_2Ba_2Cu_3O_x$ ceramics *in vacuo* (10^{-4} Pa) with heating of the specimens to 1173 K was studied.¹⁰¹ At 773–923 K, oxygen evolution from the yttrium and thallium ceramics was observed. Oxygen was not evolved from the bismuth and lanthanum ceramics in the temperature range studied. According to the published data,⁸⁹ the evolution of oxygen from the $Bi_2Sr_2CaCu_2O_x$ system *in vacuo* occurs only in the temperature range of 1223–1323 K.

Thermogravimetric analysis showed¹⁰² that the $Bi_2Sr_2Ca_2Cu_4O_x$ ceramic contains over-stoichiometric oxygen: a specimen prepared in an oxygen atmosphere has the composition $Bi_2Sr_2Ca_2Cu_4O_{11.38}$. The existence of the excess oxygen is explained by the presence of copper ions in a high oxidation state (Cu^{3+}). This observation was also confirmed in other studies.^{103–105}

A considerable increase in the superconductor transition temperature of the $Bi_2Sr_2CaCu_2O_{8+x}$ ceramic was observed after it was annealed in oxygen.¹⁰⁶ Raman spectroscopy studies showed that oxygen is included in the Bi–O layers and the increase in T_c is due to the oxygen exchange between the Bi–O and Cu–O layers (see Fig. 1c).

The authors of the present review studied the effect of low-temperature (77.4–100 K) adsorption of O_2 , Ar and N_2 on the superconductivity of a $GdBa_2Cu_3O_{7-x}$ thin film.¹⁰⁷ All experiments were conducted *in situ* in an adsorption reactor placed in the probe of a magnetic susceptibility measuring device. The temperature dependence of the real and imaginary parts of magnetic susceptibility, $\chi'(T)$ and $\chi''(T)$, were recorded after the next gas portion was injected into the reactor at 77 K. All of the gases mentioned above affected the shape of the $\chi'(T)$ curve in the vicinity of T_c and 'shifted' the maximum of the $\chi''(T)$ curve towards the low-temperature region. The half-width of the $\chi''(T)$ peak decreased with an increase in the quantity of injected argon and nitrogen and increased upon injection of oxygen; this meant an increase and decrease in the critical currents in the superconducting film with an increase in the degree of its coverage with the gas molecules. The effects of the gases were reversible: removal of the adsorbed molecules by evacuation or by purging with helium at room temperature resulted in complete restoration of the original shapes of the $\chi'(T)$ and $\chi''(T)$ curves.

Comparison of experimental $\chi''(T)$ curves¹⁰⁷ with results of theoretical calculations for the hysteresis losses in thin superconductors^{108,109} afforded critical current densities extrapolated to 0 K, $J_c(0)$, and their dependence on the degree of surface coverage with adsorbed gas molecules (Fig. 3). The adsorption of

Figure 3. Dependence of J_c extrapolated to 0 K on the degree of coverage of the $\text{GdBa}_2\text{Cu}_3\text{O}_{7-x}$ film surface with N_2 (1), Ar (2) and O_2 (3) molecules.¹⁰⁷

argon and nitrogen is accompanied by a small increase in $J_c(0)$, whereas the adsorption of oxygen decreases this parameter. On the other hand, the superconducting transition temperature did not vary with an increase in the degree of surface coverage; only 'blurring' of this transition in the vicinity of T_c increased.

The decrease in the critical current density in the case of low-temperature oxygen adsorption is due to the effect of the paramagnetic O_2 molecule on the transport characteristics of the intergranular layers. In fact, the magnetic field strength at a distance from the adsorption site of an oxygen molecule equal to the diameter of this molecule is ~ 10 T. This field strength is quite sufficient for a total perturbation of superconductivity of the intergranular layers. The rather small decrease in the critical current density observed probably results from the fact that the distances of the adsorption sites of the oxygen molecules from the superconducting phase exceeds substantially the molecule size, *e.g.*, due to the presence of a 'buffer' non-superconducting oxide layer on the film surface.

The 'blurring' of the superconducting transition due to the low-temperature adsorption of oxygen, argon or nitrogen can be caused by many reasons. A most likely reason involves inclusion of the molecules of these gases directly into the crystal lattice of the material. This hypothesis was suggested long ago (see below) and was partially confirmed experimentally for argon adsorption.¹¹⁰ It is likely that the inclusion of simple molecules into polycrystalline HTSC oxides at low temperatures is facilitated by the presence of numerous defects and oxygen vacancies in the crystal lattices of these materials. For instance, the high surface defectiveness is indicated by experimental results of a study of electron photoemission from the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface¹¹¹ which showed that if the ceramic is crushed, the lattice oxygen leaves the surface instantly even at the liquid nitrogen temperature.

Similar changes in the superconductivity characteristics were recorded for the low-temperature adsorption of oxygen on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic.¹¹² At 77.4 K, this adsorption results in a strong decrease in the transport critical current. The amplitude of the changes was much greater than that in the case of a superconducting film; this is probably due to the presence of a large number of weak bonds between the granules.

2. The effect of hydrogen

The specifics of the interaction of hydrogen with metal oxide superconductors primarily result from the presence of the O^{2-} and O^- ions and possibly O^0 in the anion sublattice; hydrogen readily forms chemical bonds with these species to give OH^- ions or water molecules.¹¹³ Hydrogen that has penetrated into the crystal lattice of an HTSC material reacts with the metal ions to change their effective oxidation state. All of these changes affect, directly or indirectly, the hole concentration in the CuO_2 plane, and hence, the superconducting transition temperature.

The neutron diffraction method was used to study hydrogen adsorption on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic in the temperature range from 333 to 593 K.¹¹⁴ At low temperatures, hydrogen is preferentially adsorbed on the granule boundaries, but above 493 K, it undergoes chemical reactions with the superconductor material. Hydrogen adsorption at elevated temperatures results in partial amorphisation of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ accompanied by the evolution of a considerable amount of metallic copper. According to the reported data,¹¹⁵ treatment of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic with hydrogen at 393–473 K results in a strong decrease in the low-field magnetic susceptibility and suppression of magnetic hysteresis at high fields. The superconducting transition temperature is not changed in this case. The suppression of the magnetic properties of the HTSC material is explained by the formation of metal hydrides in the inter-granular layers; the invariance of T_c is explained by the stable superconductivity of single crystals of the ceramic superconductor.

The $\text{EuBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was treated with hydrogen at pressures of 1.3–10.0 kPa and temperatures of 393–483 K.^{116,117} This did not change the superconducting transition temperature. However, the formation of hydride and hydroxide phases [*e.g.*, CuH_2 , $\text{Ba}(\text{OH})_2$ and others] on the granule surfaces resulted in a decrease in the fraction of the superconducting phase, modification of the Josephson contacts, an increase in their electric conductivity and a decrease in the percolation conductivity.

It was found for the first time that the dependence of the critical current I_c on the quantity of hydrogen absorbed by the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic is non-monotonic and passes through a maximum at low concentrations of the latter.¹¹⁸ The position of the maximum depends on the specimen density and correlates with the minimum position on the electric resistance curve. Based on these data, the conclusion was made that the enhanced conductivity of the inter-granular layers at low concentrations of absorbed hydrogen is due to the reduction of oxides with hydrogen, which favours the formation of metallic copper and compaction of the layers between the granules, and due to additional ionic conductivity resulting from the presence of the H^+ and OH^- ions.

The superconductivity parameters of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic depend strongly on the oxygen concentration in the material lattice. It is well known that the oxygen-deficient $\text{YBa}_2\text{Cu}_3\text{O}_6$ ceramic is a semiconductor and displays antiferromagnetic properties, while the superoxidised $\text{YBa}_2\text{Cu}_3\text{O}_7$ ceramic has metallic properties. The effect of hydrogen inclusion into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic with various oxygen contents at a temperature of 441 K in the pressure range from 1 to 3 atm was studied by the muon spin rotation method.¹¹⁹ It was shown that hydrogen intercalation results in magnetic ordering of the copper atoms; the amount of hydrogen required for this depends on the oxygen index: the more oxygen the ceramic contains the more hydrogen is required. Thus, hydrogen intercalation results in a formal decrease in the oxygen index. This requires one hydrogen atom per two oxygen atoms. It was concluded that hydrogen in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ plays the role of an electron donor which decreases the number of holes.

The intercalation of hydrogen into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and $\text{Bi}_2\text{Ca}_2\text{SrCu}_2\text{O}_{8+x}$ ceramics at 473–503 K and at a pressure of 0.9 atm was studied.¹²⁰ The concentration of holes in the superconductors decreased in a ratio of one hole per one hydrogen atom upon hydrogen intercalation. In addition, the superconducting transition temperature depended strongly on the position occupied by hydrogen in the lattice. It was thus concluded that T_c is primarily determined by the mobility of holes in the CuO_2 planes. This was confirmed by an X-ray diffraction study of the $\text{EuBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic.¹²¹ It was shown that the penetration of hydrogen into the material crystal structure along the CuO_2 planes begins at relatively low temperatures, 393–423 K, and at pressures of 5–10 kPa. A strong decrease in the thermal expansion factor was observed, which is believed to result from changes in the electronic structure of the material and the metal–dielectric

transition due to a decrease in the concentration of the oxygen vacancies.

A more detailed analysis of the hydrogen effect on the structure of yttrium and bismuth ceramics was made.¹²² The inclusion of hydrogen results in structural changes in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ lattice depending on the oxygen index.^{123–125} Subsequent saturation of the ceramic with hydrogen results in the formation of amorphous hydride phases where hydrogen occupies interstitial positions. A solid solution of hydrogen in the ceramic, similar to metal–hydrogen solid solutions, can be formed.

According to NMR data,¹²⁶ the diffusion of hydrogen into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic occurs on the oxygen vacancies in the Cu–O chains and along the *a* or *b* axes on the interstices in the Y planes. The activation energies of these processes are 0.29 and 0.25 eV, respectively. The diffusion of hydrogen ceases following exposure of the ceramic to hydrogen at room temperature for three to four months, and the hydrogen atoms form strong O–H bonds. It was found by ^1H NMR spectroscopy that hydrogen diffusion also occurs in hydrogenated $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic at $T < 200$ K.¹²⁷ At temperatures from 130 to 92 K, the hydrogen atoms are mostly localised at the O(4) and O(5) lattice points. The inelastic neutron scattering and diffraction methods afforded the vibration spectra of hydrogen atoms in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic treated with hydrogen at 373 K.¹²⁸ Only several percent of the absorbed hydrogen participated in the formation of a solid solution; the H atoms occupy the octahedral positions formed by four Y atoms and two Cu atoms at the Cu(2) positions (Fig. 4). The rest of the hydrogen atoms are involved in an amorphous non-superconducting phase.

The NMR and X-ray diffraction methods were used to study the absorption of hydrogen and deuterium with the $\text{YBa}_2\text{Cu}_3\text{O}_7$ and $\text{YBa}_2\text{Cu}_3\text{O}_6$ ceramics at 473 K.¹²⁹ The incorporation of the hydrogen isotopes into $\text{YBa}_2\text{Cu}_3\text{O}_7$ results in partial removal of the chain oxygen from the O(1) positions and formation of O–H

bonds. No new bonds are formed in the $\text{YBa}_2\text{Cu}_3\text{O}_6$ ceramic, and no changes in the lattice parameters with increase in the hydrogen content are observed.

Pre-treatment of an yttrium HTSC ceramic *in vacuo* followed by treatment with hydrogen at 400–600 K and 2.6 kPa caused a considerable decrease (by 150 K) in the temperature at which oxygen enters the tetragonal $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ phase.¹³⁰ The specimen became a superconductor ($T_c = 80$ K) after such low-temperature intercalation of oxygen; the ‘width’ of transition into the superconducting state was 15 K. If treatment of the specimen with oxygen is carried out at the same temperatures immediately after evacuation, it does not become a superconductor. It was shown¹³¹ that the decrease in the temperature at which oxygen enters the ceramics is caused by the transformation of the tetragonal phase of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ into the orthorhombic phase upon hydrogen treatment. The lattice parameter *b* decreases in this case since the hydrogen atoms occupy the oxygen vacancies along the direction *b* in the plane formed by CuO chains. Nevertheless, superconductivity is absent down to 4.2 K on cooling of the ceramics treated only with hydrogen. This is explained¹³¹ by the small orthorhombic parameter *R* which is 10^{-3} for the hydrogenated ceramics, whereas it is above 3×10^{-3} for the superconducting yttrium ceramics.

Similar changes in the physicochemical properties were observed upon treatment of superconducting bismuth oxides. The fraction of the superconducting phase and the superconducting transition temperature were found to decrease upon reduction of a $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_z$ single crystal with hydrogen (a 10 : 90 H_2 : N_2 mixture) at 673 K.¹³² Analysis of the X-ray absorption spectra led to the conclusion that reduction with hydrogen decreases the formal oxidation state of copper and the number of holes in the CuO_2 planes; this is the reason for the decrease in T_c .

In a study of the effect of hydrogen treatment on the structure of the bismuth-containing HTSC ceramic, the specimens were kept for several hours in a stream of hydrogen at 573 K.¹³³ Measurements of the electric conductivity of the specimens showed that the ceramic loses superconductivity completely and becomes a semiconductor. Hydrogenation of the ceramic results in a decrease in the unit cell volume, as shown by X-ray diffraction analysis. It should be noted that, on the contrary, hydrogenation of the yttrium HTSC ceramic increases the unit cell volume.

Thus, the type of effect of hydrogen on the properties of an HTSC material depends strongly on the treatment mode and temperature. At relatively low temperatures (up to 473 K), hydrogen mostly reacts with the granule surfaces and forms amorphous hydride phases involving metal atoms of the ceramic. In some cases, insignificant intercalation of hydrogen into the crystal structure of the material is observed. This phenomenon is accompanied by degradation of the magnetic properties of the superconductor and a decrease in the transport current density. As a rule, the superconducting transition temperature changes only slightly.

As the temperature of hydrogen treatment is increased, the superconductivity of HTSC materials decreases abruptly, until it is lost completely. This results from the incorporation of hydrogen into the crystal structure of the material which changes the T_c and the formal oxidation state of copper and decreases the concentration of holes in the CuO_2 planes.

High reactivity of hydrogen in the 400–470 K range found in a series of studies^{134–136} gives reasons to assume that the protonic conductivity of hydrogen-containing barium–yttrium cuprates is rather high. However, the originally high metallic conductivity of cuprates of the $\text{LnBa}_2\text{Cu}_3\text{O}_7$ family (where Ln indicates yttrium or another rare-earth element) ‘masks’ strongly weaker ionic conductivity. Studies of hydrogenated cuprates of the general formula $\text{H}_y\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ showed¹³⁷ that their specific resistivities increase by almost six orders if the hydrogen index *y* increases from 0 to 2 and decrease by three orders upon oxidation of the ceramics with *y* = 2 if the *x* index changes from 0.1 to 0.8.

Figure 4. Possible locations of hydrogen atoms in the crystal lattice of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$.¹³⁸

Almost all aspects of the physicochemical interaction of hydrogen with superconducting cuprates were covered in one of the latest reviews on the effect of hydrogen on HTSC materials.¹³⁸ Figure 4 shows the crystal structure of the orthorhombic phase of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with indication of the positions where the hydrogen atoms are localised according to numerous studies. One can see that the intercalation of hydrogen atoms occurs along three main directions, *i.e.*, into the copper–oxygen bridges, chains and oxygen vacancies. However, the conductive CuO_2 layers remain unaffected. Hence, the observed changes in the electrophysical properties of HTSC materials are due to the electron density redistribution between the CuO_2 layers and the copper–oxygen chains $\text{O}-\text{Cu}(1)-\text{O}-\text{Cu}(1)-\text{O}$. As a rule, hydrogen intercalation into HTSC materials suppresses the superconductivity, while the superconducting transition temperature decreases (with rare exceptions). Figure 5 shows the dependence of the temperature of the onset of superconducting transition $T_{c,\text{on}}$ of an $\text{H}_y\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ thin film on the hydrogen content. If the hydrogen concentration increases, $T_{c,\text{on}}$ decreases monotonically, while the transition width increases from 0.8 to 6.2 K. It should be noted that at the hydrogen content of ~ 0.3 atoms per cell, a sharp bend of the curve is observed; this correlates with the bend on the dependence of T_c on the oxygen content (see Fig. 2). This probably indicates that the hydrogen atoms (donors) react readily with weakly bound oxygen ions (electron acceptors), thus changing the concentration of the current carriers in the HTSC material.

Figure 5. Dependence of the temperature of the onset of superconducting transition ($T_{c,\text{on}}$) of thin $\text{H}_y\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film on the hydrogen content (y) in unit cell;¹³⁸ (1) from electric resistance measurements; (2) from magnetic susceptibility measurements.

3. The effect of halogens

Numerous studies on the effect of the crystal structure and oxidation states of the chemical elements constituting an HTSC material on superconductivity showed that the holes serve as charge carriers in the superconducting state; these holes are genetically related to the p states of the oxygen ions, and their concentration is an important characteristic of a superconductor.^{139, 140} It thus follows that the anionic sublattice plays an essential role in superconductivity. One of the ways for changing the anionic sublattice defectivity involves doping with other anions, *e.g.*, halides.

