Isothiazoles (1,2-thiazoles): synthesis, properties and applications

R V Kaberdin, V I Potkin

Contents

I. Introduction	673
II. Synthesis of isothiazoles	673
III. Chemical transformations of isothiazoles	684
IV. Areas of application of isothiazoles	690
V. Conclusion	691

Abstract. The most recent achievements in the chemistry of isothiazoles are generalised and systematised. The main applications of isothiazole derivatives are surveyed. The bibliography includes 293 references.

I. Introduction

Isothiazoles constitute a relatively novel class of heterocyclic compounds. Their ancestor, 1,2-thiazole, was first obtained in 1956.¹

Other 1,2-azoles had been rather well studied by that time, both theoretically and with respect to their practical applications. Further rapid progress in the chemistry of isothiazole and intense studies into the synthesis and chemical conversions of its derivatives carried out in the 1960–1990's were caused primarily by the extraordinarily broad range of useful properties manifested by various representatives of this class of compounds. Isothiazole-containing penicillins and cephalosporins competed successfully with ampicillin in their activities against gram-positive and gram-negative bacteria.^{2,3} In the last decade of the 20th century, some isothiazole derivatives were found to be efficient in the treatment of Alzheimer's disease,⁴ as antiinflammatory, antithrombotic and anticonvulsive drugs^{5,6} and serine protease inhibitors;^{7,8} physiologically active compounds interacting with glutamate receptors were synthesised.⁹ Auxin transport inhibitors based on isothiazoles^{10–14} are added to herbicides to enhance their activity. Isothiazole derivatives manifest synergistic effects when added to other biocidal preparations.^{15–19} Compositions containing isothiazole derivatives are used as protectors for polymers, dyes, detergents²⁰ and leather goods,²¹ for decontamination of pigments, latexes, foodstuffs²² and waste,²³ as antifouling agents,^{24,25} etc. Recently, isothiazoles have been patented for use in colour photography for stabilisation of photomaterials^{26,27} and as an inkbase for printers.^{28,29} Industrial production of some isothiazolones, which represent broad-spectrum biocides and are safe for human beings, animals and environment, has begun.³⁰

R V Kaberdin, V I Potkin Institute of Physical Organic Chemistry, National Academy of Sciences of Belarus, ul. Surganova 13, 220072 Minsk, Belarus. Fax (37-517) 284 16 79. Tel. (37-517) 284 16 00. E-mail: ifoch@ifoch.bas-net.by (R V Kaberdin) Tel. (37-517) 284 09 72. E-mail: potkin@ifoch.bas-net.by (V I Potkin)

The first data on the chemistry of isothiazoles were reviewed by Wooldridge *et al.*^{31,32} Further progress in the synthesis and conversions of isothiazoles is documented in the reviews^{33–39} some of which are inaccessible for Russian readers as well as in the monographs^{40–45} where isothiazoles are considered only in conjunction with other heterocyclic compounds. The fundamental monograph by Houben-Weyl,⁴⁶ which contains more than 500 references including some published in 1992, represents the most systematic and full generalisation of the experimental data on the chemistry of 1,2-thiazoles. The first review devoted to the physical and chemical properties of 1,2-azoles was published in Russian in 1979.⁴⁷ In addition, isothiazoles and their benzoannelated analogues are discussed in 'Comprehensive Organic Chemistry'.⁴⁸

The necessity for systematisation and generalisation of the newest data on isothiazoles stems from the appearance, in the past decade, of a great number of publications devoted to the synthesis, conversions and applications of this class of compounds. The material described here covers original papers and patent data published over the period 1993–2001 inclusive. In some cases, earlier sources concerned with the methods for isothiazole synthesis are cited for the sake of completeness.

II. Synthesis of isothiazoles

Isothiazole (**1**) was first prepared by the oxidation of 5-amino-1,2-benzisothiazole (**2**) with an alkaline solution of potassium permanganate with subsequent decarboxylation of isothiazole-4,5-dicarboxylic acid (**3**).^{1,49}

This synthetic procedure has a purely historical significance. Later, isothiazoles were synthesised from simpler and more accessible compounds.

1. Synthesis of isothiazoles based on cyclisation reactions

The main methods for the construction of the isothiazole ring are based on cyclisation of compounds containing N–C–C–C–S fragments and heterocyclisation of compounds containing nitrogen, sulfur and carbon atoms.

Received 3 June 2002

Uspekhi Khimii 71 (8) 764–787 (2002); translated by R L Birnova

a. Synthesis of isothiazoles from compounds containing the N—C—C—C—S group

The construction of the isothiazole ring from compounds containing a preformed N—C—C—C—S fragment is the most attractive approach. Thus various 5-aminoisothiazole derivatives **4** can be prepared by the oxidation of 2-aminoalk-1-enethiocarboxamides **5**.⁵⁰

R = Et, Prⁱ, Buⁿ, Buⁱ, Bu^t, cyclo-C₆H₁₁.

Oxidation of 3-amino-3-(dialkylamino)thioacrylic acid amides **7** gives the 3,5-diaminoisothiazole derivatives **6**.⁵¹

R = Alk.

A procedure for the synthesis of alkyl 3-methyl-5-ethoxycarbonylaminoisothiazole-4-carboxylates (**8**) by the oxidation of substituted thioamides **9** with selenium dioxide has been developed recently.⁵²

R = Me, Et.

b. Synthesis of isothiazoles from sulfur and compounds containing the C—C—C—N fragment

The construction of the isothiazole ring from sulfur and compounds containing the C—C—C—N fragment is relatively little studied. This approach makes use mainly of nitriles.⁴⁶

Thus the electrolysis of 3-aryl-2-phenylsulfonylacrylonitriles (**10**) in acetonitrile or DMF using a chemically active sulfur-graphite electrode affords bis(5-arylisothiazol-3-yl) di- or trisulfides (**11**).⁵³

Ar = Ph, 4-MeC₆H₄, 4-PhC₆H₄; n = 2, 3.

In the case of 2-phenyl-3-phenylsulfonylacrylonitrile (**12**), di(isothiazolyl) disulfide **13** containing the (Z)-2-cyano-2-phenylvinylthio group in position 3 of one of the isothiazole rings was obtained.⁵³

It is believed that electrochemical synthesis of sulfur-containing compounds consists in the elimination of the phenylsulfonyl group with concomitant addition of a polysulfide anion produced upon electroreduction of elemental sulfur.

According to the patent data,⁵⁴ substituted α -amino ketones react with thionyl chloride to give the corresponding 4-hydroxyisothiazoles. Thus the reaction of amino ketone **14** with SOCl₂ in DMF yields isothiazole **15**. When thionyl chloride was used in excess, the reaction products contained both isothiazole **15** and di(isothiazolyl) sulfide **16**.

The authors of the present review together with Yu A Oldekop have demonstrated^{55–57} that heating of 2-nitropentachlorobuta-1,3-diene (**17**) with sulfur resulted in its heterocyclisation and the formation of 4,5-dichloro-3-trichloromethylisothiazole (**18**).

This reaction offers a new approach to the construction of the isothiazole ring. It is known that the reaction of halobutenes and -butadienes with sulfur is used for the synthesis of the corresponding halogenothiophenes.⁵⁸ In the case of nitrodiene **17**, the reaction follows a different route: the heterocyclisation involves the nitro group and is accompanied by the evolution of sulfur dioxide. The yield of isothiazole **18** reaches 52%. Tetrachlorothiophene (yield 4%) is the side product in this reaction. Apparently, the reaction has a radical character, since sulfur molecules exist in the form of reactive biradicals S_n at high temperature.⁵⁹

c. Synthesis of isothiazoles using cycloaddition and condensation reactions

The methods for the synthesis of isothiazoles using cycloaddition and condensation reactions of compounds containing a set of essential fragments are the most well-studied and attract, as before, the attention of investigators.

Thus the 1,3-dipolar cycloaddition of nitrile sulfide **19** to dimethyl acetylenedicarboxylate (**20**) yields the isothiazole derivative **21** the structure of which has been confirmed by X-ray diffraction analysis.⁶⁰

The reactions of 1-cyano-3-(2-oxo-1,3,4-oxathiazol-5-yl)adamantane (**22**) and 1,4-bis(2-oxo-1,3,4-oxathiazol-5-yl)adamantane (**23**) prepared from the corresponding adamantanecarboxamides and chlorosulfonylcarbonyl chloride with the alkyne **20** result in the decarboxylation of the oxathiazolone fragment. The reactions of the nitrile sulfides formed with the alkyne **20** proceed as 1,3-dipolar cycloadditions and yield 1-cyano-3-(4,5-dimethoxycarbonylisothiazol-3-yl)adamantane (**24**) and 1,3-bis(4,5-dimethoxycarbonylisothiazol-3-yl)adamantane (**25**), respectively.⁶¹

The reaction of nitrile sulfides of the thiophene series with dimethyl fumarate (**26**) gives substituted 4,5-dihydroisothiazoles **27**.⁶²

The cycloaddition of 3,4,6-tri-*O*-benzyl-2,5-anhydro-D-allo-nonitrile *N*-sulfide (**28**) to dimethyl acetylenedicarboxylate (**20**) or dimethyl fumarate (**26**) followed by the oxidation of the reaction products with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) results in *O*-benzyl-3-(β -D-ribofuranosyl)isothiazolidinecarboxylate **29a**, which was used for the preparation of the C-nucleoside **29b** and isothiazolo[4,5-*d*]pyrimidine analogues of the natural C-nucleosides pyrazofurin (**30**) and formycin (**31**).⁶³

The use of 1,3,5-trichloro-1,3,5,2,4,6-trithiatiazine (**32**) seems to be very promising for the synthesis of isothiazoles.

It was found that ordinary allylic compounds of the type **33** react with the reagent **32** as two-carbon units to give 1,2,5-thiadiazoles **34** and as three-carbon units to give isothiazoles **35**. The ratio of compounds **34** and **35** depends on the reaction conditions and the nature of the substituents.⁶⁴

Thus 1,3-diphenylpropene (**33**, $\text{R}^1 = \text{R}^2 = \text{Ph}$) reacts with two equivalents of compound **32** in boiling CCl_4 to give 3,5-diphenylisothiazole **35** in 53% yield. The introduction of a substituent at the central carbon atom of the allylic system suppresses the formation of thiadiazoles. 4-Methyl-3,5-diphenylisothiazole was obtained from 2-methyl-1,3-diphenylpropene without any admixtures of the corresponding thiadiazole.

The presence of terminal electron-withdrawing groups in the allylic derivatives **33** increases their reactivities with respect to the reagent **32**.⁶⁴

In the case of non-symmetrical allylic compounds, the reaction proceeds regiospecifically and affords an isomer with the electron-withdrawing group adjacent to the sulfur atom of the ring. Thus the reaction of the trimer **32** with ethyl 3,3-dibenzylacrylate affords isothiazole **36** in 66% yield.⁶⁴

Trithiatiazine trichloride **32** can be used for the preparation of isothiazole derivatives from other heterocyclic compounds.

It was shown⁶⁵⁻⁶⁷ that treatment of di- and trisubstituted furans **37a-c** with trithiatiazine trichloride **32** in boiling CCl_4 results in their one-step conversion into 5-benzoylisothiazoles **38a-c** in high yields.

R = H (**a**), Ph (**b**), Br (**c**).

2,5-Disubstituted furans **39a–c** give similar products **40a–c** (yields 50%–60%) with compound **32** upon boiling in CCl₄ or toluene.⁶⁵

R = 4-MeC₆H₄ (**a**), 4-MeOC₆H₄ (**b**), Bu^t (**c**).

It is assumed that heating of 1,3,5-trichloro-1,3,5,2,4,6-trithiazine (**32**) results in its fragmentation and the formation of the reactive monomer **A** which attacks the furan molecule to give the intermediate **B**. Recyclisation of the latter affords isothiazoles.⁶⁵

It has been shown⁶⁸ that fully substituted furans do not react with the reagent **32**, since the elimination of HCl requires the presence of a hydrogen atom in the β-position of the starting furan.

Yet another route to the synthesis of 5-acylthiazoles **41** is based on the reaction of 2,5-disubstituted furans with ethyl carbamate, SOCl₂ and pyridine.⁶⁸

R¹ = R² = Ph, 4-MeC₆H₄, Bu^t; R¹ = 4-MeOC₆H₄, R² = 4-NO₂C₆H₄.

In contrast with 2,5-diphenylfuran (**37a**), the reaction of 2,5-diphenylthiophene (**42**) with the reagent **32** gives 5-benzoyl-3-phenylisothiazole (**38a**) in low yield. Presumably, the latter is formed upon oxidation of the intermediate 5-thiobenzoyl derivative **43**.⁶⁹

Reactions of *N*-substituted 2,5-diphenylpyrroles **44a–e** with compound **32** afford mixtures of thiazolyl-substituted imines **45a–e** and 3,4-dichloropyrrole derivatives **46a–e**. The ratio of the reaction products depends on the nature of the substituent R.⁶⁹

R = Ph (**a**), 4-MeOC₆H₄ (**b**), 4-O₂NC₆H₄ (**c**), MeOC(O) (**d**), Bu^tOC(O)H (**e**).

Compounds **45b,e** are formed as two geometrical isomers. Imine **45b** is easily hydrolysed to give ketone **38a**. The imine **45d** formed from *N*-methoxycarbonylpyrrole (**44d**) is completely hydrolysed even at room temperature to give ketone **38a**.

It is of note that the reaction of 1-methyl-2,5-diphenylpyrrole (**47**) with the reagent **32** follows a different route and results in the formation of bi(1,2,5-thiadiazol-3-yl) **48**; 5-benzoyl-3-phenylisothiazole (**38a**) is formed in only trace amounts.⁶⁹

Condensation of 2-dialkylaminomethyldithiomalonates **49**, the reaction products of dithiomalonates **50** with formamide acetals, with hydroxylamine-*O*-sulfonic acid results in isothiazoles **51**.⁷⁰

R¹, R³ = Me, Et; R² = Me, Ph.

Schulze *et al.*⁷¹ have developed two procedures for the synthesis of isothiazoles **52a–c** containing fluoro-substituted aryl groups. The first of them is based on the reaction of β-thiocyanatocinnamaldehydes **53a,b** with ammonium thiocyanate (**54**). Isothiazoles **52a,b** were obtained in good yields (~60%). In this case, ammonium thiocyanate (**54**) acts as a source of ammonium required for ring closure. It is noteworthy that ammonium thiocyanate (**54**) was employed previously for the preparation of 4- and 5-alkylisothiazoles.⁷²

The second route is based on the use of enamino thiones **55a–c** as starting compounds; their reaction with hydroxylamine-*O*-sulfonic acid gives isothiazoles **52a–c**. In this case, the yields reach 98%.

Ar = 4-CF₃C₆H₄ (**a**), 3-CF₃C₆H₄ (**b**), 3-FC₆H₄ (**c**).

Approaches to the synthesis of isothiazolium salts **56** were developed based on cinnamaldehydes **53a,b,d,e** and enamino thiones **55d–g**.⁷¹

$\text{Ar}^1 = 4\text{-CF}_3\text{C}_6\text{H}_4$ (**53a**, **55f**), $3\text{-CF}_3\text{C}_6\text{H}_4$ (**53b**, **55g**), $4\text{-FC}_6\text{H}_4$ (**53d**, **55d**), $4\text{-MeOC}_6\text{H}_4$ (**53e**, **55e**); $\text{Ar}^2 = \text{Ph}$, $4\text{-MeOC}_6\text{H}_4$.

4-Thiocyanato-1-aza-1,3-dienes **57** prepared from β -thiocyanato α,β -unsaturated aldehydes **58** and arenesulfonohydrazides **59** undergo cyclocondensation to yield *N*-arylsulfonylisothiazol-2-ylimines **60** and the corresponding *N*-arylsulfonyl-2-aminoisothiazolium salts **61**.⁷³

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**a**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$ (**b**);

$\text{R}^1\text{--R}^2 = (\text{CH}_2)_n$, $n = 3$ (**c**), 4 (**d**), 5 (**e**);

$\text{Ar} = \text{Ph}$, $4\text{-MeC}_6\text{H}_4$, $4\text{-BrC}_6\text{H}_4$, $2,4,6\text{-Me}_3\text{C}_6\text{H}_2$, $2,4,6\text{-Pr}_3\text{C}_6\text{H}_2$.

Thus, depending on the nature of the substituents R^1 , R^2 and Ar , the reactions of unsaturated thiocyanato aldehydes with arenesulfono hydrazides afford different products. Isothiazoles are formed directly from compounds **58a,b**, whereas alicyclic thiocyanato aldehydes **58c–e** yield stable hydrazones **57**. Treatment of the latter with perchloric acid yields isothiazolium salts **61c–e**.

A convenient procedure for the synthesis of *N*-acylisothiazolidinium trifluoroacetates **62**, which includes treatment of *N*-acylamino sulfoxides **63** with trifluoroacetic anhydride, has been developed.⁷⁴

$\text{R} = \text{Bu}^t$, Ph .

2. Synthesis of isothiazoles from other heterocyclic compounds

Methods of synthesis of substituted isothiazoles from other heterocyclic compounds find wide application despite the fact that they belong to the most ancient ones. Thus 3,5-disubstituted isothiazoles **64a,b** were prepared from isoxazoles **65a,b** by the reaction with phosphorus pentasulfide in pyridine.⁷⁵

$\text{R} = \text{H}$ (**a**), MeO (**b**).

The reaction of 2-imino-3,4-dihydro-2*H*-pyrrole **66** with sulfur on heating is accompanied by dehydrogenation and incorporation of the sulfur atom into the pyrrole ring resulting in the previously unknown thiazolylisothiazoles **67**.⁷⁶

The thermal fragmentation of 1,4,2-dithiazines in the presence of dienophiles aimed at the synthesis of 1,4-dithyines has been studied.⁷⁴ It was found that 1,4,2-dithiazine derivatives **68** react with dimethyl acetylenedicarboxylate (**20**) on heating in *o*-dichlorobenzene to give a mixture of dimethyl 4,5-dimethylthiophene-2,3-dicarboxylate (**69**) and 3-(4-bromophenyl)-4,5-dimethylisothiazole (**70**). The latter is formed upon thermolysis of dithiazine **68** and is accompanied by a loss of the sulfur atom from position 4.⁷⁷

A new method for the synthesis of the isothiazole ring from 4-chloro-5-dicyanomethylidene-5*H*-1,2,3-dithiazole (**71**) prepared by the condensation of 4-chloro-1,2,3-dithiazole-5-thione with tetracyanoethylene oxide has been proposed recently. Treatment of the nitrile **71** with morpholine or benzyltriethylammonium chloride gives 3-morpholino- (**72a**) and 3-chloroisothiazole-4,5-dicarbonitriles (**72b**), respectively.⁷⁸

A new simple procedure for the synthesis of isothiazoles from primary enamines and 4,5-dichloro-1,2,3-dithiazolium chloride (**73**) has been developed. Thus the reaction of methyl 3-aminocrotonate (**74a**) and 3-aminocrotononitrile (**74b**) with the salt **73** under mild conditions ($20\text{ }^\circ\text{C}$, dichloroethane) afforded

4-methoxycarbonyl-5-cyano-3-methylisothiazole (**75a**) and 4,5-dicyano-3-methylisothiazole (**75b**).⁷⁹

R = CO₂Me (**a**), CN (**b**).

Presumably, the conversion of enamine **74a** into isothiazole **75a** upon treatment with the salt **73** proceeds similarly to its conversion into isothiazole **76** under the action of thiophosgene used by Woodward *et al.* in the synthesis of colchicine back in 1965.⁸⁰

3. Synthesis of isothiazole derivatives by modification of compounds containing the isothiazole ring

The syntheses of functionalised isothiazoles by exchange of substituents in the isothiazole ring or by transformation of the side chain of accessible derivatives are well documented.⁴⁶

a. Substitution reactions

Recently, Russian chemists have developed novel procedures for the synthesis of halogenated isothiazoles.^{81–83} Thus bromo- and iodoisothiazoles **78–83** have been synthesised from the readily available 3-hydroxyisothiazole (**77**).⁸¹

NBS, *N*-bromosuccinimide.

The possibility of synthesis of alkenylhaloisothiazoles by palladium-catalysed cross-coupling of the halogen derivatives **80** and **83** with the terminal alkenes **84a–d** (the Heck reaction) has been studied.⁸² It was found that 3,4-dibromo-5-iodoisothiazole (**83**) does not react with alkenes under the reaction conditions. 3-Bromo-4-iodoisothiazole **80** enters into the Heck reaction with the alkenes **84a–c** in the presence of the catalytic system Pd(OAc)₂–NEt₃ to give 4-alkenyl-3-bromoisothiazoles **85a–c**. 4,4'-Bi(3-bromoisothiazole) (**86**) is the side product in this reaction; it is also formed in the absence of the alkene.

R = Ph (**a**, 60%), CO₂Me (**b**, 29%), CN (**c**, 33%).

3-Bromo-4-(1-oxopropan-2-yl)isothiazole (**87**) and biisothiazolyl **86** were isolated from a complex mixture of reaction products of isothiazole **80** with allyl alcohol (**84d**).

Under conditions of metal-complex catalysis, bromo- and iodoisothiazoles react with terminal alkynes.⁸³ Thus tribromoisothiazole (**82**) reacts with phenylacetylene (**88a**), oct-1-yne (**88b**), propargyl alcohol (**88c**) and methoxymethylacetylene (**88d**) in the presence of (PPh₃)₂PdCl₂ even at 20 °C to give the cross-coupling products (**89a–d**).

R = Ph (**a**), n-C₆H₁₃ (**b**), CH₂OH (**c**), CH₂OMe (**d**).

The highest yields (20%–56%) were obtained with 4 mol.% of (PPh₃)₂PdCl₂. 1,4-Diphenylbuta-1,3-diyne was isolated as a side product in the reaction of isothiazole **82** with phenylacetylene **88a**.

It should be noted that unsubstituted acetylene does not enter into the cross-coupling reaction with isothiazole **82** even at 80 °C; the reaction mixture contained only 3,4-dibromoisothiazole (**79**), the partial reduction product of the tribromide **82**. Compound **79** did not react with phenylacetylene, *i.e.*, only the bromine atoms in position 5 were active in the cross-coupling reaction. 5-Iodoisothiazoles were found to be the most reactive compounds. The reactions of 3,4-dibromo-5-iodoisothiazole (**83**) and 3-bromo-4,5-diiodoisothiazole (**81**) with terminal alkynes **88a,d** occur in the presence of 2 mol.% of (PPh₃)₂PdCl₂ and result in the corresponding 3,4-dibromo-5-alkynyl- (**90**) and 3-bromo-4-iodo-5-alkynylisothiazoles (**91a,b**).

Compounds	X	R
90	Br	Ph
91a	I	Ph
91b	I	CH_2OMe

The side reaction products of terminal alkynes with 3,4-dibromo-5-iodo-1,2-thiazole (**83**) and 3-bromo-4,5-diiodo-1,2-thiazole (**81**), viz., the dibromide **79** and 3-bromo-4-iodo-1,2-thiazole (**80**), represent the reduction products of iodine in position 5.

3-Bromo-4-iodo-1,2-thiazole (**80**) enter into cross-coupling reactions with phenylacetylene (**88a**) under conditions of metal-complex catalysis to give 3-bromo-4-(phenylethynyl)-1,2-thiazole (**92**).⁸³

3-Bromo-4-(3-methoxyprop-1-ynyl)-5-(phenylethynyl)-1,2-thiazole (**93**), the first representative of isothiazoles with two alkynyl substituents, was synthesised by the reaction of 3-bromo-4-iodo-5-(phenylethynyl)-1,2-thiazole (**91a**) with methoxymethylacetylene (**88d**) under similar conditions.⁸³

4,5-Dichloro-3-trichloromethylisothiazole (**18**) reacts smoothly with various nucleophilic reagents resulting in the substitution of the chlorine atom in position 5 of the isothiazole ring. Thus its reactions with sodium methoxide, ethoxide and isopropoxide afford the corresponding 5-alkoxy-4-chloro-3-trichloromethylisothiazoles (**94a–c**) in 73%–78% yields. The reaction of isothiazole **18** with piperidine results in 4-chloro-5-piperidino-3-trichloromethylisothiazole (**95**).⁵⁶

The reaction of methyl 4,5-dichloroisothiazole-3-carboxylate (**96**) with sodium methoxide in methanol at $20^\circ C$ proceeds in a similar way and yields methyl 5-methoxy-4-chloroisothiazole-3-carboxylate (**97**).⁸⁴ At a higher temperature, the saponification of the ester **96** occurs. The reaction of sodium methoxide with 4,5-dichloroisothiazole-3-carboxylic acid piperidide (**98**) prepared by treatment of the ester **96** with piperidine yields compound **99**,

the substitution product of the methoxy group for the chlorine atom in position 5.⁸⁴

A vast variety of 4-aryl- and 4-heteroaryl isothiazoles were prepared from substituted 4-iodoisothiazoles.^{85–88} This is exemplified in the synthesis of 5-cyclopropyl-4-(2-methylsulfonyl-4-(trifluoromethyl)benzoyl)isothiazole (**100**) from 5-cyclopropyl-4-iodoisothiazole (**101**) by treatment with methylmagnesium bromide and 2-methylsulfonyl-4-(trifluoromethyl)benzoyl chloride (**102**).

N-Alkylisothiazolecarboxamides are synthesised from iodoisothiazoles by treatment with CO and amines in the presence of palladium catalysts.⁸⁹ Thus *N*-octyl-3-methylisothiazole-5-carboxamide (**103**) was prepared by heating a 5-iodo-3-methylisothiazole (**104**)–octylamine–triphenylphosphine mixture in an atmosphere of CO (10 atm) in the presence of $(PPh_3)_2PdCl_2$ ($100^\circ C$, 6 h).

A convenient regiospecific method for the synthesis of isothiazole derivatives of the type **106** and **107** based on the reactions of thiazol-4-ylmagnesium bromide (prepared from 4-iodoisothiazole (**105**) and ethylmagnesium bromide) with carbonyl compounds has been developed.⁹⁰

R¹ = Ph, 4-ClC₆H₄, 2,4-Cl₂C₆H₃, Ph; R² = H, OEt.

For the first time, isothiazolyl gold(I) complexes were prepared by the reaction of isothiazol-5-yl lithium with gold(I) chloride or tetrahydrothiophene(pentafluorophenyl)gold; their protonation or alkylation gave the corresponding isothiazolinyldiene complexes.⁹¹

b. Modification of amino, hydroxy, carboxy and other groups and functionalisation of the side chain in isothiazole derivatives

In-depth studies into biological properties of functionalised isothiazoles carried out in the past decade were aimed at the development of methods for the synthesis of such compounds based on the known amino- and hydroxyisothiazoles, isothiazolecarboxylic acids and their chlorides, *etc.*, and by functionalisation of the side chain.⁴⁶

Heating of a 5-amino-4-chloro-3-methylisothiazole (**108**) – (4-trifluoromethylphenyl)acetyl chloride (**109**) mixture in xylene gave *N*-isothiazol-5-ylamide **110**.⁹²

A vast variety of novel useful *N*-isothiazol-5-ylamides have been prepared starting from structurally more complex acid chlorides and aminoisothiazoles containing various substituents in positions 3 and 4.^{92, 93}

The methods for the synthesis of acylated 5-aminoisothiazoles of the type **111** and **112** have been developed.^{94–96}

R¹, R², R³, R⁴ = H, CN, NO₂, CHO, alkyl, halogenoalkyl, alkoxyalkyl, alkoxy, alkylthio;
X = alkylene, alkyleneoxy; Y, Z = O, S.

For example, acylated 5-aminoisothiazole **113** was prepared from 4-chloro-5-[4-(4-cyanophenoxy)phenyl]acetyl amino-3-methylisothiazole (**114**) by treatment with NaH in tetrahydrofuran and then with a twofold excess of allyloxycarbonyl chloride.⁹⁵

Carboxylic acids and acid chlorides of the isothiazole series are convenient starting compounds in the synthesis of isothiazolecarboxamides. Thus a series of biologically active amides **116** have been synthesised from 3-methylisothiazole-5-carbonyl chloride (**115a**) and 3,4-dichloroisothiazole-5-carbonyl chloride (**115b**) and various amines in the presence of triethylamine or pyridine.^{97–101}

R¹ = H, R² = Me (**115a**); R¹ = R² = Cl (**115b**);
R³ = Ph, C₆H₅SO₂, 4-ClC₆H₄, 1,2,4-triazolyl, pyrazolyl, piperazinyl;
R⁴ = H, Et.

Amides **116** (R³ = Het, R⁴ = H) can be prepared by the reaction of 3,4-dichloroisothiazole-5-carboxamide with derivatives of the corresponding heterocyclic compounds.¹⁰¹

5-Amino-3-methylisothiazole-4-carboxylic acid (**117**) is the starting compound in the synthesis of structurally more complex amides. Thus the reaction of the chloride **118** with 4-methylthioaniline and subsequent acylation with acid chlorides yields 5-acylaminoisothiazole-4-carboxamides **119**.¹⁰²

R = Me, Et, Ph.

The reaction of 5-benzoylamino-3-methylisothiazole-4-carboxylic acid (**120**) with *p*-chloroaniline in the presence of pyridine as the catalyst and alkoxycarbonyl chloride as the activating reagent gave 5-benzoylamino-3-methylisothiazole-4-carboxylic acid (**121**) *p*-chloroanilide.¹⁰³

R = Me, Et, Prⁿ.

3-Hydroxyisothiazole and its 4-halogeno derivatives react with acetals in the presence of toluene-*p*-sulfonic acid to give mixed acetals. For example, the reaction of isothiazole **77** with acetaldehyde dimethyl acetal results in 3-(1-methoxyethyloxy)isothiazole (**122**).¹⁰⁴

The reaction of 5-chloro-3-hydroxyisothiazole (**123**) with malonic dialdehyde bis(dimethylacetal) (**124**) in propionic acid yields a mixture of 5-chloro-3-(1,3,3-trimethoxypropyl)oxyisothiazole (**125**) and 1,3-bis(5-chloroisothiazol-3-yloxy)-1,3-dimethoxypropane (**126**).¹⁰⁵

A great number of isothiazole derivatives of the general formula **127** have been prepared using a similar approach.

R = Alk(C₁–C₁₈); X¹ = H, Br, Cl, Me; X² = H, Br, Cl;
Y–Z = HC(CH₂)_nCH.

4,5-Disubstituted 3-hydroxyisothiazoles react with various allylic bromides to give alkenyl ethers of 3-hydroxyisothiazoles **128–130**.¹⁰⁶

R¹, R² = H, Cl, alkyl(C₁–C₄); R³ = H, alkyl, alkenyl, alkynyl, Ph, *etc.*;
R⁴, various electron-withdrawing groups;
R⁵ = H, alkyl; Y = O, S, SO₂.

The condensation of isothiazole **77** and its 5-methylthio derivative **131** with arenesulfonyl chlorides **132** in the presence of a base yields the corresponding 3-arylsulfonyloxyisothiazoles **133**.¹⁰⁷

R¹ = H (**77**), SMe (**131**); R² = H, 4-Me, 2-NO₂, 4-NO₂, 4-Br, 2-CO₂Et.

Aldehydes and ketones can be used for the functionalisation of isothiazoles. The reaction of the lithium derivative prepared by the metallation of 3-methyl-5-phenylisothiazole (**134**) with *n*-butyllithium in the presence of a lithium isopropylcyclohexylamide–*N,N,N',N'*-tetramethylenediamine system (LICA–TMEDA) with carbonyl compounds leads to hydroxy derivatives **135**.¹⁰⁸

R¹ = H, R² = Et, CH=CH₂, Ph, CH=CHPh;
R¹–R² = (CH₂)_n, n = 4, 5; R¹ = Ph; R² = Me, CH=CH₂,
Ph, CH=CHPh.

The alkylation of a lithium derivative of isothiazole **134** with alkyl iodides or bromides gives compounds **136a–c** in up to 83% yields.¹⁰⁹

R = Me, X = I (**a**); R = Bn, X = Br (**b**); R = Bu, X = Br (**c**).

The condensation of 4-acetyl-5-chloro-3-methylisothiazole (**137**) with some aromatic and heterocyclic aldehydes involves the methyl group of the acetyl group rather than the methyl group in position 3 of the isothiazole ring to give α,β-unsaturated carbonyl compounds **138**.¹¹⁰

R = 2-ClC₆H₄, 4-ClC₆H₄, 4-Me₂NC₆H₄, 2-furyl.

(3-Chloro-4-cyanoisothiazol-5-yl)hydrazine (**139**) reacts with aromatic aldehydes to give the corresponding (3-chloro-4-cyanoisothiazol-5-yl)hydrazones **140**.¹¹¹

Ar = Ph, 4-O₂NC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 2,4-Cl₂C₆H₃, 3-O₂NC₆H₄, 2,4-(O₂N)₂C₆H₃, 4-HOC₆H₄, 2-HOC₆H₄, 3-MeOC₆H₄, 2-MeOC₆H₄.

Treatment of 4-cyano-3-hydroxy-5-methylthioisothiazole (**141**) with allyl bromide in the presence of potassium carbonate in DMF and subsequent treatment with iodine, potassium iodide and KOH yield the iodopropargyloxy derivative **142**.¹¹² Other cyanoisothiazole derivatives containing various alkyl, alkenyl and alkynylthio groups in positions 3 and 5 were synthesised using a similar approach.¹¹²

3,4-Dichloroisothiazole-5-carboxylic acid derivatives **143** (X = O, S; R is substituted alkyl, aryl and heterocyclic residues containing halogen, CN, NO₂, carbonyl, halogenalkylthio and other groups) have been synthesised recently from the acid chloride **115b**.¹¹³

4. Miscellaneous reactions for the synthesis of isothiazole

The preparation of 3-substituted 4,5-diaminoisothiazoles used in the synthesis of novel heterocyclic systems (see Section III) is based on the conversions of 5-acetylamino-3-methyl-4-nitroisothiazole (**144**) which is readily obtainable from the commercially available 5-amino-3-methylisothiazole hydrochloride.¹¹⁴

Isothiazole **145** non-substituted in position 3 is formed upon oxidation of isothiazole **144** to carboxylic acid **146** and subsequent decarboxylation.

4,5-Diaminoisothiazoles **147a,b** are obtained from compounds **144** and **145** by deacetylation and reduction of the nitro group in the derivatives **148a,b**.¹¹⁴

R = Me (a), H (b).

5-(*N*-Alkylamino)-4-nitroisothiazoles **149a–c** were synthesised in high yields by the alkylation of sodium salts of 5-amino-4-nitroisothiazoles **148**. The reduction of the nitro group in compounds **149a–c** gives 5-(*N*-alkylamino)-4-aminoisothiazoles **150a–c**.¹¹⁵

R¹ = R² = Me (a); R¹ = H, R² = Me (b); R¹ = Me, R² = Buⁿ (c).

4,5-Diamino-3-cyanoisothiazole (**151**) was obtained from 5-acetylamino-4-nitroisothiazole-3-carboxylic acid (**146**) in four steps which included the conversion of the carboxy group into the nitrile group and the reduction of the nitro derivative to diamine **151**.¹¹⁵

3-Acetamido-4-amino-5-(*N*-methylamino)isothiazole (**152**) is the starting compound in the synthesis of novel annelated heterocycles. This is prepared from ethyl 3-amino-5-(*N*-methylamino)-isothiazole-4-carboxylate (**153**) which is converted into the nitro derivative **154** in several steps. Selective removal of the acetyl protective group from the amino group in position 5 by treatment with methanolic ammonia and subsequent reduction of the 3-acetamido-5-(*N*-methylamino)-4-nitroisothiazole (**155**) formed completes the synthetic scheme.^{115, 116}

4-Dibromoaminoisothiazoles **156a–c** used in the synthesis of the bisisothiazolopyrazine system are prepared by the reaction of 4-aminoisothiazoles **157a–c** with dibromoisocyanuric acid.^{117–119}

$R^1 = \text{Br}; R^2 = \text{Me}$ (a), Ph (b); $R^1 = R^2 = \text{Cl}$ (c).

A procedure for the synthesis of 3,4-dichloro-5-cyanoisothiazole by the chlorination of the reaction product of carbon disulfide with NaCN in DMF¹²⁰ has been improved.¹²¹ 3,4-Dichloro-5-cyanoisothiazole synthesised (yield ~ 88%) was converted into 3,4-dichloroisothiazole-5-carboxylic acid, which is employed in the synthesis of efficient plant growth regulators. Analogously, 3,5-dichloroisothiazole-4-carboxylic acid was prepared from 3,5-dichloro-4-cyanoisothiazole.¹²²

4,5-Dichloroisothiazole-3-carboxylic acid (**158**) was prepared by hydrolysis of the trichloromethyl group of 4,5-dichloro-3-trichloromethylisothiazole (**18**) with fuming nitric acid and subsequent treatment of the reaction mixture with water.⁵⁶

The direction of reduction of the isothiazole **18** depends on the nature of the reducing agent. Boiling with zinc powder in ethanol results in the partial reduction of the trichloromethyl group and the formation of 4,5-dichloro-3-dichloromethylisothiazole (**159**). When tin dichloride is used, isothiazole **18** undergoes dechlorodimerisation resulting in 1,2-bis(4,5-dichloroisothiazol-3-yl)tetrachloroethane (**160**) in high yield.⁵⁶

The oxidation of 3-alkoxy-5-alkyl-4-cyanothioisothiazoles **161** under the action of Oxone ($2\text{KHSO}_3 \cdot \text{KHSO}_4 \cdot \text{K}_2\text{SO}_4$)

involves selectively the exocyclic sulfur atom and affords the corresponding 5-alkylsulfonylisothiazoles **162** in high yields.^{123, 124}

$R^1, R^2 = \text{H}, \text{C}_1\text{--C}_{12}\text{-alkyl}, \text{C}_2\text{--C}_7\text{-alkenyl}, \text{C}_3\text{--C}_7\text{-alkynyl}, \text{C}_3\text{--C}_7\text{-cycloalkyl}, \text{Ph}, \text{PhO}$.

The oxidation of the methylene group in substituted acetamide **163** by dimethylformamide dimethylacetal (**164**), which can be regarded as a variant of the condensation reaction associated with the elimination of two MeOH molecules, gives enamino ketone **165**.¹²⁵

The chlorination of 5-[2-(*N-tert*-butyldimethylsilylamino)vinyl]isothiazoles **166** with *N*-chlorosuccinimide (NCS) proceeds selectively at the vinyl group resulting in the *Z*-isomers of isothiazole **167**.¹²⁶

$R = 4\text{-ClC}_6\text{H}_4, \text{Ph}$.

The monochlorination of related compounds with *N*-chlorosuccinimide also proceeds in a selective manner.

Isothiazoles **168** and **169** react with AgO_3SCF_3 to give dimeric silver(I) complexes the isothiazole fragment in which is linked to the metal centre through the nitrogen atom.¹²⁷

$n = 1, 2$.

$R = [\text{Et}_2\text{N}(\text{CH}_2)_2]_2\text{N}, n = 1;$
 $R = \text{MeS}, n = 2$.

Treatment of selenolo[2,3-*d*]isothiazole (**170**) with methyl-lithium yields a mixture of compounds including isothiazole **171**.¹²⁸

Treatment of 5-substituted 4,5-dihydro-3-ethoxycarbonylisothiazolo[4,3-*d*]pyrimidin-7(6*H*)-ones with hydrazine is accompanied by the opening of the dihydropyrimidinone ring and the formation of 4-amino-3-carbamoyl-5-hydrazinocarbonylisothiazole (**172**).¹²⁹

It is of note that the ring opening reactions in bicyclic isothiazole derivatives described above present purely theoretical interest.

The reactions of 3,7-dichlorodiiisothiazolo[4,5-*b*:4'5'-*e*]pyrazine (**173**) with benzylamine, aniline and morpholine are accompanied by the opening of the pyrazine ring to give *N,N'*-bis-(5-amino-3-chloroisothiazol-4-yl)diazenes (**174a–c**). The reaction of compound **173** with benzylamine gives 3,7-bis(benzylamino)bisisothiazolo[4,5-*b*:4'5'-*e*]pyrazine (yield 5%) as a side product.¹³⁰

$\text{R}^1 = \text{H}, \text{R}^2 = \text{Bn}$ (**a**, 25%); $\text{R}^1 = \text{H}, \text{R}^2 = \text{Ph}$ (**b**, 25%);
 $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$ (**c**, 28%).