The disappearance of electrical resistance at 155 K on $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ specimens synthesised with the use of BaF_2 as one of the starting reagents was detected for the first time in 1987 (Ref. 141). Since that publication, numerous studies on the replacement of the anionic sublattice by halogens have appeared. The presence of fluorine can both improve superconductivity^{142–149} and impair it.^{150, 151} For example, treatment of the $\text{YBa}_2\text{Cu}_3\text{O}_{6.7}$ ceramic with $T_c = 65$ K with NF_3 at 613 K and with CCl_4 at 523–573 K increased T_c to 90 K in both cases.¹⁵² Presumably, the halogen atoms are incorporated in the O(4) position along the CuO chains, *i.e.*, in a sense, halogenation is similar to saturation of oxygen-deficient ceramics with oxygen. If

treatment is continued, the halogen anions occupy the O(5) positions but T_c is not increased any more. The effect of ‘soft’ fluorination on the degradation of powders of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ composition in a humid atmosphere was studied.¹⁵³ The fluorination of powders was carried out in 49% hydrofluoric acid vapour at room temperature in a closed vessel. The physical properties and superconductivity of the powders were almost unchanged, but their stability in humid atmosphere increased considerably. This phenomenon is rationalised as being due to the higher stability of the resulting fluorides, BaF_2 and CuF_2 , to water and prevention of further interaction of water with the superconductor granules. The presence of barium fluoride in synthesised thallium-containing ceramic cuprates with composition $\text{TlBa}_2\text{Ca}_2\text{Cu}_3\text{O}_x$ doped with zirconium, hafnium, ruthenium and tin oxides improved their critical parameters noticeably.¹⁵⁴ However, there is no satisfactory explanation of the effect of barium fluoride on the properties of thallium-containing cuprates.

In a continuation of this work, the composition and properties of thallium-containing HTSC ceramics obtained in the presence of metal fluorides were studied.¹⁵⁵ The specimens modified in this way are characterised by higher content of the superconducting phase, smaller granule sizes and more pronounced transition in the superconducting state in comparison with the specimens obtained under the same conditions but without addition of fluorides.

Enrichment of the $(\text{Tl}_{0.5}\text{Pb}_{0.5})\text{Sr}_{1.6}\text{Ba}_{0.4}\text{Ca}_2\text{Cu}_3\text{O}_z$ ceramic with fluorine carried out by the addition of CuF_2 during the synthesis improves considerably its superconductivity.¹⁵⁶ The superconducting transition temperatures increase from 120 to 125 K, and the critical current density increases by 300%. According to X-ray diffraction data, the fluorine atoms replace the oxygen atoms in the CuO_2 plane. Changes in the morphology of the specimens due to the increase in the ceramic granule sizes are observed. The increase in T_c is explained¹⁵⁶ by optimisation of the concentration of charge carriers in the CuO_2 plane by the fluorine atoms, whereas in ceramics devoid of fluorine, the concentration of these carriers is apparently far from optimum because of the high oxygen content.

NMR and EPR spectroscopic methods were used to study the intercalation of halogens into the crystal lattice of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$.¹⁵⁷ The halogenation was carried out by exposing the specimens in a stream of gaseous NF_3 or CCl_4 diluted with N_2 at 573 and 523 K, respectively. The intercalated chlorine atoms are inserted in the chains between two copper atoms, while the fluorine atoms occupy the oxygen vacancies, as follows from the higher fluorine concentration in the materials with smaller oxygen indices.

The mechanism of the formation of halogen-containing HTSC phases based on $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ was studied.¹⁵⁸ The intercalation of halogens (Cl_2 , Br_2 , I_2) into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ lattice was carried out in the temperature range of 423–523 K. An X-ray anomalous dispersion and Mössbauer spectroscopic studies of the specimens obtained showed that the interaction of halogens with the tetragonal phase of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ occurs as intercalation of halogens into the anionic vacant positions of the Cu(1) layer (see Fig. 1b). Charge transfer from the CuO_2 plane to halogens results in the formation of holes, which favours the manifestation of superconductivity ($60 < T_c < 93$ K) acquired by the resulting intercalation compounds. The chloride anion, unlike other halide anions, changes the ceramic’s microstructure owing to its large size; this results in the formation of stresses and dislocations and manifests itself as a decrease in the critical current. A study of the surface layers of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ tetragonal phase after its bombardment with chloride ions showed that implantation of chloride anions results in the formation of a orthorhombic phase layer near the surface; its thickness approximately equals the anion penetration depth.¹⁵⁹ This layer has the properties of a superconductor with a critical temperature of *ca.* 70 K.

In a study of chlorine-containing phases of the type $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}\text{Cl}_y$ synthesised with the use of PCl_5 as a chlorinat-

ing agent, it was assumed¹⁶⁰ that at low temperatures the halogens are localised in chains around the copper atoms Cu(1) and the O(5) vacant positions are occupied first. An increase in the halogenation depth results in replacement of the O(4) chain oxygen atoms. Further halogenation under more drastic conditions results in replacement of the O(1) atoms, and the resulting phase has the limiting composition $\text{YBa}_2\text{Cu}_3\text{O}_4\text{Cl}_4$. The conclusion was made¹⁶⁰ that the decisive role in maintaining the superconductivity of halogen-containing phases belongs to the nature of the bridging atoms located at the O(1) position, which link the CuO_2 layers to the Cu(1) chain atoms: the electron-withdrawing properties of these bridging atoms induce superconductivity.

The change in the superconducting transition temperature due to the intercalation of HgBr_2 into polycrystalline $\text{Bi}_2\text{Sr}_{1.5-y}\text{La}_y\text{Ca}_{1.5}\text{Cu}_2\text{O}_x$ specimens with $0.0 \leq y \leq 0.4$ was studied.¹⁶¹ The specimens were obtained by keeping a tube containing certain weighed samples of HgBr_2 and the original superconducting ceramic at 508 K for 4 h *in vacuo*. An X-ray diffraction study showed that HgBr_2 is intercalated between the Bi—O planes. Figure 6 shows the dependence of T_c on y for the original and treated specimens. One can see that after treatment T_c decreases for the specimens with $y < 0.2$ and increases for the specimens with $y > 0.2$. It is believed that the intercalation of HgBr_2 changes the charge on the copper ions located in the conducting planes. The correlation relationships between the change in the copper charge (Δn) and T_c are reported;¹⁶¹ it follows from this relationship that Δn depends linearly on the concentration of the added compound and correlates with the concentration of the charge-carrying holes.

Upon treatment of non-superconducting ceramic specimens of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (tetragonal phase) with bromine vapour at 503 K and iodine vapour at 673 K without contact with air, they acquired superconductivity; the T_c values were 80–85 and 55 K, respectively.¹⁶²

The chemical interaction of iodine with the lattice copper ions can be a possible reason for the appearance of superconductivity in iodinated specimens. A similar assumption was made in a Raman spectroscopic study of the tetragonal $\text{YBa}_2\text{Cu}_3\text{O}_{6.1}$ ceramic treated in a iodine atmosphere. Iodine reacts with copper to 'extract' it from the lattice.¹⁶³ Oxygen is redistributed over the lattice, occupies the vacant sites in the chain and thus provides the possibility for superconductivity to occur. The same conclusion was also made in yet another study.¹⁶⁴ X-Ray diffraction analysis performed after annealing of the non-superconducting phase $\text{YBa}_2\text{Cu}_3\text{O}_6$ in iodine vapour at 553–653 K showed that the superconducting orthorhombic phase had appeared and reflexes of foreign phases were detected, which possibly corresponded to copper, barium and yttrium iodides. Treatment of the $\text{YBa}_2\text{Cu}_3\text{O}_7$ orthorhombic phase under similar conditions was not accompanied by either structural parameter changes or formation of

foreign phases. Annealing a powder mixture of the $\text{YBa}_2\text{Cu}_3\text{O}_6$ and $\text{YBa}_2\text{Cu}_3\text{O}_7$ phases *in vacuo* at 493 K (which is much lower than the temperature of oxygen liberation, 623 K) was accompanied by the intergranular oxygen transfer from the $\text{YBa}_2\text{Cu}_3\text{O}_7$ phase to the $\text{YBa}_2\text{Cu}_3\text{O}_6$ phase and resulted in a phase with composition $\text{YBa}_2\text{Cu}_3\text{O}_{6.65}$. This suggests the high diffusion mobility of oxygen at low temperature in the lattices of the ceramics studied.

Thus, the basic mechanism of the effect of iodine on the superconducting properties of yttrium ceramics apparently involves oxygen transfer into the tetragonal phase; this oxygen can be liberated from the neighbouring phases under the effect of halogen atoms. Treatment of the tetragonal phase with iodine vapour at 543 K resulted in a continuous series of $\text{YBa}_2\text{Cu}_{3-y}\text{O}_x\text{I}_z$ solid solutions which possessed superconductivity.¹⁶⁵ The reaction of iodine with the crystal lattice of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ single crystals depends essentially on the initial oxygen content.¹⁶⁶ At the maximum oxygen content (the specimen with $T_c = 92$ K), no reaction of the crystals with iodine was observed. However, the stoichiometric cationic compositions of the crystals of orthorhombic ($T_c = 55$ –60 K) and tetragonal phases changed and an amorphous layer of varying thickness was formed on the surface; this was followed by complete destruction of the specimens. The penetration of iodine into the matrix was determined by the presence of oxygen vacancies in the principal planes. Ordering of the iodine atoms included in the crystal lattice was not observed.

Two-phase specimens were formed upon bromination: the original tetragonal phase coexisted with a orthorhombic phase in the ratio $\sim 1:1$. The iodinated specimens consisted completely of a orthorhombic phase. The parameters of the orthorhombic phases in the iodinated and brominated specimens are similar. Thus, the halogen atoms occupy presumably the vacancies of the O(4) type along the b axis (see Fig. 1b).¹⁶² It was assumed on the basis of EPR spectra that halogenation results in the transfer of negative charge to the CuO chains and formation of holes at the CuO_2 planes.

A study of iodine intercalation at 23 K into the $\text{Bi}_2\text{Sr}_2\text{Ca}_{1-y}\text{Y}_y\text{Cu}_2\text{O}_8$ ceramic by X-ray diffraction analysis showed that iodine is incorporated in the BiO—OBi double layers in such a way that the distance between them increases.¹⁶⁷ The superconducting transition temperature decreases by 10 K because the concentration of the hole carriers exceeds the optimum level.

The effect of iodine and oxygen intercalation on the physical properties and superconductivity of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ single crystals was studied.¹⁶⁸ The starting single crystals and elementary iodine were sealed in an evacuated glass tube, heated to 453 K and kept for 330 h at the same temperature. The oxidation of single crystals with oxygen was carried out at 10 atm and 823 K for 140 h, or at 600 atm and 673 K for 320 h. The resistance and magnetic measurements of the thus treated samples showed that the dimensionality of the superconducting system changes from two to three, T_c decreases, and the activation energy of magnetic flux creep changes. According to the model suggested for the explanation of these phenomena, the HTSC material acquires a multilayered structure with alternation of the superconducting and normal layers due to the intercalation of iodine and oxygen. The 'proximity' effect results in the redistribution of the charge carriers between the layers and hence in changes in the physical properties and superconductivity parameters. The structural ordering of atoms in superconducting $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{I}_y\text{O}_x$ single crystals containing intercalated iodine was studied by low-energy electron diffraction, Auger and photoelectron spectroscopy on chipped surfaces, as well as by transmission electron spectroscopy.¹⁶⁹ It was shown that iodination results in a superstructure with ordered aggregates of iodine molecular complexes in the empty channels formed upon distortion of the original lattice by structural modulation.

Figure 6. Dependence of the superconducting transition temperature of the $\text{Bi}_2\text{Sr}_{1.5-y}\text{La}_y\text{Ca}_{1.5}\text{Cu}_2\text{O}_x$ ceramic on y :¹⁶¹ (1) starting specimen; (2) sample after treatment with HgBr_2 .

In yet another study,¹⁷⁰ the intercalation of iodine in bismuth-based ceramics was carried out in a sealed tube, which was heated to 458 K over a period of 6 h and kept for 240 h at this temperature. According to the nuclear quadrupole resonance data, the iodinated $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ specimens contain no chemical bonds of the Bi–I and Cu–I types, *i.e.*, iodine in them is in atomic or molecular form and is truly intercalated. The superconducting transition temperature of the iodinated ceramic was 73 K.

Thus, halogenation of the yttrium-containing oxygen-deficient ceramic consisting of a $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ tetragonal phase results in orthorhombic phases with $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}\text{Hal}_y$ composition. The new phases have superconducting properties with approximately the same T_c as the usual superconducting ceramics, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$. The iodinated ceramic is an exception, its T_c is no higher than the liquid nitrogen temperature. The formation of superconducting phases upon ceramics' halogenation is explained by inclusion of halogens at the oxygen O(1) positions; the halogens 'withdraw' the electronic charge from the CuO_2 planes onto themselves, which in turn increases the concentration of holes.

4. Degradation of high-temperature superconducting materials exposed to CO_2 and H_2O

Exposure of HTSC materials to atmospheric carbon dioxide and water results in their degradation accompanied by the loss of superconductivity and degradation of the superconducting phases. Therefore, the problem of storage and stabilisation of HTSC materials is of major importance. One of the first reviews on the chemical degradation of superconductors is found in Ref. 171.

The reaction of CO_2 with the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic starts at room temperature.¹⁷² The decrease in the critical intergranular current correlates with the intensity of the CO_2^+ peak in the mass spectra of the gases evolved from the ceramic; this suggests that carbonates are localised at the granule boundaries. When synthesis is carried out in the air at high temperatures, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ absorbs CO_2 . The maximum absorption is observed at 1173 K, and the amount of absorbed CO_2 with respect to carbon reaches 0.05% of the ceramic mass.¹⁷³ A study of the decomposition of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic in a 5% CO_2 + 95% O_2 mixture at 1088 K showed that the nuclei of the $\text{Y}_2\text{Cu}_2\text{O}_5$ and BaCO_3 phases are initially formed very fast, and then a 'green' phase of Y_2BaCuO_5 and CuO appears. The formation of BaCO_3 at the boundaries between the granules upon treatment of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with pure CO_2 at 1123 K for 2 h was reported.¹⁷⁴

The powdered $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic reacts with CO_2 at 1273 K both in the absence and in the presence of moisture to give decomposition products such as BaCO_3 , $\text{Y}_2\text{Cu}_2\text{O}_5$, CuO , Cu_2O and Y_2O_3 .¹⁷⁵ In the 90% CO_2 + 10% O_2 mixture, the decomposition products differ somewhat: they do not contain Cu_2O and Y_2O_3 .

A detailed study of the kinetics of the reaction between powdered $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and pure CO_2 in the temperature range of 823–1163 K was carried out.¹⁷⁶ The reaction of the ceramic with CO_2 can be described by the equation:

where Y_2BaCuO_5 is an intermediate. In the temperature range of 823–1088 K this reaction limits the overall rate of the process and has an order of 1.5 with respect to the ceramic; its activation energy is 95 kJ mol⁻¹. Subsequent 'carbonisation' of the ceramic occurs according to the equation:

The presence of an alkaline-earth element in the HTSC ceramics provides a material with basic properties and hence makes it capable of absorbing CO_2 when in contact with air.

Calcination of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic during synthesis at 1223 K in air containing more than 1% carbon dioxide results in a non-superconducting tetragonal phase.¹⁷⁷ It is formed due to hindered oxygen exchange because of the formation of carbonate films on the material surface. The carbonates and decomposition products are mainly formed at the granule boundaries; this decreases considerably the critical intergranular current of the superconductor.

In the initial stage of the reaction of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with water vapour and carbon dioxide, the kinetics of water sorption is consistent with a process occurring at the internal grain boundaries and it is well described by a first order equation.¹⁷⁸ The diffusion of water vapour to the internal layers of the ceramic is the rate-determining step for CO_2 transfer. If the ceramic is pre-treated with water vapour, the CO_2 transfer occurs extremely quickly and is characterised by an effective diffusion factor exceeding 10⁻⁶ cm² s⁻¹. This is assumed to be due to water vapour condensation in the material pores.

Prolonged annealing of a $\text{Bi}_{1.6}\text{Pb}_{0.4}\text{Sr}_{1.7}\text{Ca}_{2.3}\text{Cu}_{3.0}\text{O}_{10+x}$ powder at 1123 K decreased slightly the carbon content in the specimen from 0.02 mass % after 24 h to 0.01 mass % after 192 h.¹⁷⁹ The powdered HTSC ceramic quickly absorbs carbon dioxide if stored in air: the content of carbon in the ceramic increases by a factor of two in 15 h, reaches 0.1 mass % in 240 h and then remains almost unchanged. An increase in the carbon content in bulk specimens from 0.019 mass % to 0.13 mass % is accompanied by a decrease in the critical current density from 280 to 150 A cm⁻².

The $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic readily reacts with water vapour even at room temperature to form the 'green' phase Y_2BaCuO_5 according to the equation:^{180, 181}

If this occurs in the presence of CO_2 , the resulting barium hydroxide immediately reacts with carbon dioxide:¹⁸²

Thus, in this case water acts as a catalyst of carbonate formation.

Owing to the high basicity of barium oxide, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ can react with CO_2 in humid atmospheres even at very small CO_2 partial pressures.¹⁸³ The products of hydration ageing of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic were studied.¹⁸⁴ The morphology of the new formations was studied using a scanning electron microscope. The original grain surface was rather smooth, but small protrusions and cracks appeared there after exposure to water vapour for one hour. If exposure was increased to 2.5 h, the ceramic's grains became covered with thin needles. An even longer exposure promoted the integration of the new formations which gradually covered the entire grain surfaces. X-Ray diffraction analysis showed that the new formations consist of barium hydroxide, $\alpha\text{-Ba(OH)}_2$, and the Y_2BaCuO_5 'green' phase.

Similar studies carried out using electromagnetic radiation absorption in the range of 1–3 MHz made it possible to follow the character of intergranular medium changes in specimens of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic exposed to moisture.¹⁸⁵ The changes in the chemical composition (degradation) of certain granules can occur at a depth of 0.3–1.0 μm from the surface depending on the specimen density. The formation of such a layer interferes with subsequent changes. Noticeable degradation of specimens with a density above 5.4 g cm⁻³ is observed in water after 10 h whereas in ordinary atmosphere it takes 5 months. Subsequent exposure to water little affects the superconductivity characteristics of the specimens.

The surface state and microstructure affect the reaction of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic with water.¹⁸⁶ Generally, the average pore size in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic is $\sim 1 \mu\text{m}$ at an average grain size of 3–20 μm .¹⁸⁷ Analysis of data on small angle neutron scattering at the liquid nitrogen temperature led to the conclusion

that the majority of pores in the yttrium ceramic are open.¹⁸⁸ Thus, water can react not only with the outer but also with the inner surface by penetrating through the open pores. Water diffusion is an activation process. The activation energy is ~ 0.033 eV, this order of magnitude corresponding to the energy of a thermal quantum. Surface polishing of pellets of a sample accelerates the degradation three- to five-fold; apparently, this is caused by an increase in the number of open pores connected to the surface as a result of polishing. Hydration of textured specimens is strongly hindered, probably due to the small number of boundaries because of strong binding between the oriented grains, the concentration of oxygen vacancies in the intergranular spaces is rather small, and penetration of hydroxy groups inside the pellet is hindered. The penetration depth of water molecules into a textured specimen after ageing in water for 10 h at room temperature is 5 times smaller than the depth of its penetration into an isotropic ceramic.

Isothermal oxidation of hydrated $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic is accompanied by a stepwise increase in the sample mass, which indicates the presence of two oxidation steps, 'slow' and 'fast'.¹⁸⁹ The oxidation rate decreases proportionally to the water concentration in the material. The OH^- ions play a role of stoppers for defects of different dimensionality (oxygen ions, twinning structure boundaries) in their movement through the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ lattice. Presumably, during the 'slow' oxidation stage of the yttrium ceramic, the boundaries of the twinning structure between the crystallites of this compound are in the state of accelerated movement due to thermal activation and 'stripping' of these boundaries from localised proton-containing ions in the near-surface zone. Subsequent movement of these boundaries occurs in the matrix free of impurities.

The $\text{YBa}_2\text{Cu}_4\text{O}_8$ ceramic and $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ specimens with an admixture of silver are much more stable against moisture than non-doped $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic.^{190, 191} This is explained by a more compact arrangement of granules consolidated by metallic silver particles in doped ceramics; this evidently interferes with fast diffusion of the water molecules in the material bulk. The effect of silver on the stability of powders with composition $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ in a humid atmosphere was studied.¹⁹² The composition of the surface was studied using an electron probe X-ray microanalyser and X-ray photoelectron spectroscopy. If the water content in the powder is above 1.6 mass %, silver (5 mass % – 15 mass %) has a stabilising effect. In order to increase the critical current, it is recommended to add 15 mass % of silver to the moist powder (1.6 mass % H_2O). On the surfaces of ceramics containing this amount of silver, the latter is present in the form of separate inclusions. At the Ag content of 5 mass % – 15 mass %, superconductivities of the ceramics remain practically the same as those for the original $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ specimen.

If the $\text{EuBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic is treated with water, the evolution of oxygen is preceded by dissolution of an insignificant amount of Ba^{2+} ions ($\sim 7\%$ of the total amount of barium in the ceramic).¹⁹³ The europium ceramic is much more stable than the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic, which undergoes 50% decomposition in a humid atmosphere at room temperature. Noticeable decomposition of $\text{EuBa}_2\text{Cu}_3\text{O}_{7-x}$ (i.e. evolution of gaseous O_2 and passage of Ba^{2+} cations into solution) starts 2 h after the contact with water at 333 K and occurs according to the equation:

The decomposition of the ceramic at 353 K starts almost immediately. Complete reduction of Cu^{3+} to Cu^{2+} occurs only at 373 K. The decomposition of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic in distilled water and in solutions of sodium sulfate and barium chloride was studied.¹⁹⁴ It was shown that the presence of barium ions interferes with the hydrolytic decomposition of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$; after treatment with 10^{-2} M aqueous solution of BaCl_2 , the ceramic retains superconductivity even after boiling.

Hydrolysis of the ceramic is accompanied by leaching of barium cations, and addition of sulfate ions to water which binds barium ions causes complete decomposition of the superconductor. This is explained by equilibrium displacement upon changes in the reaction product concentration in accordance with the thermodynamic laws.

An interesting feature of the behaviour of water present in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was noted.¹⁹⁵ It was found that the superconducting phase cannot release water at temperatures of oxidative annealing (673–873 K). It is believed that this results from geometrical factors related to lattice distortion as a result of oxidative annealing, which hinders the exit of proton-containing ions from the O(5) positions.

It was found by thermal desorption methods that water on the surface of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic can be physically adsorbed and structurally bound (in the latter case, the bond energy equals 145 kJ mol^{-1}).^{196, 197} The water molecules can occupy two types of positions, viz., the position in the yttrium plane between the CuO_2 planes and the position between two Cu(1) copper atoms (see Fig. 4).

EPR studies showed¹⁹⁸ that inclusion of water molecules into the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ lattice results in the appearance of the Cu^{2+} paramagnetic centres at the Cu(2) positions in the CuO_2 layers. The EPR signal intensity depends on the water content in the ceramic. It is assumed that these paramagnetic centres are formed due to non-uniform deformation along the CuO_2 plane rather than due to decomposition of the material.

A radiothermoluminescence study of the moisture-induced degradation of the $\text{RBa}_2\text{Cu}_3\text{O}_{7-x}$ type HTSC materials (R = Y, Sm, Eu, Ho) showed that barium hydroxide is the compound responsible for radiothermoluminescence.¹⁹⁹ The radiation intensity is much lower if the specimen contains a minor amount of the original compounds which did not react under the conditions of solid-phase synthesis of the HTSC material.

The possibility of protection of materials based on $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ from degradation in water vapour by applying coatings of paraffin, poly(vinylbutyral) and oxidised triglycerides of unsaturated fatty acids was studied.²⁰⁰ The last named was found to be the most effective.

5. The effect of Ar, He and N_2 adsorption

Noble gases, viz., Ar and He, as well as N_2 , do not react chemically with the material, and hence, the major factors of their effect on superconductivity can involve inclusion into the crystal structure of the material or surface 'charging' due to adsorption.

The effect of argon on the electric conductivity of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was studied.¹¹⁰ The specimens were kept for several days *in vacuo* (10^{-3} Pa) at room temperature, then purged for three days with pure argon at the same temperature. After that, they were analysed by the resistance method at currents of 50, 500 and 5000 μA . An abnormal dependence of the electric conductivity on temperature was found when the latter was increased from 200 to 300 K: the resistance of a sample abruptly almost doubled at a current of 50 μA ; the increase was only several percent at 500 μA , whereas no abnormal increase in resistance at all was observed at 5000 μA . Apparently, this dependence of the electric resistance on current in this temperature range cannot be due to any manifestation of superconductivity. An increase in the current flowing through a superconducting specimen should result in the violation of the superconducting state and in the increase in resistance, rather than in the opposite effect observed in the experiment.

An Auger scanning microscopic study of specimens treated with argon revealed the presence of argon atoms in the near-surface layer ($\sim 100 \text{ \AA}$). The observed phenomenon is explained¹¹⁰ by the oxygen disordering in the lattice on the superconductor surface and the formation of a tetragonal non-superconducting phase, which is responsible for the resistance increase, in the gaps between the granules. However, the resistance of the specimens treated with argon decreased with a decrease in

temperature. Apparently, this is due to the fact that below room temperature, oxygen and oxygen vacancies can become ordered, and the semi-conducting tetragonal phase can be transformed to the orthorhombic phase, which displays metallic properties.²⁰¹

An increase in T_c and J_c due to intercalation of simple gases into HTSC ceramics was observed repeatedly.^{110, 202–204} However, no reliable information on this phenomenon is available so far. Apparently, this can be associated with a very strong dependence of superconductivity of a material on its structure; because of this, small and hardly controlled changes in the crystal lattice parameters due to intercalation can change essentially the properties affecting superconductivity.

A substantial increase in T_c was observed upon low-temperature (~ 78 K) treatment of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ superconductor in N_2 , Ar, O_2 and He streams.²⁰³ In particular, T_c increased from 90 to 141 K upon treatment with nitrogen. Treatment with hydrogen did not affect T_c . The change in the superconducting transition temperature correlates with the duration of treatment. The change in the parameters of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ superconductivity was assumed to be due to the inclusion of the gas molecules in the superconductor lattice. This changes the energetic state of the lattice and hence increases the energy of interaction between the carriers of superconductivity current, *i.e.*, the Cooper pairs. If the temperature increases, the gas starts to desorb; the Cooper pairs become unstable, and the superconductor passes in the normal (non-superconducting) state. However, it is unclear from this explanation why gases as different in nature as nitrogen, argon, oxygen and helium behave similarly. It is known, for example, that helium is not adsorbed at all on solid surfaces at the liquid nitrogen temperature.²⁰⁵

In an attempt to reproduce the effects described above, Granados *et al.*²⁰⁶ failed to observe an increase in T_c during low-temperature treatment of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic with helium. Therefore, the results considered above are attributed to experimental errors. A reason for the T_c increase could involve the rather fast heating of the specimen, which at certain helium pressures usually results in overestimation of T_c in resistance measurements.

Low-temperature treatment (77.4 K) of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic with nitrogen at normal pressure and with hydrogen at pressures up to 300 atm resulted in changes in T_c which increased or decreased depending on the duration of treatment.²⁰⁴ Similar results were obtained upon treatment of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with benzonitrile. After keeping the specimen in liquid benzonitrile for 11 h at room temperature, the T_c increased by 2 K. The T_c value was determined by measuring the electric resistance and magnetic susceptibility of a superconductor heated from 77.4 to 100 K. After several measurements, the original T_c value was almost restored. The similar effect of foreign molecules with completely different chemical properties on the superconductivity of the oxide $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ led to the conclusion²⁰⁴ that foreign molecules penetrate into the ceramics due to diffusion along the granule boundaries and microcracks, thus creating mechanical stress.^{207–209} The adsorbed phase propagating along the surface of a granule or a microcrack ‘bursts open’ the granules at the contact site, and the resulting mechanical stress can be quite strong. In the zones adjacent to the crack mouths, the ceramic material appears to be under huge pressure, which is believed to result in a local change in the superconducting transition temperature.

IV. The effects of adsorption and intercalation of organic molecules on the properties of high-temperature superconductors

The effects of organic compounds on the properties of superconductors are considerably more diverse than those of simple molecules. They can affect HTSC materials due to a number of their specific properties (ability to form complexes with metal

ions, to create regular layered structures that have electric conductivity, to be mechanically implanted in the superconductor material, to form charge transfer complexes), and also due to the possible presence of stable paramagnetic centres in their molecules.

1. Adsorption of organic compounds

The effects of adsorption of organic compounds on superconductivity was first studied on films of low-temperature metal superconductors.^{210–214} The adsorption of 3,4,7,8-tetramethyl-1,10-phenanthroline (TMP) on a thin vanadium film increased the superconducting transition temperature by 0.09 K.²¹⁰ The assumption was made that this effect is caused by the electronic properties of the adsorbed molecule, namely, the electronegativity parameter

$$\psi = \frac{I + A}{2},$$

where I is the ionisation potential and A is the electron affinity.

Subsequent studies covered a much wider range of organic molecules of various nature with a very wide range interval of electronegativities (Table 1).^{211–214} Thin vanadium and indium films (~ 10 nm thick) with $T_c = 2.4$ and 4.1 K, respectively, were used as superconductors. The films were obtained by vapour deposition of the pure (99.999%) metals in a high vacuum (10^{-6} Pa) onto a single-crystal quartz substrate. The molecules of organic compounds, mainly those with planar structures, were deposited on the films by evaporation *in vacuo* or by chemical methods. The superconducting transition temperatures and the critical currents before and after the adsorption were determined by the contact resistance method. For a vanadium film, good correlation was observed between the electronegativity and the sign of the T_c change upon adsorption of 14 different organic compounds. Adsorption of electron-donating molecules (anthracene, tetracene, perylene, *etc.*) with low electronegativity ($\psi \approx 3.9$ eV) caused an increase in T_c . Conversely, electron-acceptor molecules, for example, tetracyanoquinodimethane with $\psi \geq 5.5$ eV, decreased the T_c . Similar regularities were also noted for an indium film.

However, there are exceptions. For example, the superconducting transition temperature increased upon deposition of

Table 1. Changes in T_c upon adsorption of organic compounds on low-temperature metallic superconductor films and certain physicochemical parameters of these compounds.²¹⁴

Adsorbed compound	T_c /K	ΔT_c /K	I /eV	A /eV	ψ /eV
Thin vanadium film					
Anthracene	2.33	+0.10	7.23	0.42	3.83

Tripyridyl-s-triazine	3.6	+0.05	—	—	—
Titanium dicyclopentadienyl dichloride	2.42	−0.05	—	—	—
Thin indium film					
TMP	4.1	0.00	8.65	—	—
TCQDM	4.09	−0.23	—	1.7	>5.5

Note. TMP is 3,4,7,8-tetramethyl-1,10-phenanthroline; TCQDM is tetracyanoquinodimethane.

electron-accepting tripyridyl-*s*-triazine molecules on a vanadium film. The electron-donating TMP molecules affected vanadium and indium films differently: the adsorption of TMP on the vanadium film increased T_c , whereas that on the indium film did not change T_c .²¹⁴ This was explained by the formation of a 'metal atom – organic molecule' complex. In the case of vanadium, which is a transition metal, a bond is formed between an unoccupied *d* orbital and a molecular π orbital of the organic molecule; this favours the transfer of an electron to the superconductor film and hence changes its superconductivity. Unlike vanadium, indium does not have a similar *d* orbital, therefore TMP adsorption does not affect its properties.

In yet another work,²¹⁴ the effects of the adsorption of organic compounds on the critical current of superconducting films was also studied. The adsorption of electron donors, *viz.*, tetracene and perylene, on a vanadium film resulted in an increase in the critical current. Although a rather good correlation exists between the electronegativity of organic molecules, ψ , and the critical parameters of superconductivity of the vanadium film, I_c and T_c , the detailed mechanism of this phenomenon remains unclear. This can be due to charging of the superconducting film surface upon adsorption of organic compounds. For example, it was shown²¹⁵ that the superconducting transition temperature of an indium film depends on the surface charge sign. A strong acceptor, TCQDM, 'withdraws' electrons from the superconductor bulk, the concentration of the charge carriers decreases, and T_c decreases by 0.23 K. A decrease in T_c was also observed in an external electrical field where the film surface was charged positively.

With the advent of oxide-based HTSC materials, research into the effect of adsorption of organic compounds on the critical parameters of superconductivity has gained new impetus. An organic dye, octaethylporphyrin, was applied onto a plate 3 mm long and 50 μm wide made of a 100 nm thick $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film on a MgO (100) single crystal substrate.²¹⁶ After cooling the specimen below T_c , the superconductor was irradiated, and the dependence of the current on the wavelength of incident light was measured. The system response to the light and the wavelength selectivity were much more significant at temperatures below T_c . The strongest response estimated as the current passing through the plate was observed at a wavelength of 600 nm corresponding to the maximum absorption of the dye.

The effect of a deposited conducting polymer, polypyrrole, on superconductivity of an $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film was studied.²¹⁷ The electric conductivity of the film at temperatures higher than T_c , as well as the T_c itself, depend on the electric properties of the polymer. The dielectric polymer little affects the electric properties of the film. The polymer in the conducting or oxidised forms decreases T_c of the superconducting film by 15 K. Chemical or electrochemical reduction of the polymer results in restoration of the original T_c value. In order to explain these phenomena, the authors put forward two assumptions: (1) the polymer in the oxidised state does not affect the concentration of weakly bound oxygen in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film, and hence the change in T_c is not related to oxygen; (2) the observed change in T_c is caused by the 'proximity' effect, *i.e.* partial penetration of the Cooper pairs into the conducting polymer layer.

In continuation of these experiments, temperature dependences of the contact resistance at the boundaries between the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, $\text{GdBa}_2\text{Cu}_3\text{O}_{7-x}$ and $\text{Bi}_{1.7}\text{Pb}_{0.3}\text{Sr}_{1.6}\text{Ca}_{2.4}\text{Cu}_3\text{O}_{10}$ HTSC ceramics, on the one hand, and the oxidised form of a deposited conducting polymer, poly(3-hexylthiophene), on the other hand, were studied.²¹⁸ The electric resistance of this contact decreases around T_c . It was assumed that ceramics in the superconducting state can induce a kind of superconductivity in the polymer, in other words, this phenomenon can be directly related to the 'proximity' effect.

Exposure of an $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powder to organic donor-acceptor electron-transport (DAET) systems (for example, $\text{DMF}-\text{CCl}_4$, 2,2'-bipyridyl-monoethanolamine, $\text{DMSO}-\text{CCl}_4$, *etc.*) was accompanied by partial etching of the ceramic without

considerable change in its phase composition.^{219,220} Etching removes the labile near-surface oxygen and exposes the more perfect structured layers; the contact between the granules and their ability to sinter are improved. The concentration of oxygen in the material bulk does not change. Thus, etching of HTSC ceramics powder with DAET-systems under mild conditions results in modification of the surface layers of the species and is accompanied by stabilisation of the superconducting state and improvement of the superconductor quality.