A mechanistic scheme for the synthesis of compounds **174a–c** has been proposed. Its first step consists in the addition of the amine at the $\text{C}=\text{N}$ bond of the pyrazine ring. Interestingly, the reaction of compound **173** with MeONa in MeOH results in 5,6-dimethoxy-3-chloroisothiazolo[4,5-*b*]pyrazine, *i.e.*, in the opening of one of the isothiazole rings. The difference in the behaviour of compound **173** in the reaction with the alkoxide anion and amines is explained by the difference in their basicities as well as by the presence of a mobile hydrogen atom in the amines which ensures their addition at the multiple bonds of the pyrazine ring.¹³⁰

5. Synthesis of isothiazole 1,1-dioxides

Methods for the synthesis, reactions and biological properties of isothiazole 1,1-dioxides were reviewed in 1997.¹³¹ Here we consider only the most recent publications. Thus a novel procedure for the synthesis of 4-amino-3,3-dimethyl-2,3-dihydroisothiazole 1,1-dioxide derivatives **175** based on substituted *N*-benzyl-*N*-sulfonylaminonitriles **176** has been developed recently. The cyclisation was performed by treatment with sodium hydride in acetonitrile.¹³²

$\text{R} = \text{H}, \text{Me}, \text{Ph}; \text{X} = \text{H}, 4\text{-Cl}, 3\text{-Cl}.$

Other 4-amino-2,3-dihydroisothiazole 1,1-dioxide derivatives,¹³³ particularly compounds containing a cyano group in position 5, were prepared using analogous methods.^{134–136}

In the presence of bases, phenylmethanesulfonamide (**177**) reacts with dimethyl oxalate to give 4-hydroxy-5-phenylisothiazol-3(2*H*)-one 1,1-dioxide (**178**). It is assumed that the linear methyl *N*-(benzylsulfonyl)oxalamidate **179**, which is formed first, undergoes further cyclisation. A complex of dioxide **178** with DMF has been prepared.¹³⁷

6. Synthesis of dihydroisothiazolones

Among representatives of this group, dihydroisothiazol-3-ones possessing high biological activities hold the greatest interest. The data on these compounds are summarised in the review.¹³⁸

Some novel data on the synthesis of dihydroisothiazolones have been published recently. Thus the chlorination of 2-(*N*-methylcarbamoyl)ethanethiol (**180**) or bis[2-(*N*-methylcarbamoyl)ethyl] disulfide (**181**) gave a mixture of 2,3-dihydro-2-methylisothiazol-3-one (**182**) and 5-chloro-2,3-dihydro-2-methylisothiazol-3-one (**183**).¹³⁹

Isothiazol-3-ones **182** and **183** can also be prepared by treatment of compounds **180** and **181** with thionyl chloride.^{140, 141}

5-Chloro-2,3-dihydro-2-octylisothiazol-3-one (**184**) was synthesised by treatment of disulfide **185** with SO_2Cl_2 .¹⁴²

The clathrate of compound **184** containing four molecules of 4,4'-dihydroxydiphenylmethane manifests increased solubility in water.

A procedure for the synthesis of isothiazol-3-one derivatives **187** from 3-alkylthio-2-cyano-3-mercaptoacrylamides **186** has been developed.¹⁴³

$\text{R}^1, \text{R}^2 = \text{H}, \text{lower alkyl}, \text{alkenyl}, \text{alkynyl}, \text{aryl}, \text{aralkyl}, \text{hetarylalkyl}.$

The synthesis of isothiazol-3-ones devoid of highly toxic and carcinogenic nitrosoamines has been described in a patent.¹⁴⁴

III. Chemical transformations of isothiazoles

Isothiazoles manifest aromatic properties and enter into the same reactions as other heteroaromatic compounds. Ring opening and transformations of the isothiazole ring, which give either functionalised alkenes or other heterocyclic compounds, deserve special attention. Addition reactions of isothiazoles leading to novel bisheterocyclic structures containing an isothiazole fragment are especially attractive. Oxidation reactions of the sulfur atom of the isothiazole ring yield reactive dioxides and present significant interest.⁶⁴

1. Condensation reactions

In recent years, isothiazole derivatives were used as starting compounds for the synthesis of several novel bicyclic compounds. Thus the reaction of 4,5-diamino-3-methylisothiazole (**147a**) with diethoxymethyl acetate affords 3-methylimidazo[4,5-*d*]-isothiazole (**188a**) in low yield. Unsubstituted imidazo[4,5-*d*]iso-

thiazole could not be prepared from compound **147b**.¹¹⁴ Isothiazoles **147a,b** easily undergo cyclisation with thiocarbonyldiimidazole (**189**) to give unstable thiones **190a,b** which are methylated *in situ* in alkaline media under the action of Me_2SO_4 to give 5-methylthioimidazo[4,5-*d*]isothiazoles (**191a,b**) in good yields. Sodium salts of thiones **190a,b** are also alkylated by benzyl and allyl bromides to give the corresponding imidazo[4,5-*d*]isothiazoles **191c–f** in preparative yields.^{114, 115}

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**191a**); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$ (**191b**);

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bn}$ (**191c**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{All}$ (**191d**);

$\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Bn}$ (**191e**); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{All}$ (**191f**).

6-Alkyl-5-methylthioimidazo[4,5-*d*]isothiazoles **192a–c** were prepared by treatment of 5-(*N*-alkylamino)-4-aminoisothiazoles **150a–c** with thiocarbonyldiimidazole (**189**) and subsequent methylation. The reactions of isothiazoles **150a,c** with diethoxymethyl acetate result in compounds **193a,c**.¹¹⁵

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**a**); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$ (**b**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Bu}^n$ (**c**).

3-Amino-6-methyl-5-methylthioimidazo[4,5-*d*]isothiazole (**192d**) was obtained in good yield by successive treatment of 3-acetamido-4-amino-5-(*N*-methylamino)isothiazole (**152**) with thiocarbonyldiimidazole (**189**) and dimethyl sulfate.¹¹⁵

It should be noted, however, that not all 4,5-diamino-3-*R*-isothiazoles yield annelated products. Thus isothiazole **151** containing a cyano group in position 3 does not react with either diethoxymethyl acetate or thiocarbonyldiimidazole.¹¹⁵

Two approaches to the synthesis of 3,7-disubstituted bisisothiazolo[4,5-*b*:4',5'-*e*]pyrazines **193a–c**, the first compounds containing a novel heterocyclic system, have been proposed.^{117–119} It was found that the reaction of 3,5-dichloro-4-dibromoaminoisothiazole (**156c**) with a $\text{Cu}(0)$ –collidine system affords 3,7-dichlorodisothiazolo[4,5-*b*:4',5'-*e*]pyrazine (**193c**) in 67% yield.¹¹⁷ Zlotin *et al.*¹¹⁸ suggested that this reaction has a radical character and studied the effect of UV light on isothiazoles **156a–c**. Irradiation of compounds **156a,c** with a mercury lamp results in the cleavage of the $\text{N}–\text{Br}$ bond and the formation of radicals **194a,c**; their further transformations depend on the nature of the solvent used. Thus in dichloromethane, isothiazole **156c** is converted into 4-amino-3,5-dichloroisothiazole virtually completely (**157c**). In CCl_4 , 3,7-disubstituted diisothiazolo[4,5-*b*:4',5'-*e*]pyrazines **193a,c** (yields 58% and 76%, respectively) are the main reaction products of compounds **156a,c**; their formation seems to proceed *via* the intermediate compounds **195a,c**. *N,N'*-Di(isothiazol-4-yl)diazenes **196a,c** (yields 37% and 13%, respectively) were identified as the side products.¹¹⁸

$\text{R}^1 = \text{Br}$, $\text{R}^2 = \text{Me}$ (**a**), Ph (**b**); $\text{R}^1 = \text{R}^2 = \text{Cl}$ (**c**).

5-Bromo-4-dibromoamino-3-phenylisothiazole (**156b**) manifests a similar behaviour upon irradiation with UV light; 3,7-diphenyldisothiazolo[4,5-*b*:4',5'-*e*]pyrazine (**193b**) and *N,N'*-bis(5-bromo-3-phenylisothiazol-4-yl)diazene (**196b**) are the main reaction products.¹¹⁹

The isothiazolium salt **197** is condensed with cyclopentadienyl-, *tert*-butylcyclopentadienyl- and di-*tert*-butylcyclopentadienyllithium to give thialenes **198**.¹⁴⁵

$R^1 = R^2 = R^3 = H$; $R^1 = Bu^t$, $R^2 = R^3 = H$;
 $R^1 = R^3 = H$, $R^2 = Bu^t$; $R^1 = R^3 = Bu^t$, $R^2 = H$.

Reactivities of certain isothiazole 1,1-dioxide derivatives have been studied.¹⁴⁶ It was found that 3-diethylamino-4-(4-methoxyphenyl)isothiazole 1,1-dioxide (**199**) reacts with sodium azide in ethanol to give a mixture of dihydroisothiazole oxides **200** and **201** and isothiazolotriazoles **202** and **203** in a ratio 72 : 12 : 9 : 7.¹⁴⁶

Cycloaddition of the dioxide **199** to arylalkyl and aryl azides results in *N*-arylalkyl- or *N*-arylthiadiazabicyclo[3.1.0]hexene **204**. The unstable cycloadducts **205**, which are formed first (in some cases, they were isolated from the reaction mixture), easily eliminate the nitrogen molecule.

$R = Ph$ (**a**), Bn (**b**), $PhCH_2CH_2$ (**c**), $4-MeOC_6H_4$ (**d**), $4-O_2NC_6H_4$ (**e**).

Thermal rearrangement of *N*-aryl- and *N*-phenyl-substituted bicyclic compounds **204a,c-e** affords 1,2-thiazete 1,1-dioxides **206a,c-e**, 1,2,6-thiadiazine 1,1-dioxides **207a,c-e** and pyrazole derivatives **208a,c-e**. Under optimum conditions, compound **207a** was isolated in 51% yield.

If the aziridine nitrogen atom has a benzyl substituent (compound **204b**), the reaction follows a different route to afford the thiadiazine derivative **207b** and pyrimidine **209**.¹⁴⁷

$R = Ph$ (**a**), Bn (**b**), $PhCH_2CH_2$ (**c**), $4-MeOC_6H_4$ (**d**), $4-O_2NC_6H_4$ (**e**).

4-Aryl-3-diethylamino-5-*R*-isothiazole 1,1-dioxides enter into cycloaddition reactions with diazoalkanes to give bicyclic compounds **210** with high regio- and stereoselectivity. The reaction with diazomethane yields a mixture of tautomeric pyrazolines **210** ($R^1 = R^2 = H$) and **211**. Thermolysis of compounds **210** and **211** follows two routes. The loss of the nitrogen molecule leads to 2-thia-3-azabicyclo[3.1.0]hex-3-ene 2,2-dioxides **212**. Elimination of SO_2 and diethylcyanamide from the cycloaddition products results in the corresponding pyrazoles.¹⁴⁸

$R^1 = R^2 = H, Me$; $R^1 = H$, $R^2 = CO_2Et$; $R^3 = H, Me, Ph$;
 $Ar = Ph, 4-MeC_6H_4, 4-MeOC_6H_4$.

The readily available dioxide **199** enters into cyclocondensation reactions with oxazolones **213a-e** and munchnones **214a-h**, which are prepared by cyclisation of (*N*-aroylamino)arylacetic acids **215a,b**.¹⁴⁹

The reactions with compounds **215a** afford 4,6-diaryl-3-diethylamino-3a,4-dihydro-3a-(4-methoxyphenyl)-6a*H*-pyrrolo[3,4-*d*]-isothiazole 1,1-dioxides (**216a-e**) (yields 60%–74%) and their isomers **217a-d** (yields 5%–13%). 4,6-Diaryl-3-diethylamino-3a-(4-methoxyphenyl)-5-methyl-3a,4-dihydropyrrolo[3,4-*d*]isothiazole 1,1-dioxides **218a-h** are the main products in the reaction with munchnones **214a-h**.¹⁴⁹

Compounds 216, 217	Ar^1	Ar^2
a	Ph	Ph
b	$4-ClC_6H_4$	Ph
c	Ph	$4-ClC_6H_4$
d	$4-MeC_6H_4$	Ph
e	Ph	$4-MeC_6H_4$

Compound 218	Ar ¹	Ar ²	Compound 218	Ar ¹	Ar ²
a	Ph	Ph	e	4-MeOC ₆ H ₄	Ph
b	Ph	4-MeC ₆ H ₄	f	Ph	4-FC ₆ H ₄
c	4-MeC ₆ H ₄	Ph	g	Ph	4-BrC ₆ H ₄
d	Ph	4-MeOC ₆ H ₄	h	Ph	4-NO ₂ C ₆ H ₄

The cycloadducts **216** and **218** are decomposed at elevated temperatures or in alkaline media with the elimination of SO₂ and diethylcyanamide to give 2,3,5-triarylpyrroles **219** and 1-methyl-2,3,5-triarylpyrroles **220**, respectively.¹⁴⁹

DBU, diazabicycloundecene.

4-Amino-3-carbamoyl-5-(ethoxycarbonyl)isothiazole is used in the synthesis of the isothiazolo[4,5-*d*]pyrimidine derivatives **221**.¹⁵⁰

R = 2-OMe, 2-Cl, 3-Br, 3-NO₂.

2. Ring transformation reactions

In recent years, some readily available isothiazolium salts have been used in the synthesis of other heterocyclic compounds, pyrrole derivatives, in particular. Thus the reactions of *N*-alkoxycarbonylmethyl- and *N*-cyanomethylisothiazolium **222** salts with

triethylamine result in the elimination of sulfur and recyclisation resulting in pyrrole-2-carboxylic acid derivatives **223**.¹⁵¹

R¹ = CO₂Me, CO₂Et, CN; R² = H, Me, Ph;

R³ = H, Ph, 2-MeC₆H₄, 4-FC₆H₄, CO₂Et;

R⁴ = Ph, , NHPh, SMe, 4-ClC₆H₄, ; X = Cl, Br.

Aminopyrroles **224** were obtained from isothiazolium salts **225** in a similar way (yields 70%–90%).¹⁵²

R¹ = H, alkenyl, aryl, NO₂; R², R³ = H, substituted or unsubstituted alkyl, Ar, HetAr; R⁴, R⁵ = H, heterosubstituted aryl or alkyl; X = Hal, ClO₄⁻, BF₄⁻, HSO₄⁻, SO₄²⁻, OH⁻, CF₃SO₃⁻.

The mechanism of formation of 3-aminopyrrole derivatives in the desulfurisation of isothiazolium salts has been studied.¹⁵³ It was found that pyrrole **226** is formed from the salt **227** by a cascade of reactions *via* thioamide **228**.¹⁵³

A convenient procedure for the synthesis of 2-phenylthiocarbonylmethylidenedihydrothiazole derivatives **229** from isothiazolium chlorides has been developed.¹⁵⁴

R¹ = Ac, EtCO; R² = CO₂Et, CO₂Me; R³ = Me, Et.

N-Arylisothiazolium salts **230** containing an activated methyl group in position 5 dimerise into thiadiazapentalenes **231** upon treatment with a base. The sulfur atom of one molecule of the salt is attacked by an activated methyl group of another molecule to give the intermediates **232**. Subsequent oxidative closure of the ring *via* zwitterionic intermediates **233** results in thienothiadiaza-pentalenes **231**. A competing reaction gives 5-(2-thienyl)isothiazolium salts **234** with elimination of aniline.¹⁵⁵

Ar = Ph, 4-MeC₆H₄; X = Cl⁻, ClO₄⁻; B = (cyclo-C₆H₁₁)₂NH.

The reaction between the salts **230** and **235** catalysed by dicyclohexylamine in methanol or DMSO yields 'mixed' thiadiazapentalenes **236** upon oxidative cyclisation and salts **237** upon elimination of aniline.^{156, 157}

Ar¹ = Ph, 4-MeC₆H₄; Ar² = Ph, 4-MeC₆H₄, 4-MeOC₆H₄.

Photochemical reactions of several isothiazoles have been studied. Irradiation of 4-phenylisothiazole yielded small amounts of 4-phenylthiazole (**238**). When the photolysis was carried out in the presence of triethylamine, this rearrangement becomes predominant.¹⁵⁸

The effect of triethylamine and the solvent polarity on the photochemical reaction of 5-phenylisothiazole (**239**) has been studied.¹⁵⁹ It was found that irradiation in the absence of triethylamine gives 4-phenylthiazole (**238**) as the main product (yield 15%). Other reaction products are represented by 3-phenylthiazole (**240**) and 2-phenylthiazole (**241**). In the presence of Et₃N, 5-phenylthiazole (**242**) is the main product (yield 14%).

Irradiation of 5-phenylisothiazole (**239**) in polar solvents makes this rearrangement more regioselective. The photolysis in methanol in the presence of Et₃N gives exclusively compounds **238** and **242** (yields 9% and 34%, respectively). In a more polar solvent (*e.g.*, 2,2,2-trifluoroethanol), only thiazole **241** was identified in the reaction mixture; in the presence and in the absence of Et₃N, its yield was 42% and 32%, respectively.¹⁵⁹

3. Ring opening reactions

Under conditions of phase-transfer catalysis [PhH, H₂O, tris(2,6-dioxaheptyl)amine], the reaction of 3,5-dimethylisothiazole (**243**) with acetylcobalttetracarbonyl generated *in situ* from Co₂(CO)₈, CO and MeI is accompanied by ring opening and *N*-acylation, resulting in thione (**244**) (the ratio of the *E*- and *Z*-isomers is equal to 1 : 10).¹⁶⁰

Other *N*-acylated unsaturated thiones are synthesised from isothiazoles in a similar way.

A convenient procedure has been developed for the synthesis of phenylthiocarbonylketene *S,N*-acetals (**246**) based on the reaction of 2-alkyl-3-alkylthio-5-phenylisothiazolium salts (*e.g.*, the salts **245**) with sodium borohydride.¹⁶¹

The reaction of 3-diethylamino-4-(4-methoxyphenyl)isothiazole 1,1-dioxide (**199**) with organomagnesium compounds in THF occurs *via* ring opening leading to a mixture of *E*- and *Z*-isomers of 3-substituted 2-arylpropeneamides **247**.¹⁶²

R = Me, Et, Ph, HC≡C, MeC≡C, PhC≡C.

The chemistry of the 4-nitroisothiazole-5(2*H*)-imine derivatives **248**, particularly, their isomerisation and desulfurisation, has been discussed in the papers^{163, 164} and a recent review.¹⁶⁵

It has already been noted (Section III.2) that the photolysis of 4-phenylisothiazole in benzene gives small amounts of 4-phenylthiazole (**238**) as a result of a rearrangement; cyanothiol **249**,

which was trapped as benzyl sulfide **250**, is the main photolysis product in the absence of a base.¹⁵⁸

4. Miscellaneous reactions of isothiazole derivatives

The oxidation of 4,5-disubstituted isothiazoles with hydrogen peroxide results in the corresponding isothiazol-3(2*H*)-one 1,1-dioxides **251**.¹⁶⁶

$\text{R}^1 = \text{Me, Ph, H; R}^2 = \text{Me, Ph, 4-BrC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Dioxides **253**, **254** are the oxidation products of the isothiazolium salts **252**.¹⁶⁷

$\text{R} = \text{Alk, Ph}$.

5-Bromo-3-diethylamino-4-(4-methoxyphenyl)-2,3-dihydroisothiazole 1,1-dioxide (**255**) reacts smoothly with various organotin compounds in the presence of palladium catalysts to yield the corresponding 5-substituted derivatives **256**.¹⁶⁸

$\text{R} = \text{CH}_2=\text{CH, Ph, HetAr, Ar}$.

The reaction of the vinyl derivative **256** with nitrile oxides yields the cycloadducts **257a–e**, which are rearranged into 4,5-dihydro-5-(isoxazol-5-yl)isothiazole 1,1-dioxides **258a–e** (an equimolar mixture of *cis*- and *trans*-isomers) upon heating in DMSO.¹⁶⁹

$\text{Ar} = 3,5\text{-Cl}_2\text{-2,4,6-Et}_3\text{C}_6$ (**a**), $2,6\text{-Cl}_2\text{C}_6\text{H}_3$ (**b**), $4\text{-ClC}_6\text{H}_4$ (**c**), $2,4,6\text{-Et}_3\text{C}_6\text{H}_2$ (**d**), $4\text{-NO}_2\text{C}_6\text{H}_4$ (**e**).

3-Diethylamino-2,3-dihydro-5-(1-ethoxyvinyl)-4-(4-methoxyphenyl)isothiazole 1,1-dioxide (**259**) enters into the cycloaddition

reaction with 2,4,6-triethylbenzonitrile oxide to give the dihydroisoxazole derivative **260**.¹⁶⁹

2,6-Dichlorobenzonitrile oxide reacts with isothiazolone (**261a**) at the double bond to give isoxazolecarboxanilide (**262**) as a result of transformation of the primary cycloadducts formed. Contrary to expectations, 2,4,6-triethylbenzonitrile oxide adds to the exocyclic carbonyl group of isothiazolone **261b** to give the monoadduct **263** and the bisadduct **264**.¹⁷⁰

An efficient approach based on the Michaelis reaction is used in the synthesis of 5-substituted 3-amino-4-arylisothiazole 1,1-dioxides and their 4,5-dihydro derivatives. The addition of thiols, alcohols and trifluoroacetamide to 3-diethylamino-4-(4-methoxyphenyl)isothiazole 1,1-dioxide (**199**) in the presence of bases

TEBA – Cl, triethylbenzylammonium chloride.

occurs regioselectively and yields a mixture of (4*S*,5*S*)- and (4*R*,5*S*)-diastereomers of 5-substituted 4,5-dihydroisothiazole 1,1-dioxides **265**–**267**.¹⁷¹

The reaction of the 5-bromo-derivative **255** with thiols or amines gives the substituted products of the bromine atom **268** and **269**.¹⁶⁸

IV. Areas of application of isothiazoles

As noted above, isothiazole derivatives manifest a broad spectrum of useful properties. Back in 1967, isothiazoles were used as starting compounds in the synthesis of highly efficient penicillins and cephalosporins,^{2,3} which gave a strong impetus to systematic studies of the biological properties of isothiazole derivatives. In 1988, Mel'nikov who studied the production and application of pesticides and plant growth regulators drew attention to the broad potentialities of isothiazole derivatives.¹⁷² Recent years have been marked by numerous publications (including patents and patent applications) devoted to various applications of isothiazoles as efficient agrochemical and medicinal agents.

It was found that 4-benzoyl- and 4-(hetaroyl)isothiazole derivatives manifest herbicidal activities.^{85–88,173} There is evidence of the use of substituted isothiazole-5-carboxamides **270**,¹⁷⁴ isothiazolylpyridines **271**¹⁷⁵ and dihydroisothiazolone derivatives as herbicides.¹⁷⁶

$R^1 = H, (\text{un})\text{substituted alkyl}, (\text{un})\text{substituted acyl};$

$R^2 = (\text{un})\text{substituted aryl}, \text{hetaryl};$

$Z = (\text{un})\text{substituted } C_1-C_4\text{-alkylene}.$

$R^1 = Hal, MeO, FCH_2O, F_3CO;$
 $R^2 = CN, CO_2H, CHO.$

When used as herbicides, isothiazole derivatives manifest synergistic effects and are included in various compositions. Thus compounds **272** are auxin transport inhibitors and are used together with other herbicides in order to enhance their action.^{10–14}

$R^1, R^2 = H, F, Cl; M = H, Na.$

The role of herbicides in these compositions is played by different compounds, *e.g.*, dicamba, glifosat, 2,4-D¹⁰ and herbicides based on phenoxypropionic¹¹ and phenoxybutyric acids.¹⁴

Some isothiazoles manifest high insecticidal activities. These include 4,5-dihydro-1*H*-pyrazole derivatives containing various isothiazole substituents in position 4,^{177,178} 1,2,3-triazole derivatives containing isothiazole substituents in position 3,¹⁷⁹ *etc.* The cyanoisothiazole derivatives **161** manifest high insecticidal activities against termites.¹⁸⁰

Many isothiazole derivatives, particularly acylated 5-aminoisothiazoles,^{94,95} isothiazolecarboxamides,^{96–98} 4-cyanoisothiazoles,^{112,123,124} 3,4-dichloroisothiazole-5-carboxylic acid and its derivatives,¹²¹ *etc.*, manifest fungicidal activities. (3-Methylisothiazol-5-yl)(2,6-dinitro-4-trifluoromethylphenyl)amine (**273**) is used as an agrochemical.¹⁸¹

Many heterocyclic and aromatic compounds containing various isothiazole residues^{182,183} and 3-isothiazolone derivatives^{184–189} in their side chains manifest high fungicidal activities. Isothiazolones are broad-spectrum biocides; they are included in various compositions including commercial ones. They hold great promise for the technology and agriculture being non-harmful to humans, animals and the environment.^{20,23,30,190–197}

Isothiazole and isothiazolone derivatives are used in photography,^{198–212} cosmetics,^{213–215} and as dyes;^{216–218} besides, they are components of synergistic bactericidal preparations^{219–225} and are used in the chemiluminescent analysis^{226,227} of radiographic visualisation.²²⁸ Many of them are antifouling agents.^{229–235}

A great number of isothiazole derivatives manifest high antimicrobial activities and are widely used for the protection of natural and technical materials, plants and other objects from harmful microorganisms. These include 3-alkoxyisothiazoles (particularly, compound **122**),¹⁰⁴ allylic ethers **128–130**,¹⁰⁶ 5-aminoisothiazoles,²³⁶ 3,5-diaminoisothiazole derivatives **6**,⁵¹ isothiazolecarboxamides¹⁰¹ and the derivatives **125** and **126**.¹⁰⁵

The overwhelming majority of compounds endowed with antimicrobial activities were found among isothiazolone derivatives.^{237–265} It was found that the addition of even the simplest isothiazolones to various compositions, *e.g.*, 2-methyl- or 5-chloro-2-methyl-2,3-dihydroisothiazol-3-one, increase markedly their activities.^{266–271}

Some isothiazole derivatives manifest different types of biological activities. Thus acylated aminoisothiazoles (compounds **165**^{125,272} and **274**²⁷³) are used as insecticides and acaricides.

Compositions possessing bactericidal and fungicidal properties were prepared from some dihydroisothiazolones.²⁷⁴ Cyanoisothiazoles¹¹² are used as fungicides and bactericides. Compositions comprising aminoacrylamides and trisubstituted isothiazoles possess insecticidal, fungicidal and herbicidal activities.²⁷⁵ Compounds **275** have been patented as nematocides, insecticides and acaricides.²⁷⁶

$R = CF_2=CHCH_2CH_2SO_n, n = 0-2$.

N-Isothiazol-5-ylamides (e.g., compound **110**⁹²) manifest an even broader range of pesticidal activities and possess nematocidal, insecticidal, miticidal and fungicidal properties.

An intense search for therapeutic agents among isothiazole derivatives has been carried out over the past decade. Cephalosporins containing a (4-carboxy-3-hydroxyisothiazol-5-yl)thiomethyl group in position 3 (**276**) are used as medicinal drugs possessing a broad spectrum of antibacterial activities, particularly with respect to gram-negative bacteria.²⁷⁷

Isothiazolyl aminoalkyl ketones were patented as myorelaxants.²⁷⁸ 5-Carboxy-3-phenylisothiazoles, particularly 4-amino-3-(3-trifluoromethylphenyl)isothiazole-5-carboxylic acid (**277**), were recommended for use as antiinflammatory agents.²⁷⁹⁻²⁸¹

Dihydroisothiazol-3-one 1,1-dioxide derivatives inhibit serine proteases. They have been recommended for the treatment of various inflammatory diseases and as antimetastatic agents.^{7,8} Some aromatic and heterocyclic compounds containing isothiazole residues inhibit phosphodiesterase and are widely used in the clinical practice as antiasthmatic drugs and in the treatment of diabetes, hypertension, allergic rhinites, nephritis and other diseases.^{282, 283}

Compounds **278** and their salts have been patented as effective agents for the treatment of Alzheimer's disease.⁴

$R^1 = H, \text{ alkyl, cycloalkyl, (un)substituted phenyl};$
 $R^2 = \text{substituted pyrrolidinyl}.$

Trisubstituted isothiazole derivatives containing an amino acid or cyclobutene fragment in position 3 were recommended for the treatment of brain ischemia, Huntington's and Parkinson's diseases, epilepsy, Alzheimer's disease, schizophrenia, stress, anxiety and various memory disorders.²⁸⁴

5-Hydrazinoisothiazole derivatives act as immunodepressants,²⁸⁵ whereas 3-isothiazolone derivatives are included in the composition of weight reduction drugs.²⁸⁶ They are also used for modification of the interleukin-5 receptor.²⁸⁷

The isothiazole ring is the constituent of various physiologically active compounds. Thus heterocyclic derivatives of urea containing an isothiazole substituent act as antagonists of 5-HT_{2C} and 5-HT_{2B} receptors and are used in the preparation of antidepressant drugs and in the treatment of Alzheimer's disease, schizophrenia, etc.²⁸⁸ Compound **279** is a highly efficient antag-

onist of 5-HT_{2B} receptors, although its activity is not too high.²⁸⁹⁻²⁹¹ 2-Amino-3-(3-hydroxy-5-methylisothiazol-4-yl)propionic acid (**280**), the isothiazole analogue of 2-amino-3-(3-hydroxy-5-methylisoxazol-4-yl)propionic acid (**281**, AMPA), blocks the activation of glutamate receptors which are crucial for brain ischemia, Alzheimer's disease, hypoglycemia, etc.^{292, 293}

V. Conclusion

As can be seen from the material presented above, new original methods for the synthesis of many isothiazole derivatives have been developed in recent years. These include some previously unknown heterocyclisation reactions (e.g., the syntheses based on α -amino ketones and 2-nitropentachloro-1,3-butadiene), the syntheses of isothiazoles from other, more accessible heterocyclic compounds (particularly, the syntheses based on trithiatiazine trichloride) as well as the syntheses of previously unknown fluoro-substituted isothiazoles. Studies aimed at the functionalisation of isothiazoles, e.g., cross-coupling reactions which made possible the synthesis of previously unavailable derivatives (e.g., isothiazoles containing two acetylene groups) have received further development. The syntheses of biologically active amides, isothiazolones and highly reactive 1,1-dioxides have been carried out. Isothiazoles were used as starting materials for the synthesis of novel, previously unavailable biheterocyclic structures, such as imidazoisothiazoles, diisothiazolopyrazines, isothiazolotriazines, substituted pyrroloisothiazole 1,1-dioxides and other compounds.

Methods for the synthesis of various heterocyclic compounds (pyrazoles, thiadiazapentalenes and other hardly accessible compounds) from readily available isothiazole derivatives have been developed.

High biological activities of isothiazoles is the main impetus for conducting in-depth studies in the field of isothiazole chemistry. More than 50% of work cited in this review are patents devoted to the synthesis and applications of isothiazoles as efficient agrochemical and medicinal preparations.

Obviously, the exceptionally broad spectrum of useful properties of isothiazoles determines the expediency of further studies into their chemistry. We hope that the present review will help attract more attention to this field of chemistry.

The use of molecular-statistical methods for the calculation of thermodynamic characteristics of adsorption for identification of organic compounds by gas chromatography – mass spectrometry

A K Buryak

Contents

I. Introduction	695
II. Semiempirical molecular-statistical theory of adsorption	696
III. The use of theoretical methods for identification of compounds	701

Abstract. The current state of research on the theoretical description of adsorption in the Henry region by semiempirical molecular-statistical procedures, as applied to identification of organic compounds in complex mixtures, is considered. Various approaches to correcting the atom–atom potential parameters used to determine thermodynamic characteristics of adsorption are compared. Examples of calculations involved in the chromatographic and chromatography–mass spectrometric identification of model and real organic compounds including isomers are given. The bibliography includes 89 references.

I. Introduction

Identification of organic compounds in mixtures is one of the most complicated problems of physical organic chemistry. The main difficulty arising in the work with mixtures is that simultaneous solution of two problems is required: the mixture should be separated into components and the components should be identified. At present, the most informative and reliable method for identification of organic compounds is the chromatography–mass spectrometry (GC-MS) technique.¹ Modern instruments make it possible to analyse volatile compounds in the gas chromatography–mass spectrometry mode (GC-MS) and non-volatile compounds, in the liquid chromatography–mass spectrometry mode (LC-MS).² The use of different ionisation techniques allows one to produce stable molecular ions, to vary fragmentation and to detect both positive and negative ions.^{2,3} In recent years, the range of masses that can be determined has markedly extended due to application of new ionisation techniques.⁴ A significant advantage of mass spectrometry is the possibility to determine the masses of molecular and fragment ions in the high-resolution mode with an accuracy of millionths of atomic mass units. Thus, it is possible to determine almost unambiguously the elemental compositions of molecules.⁵ The only limitation that holds up extensive use of high-resolution mass spectrometers for identification of substances is their high cost, which is 5–10 times as high as the cost of instruments for routine analysis.⁶ Chromatography–IR spectroscopy or chromatography–NMR spectroscopy could be possible alternatives to the

GC-MS;⁷ however, the development of these techniques is held up by relatively low sensitivity of IR spectroscopy and insufficient speed of operation of NMR spectrometers.

Even a highly potent method such as high-resolution mass spectrometry does not allow reliable identification of isomers in complex mixtures. This is due to the fact that differences in the fragmentation can hardly be attributed unambiguously to the structure of a particular isomer. Therefore, the use of chromatographic data for identification of substances becomes very important.⁸ The procedures for chromatographic identification of compounds based on the use of reference compounds, specific detectors, preliminary chemical reactions,⁹ chromatographic spectra¹⁰ and dependences of retention indices on various molecular characteristics¹¹ have been developed fairly comprehensively and we do not consider them here. However, all these methods are much inferior to the GC-MS technique in labouriousness, information content and reliability.

When discussing the GC-MS identification, one should note that the methods of structure determination based on mass spectrometry data can be classified into three groups.

(1) Library search which consists in comparing the spectrum of an unknown compound with the spectra deposited in databases or libraries and selecting those spectra that fit best the spectrum of the compound under study.¹²

(2) Methods for representing the compound structure on the basis of fragmentation rules.¹³

(3) Methods for substance identification consisting in determination of structural features by statistical analysis.¹⁴

Successful utilisation of mass spectrometry and determination of the structures of organic compounds requires the use of empirical rules and regularities elucidated in the studies of large numbers of compounds belonging to different structural classes,^{13,15} the presence of vast libraries of standard mass spectra (up to 300 thousand) of compounds, the use of high-end software for image recognition which resort to data of other spectroscopic methods¹⁶ (not only experimental but also obtained by calculations¹⁷) for structure determination and advanced computing machinery. The use of GC-MS provides not only mass-spectroscopic but also chromatographic information, namely, the retention indices for various stationary phases. These values are sufficiently accurate because a mass spectrometer is a highly selective detector and chromatographic peaks are usually much better resolved in ionic mass chromatograms than in chromatograms recorded with other detectors.

Combination of chromatographic identification techniques with GC-MS to identify isomers in complex mixtures is usually resorted to in investigations carried out along two lines, namely, identification based on semiempirical molecular-statistical calcu-

lations of retention values¹⁸ and identification using retention indices calculated theoretically.¹⁹

Retention index is a qualitative characteristic of a molecule correlated with physicochemical parameters, for example, with the molecule polarisability or with the melting or boiling point of the substance.^{8, 11, 19} Numerous equations have now been found to relate retention parameters (calculated as retention indices) to various physicochemical properties of molecules, in particular, isomer molecules.²⁰ Commonly, these equations make use of so-called increments which characterise separate fragments of a molecule that can be joined to form a new molecule. The main drawback of this approach is that assembling the increments gives an approximate geometrical structure rather than the real molecule. Therefore, fine intramolecular effects, especially those characteristic of isomers, can be taken into account only by introducing special corrections, which are rather arbitrary.²¹ Generally, this situation resembles the situation faced by an attempt to obtain precise values for molecular polarisability in terms of additive schemes — one too many corrections are needed to reach high accuracy. One more drawback of this method is the necessity of experimental determination of increments on the basis of a broad range of reference molecules.²² Extensive databases of experimental retention indices have now been composed; they can be efficiently used to identify separate classes of organic molecules.^{23, 24} Such bases are also supplemented by theoretically calculated indices; however, these have not yet found wide use.

Using the semiempirical molecular-statistical theory of adsorption, one can calculate the thermodynamic characteristics of adsorption (TCA) including the retention values for organic molecules of various classes. The theory is based on the use of atom–atom potentials (AAPs) for the interaction between the sorbent and sorbate atoms. An important advantage of this theory is the fact that the calculations of retention indices are based on the real structures of molecules, determined from electron diffraction data or constructed with allowance for the regularities of variation of bond angles and bond lengths. In the case of isomers, the TCA calculations alone based on real data on the molecular structure permit reliable identification of compounds.

II. Semiempirical molecular-statistical theory of adsorption

1. Scope of molecular-statistical calculations

To date, molecular-statistical calculations of TCA have been carried out for a broad range of adsorbents and adsorbates. The calculations of TCA for inert gases, simple polar molecules and hydrocarbons on zeolites of various types²⁵ and on porous crystalline silica (silicalite) have been reported.^{26–28} The molecular-statistical calculations have been developed most thoroughly for systems comprising graphitised thermal carbon black (GTCB) and hydrocarbons or their derivatives.²⁹ Graphitised thermal carbon black is a good model sorbent because it has a homogeneous planar surface the geometry and the chemical properties of which have been studied in sufficient detail. Vast experimental information on the adsorption of organic compounds of various classes on the GTCB surface has been accumulated.^{29, 30} The main reason why the molecular-statistical calculations for the adsorption on GTCB surface are being developed and improved is the fact that this process is exceptionally sensitive to the structure of adsorbed molecules. This creates conditions for the separation of geometric isomers.^{30–32} In most cases, a combination of the molecular-statistical calculations and GC-MS data provides unambiguous identification of individual isomers in complex mixtures.^{18, 32}

2. The procedure of molecular-statistical calculations

Kiselev and Poshkus^{29, 30} developed a semiempirical molecular-statistical method for the calculation of thermodynamic characteristics of the physical adsorption of gases on GTCB at very low surface coverages. Within the framework of this method, the

Henry constant (K_1) for the adsorption of quasi-rigid molecules is calculated using the equation

$$K_1 = \frac{1}{4\pi} \int \left(\frac{2\pi kT}{\Phi_z''} \right)^{1/2} \exp\left(-\frac{\Phi_0}{kT}\right) \sin \Theta d\Theta d\psi, \quad (1)$$

where Φ_0 and Φ_z'' are the potential function Φ values for the interaction between the adsorbate and adsorbent molecules in a potential minimum and its second derivative with respect to the distance z from the center of gravity of the molecule to the adsorbent surface; Θ and ψ are Euler angles, which define the orientation of the molecule relative to the adsorbent surface. The Φ_z'' and Φ_0 values and the equilibrium distance z_0 depend on Θ and ψ . The potential function Φ is presented as the sum of the AAPs for the interaction of each atom of the adsorbed molecule (A) with each carbon atom of GTCB (C_{GTCB}).

$$\Phi = \sum_A \sum_{C_{\text{GTCB}}} \varphi_{A...C_{\text{GTCB}}}. \quad (2)$$

The $\varphi_{A...C_{\text{GTCB}}}$ potential is written in the Buckingham–Corner form (6, 8, exp)

$$\varphi_{A...C_{\text{GTS}}} = -C_6 r^{-6} - C_8 r^{-8} + B \exp(-qr), \quad (3)$$

where C_6 , C_8 are the parameters of the dipole–dipole and dipole–quadrupole dispersion interaction potentials; r is the interatomic distance; B and q are parameters of the repulsion potential. The C_8 and C_6 values are estimated using approximate quantum-mechanical formulae. The parameter C_6 is found using the Kirkwood–Müller relation

$$C_6 = -6m_e c^2 \frac{\alpha_a \alpha_b}{(\alpha_a/\chi_a) + (\alpha_b/\chi_b)}, \quad (4)$$

where m_e is the mass of an electron; c is the velocity of light; α_a , α_b are polarisabilities of atoms a and b ; χ_a and χ_b are diamagnetic susceptibilities of atoms a and b .

The parameter C_8 is estimated using the formula

$$C_8 = \frac{45h^2}{32\pi^2 m_e} \alpha_a \alpha_b \left[\frac{1}{2} \left(\frac{\alpha_b/\chi_b}{\alpha_a/\chi_a} + 1 \right)^{-1} + \frac{1}{2} \left(\frac{\alpha_a/\chi_a}{\alpha_b/\chi_b} + 1 \right)^{-1} \right], \quad (5)$$

where h is Planck's constant. The repulsion parameter B is expressed in terms of the equilibrium interatomic distance r_0 and other AAP parameters using the equilibrium condition for all the attraction and repulsion forces for $r = r_0$

$$\left(\frac{d\varphi}{dr} \right)_{r=r_0} = 0, \quad (6)$$

$$B = \frac{6C_6 \exp(qr_0)}{qr_0^7} \left(1 + \frac{4C_8}{3C_6 r_0^2} \right). \quad (7)$$

The parameter q is taken to be 35.7 nm^{-1} . The equilibrium distance r_0 is normally estimated using crystal parameters or data on the interaction of atoms of the adsorbate molecule with GTCB. In particular, the value $r_0 = 0.382 \text{ nm}$ was accepted for $C...C_{\text{GTCB}}$ (this value was obtained from data on the graphite lattice properties) and $r_0 = 0.341 \text{ nm}$ was taken for $H...C_{\text{GTCB}}$. The summation of φ over the GTCB carbon atoms above the graphite basis plane is done using the Crowell approximation.³⁰ The potential function Φ_i for the interaction of an i -th atom of the molecule with the graphite basis plane is calculated from the equation

$$\begin{aligned} \Phi_i = & -C_{6,i} \frac{\pi^9}{2d^4} \zeta \left[\frac{z_i}{d}, 4 \right] - C_{8,i} \frac{\pi^9}{3d^6} \zeta \left[\frac{z_i}{d}, 6 \right] + \\ & + \frac{2B_i \pi^9}{q^2} (qz_i + 1) e^{-qz}, \end{aligned} \quad (8)$$

where $\vartheta = 0.382 \times 10^{-3} \text{ nm}^{-2}$ is the number of carbon atoms per unit area of the graphite basis plane; d is the interplanar spacing in graphite equal to 0.356 nm; ξ is the Riemann zeta function; z_i is the distance from the i -th atom to the plane passing through the centres of atoms of the outermost atomic layer of graphite. Relation (8) takes into account the contribution of only the outermost atomic layer of graphite to the repulsion energy.

The differential molar changes of the intrinsic energy ΔU_1 and entropy ΔS_1 upon adsorption are calculated using the relations

$$\Delta U_1 = RT^2 \frac{d \ln K_1}{dT}, \quad (9)$$

$$\frac{\Delta S_1}{R} = \ln K_1 + T \frac{d \ln K_1}{dT} - 1. \quad (10)$$

A special program is used to calculate the TCA.³³ The parameter C_6 is first estimated from Eqn (4). However, the K_1 and ΔU_1 values found using the C_6 value determined in this way differ markedly from the corresponding experimental data.²⁹ Therefore, the AAPs for the interaction of atoms in the adsorbate molecule with GTCB ($\varphi_{H...C_{GTCB}}$ and $\varphi_{C...C_{GTCB}}$ for each atom of the molecule in different valence states) are further corrected using relations (4)–(11) and the experimental K_1 values for one or two simple representatives of the class of hydrocarbons under consideration. The $\varphi_{H...C_{GTCB}}$ and $\varphi_{C(sp^3)...C_{GTCB}}$ values are corrected assuming that the parameters C_8/C_6 , r_0 and q , estimated in terms of the properties of the adsorbate and the adsorbent taken separately, differ only slightly from the exact values and that the following equality holds:

$$\frac{C_{6,C...C}}{C_{6,C...H}} = \frac{C_{6,C...C}^{KM}}{C_{6,C...H}^{KM}}, \quad (11)$$

where $C_{6,C...C}$ and $C_{6,C...H}$ are the values of parameters that satisfy experimental data; $C_{6,C...C}^{KM}$ and $C_{6,C...H}^{KM}$ are the C_6 values estimated using the Kirkwood–Müller formula. If these assumptions are valid, the corrected potential functions φ are related to the rough functions φ^* in the following way:

$$\varphi = \beta \varphi^*, \quad (12)$$

$$\Phi = \sum_A \sum_{C_{GTCB}} \varphi = \beta \sum_A \sum_{C_{GTCB}} \varphi^* = \beta \Phi^*, \quad (13)$$

where

$$\beta = \frac{C_{6,C...C}}{C_{6,C...C}^{KM}} = \frac{C_{6,C...H}}{C_{6,C...H}^{KM}}. \quad (14)$$

The β coefficient is usually determined by comparing the K_1 values calculated on the basis of Φ^* with those found experimentally. The equations for the interaction potentials of atoms in alkanes with GTCB corrected in this way (kJ mol^{-1}) have the form

$$\varphi_{C(sp^3)...C_{GTCB}} = -1.386 \times 10^{-3} r^{-6} - 2.148 \times 10^{-5} r^{-8} + 1.89 \times 10^5 \exp(-35.7r), \quad (15)$$

$$\varphi_{H...C_{GTCB}} = -0.498 \times 10^{-3} r^{-6} - 0.950 \times 10^{-5} r^{-8} + 3.60 \times 10^4 \exp(-35.7r). \quad (16)$$

The K_1 and ΔU_1 values calculated using these potentials for alkanes with known molecular structures are close to experimental results. Assuming that the $\varphi_{H...C_{GTCB}}$ potential of the hydrogen atom in a hydrocarbon molecule does not depend on the valence state of the carbon atom and that the r_0 and q parameters are identical for carbon in any valence state, it was found that

$$\varphi_{C(sp^2)...C_{GTCB}} = \delta \varphi_{C(sp^3)...C_{GTCB}}, \quad (17)$$

where δ is the parameter depending on the valence state of the carbon atom.

Using the experimental K_1 values, it was found for ethylene that

$$\varphi_{C(sp^2)...C_{GTCB}} = -1.48 \times 10^{-3} r^{-6} - 2.30 \times 10^{-5} r^{-8} + 2.026 \times 10^5 \exp(-35.7r). \quad (18)$$

Relying on the K_1 values determined experimentally for acetylene adsorption, the potential $\varphi_{C(sp)...C_{GTCB}}$ can also be calculated. These potentials were used to calculate the TCA for a large number of hydrocarbons: alkanes,³⁴ cycloalkanes,^{29, 35} alkenes, alkynes³⁶ and aromatic hydrocarbons³⁷ on the GTCB surface. In the case of hydrocarbons with known molecular structures, the TCA values found in this way coincide with the corresponding experimental values to within the error of determination.

The above-described procedure was used to determine the AAPs for the interaction of the carbon atoms in graphite with oxygen in two valence states (in ethers and ketones)³⁸ and to calculate the TCA for a number of oxygen-containing organic compounds on the GTCB surface.³⁹

Guiochon and coworkers^{40, 41} also used the molecular-statistical method for calculation of the TCA for various hydrocarbons and their chlorinated derivatives; however, these calculations were performed using uncorrected AAPs, therefore, the calculated and experimental TCA markedly differ. When calculating Φ for complex conjugated molecules, researchers attempted to take into account the anisotropy of graphite polarisability.⁴² For chloro-derivatives of aromatic hydrocarbons, it was found that the order of elution of isomers out of the column is better described by a model that does not take into account the electrostatic interaction of the adsorbate molecule with the adsorbent surface.⁴¹

Apart from the organic compounds mentioned above, adsorption of noble gases^{29, 30} and nitrogen,⁴³ sulfur- and selenium-containing⁴⁴ compounds on the GTCB surface has also been studied. Some of the AAP parameters known to date are listed in Table 1. Satisfactory agreement of the experimental results with the theoretical results obtained using these parameters is attained in those cases where the mutual influence of atoms in the adsorbed molecule is insignificant. When the mutual influence of atoms is substantial, corrections should be applied to the AAPs. In some

cases, the calculations are hampered by the absence of precise structural parameters for sorbate molecules.⁴⁵

Thus, fairly good agreement between the calculated and experimental TCA values for compounds with known molecular structures is attained if corrected AAP values are used to calculate the potential function of intermolecular interactions.

However, for some molecules, TCA cannot be predicted with a satisfactory accuracy. For example, during identification of isomers in mixtures, the sequence of isomer emergence from the column with GTCB predicted by calculations does not coincide in some cases with the experimental one. This is due to the difference between the AAP parameters for atoms incorporated in the molecule in question and the parameters corrected using the reference molecules. The difference is caused by the change in the nearest environment or valence state of the atom, manifested as a change in polarisability. Therefore, to identify separate isomers in complex mixtures and to determine reliable TCA (especially, the Henry constants), one must find the precise values for the AAP parameters.

3. Correction methods for the parameters of the atom – atom potentials

Several methods for correcting the AAP parameters have been developed to date.

a. Traditional method

The approach proposed by the developers of the semiempirical molecular-statistical theory of adsorption²⁹ can be considered to be the first of the known methods for correcting the AAP parameters. This approach is based on determination of individual AAPs (using reference molecules) for atoms forming the molecule under study, including chemically identical atoms in different valence states. In terms of the semiempirical molecular-statistical theory,²⁹ the AAP parameters are determined from approximate quantum-mechanical formulae (see above) using some characteristics of adsorbate and adsorbent atoms, *e.g.*, polarisability, diamagnetic susceptibility and equilibrium distances. The atom – atom potentials determined for the interaction of atoms of the adsorbate molecule with the adsorbent (GTCB) carbon atoms are corrected using the comparison of the theoretical and experimental Henry constants K_1 for the adsorption of a representative of the class of compound studied. The correction is carried out using so-called reference molecules, whose adsorption has been studied most comprehensively. The obtained AAPs are assumed to be transferable, *i.e.*, they allow correct prediction of the TCA for any molecule that contains the corresponding atoms. This procedure was used to determine and correct the AAP parameters for the adsorption of alkanes, alkenes, alkynes and aromatic hydrocarbons on GTCB; methane and ethane, ethylene, acetylene, and benzene, respectively, served as the reference molecules. In these calculations, three AAPs for carbon atoms corresponding to the sp^3 , sp^2 and sp^1 hybridisation states were found; they differ only by the correction factors, which are equal to 1.00, 1.07, and 1.27, respectively. Two AAPs for the oxygen atoms in ethers and ketones were found in the same way; they differ by the correction factors, which are 0.72 and 0.92, respectively.³⁸ The AAPs for sulfur, selenium,⁴⁴ fluorine,⁴⁶ chlorine,⁴⁷ and bromine⁴⁸ were determined. The corresponding correction factors are equal to 0.87, 0.89, 0.85, 0.95 and 0.76, respectively. Actually, this approach is similar to the calculation of polarisabilities, diamagnetic susceptibilities, and the dipole moments of molecules in terms of additive schemes.⁴⁹ The AAPs determined in this way were used to predict the TCA for a number of hydrocarbons and their derivatives, which are in good agreement with experimental data.^{36,38,46} However, for many molecules [both relatively simple ones such as *ortho*-halobenzenes,⁵⁰ perhydroanthracenes, perhydrophenanthrenes,⁵¹ heterocyclic nitrogen-containing compounds,^{52,53} and fairly complex molecules such as molecules with abnormal geometric parameters (strained mole-

cules), with bulky substituents, with several heteroatoms, and their unusual combinations], the TCA could not be correctly predicted.

The main drawbacks of the above method are as follows. For each valence state (and, in the general case, for each type of the atom nearest environment), one must know a separate AAP, which has to be corrected on the basis of experimental data for reference molecules. However, the number of these AAPs may become too large (especially for carbon, oxygen and nitrogen atoms), which would complicate the calculation. In addition, this procedure does not take into account the changes in the AAPs caused by the influence of atoms not bound by valence bonds.

b. Taking into account the dependence of the atom – atom potentials on the bond angles

The method proposed by Arkhipova⁵⁴ takes into account the effect of the change in the geometric parameters of a molecule on the carbon atom hybridisation and, correspondingly, on the AAP parameters. A pattern of dependence of AAP parameters on the deviation of the bond angles formed by carbon atoms from the ideal values corresponding to the sp^3 , sp^2 and sp^1 hybridisation states has been proposed. Using this dependence, one can determine more precisely the AAP values for atoms that form non-ideal bond angles. The results obtained by this method for a series of strained molecules (for example, cyclopropane derivatives and some bicyclic compounds) are in good agreement with experimental data. An example illustrating the efficiency of this method is the correct (experimentally confirmed) prediction of the order of elution of C_8H_{12} isomers, cyclobutadiene and bicyclo[3,3,0]oct-1,5-ene, from a column with GTCB, which could not be determined without applying corrections.

However, this method also suffers from serious drawbacks: first, it is applicable only to molecules with a known geometry because corrections are based on structure differences; second, determining a correction requires the knowledge of, at least, two boundary potentials, because the correction provides some intermediate value of the AAP parameters; third, this method cannot be used to correct the AAP parameters that change under the influence of non-bonded atoms, which does not distort the geometric structure of the molecules. Other 'AAP parameter – atom property' relationships have also been constructed; the atom properties used in these relationships are, in particular, the polarisability, the effective charge, the shielding constant, and the hybridisation state. The methods based on these dependences suffer from the above drawbacks.⁵⁵

c. Variation of the parameters of atom – atom potentials

The variation of the AAP parameters is done in order to minimise the discrepancy between the experimental and calculated data for all molecules of the group chosen for the investigation; this can be done, for example, by the regularisation technique.⁵⁶ A single parameter can also be varied. For example, in the calculation of AAP for a series of bromobenzene molecules, the role of this parameter was played by the equilibrium distance between the GTCB carbon atom and the bromine atom.⁴⁸

However, this method allows one to attain the optimal agreement between the experimental and theoretical results only for the considered group of molecules. The transfer of parameters corrected for a given group of molecules to other (even 'related') molecules usually results in a deviation between the experimental and calculated values for new molecules. For example, the AAP values corrected by varying the GTCB carbon – halogen equilibrium distance are in good agreement with experimental data only for the molecules of halobenzenes containing no halogen atoms in *ortho*-positions.⁴⁸ Otherwise, to describe experimental data with a satisfactory accuracy, additional corrections taking into account the mutual influence of atoms (corrections for *ortho*-effects) should be applied when calculating the AAPs.

d. The use of corrected initial data for the calculation of atom – atom potentials

It is known⁵⁷ that the mutual influence of atoms can change their polarisabilities. In calculations of the TCA, these changes are taken into account either by applying additional corrections to the equations for AAP⁴⁸ or by using corrected polarisabilities. In our opinion, the use of corrected polarisabilities is most efficient for calculating the TCA of perhalogenated compounds, first of all, freons, for which isostructural fragments can hardly be chosen (or there are too many of them). The adsorption heats⁵⁸ of such compounds are described satisfactorily, within the experimental error, without introducing any corrections; however, for predicting the Henry constants, the correction of the AAPs is necessary. The method in which corrected initial data (first of all, polarisabilities and diamagnetic susceptibilities) are used in the calculation of the AAP parameters is of undisputed interest also due to the fact that a vast experimental base has now been accumulated and detailed additive schemes for polarisability calculations for molecules of diverse compounds,⁵⁹ especially perhalogenated ones, have now been developed.

A shortcoming of this method is the need to measure the polarisabilities, which requires a substantial amount of the material. In addition, one should borne in mind the relatively low accuracy of the polarisability values calculated according to additive schemes,^{60,61} which can lead to greater errors in the calculations of the TCA.

e. The introduction of corrections for *ortho*-effects

Changes in the AAP parameters are due to the mutual influence of atoms, in particular, when they occupy *ortho*-positions.⁶¹ By varying these parameters, one can attain the correspondence between experimental and theoretical data for an *ortho*-substituted molecule with known experimental TCA. The corrected AAPs can be used for the calculation of TCA for other molecules with atoms in *ortho*-positions. The applicability of this approach (the introduction of corrections for the *ortho*-effect) was demonstrated in relation to halobenzenes.⁴⁸ Actually, this method for correcting the AAPs is similar to the method using reference molecules (and, correspondingly, the drawbacks are also the same) but applies to a more limited group of molecules. In some cases, additional corrections are required to bring the theoretical results in correspondence with the experiment, for example, *ortho* – *ortho*-effect corrections.⁶² As an example, one can consider 1,2-dichlorobenzene and 1,2,3-trichlorobenzene molecules in which corrections for the *ortho*- and *ortho* – *ortho*-effects are required.

Probably, it is expedient to apply such corrections to molecules that possess specific properties, for example, to adamantane in which 1-substituents are subject to the 'cage effect', which is also involved in adsorption.

The term 'cage effect' implies the overlap of the electronic orbitals of the carbon atoms at the 1-positions which are not bound by valence bonds. This overlap brings about a substantial difference between the properties of 1- and 2-substituted isomers, which is manifested, in particular, in the chromatographic separation on phases having different polarity. The allowance made for the cage effect for chloro-⁶³ and amino-substituted adamantane isomers⁶⁴ permitted the prediction of the correct order of isomer elution from a column packed with GTCB, whereas traditional calculations⁶⁵ did not provide a correct prediction. The overlap of the orbitals of the bridgehead carbon atoms and their influence on the substituent (amino group) polarisability is illustrated by Fig. 1.

Figure 1. Cage effect in the 1-aminoadamantane molecule.

f. The method of isostructural fragments

The method of isostructural fragments⁶⁶ (IF) is based on the use of AAPs corrected for some single molecule or its fragment in the calculations made for other molecules containing the same fragment. For a molecule containing the isostructural fragment, the AAPs are corrected by processing the theoretical and experimental values by the least-squares calculations, their agreement being attained by varying the correction factor. In doing this, the AAPs for atoms of one sort are changed, in order to decrease the total number of AAPs used in calculations. The IF is chosen on the basis of comparison of the geometrical structures of molecules of the group under interest; in particular, the specially obtained electron diffraction data, the known regularities of the change in the bond angles and bond lengths in groups of related molecules, or the results of quantum-chemical calculations can be compared. Usually, molecules with a geometrical structure (or its fragment) common to the given class of molecules are chosen as the IF. For example, in the case of cyclopropane derivatives, this is the cyclopropane molecule, and for *ortho*-substituted chlorobenzenes and naphthalenes, this is the 1,2-dichlorobenzene molecule.

In fact, the IF method allows one to overcome the limitations of the atom – atom approximation and takes into account the mutual influence of atoms and groups of atoms including the change in the polarisabilities and geometric parameters of the interacting fragments.

g. The method of variation of the molecular geometry

An important benefit of the semiempirical molecular-statistical theory of adsorption is the use of structural parameters of molecules in the TCA calculations. However, this benefit is simultaneously a drawback, because exact parameters of the molecular structure have been determined for a limited range of substances and, normally, they are lacking for most of isomers. An alternative to all the methods of AAP correction considered above is the method of variation of the geometric parameters of the molecule. This procedure has been used to predict the retention values for perhydroanthracenes and perhydrophenanthrenes.⁵¹ By using this variation, the researchers predicted the order of isomer elution from a GTCB column that coincided with the experimental results. However, the geometry variation, especially for molecules with an unknown structure, is legitimate only in the case of quantitative comparison of theoretical and experimental data, and, naturally, it is impossible to estimate the variation of the AAP parameters in terms of this method.

4. Comparison of various methods for the correction of the atom – atom potential parameters

Among the methods for correcting the AAP parameters considered above, the following are most important: the method based on the use of corrected initial data (first of all, polarisability); the introduction of *ortho*-effect corrections and the IF method. The Henry constants calculated using the AAP parameters corrected by these methods for a number of molecules have been compared.^{66,67} The results of comparative analysis confirm the good prospects of the IF method.

For a number of chlorobenzenes with different degrees of substitution, the Henry constants were calculated using the AAP values corrected by various methods and the results were com-

pared. The chlorobenzene molecules were chosen as the model series because they represent groups of isomers, and the sequence of elution of isomers from a GTCB column is an important criterion of the reliability of calculations. In addition, both experimental and calculated TCA determined by various methods are available for molecules of this series (Table 2).^{41, 47, 48, 68} Of all possible TCA that can be calculated using the semiempirical molecular-statistical adsorption theory, the Henry constants were chosen as the characteristics most sensitive to variations of the AAP parameters and the geometrical structures of molecules. It was shown^{48, 50} that even for molecules containing no strained fragments or *ortho*-arranged atoms, the experimental and theoretical values of the Henry constants can be brought in correspondence by correcting the AAP only in terms of the procedure of reference molecules. Therefore, corrections were applied to the already corrected potential, which was 5% smaller than the initial one.

In the calculations in terms of the IF method, known AAPs tested in the calculations of TCA for chlorobenzenes were used as the basic parameters. The IF chosen were 1,2-di- and 1,2,3-trichlorobenzenes. Relying on the experimental data for these molecules (the Henry constants and their differences for isomers

Table 2. Values $\ln K_1$ ($\text{cm}^3 \text{m}^{-2}$) for the adsorption of chlorobenzenes on GTCB at 473 K obtained experimentally and calculated using the AAPs corrected by various methods.⁵⁰

Molecule	Experiment	Calculations				
		1	2	3	4	5

Notes. The correction of the AAPs by method 1 was carried out using the reference 1,4-dichlorobenzene molecule;⁴⁸ the correction by method 2 was based on the experimental polarisability value determined in Ref. 60 for the chlorine atoms in 1,2-dichlorobenzene (in the calculations of $\ln K_1$ for other chlorobenzenes, these corrected AAP values were used only for *ortho*-arranged chlorine atoms); in method 3, the corrections for the *ortho*- and *ortho-ortho*-effects were taken from Refs 48, 50; in the case of method 4, 1,2-di- and 1,2,3-trichlorobenzenes were chosen as the isostructural fragments; the corrections for the AAPs based on the experimental Henry constants or the differences between the retention of neighbouring isomers is 0.92 for the fragment containing two chlorine atoms in *ortho*-positions and 0.91 for the fragment containing three atoms of this type; in the correction by method 5, the molecular geometry was varied assuming that *ortho*-chlorine atoms cause a deflection of the carbon–chlorine bond from the benzene ring plane; for the first five chlorobenzene molecules, the angles of deflection of the carbon–chlorine bonds from the benzene ring plane were taken from Ref. 48, while for other isomers, the transferability of the angles was assumed, in particular, in calculations of the Henry constant for 1,2,3-trichlorobenzene, a value of 78 was taken, as for 1,2,4-trichlorobenzene, while in the case of 1,2,3,4- and 1,2,3,5-tetrachlorobenzenes, this value was 128, as for the 1,2,4,5-substituted isomer.

closest in retention values), researchers obtained corrections for the AAPs to describe the interaction between the chlorine atom and the graphite carbon atom. In any case, the molecular-statistical calculations were carried out as described above (see Section II.2). The geometric parameters of molecules were found either from electron diffraction data or by combining the known parameters for other molecules of the given group.

However, the introduction of corrections by some procedures does not always provide the best correspondence between the experimental and calculated data. For example, the use of the method of reference molecules, the method of correcting the polarisability values and the geometry variation give rise to inconsistency between the experimental and calculated orders of isomer elution out of a GTCB column, and for some isomers, the experimental and theoretical $\ln K_1$ values differ appreciably (see Table 2). The best results are provided by the IF method and by applying the *ortho*-effect corrections.

The IF method appears to be more versatile and reliable because its application rules out the uncertainty related to the geometrical structures of molecules. Naturally, it is suitable for refining the parameters of AAPs not only for the molecules considered above. In our opinion, this method is especially advantageous for calculating the TCA of complex (in particular, isomeric) molecules containing heteroatoms and strained fragments.

5. Combination of the gas chromatography – mass-spectrometry data with semiempirical molecular-statistical calculations

When calculating retention indices, in particular, Kovac indices, an approximate rather than real structure of the molecule is actually used.^{8, 10} Therefore, in those cases where corrections for definite effects have not been applied, identical values are usually obtained for isomers. The corrections are not transferable: usually, they are applicable only to the group of molecules for which they have been determined. When the retention indices are calculated within the framework of the semiempirical molecular-statistical adsorption theory, the real structure of the molecule is used.^{18, 30} To increase the efficiency of GC-MS identification, one should take into account the retention indices calculated in terms of this theory. Scheme 1 represents the pattern of usual GC-MS identification,^{1, 5} while Scheme 2 shows the identification procedure based on the molecular-statistical calculations.⁶⁷

The first stage consists in molecular-statistical calculations performed to estimate tentatively the possible efficiency of the chromatographic column. The tentative calculations help to answer the key question of whether the isomers under consideration can be separated by chromatography using a GTCB column. Adsorption of a broad range of substances on this sorbent has now been studied, but their number, of course, is not

Scheme 2

commensurate with the number of known organic compounds; therefore, the tentative calculation of the TCA is a necessary item in the research. In addition, these calculations permit one to optimise the conditions of the chromatographic experiment planned, to choose the temperature, the carrier gas velocity, the adsorbent weight and the column length.

The next stage is the GC-MS study in which individual isomers are to be separated and identified on the basis of differences in the mass spectra or, if the spectra are identical, it is necessary to confirm that the substances being analysed belong to the group of isomers in question. The efficiency and selectivity of the chromatographic separation is evaluated on the basis of the observed overlapping mass spectra. The modern instrumentation and computer software for data processing allow this to be done in the mass chromatography and mass fragmentography modes. To verify the completeness of separation attained on a micropacked column with GTCB, it is expedient to record the chromatogram on a highly efficient capillary column most appropriate regarding the selectivity (in order to compare the results obtained with different columns).

The next stage is conduction of molecular-statistical calculations for isomers using corrections for the possible variations of the AAP parameters. In the simplest case, identification can be performed by comparing the sequence of isomer elution from a GTCB column observed experimentally with the calculated one. The experimental retention indices and those determined by molecular-statistical calculations can also be compared, which is generally preferred. In addition, the data on the molecular structure used in the calculations can be verified by examining fragmentation of the molecule, induced, for example, by an electron impact.

Comparison of Schemes 1 and 2 shows that the identification procedure resorting to molecular-statistical calculations provides more reliable results. It is evident that combination of the results obtained in terms of the molecular-statistical theory with the results of a mass-spectrometric experiment would allow one to increase the efficiency, reliability and the information contents of the method and, hence, to solve the problem of isomer identification at a new level.

Correlation equations that relate the Henry constant,⁶⁹ the second virial coefficient of the intermolecular interaction,⁷⁰ or the

heat of adsorption⁷¹ to some characteristics of the molecule are usually considered as alternatives to the molecular-statistical calculations. The critical temperature and pressure or both,⁷¹ the molecular refraction,⁷² the dipole moments and the boiling points⁷³ are used most often. An advantage of such calculations is the possibility of changing the sorbent^{71,73} or specifying the degree of its inhomogeneity,⁷⁴ which helps to elucidate the applicability of a sorbent to the separation and analysis of a particular group of substances. Good correlation coefficients are usually obtained for series of related molecules;⁶⁹ however, the relationship between the molecular structure and the physico-chemical characteristics of adsorption remains obscure. Therefore, these methods are suitable only as auxiliary ones in the identification of isomers.

An *ab initio* molecular-statistical method for calculation of the Henry constant has been developed.^{75–80} The method makes use of the relationship between the structural characteristics of molecules and the energetic, geometric and topological^{81–84} properties involved in the adsorption. Unlike the traditional semiempirical molecular-statistical theory, the main idea of this approach has been the refusal of the additivity principle for AAP. Instead, the view of generalised charge of the molecule was introduced and a law for summing these charges was postulated. This theory was used to calculate the TCA for various types of hydrocarbons on GTCB and to determine the Kovac indices on a nonpolar stationary liquid phase (squalane). The calculated values are in good agreement with experimental data. This calculation method appears rather promising; however, it belongs to quantum chemistry and requires a separate review to be described.

III. The use of theoretical methods for identification of compounds

Mixtures of isomers can be separated into groups in conformity with the known numbers of isomers present. The simplest situation arises when the mixture is known to contain all the possible isomers or when this can be determined from the results of a GC-MS experiment. When analysing mixtures of isomers with a 'rigid' structure on a GTCB column, one should merely calculate the order of elution and thus identify the isomers. Such procedure has been carried out for the components of a mixture of *endo*- and *exo*-tetrahydrobicyclopentadienes. The *endo*-isomer has lower TCA and, correspondingly, it is the first to come out of the GTCB column. In this case, the fact that the mass spectra of the isomers are identical does not hamper the analysis.⁶⁷

The isomers of 1-methyl-1,2-dicyclopentylcyclopropane³² are more complex objects for identification, as their molecules are capable of internal rotation. The internal rotation angles are unknown; therefore, these isomers can be identified only on the basis of calculations performed for all the possible values of these angles; the differences between the Henry constants were calculated and compared with the difference found in the experiment. Upon this comparison, it was found that the *cis*-isomer is the first to come out of the GTCB column. In this case, the molecular-statistical calculations represent the only possible method for identification because the mass spectra of the isomers are identical.

The isomer mixtures for which the composition can be suggested from a known chemical reaction pattern can reasonably be regarded as another group. The catalytic oxidative dimerisation of methyl-, fluoro- and chlorobenzenes normally furnishes mixtures of six isomers containing one substituent in each benzene ring. Using molecular-statistical calculations, all the isomers of dimethyl-⁸⁵ and dichlorobiphenyls⁸⁶ were identified based only on the order of their elution from a GTCB column. The molecular-ion mass chromatograms are presented in Fig. 2. The following calculated values of $\ln K_1$ ($\text{cm}^3 \text{m}^{-2}$) were obtained for dichlorobiphenyls at 475 K and dimethylbiphenyls at 450 K:

Substituent position	2,2'	2,3'	2,4'	3,3'	3,4'	4,4'
Methyl	3.02	3.42	4.24	5.42	6.24	7.12
Chlorine	2.39	4.25	4.78	5.75	6.24	7.20

Despite the fact that only traces of 2,2'-substituted isomers were present, they were identified on the basis of mass spectra.⁸⁷

In the case of difluorobiphenyls, the chromatogram exhibits only five peaks. To identify the isomers in conformity with Scheme 2, the Henry constants and the numbers of theoretical plates needed for the complete (n_1) and partial (n_2) resolution of each isomer pair were calculated. This gave the following results:

Isomer pair	2,2' and 2,3'	2,3' and 2,4'	2,4' and 3,3'	3,3' and 3,4'	3,4' and 4,4'
n_1	22	1500	22	5100	3500
n_2	5	380	5	1300	900

For some isomers, only partial resolution is possible and this is confirmed by the chromatogram presented in Fig. 3 *a*. It can be seen that the mixture contains 2,2'-difluorobiphenyl, which is the first to be eluted. To verify this, a chromatogram on a capillary column was obtained; however, in this case, too, the isomers could not be completely resolved (Fig. 3 *b*). The isomers cannot be identified using a mass spectrometry because they exhibit identical mass spectra. Therefore, comparison of the calculated and experimental retention values is the only way to confirm the presence of all isomers in the mixture. The results of calculations confirming that a mixture of difluorobiphenyls also contains all six isomers have been reported.⁸⁷

Figure 2. Molecular ion mass chromatograms of dimethylbiphenyl (*a*) and dichlorobiphenyl (*b*), $m/z = 182$ and $222(224)$, respectively.^{85,86}

Figure 3. Chromatograms of a difluorobiphenyl isomer mixture obtained on a micropacked column with GTCB (*a*) and a capillary column (*b*).⁸⁷ Isomer (position of the substituent): (1) 2,2'; (2) 2,3'; (3) 2,4'; (4) 3,3'; (5) 3,4'; (6) 4,4'.

The advantages of calculations using the AAPs corrected by the IF method can be demonstrated in relation to the identification of trace impurities formed upon the catalytic oxidative dimerisation of chlorobenzene.^{66,88} The isostructural fragments used are presented in Fig. 4. The results of identification of the major components, dichlorobiphenyls, are presented above. The formation of trichlorobiphenyls can easily be confirmed on the basis of mass-spectrometry data; however, it is impossible to identify individual isomers, as their mass spectra are identical. Figure 5 shows the mass chromatograms of the molecular ions of tri- and dichlorobiphenyls with $m/z = 256$ and 226 , respectively. It can be seen that the trichlorobiphenyls come out of the column with GTCB between two groups of dichlorobiphenyls.

All the dichlorobiphenyls have been identified (see above), and their Henry constants can be used as the reference values in the identification of trichlorobiphenyl isomers. The results of calculations of the Henry constants for *ortho*-substituted tri- and dichlorobiphenyls are listed in Table 3. In this case, there is no need to carry out calculations for all the isomeric trichlorobiphenyls, because only *ortho*-substituted isomers have retention times

Figure 4. Isostructural fragments (marked by dashed lines) in molecules used for correction of the AAP parameters in calculations of the Henry constants of chlorobiphenyls.

Figure 5. Characteristic-ion mass chromatograms of di- and trichlorobiphenyls obtained from the chromatograms for total ion currents in the separation of a chlorobiphenyl mixture on a capillary (a) and micropacked (b, c) columns.⁶⁶ The characteristic ion has $m/z = 256$ (a, b), 226 (c).

comparable with the retention times of dichlorobiphenyls. It can be seen from Table 3 that the elution of 3,3'-dichlorobiphenyl from the GTCB column is preceded by the elution of 2,4,6-, 2,6,4'- and 2,3,6-trichlorobiphenyls. The isomer whose retention time is close to that of 2,3'-dichlorobiphenyl is 2,3,2'-trichlorobiphenyl, while the compound with a retention time similar to that of 3,3'-dichlorobiphenyl is 2,5,4'-trichlorobiphenyl. It is noteworthy that the efficiency of separation of these isomers achieved on a microcolumn packed with GTCB is higher than that on a capillary column with a slightly polar liquid stationary phase. This outcome is attributable to the high 'sensitivity' of the GTCB surface to the structural differences between the adsorbed molecules. In view of the large difference between the Henry constants for tri- and dichlorobiphenyls (see Table 3), one can state that in this case, complete separation of the mixture has been attained and each chromatographic peak really corresponds to a single isomer.

In the case of nonsymmetrical molecules, for example, 2,3,2'-trichlorobiphenyl, two conformers can exist differing by the internal rotation angles. Since the structure of the adsorbed molecule is unknown, the calculations were carried out for the two possible conformations, *syn* and *anti*.

The catalytic oxidative dimerisation of toluene⁸⁵ was found to give, in addition to dimethylbiphenyls, impurities with a molecular mass of 196. The chromatograms obtained using a GTCB

2,5,4'-Trichlorobiphenyl	53	4.87

column (Fig. 6) show that the retention time of these compounds is close to the retention time of 2,4-dimethylbiphenyl. On the basis of analysis of the regular features of retention on GTCB, one can state that compounds with higher molecular masses can have

Figure 6. Characteristic-ion mass chromatograms of dimethylbiphenyls (a) and impurities (b, c) obtained on a micropacked GTCB column.⁸⁸ The characteristic ion has $m/z = 182$ (a), 196 (b), 104 (c).

shorter retention times only when their molecules are nonplanar, in particular, for large internal rotation angles. A dimethylbiphenylmethane or *ortho*-substituted trimethylbiphenyl structure can be proposed for these compounds. In this case, identification of the impurities using mass spectra confirmed the validity of the assumption. Analysis of the recorded mass spectra provides the conclusion that the isomer whose spectrum contains a large peak with $m/z = 104$ (Fig. 7 *a*) corresponds to the group of dimethylbiphenylmethanes. The mass spectrum of the other compound (Fig. 7 *b*) resembles most closely the spectrum of trimethylbiphenyl but this assignment can hardly be confirmed on the basis of library search, as the published data are scarce. In order to identify this compound, molecular-statistical calculations of $\ln K_1$ ($\text{cm}^3 \text{m}^{-2}$) were carried out for all possible trimethylbiphenyl isomers containing at least one methyl group in the *ortho*-position relative to the bond connecting the benzene rings. The results of these calculations are presented below.

Substituent position	$\ln K_1$	Substituent position	$\ln K_1$
2,3,2'	3.32	2,5,4'	3.53
2,3,3'	8.16	2,6,2'	3.67
2,3,4'	10.14	2,4'	4.24
2,4,2'	3.93	2,6,3'	4.29
2,4,4'	10.1	3,3'	5.42
2,5,2'	3.64	2,6,4'	4.86
2,5,3'	7.24		

Yet another example of utilisation of the method in question for compound identification is analysis of an industrial mixture of chlorobiphenyls for the most toxic, 'dioxin-like' isomers.^{66,67,89} The results of chromatographic separation of this mixture on micropacked and capillary columns showed that the degree of separation obtained on a micropacked column for a mixture containing tri- and tetrachlorobiphenyls is adequate for the molecular-statistical identification of isomers by comparison with characteristic-ion mass chromatograms of tri- and tetrachlorobiphenyls (Fig. 8). The results of calculation of the Henry

Figure 7. Mass spectra of various impurities with identical molecular ions detected in the reaction mixture resulting from catalytic dimerisation of toluene.^{67,88}

Figure 8. Molecular-ion mass chromatograms of trichloro- ($m/z = 256$) and tetrachlorobiphenyls ($m/z = 292$) obtained on a micropacked GTCB column (*a*) and on a capillary column (*b*).^{67,89}

constants for tetrachlorobiphenyl isomers were compared with this constant for 4,4'-dichlorobiphenyl, present in the mixture and used as the standard. This comparison made it possible to find out that the retention times of all tetrachlorobiphenyls present in the mixture are shorter than that of the 4,4'-substituted isomer, whereas the retention time of the 'dioxin-like' 3,4,3',4'-tetrachlorobiphenyl is longer. Thus, the mixture under study does not contain the most toxic *ortho*-unsubstituted isomers.

* * *

The gas chromatography – mass spectrometry method considered in this review, which was used for mixture identification, appears to be the only reliable method known to date suitable to identify the belonging of isomers to a particular class of compound. Naturally, the examples cited do not cover all the possible fields of GC-MS application but they demonstrate that in combination with molecular-statistical calculations, this method provides the most reliable results. When discussing the semiempirical molecular-statistical theory, one should note one substantial limitation, namely, that the theory is applicable only to adsorption on the GTCB surface. Nevertheless, the experience accumulated for decades demonstrates high potency of this theory in complex situations, which often arise during chromatographic identification of organic compounds.

IV. Construction of nitroarene-based heterocyclic systems	718
V. Conclusion	719

Abstract. Data on new methods for the synthesis of fused azines by nucleophilic attack on the unsubstituted carbon atom of azines and nitroarenes are generalised. The review surveys tandem reactions of azines with binucleophiles comprising nucleophilic addition A_N-A_N , nucleophilic addition–substitution $A_N-S_N^{ipso}$, and nucleophilic substitutions $S_N^H-S_N^{ipso}$ and $S_N^H-S_N^H$. Intramolecular S_N^H reactions of azines and nitroarenes and other methods for the synthesis of fused heterocycles based on S_N^H nucleophilic substitution are also discussed. The bibliography includes 69 references.

I. Introduction

The main procedures for the functionalisation of aromatic compounds involve electrophilic (S_EAr) and nucleophilic (S_NAr) substitution reactions. The S_EAr reactions, typical primarily of carbocyclic compounds, proceed predominantly as the electrophilic substitution of hydrogen. Strictly speaking, these transformations would be more correctly designated as S_E^HAr because less common reactions accompanied by the displacement of non-hydrogen groups (CO_2R , NO_2 , NR_2 , etc.) are conventionally symbolised by $S_E^{ipso}Ar$.

Transformation S_EAr (S_E^HAr):

Transformation $S_E^{ipso}Ar$:

E is an electrophile.

Nucleophilic aromatic substitution reactions involve most often the *ipso*-substitution ($S_N^{ipso}Ar$) at the C_{Ar} atom bound to the

Hal, N, O, P or S atoms.¹ Some S_NH reactions have long been used in industry (synthesis of nitrophenols, alizarin, 2-aminopyridine). The preparation of *p*-phenylenediamine from nitrobenzene and benzamide is currently one of the most advanced organic syntheses used in industrial processes.²

Nu is a nucleophile; EWG is an electron-withdrawing group.

Presently, the S_N^{ipso} and S_N^H reactions and related processes are used as the main procedures for the modification of π -electron-deficient aromatic systems.^{1,3} It should be noted that methods based on nucleophilic attack on the unsubstituted carbon atom of aromatic compounds have some advantages. Thus, the preliminary introduction of nucleofuges (Cl, NO_2 , SO_3H , etc.) into the ring is not needed here and the hydride ion serves formally as the leaving group. In many reactions, water is removed from the reaction mixture as a by-product, which is of importance for the commercial use of these reactions in connection with increasing industrial requirements for environmental safety.

It should be noted that an aromatic substrate must be activated to be involved in the S_N^H processes. In reactions with arenes, this is most often achieved by the introduction of an electron-withdrawing substituent, for example, the nitro group, into the ring. In the reactions with heterocyclic compounds, the presence of the aza group is often quite sufficient. This group is comparable to NO_2 in its electron-withdrawing effect and also directs nucleophilic attack at positions 2 and 4.¹

The present review surveys the data on the use of nucleophilic attack on the unsubstituted carbon atom of azines and nitroarenes for the construction of new heterocyclic systems.

II. Main transformation paths of σ^H adducts

According to the modern notion of nucleophilic aromatic substitution reactions proceeding as 'addition–elimination', the first step of the nucleophilic attack on activated aromatic substrate **1** gives rise to intermediates of two types, viz., σ^X adducts (Meisenheimer complexes) **2** or σ^H adducts (Servis complexes) **3**. Even in the presence of a leaving group in the ring, the *ipso*-substitution is

always preceded by the rapid and reversible formation of σ^H adducts as kinetically controlled products.⁴

X is a leaving group; EWG is N_2 , NO_2 , NO , CO_2R , etc.

The σ^H adducts **3** differ substantially in stability. Thus, both unstable short-lived species and stable anionic complexes and dihydro compounds are known.¹ In the nitroarene series, the stability of σ^H adducts increases as the number of electron-withdrawing groups in the nucleus is increased. Thus, the existence of σ^H adducts, viz., di- and trinitrobenzene derivatives, was unambiguously proved, whereas the corresponding mononitrobenzene derivatives were not, to our knowledge, detected.

The σ^H intermediates derived from azines can be stabilised both by the introduction of electron-withdrawing groups, including the aza group, and through protonation of anionic forms and their transformations into neutral dihydro compounds. Clearly, the σ^H adducts generated from cationic forms of azines do not bear a charge. On the whole, σ^H adducts (Servis complexes) are generally more stable than their σ^X analogues (Meisenheimer complexes). The nature of the leaving group is the main factor responsible for the high stability of σ^H adducts. Unlike good leaving groups, such as Hal , CN , NO_2 , SO_3H , etc., which are readily solvated as X^- anions, the hydride ion is not susceptible to solvation and it was not detected as a kinetically independent species in solutions. The occurrence of hydrogen in the form of the proton H^+ or the radical $H^\bullet$ is thermodynamically much more favourable than its occurrence as the hydride ion H^- . Therefore, aromatisation, which proceeds either through oxidative processes or with the involvement of auxiliary leaving groups (autoaromatisation) rather than *via* the direct abstraction of a hydride ion, is the bottleneck of S_N^H processes. Hence, nucleophilic attack on the unsubstituted carbon atom of arenes (hetarenes) affords (under particular conditions) S_N^H -reaction products. If none of the mechanisms of aromatisation takes place, σ^H adducts can undergo dissociation. This is particularly true for σ^H adducts generated from nitroarenes. The σ^H adducts derived from heteroarenes can be involved in alternative reactions resulting in the ring opening or recyclisation (for example, ANRORC transformations).^{5,6}

Oxidative aromatisation is a variation of the S_N^H reactions in which elimination occurs as a redox process.¹ In this type of reaction, both inorganic (atmospheric oxygen, halogens, hypohalogenites, sulfur, metal cations, etc.) and organic (quinones, triarylmethyl, tropylium and heterocyclic cations, etc.) reagents can be used as oxidisers. Besides, oxidative aromatisation can be performed electrochemically. In the absence of an oxidising agent, the starting π -electron-deficient arene (heteroarene) can serve as such a reagent. An oxidiser abstracts electrons from the σ^H adduct and hydrogen is most often eliminated as a proton.¹

As an example of the oxidative S_N^H processes, we refer to the reactions of naphthalene activated by chromium carbonyl with organolithium compounds. The resulting σ^H adduct undergoes aromatisation under the action of elemental iodine.⁷

Autoaromatisation proceeds if the σ^H adduct contains a nucleofuge, which is initially present in either the substrate or the reagent. In this case, the nucleofuge group X (which is readily solvated) serves as an oxidiser and is eliminated together with the electron pair from the σ^H adduct as the X^- anion, whereas hydrogen leaves as a proton.