Room-temperature treatment of an $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powder with an excess of 1-hydroxy-2,2,6,6-tetramethylpiperidine (HTMP), which is readily oxidised into a stable nitroxyl radical even on treatment with atmospheric oxygen, is accompanied by extraction of weakly bound oxygen from the specimen bulk.²²¹ An EPR study of the radical accumulation kinetics made it possible to determine the amount of the oxygen extracted and to estimate the activation energy of this process. The determined activation energy, $\sim 16 \text{ kJ mol}^{-1}$, is comparable with E_a for the diffusion of highly reactive oxygen in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$. It is much smaller than the values that characterise the evolution of weakly bound oxygen to the gas phase upon thermal desorption (at $x < 0.006$, $E_a = 120 \text{ kJ mol}^{-1}$). Apparently, this difference can be explained by the fact that HTMP adsorbed on the ceramic lowers the activation barrier for oxygen exit from the surface layer of the specimen. As the weakly bound oxygen is extracted, the superconductivity is impaired and disappears completely if more than 0.03 a.u. of oxygen is lost. Since a rather small change in the oxygen content cannot cause such a strong degradation of the superconductor, the actual major role is probably played by the magnetic moment of stable nitroxyl radicals formed during HTMP oxidation (see below). In another study,²²² the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was converted into a metastable state by mild removal of oxygen from the O(4) position (see Fig. 1*b*) at 523 K using a different organic reducing agent, namely, azobenzene. The type of the kinetic dependence for oxygen removal from the Cu(1) layers allows one to assume that it involves the diffusion mechanism. The dynamics of the change in the crystal lattice parameters *a*, *b* and *c* depending on the oxygen concentration was followed. Subsequent treatment of the ceramic with iodine resulted in restoration of the lattice parameters to the original values (*i.e.* to those before the reaction with azobenzene).

Treatment of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ with methanol²²³ containing $\sim 20 \text{ mass } \%$ of HTMP and 10% KOH as an HTMP oxidation catalyst²²⁴ was also accompanied by extraction of weakly bound oxygen from the ceramics. The superconductivity parameters of the ceramics after this treatment strongly depended on their initial properties and on the methods of preparation. The superconductivity parameters of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ specimens obtained by cryochemical technology (A) and by self-propagating high-temperature synthesis (B) changed essentially upon contact with HTMP and KOH in methanol at 313 K for 120 min. The superconducting transition temperature of the specimen A decreased strongly (to 60 K). This was explained²²³ by removal of reactive oxygen from the O(4) and O(5) positions of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ crystal lattice. The specimen B displayed no trend to form a phase with $T_c = 60 \text{ K}$, and the change in its superconducting transition temperature was smaller. This phenomenon is due to the specifics of structural transformations on the ceramic's surface, which hinder oxygen diffusion from the specimen bulk.^{225,226} These transformations were not observed in the oxygen extraction from the $\text{Bi}_2\text{Sr}_2\text{CaCu}_3\text{O}_{8+x}$ ceramic, and the superconductivity was suppressed completely. However, brief treatment with HTMP (15 min) increased the superconducting transition temperature by 13 K. It should be noted that a similar phenomenon was observed upon removal of a small amount of oxygen ($x \approx 0.03$) from the $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ ceramic.^{227–230} This is probably due to the extraction of the highly reactive oxygen intercalated between the $\text{BiO}-\text{O}(\text{Bi})$ layers and the essential increase in the unit cell parameter *c*. Prolonged treatment

did not change T_c , but the fraction of the superconducting phase decreased to complete loss of superconductivity.

The much weaker effect of treatment with methanol containing 10% KOH on the specimen A than on the specimen B was explained by the higher oxidising and catalytic activity of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic obtained by self-propagating high-temperature synthesis.²³¹ The extraction of oxygen from $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ was accompanied by an insignificant decrease in the fraction of the superconducting phase and, as in the previous case, an increase in the superconducting transition temperature by 11 K. The difference between the effect of the 10% KOH solution in methanol and the effect of the HTMP solution in methanol is due to the fact that methanol cannot react with the weakly bound oxygen responsible for the material superconductivity.

In one of the first studies on the chemical modification of HTSC material surfaces,²³² various ferrocene derivatives containing aminoalkyl, aminoaryl, thiol, phosphino, amide and hydroxymethyl functional groups were adsorbed at room temperature onto the surfaces of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic and thin film from a solution in acetonitrile. The solution concentration of the reagents was 10^{-3} mol litre $^{-1}$. It was shown by cyclic voltammetry that only molecules containing aminoalkyl, aminoaryl and thiol groups are adsorbed. This implies that preferential adsorption occurs on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface. Ferrocenes containing such substituents as amide, phosphino and hydroxymethyl groups are virtually not adsorbed on HTSC materials. The pronounced ability of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ to adsorb amino groups is explained by the presence of the Cu(II) and Cu(III) ions on its surface. The adsorption of ferrocene derivatives with thiol groups is explained by the high oxidising ability of the superconducting material, on the one hand, and by the reducing properties of thiol groups, on the other hand. Treatment of thin $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film with solutions of various ferrocene derivatives in acetonitrile for 3 h at room temperature did not affect its superconductivity. An increase in the treatment time to 48 h decreased T_c by 2 K. It was noted that covering of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface with a monolayer of molecules of substituted ferrocenes makes the HTSC material resistant against moisture.

Cyclic voltammetry was used to study the effect of small amounts of water on the adsorption of 11-mercaptoundecanoyl-ferrocene (MUF) on the surface of the $\text{Ti}_{1.4}\text{Ba}_2\text{CaCu}_2\text{O}_z$ ceramic.²³³ The presence of 5% water in a 0.1 M solution of MUF in acetonitrile decreased considerably the degree of coverage of the ceramic's surface with MUF molecules. If ethanol was used as the solvent, adsorption virtually did not occur. However, adsorption of MUF from dehydrated solvents gave a dense and stable monomolecular layer of chemisorbed MUF. It is believed that water affects adsorption due to a BaCO_3 layer formed as a result of corrosion, which does not adsorb MUF.

Direct proof of the chemical interaction between the amino groups and the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ surface was obtained in studies using Raman spectroscopy.²³⁴ It was shown that 4-aminopyridine molecules are chemisorbed on the superconductor surface to form a dense monomolecular layer of vertically arranged molecules; the amino group is coordinated with the surface copper atoms of the superconductor (Fig. 7).

A small review of the early studies on the adsorption of organic molecules on HTSC materials²³⁵ presented data on the chemisorption of ferrocenes containing various ligands, on the Raman spectra of monomolecular layers on HTSC material surface and on the kinetics of adsorbent-adsorbate exchange. Special attention was given to the practical use of HTSC materials modified with adsorbed organic molecules. For example, monolayer adsorption of hydrophobic molecules on HTSC materials can be used to prevent their corrosion in a humid atmosphere. In addition, this treatment increases considerably the adhesion between the polymer and the HTSC material. Superconductors coated with a monolayer of organic molecules can serve as the basis for obtaining synthetic tunnelling contacts used in super-

Figure 7. Coordination of adsorbed 4-aminopyridine molecules on the surface of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ HTSC ceramic.²³⁴

conducting quantum interferometer probes. They can also be useful for solving a number of fundamental problems of the physics of HTSC materials.

Adsorption of naphthalene on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic was accompanied by an increase in T_c and the transport critical current.²³⁶ The treatment was carried out by immersion of samples in chloroform solutions of naphthalene of different concentrations. According to gravimetric data, this treatment results in covering of the surface of the samples with a shell of naphthalene molecules from one to several hundred monolayers thick. The transport critical current was measured with a vibrating magnetometer using a ring cut from the ceramic under study; the superconducting transition temperature was determined by recording the real part of magnetic susceptibility. Adsorption of naphthalene from 0.2 M solution in chloroform did not affect the critical superconductivity parameters of the specimen. An increase in the naphthalene concentration to 1 mol litre $^{-1}$ increased the T_c by 1.5 K. Further increase in the naphthalene concentration did not change T_c considerably. For example, the T_c increase due to treatment of the specimen with a saturated solution (3.5 mol litre $^{-1}$) was 1.62 K. If naphthalene is washed off from the specimen with pure chloroform, the original superconducting transition temperature was restored almost completely (Fig. 8).

It has to be noted that the absolute value of the signal amplitude χ' did not depend on the treatment of the specimen. Hence, naphthalene adsorption does not change the fraction of the superconducting phase in the specimen. The transport critical current after naphthalene adsorption from a saturated solution increased by 20%. Additional experiments on measurements of the total current decay in a superconducting ring were carried out in order to analyse this interesting phenomenon. It was found that treatment of a specimen with naphthalene does not affect the decay rate and hence does not affect the pinning energy of the Josephson vortices.

The mechanism of the effect of adsorbed naphthalene on superconductivity has not been determined so far. Probably, a bond between an unoccupied d orbital of the Cu(III) ion in the superconductor and the molecular π orbital of naphthalene is

Figure 8. Temperature dependence of the real part (χ') of magnetic susceptibility of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic;²³⁶ (1) original specimen; (2) after treatment with saturated solution of naphthalene in chloroform; (3) after washing the treated specimen with pure chloroform.

formed, which favours electron transfer to the superconductor and hence changes its properties.

The change in the superconducting transition temperature caused by the naphthalene adsorption cannot be explained by donor-acceptor interactions, since interactions of electron donors with superconductors having hole-type conductivity most probably decrease the concentration of the charge carriers and hence decrease rather than increase T_c . The increase in T_c observed in the experiment is probably determined by the effective charging of the superconductor granule surfaces upon adsorption of naphthalene molecules.²³⁷

As shown above, the effect of adsorption of organic molecules on the properties of HTSC materials primarily results from donor-acceptor interactions or redox reactions involving copper and oxygen ions. On the other hand, the high sensitivity of the critical parameters of superconductivity to external magnetic field provides a reason to assume that the superconductor properties are strongly affected by paramagnetic species, *i.e.*, radicals possessing magnetic moments.

The effect of adsorption of a stable nitroxyl radical, 2,2,6,6-tetramethylpiperidin-*N*-oxyl (TEMPO), on the transport properties of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ superconducting ceramic was studied.^{238, 239} Adsorption was carried out at room temperature by immersing the ceramics in a 0.2–2.0 M chloroform solution of TEMPO. The specimen was kept in the solution for 12 h and dried in air. The critical current was measured as a function of temperature using a vibrating magnetometer. In reference experiments, the specimens kept in pure chloroform for 30 days did not show any effect of chloroform on the ceramic's properties. The superconducting transition temperature was measured by recording the magnetic susceptibility on an alternating current magnetometer. Figure 9 shows the dependences of the transport current I_c on temperature at various radical concentrations in the starting solution. It is evident that radical adsorption affects rather strongly the critical current in the temperature range from 77.4 to 86 K. At a content of adsorbed radicals in the ceramic equal to 1.7×10^{-2} mass %, the critical current was higher than that in the original non-treated specimen over the entire temperature range studied. Further increase in the content of radicals decreased I_c (see Fig. 9). The superconducting transition temperature of the ceramic before and after adsorption of radicals remained the same.

The mechanism of the effect of adsorbed molecules with their own magnetic moments on superconductivity is probably rather complicated. The results of additional experiments carried out specially to reveal the characteristic features of this effect were analysed within the framework of the intergranular conductivity

Figure 9. Temperature dependence of the critical current in the $\text{TEMPO}_y\text{-YBa}_2\text{Cu}_3\text{O}_{7-x}$ composite material at the following concentrations of the stable radical: 0 mass % (1), 1.7×10^{-2} mass % (2), 4.2×10^{-2} mass % (3), 8.5×10^{-2} mass % (4), 1.7×10^{-1} mass % (5).^{238, 239}

Figure 10. Dependence of the critical current extrapolated to 0 K and the exponent n in the Eqn (3) on the concentration of stable radicals TEMPO in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic.^{238, 239}

model.²⁴⁰ The general temperature dependence of the critical current for various contacts between the granules has the form

$$I_c(T) = I_c(0) \left(1 - \frac{T}{T_c}\right)^n, \quad (3)$$

where $I_c(0)$ is the critical current obtained by extrapolation to 0 K; n is an index reflecting the nature of contacts between the granules, which can vary from 1 to 2. Figure 10 presents the calculated dependences of the critical current $I_c(0)$ and the index n on the concentration of radicals.^{238, 239} It is evident that n is equal to 2 in the absence of radicals and $n < 2$ at their low concentrations. This means that upon adsorption of a radical, an SNS contact is transformed to an SNINS contact, or, in other words, the intergranular bond is improved and approaches a character close to the classical Josephson transition.²⁴⁰ On the other hand, the absolute value of the critical current also decreases, apparently due to the effect of the radical magnetic field on the intergranular bond. If the radical concentration is increased further, n eventually becomes equal to two. The change in the intergranular conductivity correlates with the change in the critical current $I_c(0)$. The increase in the latter at high radical concentrations is probably due to a specific behaviour of the highly concentrated magnetic media. For example, it is known that at a concentration of paramagnetic species above a certain value a significant change in the spin orientation is observed and the total magnetic moment of the medium decreases. Hence, in our case the increase in the concentration of stable radicals should weaken the effect of the magnetic moments on the conductivity of the intergranular layer, which is confirmed experimentally.

A study of the transport properties of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ HTSC ceramic upon magnetic field trapping by granules of the specimen showed that an increase in the critical current between the granules is actually observed at certain parameters of the magnetic field 'uptaken' by the granules.²⁴² Moreover, treatment of a superconducting ceramic ring with stable radicals does not change the decay rate of the current induced in the ring. Hence, additional pinning centres are not formed, and probably the increase in the transport critical current in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic after adsorption of stable radicals mostly occurs due to 'uptake' of magnetic field of a radical in the specimen granules. It was shown experimentally²⁴¹ that interaction of the Josephson and Abrikosov vortices can increase the critical current essentially. An effect on the intergranular bonding and the donor-acceptor properties of the stable radical, which probably manifests itself as a change in the index n in Eqn (3), cannot be ruled out either. However, the major role still belongs to the 'uptake' of the radical magnetic field into the specimen granules.

The critical parameters of superconductivity of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic containing adsorbed radicals depend on

the temperature to which a specimen has been cooled prior to the measurements.²⁴³ The type of the temperature dependence of magnetic susceptibility indicates an increase in the critical parameters of superconductivity upon cooling of the specimen. The explanation for this is that at lower temperatures, greater magnetic flux from the radical molecules is 'uptaken' by the granules, resulting in an increase in the critical parameters.

The effect of the adsorption of a stable diphenylpicrylhydrazyl radical (DPPH) on the superconductivity of the $\text{Bi}_{1.8}\text{Pb}_{0.5}\text{Sr}_{1.9}\text{Ca}_{2.5}\text{Cu}_{3.2}\text{O}_z$ ceramic was studied.²⁴⁴ Before an experiment, the surface of the specimen to be studied was freed from adsorbed water, CO_2 and organic contaminants by calcination in an oven at 473 K *in vacuo* for one hour. Then the cleaned specimen was transferred into a glass tube containing DPPH powder and sealed. The adsorption of DPPH was carried out by heating the tube to 473 K for 20 min. After that, the tube was broken, and the specimen was transferred into a cell for measurement of magnetic properties. For reference purposes, the procedure described above was also carried out in the absence of DPPH. The superconductivity parameters of the specimen under study were measured with an alternating current magnetometer. Figure 11 presents the temperature dependence of the magnetic susceptibility of the $\text{Bi}_{1.8}\text{Pb}_{0.5}\text{Sr}_{1.9}\text{Ca}_{2.5}\text{Cu}_{3.2}\text{O}_z$ ceramic. It is evident that upon adsorption of the radical, the curve shifts towards the low-temperature region; this indicates that the current-carrying ability of the specimen decreases. Thermal treatment of the ceramic also deteriorates superconductivity, but in this case the change is much less. The experimental values of magnetic susceptibility were compared with the real part of the magnetic susceptibility calculated within the framework of the simple Kim model.²⁴⁵ Good agreement between the experimental results and the calculations were achieved with the assumption that the intergranular layer is affected by a static magnetic field of 0.13 mT (see Fig. 11, curve 2).

Given the magnetic induction B , one can estimate the distance d between an adsorbed radical molecule and an intergranular contact:

$$d = \left(\frac{2\mu}{B} \right)^{1/3}, \quad (4)$$

where $\mu = g\beta S$ is the magnetic moment of the radical, $g = 2$ is the g -factor of a free electron, β is the Bohr magneton, $S = 1/2$ is the spin quantum number. Substituting the above value of $B = 0.13$ mT in the formula (4), we obtain $d = 5.6$ nm. This distance is in good agreement with the thickness of the non-superconducting layer, which is generally located on the superconductor surface and is estimated as 3–5 nm.²⁴⁶ Such consistency supports the suggested model of the effect of the magnetic

Figure 11. Temperature dependence of magnetic susceptibility of the $\text{Bi}_{1.8}\text{Pb}_{0.5}\text{Sr}_{1.9}\text{Ca}_{2.5}\text{Cu}_{3.2}\text{O}_z$ ceramic;²⁴⁴ (1) original specimen; (2) after adsorption of the DPPH radical; (3) after heating in a sealed tube for 1 h. Solid lines — experiment, dashed lines — calculated real part of magnetic susceptibility within the simple Kim model.

Figure 12. EPR spectra of the DPPH radical adsorbed on the surface of the $\text{Bi}_{1.8}\text{Pb}_{0.5}\text{Sr}_{1.9}\text{Ca}_{2.5}\text{Cu}_{3.2}\text{O}_z$ superconducting ceramic recorded at the temperatures: 77.4 (1), 89 (2) and 125 K (3).²⁴⁴

field of adsorbed radicals on the intergranular current in superconducting ceramics.

The EPR spectrum of the DPPH radical adsorbed on the surface of the $\text{Bi}_{1.8}\text{Pb}_{0.5}\text{Sr}_{1.9}\text{Ca}_{2.5}\text{Cu}_{3.2}\text{O}_z$ ceramic in superconducting state at 77.4 K consists of two lines (Fig. 12). As the specimen is heated, the high-field line of the doublet starts to shift downfield and, since the position of the low field line remains unchanged, splitting decreases. At 125 K, *i.e.*, at a temperature above T_c , the high-field line coalesces with the low-field one, and a singlet corresponding to the line in the EPR spectrum of the DPPH radical remains. It follows that the low-field line of the doublet, the position of which is not changed, corresponds to the adsorbed radical located at a great distance from the superconducting phase. For this reason, this phase does not affect the low-field line. The shift of the high-field line with the increase in temperature can be caused by the following reasons. First, the magnetic flux trapped by granules of a superconducting specimen (the Abrikosov vortices) located in an external magnetic field with $B_0 \approx 0.33$ mT changes the magnetic field parameters in the vicinity of the adsorbed radical. Second, the magnetic moment of the adsorbed radical has a 'mirror' image in the diamagnetic surface of the superconducting specimen, and probably the line position in the EPR spectrum of the radical is actually determined by the magnetic field of this 'mirror' dipole.