There are several types of autoaromatisation of σ^H adducts. If the leaving group is located in the aromatic ring in the *ortho* position with respect to the carbon atom subjected to the attack, these reactions are said to be *cine*-substitution reactions. Thus in the reactions of 6-bromoazolopyrimidines with indole and its derivatives,⁸ the hydrogen atom at position 7 of the triazolopyrimidine system is replaced and the bromine atom leaves the adjacent position 6.

Numerous S_N^H reactions in the series of azine *N*-oxides and their derivatives (deoxygenative substitution of hydrogen)⁹ belong to the *cine*-substitution processes. In this case, the *N*-oxide, *N*-alkoxide or *N*-acyloxy functional group serves as the auxiliary leaving group in the second step involving elimination of the hydrogen atom from the σ^H adduct. For example, in the reactions of substituted 1,2,4-triazine *N*-oxides with cyanamide, σ^H adduct **4** undergoes aromatisation through 1,2-elimination of the water molecule.¹⁰

R = H, Et, Ph; B is a base.

If the reaction centre and the nucleofuge group X are separated by one or more atoms, the reactions are said to belong to *tele*-substitution processes. Here, the substituent X can be either bound to the aromatic nucleus (Scheme 1) or located in the side chain (Scheme 2). In the former case (see Scheme 1), the reactions proceed through the formation of σ^H adduct **5**, which undergoes aromatisation *via* 1,4-elimination of HBr with abstraction of the *tele*-arranged bromine atom.

In the latter case (see Scheme 2), aromatisation of the σ^{H} adduct is achieved through the abstraction of the chlorine atom from the trichloromethyl substituent. Reduction of $\text{S}_{\text{N}}^{\text{H}}$ -reaction product **6** with zinc led to the thiazine-ring closure.¹¹

The so-called vicarious nucleophilic substitution where a good leaving group X is present in the nucleophile residue belongs to well-studied autoaromatisation reactions of σ^{H} adducts.^{12–15} For example, the attack of sulfenamides on the unsubstituted carbon atom of 3-chloro-1-nitrobenzene (**7**) afforded adduct **8** whose structure allows the RSH group to undergo β -elimination.¹⁵

Vicarious autoaromatisation of σ^{H} adducts readily proceeds in the case of azoles,¹⁶ azines¹⁷ and nitroarenes¹⁷ and this process provides the basis for the construction of heteroaromatic systems, for example, of the indole^{18,19} and quinoline²⁰ rings.

III. Construction of azine-based heterocyclic systems

Azines containing two or more heteroatoms differ substantially from nitroarenes in that they can be subjected to the double nucleophilic attack. One-pot syntheses of fused heterocyclic

systems are based on the tendency of azines to form cycloadducts in reactions with bifunctional nucleophilic reagents.

1. Tandem reactions $\text{A}_{\text{N}}-\text{A}_{\text{N}}$

There are a large number of examples of the construction of fused heterocyclic systems by the replacement of two adjacent good leaving groups in pyridine, quinoline, pyrimidine, pyrazine, quinoxaline and other rings under the action of bifunctional nucleophiles.²¹ The main limitation of this method is that only azaaromatic compounds containing two nucleofuge groups at positions 1 and 2 can be used in such reactions.

The ability of unsubstituted azines to form cycloadducts in reactions with binucleophiles provides the basis for another procedure for the synthesis of fused heterocyclic systems.

It should be noted that although heterocyclic systems contain aza groups comparable to the nitro group in its electron-withdrawing properties, additional activation of the substrate is often required for the reaction to proceed. One of the commonly used procedures for the activation of azines in these transformations involves quaternisation of the nitrogen atoms in the ring. Some nucleophiles can react with azine salts. However, activation by acids is not necessarily applicable because it is accompanied by deactivation of the nucleophile. Another method involving alkylation of the azine ring is free from this drawback. The latter method was used in a large number of syntheses of fused heterocycles from N -alkylazinium salts. Thus, the *ortho*-cyclisation processes occurring in the reactions of 1,3-binucleophiles with quaternary 1,4-diazinium salts have been described.²⁰ One-pot syntheses of imidazopyrazines, imidazopteridines, furoquinoxalines, pyrroloquinoxalines, imidazoquinoxalines and thiazoloquinoxalines have been reported.²¹ Table 1 gives examples of the construction of fused azine-based heterocyclic systems using tandem reactions of the $\text{A}_{\text{N}}-\text{A}_{\text{N}}$ type. All these systems were prepared by cyclisation of triazinium (**9**), N -alkylquinoxalinium (**10**), N -alkylpyrazinium or N -alkylpteridinium salts with such 1,3-binucleophiles as β -diketones, thioamides, dithiocarbamates, thiourea derivatives, *etc.*

$\text{X} = \text{H}, \text{Alk}$; X, Y are nucleophilic groups.

Unlike the $\text{S}_{\text{N}}^{\text{ipso}}-\text{S}_{\text{N}}^{\text{ipso}}$ reactions in which thiourea derivatives act as N,S -binucleophiles,^{30–33} the $\text{A}_{\text{N}}-\text{A}_{\text{N}}$ reactions involve these derivatives exclusively as N,N' -binucleophiles.³⁴

An important characteristic feature of the $\text{A}_{\text{N}}-\text{A}_{\text{N}}$ reactions is the reversible formation of cyclic products. Due to the reversibility of the double addition and ambident character of the nucleophiles used, these reactions can yield regioisomeric cyclisation products. For example, tetrahydrothiazolo[4,5-*b*]quinoxaline **11** formed by the reaction of the N -alkylquinoxalinium salt **10** with thioamide **12** under kinetically controlled conditions in aprotic solvents can be subjected to different types of isomerisation. Upon heating in ethanol, compound **11**, containing the aryl group in the side chain ($\text{R}^2 = \text{Ph}$), underwent isomerisation to give thiazoloquinoxaline **13**. When $\text{R}^2 = \text{Me}$, isomerisation proceeded with the involvement of the methyl group to give pyrrolo[2,3-*b*]quinoxaline-2-thione **14** as the cyclisation product.²¹

Due to the tendency of cycloadducts to dissociation, not only regio- but also stereoisomers can be generated. An example is the construction of the tetrahydropyrrolo[2,3-*b*]quinoxaline ring. The reaction under the kinetically controlled conditions (activation of the nucleophile with a base) gave rise to stereoisomer **15** having the *exo* configuration, whereas the reaction in the absence of a base afforded both the *exo* isomer and the thermodynamically more stable *endo* isomer **16**, the rearrangement **15** $\rightarrow$ **16** being possible.³⁵

Note. In all reactions, the yields of the products were higher than 80%.

$R^1 = \text{Me, Et}$.

The reactions of 1,4-diazinium salts with 1,4-bifunctional nucleophiles are very similar to the annelation of five-membered rings to the pyrazinium ring. The reactions of *N*-alkyl-1,4-diazinium salts with 1,4-binucleophiles afforded a series of tetrahydropyrazines and tetrahydroquinoxalines fused with different

heterocycles, such as pyrazine, oxazine, thiadiazine and triazine rings (see Table 1). For example, cyclisation of quinoxalium salts with amide oximes and amidrazones afforded partially hydrogenated derivatives of new heterocyclic systems, viz., 1,2,4-oxadiazino- (**17**) and 1,2,4-triazolo[5,6-*b*]quinoxalines (**18**).²²

$R^1 = \text{Me, Ph, Bn, 4-BrC}_6\text{H}_4$; $R^2 = \text{H, Ph}$; $R^3 = \text{H, COPh}$.

The reactions with amidrazones were carried out with pre-isolated adduct **19** prepared by the reaction of the *N*-methylquinoxalium cation **10** with diethylamine to prevent the formation of tetrazines from amidrazones in a basic medium.²²

Like the products obtained in the A_N-A_N reactions of 1,4-diazinium salts with 1,3-binucleophiles, cycloadducts prepared by the addition of 1,4-binucleophiles to 1,4-diazinium salts readily undergo dissociative destruction and isomerisation in protic solvents in the presence of catalytic amounts of acids.³⁶

Dissociation of the cycloadducts is initiated both by mineral acids³⁷ and CH-acids, in particular, by acetylacetone and acetoacetic esters. In the latter case, the reactions afforded new fused heterocyclic systems.³⁸ First, the starting thiadiazinoquinoxaline

20 dissociated to yield the quinoxalinium cation **10** and thiobenzhydrazide (**21**). The latter reacted with a β -dicarbonyl compound to give hydrazone, which underwent intramolecular cyclisation to form thiadiazole **22**. The final step involved the tandem reaction A_N-A_N in which the compound **22** acted as a binucleophile.

R = OAlk.

To prevent dissociation of the cycloadducts, the NH group of the tetrahydropyrazinium ring can be subjected to acylation.²¹ The acyl derivatives are much more stable than the starting cycloadducts and do not dissociate even in acidic solutions.

Another way of stabilising hydrogenated σ^H adducts is based on abstraction of hydrogen atoms together with the electron pair from the reaction centres in the presence of oxidising agents^{1,12} (oxidative S_N^H process). In some reactions, σ^H adducts are produced in quasistationary concentrations. Here the presence of an oxidising agent in the reaction mixture is a necessary condition for an arene to interact with a nucleophile. This type of reaction will be considered below.

1,2,4-Triazines are similar to 1,4-diazines in reactivity. In the reactions with binucleophilic reagents, these compounds are prone to form addition products at the *ortho*-atoms. For instance, protonated 1,2,4-triazines and their alkyl derivatives **9** readily reacted with acetoacetamides to give tetrahydropyrrolo[1,2,4]triazines.^{24,25} Cycloadducts **23** derived from protonated 1,2,4-triazines are unstable and can be isolated only as salts of trifluoroacetic acid. Dissociation of these compounds can be prevented by nitrosation of the nitrogen atom adjacent to the reaction centre. *N*-Nitroso derivatives **24** are more stable and could be isolated as free bases.²⁴

R¹ = H, Et; R² = SMe, morpholinyl.

Another procedure for the synthesis of pyrrolotriazines involves the reaction of 1,2,4-triazine derivative **25** with ketene aminal **26**. These reagents, which are widely used in the inverse-electron demand Diels–Alder reactions,³⁹ react with triazinium salts as C,N-binucleophiles.⁴⁰

The reactions of 1-alkyl-3-phenyl-1,2,4-triazinium salts **27** with nitromethane in the presence of triethylamine are extraordinary processes. Depending on the nature of the *N*-alkyl group, either one or two molecules of the triazinium salt can participate in these reactions giving rise to adduct **28** or cage compound **29**, respectively.⁴¹ The reactions are accompanied by the addition of the solvent molecule (EtOH). In the latter reaction, nitromethane acts as a 1,1-binucleophile. This is a rare example of one-step syntheses of complex cage heterocycles.

In addition to *N*-alkyltriazinium salts, *N*-acyl derivatives can also react with binucleophiles, activation by acylation often being advantageous over activation by alkylation.²⁸ Thus, a new approach to the synthesis of thiazolo[4,5-*e*][1,2,4]triazines **30** and **31** was proposed on the basis of the tandem nucleophilic addition of alkyl- and arylthioamides to 1,2,4-triazine derivatives **32** in acetic anhydride.²⁸ Attempts to prepare thiazolo[4,5-*e*][1,2,4]triazines from 1-alkyl-1,2,4-triazinium salts failed.

Aromatic ambident C-nucleophiles can participate in the A_N-A_N reactions with 1,2,4-triazinium salts.²⁶ For instance, 3-methylthio- and 3-amino-1,2,4-triazines **32** reacted with resorcinol in the presence of trifluoroacetic acid. The addition of the aromatic ring of resorcinol at the C(5) atom of the triazine followed by nucleophilic attack of the oxygen atom on the C(6) atom afforded benzofurotriazines **33**. Intermediate monoaddition product **34** was isolated only with the use of a softer activating agent, *viz.*, boron trifluoride etherate.²⁶

R = SMe, NH₂.

In the reactions with binucleophilic resorcinol, azolo-annealed 1,2,4-triazines **35** are more inert and their reactions stop at the stage of formation of monoaddition products.

X = CH, N.

This is attributable to the fact that the adduct **36** occurs predominantly in the conformation unfavourable for cyclisation, the conformation being stabilised by an intramolecular hydrogen bond.²⁷

R = H, Me.

Compounds 37 , 38 , 39	X	Y	Z

b	CCN	CCN	N
c	N	CH	N
d	N	CSMe	N
e	N	CCF ₃	N
f	N	N	N

A different situation occurs when azines with the 1,3-arrangement of the heteroatoms are used as the substrate. These compounds tend to add binucleophiles at the atoms located in the *meta* positions of the heteroaromatic ring with respect to one another. Actually, the reactions of azolopyrimidines **37a–f** with 1,3-binucleophilic phenols gave rise to cage structures **38a–f** and **39a–f**.²⁹

To summarise, it should be noted that the nature of the interactions of azinium cations with binucleophiles depends on the relative arrangement of the aza groups. The presence of heteroatoms at positions 1 and 4 (pyrazine, quinoxaline or 1,2,4-triazine rings) is most favourable for the formation of fused heterocycles. The reactions of diazines containing heteroatoms at positions 1 and 2 or at positions 1 and 3 are often accompanied by side reactions.²¹ Examples of the construction of new heterocyclic systems *via* the addition of binucleophiles at the *ortho* or *meta* positions are few in number.^{29, 42}

It should also be remembered that the A_N–A_N reactions are often complicated by the dissociation of primary cycloadducts formed under kinetically controlled conditions and their transformations into thermodynamically more stable compounds. These processes can be accompanied by changes not only in the regioorientation but also in the nature of the annelated ring. The A_N–S_N^{ipso} and S_N^H–S_N^{ipso} reactions considered in the following section lack this property.

2. Tandem reactions A_N–S_N^{ipso} and S_N^H–S_N^{ipso}

Azaaromatic compounds containing heteroatoms at positions 1 and 4 can add binucleophiles to the unsubstituted carbon atoms at positions 2 and 3.²¹ Let us consider the reactions of azines bearing a leaving group in one of these positions. The use of these substrates substantially increases the preparative potential of the reactions with binucleophiles due to a combination of the A_N, S_N^H and S_N^{ipso} processes. The transformations of this type can involve both non-activated azines and their quaternary salts. For example, the reactions of 2-chloroquinoxaline (**40**) with enolates led to the addition of the carbanion to the unsubstituted C(3) atom. The replacement of the chlorine atom in the resulting adduct followed by oxidation under the reaction conditions gave rise to furoquinoxaline **41**.⁴³

The reactions of 2-chloroquinoxaline with aromatic nucleophilic reagents proceed as the tandem sequence S_N^H–S_N^{ipso} (apparently, with the involvement of hydrogen) to form benzofuroquinoxalines **42**.⁴⁴

The presence of a leaving group possessing the electron-donating properties (for example, the methoxy group) in the azine ring leads to a decrease in the electrophilicity of the ring. The reactions with such non-activated substrates often do not take place. In this case, the azine ring can be activated with the use of a

conventional approach, *viz.*, by quaternisation of the nitrogen atoms of the heterocycle. Thus, 5-methoxy-1-methyl-3-phenyl-1,2,4-triazinium tetrafluoroborate (**43**) is more reactive than its non-quaternised analogue and its reaction with *m*-phenylenediamine at 20 °C proceeded by the tandem process $A_N-S_N^{ipso}$ to form triazacarbazole **44**.⁴⁵

The reaction of the triazinium salt **43** with resorcinol proceeded through a cascade of transformations. This reaction was complicated by dequaternisation of the triazine ring to yield 5-methoxy-3-phenyl-1,2,4-triazine (**45**). The reaction afforded 6-(2,4-dihydroxyphenyl)-5-methoxy-3-phenyl-1,2,4-triazine (**46**) as the major product generated *via* the nucleophilic substitution of hydrogen in the triazine ring.⁴⁵

(a) resorcinol, methanol, Δ ; (b) resorcinol, DMF, 20 °C.

The reaction performed in dimethylformamide afforded benzofurotriazine **47** as the major product generated through several reactions, *viz.*, dequaternisation, S_N^H and S_N^{ipso} . It is most likely that the reaction involves dequaternisation as the first step followed by the attack of the nucleophile on the C(6) atom. In the final step, the methoxy group at position 5 is replaced and cyclisation occurs. This assumption was confirmed by a special experiment in which non-quaternised 5-methoxy-3-phenyl-1,2,4-triazine was used as the substrate (**45**). The latter reacted with resorcinol in the presence of boron trifluoride etherate to give benzofurotriazine **47**.

Analogously, triazinium salts react with *N,N*-binucleophiles.⁴⁵ The reaction of the salt **43** with thiosemicarbazide

proceeded through the A_N and S_N^{ipso} transformations to yield imidazo[4,5-*e*][1,2,4]triazine-6-thione (**48**).

The isolation of intermediate **49** has been reported.⁴⁵ This is additional evidence that the unsubstituted carbon atom of the triazine ring is subjected to the initial nucleophilic attack, whereas the substitution of the nucleofuge (OMe) is a secondary process resulting in cyclisation.

It should be noted that the reaction can also follow the 'traditional' (S_N^{ipso}) pathway. The reaction of the salt **43** with semicarbazide afforded imidazotriazine **50** along with triazine **51**, which is a product of *ipso*-substitution of the methoxy group in 5-methoxy-3-phenyl-1,2,4-triazine **45** generated through dequaternisation of the substrate.⁴⁵

It is noteworthy that the nucleophilic attack in all the reactions under consideration occurs primarily on the unsubstituted carbon atom, although the methoxy group would be expected to be replaced according to the classical theory of nucleophilic aromatic substitution. Moreover, the methoxy group is located at position 5 of the 1,2,4-triazine ring, which is most reactive⁴⁶ with respect to nucleophiles. However, steric effects play the key role in these reactions¹ and σ^H adducts are initially generated in all processes. In the salt **43**, the methyl group at the N(1) atom adjacent to the reaction centre is responsible for substantial stabilisation of the compound **49**, which was isolated in the crystalline state. The reactions of the triazine **45** with nucleophiles (in particular, with semicarbazide) also can afford σ^H adducts upon attack on the C(6) atom. However, this process is reversible due to the absence of the methyl group at the nitrogen atom adjacent to the reaction centre and *ipso*-substitution of the methoxy group giving rise to compound **51** prevails.

The preparation of 6-azapurine derivatives by the reactions of 5-methoxy-1,2,4-triazines, for instance, of the compound **45**, with urea derivatives (Scheme 3) provides another example of the use of the $A_N-S_N^{ipso}$ and $S_N^H-S_N^{ipso}$ tandem reactions in the synthesis of fused heterocycles. In these reactions, acetic and trifluoroacetic anhydrides were used for activation of the substrate.⁴⁶

The reactions of *N*-acyl-1,2,4-triazinium salts generated *in situ* with urea derivatives include a series of successive steps. Depending on the nature of the reagents and reaction conditions, both open-chain adducts **52** and their cyclisation products **53**–**55** can be isolated (see Scheme 3).⁴⁷

The use of acylating reagents makes it possible, first, to activate the triazine ring to nucleophilic attack and, second, to stabilise a σ^H adduct. Besides, the acyl substituent can serve as an auxiliary group responsible for the occurrence of the S_N^H reaction. For example, the final step of the reaction of the 1,2,4-triazine **45**

with urea derivatives involves elimination of acetic or trifluoroacetic aldehyde from the σ^H adduct, *i.e.*, the process as a whole can be considered as a variation of *cine*-substitution reactions.

Note also that the reaction of compound **45** with dimethylurea at 20 °C stopped at the stage of formation of adduct **53**, which is a cyclic Meisenheimer complex. The latter was isolated in the crystalline state. This is a rare example of a reaction proceeding according to the S_N^{iso} scheme in which an intermediate was isolated.²

To summarise, combination of the A_N and S_N^H strategies with *ipso*-substitution is, undoubtedly, a powerful tool for the construction of various fused heterocyclic systems. The only limitation is that there is a need to synthesise a substrate containing a leaving group in the position required for cyclisation. However, this drawback is compensated by the high stability of the resulting products and the fact that they cannot undergo dissociation, which is often observed in the A_N – A_N reactions.

3. Tandem reactions S_N^H – S_N^H

Only a few examples of the double nucleophilic substitution of hydrogen are known. All these reactions involve oxidative aromatisation of σ^H adducts.^{48,49} Thus, oxidation of cycloadducts **56**–**58**, which were prepared by the A_N – A_N reactions of quinoxalinium salts, by potassium permanganate led to their aromatisation.⁴⁸

In this case, the S_N^H process is a convenient way of stabilising σ^H adducts. Compounds **59**–**61**, unlike their partially hydrogenated analogues, cannot undergo dissociation at all.

To our knowledge, the reactions of pyrimido[4,1-*c*]pyridazines **62** with diamines in the presence of an oxidising agent are the only examples of the tandem reactions S_N^H – S_N^H proceeding *in situ* without isolation of intermediate σ^H adducts.⁴⁹ The reactions involve the addition of the nucleophile at position 4 of the heterocyclic system followed by intramolecular cyclisation to form tricyclic product **63**.

4. Intramolecular S_N^H reactions

New heterocycles are often generated by the intramolecular attack of a nucleophilic functional group present in the side chain of the heterocyclic substrate. The intramolecular S_N^H reactions were used for structural modifications of fluoroquinolone antibiotics.^{50,51} For example, the reactions of 1-amino-substituted fluoroquinolones **64** with acetylacetone afforded tricyclic compound **65**.⁵⁰

The mechanism of formation of the tricyclic product **65** involves condensation of the *N*-aminoquinolone **64** with acetylacetone followed by the intramolecular nucleophilic attack on the C(2) atom of the resulting diketone **66** and oxidation of σ^{H} adduct **67** with atmospheric oxygen.

The synthesis of pyrazolo[4,3-*e*][1,2,4]triazines **68** using the reactions of 5-acyl-1,2,4-triazines **69** with arylhydrazines in an acidic medium is another example of the intramolecular $\text{S}_{\text{N}}^{\text{H}}$ process.⁵²

$\text{R}^1 = \text{Me}, \text{Et}, \text{Pr}^n; \text{R}^2 = \text{Ph}, \text{SMe}; \text{Ar} = \text{Ph}, 4\text{-Tol}, 4\text{-ClC}_6\text{H}_4, 2,4\text{-Cl}_2\text{C}_6\text{H}_3$.

This synthesis involved the successive formation of hydrazones **70** and intramolecular substitution of hydrogen.⁵² Analogous transformations were also observed upon alkylation of quinoxaline-3-carbaldehyde hydrazones **71**. These reactions led to the intramolecular nucleophilic substitution of hydrogen at the α position with respect to the quaternary nitrogen atom.⁵³

$\text{R} = \text{H}, \text{Me}, \text{Ph}, \text{Bn}, 4\text{-O}_2\text{NC}_6\text{H}_4, 4\text{-O}_2\text{CC}_6\text{H}_4$.

Yet another example of the intramolecular oxidative nucleophilic substitution of hydrogen is the reaction of 2-aminoquinoxaline **72** with acetylacetone or cyclohexanone.⁵⁴ Schiff's bases **73** generated in the course of the reactions underwent spontaneous cyclisation to pyrrolo[2,3-*b*]quinoxaline derivatives **74**.

The intramolecular *tele*-substitution to form thienoquinoxalines **75** was observed upon treatment of compounds **76** derived from chloro- or iodoquinoxaline derivatives **77** with sodium trithiocarbonate.⁵⁵

$\text{R}^1 = \text{H}, \text{Cl}; \text{R}^2 = \text{H}, \text{SiMe}_3, \text{Bu}^n, \text{Bu}^t, 4\text{-MeOC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-IC}_6\text{H}_4, 5\text{-F}_3\text{CC}_5\text{H}_3\text{N}$.

Aromatisation of σ^{H} adduct **78** occurred through elimination of the bromine atom from the thiophene ring that formed.

The reaction of pyrazine **79** with pyridine provides an interesting example of an intramolecular $\text{S}_{\text{N}}^{\text{H}}$ reaction.⁵⁶

This reaction was not completed by the formation of product **80** by the *ipso*-substitution of the chlorine atom. Under the action of an excess of pyridine, the carbanionic centre was generated in the side chain of the pyrazine ring and intramolecular cyclisation took place. Cycloadduct **81** underwent aromatisation through elimination of the proton together with the tosyl substituent.

For nitroarenes, commonly used procedures for the construction of heterocycles are based on the nucleophilic substitution of hydrogen followed by cyclisation of the S_N^H -reaction product involving the *ortho*-substituent.¹⁴ This strategy, as applied to compounds of the heterocyclic series, is exemplified only by the reactions of 6-nitrotriazolo[1,5-*a*]pyrimidines **82** with acyl derivatives **83** of aromatic and heteroaromatic compounds giving rise to products of addition at the C(7) atom (**84**).⁵⁷

$R^1 = H, Me; R^2 = Ph, 4-HalC_6H_4, 2-thienyl, 2-furyl$.

Reduction of the nitro group in the adducts **84** by tin(II) chloride did not stop at the formation of the corresponding amine **85** and afforded triazolopyrrolopyrimidine **86** as a result of oxidative aromatisation of the amine **85** followed by intramolecular cyclisation of product **87**.

IV. Construction of nitroarene-based heterocyclic systems

Most of the procedures for the direct annelation of heterocycles to nitroarenes consist in intramolecular S_N^H processes followed by cyclisation. In spite of the fact that the ring closure is not necessarily associated with the nucleophilic attack on the unsubstituted carbon atom, the S_N^H reactions of nitroarenes with binucleophiles are the key steps in these syntheses. These methods open up approaches to a wide range of biologically active indoles and quinolines, including those of natural origin. Since these methods have been surveyed in the recent review,¹⁴ we consider these questions only briefly.

Procedures for annelation of five- and six-membered heterocycles to nitroarenes are based on oxidative and intramolecular vicarious nucleophilic substitution of hydrogen. The syntheses of nitroxyindoles **88**⁵⁸ and **89**¹⁴ are examples. In the former case,

aromatisation of the σ^H adduct proceeds through the vicarious mechanism. The latter reaction involves oxidative aromatisation.

The intramolecular vicarious substitution of hydrogen in nitrophenyl- (**90**) and nitrobenzylchloromethylsulfonamides (**91**) led to annelation of five- and six-membered rings, respectively, to the arene ring.^{59–62}

Interestingly, the initially formed cyclisation product **92** can be readily transformed into the quinoline derivative. Thermolysis of the compound **92** led to SO_2 extrusion with the formation of azaxylene **93**. The subsequent intramolecular [4 + 2]-cycloaddition afforded tetrahydroquinoline **94**.^{59–62}

The intramolecular S_N^H reactions can be employed for the preparation of the key compounds used in the syntheses of some natural substances. For instance, the synthesis of the natural antitumour drug makaluvamine C (**95**) found in marine sponges involved the closure of the six-membered ring on the basis of the oxidative S_N^H reaction.^{63, 64}

$CAN = (NH_4)_2Ce(NO_3)_6$.

The reactions of nitroarenes with bifunctional nucleophilic reagents can be accompanied by intramolecular cyclisation with the participation of such substituents in the aromatic substrate, as CN, NO_2 , etc. For example, the presence of the amino group in substituted *m*-nitroanilines made it possible to synthesise indole derivatives by its reactions with acetophenones⁶⁵ or phenylacetonitrile.⁶⁶ Isocyanonitrobenzenes can also be involved in analogous transformations. Thus, the product of the S_N^H reaction of compound **96** with α -chloromethyl sulfone **97** underwent spontaneous cyclisation to give nitroindole **98**.⁶⁷

In some cases, cyclisation of nitroarenes proceeds with the involvement of the nitro group itself. For instance, nitrophenyl-acetonitriles **99** (Z = CN) generated by the S_N^H reactions can be readily alkylated. The resulting compounds **100** contain the nucleophilic centre in the side chain. In the presence of bases, these compounds undergo cyclisation involving the nitro group to yield *N*-hydroxyindole derivatives **101**.^{19, 68, 69}

Y = Cl, Br, OMe; Z = CN, CO₂Bu, Tos, SO₂Ph;
R = Et, n-C₇H₁₅, CH = CH₂, CO₂Et, CONMe₂.

This approach can also be used in the annelation of a six-membered ring to an arene ring. For example, benzyl sulfone **102** was subjected to Michael condensation with α,β-unsaturated esters of carboxylic acids. In the presence of bases, the intermediate generated in this process underwent a series of transformations involving the nitro group to form quinoline *N*-oxide **103**.¹⁴

The reactions in which the heterocycle closure takes place *in situ* without isolation of intermediates are of particular interest.²⁰ For example, the reaction of nitronaphthalene **104** with sulfone **105** was not completed by the formation of the σ^H adduct. Under the reaction conditions, this adduct underwent aromatisation through an intramolecular redox process and cyclisation to give quinoline derivative **106**.

DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.

The syntheses in which annelation of the heterocycle proceeds with the participation of the amino group generated by reduction of the nitro group of nitroarenes can be considered separately. In these syntheses, acetonitrile and acetophenone derivatives, silyl ethers of ketones, CH-active derivatives of carboxylic acids and other polyfunctional derivatives are used as nucleophiles. Both S_N^H-reaction products and σ^H adducts can be subjected to reductive cyclisation. For example, the reaction of *o*-nitroanisole **107** with (4-chlorophenoxy)acetonitrile was accompanied by vicarious nucleophilic substitution S_N^H to produce cyanomethyl derivative **108**. Reduction of the latter led to annelation of the pyrrole ring to the anisole ring to give methoxy-substituted indole **109**.⁶⁸

Examples of reductive cyclisation of σ^H adducts of nitroarenes have been reported. Thus, the σ^H adduct formed in the course of the fluoride-induced addition of trimethylsilyloxyethylene **110** to nitroarenes underwent cyclisation into indolin-2-one **111** under the action of tin(II) chloride.⁶⁹

TASF = (Me₂N)₃S(Me₃SiF₂).

V. Conclusion

In the present review, we generalised and analysed the reactions of azines and nitroarenes containing at least one unsubstituted aromatic carbon atom with bifunctional nucleophilic reagents. These transformations were considered in the context of the construction of fused heterocycles. All the above-considered syntheses share a common trait, *viz.*, the initial attack of a nucleophile on the unsubstituted carbon atom of azine or nitroarene to give σ^H adducts, which are generated rapidly and

reversibly regardless of the presence of nucleofugal groups in the substrate. Subsequent transformations of σ^H adducts depend on the nature of the substrate and nucleophilic reagent.

The formation of cyclisation products is most typical of azines containing heteroatoms at positions 1 and 2, 1 and 3 or 1 and 4. Cycloadducts prepared by the A_N-A_N reactions can be subjected to dissociation and isomerisation. These products can be stabilised by acylation, nitrosation, alkylation or further S_N^H -transformations. Fused heterocycles prepared in the tandem reactions $A_N-S_N^{ipso}$ and $S_N^H-S_N^{ipso}$ are more stable and are not prone to isomerisation.

To construct heterocycles from nitroarenes, it is most often necessary to introduce an additional functional group into the aromatic ring although the nitro group by itself can be of use.

To summarise, the data surveyed in this review provide evidence that nucleophilic attack on the unsubstituted carbon atom of azines and nitroarenes is a powerful tool for the synthesis of fused heterocycles.

VI. Conclusion	738

Abstract. The published data on the synthesis, physicochemical properties, structures and reactions of 1,3-(1,3,5)- and 1,4-(1,4,5)-substituted tetrazolium salts are systematised and generalised. Their applications as starting compounds in the preparative chemistry of heterocyclic derivatives and some other branches of science and technology are reviewed. The bibliography includes 122 references.

I. Introduction

Compounds containing positively charged tetrazole rings have been known since the end of the 19th century, since the first description of 2,3-substituted tetrazolium salts **1**. Later, these compounds were given considerable attention in connection with their reduction into brightly coloured formazane under the action of various reagents. At present, practical applications of 2,3-substituted tetrazolium salts are based on chemical, biochemical, electrochemical and radiochemical reduction. These compounds proved to be especially useful in biochemical, microbiological, histochemical and cytochemical studies, analytical chemistry and clinical analysis as well as components of ionising radiation monitors and photosensitive materials, germination indicators of grain crops and phase-transfer catalysts.^{1–5} Other types of tetrazolium salts which differ in the positions of substituents at the nitrogen atoms have not received much attention until recently.

The situation has changed in the past decade owing to the appearance of a great number of publications devoted to 1,3- (**2**) and 1,4-substituted (**3**) tetrazolium salts.

Received 5 June 2002

Uspekhi Khimii 71 (9) 819–839 (2002); translated by R L Birnova

In many respects, this is due to the development of synthetic methods including selective procedures, which make possible direct synthesis of tetrazolium salts **2** and **3** with predetermined compositions and structures which can be used in organic chemistry and some other branches of science and technology. However, systematised data on the synthesis, properties and applications of these compounds are still absent in the literature. Previously published reviews^{1–5} deal with the description of mostly 2,3-substituted tetrazolium salts. The reviews devoted to the chemistry of tetrazoles^{6–8} and some of its particular aspects^{9–11} published in the past decade provide separate and, sometimes,^{8,10,11} very scarce data on 1,3- and 1,4-substituted tetrazolium salts.

The aim of the present review is to generalise the information on 1,3- and 1,4-substituted tetrazolium salts over the past 10–15 years in order to highlight current trends in their synthesis with special emphasis on the availability of tetrazolium salts and their efficacy in organic synthesis. Earlier publications that have not been cited in other reviews and monographs are also surveyed.

Depending on the nature of the substituent at C(5), tetrazolium salts **2** and **3** can be divided into two groups, viz., 1,3- and 1,4-disubstituted tetrazolium salts containing a labile hydrogen atom at the carbon atom of the heterocycle and 1,3,5- and 1,4,5-trisubstituted tetrazolium salts where $R^1 \neq H$. Yet another class of 1,3,5-trisubstituted tetrazolium salts, viz., compound **2** with the substituent R^1 represented by an anionic group [O^- , NH^- , $-C(CN)_2$, etc.], are referred to as mesoionic tetrazoles.¹² As the behaviour of these internal salts differs drastically from that of ordinary tetrazolium salts, they are not considered in the present review.

II. Methods for the synthesis of tetrazolium salts

All currently known approaches to the synthesis of 1,3- and 1,4-substituted tetrazolium salts can be classified into two main groups: (1) transformations of tetrazoles and (2) heterocyclisation of polynitrogenous linear structures.

The first group includes a broad range of processes, in the first place, direct exhaustive alkylation of tetrazoles at the endocyclic nitrogen atoms, i.e., quaternisation. Reactions involving exocyclic atoms of mesoionic tetrazoles and 1,4-dihydrotetrazoles and reactions affecting both endo- and exocyclic atoms of functionalised tetrazoles leading to the formation of annelated tetrazolium salts are also related to this group. Conversions of some tetrazolium salts into other ones do not have as a rule any preparative

significance and are considered in the section devoted to the chemical properties of tetrazolium salts.

The second group includes few heterocyclisation reactions the main advantage of which is that they exclude the use of tetrazoles in the synthesis of tetrazolium salts.

Quaternisation of tetrazoles is the most popular and simple procedure for the synthesis of 1,3- and 1,4-substituted tetrazolium salts. This method is based on two approaches which differ in the nature of the alkylating reagents and the reaction media. The practical significance of quaternisation reactions has increased considerably in the past decade owing to the ready availability of diverse tetrazole derivatives.^{6–10}

1. Quaternisation of tetrazoles in organic media

In the early 1950's, it was shown for the first time that *N*-substituted tetrazoles, particularly 1-aryl-5-methyltetrazoles, react with methyl iodide to yield quaternary salts.¹ Later, it was established that quaternisation is largely a general process which involves all isomeric *N*-substituted tetrazoles^{13–37} including fused ones;^{16, 20, 24, 34} the role of alkylating reagents is played by alkyl halides, alkyl sulfates, oxonium salts and related compounds of which methylating and ethylating reagents^{13–37} as well as α -halogeno carbonyl compounds (bromoacetone^{18, 35, 37} and phenacyl bromides^{21, 27, 35, 37}) are studied most extensively. The mechanisms of quaternisation of *N*-substituted tetrazoles still remain obscure. It can be assumed, however, that similar to other azoles, quaternisation of tetrazoles occurs by an S_N2 mechanism. The azole molecule, which plays the role of a nucleophilic reagent with respect to alkyl halide, passes into a quaternised form. This reaction is accompanied by the Walden inversion.^{38, 39}

Quaternisation of tetrazoles for the synthesis of tetrazolium salts poses certain problems. In the first place, this is due to the non-selectivity of this reaction due to the ambident character of the tetrazolium ring^{3, 6, 7} and the necessity to separate the mixtures of isomeric tetrazolium salts formed. Thus quaternization of 1-mono- and 1,5-disubstituted tetrazoles **4** yields a mixture of isomeric tetrazolium salts **2** and **3**.^{13, 15–25, 27, 28, 31, 32–37}

In the case of 1-monosubstituted tetrazoles **4** ($R^1 = H$), the predominant reaction is the attack at the N(4) atom^{13, 15, 18, 21, 28, 33} manifesting the highest basicity (proton affinity) irrespective of the nature of the R^2 substituent.^{6, 8, 40} The presence of a substituent at C(5) increases the content of the 1,3-substituted tetrazolium salt **2** which becomes predominant in the presence of bulky substituents R^1 . Individual salts can be isolated from the mixtures owing to differences in the solubilities of the isomers. In most cases, 1,4,5-isomers are soluble in water and lower alcohols less readily than 1,3,5-isomers. Sometimes, individual salts **3** precipitate immediately.^{14, 22, 25, 32} This approach is largely used in the synthesis of 1,4-substituted tetrazolium salts (Table 1).

The use of 2-mono- and 2,5-disubstituted tetrazoles for the synthesis of 1,3-substituted tetrazolium salts seems to be more appropriate, since the quaternisation of the latter proceeds selectively at the N(4) atom (Table 2). However, by reason of the lower basicity of this type of tetrazole,⁴¹ their quaternisation requires more drastic conditions (elevated temperatures and

sometimes high pressure) than that for tetrazoles **4**.^{3, 17, 18, 21, 23, 27–29, 35–37}

The use of tetrazole and its 5-monosubstituted derivatives **5** as starting compounds in the synthesis of tetrazolium salts is rather attractive, since the methods for the preparation of compounds **5** have been well developed.⁴² Nevertheless, exhaustive alkylation of this type of tetrazole has been studied for a limited number of compounds only. Thus the methylation of 5-methyltetrazole with an excess of methyl iodide (40 °C, 10 days) yields a mixture of 1,4,5- and 1,3,5-trimethyltetrazolium iodides in a 68 : 32 ratio.¹⁴ Later, it was found that tetrazoles with substituents in position 5 react with an excess of dimethyl sulfate upon heating to give 1,3- (**6**, $X = \text{MeSO}_4^-$) and 1,4-dimethyl-5-*R*-tetrazolium methyl sulfates (**7**, $X = \text{MeSO}_4^-$) (Table 3).^{32, 33} The ratio of the isomers formed depends on the nature of the substituent at the C(5) atom; owing to steric factors, the proportion of the 1,3,5-isomer **6** increases in the following order: $R = \text{Me, Et, Ph, Bu}^t$ (19%, 31%, 55% and 91%, respectively).³² The isolation of the main isomer is achieved by precipitation of the corresponding perchlorates³² and picrates³³ (see Table 3).

To conclude, special mention should be made of a study²⁶ which represents an approach to the mathematical estimation of the feasibility of quaternisation and alkylation of some azoles including tetrazoles. The authors attempted to correlate the sum of normalised potentials with pK_a values of azoles and demonstrated the applicability of these principles in several reactions.

2. Quaternisation of tetrazoles in acidic media

The methods for the synthesis of tetrazolium salts based on quaternisation of tetrazoles with alcohols in acidic media were proposed in the past decade^{22, 30, 33, 36, 43–49} and are being intensively developed at present. The studies into the alkylation of 5-*R*-tetrazoles in strong acids which, contrary to the reactions occurring in neutral media, proceed selectively at the N(2) atom, formed the basis for these methods.^{50–52} Kinetic studies and an analysis of reaction mechanisms revealed that the selectivity is due to blocking of the most nucleophilic N(4) atom because of its protonation.^{53, 54} Later, it was found that the regioselectivity of the tetrazole alkylation in acidic media remains in the quaternisation. This allowed development of efficient procedures for the synthesis of tetrazolium salts and enlargement of their range by virtue of quaternising reagents that made it possible to introduce branched substituents onto the 'pyridine' nitrogen atom. It is now established that quaternisation of tetrazoles can be effected by alcohols that generate stable carbocations (*e.g.*, *tert*-butyl^{17, 22, 33, 36, 45–49} and diacetone alcohols,^{46, 47} 2,5-dimethylhexane-2,5-diol,³⁶ isopropyl alcohol,⁴⁹ 1-phenylethanol,⁴⁹ adamantan-1-ol⁴³ and α -ferrocenyl-substituted alcohols) in acidic media.⁴⁴ These reactions are usually carried out in strong mineral acids (*e.g.*, perchloric, sulfuric, tetrafluoroboric)^{33, 36, 45–49} or biphasic systems consisting of an organic solvent (ether, dichloromethane) and an acid.^{17, 22, 44} The direction of quaternisation cannot always be predicted unequivocally, since it depends on many factors, such as the nature of the substrate and the alkylating reagent, medium acidity and reaction time.