2. Intercalation of organic molecules into the crystal structure of high-temperature superconducting materials

A characteristic feature of HTSC materials is their layered structure which plays an important role in the transition to the superconducting state. As noted above and as has been shown by Bulaevskii,²⁴⁷ intercalation of atoms and molecules into the structure of layered solids changes essentially their chemical and physical properties. For example, intercalation of pyridine molecules into the TaS_2 superconductor was accompanied by a significant increase in the superconducting transition temperature (from 0.5 to 4.5 K).²⁴⁸ Hence, one can expect that intercalation of organic molecules in an HTSC material would affect strongly the critical parameters of superconductivity. It was even suggested that intercalation of organic molecules in layered inorganic materials can result in superconductors with high critical temperatures.²⁴⁹

Bismuth oxide- and thallium oxide-containing superconductors can be suitable objects for studying the effect of intercalation on superconductivity. In fact, the magnetic properties of the $\text{Bi}_{1.7}\text{Pb}_{0.3}\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_z$ ceramic with $T_c = 105$ K underwent interesting changes on treatment with benzene.²⁵⁰ A powder with a particle size of ~ 50 μm obtained by grinding bulk ceramic specimens was placed in benzene and kept at room temperature for a period from 10 min to 2.5 h. Then benzene was evaporated at 308 K, and the powder was placed in molten paraffin in order to

prevent electrical contact between the granules. As a rule, the specimens obtained by this method manifested weak paramagnetism with an absolute susceptibility of 10^{-7} or ferromagnetism with a magnetisation of 10^{-9} A m² g⁻¹.

Specimens of the ceramic that had been kept in benzene for 20–30 min had unusual electrophysical properties. First, rather high diamagnetic response was recorded at room temperature and hysteresis phenomena were observed in low magnetic fields. For example, the magnetisation in a field of 10 mT at 300 K was 8×10^{-6} A m² g⁻¹. Second, a stepwise change in the external magnetic field was accompanied by magnetisation relaxation. Third, if the temperature of the specimen was cycled in the range from 77.4 to 300 K, the initial magnetisation decreased gradually. For example, the maximum magnetisation of a specimen was 2×10^{-5} A m² g⁻¹ after the first cooling, whereas it was as low as 8×10^{-6} and 4×10^{-6} A m² g⁻¹, respectively, after the second and third cooling. Fourth, the EPR spectrum of the specimen at 300 K contained a low-field microwave absorption signal. Repeated cyclic changing of the specimen temperature decreased this signal. X-Ray diffraction analysis revealed additional reflections, apparently due to a new phase that was formed in the specimen. Such unusual physical properties of the Bi_{1.7}Pb_{0.3}Sr₂Ca₂Cu₃O_z ceramic containing intercalated benzene can be a manifestation of superconductivity. Therefore, the authors of this study²⁵⁰ believed that they could detect a small fraction of a superconducting phase in a specimen at room temperature. Unfortunately, the phenomena described above were only observed on some specimens. They could not be reproduced in other specimens, and the fraction of the superconducting phase could not be increased by varying the treatment conditions.

Later, a detailed study of the intercalation of planar aromatic molecules into superconducting ceramics was undertaken.²⁵¹ Intercalation of benzene and phthalocyanine complexes of copper and nickel into bismuth-containing ceramics, Bi₂Sr₂CaCu₂O_z and Bi₂Sr₂Ca₂Cu₃O_z, and into a thallium-containing ceramic, Tl₂Ca₂BaCu₂O_z, were carried out in sealed tubes at 273–423 K. As in yet another study,²⁵⁰ the ceramics studied displayed unusual physical properties at room temperature: the specimens retained magnetisation for some time after the external magnetic field was turned off; a low-field microwave absorption signal was observed; the magnetisation curves had unusual shapes; negative magnetisation was recorded in low magnetic fields (1–2 mT). X-Ray diffraction and Raman spectroscopic data showed that these organic compounds were located between the Tl–O or Bi–O double layers (see Fig. 1 c).

Intercalation of zinc and nickel phthalocyanine complexes also affected the properties of bismuth- and thallium-containing HTSC ceramics. In Ref. 252, as in previous studies,^{250, 251} unusual physical properties of these ceramics at room temperature were reported. For example, at 300 K the magnetisation of a metal phthalocyanine intercalated in the ceramics was found to be anomalously high, two orders of magnitude higher than the magnetisation of a free metal phthalocyanine complex. In the superconducting state (at 90 K), the magnetisation of the ceramics with the intercalated complex was one order of magnitude smaller and was equal to 10^{-2} A m² g⁻¹. The temperature dependence plots of the magnetisation of (NiPc)_{0.1}Bi₂Sr₂CaCu₂O_z and (NiPc)_{0.09}Tl₂Ca₂BaCu₂O_z specimens (Pc = C₃₂H₁₆N₈) obtained on cooling in magnetic fields and without a field showed noticeable differences starting from 250 K. Such unusual magnetic properties can indicate that the specimens display superconductivity at rather high temperatures. Certain assumptions on the nature of the observed phenomena were made.^{250–252} It was assumed that molecules of aromatic compounds characterised by strong electron delocalisation form new composite materials when introduced into the structure of a layered superconductor. These materials manifest unusual physical properties which resemble in certain respects the properties of superconductors; this is primarily due to the possible formation of quasi-species — ‘anyons’ with

half-integer statistics. It was shown theoretically²⁵³ that similar quasi-species present in two-dimensional electronic systems can generate a superconducting state, the transition to which occurs by a mechanism different from the generally accepted one and which is characterised by a higher T_c .

In addition, the superconductivity of intercalated composites can be explained using the exciton mechanism.²⁵⁴ In fact, intercalation of organic molecules into layered crystal systems results in ‘sandwiches’ that consist of alternating thin metal layers and dielectric intermediate layers. An electron–hole pair (exciton) can be formed in such systems. High magnetisation of intercalated bismuth- and thallium-containing HTSC oxides can also be due to the joint orbital contribution of π -electrons of aromatic molecules, which can form two-dimensional conducting layers due to the structural features of the material. According to X-ray diffraction data,²⁵² intercalation changes the material structure substantially. Not only do the distances between the structural Tl–O and Bi–O layers change, but also those between the atoms along the *a* and *b* axes (see Fig. 1 c). These transformations affect the electronic condition of the copper ion and result in transition from the usual phase with antiferromagnetic ordering of the copper spin states to the ferromagnetic phase. The effect of the amount of the metal phthalocyanine intercalated in the ceramics on this process was observed for the (NiPc)_yBi₂Sr₂CaCu₂O_z system.²⁵²

V. The effect of superconductivity on the electronic state of the adsorbed molecules and on adsorption processes

The effect of the substrate superconductivity on the fluorescence lifetime of an adsorbed dye, 1,4-bis(5-phenyloxazol-2-yl)benzene (POPOP), was studied.²⁵⁵ Adsorption of the dye on a YBa₂Cu₃O_{7–x} ceramic substrate was carried out by treating the specimen with a 10^{-3} M POPOP solution for 100 s in toluene followed by drying in air. As a result of this treatment, the width of the superconducting transition temperature of the substrate, $\Delta T = 1$ K, expanded to $\Delta T = 8$ K towards low temperatures. The fluorescence lifetime τ at each particular temperature was calculated using an exponential kinetic curve of the decay of the dye fluorescence excited by light with a wavelength of $\lambda = 330$ nm. Figure 13 presents the temperature dependences of the relative specific resistance of the substrate (ρ/ρ_{298} , where $\rho_{298} = 2 \times 10^{-3}$ Ω cm is the substrate specific resistance at 298 K) and the lifetime of fluorescence of adsorbed POPOP (τ). If temperature is decreased, an abrupt increase in τ is observed in the region of transition into the superconducting state. In control experiments, where the fluorescence lifetime of POPOP molecules adsorbed on a non-superconducting substrate with similar com-

Figure 13. Temperature dependences of the relative specific resistance of the YBa₂Cu₃O_{7–x} support and the fluorescence lifetime of POPOP adsorbed on this support.²⁵⁵

position was measured, no such dependence of τ on temperature was observed.

Thus, the abrupt increase in the lifetime of the electronically excited singlet state of POPOP upon temperature decrease is due to the specific features of the superconducting state of the substrate. Probably, the following aspects are most important. First, the transition of the ceramic in the superconducting state is accompanied by small structural changes of its crystal lattice,^{256, 257} which can affect the geometry of the adsorbed molecule and thus change the lifetime of the excited electronic state. Second, the transition into the superconducting state changes the dielectric constant of the surface layer of the HTSC material;²⁵⁸ this results in a change in the electric field strength near the surface and hence can affect the probability of nonradiative transitions of the excited molecules of the adsorbate. Third, the transition of the substrate in the superconducting state can weaken the interaction of the electronically excited adsorbate molecule with the conductivity electrons of the substrate, which also affects the luminescence lifetimes.

The effect of the substrate superconductivity on the electronic state of the adsorbed molecule was observed:²⁵⁸ the fluorescence quantum yield of an organic dye, erythrosine, adsorbed on a superconductor surface changed in a stepwise manner at the superconducting transition temperature of the substrate. A bulk ceramic specimen of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ($T_c = 87$ K), an epitaxial polycrystalline film of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ($T_c = 50$ K) and a low-temperature superconductor film of NdN ($T_c = 13.5$ K) were used as the superconductors. The fluorescence quantum yield of erythrosine applied on the low-temperature superconductor NdN underwent a small (5%) stepwise change at T_c , while the quantum yield above and below this point virtually did not depend on temperature. A different behaviour was observed where the dye was adsorbed on HTSC substrates. The fluorescence quantum yield of erythrosine adsorbed on a $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ polycrystalline film increased by 100% as the latter has passed in the superconducting state. The quantum yield of erythrosine adsorbed on the bulk $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramic changed substantially around the temperatures of 50 and 90 K, which correspond to two superconducting subsystems, *viz.*, the intergranular layers and granules, respectively. The conclusion was made²⁵⁸ that the fluorescence quantum yield of the dye changes upon transition of the adsorbate in the superconducting state owing to the change in the dielectric constant of the material.

An original way for the separation of diamagnetic and paramagnetic molecules on a porous membrane made of a superconducting material, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, was reported.²⁵⁹ In the superconducting state, the porous ceramic is 'transparent' for nitrogen molecules but does not pass the paramagnetic molecules of oxygen. The O_2 : N_2 concentration ratio decreased by a factor of six after a gas mixture (air) has passed through such a membrane. There was no gas separation effect with a non-superconducting membrane at the same temperatures, which is explained by high (comparable with the energy of thermal movement of molecules) energy of interaction between the magnetic moment of a triplet oxygen molecule and its mirror image in the superconducting surface of the membrane material. As a result, the effective cross-section of interaction of the oxygen molecule with the superconductor increases and a paramagnetic oxygen molecule penetrates the membrane with greater difficulty than a diamagnetic nitrogen molecule.

The features of interaction of HTSC materials with charged or magnetoactive species provide the possibility of using these materials for practical purposes. For example, the focusing of electron and ion beams passing through a superconducting tube made of HTSC ceramics was identified and studied.^{260–262} A theoretical estimate²⁶⁰ of the focusing effect of a superconducting surface on the beam of free electrons or ions showed that at certain velocities of the beam the focusing force can be comparable to, or even exceed, the force of Coulomb repulsion of the charged species in the beam. The vast experimental and theoretical material that

has been accumulated shows the possibility of using HTSC materials for these purposes.²⁶¹ For example, the passage of an electron beam through a superconducting tube from bismuth-containing ceramics with $T_c = 105$ K was studied experimentally:²⁶² an electron beam with an energy of 340 keV, an intensity of 0.8 kA and a diameter of 8 mm was directed into a superconducting tube. The electron beam leaving the tube was focused to a diameter of 1.1 mm.

The authors of the present review have thoroughly studied the interaction of a superconductor with magnetoactive species.^{263, 264} Specific features of the low-temperature adsorption and desorption of oxygen and argon on a 0.25–0.50 mm fraction of powder of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ superconducting ceramic were studied. The adsorption isotherms of argon and oxygen in the temperature range from 77.4 to 98 K were obtained.

The desorption curves coincided completely with the adsorption curves. Hence, the adsorption of argon and oxygen on the oxide $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ is reversible and can be regarded as physical adsorption. The experimental isotherms of the argon and oxygen adsorption in the entire temperature range studied correspond to the 'second type'²⁶⁵ and are well described by the BET polymolecular adsorption theory.²⁶⁶ The temperature dependence of the superconducting adsorbent specific surface calculated using the BET equation for oxygen adsorption differs essentially from the similar dependence obtained for argon adsorption (Fig. 14). According to the BET theory, the geometrical dimensions of the surface do not depend on temperature and are determined by the nature of the material. This assumption is totally consistent with the low-temperature adsorption of argon. The specific surface of the specimen measured with respect to argon was found to be $1.05 \text{ m}^2 \text{ g}^{-1}$.

Figure 14. Temperature dependences of the specific surface measured by the BET technique from adsorption of Ar (1) and O_2 (2, 3) on the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ adsorbent in superconducting (1, 3) and non-superconducting states (2).²⁶³

A different situation is observed for the adsorption of paramagnetic oxygen molecules. At 77.4 K where the adsorbent is in the superconducting state, the amount of oxygen adsorbed in a monolayer is more than twice as small as that in the case of argon. As temperature increases, the amount of adsorbed oxygen increases, and when the adsorbent is no longer in the superconducting state, oxygen is adsorbed exactly in the same way as diamagnetic argon (see Fig. 14). Adsorption of oxygen on a non-superconducting adsorbent prepared by heating the original superconducting adsorbent in air to 873 K followed by quenching to room temperature was studied for reference purposes. In this case, the specific surface does not depend on temperature, and its small decrease in comparison with the specific surface of the original superconducting adsorbent is apparently due to partial sintering of small granules during thermal treatment of the ceramic at 873 K.

The anomaly observed in the low-temperature adsorption of molecular oxygen on HTSC ceramics is undoubtedly due to the

paramagnetism of O_2 molecules and the superconducting state of the adsorbent. It is believed²⁵⁹ that perfect diamagnetism of the adsorbent in the superconducting state favours its additional interaction with the paramagnetic oxygen molecule. However, estimates show that the energy of repulsion between the magnetic moment of oxygen and its mirror image in the superconducting adsorbent can be comparable with the energy of thermal movement only at distances equal to the molecular diameter. This does not consider the London penetration depth of magnetic field into the superconductor and the thickness of the possible non-superconducting phase layer on the adsorbent surface. A more reasonable assumption is that the repulsive force arises due to the interaction between the magnetic moment and the magnetic flux 'uptaken' by the granules of the superconducting adsorbent.²⁶⁷

As the temperature is increased, the adsorbent diamagnetism decreases and the amount of adsorbed oxygen increases synchronously, tending to a limit which corresponds to complete surface coverage. Measurements of the 'pure' heat of adsorption

$$Q_a = q_{st} - q_L,$$

(where q_{st} is the isosteric heat of adsorption and q_L is the heat of condensation of the adsorbate on a planar surface) also indicate a significant difference between the adsorption of molecular oxygen on superconducting and non-superconducting adsorbents. As the surface of a non-superconducting adsorbent is covered with oxygen, Q_a decreases monotonically (Fig. 15). This agrees with the common concept of adsorption on non-porous solids with the 'classical' non-uniform surface. Conversely, Q_a increases in the case of oxygen adsorption on superconducting adsorbents. This can be a consequence of the formation of new adsorption sites as the surface is covered with oxygen molecules due to violation of superconductivity in the near-surface zone by the strong magnetic field of the adsorbed molecules.

In continuation of previous works,^{263, 264} the heat transfer from a heater to a superconductor by argon, nitrogen, helium and oxygen molecules was studied.²⁶⁸ It is well known that the heat transfer from gas to solid occurs efficiently only in the case if the collision of the gas molecules with the surface is inelastic. Therefore, based on the above data on the adsorption of paramagnetic molecules,^{112, 263} it can be assumed that oxygen transfers heat to a superconductor less efficiently than molecules which have no magnetic moment. The efficiency of heat transfer by gas molecules to the surface of the $YBa_2Cu_3O_{7-x}$ superconducting ceramic was estimated as the time required for heating the specimen to T_c . Specimens of the $YBa_2Cu_3O_{7-x}$ ceramic had different critical parameters: the specimen Y1 was characterised by a large strength of the first critical magnetic field of the granules $H_{c1g} = 1.02 \times 10^4 \text{ A m}^{-1}$ and $T_c = 89.1 \text{ K}$, while the specimen Y2 had the following parameters: $H_{c1g} = 1.4 \times 10^3 \text{ A m}^{-1}$ and $T_c = 91.3 \text{ K}$. The electron micrographs of the cross-sections of specimens Y1 and Y2 taken with a scanning electron microscope showed that their morphologies differ essentially: the specimen Y1

Figure 15. Dependence of the 'pure' heat of adsorption (Q_a) of oxygen on the $YBa_2Cu_3O_{7-x}$ ceramic in superconducting (1) and non-superconducting (2) state on the degree of surface coverage (θ) with molecular oxygen in the temperature range of 77.4–96 K.²⁶³

Figure 16. Scheme of measuring cell for recording the heating rate of HTSC materials in nitrogen or oxygen media;²⁶⁸ (1) external glass flask of the measuring cell; (2) heater; (3) quartz tube; (4) specimen; (5) capron thread; (6) thermal insulation.

consists of distinct oriented monolithic blocks with characteristic cross sizes of $\sim 40 \times 100 \mu\text{m}$, whereas the specimen Y2 consists of randomly oriented granules with an average size of $\sim 10 \mu\text{m}$.

The period from the moment when the heater has been turned on to the moment when the ceramic passes into the normal state was measured in different gaseous media in a cell (Fig. 16) placed in a mutual inductance coil for recording the magnetic susceptibility of the specimens. Figure 17 shows the experimental depend-

Figure 17. Dependence of the time required for heating a specimen to the superconducting transition temperature on the pressure of oxygen (1) and nitrogen (2) in the measuring cell;²⁶⁸ (a) measurements on the Y1 specimen; (b) measurements on the Y1 specimen coated with a paraffin film; (c) measurements on the Y2 specimen.

Figure 18. Dependence of the time of the Y1 specimen heating to the temperature of superconductivity loss on the external magnetic field strength.²⁶⁸

ences of time (t_c) required for heating the specimen to the superconducting transition temperature in a nitrogen or oxygen atmosphere on the pressure of these gases in the measuring cell. When the specimen Y1 was heated in oxygen, the time t_c was obviously greater than that in nitrogen. On the specimen Y2 and on the specimen Y1 coated with a paraffin film, the time t_c did not depend on the atmosphere in which heating was carried out. In addition, the time of heating of the specimen Y1 in oxygen depended on the strength of external magnetic field imposed on the specimen after cooling (Fig. 18). The time t_c remained unchanged if the strength of the external magnetic field did not exceed H_{clg} for the particular specimen. Further increase in field strength resulted in a decrease in t_c . Based on these experiments, it can be concluded that heat transfer by oxygen molecules to a superconducting specimen with high critical parameters occurs with lower efficiency.

The essential difference of the oxygen molecule from the nitrogen molecule is its magnetic moment, therefore it can be believed that its interaction with the superconductor is responsible for the observed phenomenon. As shown above,²⁶³ the magnetic moment of oxygen can favour the decrease in its adsorption on the superconductor surface. Apparently, in this case the oxygen molecules transfer heat less efficiently because they are elastically reflected from the superconductor surface. Taking into account that the character of collisions of oxygen molecules with a superconductor surface depends on its critical parameters, it is possible to suggest a new model of the interaction of the magnetic moment of oxygen with superconductors. In contrast to the previously suggested model of interaction between the magnetic moment and the Meissner superconductor phase,²⁵⁹ it is assumed^{267,269} that the repulsive force of the magnetic moment from the superconductor surface is described by the power function

$$F \propto d^{-n},$$

where the index n depends on the distance d between the magnet creating the magnetic field and the superconductor. At long distances and in the cases where the magnetic field strength of the magnet does not exceed the first critical field strength of the superconductor, $n = 4$; this corresponds to the ordinary dipole–dipole interaction. At short distances, *i.e.*, in sufficiently strong magnetic fields, the character of interaction of the magnet with the superconductor changes substantially. The magnetic field of the magnet penetrates into the superconductor bulk; as a result, the superconductor passes into a mixed state. In this case, interaction is described by the vortical model, according to which the magnetic flux from the magnet is ‘uptaken’ by the bulk of the granules, creating a grid of vortical lines reaching the superconductor surface and capable of interacting with the magnet. The interaction energy is expressed by the formula²⁷⁰

$$E = \frac{mH_{clg}\delta}{\pi d}, \quad (5)$$

where m is the magnetic moment and δ is the superconductor thickness. It should be noted that in this case the energy of interaction depends on distance much more weakly than in the Meissner model (d^{-1} instead of d^{-3}).

According to the estimate made, the energy of interaction between the magnetic moment of oxygen and the surface of the specimen Y1 is rather high and is comparable with the thermal energy kT at a distance $d \approx 5$ nm. This distance is much larger than the oxygen molecule size and the thickness of the possible non-superconducting phases usually present on HTSC surfaces. The energy of interaction with the surface of the specimen Y2 becomes equal to the thermal energy kT only at $d \approx 0.05$ nm, which is less than the oxygen molecule size, hence repulsion does not occur in this case. This agrees with the experimental results mentioned above.

Thus, superconductivity affects the adsorption and collision of paramagnetic molecules with the superconductor surface.^{263,264,268} It is important that these processes are also controlled by the external magnetic field.²⁷¹

Heterogeneous chemical reactions are very ‘sensitive’ to the state of the surface. The recoil force, which appears during desorption of hydrogen molecules which acquire nonequilibrium translational energy upon their recombination at the surface was measured after keeping a $YBa_2Cu_3O_{7-x}$ superconductor in a stream of hydrogen atoms.²⁷² The measurements were carried out by the weighing method in the temperature range of 78–350 K. The recoil force did not depend on temperature as long as the superconductor was in the ordinary state. After its transition to the superconducting state, a decrease in the recoil force was recorded. This was explained by a change in the magnetic state of the surface. The temperature dependence of the recoil force correlates well with changes in the relative intensity of the ferromagnetic resonance absorption of the superconductor. This correlation suggests that the recombination of hydrogen atoms occurs at the antiferromagnetically ordered Cu^+ surface ions. Cooling of the substrate changes the magnetic ordering and hence affects the concentration of the Cu^+ ions at the surface. The decrease in the recoil force below the superconducting transition temperature of the substrate is apparently due to magnetic shielding of the Cu^+ ions due to of the total diamagnetism of the superconductor.

The low-temperature catalytic reaction of the *ortho*–*para* conversion of molecular hydrogen on the superconducting catalyst $YBa_2Cu_3O_{7-x}$ was studied.^{273,274} The catalytic activity of the superconductor at various temperatures was estimated by chromatographic measurement of the amplitude of *para*-hydrogen signal on exit from the reactor. The temperature dependence of the effective rate constant of catalytic *ortho*–*para* conversion is

Figure 19. Temperature dependences of the effective rate constant of the *ortho*–*para* hydrogen conversion on the superconducting catalyst $YBa_2Cu_3O_{7-x}$ (1) and the real part of the relative magnetic susceptibility of this catalyst (2).²⁷³

presented in Fig. 19. One can see that the conversion rate decreases abruptly starting from 90 K. This temperature is close to the superconducting transition temperature of the catalyst determined from magnetic susceptibility (see Fig. 19, curve 2). Analysis of the possible magnetic mechanisms of hydrogen *ortho*–*para* conversion on oxide catalysts^{275–278} made it possible to conclude that the magnetic state of the catalyst's surface plays an important role in these processes. Before a catalyst is transferred to the superconducting state, *ortho*–*para* conversion of hydrogen occurs on the paramagnetic centres; the Cu²⁺ cations play this role in HTSC materials. Superconductivity changes essentially the magnetic state of the catalyst and it acquires a new property, *i.e.*, becomes a pure diamagnetic. The currents flowing along the surface shield the magnetic field of the paramagnetic centres and thus 'switch off' the basic mechanism of the low-temperature catalytic *ortho*–*para* conversion. As a result, the effective reaction rate constant decreases by several orders of magnitude.

VI. Conclusion

Analysis of the experimental and theoretical data presented above shows that the specific features of interaction of external molecules with HTSC materials are determined by a wide range of various physicochemical processes. The thermodynamic metastability of almost all of the known high-temperature superconductors^{60, 279, 280} probably has certain impact on the processes involved in the synthesis of HTSC materials and on the effects of external molecules on these processes. The study of superconductivity in HTSC materials requires rather complex problems to be solved. Of these, the reproducible synthesis and chemical stability of the final material present important problems. Apparently, the wide scatter of the experimental results for the thermodynamic characteristics, critical parameters of superconductivity, *etc.* reported by different authors is due to this problem. Nevertheless, a number of important conclusions can be made.

1. Depending on the temperature of treatment of oxide HTSC materials by foreign molecules of simple compounds, the phenomena resulting from their effect on the superconductivity of these materials can be separated in two groups.

The phenomena observed on treatment of HTSC materials at temperatures up to 473 K correspond to the first group. As a rule, such treatment little affects superconductivity. It is important that this problem is far from clarified even now, despite numerous publications on this matter. The experimental results obtained by different groups of authors and the conclusions made on this basis on the nature of the effect are usually contradictory and inconsistent. Nevertheless, studies in this temperature range are very important for understanding the physicochemical processes that occur on superconductor surfaces.

The second group includes phenomena caused by treatment of HTSC materials at temperatures above 473 K. Such treatment often affects strongly the parameters of superconductors. As a rule, the experimental results obtained in different studies are reproduced satisfactorily. The effect of simple molecules on the properties of superconductors in this temperature range is caused by the intercalation of molecules in its crystal lattice and/or by their chemical reactions with the ions of an HTSC material. As a rule, the action of simple molecules at temperatures above 473 K results in superconductivity degradation.

Intercalation of oxygen, which plays a key role in the formation of the superconducting phase, deserves special attention. Numerous studies showed that halogen molecules or atoms incorporated in the lattices of HTSC ceramics can play the same role as the oxygen atoms. For example, the non-superconducting tetragonal phase of YBa₂Cu₃O_{7–x} passes in the superconducting orthorhombic phase upon intercalation of halogens.

2. The range of effects of organic compounds on the characteristics of superconductivity is much more diverse. The first studies

along this line carried out on low-temperature superconductors showed that the donor–acceptor interaction of organic molecules with the superconductor material results in a considerable change in the critical parameters of superconductivity. The changes in T_c and I_c correlate with the electronegativity of the adsorbed molecules. Similar phenomena were observed later in the studies of HTSC materials.

The superconductivity parameters of oxide materials depend on the electronic properties of adsorbed molecules or a deposited polymeric film. Dielectric polymers little affect superconductivity, whereas conducting polymers decrease T_c . This effect is apparently due to the 'proximity' effect.

It has been proven that intercalation of planar organic molecules into the space between the crystal lattice layers in HTSC materials changes their characteristics considerably. In some cases the specimens display unusual physical properties.

Adsorption of stable organic radicals affects the magnetic state of the superconductor surface and the electric resistance of the intergranular layers; as a result, I_c changes.

3. In turn, superconductivity can affect noticeably various physicochemical processes occurring on the superconductor surface. For example, transition of a material into the superconducting state changes the luminescence characteristics of organic dyes adsorbed on the surface of an HTSC material (the quantum yield and the position of the maximum in the luminescence spectrum). Systems in which the energy of interaction between the superconductor and paramagnetic molecules from the environment is comparable with the energy of the adsorption interaction were found among HTSC materials. Owing to this, superconducting membranes can separate gas mixtures of paramagnetic and diamagnetic molecules. At the liquid nitrogen temperature, the superconducting adsorbent adsorbs paramagnetic oxygen molecules several-fold more weakly than diamagnetic argon atoms. This is probably due to the repulsive interaction of the magnetic moment of the molecule with the magnetic flux 'uptaken' by the specimen granules.

4. The low-temperature heterogeneous-catalytic *ortho*–*para* hydrogen conversion occurring at the paramagnetic centres of the adsorbent is also very sensitive to the surface state, and its rate decreases by several orders of magnitude as the catalyst passes into the superconducting state. This phenomenon can be explained by shielding of the catalytically active paramagnetic centres located on the superconductor surface, which is caused by the substrate diamagnetism.

IV. Synthesis of porphyrins	314
V. Synthesis of bisporphyrins	318
VI. Conclusion	322

Abstract. The methods for the synthesis of pyrroles, dipyrrolylmethanes and porphyrins derived from them are analysed, systematised and generalised. The bibliography includes 82 references.

I. Introduction

The methods for the synthesis of porphyrins are highly diverse and their choice is determined by the nature and mutual arrangement of substituents to be incorporated into the porphyrin molecule. Those suitable for the preparation of relatively simple porphyrins can be inapplicable for the synthesis of more complex compounds. Consideration of these methods is appropriate to begin with a brief survey of different types of porphyrins (compounds **1–4**).

The first type of porphyrins includes those which comprise identical substituents in the β -positions of the pyrrole rings and symmetrical *meso*-substituted porphyrins (compounds **1**). These compounds are usually prepared by one-step condensation of four identical pyrrole molecules into porphyrin.

The second type of porphyrins (porphyrins **2**) have a more complex structure which retains certain features of symmetry. These compounds are synthesised *via* intermediate dipyrrolylmethanes, -methenes and pyrroketones; since these molecules contain two different substituents, four isomeric products can be formed.

The third group of porphyrins includes porphyrins **3** with three different substituents and symmetrical dipyrrolic fragments. In some cases, dipyrroles can be used as precursors of porphyrins **3**.

The fourth type of porphyrins (porphyrins **4**) comprise more than three different substituents. Their synthesis is preceded by the formation of linear tetrapyrrole molecules which are closed to form the corresponding cyclic structures in the final stage. Thus, *a*- and *b*-oxobilanes, *b*-bilenes and *a,c*-biladienes are typically used as intermediate compounds.

To date, numerous novel procedures for the synthesis of porphyrins have been developed. However, all of them include the formation of methine bridges from methyl or bromomethyl groups in the α -position of pyrrole, dipyrrolylmethane or -methene. The choice of a synthetic procedure is largely determined by the desired symmetry of the porphyrin molecule. The syntheses based on the use of symmetrical dipyrrolylmethanes the cyclisation of which yields porphyrins with a high degree of symmetry (C_{2v}) are of particular interest in this respect. The obvious advantages of this method are the simplicity of preparation of starting dipyrrolylmethanes and sufficiently high yields (50%–60%) of porphyrins. Bisdipyrrolylmethanes were used in the synthesis of sterically hindered, dimeric and polymeric porphyrins.

II. Synthesis of pyrroles

Pyrroles are the key compounds in the synthetic chemistry of porphyrins. These compounds are readily available and yield porphyrins upon condensation. This circumstance determined the wide application of pyrroles in the synthesis of *meso*-alkyl- and *meso*-arylporphyrins including a whole array of sterically hindered porphyrins.

Unsubstituted pyrrole is usually prepared by pyrolysis of ammonium mucate.¹ Substituted porphyrins can be synthesised in two ways, *viz.*, by chemical modification of the macrocycle and by condensation of pyrroles with a predetermined set of substituents. The latter approach is more advantageous, since it provides greater scope for synthesis.

A vast variety of pyrroles have been described in the literature. The derivatives **5** containing electron-withdrawing groups are synthesised, as a rule, by the Knorr method,² *viz.*, by condensation of aminoketones **6** with β -dicarbonyl compounds **7**.

The aminoketones **6** are usually prepared by the reduction of the oximes which, in turn, are formed upon nitrosation of ketones or β -dicarbonyl compounds with sodium nitrite in glacial acetic acid.² Zinc in acetic acid is typically used as the reducing agent. Although the yields in this synthesis do not exceed 40%–60%, this procedure has found wide application owing to simplicity and availability of the starting compounds.

Kleinspehn³ performed the synthesis of α -ethoxycarbonyl (**10a**) or α -cyanopyrroles **10b** by condensation of oximes **8** with β -diketones **9**.

R¹ = CO₂Et (**a**), CN (**b**).

Later, it was shown⁴ that α -hydroxyimino β -keto esters, *e.g.*, compound **11**, can also enter into the reaction of reductive condensation with alkyl- β -diketones. This method was used in the synthesis of pyrrole **10a**.

Pyrroles containing a halogenomethyl or an acetoxymethyl group in one of the α -positions are most commonly used in the synthesis of dipyrrolylmethanes. Different approaches to the synthesis of these compounds were compared by Semeikin *et al.*⁵ α -Chloromethylpyrroles **12a** are prepared by treatment of pyrroles **10a** with sulfuryl chloride or *tert*-butyl hypochlorite on cooling.⁵ The yields of reaction products strongly depend on the temperature of the reaction mixture. Diethyl ether, dichloromethane or glacial acetic acid are used as the solvents. Bromination of α -methylpyrroles **10a** with molecular bromine in diethyl ether or acetic acid results in strong resinification which significantly reduces the yields of pyrroles **12b**.

(a) SO₂Cl₂ [**12a**, R² = Cl (85%)]; (b) Br₂ [**12b**, R² = Br (73%)];

(c) Pb(OAc)₄ [**12c**, R² = OAc (95%)].

Acetoxymethylpyrroles **12c** can be prepared by the reaction of the halogenomethyl derivatives **12a,b** with sodium acetate in acetic acid; however, direct oxidation of α -methylpyrroles **10a** with lead tetraacetate is more efficient.⁵ Acetoxymethyl derivatives are less readily hydrolysed and oxidised in air than compounds **12a,b**, which makes them especially attractive for further syntheses.

The methods for the synthesis of isomeric butylpyrrole derivatives in high yields have been proposed.^{6–10} The reaction of acetylacetone with butyl bromide in DMF or acetone in the presence of anhydrous potassium carbonate yields 3-butylpentane-2,4-dione; its condensation with ethyl hydroxyiminoacetate **11** in the presence of acetic acid and zinc dust gives 4-butyl-2-ethoxycarbonyl-3,5-dimethylpyrrole (**13**).

As a rule, α -monosubstituted pyrroles are the target products in such syntheses. The oxidation of the α -methyl group of pyrrole **13** with sulfuryl chloride in diethyl ether results in 4-butyl-5-carboxy-2-ethoxycarbonyl-3-methylpyrrole. Its decarboxylation is carried out in two steps, *viz.*, by substitution of iodine for the carboxy group by treatment with iodine and sodium hydrogen carbonate in aqueous ethanol and subsequent reduction of the α -iodopyrrole formed with tin dichloride. These reactions result in 4-butyl-2-ethoxycarbonyl-3-methylpyrrole (**14**) in sufficiently high yield.^{6–10}

A reaction sequence was proposed^{6–10} which leads to 3-butyl-2-ethoxycarbonyl-4-methylpyrrole (**15**), a key compound in the synthesis of many di- and tetrapyrroles,[†] from the readily available α -ethoxycarbonylpyrrole **13**. To this end, compound **13** was transesterified with benzyl alcohol; the resulting ester was oxidised with sulfuryl chloride at the α -methyl group and esterified with ethanol. The diester formed was subjected to hydrogenolysis on a palladium catalyst. The resulting 3-butyl-5-carboxy-2-ethoxycarbonyl-4-methylpyrrole was decarboxylated *via* the iodo derivative using a standard procedure:

The pyrroles **14** and **15** can be used for further transformations both directly and in the form of formyl derivatives which can be

[†] It is of note that only α -unsubstituted pyrroles containing a small methyl group in the vicinal β -position have previously been used in the synthesis of dipyrrolylmethanes.^{11–20} However, later it was found that the steric factor has no effect on the condensation reaction.^{7, 21–23}

easily obtained by the reaction of these pyrroles with dimethylformamide in the presence of phosphorus oxychloride or benzoyl chloride. In many reactions, *e.g.*, in chlorination with thionyl chloride, the aldehyde group is protected.^{7,24} To this end, formylpyrroles are treated with dicyanomethane; deprotection is carried out by alkaline treatment. This procedure was used in the synthesis of 4-butyl-5-chloromethyl-3-methylpyrrole 2-carbaldehyde from 3-butyl-2,4-dimethylpyrrole.