1,3-Disubstituted tetrazolium salts **8** and **9** were obtained in high yields by quaternisation of 1-monosubstituted tetrazoles with *tert*-butyl^{36, 45, 47} and isopropyl⁴⁹ alcohols in 72% perchloric acid at 20 °C and contained no admixtures of the corresponding 1,4-isomers.

^a With decomposition.

The regioselectivity of quaternisation is achieved by virtue of complete protonation of 1-*R*-tetrazole at the most nucleophilic nitrogen atom N(4) with the formation of the 1-*R*-4*H*-tetrazolium cation **10** in which the N(2) and N(3) atoms are susceptible to electrophilic attack. The attack at the N(2) atom is sterically hindered due to the presence of a substituent at the N(1) atom. Therefore, the carbocation generated from the alcohol, attacks the tetrazolium cation at the N(3) atom.⁴⁵

The assumption of a reaction of the azolium cation with the carbocation is unusual at first glance; however, the results of quantum-chemical calculations^{45, 53} suggest that such a reaction is possible, since the N(2) and N(3) atoms of the 1-*R*-4*H*-tetrazolium cation **10** retain sufficiently high π -electron density.

Selective preparation of 1,3-disubstituted tetrazolium salts demands special conditions to be met, which ensure complete protonation of the starting tetrazoles⁴⁵ and exclude the possibility of isomerisation of 1,3-substituted tetrazolium salts into the corresponding 1,4-isomers in the course of the reaction.^{45, 55} Moreover, quaternisation occurs smoothly only in the case of 1-alkyltetrazoles.⁴⁵ 1,4-Disubstituted tetrazolium salts **11** are formed as reaction products in the quaternisation of some 1-aryltetrazoles with *tert*-butyl alcohol. Their proportion increases in the presence of electron-withdrawing groups in the aryl substituent,^{36, 45, 47, 49} which is explained⁴⁹ by lower basicity of 1-aryltetrazoles in comparison with their alkyl analogues.⁴¹

Under certain conditions, individual 1,4-disubstituted tetrazolium salts **13** and **14** can also be prepared by quaternisation of 1-*R*-tetrazoles with α -ferrocenyl-substituted⁴⁴ or diacetone alcohols.^{46, 47}

$R^1 = \text{Bn, Ph, 4-MeOC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4$; $R^2 = \text{H, Me, Ph}$;
Fc = $\text{C}_5\text{H}_4\text{FeC}_5\text{H}_5$; X = $\text{ClO}_4, \text{BF}_4$.

$R = \text{Me, Bn, cyclo-C}_6\text{H}_{11}, \text{Ph, 4-MeOC}_6\text{H}_4, 3\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-HO}_2\text{CC}_6\text{H}_4, 2\text{-HO-4(5)-NO}_2\text{C}_6\text{H}_3$.

Because of steric hindrances, the aforementioned isomerisation of tetrazolium salts is not realised in the quaternisation of 1,5-disubstituted tetrazoles, which allows selective preparation of 1,3,5-trisubstituted tetrazolium salts **15** (Table 4).

1,3-Disubstituted tetrazolium salts **16** ($R^2 = \text{H}$) are formed in high yields upon quaternisation of 2-monosubstituted tetrazoles with alcohols in the presence of acids (Table 5). The yields of 1,3,5-trisubstituted derivatives in the reaction of 2,5-disubstituted

tetrazoles with *tert*-butyl alcohol in the presence of HBF₄ (see Ref. 30) do not exceed 50% (see Table 5), apparently due to steric hindrances preventing the introduction of the substituent into position N(4).

The synthesis of the salt **17** shows that quaternisation can successfully involve diols, which opens up new opportunities for the selective synthesis of binuclear tetrazolium salts.³⁶

1,3-Di-*tert*-butyl-5-*R*-tetrazolium salts **18a–d** were prepared by exhaustive alkylation of tetrazole (**5a**) and 5-methyltetrazole (**5b**) with *tert*-butyl alcohol in the presence of strong acids.^{33, 45} The selectivity of alkylation is explained by the intermediate formation of 2-*tert*-butyl-5-*R*-tetrazoles **19a,b** in which only the

N(4) atom is accessible for quaternisation. In the case of 5-phenyl-tetrazole (**5c**), the expected tetrazolium salts are not formed, presumably due to steric hindrances. In this case, 2-*tert*-butyl-5-phenyltetrazole (**19c**)³³ or its protonated form, viz., 3-*tert*-butyl-5-phenyl-1*H*-tetrazolium perchlorate (**20**), was isolated as the alkylation product.⁴⁵

It may be expected that the methods for the synthesis of tetrazolium salts based on quaternisation of tetrazoles in the presence of strong acids will be developed further. Their attractiveness is due both to the availability of the starting compounds and the selectivity and simplicity of the reactions. The use of novel functionalised reagents in the quaternisation reaction will enable one to extend the range of available tetrazolium salts.

3. Miscellaneous methods based on the transformations of tetrazole derivatives

Disubstituted tetrazoles containing reactive groups at the C(5) atom react with bifunctional reagents to give annelated tetrazolium salts. It was shown, in particular,⁵⁶ that the condensation of 1-substituted 5-aminotetrazoles **21** with β-diketones, β-chloro-vinyl ketones and aldehydes as well as with malonaldehyde acetals yields 1-substituted tetrazolo[1,5-*a*]pyrimidinium salts **22a,b**. This reaction proceeds at 20 °C or upon short-term heating of solutions of the reactants in acids (*e.g.*, acetic, trifluoroacetic, perchloric) or in ethanol in the presence of perchloric acid.

$\text{R}^1 = \text{Me}, \text{CH}=\text{CH}_2, \text{CH}_2\text{CH}=\text{CH}_2, \text{Bn}, \text{Ph}, \text{HO}_2\text{CCH}_2$; $\text{R}^2 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^3 = \text{H}, \text{Me}$; $\text{R}^4 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^3-\text{R}^4 = (\text{CH}_2)_4$; $\text{X} = \text{Cl}, \text{OH}$.

2-Substituted 5-aminotetrazoles **23** generate 2-substituted tetrazolo[1,5-*a*]pyrimidinium salts **24** under analogous conditions.⁵⁶

$\text{R}^1 = \text{Me}, \text{CH}_2\text{CH}=\text{CH}_2, \text{Bn}$; $\text{R}^2 = \text{H}, \text{Me}, \text{Ph}, \text{CO}_2\text{H}$; $\text{R}^3 = \text{H}, \text{Me}$; $\text{R}^4 = \text{H}, \text{Me}, \text{Ph}$; $\text{R}^3-\text{R}^4 = (\text{CH}_2)_4$; $\text{X} = \text{Cl}, \text{OH}$.

1-Aryl-5-mercaptotetrazoles **25a,b** react with α - and β -halogeno ketones with heating to give tetrazolylthioalkyl ketones which undergo cyclisation under the action of sulfuric acid in the presence of HClO_4 to give thiazolo[3,2-*d*]tetrazolium (**26**) and tetrazolo[5,4-*b*][1,3]thiazinium perchlorates **27**, respectively.^{7, 57}

$\text{R}^1 = \text{H}$ (**25a**), Cl (**25b**);

26: $\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Bu}^t, \text{Et}, \text{Ad}, \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-C}_6\text{H}_5\text{C}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4$;

27: $\text{R}^1 = \text{H}, \text{Cl}$; $\text{R}^2 = \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-FC}_6\text{H}_4$.

Treatment of 5-mercaptotetrazoles **25a** and **28** substituted by epoxy bromides in position N(1) with heating affords 6-hydroxy-1-*R*-6,7-dihydro-5*H*-tetrazolo[5,4-*b*][1,3]thiazinium bromides **29** in relatively low yields.⁵⁷

$\text{R}^1 = \text{Ph}, \text{cyclo-C}_6\text{H}_{11}$; $\text{R}^2, \text{R}^3, \text{R}^4, \text{R}^5 = \text{H}, \text{Me}$.

The reaction of 1-phenyltetrazol-5-ylsulfenyl chloride with 3,3-dimethylbut-1-ene in nitromethane in the presence of lithium perchlorate yields 7,8-dihydro-6,6,7-trimethyl-2-phenyl-6*H*-tetrazolo[4,5-*b*][1,3]thiazinium perchlorate (**30**). It has been shown that the heterocyclic compound **30** is formed in the A_{E} reaction of an alkene with sulfenyl chloride due to the tandem rearrangement–cyclisation occurring by a π -route.⁵⁸ The reaction of this sulfenyl chloride with styrene or 1-phenylpropene yields 2,3-dihydrothiazolo[3,2-*d*]tetrazolium salts **31a,b**.⁵⁹

$\text{R} = \text{H}$ (**a**, 47%), Me (**b**, 52%).

1,3,5- and 1,4,5-Trisubstituted tetrazolium salts can be prepared in more than 70% yields from mesoionic tetrazoles **32**^{12, 60, 61} and 1,4-dihydropyridotetrazoles **33**,^{17, 62} in which the exocyclic atoms are readily involved in alkylation and protonation.

$\text{X} = \text{O}, \text{NH}, \text{NPh}$.

$\text{X} = \text{NMe}, \text{S}$.

Analogous reactions with fused tetrazole derivatives, with pyrrolotetrazoles **34** and **35** in particular, also proceed smoothly.⁶³

Special mention should be made of the reaction of readily available 1,3-diphenyltetrazolium-5-olate¹² (36) with phosphorus pentachloride⁶¹ and trifluoromethanesulfonic anhydride⁶⁴ which yields functionalised tetrazolium salts 37 and 38.

4. Heterocyclisation reactions

The main advantage of the synthesis of tetrazolium salts by heterocyclisation is that this excludes preliminary synthesis of tetrazole derivatives. Reactions of alkyl and aryl azides with nitrilium salts which proceed as [3 + 2]-cycloaddition and result in 1,4,5-trisubstituted tetrazolium salts in good yields have the greatest preparative significance (Table 6).^{22, 65, 66}

An intramolecular version of this reaction is also known. It was shown³¹ that cyclisation of the *in situ* generated *N*-methyl- ω -azidonitrilium triflates 39 is a rather convenient and efficient procedure for the synthesis of annelated 1,4,5-trisubstituted tetrazolium salts 40.

Table 6. The synthesis of 1,4,5-trisubstituted tetrazolium salts by the reaction of azides with nitrilium salts.

^a With decomposition.

Heterocyclisation reactions can also be employed for the synthesis of 1,3,5-trisubstituted tetrazolium salts. The use of these reactions is limited due to the low availability of the starting reagents; it has been reported, however,⁷ that the hydrazinium salt **41** is converted into 1-benzyl-3,5-diphenyltetrazolium iodide (**42**) under the action of a base.

1,3-Diaza-2-azoniaallene salts **43a,b** [Ar = 2,4,6-Cl₃C₆H₂ (**a**), 4-ClC₆H₄ (**b**)] generated *in situ* from *N*-chlorotriazenes **44a,b** react with carbodiimides to give dihydrotetrazolium derivatives **45** which are converted into 5-alkylamino-1,3-diaryltetrazolium salts **46** upon heating.^{67, 68}

III. Physicochemical properties and structures of tetrazolium salts

In the individual state and under normal conditions, tetrazolium salts are stable crystalline compounds (except for the salts containing the MeSO₄[−] anion) frequently isolated as viscous fluids (see, *e.g.*, Refs 23, 28, 32). 1,4-Dialkyltetrazolium perchlorates manifest higher melting temperatures than the 1,3-isomers.⁴⁵ Certain 1,3-dialkyltetrazolium perchlorates possess rather low (for ionic compounds) melting temperatures (~70–80 °C, see, *e.g.*, Refs 45, 46, 48). This allows the preparation of ionic fluids possessing unique properties presently established for other azolium salts.^{69, 70}

1. NMR spectra

NMR spectroscopy is one of the main techniques for the identification of tetrazolium salts. The chemical shift (CS) of the endocyclic carbon atom in the ¹³C NMR spectra strongly depends on the isomer type. The signals for carbon C(5) in 1,3-substituted tetrazolium salts **2** are downfield shifted by 7–16 ppm in comparison with the corresponding signals for 1,4-isomers^{71, 72} (Table 7). It is noteworthy that the nature of the substituents at the nitrogen atoms of the ring has little effect on the CS, being equal to ~147–151 ppm for 1,3-disubstituted, and ~138–142 ppm for 1,4-disubstituted tetrazolium salts. In the case of trisubstituted derivatives, the magnitude of the CS depends critically on the nature of the substituent at C(5). The signal of the C(5) atom characteristic of all ¹³C NMR spectra is shifted upfield in the following series of substituents: Prⁱ > Me > NH₂ > Cl > Br > I.^{15, 18, 21, 22, 28, 61, 71–75} A comparative study^{71, 72} of the NMR spectra of tetrazolium salts and related tetrazoles revealed that the quaternisation at the α-nitrogen atom of *N*-substituted tetrazoles little affects the magnitude of the CS of the C(5) atom (~1–4 ppm), while the quaternisation of the β-atom significantly changes it as can be evidenced from the downfield shift of 7–10 ppm. The slight change in the CS observed upon quaternisation of the N(4) atom is due to the oppositely directed effect of two factors, *viz.*, the electronegative group N= (the downfield shift) and the decrease in the order of the N–C bond in the cation formed as a result of polarisation (the upfield shift).

The ¹H NMR spectra of tetrazolium salts non-substituted in position 5 are characterised by a downfield shift of the signal for the proton at the endocyclic carbon atom and a significant (by ~20 Hz) increase in the spin–spin coupling constant (SSC) ¹J(¹³C–¹H) in comparison with the starting compounds.^{23, 30, 44, 71, 72} The CS value of the proton at C(5) strongly depends on the structure of the salt and the type of solvent. Chemical shifts of isomeric 1,3- and 1,4-disubstituted tetrazolium salts differ by ~0.5–1 ppm and even more.^{30, 43–49} Thus the CS of 1,4-dialkyltetrazolium perchlorates and tetrafluoroborates are 11.1–11.9 ppm, whereas those of 1,3-isomers are 10.2–10.9 ppm [in (CD₃)₂SO]. On going from DMSO to MeCN, the signal for the proton in the ¹H NMR spectrum is shifted upfield (10.6–10.9 ppm for 1,4-substituted and 9.6–10.1 ppm for 1,3-substituted derivatives).^{30, 43–49}

Identification of tetrazolium salts on the basis of ¹H NMR spectra often makes use of characteristic CS of the protons of the substituent owing to magnetic equivalence (or non-equivalence) of the groups. Thus the CS of the protons in the alkyl groups (Me, Et, Bu^t) in positions N(1) and N(4) differ considerably from those of the analogous substituents at the atoms C(5) and N(3).^{3, 14, 17, 18, 21, 35, 36, 49, 71}

NMR spectroscopy allows both identification of tetrazolium salts and an analysis of the conjugation of the tetrazole fragment with the substituent. Thus the change in the CS of the carbon atoms of the vinyl group in the ¹³C NMR spectra upon quaternisation of vinyltetrazoles allows one to conclude that there is a decrease in the *p*,*π*-conjugation in *N*-vinyltetrazolium salts and an increase in the *p*,*π*-conjugation in *C*-vinyltetrazolium salts as compared to the starting tetrazoles.²⁸ These data are consistent with the results of quantum-chemical calculations of geometric

Table 7. The chemical shift values of the signals of C(5) atoms of 1,3- (**2**) and 1,4-substituted tetrazolium (**3**) salts determined from ^{13}C NMR spectra (δ).

2. X-Ray diffraction analysis

By now, crystal structures of eight tetrazolium salts, viz., 5-(1,5-diphenyl-3-formazany)-1,3-diphenyltetrazolium chloride (**48**),³ 1,3-di-*tert*-butyl-5-methyltetrazolium picrate (**18d**),³³ 5-(4-chlorophenyl)-1-methyl-3-phenyl- (**49**),²⁹ 1,3-di-*tert*-butyl- (**50**),⁴⁸ 1-*tert*-butyl-3-isopropenyl- (**51**),⁴⁸ 1-(2,2-dimethyl-4-oxopentyl)-4-methyltetrazolium perchlorates (**52**),⁴⁶ tetrazolo[4,5-*b*][1,3]thiazinium- (**30**)⁵⁸ and thiazolo[3,2-*d*]tetrazolium perchlorates **31b**, have been established.⁵⁹

The tetrazole rings in tetrazolium salts and other tetrazole derivatives are planar. The parameters of the tetrazole ring depend critically on the type of the salt. Thus the C(5)–N(1) [1.317(4) Å] and C(5)–N(4) [1.315(4) Å] bond lengths in the cation **52** are practically identical and intermediate between the double and ordinary bond lengths, N(2)–N(3) [1.276(4) Å] being the shortest bond and close to a double bond. The values of the bond angles at the N(2) and N(3) atoms practically coincide with that in a regular pentagon, while those at the N(1) and N(4) atoms approximate it. These data suggest that the structure of the 1,4-disubstituted tetrazole ring is close to that of a symmetrical ring with delocalisation of the excess positive charge over the N(4)–C(5)–N(1) fragment.⁴⁶ A similar structure is characteristic of the tetrazole ring of fused 1,4,5-trisubstituted tetrazolium salts **30** (see Ref. 58) and **31b** (see Ref. 59).

The heterocycles of 1,3-substituted tetrazolium salts are non-symmetrical. The N(2)–N(3) [1.287(3)–1.299(3) Å] bond in the cations **18d**, **48**–**51** is the shortest bond; the N(4)–C(5) [1.300(4)–1.314(3) Å] bond length differs from it only insignificantly. This suggests that the positive charge of 1,3-substituted tetrazolium salts is predominantly localised on the N(3) atom rather than on the N(1) atom which represents the quaternisation site.⁴⁸ The non-coincidence of the quaternisation site and the site of localisation of the positive charge in the case of some tetrazolium salts was established experimentally: the quaternisation of *N*-substituted tetrazoles differing in the positions of substituents gave identical compounds.^{30, 48} The exocyclic N–C bonds in the cations under study lie in the plane of the ring. Their lengths are rather similar and differ only insignificantly from the length of the corresponding ordinary bond N–C with the exception of the N(3)–C(Me) bond in the cation **51**. Its length [1.440 Å] is somewhat smaller than that of an ordinary bond, while its torsion angles deviate by no more than 10.6° from 0° or 180°, which is suggestive of the conjugation of the π -systems of the tetrazole ring with the C=C bond.⁴⁸

IV. Reactions of tetrazolium salts

Systematic studies of the chemical properties of 1,3- and 1,4-substituted tetrazolium salts were not carried out until recently. This section is devoted to the consideration of the most important

electrophilic and nucleophilic substitution reactions of tetrazolium salts at the carbon atom of the heterocycle and other transformations under the action of various reagents.

1. Substitution reactions at the carbon atom of the heterocycle

Only very few cases of substitution of the hydrogen atom in position C(5) of 1-monosubstituted tetrazoles were described before the 1980's. These include deuterium–hydrogen exchange, lithiation, mercuration and bromination.^{72, 80, 81} It was believed that the problems encountered in the electrophilic substitution of hydrogen were caused by the deactivation of position 5 by annular nitrogen atoms.⁸² With regard to disubstituted tetrazolium salts, the only known case was the isotope exchange in alkaline and acid media.

It is assumed that this exchange proceeds through the intermediate formation of ylide **53** or its isoelectronic analogue, carbene. It was shown that the kinetic CH-acidity changes in the following order: 2-R-tetrazoles < 1-R-tetrazoles < 1,3-disubstituted tetrazolium salts < 1,4-disubstituted tetrazolium salts.^{80, 81, 83–85}

The first successful attempts at aminomethylation^{86, 87} and iodination of 1-R-tetrazoles were reported in the late 1980's–early 1990's.^{88, 89} The experimental data suggest that these reactions proceed through the intermediate formation of an ylide, which accounts for the introduction of a substituent into position 5. This reaction begins with an attack of an electrophilic reagent at the most nucleophilic N(4) atom and the formation of a tetrazolium cation, which is further deprotonated into the intermediate ylide (carbene) **A** stabilised by intramolecular rearrangement.

E = I, CH₂NAlk₂; R = Ar, Alk, H.

Simultaneously electrophilic substitution at the C(5) atom of tetrazolium salts was reported. It was shown, in particular, that the substitution of lithium for hydrogen in 2,3-diaryltetrazolium salts occurs under the action of *tert*-butyllithium or lithium bis(trimethylsilyl)amide.^{90, 91} The condensation of 1,3-diphenyltetrazolium tetrafluoroborate with a diazonium salt in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), which favours the formation of a mesoionic carbene, viz., 1,3-diphenyltetrazolyene (**54**), has been described.⁶⁰

It was found that 1,3-diaryltetrazolium salts undergo mercuriation upon heating with mercury(II) acetate in dimethyl sulfoxide to yield bis(tetrazolio)mercury(II) salts **55** the mercury atom in which is easily replaced by a halogen.⁶⁰

$\text{Ar}^1 = \text{Ph}, 4\text{-MeC}_6\text{H}_4$; $\text{Ar}^2 = \text{Ph}, 4\text{-MeOC}_6\text{H}_4$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$.

Nucleophilic substitution at the C(5) atom of tetrazolium salts has been studied in more detail and is often employed in the synthesis of mesoionic tetrazoles. Thus it was shown that the ethoxy⁹² and the methylthio groups⁷³ and the chlorine atom⁶⁰ of 1,3,5-trisubstituted tetrazolium salts can be replaced by sulfide, hydroxide and selenide ions.

$\text{R}^1, \text{R}^2 = \text{Me}, \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4$; $\text{X} = \text{Cl}, \text{OEt}, \text{SMe}$;
 $\text{Y} = \text{O}, \text{S}, \text{Se}$; $\text{Z} = \text{BF}_4, \text{MeSO}_4$.

5-Ethoxy-1,3-diphenyltetrazolium tetrafluoroborate (**56**) reacts with C-nucleophiles, *e.g.*, malonic dinitrile,⁹³ lithium and sodium cyclopentadienide,^{94,95} indenide, fluorenyl and cyclopenta[def]phenanthrenide⁹⁵ to give mesoionic tetrazoles **57** and **58a–d**.

$\text{M} = \text{Li}, \text{Na}$;
 $\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{R}^4 = \text{H}$ (**a**);
 $\text{R}^1 = \text{R}^2 = \text{H}, \text{R}^3\text{--R}^4 = \text{CH}=\text{CHCH}=\text{CH}$ (**b**);
 $\text{R}^1\text{--R}^2 = \text{CH}=\text{CHCH}=\text{CH}, \text{R}^3\text{--R}^4 = \text{CH}=\text{CHCH}=\text{CH}$ (**c**);
 $\text{R}^1\text{--R}^4 = \text{--CH--CH=C--CH=CH--C--CH=CH--CH=}$ (**d**).

Mesoionic tetrazolium amides **59** were prepared by the reaction of 5-chloro-1,3-diphenyltetrazolium tetrafluoroborate **38** with N-nucleophiles, such as aliphatic amines,⁹⁶ aniline, hydroxylamine, *N*-mono- and *N,N*-disubstituted hydrazines.⁶⁰

The reaction of the salt **38** with ammonia yielded bistetrazolio-amide **60** as the main product;⁶⁰ the reaction with hydrazine and arylendiamines⁹⁷ gave tetrapolar mesoionic bistetrazoles **61**, **62**.

5-Azido-1,3-diphenyltetrazolium tetrafluoroborate (**63**) prepared by the reaction of sodium azide with the salt **38** has rich synthetic potential. The attack of strong nucleophiles, *e.g.*,

$\text{X} = \text{CN}$ (93%), $\text{SO}_2\text{C}_6\text{H}_4\text{Me-4}$ (46%).

sodium hydroxide or amines at the endocyclic carbon atom, yields substitution products. Weaker nucleophiles, such as the cyanide ion, *p*-toluenesulfonate anion, triphenylphosphine, *etc.*, attack the terminal nitrogen atom to give the addition products **67** and **68**.⁶¹

The nucleophilic substitution at the C(5) atom in 1,4,5-trisubstituted tetrazolium salts has been described exclusively for 1,4-dimethyl-5-(methylthio)tetrazolium salts. It was shown that they react with bases to give 1,4-dihydro-1,4-dimethyltetrazoles **69** and **70** (yields 27%–40%).^{7, 17, 62}

X = BF₄, MeSO₄; R = Me, PhNH.

2. The action of bases

The majority of currently known tetrazolium salts are sensitive to bases. A base attacks predominantly the two carbon atoms with the lowest electron density, *viz.*, the C(5) atom and the carbon atoms in the α -position relative to the nitrogen atoms of the heterocycle, which leads to the opening of the tetrazole ring, dealkylation or self-condensation. The salts devoid of substituents at the C(5) atom are the most susceptible to bases. The abstraction of the hydrogen atom under the action of bases is accompanied by the formation of heteroaromatic carbenes, *viz.*, tetrazolidenes. The latter, in turn, undergo fragmentation the direction of which depends on the type of the salt used. It was shown^{13, 98} that 1,4-disubstituted tetrazolium salts are split into molecular nitrogen and carbodiimides **71** under the action of tertiary amines at 20 °C. Along with other reactions, this reaction is used in the synthesis of carbodiimides (see Ref. 99) and is the sole procedure in the synthesis of, *e.g.*, vinylcarbodiimides.¹³

The carbodiimides formed, being highly reactive compounds,⁹⁹ react with an excess of the base or the solvent, or undergo intramolecular cyclisation. Thus the reaction of 1-ethyl-4-(*p*-tolyl)tetrazolium tetrafluoroborate (**72**) with diethylpropynylamine in the presence of water gives *N*-ethyl-*N'*-(*p*-tolyl)-urea (**73**).⁹⁸

4-Alkyl-1-phenyltetrazolium picrates **74** are decomposed slowly in the presence of water to yield trisubstituted urea **75**; after treatment with diethylamine, they are converted into guanidinium picrate **76**.³³

R = Me, Bu^t.

It has been reported¹³ that consecutive treatment of 1-(ethoxycarbonylmethyl)-4-methyltetrazolium tetrafluoroborate (**77**) with triethylamine and then with benzylamine, phenylhydrazine or hydrogen sulfide yields hydantoin **78**–**81**. Unfortunately, neither the methodology of these reactions, nor the yields of the target products have been reported.¹³

1-R-4-(2-Methyl-4-oxopent-2-yl)tetrazolium perchlorates **14** evolve nitrogen in the presence of bases to be transformed into 4,4-dimethyl-1-R-6-methylidene-3,4,5,6-tetrahydropyrimidin-2(1*H*)-ones **82** and 4,4,6-trimethyl-1-R-3,4-dihydropyrimidin-2(1*H*)-ones **83**, the latter being predominant.⁴⁷

R = Ph, Bn.

3-Monosubstituted quinazoline-2,4(1*H*,3*H*)-diones **85** are formed in high yields on dissolution of 4-alkyl-1-(2-carboxyphenyl)tetrazolium perchlorates **84** in dimethyl sulfoxide.⁴⁷

R = Bu^t, CMe₂CH₂COMe.

4-Alkyl-1-(2-hydroxyaryl)tetrazolium perchlorates **86** undergo recyclisation into 2-alkylaminobenzooxazoles **87** under the action of bases.⁴⁷

R = Bu^t, CMe₂CH₂COMe; Y = H, NO₂; Z = H, NO₂.

Preparation of 2-methylamino-5,7-dinitrobenzooxazole (**88**) is an example of a successful conversion of readily available 1-monosubstituted tetrazoles into benzooxazoles without the intermediate isolation of the tetrazolium salt.¹⁰⁰

1-Aryl-4-ferrocenylalkyltetrazolium salts undergo dealkylation by aqueous ammonia or sodium carbonate at 20 °C to yield 1-aryltetrazoles and ferrocenylalkyl alcohols. 1-Ferrocenylmethyl-4-phenyltetrazolium tetrafluoroborate (**89**) undergoes the Stevens rearrangement in the presence of potassium *tert*-butoxide in dioxane to give 1,5-disubstituted tetrazole **90**.⁴⁴

Fc = C₅H₄FeC₅H₅.

1,3-Disubstituted tetrazolium salts react with strong bases to give 1,3-disubstituted 3-cyanotriazenes **91a,b**.^{60, 82} Compound **91a** is decomposed under the action of the hydroxide ion resulting in diazomethane and methylcyanamide anion.

R = Me (a), Ph (b); X = Cl, BF₄.

3,5-Diaryl-1-methyltetrazolium salts **92** are resistant to the action of Et₃N in toluene at 20 °C, but react vigorously with sodium ethoxide in benzene or toluene to yield a complex mixture of reaction products among which biaryls are predominant.²⁹

Y = H: X = H, Me, MeO, Cl; X = H: Y = H, NO₂, Me, MeO, Cl;
R = Ph, C₆H₄Me-4.

1,4,5-Trisubstituted tetrazolium salts **93a,b** undergo N-dealkylation⁹⁸ or fragmentation in the presence of bases,^{25, 101} and ring-opening products always contain alkyl or aryl azide.

R = Me (a), Ph (b).

1,4,5-Trialkyltetrazolium salts **94** undergo deprotonation under the action of sodium hydride in tetrahydrofuran. This reaction has been studied in sufficiently great detail, since it allows one to prepare 1,4-dihydro-5-alkylenetetrazoles **95**, the starting compounds in the synthesis of iminoaziridines, tetrazines, and other nitrogen-containing heterocyclic systems.^{66, 102}

R¹, R² = H, Alk.

Some interesting conversions of *N*-acyl- and *N*-phenacyl-tetrazolium salts under the action of bases have been described.^{21, 27, 35, 103, 104} It was shown that tetrazolium salts can be converted into ylides, fused tetrazoles, and other heterocyclic molecules. The direction of these reactions depends on the nature

of the reagent and the substituents in the substrate. Thus 1-alkyl-5-methyl-4-phenacyltetrazolium bromides **96** are converted into ylides **97** under the action of aqueous solutions of potassium carbonate.²⁷

R = Me, Prⁿ, Prⁱ, Bu^t, CH₂Bu^t, cyclo-C₆H₁₁; X = H, Br, NO₂.

Similar conversions were observed in the case of 1,3-di- and 1,3,5-trisubstituted tetrazolium salts containing a phenacyl group at N(1) or N(3) atoms.²¹ 1,5-Dimethyl-4-phenacyltetrazolium salts **98** undergo recyclisation into 1,2,5-trisubstituted imidazol-4-ones **99** upon heating with aqueous sodium hydrogencarbonate.¹⁰³ Analogous salts **100** yield 3*a*,6-dihydro-3*H*-imidazo[1,2-*d*]tetrazoles **101** in a reaction with aqueous ammonia.¹⁰⁴

Ar = Ph, C₆H₄Br-4.

R¹ = Me, Et, Pr, Prⁱ, cyclo-C₆H₁₁, Ph, Bn, CH₂C₆H₄NO₂-4;

R² = Me, Et, Bn; X = Br, I, ClO₄, SbCl₆, PF₆.

1-Acetylmethyl-5-amino-3- (**102a**) and -4-methyltetrazolium bromides (**102b**) undergo cyclisation into 6-acetyl-2,5-dimethyl-2*H*- (**103a**) and 6-acetyl-3,5-dimethyl-3*H*-imidazo[1,2-*d*]tetrazoles (**103b**) under the action of acetic anhydride and triethylamine.³⁵

103a: 3-Me (86%); **103b**: 4-Me (51%).

3. The action of acids

The heterocycle in tetrazolium salts is usually resistant to acids. In reactions with acids, the modification affects only the substituents and is usually followed by their elimination and migration into another position of the ring.

It was found that 1-*R*-3-*tert*-butyltetrazolium perchlorates are slowly converted into 1-*R*-4-*tert*-butyltetrazolium perchlorates on storage in perchloric acid.^{45, 47, 55}

R = Me, Et, Bu^t, cyclo-C₆H₁₁, Ph, 2-HO₂C₆H₄,

2-HO-5-NO₂C₆H₃, 2-HO-4-NO₂C₆H₃.

Higher thermodynamic stability of 1,4-disubstituted tetrazolium salts in comparison with their 1,3-isomers is the driving force of this process as can be evidenced from the results of quantum-chemical calculations of the heats of formation and total energies of isomeric tetrazolium cations carried out with the use of semi-empirical^{28, 45} and *ab initio* methods (Table 9) with full optimisation of the cation geometry.

1-*tert*-Butyl-3-*R*-tetrazolium salts do not undergo isomerisation in perchloric acid, but partly lose their *tert*-butyl groups.⁴⁵ The conversion of 1-*R*-3-*tert*-butyltetrazolium salts into the corresponding 1,4-isomers is accompanied by a partial loss of the *tert*-butyl group.^{45, 55} Notwithstanding, storage of 1-*R*-3-*tert*-butyltetrazolium salts with perchloric acid has been employed for the synthesis of 1-*R*-4-*tert*-butyltetrazolium salts.^{45, 47}

In contrast to 1,3-disubstituted tetrazolium salts, 1,3,5-trisubstituted derivatives do not undergo isomerisation under similar conditions but are subject to dealkylation.⁴⁵ This property of 1,3,5-trisubstituted tetrazolium salts was used in the synthesis of mono- and binuclear 1,5-disubstituted tetrazoles where alkyl substituents are introduced into position N(1) of the tetrazole ring of 2,5-disubstituted tetrazoles with subsequent elimination of the *tert*-butyl substituent (the yields of the target products are 78%–94%).^{36, 106}

Table 9. The relative stability of tetrazolium cations (data from *ab initio* quantum-chemical calculations).

Boiling of 1-alkyl-4-aryl-5-(2-dimethylaminovinyl)tetrazolium perchlorates **104** in hydrochloric acid leads to the modification of the substituent at the C(5) atom.²⁵

R = Me, Et; X = H, Me, F, Cl, Br, I.

Treatment of 3-acetylmethyl-1,5-dimethyltetrazolium chloride (**105**) with a nitrating mixture results in mesoionic tetrazole **106**.¹⁰⁷

1,4,5- (**107**) and 1,3,5-trisubstituted tetrazolium salts (**108**) undergo cyclisation into 1*H*- and 2*H*-pyrrolotetrazoles **109** and **110** upon heating in acetic acid in the presence of sodium acetate.³⁷

R¹ = MeCO, CO₂Me; R² = Me, Ph; R³ = H, Me;
R⁴ = Me, Ph, 4-BrC₆H₄; X = BF₄, MeSO₄.

4. The action of reducing and oxidising reagents

Tetrazolium salts are highly resistant to oxidising and reducing reagents; their heterocycles are not opened when treated with these reagents. Thus the oxidation of 1,3-diaryl-5-mercaptotetrazolium salts with concentrated nitric acid leads merely to the elimination of the substituent from position C(5) and the formation of 1,3-diaryltetrazolium salts,⁶⁰ while treatment of 5-azido-1,3-diphenyltetrazolium tetrafluoroborate (**63**) with hydroiodic acid or sodium sulfite results in the reduction of the azido group to the amino group.⁶¹ At the same time, 1,4,5-trialkyl(aryl)tetrazolium salts are reduced to trisubstituted dihydrotetrazoles **111** with sodium borohydride in ethanol. These salts undergo alkylation in reactions with organolithium compounds and vinylmagnesium bromide to give tetrasubstituted dihydrotetrazoles **112**.⁶⁵

R¹ = Me, Et, Oh; R² = Ph, Me, cyclo-C₆H₁₁, Bu^t; R³ = Me, Et, Bn, Ph;
R⁴ = Me, Ph, PhC≡C, CH₂=CH; M = Li, MgBr.

5. Thermolysis

The published data on the thermal stability of tetrazolium salts are rather scarce. It was shown^{6, 14} that of 1,3- and 1,4-dimethyl-5-*R*-tetrazolium iodides, the 1,4,5-isomers are more stable. Their decomposition begins at temperatures above 265 °C (R = Me) and 130 °C (R = Ph), whereas that of 1,3,5-isomers occurs even at 130 and 70 °C, respectively. *N*-Demethylation is the main process of thermolysis leading to the formation of disubstituted tetrazoles.^{6, 14} Thermolysis of 1,3,5-trisubstituted derivative **67** is accompanied by the evolution of nitrogen and the formation of the salt **113** in 94% yield.⁶¹

Recently, the thermal stabilities of 1-methyl-4-phenyl-, 1,4,5-trimethyl-, 1,3-di-*tert*-butyl-5-methyl- and 1,3-di-*tert*-butyltetrazolium picrates have been studied using differential scanning calorimetry and complex thermal analysis (heating rate 5 °C per min in a nitrogen atmosphere).³³ Among those, 1,4,5-trimethyltetrazolium picrate [initial temperature of intense decomposition (*T*_d) 215 °C] manifested the highest stability. 1-Methyl-4-phenyltetrazolium picrate (*T*_d = 100 °C) appeared to be the least stable, which may be attributed to the easy abstraction of proton from the carbon atom of the heterocycle. Special mention should be made of the enhanced thermal resistance of poly-*N,N'*-dimethyl-5-vinyltetrazolium perchlorate in comparison with poly-*N*-methyl-5-vinyltetrazole. According to complex thermal analysis data, the decomposition of polymeric tetrazolium perchlorate is observed at temperatures above 275 °C, whereas the non-quaternised polymer is decomposed at 230 °C.¹⁰⁸

2-Methyl-5-phenyltetrazole is the main reaction product in the attempted synthesis of tetrazolium salts by quaternisation of 1-methyl-5-phenyltetrazole with methyl iodide at 130 °C.⁶ The resulting isomerisation is due to the specificity of thermolysis of the initially formed tetrazolium salt **114**; its decomposition yields predominantly 2,5-disubstituted tetrazole.⁶

The formation of tetrazolium complexes is usually the key step in the isomerisation of *N*-substituted tetrazoles, which occurs under the action of alkylating reagents^{6, 109} or acids.^{43, 55, 110, 111}

6. Photolysis

The photochemical conversions of some azido-, azo- and triazo-1,3-diaryltetrazolium derivatives have been studied recently.^{112–114} It was found^{112, 113} that the tetrazole rings of the

compounds under study are resistant to UV irradiation. Among other conversions, only the reactions of 5-azido-1,3-diaryltetrazolium salts, which yield hardly accessible tricyclic mesoionic compounds **115** and **116**, deserve special mention.