Dipyrrole structures in which pyrrole rings are linked through β -positions can be prepared from more readily available β -unsubstituted pyrroles.^{25–27} These structures and the possibilities of their chemical modification present special interest, since they permit the design of novel types of porphyrin molecules.

The acylation of 3,5-dimethyl-2-ethoxycarbonylpyrrole with the dicarboxylic acid chloride **16** and subsequent reduction of the carbonyl groups of the diketone **17** formed with diborane result in compound **18**. The bispyrrole **18** is further converted into the benzyl ester, which is further subjected to hydrogenolysis followed by decarboxylation and formylation, eventually resulting in the aldehyde **19**.²⁵ The formyl groups of the dialdehyde are protected with dicyanomethane as described above, which is followed by chlorination with sulfur chloride. This method was used in the synthesis of the dipyrrole derivatives **20**.²⁵

$n = 9-11$.

Later, Morgan and Dolphin²⁷ synthesised β -linked dipyrrolic derivatives containing an aryl fragment in their bridges. The acylation of 3,5-dimethyl-2-ethoxycarbonylpyrrole and subsequent reduction of the carbonyl group result in the hydroxy derivative **21**, which is converted into the iodo derivative **22** on substitution of iodine for the hydroxy group *via* the corresponding mesylate. The methyl group in compound **22** is eliminated from position 5 using the standard procedure, *i.e.*, *via* 5-iodopyrrole. Subsequent reaction with triphenylphosphine in boiling toluene affords the phosphonium salt **23**. Its condensation with 2,6-diformyl-4-methylanisole in dioxane in the presence of potassium carbonate results in the diene **24**. The final step in this synthesis is the catalytic hydrogenation of compound **24** leading to the target dipyrrole derivative **25** (Scheme 1).

Syntheses based on β -unsubstituted pyrroles are multistage processes, which is the common drawback, chemical conversions involve alternately α - and β -positions of the ring, which significantly complicates the synthesis. In our opinion, the use of relatively available α -unsubstituted pyrroles is more advantageous.

III. Synthesis of dipyrrolylmethanes

Porphyrins can also be synthesised from dipyrrolylmethanes and -methenes. However, both of them possess exceedingly high reactivity. This disadvantage can be overcome through the introduction of electron-withdrawing substituents. Synthesis of dipyrrolylmethanes containing such substituents is problematic. On the other hand, there exist simple and efficient procedures for the synthesis of stabilised dipyrrolylmethanes; their advantages in the synthesis of structurally complex porphyrins leave no doubt.^{28,29}

It has been established that the condensation of pyrroles **12a–c** occurs *via* pyrrolylmethyl carbocations stabilised due to the delocalisation of the positive charge.² Such cations are relatively stable both in inert solvents and in alcohols, carboxylic acids and even in water.

On boiling in ethanol in the presence of hydrobromic acid, pyrroles **12a–c** are converted into dipyrrolylmethanes in high yields.^{2,5,7,30,31} If such pyrroles contain alkyl substituents in the β -positions, dipyrrole compounds are obtained in up to 90% yields.

An efficient procedure for the synthesis of dipyrrolylmethanes containing butyl groups in positions 3 and 3' has been proposed.^{7–10,24,29,32} Bromination of the α -methyl group of the pyrrole **13** with subsequent condensation of 5-bromomethyl-4-butyl-2-ethoxycarbonyl-3-methylpyrrole in ethanol in the presence of an acid results in the 5,5'-diethoxycarbonyl derivative **26**; its alkaline hydrolysis affords bis(3-butyl-5-carboxy-4-methylpyrrol-2-yl)methane. As in the case of synthesis of bis(5-carboxy-3,4-dimethylpyrrol-2-yl)methane, lead tetraacetate proved to be the best oxidant for the starting pyrrole.⁵

Symmetrical dipyrrolylmethanes can also be prepared by the condensation of α -monosubstituted pyrroles with aldehydes. It is

self-evident that the β -positions of the pyrrole ring must be substituted with at least one electron-withdrawing substituent, which thus stabilises the product.³³ This reaction occurs under the same conditions as the self-condensation of the pyrroles **12a–c**.

The reaction of 2-benzyloxycarbonyl-3,4-dimethylpyrrole with benzaldehyde in ethanol in the presence of hydrochloric acid results in *meso*-phenyldipyrrolylmethane **27a**. Under conditions of acid catalysis, 3-butyl-2-ethoxycarbonyl-4-methylpyrrole (**15**) reacts with benzaldehyde to give dipyrrolylmethane **27b**.⁸ It was shown^{7,23} that the reaction of 4-butyl-2-ethoxycarbonyl-3-methylpyrrole (**14**) with benzaldehyde and its derivatives (XC₆H₄CHO, X = OMe, NO₂, NMe₂) in the ethanol–hydrochloric acid system results in *meso*-aryl-substituted dipyrrolylmethanes **27c–i** in good yields. Similar to compounds **27a,b**, these products (except for compound **27i** which undergoes resinification) are converted into the corresponding dicarboxy derivatives upon alkaline hydrolysis.

^a Y is *meso*-substituent.

The above-described procedure is widely employed in the synthesis of bisdipyrrolylmethanes.^{13–16, 18, 22} The reaction of pyrroles **28a–c** with dialdehydes in acid media gives high yields of compounds **29** the dipyrrolic fragments of which are linked through the *meso*-positions.

R = H (**a**), Et (**b**), Bn (**c**);

X = (CH₂)_n (n = 4, 6, 12), , , ,

3-Methyl-2-ethoxycarbonyl-4-ethylpyrroles are easily condensed in acid media with dialdehydes **30** the phenyl fragments

of which are linked by ether bridges [O(CH₂)_nO] of different lengths (n = 2–4).²³ The resulting esters **31** are easily hydrolysed to the corresponding acids in alkaline media.

n = 2–4.

Compounds with fundamentally different structures can be prepared on the basis of β -linked pyrroles. The condensation of bispyrroles **32** containing chloromethyl groups with 2-benzyloxycarbonyl-4-ethyl-3-methylpyrrole in acetic acid results in bisdipyrrolylmethanes **33** the dipyrrolic fragments of which are linked by methylene bridges through the 3,3'-positions (n = 9–11) (Scheme 2).²⁵

An alternative approach involves the condensation of 5,5'-unsubstituted bispyrrole **34** with the α -chloromethyl derivative **35** (Scheme 3).²⁷

The reaction of compounds of the type **12a–c** with α -unsubstituted pyrroles gives nonsymmetrical dipyrrolylmethanes. It was proposed³⁷ to start from bromomethylpyrrole in a sodium acetate–glacial acetic acid buffer. It is the intermediate acetoxy-methylpyrrole formed that enters into the reaction. Unfortu-

Scheme 2

n = 9–11.

Scheme 3

n = 5, 6.

nately, this reaction yields a large amount of the symmetrical dipyrrolylmethane as the side product.

The reaction of pyrroles **36** and **37** in the presence of *p*-toluenesulfonic acid in AcOH gives dipyrrolylmethane **38** in 85% yield.³⁸

Other methods for the synthesis of dipyrrolylmethanes are less popular. If chemical modification of dipyrrolylmethanes is envisaged, allowance must be made for the fact that their stabilities and reactivities with respect to electrophilic reagents are similar to those of pyrroles. Dipyrrolylmethanes are stable if they contain at least one electron-accepting group in each of their pyrrole nuclei. Also the methylene unit in dipyrrolylmethanes is readily oxidised to form dipyrrolylmethenes or ketone.

Dipyrrolylmethane 5,5'-dicarboxylic acids are prepared by heating the corresponding 5,5'-diethyl esters with aqueous alkalis with subsequent precipitation of the reaction product with a mineral acid or by hydrogenation of 5,5'-dibenzyl esters on a palladium catalyst in THF at atmospheric pressure and at room temperature.^{7, 32}

Heating of dry bis(5-carboxypyrrol-2-yl)methanes is accompanied by profound destruction; therefore, McDonald *et al.*³⁹ proposed to conduct the decarboxylation in sealed tubes in aqueous solutions of alkalis at 170–180 °C, which causes only partial destruction. In an alternative procedure,⁴⁰ the decarboxylation is carried out by boiling the dicarboxylic acids prepared from diethyl esters in DMF in an inert atmosphere.

N,N-Diethylformamide was used as a solvent for increasing the boiling temperature of the reaction mixture.⁴¹ Unfortunately, the decarboxylation of dipyrrolylmethane **39** is accompanied by intramolecular rearrangements. Subsequent formylation gives a mixture of dialdehydes **40** and **41** in a total yield of 60%.

DEF is *N,N*-diethylformamide.

If dipyrrolylmethanes have different substituents in the β-positions of the pyrrole ring, a mixture of isomeric products can be formed. To avoid this, the decarboxylation is carried out in two steps. First, the carboxy groups are substituted by iodine and then the iodo derivatives are reduced, *e.g.*, with tin(II) chloride.^{2, 7, 29}

Dipyrrolylmethane dicarboxylic acids can be decarboxylated by trifluoroacetic acid (TFA). It was found⁴² that 5,5'-unsubstituted dipyrrolylmethanes thus formed are stable in TFA at room temperature for a week. Trifluoroacetic acid was used, for example, for decarboxylation of 5-benzoyloxycarbonylpyrrol-2-yl-5'-*tert*-butoxycarbonylpyrrol-2'-ylmethane.⁴² However, TFA can induce intramolecular rearrangements in dipyrrolylmethanes.

Heating of carboxy derivatives in aqueous alkalis in the presence of hydrazine as a stabiliser seems to be the method of choice for decarboxylation of β-alkylated dipyrrolylmethanes.^{8, 29} In this case, the yield of the target product reaches 85%.

Bis(5-formylpyrrol-2-yl)methane was obtained from bis(5-benzoyloxycarbonylpyrrol-2-yl)methane by the Wilsmeier reaction. The use of phosphorus oxychloride or benzoyl chloride results in dialdehydes with practically equal yields (45%–50%).³³

An alternative procedure for the synthesis of dipyrrolylmethanedialdehydes was proposed by Mamardashvili *et al.*²⁴ who used triethyl orthoformate in TFA as the formylating reagent. 5,5'-Dicarboxy derivatives of dipyrrolylmethanes obtained by hydrogenolysis of dibenzyl esters are first dissolved 5–10 minutes after the completion of decarboxylation and triethyl orthoformate is added to the reaction mixture. This enters into the reaction with the 5,5'-unsubstituted dipyrrolylmethane formed. Apparently, a part of dipyrrolylmethane undergoes rearrangement.

The synthesis of dipyrrolylmethanes from pyrroles containing electron-withdrawing groups, *e.g.*, cyano groups, is of particular interest. This method was developed by Dolphin *et al.*⁴³ for the

synthesis of bis(5-formyl-3,4-dimethylpyrrol-2-yl)methane. This reaction consists in the condensation of pyrroles **42** and **43** in dry dichloromethane in the presence of catalytic amounts of tin(IV) chloride resulting in dipyrrolylmethane **44**; its hydrolysis by heating on a water bath with a solution of KOH in aqueous ethanol gives a poorly soluble target dipyrrolylmethane. The yield of the final product can be significantly increased by performing deprotection in an inert atmosphere.

The synthesis of 5-formyl-5'-unsubstituted dipyrrolylmethanes deserves special attention. The first compound of this series, *viz.*, 3,3'-diethyl-5-formyl-4,4'-dimethyldipyrrol-2-ylmethane, was obtained by Dolphin *et al.*⁴⁴ using decarboxylation of

5-carboxy-5'-ethoxycarbonyl-3,3'-diethyl-4,4'-dimethyldipyrrol-2-ylmethane with subsequent Wilsmeier formylation of the resulting product (Scheme 4).

In the synthesis of the monoaldehyde **45**, the formyl group of the original pyrrole was protected by reaction with malononitrile.⁴⁵

The monoformyldipyrrolylmethanes of the type **46** commonly employed in the synthesis of linear tetrapyrrolic compounds⁴² can be prepared from esters of the corresponding dicarboxylic acids using various approaches (Schemes 5 and 6).

Scheme 4

Scheme 5

Scheme 6

Scheme 7

One of these approaches consists in thermal decarboxylation of intermediate 5-formyl-5'-carboxydipyrrolylmethanes; however, if the carboxypyrrolyl fragment contains electron-withdrawing groups, the reaction is carried out *via* iodo derivatives. The presence of even one electron-withdrawing aldehyde group increases the resistance of the methylene group of dipyrrolylmethane to oxidants and prevents intramolecular rearrangements, fragmentation and resinification. The monoformyldipyrrolylmethane **46** formed can be stored for a long period of time in a dry state in the absence of oxygen.⁴²

Unsymmetrical dipyrrolylmethanes **47** are formed in high yields in the reaction of α -ethoxycarbonyl-substituted pyrroles with compounds **48** containing chloromethyl and cyanovinyl (or cyanoacryl) groups in the α -positions. The latter deactivate pyrrole **48** and prevent its self-condensation. The condensation is carried out in inert solvents, *e.g.*, dichloromethane, dichloroethane, benzene, *etc.* The dipyrrolylmethanes of the type **49** are often decarboxylated upon heating with alkalis.⁴⁶ It should be noted that the cyanoacryl group which is hydrolysed more readily than the cyanovinyl group provides more efficient protection.

The common disadvantage of the syntheses based on monoformyl derivatives of dipyrrolylmethanes is the necessity to protect the aldehyde groups prior to chemical transformations.⁴⁶ Removal of protecting groups may provoke side reactions.

IV. Synthesis of porphyrins

Dipyrrolylmethanes have been widely used in the synthesis of porphyrins since 1960. McDonald *et al.*³⁹ developed a procedure for the condensation of bis(5-formylpyrrol-2-yl)methanes with 5,5'-unsubstituted dipyrrolylmethanes under mild conditions. This reaction is carried out in glacial acetic acid in the presence of hydroiodic acid in a highly dilute solution (Scheme 7).

This process involves the formation of *b*-bilene **50** and porphodimethene **51** which is partially converted into phlorine **52**. Both the intermediate products and the phlorine **52** can be oxidised with atmospheric oxygen to yield porphyrin **53**. In some cases, self-condensation of the original bis(5-formylpyrrol-2-yl)methanes may occur to a certain extent. The yields of the porphyrins **53** prepared by condensation of symmetrical dipyrrolylmethanes by the method of McDonald are given in Table 2.

The condensation of bis(3-butyl-4-methylpyrrol-2-yl)methane with bis(3-butyl-5-formyl-4-methylpyrrol-2-yl)methane in ethanol in the presence of hydrobromic acid and subsequent oxidation of the reaction mixture with *o*-tetrachloroquinone results in 3,7,13,17-tetrabutyl-2,8,12,18-tetramethylporphyrin in 24% yield.⁹

A method for the synthesis of porphyrins from 5-formyl-5'-unsubstituted dipyrrolylmethanes has been proposed.⁴⁵ Self-condensation of compound **45** in glacial acetic acid in the presence of small quantities of acetic anhydride and hydrobromic acid gives 2,6-diacetyldeuteroporphyrin-II **54**.

R = (CH₂)₂CO₂Me.

Note. The reaction was carried out in glacial acetic acid containing HI. ^a HCl was used instead of HI.

A series of sterically hindered (strapped) porphyrins **55** were synthesised by condensation of bisformyldipyrrolylmethanes **56** in a dichloromethane – methanol mixture (30 : 1) in the presence of *p*-toluenesulfonic acid.²⁷

X is the residue of a saturated or an aromatic hydrocarbon.

Monoformyldipyrrolylmethanes have not found wide application in the synthesis of porphyrins due to their unavailability and the necessity to perform multistep syntheses.

The condensation of a symmetrical 5,5'-unsubstituted dipyrrolylmethane with triethyl orthoformate in formic acid was carried out.⁹ In this reaction, first the formylation of dipyrrolylmethane occurs followed by formation of the porphyrin. As this reaction occurs under drastic conditions, it can be accompanied by rearrangements of dipyrrolylmethane resulting in a mixture of isomeric porphyrins.

The condensation reactions of 3,3',4,4'-tetraalkyl-5,5'-unsubstituted dipyrrolylmethanes with aldehydes resulting in 5,15-dialkyl- and 5,15-diaryl derivatives of porphyrins are well documented in the literature.^{7–10} Initially, the oxidative condensation was carried out in one step, as in the case of synthesis of *meso*-tetraphenylporphyrins, *viz.*, in a boiling solvent in the presence of atmospheric oxygen.³³ In a pyridine – acetic acid mixture, the yield of porphyrins was rather low (~ 3%), but it was increased when the reaction was performed in benzene in the presence of TFA with high dilution of the reagents. It was shown^{49–52} that the use of a two-step procedure gives better results. The reaction of dipyrrolylmethane with benzaldehyde results in porphyrinogen **57**, which is further oxidised by benzoquinone derivatives to porphyrin **58**.