UV Irradiation of 1,3-diphenyl-5-phenyltetrazolium tetrafluoroborate is accompanied by the evolution of nitrogen and the formation of 1,3-diphenyltetrazolium tetrafluoroborate and benzene.¹¹⁴

V. Applications of tetrazolium salts

Until recently, 1,3- and 1,4-substituted tetrazolium salts have not been sufficiently investigated due to their unavailability and data concerning their applications are virtually absent from the literature. However, the development of procedures for their synthesis have given strong impetus to their investigations, particularly in those areas where 2,3-substituted tetrazolium salts (*e.g.*, phase-transfer catalysts, reagents for the separation of metals, *etc.*) were conventionally used before. There is evidence of successful applications of 3-*tert*-butyl-1,5-dimethyltetrazolium perchlorate (**117**) as a phase-transfer catalyst in oxidation reactions catalysed by the permanganate ion.¹¹⁵

It is of note that 1,3-substituted tetrazolium salts have a number of advantages over 2,3-derivatives in such reactions.¹¹⁶ First, these methods allow one to obtain 1,3,5-trisubstituted tetrazolium salts with various types of substituents at the carbon and nitrogen atoms of the tetrazole ring and thus to vary their physicochemical properties (*e.g.*, thermal stability, solubility, *etc.*). The methods for the synthesis of 2,3-disubstituted tetrazolium salts exclude the introduction of alkyl substituents to the nitrogen atoms of the tetrazole ring, which limits the array of available derivatives.^{1–3} Of no less importance is the relative stability of 1,3-substituted tetrazolium salts in reductive media;

therefore, they can be used in phase-transfer reduction reactions, whereas 2,3-substituted derivatives are converted into formazanes even under the action of weak reducing agents.^{1–3} Recently, a series of poly-5-vinyltetrazolium salts **118** prepared by exhaustive methylation of poly-5-vinyltetrazole have been examined as sorbents for the extraction of palladium ions from various solutions in the form of $PdCl_4^{2-}$. These include an efficient adsorbent for the selective extraction of palladium ions from spent palladium electrolytes.¹⁰⁸ It was found that 1,4-dimethyl-5-[(2-oxopropyl)thio]tetrazolium triflate (**119**) inhibits transglutaminase,¹¹⁷ and 5-(2-anilinoethyl)-1-(4-chlorophenyl)-4-ethyltetrazolium iodide (**120**) manifests antiarrhythmic activity.¹¹⁸

The addition of 1-aryl- and 1-cyclohexyl-4,5-dimethyltetrazolium chlorides **121** to photographic dyes decreases the light sensitivity of photomaterials and enhances image sharpness.¹¹⁹ 1,4-Bis(2-decanoylaminoethyl)tetrazolium methylsulfate and perchlorate **122** have been patented as corrosion inhibitors and disinfectants.¹²⁰ Tetrazolo[1,5-*a*]pyridinium salts **123**, **124** have found application as sensitizers in the recording layers of electro-photographic materials.^{56, 121}

However, 1,3- and 1,4-substituted tetrazolium salts present the greatest interest as starting materials in the synthesis of various (including hardly accessible) heterocyclic systems. Condensation reactions of these salts are employed in the synthesis of annelated heterocycles. These reactions are specific and often the only way to the synthesis of imidazo-^{35, 103} and pyrrolotetrazoles.³⁷ It was shown that recyclisation of 1,4-substituted tetrazolium salts is a convenient procedure for the synthesis of three-, five- and six-membered nitrogenous heterocycles, such as iminoaziridines and tetrazines,^{66, 102} imidazolones,¹⁰³ benzooxazoles and quinazoline-diones.^{47, 100} The conversions of substituents at the carbon atom of the heterocycles of 1,3,5- and 1,4,5-trisubstituted tetrazolium

salts can be used in the high-yield synthesis of mesoionic tetrazoles,^{21, 27, 60, 94, 95, 112–114} The use of tetrazolium salts for the generation of N-heteroaromatic carbenes,^{44, 59, 122} which occupy a special place in the chemistry of carbenes by virtue of their peculiar structures and reactivities, especially holds great promise.^{83, 122}

VI. Conclusion

Significant progress has been achieved in the synthesis and investigation of physicochemical properties of 1,3-(1,3,5)- and 1,4-(1,4,5)-substituted tetrazolium salts in the past 10–15 years. The interest in these studies is largely due to the development of methods for selective functionalisation of the tetrazole ring, which permits direct introduction of substituents on the carbon and nitrogen atoms of the heterocycle, and the recently discovered isomerisation of 1,3-disubstituted tetrazolium salts into the corresponding 1,4-disubstituted derivatives. In turn, the availability of tetrazolium salts has stimulated the search for novel areas of their applications, particularly for synthetic purposes. Recyclisation and condensation reactions of tetrazolium salts and transformations of substituents at the carbon atom of the heterocycle proved to be useful tools in the synthesis of various organic compounds. Elucidation of the synthetic potentials of tetrazolium salts presents considerable interest for further progress in preparative chemistry of nitrogen-containing heterocyclic systems and organic chemistry on the whole. In-depth studies into the properties of novel 1,3-(1,3,5)- and 1,4-(1,4,5)-substituted tetrazolium salts will make it possible to extend the range of their practical applications, e.g., the design of polynitrogenous ionogenic polymers and ionic fluids resembling those of other azolium salts and possessing unique properties. Of no less importance are further studies into tetrazole quaternisation and possible involvement of functionalised C- and N-tetrazole derivatives and various alkylating reagents in this reaction. The knowledge of regularities underlying the formation of tetrazolium cations will enhance the potentialities of quaternisation and protonation reactions for the activation of the tetrazole ring in the substitution reactions occurring at the endocyclic carbon atom.

Supramolecular chemistry of cucurbiturils

O A Gerasko, D G Samsonenko, V P Fedin

Contents

I. Introduction	741
II. Host–guest cucurbit[6]uril compounds	742
III. Supramolecular compounds of cucurbit[6]uril with metal aqua complexes	746
IV. Supramolecular compounds of cucurbit[6]uril with metal cluster aqua complexes	751
V. Cucurbit[<i>n</i>]urils (<i>n</i> = 5, 7–10)	756

Abstract. The main principles of the design of supramolecular compounds starting from organic macrocyclic cavitands, *viz.*, cucurbit[*n*]urils [C₆H₆N₄O₂]_{*n*} (*n* = 5–10), are considered. The presence of the hydrophobic inner cavity along with polar carbonyl groups forming the cucurbituril portals are responsible for high specificity of the formation of host–guest complexes. The unique ability of cucurbiturils to act as synthetic molecular containers is discussed. In these containers, bimolecular reactions between specially selected guests proceed with high regio- and stereoselectivity. The review surveys new data on the directed construction of supramolecular organic–inorganic compounds through the formation of an extensive network of hydrogen bonds between the portal oxygen atoms of cucurbiturils and water molecules of metal aqua complexes. The bibliography includes 108 references.

I. Introduction

Supramolecular chemistry is a new extensively evolving area of research focused on the association of individual molecules giving rise to more complex chemical systems formed through intermolecular (non-covalent) interactions.^{1–3} Supramolecular chemistry concerns various phenomena in different fields of science (organic, coordination and physical chemistry, biology, physics) and has a broad spectrum of possibilities due to the mutual enrichment of these areas of scientific exploration. Supramolecular chemistry deals with supramolecular ensembles, which are spontaneously self-assembled from complementary (*i.e.*, characterised by geometric and chemical compatibility) fragments in much the same fashion as spontaneous self-assembly of very complicated spatial structures in living cells. The directed construction of such systems and the design of highly ordered supramolecular compounds with desired structures and properties from molecular building blocks are fundamental problems of modern chemistry.

Intermolecular interactions holding the fragments together, *viz.*, Coulombic interactions, hydrogen bonds and van der Waals interactions, are, on the whole, much weaker than the covalent bonds in the molecule itself. To increase the strength of these bonds, their directionality and specificity, it is necessary to use rather large molecular building blocks capable of creating an extensive network of bonds due to a large contact interface.

Examples of compounds with a large number of bonded non-covalent interactions are host–guest complexes in which the inner cavity of the host molecule (or cavitand)⁴ can include a guest molecule of suitable size. Numerous complexes containing such macrocyclic organic molecules as crown ethers (**1**), cryptands (**2**), calixarenes (**3**) or cyclodextrins (**4**) as the host are presently available.

The encapsulation of inert gases, metal ions or organic molecules in the cavities of these molecules gives rise to stable compounds having unusual structures and exhibiting interesting properties. The present review surveys the synthesis and structures of supramolecular compounds prepared with the use of macrocyclic cavitands having the trivial name cucurbiturils.

Cucurbituril with composition $C_{36}H_{36}N_{24}O_{12}$ [cucurbit[6]uril (5)] consisting of six methylene-linked glycoluril fragments has been studied the most. This compound is the first example of cucurbiturils. It was prepared by Behrend *et al.*⁵ in 1905 by condensation of formaldehyde with glycoluril (condensation product of urea and glyoxal) in acidic medium. At that time, however, the procedures available did not allow one to determine correctly its composition and structure.

In 1981, Freeman, Mock and Shih⁶ reproduced the synthesis developed by Behrend and obtained a colourless crystalline compound whose structure was established by X-ray diffraction analysis. Cucurbituril **5** is a barrel-shaped macrocyclic cavitand containing carbonyl oxygen atoms (portals) at the top and bottom of the barrel. This cavitand received its trivial name for the visual similarity of its molecular shape to *Cucurbitaceae* (pumpkin family). According to the nomenclature of Chemical Abstracts, the systematic name of this compound is dodecahydro-1*H*,4*H*,14*H*,17*H*-2,16:3,15-dimethano-5*H*,6*H*,7*H*,8*H*,9*H*,10*H*,11*H*,12*H*,13*H*,18*H*,19*H*,20*H*,21*H*,22*H*,23*H*,24*H*,25*H*,26*H*-2,3,4*a*,5*a*,6*a*,7*a*,8*a*,9*a*,10*a*,11*a*,12*a*,13*a*,15,16,17*a*,18*a*,19*a*,20*a*,21*a*,22*a*,23*a*,24*a*,25*a*,26*a*-tetraoxazabispentaleno [1''',6''' : 5'',6'',7'']-cycloocta(1,2,3-*cd* : 5,6,7-*c'd'*)dipentaleno-1,4,6,8,10,12,14,17,19,21,23,25-dodecane. Hereinafter, cucurbiturils consisting of *n* glycoluril fragments will be abbreviated to *Qn* or referred to as cucurbit[*n*]uril.

The dimensions of the inner cavity of cucurbit[6]uril (**5**) (the height is 6 Å and the inner diameter is 5.5 Å) allow the molecule to accommodate small guest organic molecules or ions and the portals formed by the carbonyl groups (the diameters of the portals are 4 Å) can bind cations. The structure determination of Q6 gave impetus to investigations of its ability to act as a macrocyclic cavitand. Cucurbit[6]uril (**5**) whose cavity is similar in size to those of α -cyclodextrin and 18-crown-6 has higher negative charges on the donor oxygen atoms resulting in the enhancement of stability of its adducts with positively charged ions.^{7,8} Yet another difference between cucurbituril Q6 and other cavitands is its structural rigidity. Thus, this cucurbituril virtually retains its shape upon the inclusion of different guests and, consequently, exhibits higher selectivity in the formation of inclusion compounds.⁷

Cucurbit[6]uril (**5**) is a colourless crystalline compound, which is insoluble in water and organic solvents but is readily soluble in some mineral acids (HCl, H₂SO₄, CF₃SO₃H), carboxylic acids

(for example, HCOOH) and aqueous solutions of alkali salts. Cucurbit[6]uril serves as a convenient starting compound for the preparation of various supramolecular compounds due to its unique structure, the simplicity of the synthesis procedure and thermal stability (it does not decompose upon heating to 400 °C; see Ref. 9). Presently, cucurbit[6]uril is a readily available reagent (in particular, it can be purchased from Merck).

The results of studies devoted to the synthesis, examination of structures and properties of supramolecular compounds of cucurbiturils and investigations of thermodynamic and kinetic aspects of formation of these systems are summarised in reviews.^{7, 10–13} The present review surveys the recent advances in the chemistry of cucurbiturils achieved, primarily, in the latter half of the 1990s. Considerable attention is given to the studies aimed at the directed construction of supramolecular organic–inorganic hybrid materials, which have been performed in the last five years.

II. Host–guest cucurbit[6]uril compounds

The presence of the rather rigid inner cavity is responsible for the ability of cucurbit[6]uril (**5**) to accommodate small guest molecules. The formation of inclusion compounds was established by crystallographic methods as well as by different physicochemical methods because absorption, fluorescence and NMR spectra of guests are changed as the guest molecules go from the solvent environment (generally, from weakly acidic aqueous solutions) to the non-polar cavity of cucurbituril. Cucurbit[6]uril (**5**) forms stable inclusion compounds with amines, diamines, alkylammonium ions, benzylammonium ions and dye molecules.

1. Inclusion compounds with alkylammonium ions

Inclusion compounds of cucurbit[6]uril (**5**) with alkylammonium ions have received the most study. The hydrocarbon radical of the alkylammonium cation is encapsulated in the cavity of Q6 displacing the solvent molecules and is held in this cavity through van der Waals forces, whereas the nitrogen atom is fixed at the portal through Coulombic interactions of the cation with the oxygen atoms of the carbonyl groups. As a result, high specificity of binding of alkylammonium ions to cucurbit[6]uril is achieved.

X-Ray diffraction analysis of the supramolecular compound of Q6 with *p*-xylenediammonium chloride carried out by Freeman¹⁴ in 1984 showed that the hydrocarbon fragment of the diammonium cation $H_3N^+CH_2C_6H_4CH_2N^+H_3$ is located in the cavity, whereas two protonated nitrogen atoms are located at the portals of the macrocycle. The formation of host–guest compounds with composition 1:1 was also evidenced by X-ray diffraction data and solution NMR spectroscopic studies of supramolecular compounds of cucurbit[6]uril with alkyldiamines containing four, five or six methylene units between the nitrogen atoms.^{14–16}

The incorporation of alkylammonium cations into cucurbit[6]uril was examined by solution NMR spectroscopy in the 1980–1990s.^{15–20} It was found that the most stable inclusion compounds with cations of primary amines $H(CH_2)_nNH_3^+$ and diamines $H_3N^+(CH_2)_nNH_3^+$ are formed at *n* = 4 and *n* = 5, 6, respectively. An increase in the length of the hydrocarbon chain either hinders coordination of both amino groups of the alkyldiamine to the portals of cucurbit[6]uril or causes the hydrophobic alkyl fragment of the amine to interact with the second hydrophilic portals. A decrease in the length of the hydrocarbon chain leads to a decrease in the number of van der Waals contacts as a result of which two ammonium groups cannot be simultaneously

Figure 1. Logarithm of the formation constant (K) of inclusion compounds of cucurbit[6]uril with amines vs. the number of CH_2 groups in the chain; (1) alkylamines, (2) alkyldiamines, (3) amino alcohols.

located at the portals. The plots of the formation constants of inclusion compounds with composition 1:1 versus the chain length for alkylamines,¹⁷ alkyldiamines¹⁷ and amino alcohols¹⁸ are shown in Fig. 1. In the case of amino acids, no influence of the number of methylene groups on the stability constants was observed.¹⁸

The $\text{PhNH}(\text{CH}_2)_6\text{NH}(\text{CH}_2)_4\text{NH}_2$ ligand containing three amino groups was specially synthesised and its binding with cucurbit[6]uril (**5**) was studied.¹⁹ An important characteristic feature of this guest molecule is the presence of two nitrogen atoms involved in the diaminoalkyl fragment. Their basicity is 10^6 times as high as that of the nitrogen atom bound to the phenyl group. In addition, the formation constant of the supramolecular compound of the hexanediammonium cation with cucurbit[6]uril is approximately 100 times larger than that for the butanediammonium ion, *i.e.*, different fragments of the triamine behave differently in binding to Q6. In aqueous solutions, the constant $\text{p}K_{\text{a}}$ of the nitrogen atom of the aniline fragment in this triamine is 4.7 and it is increased to 6.7 in the presence of stoichiometric amounts of Q6. The behaviour of each region of the triamine depends on pH. In acidic solutions, the hexanediammonium fragment (more complementary to the cavity in size) is located inside the cavitand. By contrast, the butanediammonium end of the triamine is bound to Q6 at $\text{pH} > 6.7$ because the nitrogen atom of the aniline fragment is deprotonated. This system is a molecular 'switch', *i.e.*, Q6 can be moved along the triamine molecule by changing the pH.

NMR spectroscopic studies demonstrated that the rate of formation of adducts with cucurbit[6]uril (**5**) depends on the diameter of the ammonium molecules and it is independent of thermodynamic stability of the resulting complexes.²⁰ Linear

hydrocarbon chains with a diameter that is no larger than the diameter of the portals of Q6, readily penetrate into the cavity, whereas the inclusion of cyclic or branched hydrocarbons is, apparently, accompanied by deviation of the oxygen atoms at the portals from their normal positions. Studies devoted to investigations of the thermodynamic and kinetic aspects of the inclusion of bulky ligands^{21–23} demonstrated that the formation of host–guest supramolecular compounds depends, in particular, on the acidity of the medium. The formation of compounds with cucurbit[6]uril is the first example of the pH-controlled kinetics of encapsulation of organic guests into the host cavity. The inclusion of a protonated guest into the cavity of the cavitand is slow due to formation of an intermediate upon interaction of the guest with the polar oxygen atoms at the portals, whereas an unprotonated molecule is encapsulated directly in the cavity and the rate constant of this reaction is 20 times larger.²³

High specificity of binding of Q6 with ammonium ions made it possible to perform unique azide–alkyne cyclisation in which both starting components, *viz.*, propargylamine and azidoethylamine, are included in the cavity of cucurbit[6]uril and cyclisation proceeds within the cavitand.^{24,25}

Under standard conditions, azide–alkyne cyclisation proceeds in solutions rather slowly ($k_0 \sim 10^{-6} \text{ mol}^{-1} \text{ s}^{-1}$) to give two isomeric products in equal amounts. Due to interactions of the ammonium groups of the starting reagents with the opposite portals of Q6, only a certain arrangement of the components in the cavity is possible resulting in regiospecificity of this reaction (only the 1,4-addition product is generated). Besides, the reaction is substantially accelerated in the presence of catalytic amounts of cucurbit[6]uril ($k_0 \sim 10^{-2} \text{ mol}^{-1} \text{ s}^{-1}$).

2. Inclusion of dye and other guest molecules

Examples of inclusion of other guest molecules into the cavity of cucurbit[6]uril (**5**) are few in number. The sizes of the cavity allow tetrahydrothiophene, tetrahydrofuran, benzene, cyclopentanone and furan to be accommodated, which was proved by shifts of the signals in the solution NMR spectra of these compounds.^{17,26} The *para*-substituted benzene ring can also be included into the cavity of cucurbit[6]uril (if the substituents are directed toward the portals). However, the size of this ring is somewhat larger than the size of the cavity resulting in distortions of both the guest and host molecules. Calorimetric titration showed that the stability of inclusion compounds of Q6 with aliphatic alcohols as well as with acids and nitriles is unaffected by the presence of polar groups and the number of methylene units in the guest molecule.²⁷

Various dye molecules form stable inclusion compounds with cucurbit[6]uril.^{7,28–30} Most of the dyes are hydrophobic and their molecules (or molecular fragments of suitable size) can interact rather strongly with the inner cavity of the cavitand. In some cases, the encapsulation in cucurbit[6]uril leads to substantial stabilisation of dye molecules. For example, Phenol Blue ($-\text{OC}_6\text{H}_4\text{NC}_6\text{H}_4\text{NMe}_2$) decomposes in a 0.1 M HCl solution during 3 min. If this dye is incorporated into cyclodextrin, it decomposes under the same conditions during 7 min. If this dye is

encapsulated in Q6, it is stable for 7 h.²⁸ Higher stabilities of inclusion compounds of dye molecules with cucurbit[6]uril in dilute solutions of formic acid as compared to inclusion compounds with β -cyclodextrin were also confirmed by spectrophotometric measurements.²⁹ The formation of inclusion compounds of cucurbit[6]uril with dyes is used for example, in textile industry for efficient absorption of dissolved, dispersed or emulsified dyes from industrial wastes.^{7, 30}

Cucurbit[6]uril can bind surfactants and polyethylene glycols,³¹ fluorescent compounds,³² and volatile organic compounds from the gas phase.³³ The ¹²⁹Xe and ¹H NMR spectroscopic data provided evidence for the reversible inclusion of xenone into Q6 and the formation of a 1 : 1 complex in an aqueous solution.^{34, 35} In spite of the absence of Coulombic or hydrophobic interactions, the stability of this compound is comparable with the stabilities of Q6 complexes with alkylammonium ions.

3. Synthesis and structures of nanosized rotaxanes

The ability of cucurbit[6]uril (**5**) to form host–guest compounds with alkylidiammonium salts provided the basis for the directed construction of nanosized rotaxanes (coordination polymers), which are not only of interest from the viewpoint of structural chemistry but also possess a series of unique properties due to which they show promise as materials, for example, for molecular electronics.^{12, 13} Rotaxanes are supramolecular compounds in which cyclic molecules (beads) are threaded onto linear molecules containing bulky terminal groups, which keep the beads from sliding off.³⁶ Analogous structures devoid of bulky terminal groups are called pseudorotaxanes. Such macrocycles as cryptands, crown ethers, cyclodextrins and calixarenes are rather widely used in the synthesis of rotaxanes.³⁷ Compounds containing the Q6 molecule as a bead were first prepared and structurally characterised by K. Kim and co-workers.³⁸ Two protonated nitrogen atoms of the $RN^+H_2(CH_2)_4N^+H_2R$ molecule [$R = (CH_2)_3NHC_6H_3(NO_2)_2-2,4$] are fixed at both portals of cucurbit[6]uril thus holding a chain of four polymethylene groups in its cavity, whereas two bulky 2,4-dinitrophenyl groups are located at the ends of the molecule. In addition, a pseudorotaxane compound was prepared in the cited study by the replacement of the 2,4-dinitrophenyl groups with the carbamate groups. In this case, Q6 does not move along the chain due to rather strong interactions between the protonated nitrogen atoms and the carbonyl groups at the portals of cucurbit[6]uril. In crystals, these pseudorotaxanes are linked in chains through hydrogen bonds between the carbamate groups of the adjacent fragments to form one-dimensional polymers.

The formation of pseudorotaxanes in solutions containing diammonium ions and cucurbit[6]uril has been proved by different methods, *viz.*, by IR and NMR spectroscopy and mass spectrometry.^{39–44} It has been demonstrated that pseudorotaxanes can act as molecular switches, *i.e.*, an increase in pH of solutions, as in the case of diamines, leads to deprotonation of the ammonium nitrogen atoms responsible for binding with Q6 and causes the movement of the macrocycle along the chain. In some cases, however, not only an increase in acidity of the medium but also heating are required for the reverse reaction to occur.⁴³ The use of fluorenyltriamine as the guest molecule made it possible to prepare a unique highly sensitive molecular switch in which the reversible movement of Q6 along the chain is accompanied by changes in the colour of the solution and fluorescence intensity.⁴⁴ At pH 1.0, a yellow fluorescent solution of the Q6 complex with the hexanediamine fragment of fluorenyltriamine is formed. As the pH is increased to 7, Q6 moves to the butanediamine fragment of the guest molecule due to deprotonation of the aniline nitrogen atom. This process is accompanied by a change in the colour of the solution to violet and the fluorescence intensity decreases. The use of cucurbit[6]uril as a catalyst for azide–alkyne cyclisation within the cavity made it possible to prepare a polyrotaxane with desired composition⁴⁵ from which the Q6 molecules were removed by increasing the pH of the medium. As a result, oligotriazoles

containing up to nine triazole-linked monomeric units were obtained.⁴⁶

K Kim and co-workers^{12, 13} developed an original approach to the synthesis of cucurbituril-containing polyrotaxanes, which allowed them to prepare first coordination-linked polymers. Initially, Q6 are threaded onto a small organic molecule with the diamine hydrocarbon chain containing suitable terminal functional groups. Then these fragments are linked to form a coordination polymer through bonds between the donor atoms of the terminal groups of the resulting pseudorotaxanes and the metal atoms. The above-described method has particular advantages over the previously known procedures giving rise to polyrotaxanes in which such macrocycles as cyclodextrins or crown ethers are threaded onto organic polymers. First, the resulting polyrotaxanes are characterised by high structural regularity, *i.e.*, cyclic beads are present in each repeated structural unit of the polymer chain. Second, these polyrotaxanes were obtained as single crystals and characterised by X-ray diffraction analysis, whereas single crystals of cyclodextrin-containing polyrotaxanes suitable for X-ray diffraction studies are difficult to prepare because of the existence of numerous isomers with different orientations of the cone-like macrocycle.

Coordination of the donor atoms of the terminal groups of pseudorotaxanes to transition metal atoms [Cu(II), Co(II), Ni(II), Ag(I), Cd(II)] gives rise to one- and two-dimensional polyrotaxanes depending on the coordination number of the metal atom, the structure of pseudorotaxane, the size and the coordination ability of the counterion of the starting metal salt. The products of the reactions of different metal salts with the pseudorotaxanes (PR nm) are shown in Fig. 2. In these compounds, the cucurbit[6]uril molecule accommodates the molecule of dipyridylamines **6** or **7**, which contain chains of n methylene units ($n = 4, 5$) and the *para*- ($m = 4$) or *meta*-substituted ($m = 3$) terminal pyridine rings.

The reactions of pseudorotaxanes of the PR44 ($n = 4, m = 4$) and PR43 ($n = 4, m = 3$) types with aqueous solutions of cobalt(II) nitrates⁴⁷ and nickel(II) nitrates⁴⁸ afforded chain polymers. In these polymers, pseudorotaxanes can be in either the *trans* or *cis* positions at the octahedrally coordinated metal atoms to form linear chains (PR44) (see Fig. 2, structure **A**) and zigzag chains (PR43) (see Fig. 2, structure **B**), respectively. The size of the repeated zigzag fragment in the structure **B** is larger than 23 Å. The reaction of PR44 with $\text{Cu}(\text{NO}_3)_2$ also gave rise to zigzag chains where two pseudorotaxane molecules are coordinated to the copper atom in a square-pyramidal environment.⁴⁹ Silver(I) compounds tend to form linear two-coordinate complexes. The reaction of PR44 with silver tosylate [$\text{Ag}(\text{MeC}_6\text{H}_4\text{SO}_3)$] resulted in the *trans* coordination of two pseudorotaxane molecules to the metal atom giving rise to a virtually linear chain structure.⁵⁰ One-dimensional helical polymers were synthesised by the reactions of AgNO_3 (see Ref. 51) and $\text{Cd}(\text{NO}_3)_2$ (see Ref. 47) with pseudorotaxane PR53 in which the organic molecule encapsulated in cucurbituril contains five methylene groups and the *meta*-substituted terminal pyridine rings. Two silver ions and two pseudorotaxanes coordinated to these ions comprise one turn of the helix (see Fig. 2, structure **C**), the length of one fragment being equal to 17.9 Å. In the compound with cadmium, each turn of the helix (50.5 Å) consists of four pseudorotaxanes PR53 and four metal ions (see Fig. 2, structure **D**). The space between the chains in polyrotaxanes is filled with water molecules and anions linked

Figure 2. Formation of one-, two- and three-dimensional polyrotaxanes A–J (see the text) in the reactions of pseudorotaxanes with solutions of metal salts.

through an extensive network of hydrogen bonds resulting in additional stabilisation of the structure.

Unlike the above-described reaction with silver tosylate giving rise to a chain structure, the reaction of the pseudorotaxane PR44 with an aqueous solution of silver nitrate afforded a two-dimensional polyrotaxane.⁵⁰ The reaction with the use of another counterion afforded a polymeric structure in which the cucurbituril beads are threaded onto a network of face-sharing chair-shaped hexagons with silver ions occupying each vertex (see Fig. 2, structure E). Each face consists of two silver ions coordinated by two nitrogen atoms of the terminal pyridine rings of the pseudorotaxane. The length of the face is 20.9 Å and the average distance between two opposite angles is 38.0 Å. In the crystal, these two-dimensional polyrotaxane networks form superimposed interpenetrating layers with complete linkage of the hexagons. The resulting compound is the first example of polycatenane–polyrotaxane networks (catenanes are compounds consisting of interpenetrating rings). When the positions of the nitrogen atoms of the terminal pyridine rings of the pseudorotaxane are changed with the simultaneous change of the counterion, the reaction of PR43 with (CF₃SO₃) affords a two-dimensional

polyrotaxane of another type, which can be described as networks consisting of squares with cucurbituril molecules threaded onto all sides of these squares (see Fig. 2, structure F).⁴⁷ The networks are packed in layers (the distance between the layers is 12.7 Å). In this case, the catenane structure is not formed. A compound prepared by the reaction of the pseudorotaxane PR43 with copper nitrate Cu(NO₃)₂ has an analogous layered structure.⁴⁷

The *cis*-coordination of pseudorotaxanes to the metal atoms in a planar-square coordination makes it possible to prepare the so-called molecular necklaces in which several cyclic molecules are threaded onto a larger-size ring. Thus, the coordination of the ethylenediamine ligand in the [Pt(en)(NO₃)₂] complex (en is ethylenediamine) is such that pseudorotaxanes can occupy only *cis* positions on reaction with this complex to give nanocycles with three (PR44) (see Fig. 2, structure G) or four (PR43) (see Fig. 2, structure H) threaded cucurbit[6]uril molecules.⁵² A molecular necklace consisting of four rotaxane fragments was also prepared in the reaction of copper(II) nitrate with a polyrotaxane, whose angular form is dictated by the phenanthroline derivative that links two Q6 molecules.⁵³ The ring is formed upon *cis* coordination of the copper atom by the nitrogen atoms of the terminal

Scheme 1

pyridine groups of two angular pseudorotaxanes. The distance between the metal atoms in these nanocycles is ~ 20 Å (Scheme 1).

The use of molecular necklaces as large building blocks for the design of supramolecular compounds is of obvious interest. The reaction of PR53 with $\text{Cu}(\text{NO}_3)_2$ in the presence of oxalate ions afforded a supramolecular structure in which molecular necklaces consisting of six copper-bound pseudorotaxanes are linked to each other through the coordinated oxalate ions (see Fig. 2, structure I).⁵³ Each planar ring is bound to six other rings giving rise to two types of cavities in the polymer structure. The cavities of one type are located within the hexagons (the diameter is 5 Å), whereas the cavities of another type formed by oxalate ions are located between the hexagons (the diameter is 14 Å). These cavities form channels occupied by the NO_3^- ions and water molecules. The sizes of the channels are sufficiently large and allow NO_3^- ions to be replaced by the PF_6^- and tosylate ions in aqueous solutions. The replacement by bulkier anions, such as tetraphenylborate, does not occur, which is indicative of the rather high selectivity of the polyrotaxane compound in these reactions.

Three-dimensional polyrotaxanes can be prepared upon coordination of the terminal groups of pseudorotaxanes by lanthanide atoms, which typically have large coordination numbers.⁵⁴ Under hydrothermal conditions, the reaction of the pseudorotaxane PR43 containing the terminal 3-carboxyphenyl groups with $\text{Tb}(\text{NO}_3)_3$ afforded a supramolecular compound with a three-dimensional coordination network as the framework. Each lattice node is occupied by two Tb^{3+} cations (see Fig. 2, structure J; one solid circle in each lattice node corresponds to two terbium atoms) coordinated by six pseudorotaxane molecules through the carboxylate groups, with four carboxylate groups serving as bridges between the terbium atoms. As a result of a change in the position of the carboxylate group in the benzene ring, the reaction of $\text{Tb}(\text{NO}_3)_3$ with the pseudorotaxane PR44 yielded a two-dimensional polymer in which each terbium centre is coordinated by three pseudorotaxane fragments. The polycatenane-polyrotaxane structure of this compound is analogous to the structure of the two-dimensional polyrotaxane formed in the reaction of AgNO_3 with a pseudorotaxane containing the terminal pyridine groups (see Fig. 2, structure E).

Cucurbit[6]uril (**5**) has found an interesting application in the chemistry of dendrimers. In the last decade, these three-dimensional organic compounds have attracted the attention of

researchers because of their successful use in various fields of science and technology (medicine, catalysis and agriculture).⁵⁵ In the reaction of Q6 with a dendrimer containing terminal alkyldiammonium groups, the macrocycles are threaded onto these terminal groups to give a dendrimer with terminal pseudorotaxane fragments.

The use of a bulky bead as a component of the terminal groups imparts rigidity to the structure of the dendrimer. The resulting compound has a globular structure and can hold guests within its cavity. If the pH of the solution is increased, Q6 is removed and the dendrimer becomes conformationally flexible and releases the guest molecule. This reversible inclusion of molecules opens up new possibilities for using dendrimers for the transport, for example, of pharmaceuticals.

Hence, rotaxanes and pseudorotaxanes based on cucurbit[6]uril (**5**) have proved to be convenient building blocks for the construction of supramolecular compounds. Cucurbit[6]uril is rigidly fixed at the hydrocarbon chain through Coulombic and van der Waals interactions and the resulting rotaxanes and pseudorotaxanes are linked to each other through bonds between the donor atoms of the terminal groups and the metal atoms to form nanosized supramolecular compounds.

III. Supramolecular compounds of cucurbit[6]uril with metal aqua complexes

The ability of cucurbit[6]uril (**5**) to bind metal ions in aqueous solutions was discovered by Behrend and co-workers in 1905.⁵ The presence of more polar oxygen atoms in cucurbit[6]uril as compared to those in crown ethers or cryptands is responsible for the formation of stronger interactions between these oxygen atoms and metal cations. The formation constants of metal complexes with Q6 are much higher than the formation constants of complexes with the above-mentioned organic macrocycles.⁸ Besides, the rigidity of Q6 hinders its conformational changes upon complex formation, in contrast, for example, to metal complexes with crown ethers.⁵⁶ The metal cations are coordinated by the oxygen atoms located in the planes of the portals of cucurbit[6]uril rather than are included into the cavity of the cavitand. Hence, due to the unique structure of cucurbit[6]uril, it can form not only inclusion compounds with organic molecules but also mixed organic–inorganic compounds with metal cations.

In the late 1990s, interesting supramolecular compounds of Q6 with the sodium, potassium, rubidium and cesium cations were prepared.^{26, 57–59} Cucurbit[6]uril is insoluble in water but its solubility is noticeably increased in the presence of salts of these metals. These compounds were obtained as single crystals by slow diffusion of organic solvents into aqueous solutions and characterised by X-ray diffraction analysis. Metal aqua complexes are bound to the carbonyl oxygen atoms of the Q6 portals to form lids, which efficiently close the cavitand from both sides.

In the compound of cucurbit[6]uril with a sodium aqua complex (**8**), each portal of the macrocycle is coordinated to two metal cations linked to each other through a bridging water molecule (the symbol $\subset$ designates the inclusion into the cavity of the cavitand).²⁶

8

Each sodium atom is bound to two carbonyl oxygen atoms of Q6 and three water molecules. Due to formation of supramolecular compounds of the type 'barrel with two lids', the cavity of the cavitand can include and hold the tetrahydrofuran molecule (Fig. 3). However, an increase in acidity leads to protonation of the carbonyl groups at the Q6 portals, removal of the lids and release of the guest from the cavity of the cavitand. After the addition of Na_2CO_3 , tetrahydrofuran is again included into the cavity because the barrel is again efficiently closed by the lids. According to the ^1H NMR spectroscopic data, other guests, such

Figure 3. Structure of the supramolecule $\{[\text{Na}_4(\text{H}_2\text{O})_{10}](\text{C}_4\text{H}_8\text{OCC}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}(\text{SO}_4)_2 \cdot 10 \text{H}_2\text{O}$ (**8**). The cavity of the cavitaund encapsulates the tetrahydrofuran molecule.

as benzene, cyclopentanone and furan, behave analogously. The supramolecular compound of Q6 with the sodium aqua complex is the first example of a molecular container into which guests can be reversibly included through the formation and cleavage of the bonds between the metal aqua complex and macrocycle.

In the compounds with potassium (**9**)⁵⁷ or rubidium (**10**),⁵⁸ the portals of Q6 are also closed by the bridging binuclear aqua complexes serving as the lids.

9

10

Each metal atom is coordinated by four oxygen atoms at the portals of two Q6 molecules (two oxygen atoms from each molecule) (Fig. 4). This leads to the formation of hybrid

Figure 4. Structure of the supramolecular compound $\{[\text{Rb}_2(\text{OH})_2(\text{CH}_3\text{OH})_2(\text{H}_2\text{O})_2](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 17 \text{H}_2\text{O}$ (**10**) (view along the axis *a*).

Figure 5. Formation of the honeycomb-like structure in the supramolecule **9** (view along the axis *c*).

organic–inorganic polymers consisting of alternating metal aqua complexes and cucurbit[6]uril. The structures of these compounds are stabilised by van der Waals interactions due to complementarity of the chain folds, *i.e.*, the convexities of one chain match the concavities of the adjacent chains. The polymer chain surrounded by three adjacent chains is shifted by half of the translation along the axis *c* to form a honeycomb-like packing containing large channels (Fig. 5). The resulting compounds are promising for the design of porous materials, which find use in separation processes, supramolecular catalysis and optoelectronics. In the honeycomb-like structure of the compound with the rubidium ion **10**, the diameter of the channels filled with water molecules of solvation is $\sim 10 \text{ \AA}$ and the volume of these chains comprises 23% of the total volume of the structure.⁵⁸ Upon the addition of THF or ethylenediamine, the molecules of these compounds are included only into the cavity of the cavitaund, the channels remaining unoccupied.^{57, 58}

Each portal of cucurbit[6]uril in the supramolecular compound $\{[\text{Cs}_2(\text{H}_2\text{O})_2](\text{H}_2\text{OCC}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_2 \cdot 2 \text{H}_2\text{O}$,⁵⁹ like those in the above-described compounds with sodium (**8**), potassium (**9**) and rubidium (**10**), is coordinated to the metal aqua complexes. However, due to the larger ionic radius of the cesium cation, the barrel can be closed by a mononuclear cesium complex serving as the lid. The cesium atom is bound to four carbonyl oxygen atoms of cucurbituril and three water molecules. The addition of tetrahydrofuran gave rise to the inclusion compound $\{[\text{Cs}(\text{H}_2\text{O})_2\text{Cl}](\text{C}_4\text{H}_8\text{OCC}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 5 \text{H}_2\text{O}$ (**11**) in which the barrel is closed only by one lid, whereas the oxygen atom of the guest THF molecule is coordinated to the cesium ion (Fig. 6). In this case, the inclusion of tetrahydrofuran, as in the case of the sodium complex **8**, is also reversible and depends on the acidity of the medium.

The supramolecular compound of cucurbit[6]uril with the calcium aqua complex $\{[\text{Ca}(\text{HSO}_4)_2]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 13 \text{H}_2\text{O}$ is the first example of the structurally characterised cucurbituril compound. The structure of this compound, which was established by Freeman and co-workers⁶ in 1981 and refined by Freeman at a later time,¹⁴ is a polymer consisting of the alternating Q6 molecules linked to the calcium cations through the carbonyl groups. In the presence of methanol, the coordinated CH_3OH molecule is included into the cavity of the cavitaund, the shape and packing of the supramolecules remaining virtually unchanged.⁶⁰ The structure of the fragment of the chain in the $\{[\text{Ca}(\text{H}_2\text{O})_3(\text{HSO}_4)(\text{CH}_3\text{OH})]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}(\text{HSO}_4)_2 \cdot 4 \text{H}_2\text{O}$ complex (**12**) is shown in Fig. 7. Each Q6 molecule is bound to four calcium cations and each calcium cation is bound to two Q6

Figure 6. Structure of the supramolecule $\{[\text{Cs}(\text{H}_2\text{O})_2\text{Cl}](\text{C}_4\text{H}_8\text{OCC}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 5 \text{H}_2\text{O}$ (**11**). The cavity of the cavitand encapsulates the tetrahydrofuran molecule.

molecules (one carbonyl group of one molecule and two carbonyl groups of another molecule). In addition to the carbonyl groups of the Q6 molecules, the calcium ions are coordinated by three water molecules, the hydrosulfate anion, and the methanol molecule whose methyl group is located in the hydrophobic cavity of the cavitand.

Figure 7. Fragment of the chain of the compound of cucurbit[6]uril with the calcium aqua complex $\{[\text{Ca}(\text{H}_2\text{O})_3(\text{HSO}_4)(\text{CH}_3\text{OH})]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}(\text{HSO}_4)_2 \cdot 4 \text{H}_2\text{O}$ (**12**). The cavity of the cavitand encapsulates the methyl group of MeOH.

In the crystals, the polymer molecules form molecular cylinders linked to each other through hydrogen bonds and the channels are occupied by the water molecules of crystallisation and HSO_4^- anions (Fig. 8).

Figure 8. Formation of molecular cylinders (view along the a axis) in the supramolecular compound **12**. Water molecules of crystallisation and sulfate anions are omitted.

Unlike the compounds of cucurbit[6]uril (**5**) with aqua complexes of Groups 1 and 2 metals in which there are direct interactions between the metal atoms and oxygen atoms at the portals of Q6, coordination of Group 13 metals by the macrocycle occurs through hydrogen bonding between the portal oxygen atoms and coordinated water molecules of the aqua complexes. It should be noted that in the latter type of compounds, Q6 acts as an outer-sphere ligand. In supramolecular compounds with cucurbit[6]uril, distortions in the aqua complexes are much smaller than those in the case of insertions of the ligands into the first coordination sphere. Consequently, the structural information for compounds with Q6 corresponds better to the compositions and structures of aqua complexes that are actually present in solution.

In the compounds of cucurbit[6]uril with aqua and chloro aqua complexes of indium and aluminium, the metal complexes are located between the Q6 molecules and are linked to each other through a complex network of hydrogen bonds involving the portal oxygen atoms and water molecules. The complex *trans*-[InCl₂(H₂O)₄]⁺ and *cis*- and *trans*-[InCl₄(H₂O)₂][−] ions were isolated and structurally characterised in the investigation of the reaction of cucurbit[6]uril with indium nitrate in hydrochloric acid solutions.⁶¹ In the compound with composition {[InCl₂(H₂O)₄]₃(Cl⊂C₃₆H₃₆N₂₄O₁₂)}₂Cl·4 H₂O (**13**), the macrocyclic molecules form a hexagonal one-layer packing (Fig. 9), the crystallographic positions occupied by the macrocycles in this structure having the highest symmetry *D*_{6h} possible for cucurbit[6]uril. The cavity of the cavitaund contains the Cl[−] anion disordered over 12 positions. The structure of the (H₃O)₃{[InCl₄(H₂O)₂]₃(C₃₆H₃₆N₂₄O₁₂)₂}·17 H₂O compound is composed of both the *trans* and *cis* isomers of the [InCl₄(H₂O)₂][−]

Figure 9. Crystal structure of {[InCl₂(H₂O)₄]₃(Cl⊂C₃₆H₃₆N₂₄O₁₂)}₂Cl·4 H₂O (**13**).

complex. In this crystal structure, the Q6 molecules form a parquet-like packing. The reactions of Q6 with aluminium chloride and indium nitrate in aqueous solutions afforded supramolecular compounds with the aqua complexes [Al(H₂O)₆]³⁺ and [In(H₂O)₆]³⁺ with compositions {[Al(H₂O)₆](C₃₆H₃₆N₂₄O₁₂)Cl₃·18 H₂O and {[In(H₂O)₆](C₃₆H₃₆N₂₄O₁₂)}·(NO₃)₃·9 H₂O, respectively.⁶¹ In the structure of the former compound, the centres of the Q6 molecules follow the body-centered law. In the structure of the latter compound, the molecules of the macrocycle form a parquet-like packing.

In studies of the M³⁺–HCl–Q6 systems, the isostructural compounds with composition

where (M = Ga, *n* = 2;⁶² M = Fe, *n* = 3⁶³), were obtained. In the structures of these complexes, the Q6 molecules alternating with the [MCl₄][−] anions are also linked through a system of hydrogen bonds between the portal oxygen atoms and water molecules.

The reactions of lanthanide(III) nitrates and sulfates with Q6 in aqueous solutions afforded supramolecular compounds in which (according to the X-ray diffraction data) the aqua complexes are bound to the macrocycle through both the direct coordination of the metal atom by the oxygen atoms and hydrogen bonding between the coordinated water molecules and portal oxygen atoms of cucurbit[6]uril.⁶⁴ In the resulting compounds, the aqua complex : cucurbit[6]uril ratio is 1 : 1, 2 : 2 or 2 : 3. In complexes **14**–**17** with composition 1 : 1, the metal atom together with its ligand environment forms the lid that closes the Q6 molecule from one side.

Figure 10. Fragment of the {[Ce(H₂O)₅]₂(C₃₆H₃₆N₂₄O₁₂)₂}Br₆·26 H₂O structure (**18**): formation of the sandwich-type compound.

Figure 11. Fragment of the $\{[\text{Gd}(\text{H}_2\text{O})_4]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})_3\}\text{Br}_6 \cdot 45 \text{H}_2\text{O}$ structure (**20**): the triple-decker sandwich.

In the $\{[\text{Ce}(\text{H}_2\text{O})_5]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})_2\}\text{Br}_6 \cdot 26 \text{H}_2\text{O}$ complex (**18**) with composition 2:2, two cerium aqua ions are coordinated by two Q6 molecules to form a sandwich-type compound (Fig. 10).

The crystal structures of compounds **19**⁶⁵ and **20**⁶⁴ with composition 2:3 can be described as packings of nanosized triple-decker sandwiches built from alternating Q6 molecules and metal aqua complexes (Fig. 11).

The shape of this supramolecule can be approximated by a skewed cylinder whose largest van der Waals size is 33 Å. In the crystals of lanthanide(III) compounds, the supramolecules are linked in chains or layers or packed in stacks through hydrogen bonding. In these structures, large channels and cavities are occupied by water molecules of crystallisation and counterions.

The possibility of using Q6 for crystallisation of polynuclear aqua complexes was exemplified by the preparation of the mixed uranium(VI) oxochloride complex.⁶⁶ The supramolecular compound (**21**), which is composed of the tetranuclear uranium aqua complex and cucurbit[6]uril (**5**), is formed through hydrogen bonding between the coordinated uranium atoms, water molecules and carbonyl oxygen atoms of the Q6 portals (Fig. 12).

In the crystals, the Q6 molecules and aqua complexes form alternating layers linked to each other through a system of hydrogen bonds. In the aqua complexes, the uranium atoms of four uranyl groups are virtually in a single plane.

Figure 12. Fragment of the structure of the $\{[(\text{UO}_2)_4\text{O}_2\text{Cl}_4(\text{H}_2\text{O})_6](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 5 \text{H}_2\text{O}$ compound (**21**).

By comparing the modes of binding of cucurbit[6]uril (**5**) to different metals, several conclusions can be made. Thus, the carbonyl oxygen atoms of the Q6 portals are directly coordinated to the metal atoms in supramolecular compounds with alkali, alkaline earth and rare-earth metals. These most electropositive metals have rather large ionic radii ($r_{\text{ion}} = 0.97, 1.73, 1.03$ and 1.14 Å for Na^+ , Cs^+ , Ca^{2+} and La^{3+} , respectively⁶⁷) and their binding to the ligands should be considered as Coulombic (ion–dipole) interactions. In these cases, cucurbit[6]uril, which is a weak donor but contains polarised C=O groups, competes with other ligands for site in the coordination sphere about the metal atom. Group 13 metal ions have smaller radii ($r_{\text{ion}} = 0.76$ and 0.50 Å for In^{3+} and Al^{3+} , respectively⁶⁷) and their binding to the ligands is predominantly covalent. The larger charges and smaller sizes of Group 13 metal cations lead to an increase in acidity of the coordinated water molecules of aqua ions. Consequently, the protons of the water molecules coordinated to these metal cations can form much stronger hydrogen bonds with the polarised C=O groups due to which the inclusion of water into the first coordination sphere is more favourable than the inclusion of Q6. If the metal–ligand interaction is predominantly Coulombic, Q6 competes with water for sites in the inner coordination sphere of the metal atom. If this interaction is predominantly covalent, the structure is determined primarily by a system of hydrogen bonds between the aqua ligands and cucurbit[6]uril (**5**) as the outer-sphere ligand.

IV. Supramolecular compounds of cucurbit[6]uril with metal cluster aqua complexes

The use of bulky fragments, which retain their geometry and can form extensive networks of hydrogen bonds due to a large contact surface, is an important condition for the directed construction of nanosized complexes or supramolecular compounds. Molybdenum and tungsten cluster aqua complexes are suitable large molecular building blocks for the construction of supramolecular compounds with cucurbit[6]uril (**5**). Studies of interactions of Q6 with trinuclear thio and seleno complexes of these metals and their heterometallic derivatives led to the discovery of a new class of supramolecular compounds. In aqueous solutions, cluster thio and seleno complexes of molybdenum and tungsten produce the stable trinuclear aqua ions $[\text{M}_3^{\text{I}}\text{Y}_4(\text{H}_2\text{O})_9]^{4+}$ ($\text{M}^{\text{I}} = \text{Mo}$ or W ; $\text{Y} = \text{S}$ or Se) in which the metal atoms are coordinated by one μ_3 -bridging chalcogen atom and three μ_2 -bridging chalcogen atoms.^{68–71} The coordinatively unsaturated μ_2 -bridging chalcogen atoms are readily coordinated to transition and post-transition metal atoms.⁷² In this case, the trinuclear cluster (a cube without one vertex) is transformed into the cubane complex $\text{M}^2\text{M}_3^{\text{I}}\text{Y}_4$ and the μ_2 -bridging chalcogen atoms are transformed into the μ_3 -bridging atoms.

$\text{M}^{\text{I}} = \text{Mo}, \text{W}$; M^2 is the transition or main-group metal atom;
 $\text{Y} = \text{S}, \text{Se}$.

Each M^{I} atom of the cluster core ($\text{M}_3^{\text{I}}\text{Y}_4$ or $\text{M}^2\text{M}_3^{\text{I}}\text{Y}_4$) is coordinated by three water molecules. Six water molecules are in *cis* positions with respect to the μ_3 -bridging chalcogen atom in the trinuclear aqua complexes or with respect to the μ_2 -bridging chalcogen atom, which links only the molybdenum (tungsten) atoms, in the cubane heterometallic complexes. These six aqua ligands are virtually in a single plane and are well suited in size and symmetry to six carbonyl groups at each portal of Q6. In addition, the cluster aqua complexes $[\text{M}_3^{\text{I}}\text{Y}_4(\text{H}_2\text{O})_9]^{4+}$ have rather high positive charges due to which they exhibit pronounced acidic

properties and act as good donors in hydrogen bonding, whereas the oxygen atoms of the polarised carbonyl groups of Q6 are potential acceptors. This geometric and functional (donor–acceptor hydrogen bond) complementarity gives rise to an extensive network of hydrogen bonds between the macrocycles and the triangular (cubane) aqua complexes. In spite of the fact that the energy of each individual hydrogen bond is low, the presence of a system of these bonds facilitates the formation of stable supramolecular compounds.

The use of Q6 for crystallisation of chalcogenide cluster aqua complexes made it possible for the first time to isolate and structurally characterise more than 20 supramolecular compounds. The compounds were crystallised by slow evaporation (in air) of solutions of cluster aqua complexes and Q6 in dilute hydrochloric acid. The resulting crystals are insoluble or weakly soluble in aqueous solutions of hydrochloric acid in which the starting reagents are readily soluble. If the cluster : cucurbit[6]uril ratio in supramolecular compounds is 1 : 1, only one portal of Q6 is closed by the cluster complex (structural type ‘barrel with one lid’). If the cluster : cucurbit[6]uril ratio is 2 : 1, both portals are closed (structural type ‘barrel with two lids’) (Fig. 13). The distances between the carbonyl oxygen atoms of the macrocycle and aqua ligands in both structural types vary in the range of 2.5–3.1 Å. If the lids are coordinated, the cavity of the cavitant

Figure 13. Supramolecular compounds of cucurbit[6]uril with metal cluster aqua complexes: (a) barrel with one lid; (b) barrel with two lids.

becomes isolated and small molecules can be held in the molecular container. The sizes of supramolecules closed by two lids are 25–30 Å.

A wide variety of available supramolecular compounds of Q6 with molybdenum and tungsten cluster aqua complexes is associated with the nature of the chalcogenide cluster, the presence of guests in solution and the concentration of hydrochloric acid in the aqueous solutions in which the reactions proceed.

The reactions of Q6 with the trinuclear tungsten sulfide aqua complex $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ in 2 M HCl afforded products with different compositions and structures depending on the presence of pyridine in the system. The supramolecule $\{[\text{W}_3\text{S}_4(\text{H}_2\text{O})_7\text{Cl}_2](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_2 \cdot 10 \text{H}_2\text{O}$ (**22**) belongs to the structural type 'barrel with one lid' in which only one portal of Q6 is closed by the cluster complex through a system of complementary hydrogen bonds between six carbonyl groups and six aqua ligands.⁷³ In the crystal, the supramolecules are linked in zigzag chains through additional hydrogen bonds between the aqua ligands of the cluster and the portal oxygen atoms of Q6 (Fig. 14).

Under the same conditions, the reaction performed in the presence of pyridine led to destruction of the chain structure to form the layered compound $\{[\text{W}_3\text{S}_4(\text{H}_2\text{O})_8\text{Cl}](\text{PyH}\cdot\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_4 \cdot 10 \text{H}_2\text{O}$.

Figure 14. Fragment of the zigzag chain in $\{[\text{W}_3\text{S}_4(\text{H}_2\text{O})_7\text{Cl}_2](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_2 \cdot 10 \text{H}_2\text{O}$ (**22**).

$\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_4 \cdot 10 \text{H}_2\text{O}$.⁷⁴ In this compound, the cavity of the Q6 molecule includes the pyridinium cation and both portals are closed by the trinuclear cluster complexes serving as the lids. In the crystal, these supramolecules are packed in layers. Upon the inclusion of the pyridinium cation into the cavity of Q6, both the guest and host molecules adapt to each other in size resulting in distortions of their structures. Thus, the Q6 molecule becomes slightly extended, whereas the pyridine molecule slightly contracts.

However, the inclusion of a guest does not necessarily lead to such dramatic changes in the structure and packing of supramolecules. The conditions of the preparation of selenium-containing tungsten complexes **23**⁷⁵ and **24**⁷⁶ with cucurbit[6]uril also differ only by the presence of pyridine in the reaction mixture.

Both compounds have chain structures in which the supramolecules of the structural type described as a barrel with two lids are linked to each other through short (compared to the sum of the van der Waals radii of 3.9 Å) nonbonded $\text{Se}\cdots\text{Se}$ interactions (3.59–3.72 Å). The cavity of cucurbit[6]uril in compound **24** contains the pyridinium cation (Fig. 15). The chalcogen–chalcogen

Figure 15. Fragment of the chain structure in $\{[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_6\text{Cl}_3]_2(\text{PyH}\cdot\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_3 \cdot 18 \text{H}_2\text{O}$ (**24**). The cavity of cucurbit[6]uril accommodates the pyridinium cation.

Figure 16. Comparison of the chain structures in $\{[\text{Mo}_3\text{Se}_4(\text{H}_2\text{O})_8\text{Cl}]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_6 \cdot 16 \text{H}_2\text{O}$ (**25**) (matrix) and $\{[\text{Mo}_6\text{HgSe}_8(\text{H}_2\text{O})_{14}\text{Cl}_4](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_4 \cdot 14 \text{H}_2\text{O}$ (**26**) (intercalate).

gen interactions between adjacent clusters typical of trinuclear chalcogenide clusters of transition metals are of importance in the structure formation of these complexes.⁷⁷ The stronger bonding between the selenide atoms ($\text{Se} \cdots \text{Se}$) as compared to that between the sulfur atoms ($\text{S} \cdots \text{S}$) [according to the structural data available in the Cambridge Structural Database for $\{\text{M}_3\text{Y}_4 \cdots \text{Y}_4\text{M}_3\}$ compounds, where $\text{Y} = \text{Se}$ or S (see Ref. 78)] facilitates the retention of chain structures of the supramolecular compounds of Q6 with selenium-containing tungsten clusters upon the inclusion of a guest molecule. The structures of the selenium-containing complexes differ only by the mode of packing of the chains. In the crystal of compound **23**, the chains are packed to form a hexagonal motif, whereas these chains in the crystal of compound **24** form a distorted square packing.

The chalcogen–chalcogen interactions between the adjacent cluster fragments M_3Y_4 of supramolecular compounds are analogous to interactions between the adjacent layers formed by the chalcogen atoms in the layered transition metal dichalcogenides MY_2 ($\text{Y} = \text{S}, \text{Se}$).⁷⁵ An important property of the layered compounds is their ability to incorporate molecules or atoms between the layers giving rise to intercalates. A comparison of the structures of chain supramolecular compounds **25**⁷⁸ and **26**^{75, 79} shows that these compounds are regarded as a matrix and intercalate from the structural viewpoint. Thus, the mercury atom is included between the chalcogenide clusters M_3Y_4 , the

principal parameters of the supramolecules remaining virtually unchanged (Fig. 16).

Therefore, the chemistry of supramolecular compounds of chalcogenide clusters is related to the chemistry of layered compounds more closely than one would expect. In both cases, the nonbonded chalcogen–chalcogen interactions play an important role in the structure formation.

Yet another important factor that has an effect on the formation of supramolecular compounds of Q6 with metal cluster aqua complexes is the concentration of hydrochloric acid in dilute solutions in which these reactions proceed. In solutions of HCl , cluster aqua complexes give different mixed chloro aqua complexes $[\text{M}_3\text{Y}_4(\text{H}_2\text{O})_{9-x}\text{Cl}_x]^{(4-x)+}$ ($\text{Y} = \text{Se}, \text{S}$) whose compositions depend on the nature of the metal and chalcogen atoms. As demonstrated above, six *cis*-aqua ligands of the cluster are involved in complementary binding in the compounds of Q6 with Mo and W aqua complexes, whereas up to three Cl^- anions can be located in *trans* positions (for example, in the supramolecular compounds **27**⁸⁰ and **24**).⁷⁶

An increase in the concentration of hydrochloric acid leads to the replacement of the water molecules in aqua complexes by the halide ligands resulting in a sharp weakening of the cluster–cucurbit[6]uril interaction. First, the cluster complex loses a positive charge, *i.e.*, its acidity and ability to act as a donor in hydrogen bonding are decreased. Second, coordination of more than four Cl^- ligands to the cluster core requires the replacement of the *cis*-aqua ligands responsible for binding of the cluster complex to the portals of the macrocycle. Here, crystallisation of a particular form depends on other factors ($\text{Y} \cdots \text{Y}$ interactions, packing factors, *etc.*). Therefore, cucurbit[6]uril in HCl solutions acts as an outer-sphere ligand with respect to the cluster complex and forms hydrogen bonds only with some of the possible forms of $[\text{M}^3\text{Y}_4(\text{H}_2\text{O})_{9-x}\text{Cl}_x]^{(4-x)+}$.

The latter assumption is exemplified by the data on the structure of the $(\text{H}_3\text{O})_2[\text{Mo}_3\text{Se}_4(\text{H}_2\text{O})_4\text{Cl}_5]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12}) \cdot 15 \text{H}_2\text{O}$ compound (**28**) prepared from a 6 M HCl solution.⁷⁸ This compound contains triangular clusters in the $[\text{Mo}_3\text{Se}_4(\text{H}_2\text{O})_4\text{Cl}_5]^-$ anionic form. Unlike the chain compound **25** (see Fig. 16), which crystallises from a 2 M HCl solution and contains only one chloride ion per trinuclear cluster, the Mo atoms in the compound **28** are coordinated by three or four Cl^- ligands in *cis* positions with respect to μ_3 -Se. As a consequence, the Q6 molecules and the chloro aqua complexes are not involved in a system of complementary hydrogen bonds. The chloro aqua complexes are linked in the dimeric cluster aggregates $\{\text{Mo}_3\text{Se}_4(\text{H}_2\text{O})_4\text{Cl}_5\}_2^{2-}$ through short nonbonded Se $\cdots$ Se interactions. In the crystals, these dimers are packed in layers, which alternate with layers consisting of Q6 molecules.

Analogous dimers are present in the isostructural $(\text{H}_3\text{O})_4\{[\text{M}_3\text{S}_7\text{Cl}_6]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\} \cdot 8 \text{H}_2\text{O}$ compounds (**29**, $\text{M} = \text{Mo}$ or W).⁸¹ The $[\text{M}_3\text{S}_7]^{4+}$ cluster core in which the metal atoms are coordinated by the μ_3 -S ligand and three disulfide ligands μ_2 -S₂ exhibits a much higher affinity for halide ions than the $[\text{M}_3\text{S}_4]^{4+}$ core.⁸² In a 3 M HCl solution, each metal atom is coordinated by two chloride ligands due to which hydrogen bonding with Q6 becomes impossible. In this case, the structure formation depends primarily on nonbond S $\cdots$ S interactions between the bridging atoms of the disulfide ligands resulting in dimerisation of the $[\text{M}_3\text{S}_7\text{Cl}_6]^{2-}$ anions. The crystal packing consists of alternating layers of dimeric cluster anions and Q6 molecules.

The heterometallic molybdenum and tungsten aqua complexes $[\text{L}_m\text{M}'\text{M}_3\text{Y}_4(\text{H}_2\text{O})_9]^{n+}$ ($\text{Y} = \text{Se}$ or S) also interact with cucurbit[6]uril to give supramolecular adducts belonging to ‘barrels with one lid’ or ‘barrel with two lids’. In these aqua complexes, the bridging chalcogen atoms are coordinated to the transition and post-transition metal atoms and lose the ability to be involved in nonbonded $\text{Y} \cdots \text{Y}$ interactions. In the crystals, the supramolecules of heterometallic aqua complexes with cucurbit[6]uril are linked either in chains through additional hydrogen bonds, as in compounds **30**⁸³ and **31**⁸⁴ (Fig. 17), or in layers, as in supramolecular compound **32**.⁸⁵

Figure 17. Fragment of the zigzag chain in $\{[\text{Mo}_3(\text{PdCl})\text{Se}_4(\text{H}_2\text{O})_7\text{Cl}_2](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl} \cdot 7 \text{H}_2\text{O}$ (**31**).

From a comparison of compounds **31** and **32** in which only one portal of the macrocycle is closed by the cluster lid, it follows that the inclusion of the pyridinium cation into the cavity of Q6 does not lead to substantial changes in the structures of the supramolecules, *i.e.*, not only the cluster:cucurbit[6]uril ratio but also the total charge (+1) remain unchanged. Only the crystal packing undergoes essential changes. The supramolecules **31** form zigzag chains through hydrogen bonds between the aqua ligands of the cluster and the oxygen atoms at the portals of Q6 of the adjacent adduct, whereas the addition of pyridine gives rise to dimers packed in layers.

The use of Q6 for crystallisation of the reaction products of the palladium complex $[\text{Mo}_3(\text{PdCl})\text{S}_4(\text{H}_2\text{O})_9]^{3+}$ with P(III)- or As(III)-containing *n*-donor ligands made it possible to prepare and structurally characterise the $\{[\text{Mo}_3(\text{PdE}(\text{OH})_3)\text{S}_4(\text{H}_2\text{O})_6\text{Cl}_3]_2 \cdot (\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_2 \cdot n \text{H}_2\text{O}$ compounds [$\text{E} = \text{P}$, $n = 20$ (**33a**); $\text{E} = \text{As}$, $n = 19$ (**33b**)].⁸⁶ In these compounds, the Q6 molecules are closed by two cluster lids. The palladium atoms of these clusters are coordinated by the inorganic $\text{P}(\text{OH})_3$ or $\text{As}(\text{OH})_3$ ligands (Fig. 18). These are the first examples of the structurally characterised tribasic forms of phosphorous and arsenous acids.

Heterometallic indium- and tin-containing supramolecular compounds of cucurbit[6]uril **34**⁸⁷ and **35**⁷⁸ belong to the structural type described as ‘barrels with two lids’.

Figure 18. Structure of the supramolecule $\{[\text{Mo}_3(\text{PdP}(\text{OH})_3)\text{S}_4(\text{H}_2\text{O})_6\text{Cl}_3]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}^{2+}$ (**33a**).

Among the characteristic features of the crystal structure of the compound **34**, noteworthy are large channels (~ 7 Å in diameter) occupied by water molecules of solvation and Cl^- counterions. Crystallisation of the tin-containing molybdenum aqua complex with Q6 made it possible for the first time to isolate and structurally characterise the mixed chloro aqua complexes $[\text{Mo}_3(\text{SnCl}_3)\text{Se}_4(\text{H}_2\text{O})_6\text{Cl}_3]$ and $[\text{Mo}_3(\text{SnCl}_3)\text{Se}_4(\text{H}_2\text{O})_7\text{Cl}_2]^+$.

Hence, as a result of the good compatibility of the sizes and symmetry of the carbonyl groups at the portals of Q6 with those of the aqua ligands of the triangular (cubane) molybdenum and tungsten chalcogenide aqua complexes, extensive networks of hydrogen bonds are formed and the macrocycle becomes efficiently closed by the cluster lids.

As in the case of the thio and seleno analogues, the trinuclear molybdenum oxo cluster $[\text{Mo}_3\text{O}_4]^{4+}$ also interacts with Q6 through hydrogen bonds to give the supramolecular compound $\{[\text{Mo}_3\text{O}_4(\text{H}_2\text{O})_6\text{Cl}_3]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_2 \cdot 14 \text{H}_2\text{O}$ (**36**). In this compound, the portals are closed by two lids formed by the cluster cations (Fig. 19).⁸⁸ However, unlike the compounds of Q6 with chalcogenide complexes, the plane of the Mo_3 triangle in the supramolecule **36** is tilted to the plane of the portal of the macrocycle (the tilting angle is 18.5°) and the cluster cation is shifted to one end of the portal resulting in the nonequivalence of the hydrogen bonds that are formed. These differences in the structures are attributed to the smaller size of the oxo cluster as compared to the sizes of the chalcogenide clusters and also to the higher acidity of the oxo complex.

Figure 19. Structure of the supramolecule $\{[\text{Mo}_3\text{O}_4(\text{H}_2\text{O})_6\text{Cl}_3]_2(\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}^{2+}$ (**36**).

In the compound of Q6 with the binuclear niobium aqua complex $\{[\text{Nb}_2\text{S}_4(\text{H}_2\text{O})_8](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_4 \cdot 15 \text{H}_2\text{O}$ (**37**) (Fig. 20),⁸⁹ the portal of cucurbit[6]uril is incompletely closed by

Figure 20. Fragment of the chain structure in $\{[\text{Nb}_2\text{S}_4(\text{H}_2\text{O})_8](\text{C}_{36}\text{H}_{36}\text{N}_{24}\text{O}_{12})\}\text{Cl}_4 \cdot 15 \text{H}_2\text{O}$ (**37**).

the binuclear cluster and the latter is shifted to one end of the portal because of spatial incompatibility. In this case, only two water molecules *trans*-coordinated to the niobium atom are bound directly to the portal oxygen atoms of two Q6 molecules. Several more water molecules present in the hydrophilic region of the portals are involved in additional hydrogen bonds between the aqua complex and macrocycle. In the crystal, the alternating cluster niobium aqua complexes and Q6 molecules are linked in chains.

V. Cucurbit[*n*]urils (*n* = 5, 7–10)

In addition to the above-considered macrocyclic cavitand cucurbit[6]uril (**5**) consisting of six methylene-bound glycoluril fragments, there are also cucurbiturils, which are composed of a smaller or larger number of these fragments and have the shape of barrels with smaller or larger diameters.

Crystals of the cyclic pentamer were first prepared by the reaction of dimethylglycoluril with formaldehyde and structurally characterised in 1992.⁹⁰ The decamethylcucurbit[5]uril has a slightly distorted symmetry D_{5h} and its methyl groups are located at the periphery of the molecule. In the cited study, the nomenclature for cucurbiturils was proposed by analogy with that used for calixarenes. According to this nomenclature, the number of glycoluril (or substituted glycoluril) fragments is denoted by the figure in brackets and the number of substituents is represented by the prefix.

In 2000, K Kim and co-workers⁹¹ performed the reaction of glycoluril with formaldehyde in 9 M sulfuric acid and obtained a mixture of cyclisation products (*n* = 5–11) from which five-, seven- and eight-membered homologues of cucurbituril were isolated in very low yields. These compounds were structurally characterised. A comparison of their structural parameters (Table 1) demonstrates that the diameters of the cavity and portals of cucurbiturils increase as the number of glycoluril fragments in the rings is increased. A twofold increase in the inner diameter of the cavity on going from cucurbit[5]uril to cucurbit[8]uril leads to more than a fivefold increase in the volume of the cavity.

Table 1. Comparison of the structural parameters of cucurbit[*n*]urils.

Cucurbit[<i>n</i>]uril	Portal diameter /Å	Cavity diameter /Å	Cavity volume /Å ³	Molecule height /Å
<i>n</i> = 5	2.4	4.4	82	9.1
<i>n</i> = 6	4.0	5.5	164	9.1
<i>n</i> = 7	5.4	7.3	279	9.1
<i>n</i> = 8	6.9	8.8	479	9.1

Day *et al.*⁹² studied the reactions of glycoluril with formaldehyde in H₂SO₄, HCl or HBF₄ solutions by electrospray mass spectrometry and ¹³C NMR spectroscopy and established the existence of cucurbit[*n*]urils with *n* = 5–16 in solution. Based on the results of investigations into the effects of the nature of acid and its concentration, the concentrations of other reagents and the reaction temperature, a mechanism for the formation of different cucurbit[*n*]urils was proposed and the procedure for their synthesis optimised. Cucurbit[*n*]urils with *n* = 5–10 were isolated in pure form (the yields were 8%, 46%, 24%, 12%, 85% and 5%, respectively). Individual cucurbit[*n*]urils with larger numbers of glycoluril fragments are presently unavailable.

According to the results of theoretical calculations (density functional theory),⁹³ compounds containing six or seven glycoluril fragments are the most stable homologues of cucurbiturils, and decamethylcucurbit[5]uril is the most stable methyl-substituted derivative. These results agree with both the above-described experimental data and the distortions of the NCN

angles at the carbon atoms of the bridging methylene groups that link the glycoluril fragments upon assembly.

As demonstrated above (see Section II), the presence of the hydrophobic cavity along with the polarised carbonyl groups at the portals of cucurbit[6]uril (**5**) are responsible for the formation of numerous inclusion compounds. The smaller cavity in cucurbiturils allows small molecules to be encapsulated and securely held, whereas larger-size molecular containers can accommodate bulkier guest molecules. Besides, an increase in the number of the oxygen atoms at the portals is favourable for the formation of a large number of hydrogen bonds and, correspondingly, more stable supramolecular compounds.

Decamethylcucurbit[5]uril can accommodate a molecule of nitric acid. Due to the fact that the molecular size of nitric acid matches the volume of the cavity, this guest molecule can form rather short contacts and be held in the cavity through both Coulombic interactions with the carbon atoms and hydrogen bonding with the carbonyl oxygen atoms of the macrocycle.⁹⁰ It was proved by electrospray mass spectrometric study of the ammonium acetate–decamethylcucurbit[5]uril system that the N₂, O₂, methanol and acetonitrile molecules can be included into the cavity, held in the cavity through the formation of the NH₄⁺ lids and released upon the removal of these lids. This ability of the rather rigid macrocycle to accommodate small molecules is of interest for purification or separation of gas mixtures.⁹⁴

The cavity volume of cucurbit[5]uril is insufficient for the inclusion of aromatic molecules. However, according to the data from solution ¹H NMR spectroscopy, the reaction with aliphatic hexylamine afforded an inclusion compound.⁹⁵ Hexylamine and 1,6-diaminohexane are not encapsulated into decamethylcucurbit[5]uril. According to the results of X-ray diffraction analysis, the terminal ammonium groups of 1,6-diaminohexane are involved in hydrogen bonds with the portal oxygen atoms of the adjacent macrocycles to form chains.

The water solubility of cucurbit[5]uril and decamethylcucurbit[5]uril as well as the solubility of cucurbit[6]uril are substantially increased upon the addition of salts of ammonium, alkali and alkaline earth metals due to formation of complexes with cations,⁹⁶ decamethylcucurbit[5]uril giving alkali metal complexes with composition 1 : 1.⁹⁷ Cucurbit[5]uril and decamethylcucurbit[5]uril serve as ligands in transition metal complexes (M²⁺ and M³⁺). The formation constants of these complexes were determined by different experimental methods.⁹⁸ It has been also reported that decamethylcucurbit[5]uril in solution exhibits high selectivity toward Pb²⁺ cations.⁹⁷ No compounds of cucurbit[5]urils with metal cations have been structurally characterised.

Due to the larger cavity volumes in cucurbiturils consisting of seven or eight glycoluril fragments, these compounds can encapsulate bulky molecules whose sizes are too large to be included into compounds of Q6. Thus, Q7 forms inclusion compounds with *o*-carborane,⁹⁹ with the 2,3-diazabicyclo[2.2.2]oct-2-ene molecule, whose size matches excellently the cavity size and fills virtually the entire cavity resulting in a stable supramolecular compound.¹⁰⁰

The cavity sizes of cucurbit[*n*]urils (*n* = 8, 10) allows smaller macrocycles to be included giving rise to rather rare compounds. Heating of an aqueous solution of Q8 with 1,4,7,10-tetraazacyclododecane (cyclen) and 1,4,8,10-tetraazacyclotetradecane (cyclam) afforded inclusion compounds, which have been structurally characterised. These compounds are stabilised primarily through van der Waals interactions between the inner macrocycle and the cavity of the outer macrocycle.¹⁰¹ The small and large macrocycles are inclined to one another (the angle between the equatorial planes is ~38°). The ability of tetraazamacrocycles to coordinate transition metal ions (these complexes are known as catalysts, for example, of epoxidation or DNA hydrolysis) was used in the reactions of the resulting inclusion compounds with Cu²⁺ and Zn²⁺ salts. The compound containing [Cu(cyclen). (H₂O)]²⁺ in the cavity of Q8 was studied by X-ray diffraction analysis. In this compound, the macrocycles are virtually parallel to each other (Fig. 21) and the copper atom present in the inner

Figure 21. Structure of the compound containing $[\text{Cu}(\text{cyclen})(\text{H}_2\text{O})]^{2+}$ in the cavity of cucurbit[8]uril. The copper atom is represented by a large solid circle.

macrocycle additionally coordinates the water molecule, which is located in the plane of the portal of Q8 and can be replaced by other ligands. It should be noted that the cyclen coordinated by the metal atom is not encapsulated into cucurbit[8]uril because the formation of the complex with the metal atom enhances its conformational rigidity and hinders its inclusion into the cavity of Q8.

Recently, the unique compound of cucurbit[5]uril encapsulated into cucurbit[10]uril was prepared and characterised by X-ray diffraction analysis (Fig. 22).¹⁰² The molecules of the macrocycles are inclined to each other (the angle between their equatorial planes is 64°). This fact along with the ^1H and ^{13}C NMR spectroscopic data provide evidence that the macrocycles in solution undergo free rotation with respect to each other (molecular analogue of a gyroscope). The cavity of Q5 contains the chloride anion and there is a system of hydrogen bonds between the portal oxygen atoms of both macrocycles and water molecules serving as the lids of the inner pentamer (see Fig. 22). It is believed that Q5 serves as a template for the assembly of larger-size cucurbiturils. Cucurbituril Q10 is as yet unavailable as an individual compound.

Figure 22. Structure of the inclusion compound of cucurbit[5]uril in cucurbit[10]uril.

A compound of cucurbit[7]uril was prepared in which the inorganic *cis*- $[\text{SnCl}_4(\text{OH}_2)_2]$ complex is completely encapsulated in the cavity of the macrocycle.^{103, 104} A compound of Q7 with the trinuclear anionic chromium complex $[\text{Cr}_3\text{O}_{10}]^{2-}$ has been synthesised. In this compound, the molecules of the macrocycle are linked in hexagons to form large pores with a diameter of $\sim 17 \text{ \AA}$. The Q7 molecules, trinuclear anions and coordinated water

molecules are linked through an extensive network of hydrogen bonds.¹⁰⁴

Like cucurbit[6]uril, larger macrocycles form stable inclusion compounds with organic molecules whose protonated nitrogen atoms are linked to the polarised oxygen atoms at the portals through Coulombic interactions. Due to the larger sizes of the cavities, such bulky molecules as 2,6-bis(4,5-dihydro-1*H*-imidazol-2-yl)naphthalene can be accommodated in these macrocycles. Inclusion compounds with compositions 1:1 and 2:1 were prepared with cucurbit[7]uril and cucurbit[8]uril, respectively.⁹¹ The results of quantum-chemical calculations (density functional theory) of the former compound demonstrated that not only van der Waals interactions and the hydrophobic effect but also hydrogen bonding between the protonated dihydroimidazole substituents and the portal oxygen atoms of Q7 play an important role in the formation of inclusion compounds.¹⁰⁵ Two such bulky molecules are located in an even larger inner cavity of Q8. According to the X-ray diffraction data, the imidazole substituents are located outside and are bound to the portals of Q8. Two naphthalene rings within the cavity are located parallel to each other at a distance of $\sim 3.4 \text{ \AA}$, which is indicative of π - π interactions between these rings (Fig. 23).⁹¹

Figure 23. Structure of the inclusion compound of two 2,6-bis(4,5-dihydro-1*H*-imidazol-2-yl)naphthalene molecules in cucurbit[8]uril.

The encapsulation of two or more guest molecules into the cavity of the macromolecule is of great interest in view of the unique possibility of studying new types of stereoisomerism, bimolecular reactions and the behaviour of the molecules in the microenvironment. The Q8 molecule possessing a very large cavity provides rich possibilities for investigating such interactions.

K Kim and co-workers¹⁰⁶ were the first to study the selective encapsulation of two different guests into the cavity of one host. Interactions between two guests are the driving forces for the formation of supramolecular compounds. Two organic molecules, *viz.*, the electron-deficient molecule **A** and molecule **B** acting as the electron donor, are accommodated in the cavity of Q8 [**A** is the *N,N'*-dimethyl-4,4'-bipyridinium cation (methylviologen $\text{MeN}^+\text{C}_{10}\text{H}_8\text{N}^+\text{Me}$) and **B** is 2,6-dihydroxynaphthalene or 1,4-dihydroxybenzene]. It should be noted that inclusion compounds with only either molecules **A** or molecules **B** were not obtained. The data from ^1H NMR, emission and UV spectroscopy are unambiguously indicative of strong charge-transfer interactions between the guest molecules due to their tight contact within the cavity. This interaction is much stronger than the interaction

Scheme 2

between these guest molecules if they are not encapsulated in the cavity of the cavitand. The resulting inclusion compounds are rather stable, which enables one to isolate and structurally characterise these compounds. For instance, the structure of the compound of Q8 with the unsymmetrical guest, *viz.*, the cation of carboxybenzylviologen $\text{CH}_3\text{N}^+\text{C}_{10}\text{H}_8\text{N}^+\text{CH}_2\text{C}_6\text{H}_4\text{CO}_2\text{H}$, was established by X-ray diffraction analysis (Fig. 24). The methylpyridine fragment of this cation and the naphthalene ring of 2,6-dihydroxynaphthalene serving as the electron donor are located in the cavity virtually parallel to each other at a distance of 3.4 Å. This confirms the occurrence of a strong interaction, which was found by spectroscopic methods.

The ability of cucurbit[8]uril to accommodate two closely spaced guests located in particular orientations allows one to use this compound as the synthetic molecular container in which bimolecular reactions between specially selected guests can proceed with high regio- and stereoselectivity. Thus, photodimerisation between two molecules of 4,4'-diammonio-1,1'-stilbene dichloride (**38**) encapsulated into the cavity of Q8 proceeded with a much higher rate and high stereoselectivity (0.5 h, the ratio *syn* : *anti* > 95 : 5) as compared, for example, with this reaction in the presence of γ -cyclodextrin (72 h, the ratio *syn* : *anti* ~ 4 : 1).¹⁰⁷ According to the ¹H NMR spectroscopic data, Q8 forms a stable inclusion compound with two molecules **38** in solution even if the starting reagents are taken in a ratio of 1 : 1. In this case, the guests can occupy only particular positions, *viz.*, with the parallel orientation of the alkene groups involved in photodimerisation (Scheme 2).

Owing to rather rigid structures and the ability to include various molecules and ions, cucurbiturils are very attractive compounds both as synthetic receptors and convenient building

blocks for the construction of supramolecular materials. The detailed study of supramolecular compounds based on the known cucurbiturils is hindered, in particular, by their very low solubilities in water and organic solvents. Because of this, the most promising line of investigation of the chemistry of these compounds is the development of procedures for the preparation of soluble derivatives by the insertion of substituents containing different functional groups. One approach to the solution of this problem involves the synthesis of cucurbiturils by condensation of substituted glycolurils whose bridging CH groups contain either alkyl or aryl substituents instead of hydrogen atoms. However, decamethylcucurbit[5]uril containing peripheral methyl groups, which was synthesised from dimethylglycoluril,⁹⁰ also appeared to be a poorly soluble compound. The synthesis of cucurbiturils consisting of five or six cyclohexanoglycoluril fragments¹⁰⁸ is the first success after years of failed attempts. The resulting compounds were reliably characterised by different methods, among them X-ray diffraction analysis. The cyclohexane fragments formed by two carbon atoms of glycoluril and four methylene units are located at the periphery of cucurbiturils. The sizes of the cavities and portals are only slightly different from those in the unsubstituted analogues. These compounds are readily soluble in water, methanol and DMSO and moderately soluble in ethanol, DMF and acetonitrile. Good solubility in organic solvents enables one to use cyclohexanocucurbit[*n*]urils (*n* = 5, 6) as membrane ion-selective electrodes. Cyclohexanocucurbit[6]uril dissolved in water can be used for highly selective isolation of acetylcholine (neurotransmitter).¹⁰⁸

* * *

Figure 24. Encapsulation of 'heteroguests', *viz.*, electron-deficient (carboxybenzylmethylviologen) and electron-donating (2,6-dihydroxynaphthalene) molecules in cucurbit[8]uril.

To summarise, the recent advances in the chemistry of cucurbiturils surveyed in the present review provide evidence that these macrocyclic organic molecules can be considered as molecular building blocks for the directed construction of nanosized highly ordered supramolecular compounds. The advantages of cucurbiturils over other macrocyclic cavitands are the presence of a rather rigid hydrophobic inner cavity along with hydrophilic portals, which can form supramolecular compounds with metal aqua complexes through systems of hydrogen bonds. Large cucurbit[*n*]urils (*n* = 7–10), which became readily available in recent years, show considerable promise. Thus, large molecular containers can encapsulate bulkier guests, and the inclusion of two or more molecules provides a unique possibility for studying new types of stereoisomerism, bimolecular reactions and molecular behaviour in a microenvironment. This review will hopefully be found interesting and useful and contribute to the progress of the chemistry of cucurbiturils.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 01-03-32789 and 02-03-32604) and INTAS (Grant No. 2346).

Abstract. The results of investigations in the field of development and applications of proton-conducting electrolyte membranes based on aromatic condensation polymers are analysed and summarised. Primary attention is paid to the properties of the starting polymers, such as the thermal stability, water uptake and proton conductivity. General approaches to the preparation of aromatic condensation polymers with high proton conductivity are considered, including sulfonation, synthesis from monomers containing sulfonic acid groups, incorporation of alkylsulfonated substituents and formation of acid–base polymer complexes. The bibliography includes 115 references.

I. Introduction

Advanced technologies of the 21st century are thought to be associated with wide use of fuel cells that allow fuels to be utilised in the fuel cell based engines with much higher efficiency compared to internal combustion engines.¹ Currently, fuel cells are used as power sources in both stationary and mobile (motor vehicles, buses, locomotives, *etc.*) engines. The most important components of fuel cells are proton-conducting, ion-containing membranes which can operate under severe conditions. The operating conditions include, first, high operating temperatures (sometimes, they exceed 100 °C) and, second, the medium that can be chemically active towards the material the membranes are made of due to the use of aggressive fuels (*e.g.*, methanol and products of its partial oxidation), oxidants (*e.g.*, oxygen) and catalysts, and due to the generation of active radicals at electrodes (especially, at cathode).¹

Of particular interest are new proton-conducting ion-exchange membranes based on solid polymer electrolytes.^{2,3}

The idea of using organic cation-exchange membranes as solid electrolytes in electrochemical cells was first materialised in 1959.⁴ Currently, the solid polymer electrolyte fuel cells (SPEFCs) are considered to be the most promising candidate systems out of all types of fuel cells.^{5–8} These devices are frequently called also as polymer electrolyte membrane or proton exchange membrane fuel cells (PEMFCs). The structure of a PEMFC is schematically shown in Fig. 1. A polymer electrolyte membrane is sandwiched between two noncorrosive porous electrodes. Electrochemical stacks can be fabricated by mechanically compressing individual assemblies across electrically conducting separators.