The yields of porphyrins **58** synthesised by this method are given in Table 3. The yield of porphyrin **58** (R¹ = Me, R² = Buⁿ, X = 2-OMe) does not depend on the solvating properties of the solvent (Table 4), which suggests high complexity of the reaction mechanism.⁵² The strength of the organic acid used as a catalyst only slightly affects the yield of the target product but the nature of the oxidant is a critical factor (Table 4). If the condensation is performed in a boiling solvent, the rate of the reaction is naturally increased with no decrease in the yield.⁵⁰

R¹, R² = Me, Et, Bu.

It is of note that rearrangements in dipyrrolylmethanes and/or intermediate tetrapyrroles in acid media result in the formation of monoarylporphyrins in addition to diarylporphyrins.³³ In some cases, the monosubstituted porphyrin is the main or even the only reaction product, especially at elevated temperatures. The nature of the substituent in the original dipyrrolylmethane and the presence of a *para*-substituent in the benzaldehyde molecule have little effect on the yield of the target porphyrins (Table 5).

The reaction of 5,5'-unsubstituted dipyrrolylmethanes with an equimolar mixture of two aromatic aldehydes gives unsymmetrical 5,15-diphenyloctaalkylporphyrins and a mixture of all the three feasible products, which have to be further separated by chromatography or, in some cases, by chemical modification. The closer are the electronic effects of the substituents in the aldehydes, the higher are the yields of unsymmetrical porphyrins.^{33, 53}

The condensation of the dialdehydes **59** with 5,5'-unsubstituted dipyrrolylmethanes affords 'capped' porphyrins **60** in sufficiently high yields.¹⁴ This method can be used for the synthesis of other complex systems containing octamethylporphyrin and etio-porphyrin fragments.^{13–16, 18, 22} Unfortunately, porphyrins containing methyl or ethyl groups in the β -positions of the macrocycle

5,5'-unsubstituted dipyrrolylmethanes aimed at enhancement of their solubilities.^{7–10, 24, 32, 67, 68} The yields of porphyrins in the reaction of bis(4-butyl-3-methylpyrrol-2-yl)methane with benzaldehyde in *o*-xylene–TFA, methanol–*p*-toluenesulfonic acid, chloroform–acetic acid systems and in acetic acid do not exceed 2.2%, 3%, 10% and 4.1%, respectively. In condensation of bis(dimethyl- and butylmethylpyrrol-2-yl)methanes with aliphatic aldehydes RCHO [R = Alk(C₂–C₇), C₁₁H₂₃] in TFA-containing chloroform followed by oxidation of the resulting porphyrinogens with *p*-tetrachloroquinone, the yield of porphyrins did not exceed 5%.⁹

The synthesis of porphyrins from 5,5'-dicarboxy derivatives of dipyrrolylmethanes, the synthetic precursors of 5,5'-unsubstituted compounds and 5,5'-diformyldipyrrolylmethanes, appeared to be more efficient. 5,5'-Dicarboxylic acids are far more stable than 5,5'-unsubstituted derivatives, and porphyrins are formed from them in higher yields and the amounts of poorly separable admixtures are much less than in the synthesis of porphyrins from the corresponding unsubstituted and formyl derivatives of dipyrrolylmethanes.

Jackson *et al.*⁶⁹ were the first to carry out the condensation of dipyrrolylmethane **61** with triethyl orthoformate in dichloromethane in the presence of trichloroacetic acid. This reaction gives coproporphyrin-II **62** in 25% yield. A series of *meso*-disubstituted porphyrins were synthesised^{7, 8} by a modified Jackson–Kenner method.⁶⁹ In the condensation of 3,3'-dibutyl derivatives of *meso*-aryldipyrrolylmethanes **63a** with triethyl orthoformate in chloroform in the presence of TFA, the yield of porphyrins **64a** was the highest (~35%). The substitution of monochloroacetic acid for TFA decreases the yield to 17% and in the chloroform–acetic acid system the yield is 10%. The yield of porphyrins **64b** in the reaction of 3,3'-dimethyl derivatives of *meso*-alkyldipyrrolylmethanes **63b** with triethyl orthoformate in chloroform in the presence of TFA is 20%–25%.^{8, 10}

R¹ = (CH₂)₂CO₂Me, R² = H (**61**, **62**);
 R¹ = Bu; R² = Ph, C₆H₄OMe-2, C₆H₄OMe-3, C₆H₄OMe-4, C₆H₄NO₂-3, C₆H₄NO₂-4 (**63a**, **64a**); R¹ = Me; R² = Alk(C₁–C₇), C₁₁H₂₃ (**63b**, **64b**).

This method is widely used in the synthesis of 'capped' porphyrins.^{11, 27} For example, the cyclisation of bisdipyrrolylmethane **65** results in porphyrin **66**.¹¹ The methoxy groups in the substituent X in compound **66** were converted into the carbonyl groups by demethylation with boron tribromide in dichloromethane with subsequent oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (the yield of the target product is 54%).

As noted above, octamethyl derivatives of porphyrins manifest low solubility. However, the yield of porphyrins decreases drastically if the methyl groups are substituted by bulkier alkyl groups in order to increase the solubility. It was found³² that condensation of 5,5'-dicarboxy derivatives of dipyrrolylmethanes with aldehydes in pyridine in the presence of zinc acetate can increase the yield up to 20%. The highest yields are obtained with nitrobenzaldehydes, which can be attributed to the oxidising ability of the nitro group. Evidence in favour of this hypothesis can be derived from the increase in the yield of 5,15-diphenylporphyrin **68a** after addition of small quantities of nitrobenzene. The optimum ratio of the reagents (dipyrrolylmethane **67** : PhCHO : PhNO₂) is 1 : 3.6 : 3.6 (Fig. 1).

Figure 1. The dependence of the yield of porphyrin **68a** on the molar ratio of the reaction mixture components.

This method was used in the synthesis of 2,8,12,18-tetrabutyl-3,7,13,17-tetramethyl-5,15-diphenylporphyrin (**68a**) and its derivatives **68b–f** containing different substituents in the benzene rings.^{9, 32, 65} The yields of porphyrins (~20%) practically do not depend on the nature of the substituent in the benzaldehyde. 2,8,12,18-Tetrabutyl-5,15-di(2-methoxyphenyl)-3,7,13,17-tetramethylporphyrin (**68d**) is an exception; its lower yield (10%) can be attributed to steric hindrance in the condensation of dipyrrolylmethane with 2-methoxybenzaldehyde. This porphyrin exists in the form of two atropoisomers (α,α and α,β), which differ in relative positions of substituents in the phenyl fragments relative to the macrocycle plane.

The reaction of dipyrrolylmethane **67** with aliphatic aldehydes in pyridine in an inert atmosphere (180 °C, 0.5–2 h) resulted in 5,15-dialkyl derivatives of octamethylporphyrin **68g–m**.⁶⁵ The presence of a coordinating reagent (zinc acetate) in the reaction mixture markedly facilitates the cyclocondensation. The yields of porphyrins **68g–m** are maximum at the $\text{Zn}(\text{OAc})_2$:dipyrrolylmethane **67**:RCHO molar ratio of 1.5:1:1.25. It is noteworthy that depending on the chain length of alkyl substituents, the yields of porphyrins vary in the range of 15%–33%, i.e., are relatively high (cf. tetraalkyl-substituted porphyrins, which are obtained by condensation of monopyrroles in 5% to 15% yields³³). A salient advantage of this method is that reaction products do not contain even trace amounts of *meso*-monosubstituted porphyrins.

The condensation of *meso*-aryl-substituted dipyrrolylmethanes **69a,b** with aliphatic aldehydes was used in the synthesis of 5,15-dialkyl-10,20-diaryl- β -octamethylporphyrins **70a–d**.²⁴ These compounds are characterised by high solubility due to the presence of *meso*-alkyl substituents; their aryl fragments can be subject to chemical modification.

69: X = H (**a**), 4-OMe (**b**); **70:** X = H, R = Me (**a**), Et (**b**), C₆H₁₃ (**c**); X = 4-OMe, R = C₆H₁₃ (**d**).

The condensation of compounds **69a,b** with acetaldehyde and heptanal was carried out in pyridine at elevated temperatures and high pressures. The yields of *meso*-tetrasubstituted porphyrins **70a,c,d** are low (3% to 5%), which can be ascribed to steric hindrance in the cyclocondensation, and do not depend on the chain length of the alkyl substituent. Similarly, the yields of porphyrins obtained by the condensation of 5,5'-unsubstituted *meso*-aryldipyrrolylmethanes with benzaldehyde and formaldehyde are 5%–6% and do not depend on the nature of the aldehyde.²⁴

It may thus be concluded that 5,5'-dicarboxy derivatives of dipyrrolylmethanes are promising reagents in the synthetic chemistry of porphyrins. They compare favourably with 5,5'-unsubstituted dipyrrolylmethanes and formyl derivatives by relative accessibility and, which is particularly important, by their resistance to oxidation. These compounds can be used in the synthesis of porphyrins of complex structure, including position isomers.

V. Synthesis of bisporphyrins

A vast variety of bisporphyrins with different spatial arrangement of macrocycles have been synthesised from dipyrrolylmethanes. Such syntheses are typically performed by a modified McDonald method.^{11, 13, 15, 16, 70} Sessler *et al.*¹² were the first to synthesise the so-called 'gable' bisporphyrins the porphyrin fragments in which are linked through the *meta*-positions of the benzene ring. This synthesis involves the formation of intermediate dipyrrolyl structures. The reaction of compound **71** with 5,5'-diformyl derivatives of dipyrrolylmethane in methanol in the presence of *p*-toluenesulfonic acid and subsequent oxidation of the condensation product with tetrachloroquinone result in bisporphyrin **72**.¹⁵

In order to construct models which are geometrically identical to the active centres involved in photosynthesis, Sessler *et al.*¹⁶ carried out the condensation of the 5,5'-diformyl derivative of dipyrrolylmethane **73** with bisdipyrrolylmethanes **74a,b** to yield bisporphyrin **75a** with spatially approximated porphyrin nuclei and its linear analog **75b**. The same procedure was used in the synthesis of a bisporphyrin in which the porphyrin macrocycles were linked through a quinone fragment. The yield of porphyrins in the first stage of this reaction was ~5% (Scheme 8).

The synthesis of compounds in which porphyrin fragments are linked by aromatic bridges, which stabilise their spatial structure has been described.¹³ This synthesis consisted in the condensation of bisdipyrrolylmethanes **76** with bis(5-formyl-3,4-dimethylpyrrol-2-yl)methane and resulted in bisporphyrins **77** (Scheme 9).

The reaction of bis(5-formyl-3,4-dimethylpyrrol-2-yl)methane with stereoisomeric bisdipyrrolylmethanes **78** in methanol in the presence of *p*-toluenesulfonic acid and subsequent oxidation

$\text{Ar} = m\text{-C}_6\text{H}_4$ (**a**), $p\text{-C}_6\text{H}_4$ (**b**); (a) H^+ ; (b) BBr_3 , CH_2Cl_2 ; (c) $[\text{O}]$.

Scheme 9

Scheme 10

$\text{R} = \text{C}_6\text{H}_{13}$.

of the reaction mixture with tetrachloroquinone afforded spiro derivatives **79a,b** in a total yield of 5% (Scheme 10).^{22, 70} Owing to the presence of a rigid spirobisindane bridge between the macrocycles, bisporphyrins acquired fixed spatial orientation. The distances between the centres of the macrocycles are equal to 1.80 and 1.00 nm, respectively; the porphyrin fragments of compound **79b** partially overlap at an angle (see Scheme 10).

Osuka and Maruyama⁷¹ synthesised a series of bisporphyrins **80** the porphyrin fragments of which were linked through different positions of the naphthalene nucleus. The original 5,5'-unsubstituted bisdipyrrolylmethanes were prepared by the reaction of 5-unsubstituted pyrrole with the corresponding dialdehydes according to the known procedure.¹³ The naphthalene fragments ensure rigid binding of porphyrin macrocycles, which are perpendicular to their plane.

A series of bisporphyrins with a 'face-to-face' orientation of fragments (FTF-porphyrins) containing a conformationally rigid backbone between the macrocycles has been synthesised.^{18, 72, 73} The reaction of bisdipyrrolylmethane **81** with bis(3-ethyl-4-methyl-5-methoxymethylpyrrol-2-yl)methane in boiling benzene with its subsequent oxidation with tetrachloroquinone or the reaction of compound **82** with bis(3-ethyl-5-formyl-4-methylpyrrol-2-yl)methane in methanol in the presence of perchloric acid yields bisporphyrins **83** and **84**.

It has been noted^{18, 72} that bisporphyrins **83** and **84** are devoid of stereoisomers. Spectral data provide evidence in favour of the FTF-orientation of the macrocycles. Collman *et al.*⁷⁴ synthesised binuclear ruthenium and molybdenum complexes **85**, which generate coordination compounds with intramolecular metal–metal bonds upon photolysis in pyridine.

The condensation of formylanthrylporphyrin **86** with bis(3-ethyl-4-methylpyrrol-2-yl)methane has led to a compound of the FTF-type (**87**).¹⁷ Osuka *et al.*⁷⁵ carried out the synthesis of tetrakisporphyrin **89** from compound **88** and bis(5-formyl-3-hexyl-4-methylpyrrol-2-yl)methane under identical conditions.

A two-step synthesis of cyclophanes **90** containing two bridging $\text{O}(\text{CH}_2)_n\text{O}$ groups connecting the *p*-positions of the benzene nuclei, has been described.^{76–78} The condensation of dialdehydes

R = Et, Bu; $n = 2-4$.

91 with dipyrrolylmethanes was carried out in TFA-containing acetonitrile in an atmosphere of nitrogen. The freely soluble porphyrinogens formed were oxidised *in situ* with *o*-tetrachloroquinone. Cyclophane **90**, the only reaction product, could be easily separated from admixtures by column chromatography.

5,5'-Dicarboxy derivatives of dipyrrolylmethanes were also used in the synthesis of bisporphyrins. The procedure used by Collman⁷⁹ in the synthesis of cyclophanes **92** linked with the bridging (CH₂)_n (*n* = 4, 6) groups through the *meso*-positions is a modification of the Jackson–Kenner synthesis.⁶⁹ Heating of bisdipyrrolylmethanes **93** (*n* = 4, 6) with triethyl orthoformate in dichloromethane in the presence of trichloroacetic acid results in the formation of compounds **92** in very low yields.

The same procedure was used^{80–82} in the synthesis of cyclophanes **94** in which bridging groups connect the *meta*-positions of the benzene nuclei. They were synthesised by the reaction of bisdipyrrolylmethanes **95** with triethyl orthoformate in boiling chloroform containing 2% TFA. The yield of compound **94** was ~ 5%; the monomeric porphyrins were not formed.

Cyclophane **94** exists in the form of three atropoisomers (their structures are shown in Fig. 2). In bisdipyrrolylmethanes, the phenoxy groups easily rotate around the C–C bond of the bridges, thus giving rise to one or another spatial isomer depending on their orientation at the moment of cyclisation. The calculation of the structure of octamethyl analogues carried out by the molecular mechanics method⁸² confirmed the possibility of

R¹, R² = Me, Et; *n* = 3, 4.

Figure 2. The atropoisomers of cyclophane **94** containing two conformationally active ester bridges.

existence of $\alpha, \alpha, \alpha, \alpha$ -, $\alpha, \beta, \alpha, \alpha$ - and $\alpha, \beta, \alpha, \beta$ -atropoisomers. The insufficient length of bridging groups excludes the formation of the $\alpha, \alpha, \beta, \beta$ -isomer. Atropoisomers manifest different mobility in thin-layer chromatography (pyridine–hexane, 1:4) which allowed their separation. The assignment of atropoisomers was performed on the basis of ¹H NMR data as well as on the basis of analysis of their coordination properties and chromatographic behaviour.⁸⁰

A simpler procedure for the synthesis of analogous compounds has been proposed.⁷⁶ The condensation of 5,5'-dicarboxy-substituted dipyrrolylmethanes with dialdehydes in pyridine in the presence of zinc acetate resulted in cyclophanes **96** (which can also exist in the form of three atropoisomers) with

bridging $\text{O}(\text{CH}_2)_n\text{O}$ ($n = 2-4$) groups connecting the *ortho*-positions of the benzene rings.

$R = \text{Et, Bu}; n = 2-4$.

The zinc complexes formed by template synthesis were destroyed *in situ* by treatment with TFA. The molar ratio of the reaction mixture components is critical for the yields of cyclophanes **96**. Using the mathematical simulation method, it was demonstrated that the maximum yield of these compounds varied from 8% to 15% and was reached at the dipyrrolylmethane : dialdehyde : zinc acetate molar ratio of 1 : 2 : 1. These yields decrease regularly with a decrease in the number of methylene units, n . The same applies to cyclophanes which contain bridging groups connecting the *meta*- and *para*-positions of the benzene nuclei (compounds **90** and **94**) and may occur as a result of stronger spatial restrictions in cyclocondensation. The optimum duration of the reaction is 2.5 to 3 h. With a drop in temperature from 120 to 80 °C, the reaction products contain only trace amounts of cyclophanes.

It should be noted that the cyclophane **96** containing a shortened bridge $\text{O}(\text{CH}_2)_2\text{O}$ cannot form isomers; all the oxygen atoms of the ether group are arranged inwards towards the interporphyrin cavity.

Cyclophanes containing methyl and ethyl groups in the β -positions of the macrocycles are extremely poorly soluble in the majority of organic solvents; tetrabutyl derivatives are more soluble.

VI. Conclusion

The use of dipyrrolylmethanes opens up good perspectives for the synthesis of different types of mono- and bisporphyrins. At the same time, the potentialities of syntheses based on dipyrrolylmethanes are far from being exhausted. These methods hold a prominent place in the synthetic chemistry of porphyrins. The choice of particular synthetic procedures is largely determined by the symmetry of the porphyrin molecule, the mode and mutual arrangement of substituents in the macrocycle as well as by the availability of the starting compounds.