Generally, PEMFCs require humidified gases, *viz.*, hydrogen and oxygen (or air) as fuels for their operation. The electrochemical reactions occurring at electrodes are as follows:

where Q_1 is the electrical energy and Q_2 is the heat energy.

Membranes for PEMFCs⁹ must possess some specific properties, such as:

- low permeability with respect to oxygen and hydrogen (to prevent membrane breakdown);
- high swelling (to provide efficient dissociation of acids and to form a hydrated ionic phase within the thickness of the membrane);
- good water uptakes at temperatures above 100 °C;

Figure 1. A scheme of a PEMFC.

- high ion-exchange capacity sufficient to provide a conductivity of the order of $10^{-1} \text{ S cm}^{-1}$ at temperatures near 50°C ;
- high proton conductivity at temperatures above 100 and below 0°C ;
- high chemical and mechanical stability for long-term operation under severe conditions (over 2000 h for electric vehicle applications).[†]

In addition, ion-conducting films must be coated onto catalyst particles with ease. And of course, such membranes have to meet all requirements placed upon commercial products in the fuel cell market.

As a rule, proton-conducting polymers are prepared using polymer electrolytes containing negatively charged groups. The polymer electrolytes with sulfate and phosphate groups are most widely used. In dry state, they are rigid-chain, proton-conducting systems. As the content of water increases, the proton conductivity of hydrated polymer electrolytes substantially increases and can be as high as $10^{-2} - 10^{-1} \text{ S cm}^{-1}$.

The first PEMFC (a 1 kW power plant) used in an operational system was built at General Electric Co. (USA).¹⁰ The polymer membrane was made of poly(styrenesulfonic acid) (PSSA)

This type of PEMFC was used for primary power sources for the Gemini (USA) spacecrafts in the mid-1960s.

The lifetime of these PEMFCs was limited due to the degradation of the PSSA membrane under the action of $\text{HO}_2^\cdot$ radicals.

Research on fluorinated polymers^{11–14} led to considerable advances in the development of polymer electrolytes. The most widely used fluorinated polymers are prepared by copolymerisation of tetrafluoroethylene and perfluorinated vinyl ethers of the type

accompanied by hydrolysis of fluorosulfonic acid groups. The basic perfluorinated chains of such polymers determine high chemical and thermal stability, while the side chains possess the properties of strong acids.

Perfluorinated electrolyte membranes with the general formula

are also widely used.

Membrane	<i>x</i>	<i>m</i>	<i>n</i>
Nafion	6–10	1	2
Flemion	3–10	0.1	1–5
Aciplex-S	1.5–14	0.3	2–5
Dow membrane	3–10	0	2

An improved PEMFC for the Gemini spacecrafts was based on a perfluorinated Nafion membrane. This membrane possesses substantially improved characteristics compared to the PSSA membranes; particular types of Nafion membranes are characterised by lifetimes of 50 000 h. Different types of Nafion membranes have different equivalent masses (grammes of polymer per mole H^+), namely, 1200 (Nafion 120), 1100 (Nafion 117 and Nafion 115) and 1000 (Nafion 105).

[†] Optimum durability is ten years.

Perfluorinated membranes (Dowmembrane) were developed at Dow Chemical Co. (USA). They have equivalent masses of 800–850 and a dry state thickness of $\sim 5 \mu\text{m}$.

The Flemion membranes with equivalent masses ~ 1000 were developed at Asahi Glass Co. (Japan).⁵

Aciplex-S membranes developed at Asahi Chemical Industry (Japan) are characterised by equivalent masses of 1000–1200.

All the membranes mentioned above, as well as the Neosepta-F (Tokuyama, Japan) and Gore-Select (W L Gore and Associates, Inc., USA) membranes possess high proton conductivity ($10^{-2} - 10^{-1} \text{ S cm}^{-1}$) at water uptakes up to 15 H_2O molecules per SO_3H group and are characterised by good thermal, chemical and mechanical properties. On the other hand, these membranes are poor ionic conductors at reduced humidity and/or elevated temperatures. For instance, the conductivity of fully hydrated Nafion membranes at room temperature reaches $10^{-2} \text{ S cm}^{-1}$; however, it dramatically decreases at 100°C because of the loss of absorbed water in the membranes. In addition, such membranes tend to undergo chemical degradation at elevated temperatures. Finally, their fabrication is rather expensive. Therefore, the development of new solid polymer electrolytes, which combine sufficient electrochemical characteristics and low cost, is of current interest. A promising way of attacking this problem involves preparation of membranes based on aromatic condensation polymers (ACPs). The chemistry of ACPs was characterised by considerable progress in the 1960–1990s.^{15–26}

ACPs have some advantages that make them practically attractive:

- ACPs are cheaper than perfluorinated polymers, and some of them are commercially available;
- ACPs containing polar groups have high water uptakes over a wide temperature range;
- decomposition of ACPs can be to a great extent suppressed by proper molecular design;
- ACPs are easily recycled by conventional methods.

A number of reviews concerning the development of proton-conducting membranes based on polymer electrolytes are available.^{1, 7, 8, 27–30} They contain information on the advanced materials, their electrochemical properties, water uptakes and thermal stabilities. However, rapid accumulation of newly obtained results gives an impetus to further generalisation of information in this field.

In the last decade, research into PEMFCs has been most intensively carried out in the following avenues:

- development of sulfonated aromatic condensation polymers (ACPs) and membranes based on them;
- development of alkylsulfonated ACPs and membranes based on them and
- development of acid–basic polymer complexes and membranes based on them.

II. Sulfonated aromatic condensation polymers and membranes based on them

Aromatic polymers containing sulfonic acid groups can be prepared by sulfonation of high-molecular-mass ACPs or their fragments and by condensation of monomers containing sulfonic acid groups.

1. Sulfonation of high-molecular-mass aromatic condensation polymers

The simplest and most widely used method for the synthesis of sulfonated ACPs involves sulfonation of different classes of polymers, such as poly(1,4-phenylenes),^{31–33} poly(*p*-xylylene),^{34, 35} poly(1,4-oxyphenylenes),³⁶ poly(ether ether ketones) (PEEK),^{37–44} poly(arylene ether sulfones),^{3, 45–52} poly(phenylene sulfides),⁵³ poly(phenylquinoxalines),^{54–56} poly(benzimidazoles)⁵⁷ and some other ACPs. The chemical structures of sulfonated poly(4-phenoxybenzoyl-1,4-phenylene) (S-PPBP) (1), poly(*p*-xylylene) (S-PPX) (2), poly(phenylene sulfide) (S-PPS) (3),

poly(phenylene oxide) (S-PPO) (4), poly(ether ether ketone) (S-PEEK) (5), poly(ether ether sulfone) (S-PEES) (6), arylsulfonated poly(benzimidazole) (S-PBI) (7) and sulfonated poly(phenylquinoxaline) (S-PPQ) (8) are shown below.

ACPs are sulfonated using known sulfonating agents.^{58–60} In particular, PEEK can be sulfonated with concentrated sulfuric acid,⁶¹ chlorosulfonic acid,⁶² SO_3 (either pure or taken in a mixture),^{42, 48, 62, 63} a mixture of methanesulfonic acid with concentrated sulfuric acid⁶⁴ and acetyl sulfate.^{65, 66}

Sulfonation of ACPs was systematically studied taking a number of polymers (first of all, PEEK and PPBP) as examples.⁷ It was shown that sulfonation with chlorosulfonic or fuming sulfuric acid is sometimes accompanied by degradation of these polymers. The sulfonation rate of ACPs in sulfuric acid can be controlled by varying the reaction time and the acid concentration.⁶⁷ This technique allows preparation of target ACPs with sulfonation degrees ranging from 30% to 100% without chemical degradation or cross-linking of the polymers.⁶⁸ However, it should be noted that direct sulfonation reactions cannot be used for preparation of random sulfonated copolymers and sulfonation levels of less than 30%, since sulfonation in sulfuric acid occurs under heterogeneous conditions due to high viscosity of the reaction solutions.^{40, 61} For this reason, preparation of random copolymers requires the duration of the dissolution process to be shortened to 1 h. The dependences of the degree of sulfonation of PEEK and PPBP²³ on the reaction time at room temperature are shown in Fig. 2.

Figure 2. Degree of sulfonation of PEEK (a) and PPBP (b) as a function of reaction time at room temperature.⁷

Sulfonation is a kind of electrophilic substitution reaction; therefore, it strongly depends on the nature of substituents in the rings, namely, electron-donor substituents favour the reaction, whereas electron-acceptor substituents do not. For instance, in the case of PPBP the terminal phenyl ring of the side chain can be sulfonated under mild conditions that are comparable with the sulfonation conditions of PEEK. In contrast to this, the phenyl ring of the substituent in poly(4-benzoyl)-1,4-phenylene (PBP), which contains an electron-acceptor carbonyl group, cannot be sulfonated under these conditions.⁷ The sulfonation level of PPBP and PEEK reaches nearly 80% within 100 h. The degree of sulfonation of PPBP is saturated at 85%, whereas that of PEEK can be as high as 100%. This is thought to be due to steric hindrances to further sulfonation of PPBP in a viscous sulfuric acid solution.

The solubility of polymers changes as the degree of sulfonation increases. For instance, S-PEEK containing 30 mol.% sulfonic acid groups can be dissolved in DMF, DMSO and *N*-methyl-2-pyrrolidone (*N*-MP); at 70% sulfonation, the polymer is soluble in methanol and at 100%, in water. Non-sulfonated PPBP is soluble in conventional chlorinated solvents (*e.g.*, chloroform and dichloromethane), whereas S-PPBP with 30% sulfonation is insoluble in these solvents; however, the polymer can be dissolved in DMF, DMSO and *N*-MP. At sulfonation levels above 65%, S-PPBP swells in methanol and water.

Sulfonation of PEEK in concentrated sulfuric acid at room temperature is accompanied by incorporation of no more than one sulfonic acid group into each repeating unit of the polymer.^{62, 65, 69} From the results of FT-IR spectroscopy studies it follows that PEEK is sulfonated at the phenylene ring between the ether groups. Sulfonation of PPBP occurs at the *p*-position of the terminal phenoxy group.

Tsuchida *et al.*^{70, 71} reported the synthesis of poly(thiophenylsulfonic acid) containing up to two sulfonic acid groups per repeating unit. Polymerisation of 4-(methylsulfinyl)diphenyl sulfide in sulfuric acid upon heating or in the presence of SO_3 resulted in a sulfonated poly(sulfonium cation), which was then converted into the corresponding sulfonated poly(phenylene sulfide).

$m = 1-2$.

The course of sulfonation was controlled by varying the reaction time, the temperature and/or by adding SO_3 . Polymer electrolytes thus obtained are soluble in water and methanol and can form transparent films.

Novel polymer electrolytes exhibiting high proton conductivity (higher than $10^{-2} \text{ S cm}^{-1}$) were prepared by sulfonation of poly(ether sulfone) (PES).^{72, 73} In these polymers the protons of the sulfonic acid groups are partially replaced by metal ions (Mg, Ti, Al, Ln), which leads to extension of the durability of the electrolytes.

2. Synthesis of aromatic condensation polymers based on sulfonated monomers

Sulfonated ACPs are prepared both by direct sulfonation and by the polycondensation and polycyclocondensation of sulfonated compounds.

In particular, sulfonated PEEK were prepared by the reactions of sulfonated hydroquinone with difluoro-substituted aromatic compounds containing carbonyl groups:⁷⁴

An analogous procedure was employed in recent studies^{75, 76} on the synthesis of poly(arylene ether sulfones) in the reactions of sulfonated 4,4'-dichlorodiphenyl sulfone with various bisphenols.

The use of *m*-aminophenol as an additive along with bisphenols allowed the preparation of poly(arylene ether sulfones) with terminal amino groups.⁷⁷

Sulfonated poly(thiophenylene sulfones) were prepared by the interaction of sulfonated 4,4'-difluorodiphenyl sulfone with 4,4'-dimercaptobenzophenone.⁷⁸ Not only homopolymers, but also copolymers were obtained (in the latter case, a fraction of sulfonated 4,4'-difluorodiphenyl sulfone was replaced by non-sulfonated monomer) (Scheme 1).

Using this approach, one can not only prepare polymers with regular arrangement of sulfonic acid groups, but sometimes introduce a larger number of sulfonic acid groups into the ACP macromolecules compared to the sulfonation of ACPs in the last stage of the synthesis.

Sulfonated monomers were also used for the synthesis of sulfonated polyimides.^{79, 80} In particular, a sodium salt of sulfonated bis-4-[(3-aminophenoxy)phenyl]phenylphosphine oxide was used for the preparation of sulfonated polyimides (Scheme 2).⁷⁹

Of considerable interest is the use of 4,4'-diamino-2,2'-diphenylsulfonic acid^{80–82} produced on a semi-industrial scale as a sulfonated monomer for the preparation of polyimides. The reactions of a mixture of this monomer and 4,4'-diaminodiphenylmethane and 4,4'-diaminodiphenyloxide with diphenyloxido-3,3',4,4'-tetracarboxylic acid dianhydride resulted in sulfonated polyimides⁸⁰ with the following formulae:

$R = \text{O}, \text{CH}_2.$

Poly(naphthylimides) containing six-membered imide rings in the backbones^{80–86}

are characterised by substantially improved chemical resistance compared to analogous poly(phthalimides).^{87–89}

Almost all studies on the synthesis of poly(naphthylimides) based on 4,4'-diamino-2,2'-diphenylsulfonic acid were aimed at preparing copolymers with controlled properties that can be varied over a wide range.

Poly(naphthylimides) can be synthesised from sulfonated diamines, e.g., 4,4'-diaminodiphenylamino-2-sulfonic acid.⁹⁰

3. Properties of sulfonated aromatic condensation polymers

The most important properties of sulfonated ACPs are their thermal stability, water uptake and proton conductivity.

PEMFCs and other electrochemical devices operating in the temperature range 100–200 °C require polymer electrolyte membranes characterised by fast proton transfer.

Operation of PEMFCs at elevated temperatures has a number of advantages. It causes an increase in the rates of the fuel cell reactions and reduces catalyst poisoning with absorbed carbon monoxide, thus reducing the demand for catalysts.

Thermal stability of proton-conducting polymer electrolyte membranes is an important characteristic, which determines the possibility of their use for fuel cell applications.

The thermal stability of polymer membranes based on S-PPBP was studied⁷ by heating the samples followed by elemental analysis (thermogravimetric analysis, or TGA, at a heating rate of 10 deg min⁻¹ in nitrogen atmosphere) (Fig. 3).

According to the results of TGA studies, S-PPBP showed a mass loss of nearly ~20% in the temperature range between 250 and 400 °C, which corresponds to the decomposition of sulfonic acid groups.

Figure 3. TGA curve of S-PPBP with 80 mol.% sulfonation level.⁷

The dependence of the degradation temperature, T_d , of S-PPBP and S-PEEK on the degree of sulfonation is presented in Fig. 4.

Degradation of sulfonated polymers was observed between 250 and 350 °C, *i.e.*, at temperatures that are much lower than the decomposition temperatures of non-sulfonated PPBP and PEEK.

As the degree of sulfonation increased, the degradation temperatures decreased from 500 down to 300 °C for S-PEEK and from 500 down to 250 °C for S-PPBP. The results of elemental analysis of the residues indicated a dramatic (nearly tenfold) decrease in the sulfur content in the polymers after heating at temperatures above 400 °C. These data confirm that thermal decomposition occurs by desulfonation mechanism.

No thermal decomposition of sulfonated polymers was observed at temperatures below 200 °C. This means that the thermal stabilities of the polymers are sufficient for fuel cell applications even at high sulfonation levels.⁷

Figure 4. Degradation temperature of S-PPBP (1) and S-PEEK (2) as function of sulfonation level.⁷

Other proton-conducting polymer electrolytes based on sulfonated aromatic polymers also show the onset of thermal degradation at temperatures between 200 and 400 °C. Desulfonation of arylsulfonic acids occurs with ease on heating their aqueous solutions to 100–175 °C. Therefore, desulfonation imposes limitations on the thermal stability of sulfonated aromatic polymer electrolytes. Mention may be made that the presence of bulky substituents attached to the phenyl rings can to some extent favour an increase in the temperature of the onset of thermal degradation.

According to Tsuchida *et al.*,⁷⁰ highly sulfonated poly(phenylene sulfide) exhibits higher thermal stability compared to other sulfonated aromatic polymer electrolytes. This conclusion was based on the results of a TGA study of the thermal stability of poly(thiophenylenesulfonic acid) with different degrees of sulfonation. The degradation temperature of a highly sulfonated polymer (degree of sulfonation $m = 2.0$) is 265 °C, which is 125 °C higher than that of the low sulfonated polymer ($m = 0.6$). The C–S bond in the highly sulfonated polymer is stronger due to the presence of two electron-acceptor sulfonic acid substituents attached to each benzene ring. The initial mass loss of this polymer at 265–380 °C is only 13%, which corresponds to the loss of two water molecules per repeating unit. Therefore, the desulfonation reaction in this polymer slows down upon introduction of electron-acceptor.

Water is carried out in the fuel cells *via* humidified gas streams (H_2 , O_2) and enters electrodes as a result of gas diffusion. A mixture of liquid water and water vapours passes through each electrode towards the electrode/electrolyte interface and crosses it, thus assisting the hydration of the electrolyte membranes. Oxygen reduction at the cathode provides an additional source of water in the electrolyte.

Water transport in the membrane occurs in two ways, *viz.*, due to electro-osmotic drag of water by proton transfer from anode to cathode and due to diffusion of water molecules down concentration gradients that build up.

Optimum hydration level of electrolyte membranes is a key factor for normal fuel cell operation: if the electrolyte membrane is too dry, its conductivity decreases, whereas an excess of water in the membrane can lead to cathode flooding. In both cases the fuel cell performance reduces.

Absorption of water vapour by polymer films prepared from S-PEEK and S-PPBP was studied by placing the films in atmospheres with different humidities and measuring the equilibrium water content. The results obtained were found to be close to those reported in an analogous study of Nafion membranes.¹⁰ The dependence of the water uptakes of the S-PEEK and S-PPBP films on the relative humidity at room temperature is shown in Fig. 5.

Assuming that water activity and water content in the membrane obey the Raoult law, the activity coefficient of water in the

polymer is larger than unity at relative humidities exceeding a particular value. The equilibrium content of water in S-PEEK and S-PPBP increases as the sulfonation level increases. At relative humidities in the range from 0% to 50% (first region), a relatively small increase in the water uptake is observed, whereas an increase in the relative humidity from 50% to 100% (second region) leads to a much greater increase in the water uptake. The first region corresponds to water uptake due to solvation of the proton and sulfonate ions. During solvation, water is involved in the interaction with ionic components of the polymer. These interactions overcome the tendency of the polymer to exclude water due to its hydrophobic nature and resistance to swelling.⁷ The second region corresponds to the uptake of water involved in polymer swelling.

The content of water in S-PPBP (65 mol.% sulfonation) is larger than in S-PEEK with the same sulfonation level. At a relative humidity of 100% and room temperature, the content of water in S-PPBP and S-PEEK is 8.7 and 2.5 molecules per sulfonic acid group, respectively.

Picnometric measurements showed that the densities of the polymers with a sulfonation level of 65 mol.% were 1.338 (S-PEEK) and 1.373 g cm⁻³ (S-PPBP). According to the results obtained by scanning electron microscopy, both polymers exhibited very close characteristics of their surfaces and fracture surfaces.

The difference in water uptake between S-PEEK and S-PPBP can be explained by the flexibility of the phenoxybenzoyl group in the side chain of S-PPBP, which favours water permeation into the polymer and water absorption in the terminal sulfonic acid groups. The water uptake of S-PPBP is comparable with that of Nafion membranes.

DTA studies revealed a rather strong interaction between the water molecules in sulfonated hydrocarbon polymers and their sulfonic acid groups, which leads to high proton conductivities at high temperatures and low humidities.

The proton conductivity of sulfonated poly(phenylene sulfide) is 10^{-5} S cm⁻¹ at room temperature and a relative humidity of 30%. It exponentially increases as the relative humidity increases and reaches a value of 2×10^{-2} S cm⁻¹ at 94% humidity (Fig. 6). In this case, the content of water in the polymer is 10.3 molecules per sulfonic acid group. The maximum conductivity of sulfonated poly(phenylene sulfide) ($m = 2.0$) at 80 °C was 4.5×10^{-2} S cm⁻¹.

Experiments⁷ on water absorption in the S-PEEK and S-PPBP films showed that the proton conductivities of the films containing equilibrium amounts of absorbed water depend on the relative humidity. Figure 7 presents the plots of the proton conductivities of S-PPBP and S-PEEK with different sulfonation levels as a function of the relative humidity. As can be seen, the proton conductivities of the films increase with the relative

Figure 5. Water uptake of S-PPBP (1–3) and S-PEEK (4) at room temperature as function of relative humidity.⁷ Concentration of SO_3H groups in the polymer (mol.%): 30 (1), 65 (2), 80 (3) and 65 (4).

Figure 6. Proton conductivity of compound 9 ($m = 2.0$) at room temperature as function of relative humidity.⁷⁰

Figure 7. Proton conductivity of S-PEEK (1) and S-PPBP (2–5) with different sulfonation levels as a function of relative humidity at room temperature.⁷ Sulfonation level (mol.%): 65 (1), 30 (2), 65 (3), 80 (4) and 85 (5).

humidity and water uptake and can be as high as 10^{-5} S cm⁻¹ (for S-PEEK).

The proton conductivities of S-PEEK and S-PPBP with equal degrees of sulfonation (65 mol.%) at a 100% relative humidity can be compared using the plots shown in Fig. 8. As can be seen, the proton conductivity and water uptake of S-PPBP are much higher than those of S-PEEK. Moreover, the proton conductivity of S-PEEK dramatically decreases at temperatures above 100 °C, whereas that of S-PPBP is much less temperature dependent.

Sulfonated poly(phenylene sulfide) and S-PPBP exhibit stable proton conductivities at elevated temperatures. For this reason, they are considered as promising polymers for creation of proton-conducting electrolyte membranes to be used at elevated temperatures and low humidities.

On the contrary, the conductivity of perfluorinated polymer electrolytes usually appreciably decreases with increasing temperature, that is, the conductivity of such electrolytes at 80 °C is by an order of magnitude lower than at 60 °C. Perfluorinated polymer membranes become less conducting at high temperatures, since the loss of water causes the channels to collapse, thus making proton transport more difficult.

In particular, the proton conductivity of Nafion membranes at temperatures above 100 °C dramatically decreases due to their dehydration.

In Fig. 9, we present the temperature dependences of the proton conductivity of S-PEEK with a sulfonation degree of 85 mol.% at different relative humidity values.

Figure 8. Temperature dependences of proton conductivity of S-PPBP (1) and S-PEEK (2) with the same degrees of sulfonation (65 mol.%) at a relative humidity of 100%.⁷

Figure 9. Temperature dependence of proton conductivity of an S-PEEK membrane with sulfonation level of 85% at a relative humidity of 50% (1), 70% (2) and 90% (3).⁷

Similarly to Nafion membranes, the proton conductivity of S-PEEK substantially decreases as the humidity decreases.⁷⁴ The dependence of proton conductivity on humidity reflects a tendency of S-PEEK to absorb water vapours. This can be attributed to the 'liquid' proton conductivity mechanism when protons are transported in the form of hydronium ions through water-filled pores in the membrane.³⁰

S-PEEK samples exhibited a slight increase in conductivity with increasing temperature at all relative humidities (50%, 70% and 90%). This can be due to the strong interaction between the sulfonic acid groups and the absorbed water molecules.

Proton-conducting polymer electrolyte membranes based on ACPs such as S-PPBP and sulfonated poly(phenylene sulfide) contain rather large amounts of bound water. This seems to be the reason for such a salient feature of these membranes as an increased proton conductivity at high temperatures and/or low humidities. This conclusion was confirmed by the results of differential scanning calorimetry (DSC) studies of these systems.⁷

III. Alkylsulfonated aromatic condensation polymers and proton-conducting electrolyte membranes based on them

The major drawback of sulfonated proton-conducting polymer electrolytes is their degradation at 200–400 °C due to desulfonation.

By introducing alkylsulfonated substituents into the macromolecules of aromatic polymers one can prepare thermostable proton-conducting polymers. Their electrochemical properties can be controlled by varying the number of substituents and the length of alkyl chains. The water uptake and proton conductivity of alkylsulfonated polymers are close to those of sulfonated electrolytes that exhibit high thermal and chemical stability and mechanical strength.

Poly(*p*-phenyleneterephthalamido-*N*-propylsulfonate) and poly(*p*-phenyleneterephthalamido-*N*-benzylsulfonate) were synthesised based on related polyamides containing reactive NH groups.⁹¹ The polyamides were modified by treating with NaH and DMSO^{91,92} and the polyanion obtained was introduced in the reaction with 1,3-propane sultone (Scheme 3).

An analogous approach was employed in the modification of poly(benzimidazoles) (PBI).^{93–100}

Yet another synthetic route to sulfonated PBI involves treatment of the above-mentioned polyanion with 4-bromobenzylsulfonate resulting in poly[2,2'-*m*-phenylene-bi(*N*-benzylsulfonato)benzoimidazolo-5,5'-diyl] (Scheme 4).

Compared to the starting polymers, alkylsulfonated PBI are more soluble in polar organic solvents (DMAA or DMSO). The solubility depends on the degree of alkylsulfonation.

The degree of alkylsulfonation as a function of the 1,3-propane sultone:PBI ratio is plotted in Fig. 10.

The degree of alkylsulfonation of NH groups in PBI was estimated based on the results of ¹H NMR study and elemental analysis. This parameter can be controlled with ease by varying

Scheme 3

Scheme 4

the 1,3-propane sultone:PBI ratio. For instance, the alkylsulfonation level can be as high as 60 mol.% at a 1,3-propane sultone:PBI ratio of 5.0.

Figure 10. Degree of alkylsulfonation of PBI as function of 1,3-propane sultone:PBI ratio.⁷

An attempt to synthesise ethylphosphorylated PBI using the above-mentioned treatment of PBI at NH groups (Scheme 5) was reported.⁷ The substitution reaction at the NH sites of benzimidazole rings was performed successfully, but the resulting polymer was insoluble in organic solvents. The reason can be aggregation of phosphoric acid groups during the substitution reaction. Ethylphosphorylated PBI exhibited high proton conductivity ($10^{-3} \text{ S cm}^{-1}$) even in the pellet form. According to the results obtained, the presence of polar phosphoric acid groups enhances the proton conductivity of the polymer electrolytes.

Alkylsulfonation and arylsulfonation of the starting aromatic polymers was aimed at increasing their water uptakes and proton conductivities while retaining high thermal stabilities. The polymers obtained were studied by TGA in inert and oxidative atmospheres.⁹⁶ The parent PBI exhibits a very high thermal stability. In an inert atmosphere, the onset of its degradation occurs at 650 °C, a 5% mass loss is observed at 700 °C, while more than 80% of the initial mass is retained at 800 °C. Introduction of substituents that are not conjugated with the polymer backbones reduces the degradation temperature in an inert medium, which is consistent with the expectations. The degradation of poly[2,2'-*m*-phenylene-bis(*N*-benzylsulfonato)benzimidazolo-5,5'-diyl] with 22% substitution begins at 480 °C while the onset of mass loss process of poly-{2,2'-*m*-phenylene-bis[*N*-(3-propylsulfo)benzimidazolo-5,5'-diyl]} with a substitution level of 54% is observed at 450 °C. After removal of the substituents the degradation slows down so nearly 50%–60% of the initial mass is retained at 800 °C.

The degradation of PBI in an oxidative atmosphere (dry air) begins at 520 °C, which is nearly 100 °C lower than the degradation temperature of this polymer in inert medium.

Scheme 5

The degradation temperatures of substituted PBI in oxidative media are close. For all polymers, the mass loss in air is much larger than in nitrogen and the amount of the residual char is much smaller. This is first of all due to the lower stability of the starting PBI in dry air and to some extent to the introduction of substituents.

In an inert atmosphere, poly(*p*-phenylene terephthalamide) (PPTA) is stable below 550 °C. Rapid mass loss of the polymer (up to 50% of the initial mass) begins at 600 °C. After modification with propylsulfonate side groups (a 66% substitution) the polymer is stable below 400 °C; only 40% of the initial mass is retained at 800 °C. The benzyisulfonated derivative of PPTA with 66% substitution level is more thermally stable compared to the propylsulfonated derivative; its degradation begins at 470 °C. A decrease in mass of the sample down to 50% of initial mass is observed at 800 °C. The degradation temperature of PPTA in a dry air atmosphere is 70 °C lower than in nitrogen atmosphere.⁹⁶ Comparison of degradation processes of benzyisulfonated PPTA with a 66% substitution in air and in nitrogen showed that the degradation in air begins at a lower temperature. The major difference in behaviour is that the mass loss is larger while after the initial mass loss it is much smaller at high temperatures, which is due to oxidative degradation of the polymer chains. Introduction of substituents into aromatic polymers reduces their thermal stability irrespective of the medium in which degradation occurs. This is the expected manner of changes in properties, since the side groups, especially sulfonic acid groups, are not stabilised by conjugation with the polymer backbones.

Gieselmann and Reynolds concluded⁹⁶ that the benzyisulfonate side group is more stable than the propylsulfonate group irrespective of the structure of the polymer backbone. This suggests that the side group cleavage point is not only at the N—C bond. A TGA study of benzyisulfonated PBI with 75% degree of sulfonation in air at a heating rate of 1 deg min⁻¹ showed⁹⁷ that introduction of benzyisulfonate groups into the polymer reduces its thermal stability. In this case, thermal degradation begins at 370 °C while the mass loss in the temperature range 370–420 °C is attributed to the degradation of the sulfonic acid groups. The degradation mechanism of these polymer electrolytes seems to be very complex, since the results of TGA studies are affected by the residual water, impurities, sulfonation level and measurement conditions.

In air, arylsulfonated PBI is stable up to 350 °C (see Ref. 97), while benzyisulfonated PBI is stable up to 500 °C (see Ref. 96). These results are hard to compare because of different degrees of sulfonation of the PBI samples under study. One can assume that benzyisulfonated PBI is less stable than propylsulfonated PBI due to the presence of weak aryl—S bond. In fact, the degradation temperature of benzyisulfonated PBI is comparable with those of polymer electrolytes obtained by sulfonation with sulfuric acid.

The thermal stability of anhydrous propylsulfonated PBI (PBI-PS) in a nitrogen atmosphere was studied⁷ by TGA at a heating rate of 5 deg min⁻¹. Prior to analysis, all samples were vacuum oven dried at 60 °C for 48 h. However, this polymer is hygroscopic and again rapidly absorbs water after vacuum oven drying. Because of this, it was dried *in situ* and then differential thermal analysis was immediately performed.

In contrast to PBI, degradation of PBI-PS was observed in the temperature range 400–450 °C. The decomposition temperature of PBI-PS decreases as the degree of alkylsulfonation increases to 400 °C (Fig. 11); however, it is higher than the degradation temperature of perfluorinated polymer electrolytes (nearly 280 °C).

Degradation of PBI-PS was studied by elemental analysis and FT-IR spectroscopy. It was found that the intensities of SO stretching vibrations decreased after heating the PBI-PS samples above 400 °C for 1 h. These results are close to those reported by Gieselmann and Reynolds⁹⁶ who found that the degradation of PBI-PS occurs due to desulfonation. Hence, alkylsulfonated PBI is more thermally stable than sulfonated aromatic polymer

Figure 11. Decomposition temperature of PBI-PS as function of alkylsulfonation level.⁷

electrolytes characterised by degradation temperatures lying between 200 and 350 °C. The thermal stability of alkylsulfonated polymer electrolytes can be attributed to strong chemical bond between the alkyl and the sulfonic acid groups. The introduction of alkylsulfonic acid groups into thermostable polymers involving alkane sultone is one of the most important approaches to the preparation of thermostable proton-conducting polymer electrolytes.

Introduction of arylsulfonic and alkylsulfonic acid groups into aromatic polymers induces water absorption and makes them more hygroscopic. The water uptake of PBI-PS was determined⁷ by measuring the mass of the polymer before and after hydration. In Fig. 12, we present the dependence of the water uptake of PBI-PS on the relative humidity. As can be seen, the water uptake changes with the relative humidity. The equilibrium water uptake of PBI-PS increases as the relative humidity and degree of alkylsulfonation increases. The water uptake of PBI-PS with an alkylsulfonation level of 73.1 mol.% is 11.3 H₂O molecules per SO₃H group at room temperature and a relative humidity of 90% (*cf.* 11.0 H₂O molecules per SO₃H group for Nafion 117 membranes under the same conditions).

Figure 12. Water uptake of PBI-PS as a function of relative humidity at alkylsulfonation levels of 49.3 mol.% (1), 61.5 mol.% (2) and 73.1 mol.% (3).⁷

This procedure was also employed for the synthesis of butylsulfonated and (methyl)propylsulfonated PBI (PBI-BS and PBI-MPS, respectively) *via* butane sultone and methylpropane sultone. The water uptakes of these polymers differ from that of PBI-PS and are 19.5 (PBI-BS) and 27.5 (PBI-MPS) H₂O molecules per SO₃H group at a relative humidity of 90%. The water uptakes of alkylsulfonated PBI depend on the length of alkyl chains and on the degree of chain branching, that is, as the chain length and the degree of alkyl chain branching increase, the water uptake also increases. This is thought to be associated with the

greater flexibility of long alkyl chains and with larger amount of water absorbed in the cavities between the branched chains.

The specific role of the absorbed water in polymer electrolytes and the physical state of the water absorbed by polymer electrolytes were studied by IR¹⁰¹ and ¹H NMR spectroscopy (low-temperature relaxation time measurements)¹⁰² and DSC.⁷ The DSC curve of a hydrated PBI-PS film (73.1 mol.%) containing 11.3 H₂O molecules per SO₃H group is shown in Fig. 13.

Figure 13. DSC curve of hydrous PBI-PS (73.1 mol.%) film containing 11.3 H₂O molecules per sulfonic acid group.⁷ T_1 is the freezing temperature (-36.6 °C) and T_2 is the melting temperature (-21.6 °C).

The DSC curve of anhydrous PBI-PS exhibited no peaks, whereas the DSC curve of hydrated PBI-PS exhibited two peaks corresponding to phase transitions of absorbed water at -36.6 and -21.6 °C that were attributed to the freezing and melting temperatures of the absorbed water, respectively.

A study of hydrated Nafion membranes under the same conditions revealed a phase transition at 0 °C. These results indicate that the adsorbed water in the Nafion membrane is bound to a lesser extent compared to PBI-PS which can exist in the hydrated state even at elevated temperatures.

Wet PBI-PS films possess no electron conduction despite the fact that the main polymer chains are conjugated. To elucidate the nature of charge carriers in PBI-PS, the conductivity of PBI-PS films containing H₂O and D₂O was measured.⁷ The results of measurements are presented in Fig. 14. As can be seen, the conductivity of the films containing water increased with increasing water uptake and was higher than that of the PBI-PS films containing D₂O in the same temperature range. This points that the charge carrier in hydrated PBI-PS is a proton (hydronium ion).

The temperature dependence of proton conductivity of PBI-PS containing the equilibrium amount of water is shown in

Figure 14. Temperature dependence of proton conductivity of PBI-PS (61.5 mol.%) films containing H₂O (1) and D₂O (2).⁷

Figure 15. Temperature dependences of proton conductivity of PBI-PS films with the same water uptake (48%) and different degrees of sulfonation (a) and with the same degree of sulfonation (73.1%) and different water uptakes (b).⁷ (a): degree of sulfonation (mol.%): 49.3 (1), 61.5 (2) and 73.1 (3); (b): water uptake: 11.2 (1), 25.0 (2), 29.0 (3) and 48.0 (4).

Fig. 15. Hydrated PBI-PS exhibits a high proton conductivity at room temperature. The conductivity of a PBI-PS sample containing 3.1 H₂O molecules per SO₃H group reached 10^{-5} S cm⁻¹ at 80 °C and decreased slightly at higher temperatures due to a small loss of water (~ 10 mass %). The conductivity of a PBI-PS film containing more than 5.2 H₂O molecules per SO₃H group increased as the temperature increased and was as high as 10^{-3} S cm⁻¹ at temperatures above 100 °C. The proton conductivity of a PBI-PS film containing 11.3 H₂O molecules per SO₃H group was $\sim 10^{-3}$ S cm⁻¹.

The water uptake of PBI-PS films placed in an atmosphere with a relative humidity of 90% was comparable with that of Nafion membranes. The proton conductivity of Nafion membranes was as high as 10^{-3} S cm⁻¹ at room temperature; however, it decreased due to the loss of absorbed water at temperatures above 100 °C. In contrast to this, hydrated PBI-PS exhibited a high proton conductivity at temperatures above 100 °C.

The large water uptake and high proton conductivity of PBI-PS at temperatures above 100 °C are due to the specific properties of the polymer and the physical state of absorbed water.

The proton conductivity of benzyldisulfonated PBI at different values of relative humidity has been studied.¹⁰² It was found that the proton conductivity increases as the degree of substitution increases. The polymer with a 75% substitution level exhibited a conductivity of $\sim 10^{-2}$ S cm⁻¹ at 40 °C and a relative humidity of 100%.

The results obtained in the above-mentioned studies suggest that alkylsulfonated aromatic polymer electrolytes exhibit sufficient thermal stabilities for fuel cell applications at 80 °C (a typical operating temperature for perfluorinated polymer electrolyte membranes). The water uptakes and proton conductivities of these polymers are close to the corresponding values for perfluorinated polymer electrolytes at temperatures below 80 °C but are larger than the latter at temperatures above 80 °C.

The absorbed water molecules are more strongly bound to alkylsulfonated rather than perfluorinated polymers. One can assume that this is related to the difference in the absorption mechanisms and to the physical state of the absorbed water in PBI-PS and perfluorinated polymer electrolytes.

IV. Proton-conducting electrolyte membranes based on acid–base polymer complexes

Proton-conducting membranes used in PEMFC operate under severe conditions (see above). Recently, complexes of basic polymers with strong acids have attracted a considerable interest. Such complexes are characterised by stable electrochemical properties and large water uptakes at high temperatures.

Recently, new proton-conducting polymer electrolyte membranes based on PBI–orthophosphoric acid complexes have been proposed for use in PEMFCs.^{103–106}

The most important advantages of this polymer electrolyte over perfluorinated polymer electrolytes and other acid–base polymer complexes are that PBI/H₃PO₄ possesses conductivity even at low activity of water and high thermal stability of these systems. The materials based on these complexes are expected to operate over a wide range from room to high temperature in both humid and dry gas. Such complexes are prepared by immersing PBI films into phosphoric acid solutions. In particular, the preparation of PBI–strong acid complexes by immersion of PBI films into solutions of strong acids in methanol was reported.^{107, 108} The absorption level of strong acid molecules increased with an increase in the concentration of the strong acid and reached up to 2.9 molecules per repeating unit for polymer complexes **10**. An IR spectroscopy study of the complexes revealed that the acid molecules, except for H₃PO₄, protonate the nitrogen atoms in the imidazole ring. Phosphoric acid (H₃PO₄) is incapable of protonating the imidazole groups in PBI but interacts with them *via* the formation of strong hydrogen bonds between NH and OH groups.

PBI films doped with phosphoric acid were prepared by immersion of PBI films in aqueous solutions of phosphoric acid for at least 16 h.^{103–106} Upon equilibration in an 11 M H₃PO₄ solution a doping level of ~5 phosphoric acid molecules per repeating unit of the polymer was achieved.

Anhydrous sulfonated aromatic polymers are highly brittle. Recently,¹⁰⁹ new materials with high mechanical strength were reported. They were prepared using polymer blending technique by combining PBI and sulfonated polymers (S-PEEK or *ortho*-sulfonated polysulfone **11**).

Such polymer blends exhibit high proton conductivities, moderate swelling values and high thermal stabilities. The specific interaction of SO₃H groups with basic nitrogen atoms was confirmed by FT-IR spectroscopy. The acid–base interaction between the sulfonated polymer and PBI provided a material with high mechanical strength and thermal stability.

The thermal stability of PBI–strong acid polymer complexes was studied by TGA and DTA. Figure 16 presents the TGA curves of polybenzimidazole and its complexes with strong acids. As can be seen, PBI exhibits an extremely high thermal stability over the entire temperature range. Small mass losses by all samples at temperatures below 200 °C are due to the loss of water and solvent present in the membranes.

Typical proton-conducting polymer electrolytes undergo considerable degradation in the temperature range under study.

Figure 16. TGA curves of PBI (**1**) and its complexes with H₃PO₄ (**2**), H₂SO₄ (**3**), MeSO₃H (**4**) and EtSO₃H (**5**).⁷

A decrease in the degradation temperature of polymer complexes **10** was expected because of the complexation of acid molecules which easily corrode and oxidise the polymer macromolecules. However, no degradation was observed in nitrogen atmosphere. At the same time, thermal decomposition of PBI complexes with H₂SO₄, MeSO₃H and EtSO₃H begins at 330, 240 and 220 °C, respectively. After thermal decomposition of these polymer complexes in the temperature range 220–400 °C the residues were 50% of the initial masses of the samples. Therefore, complexation of PBI with H₂SO₄, MeSO₃H and EtSO₃H results in a loss of thermal stability. The decomposition of complexes is first of all due to elimination of acid molecules. This assumption was confirmed by the results of elemental analysis. At temperatures above 400 °C, the PBI chains gradually decompose under the action of high temperatures and strong acids.

Complexes **10** are thermally stable up to 500 °C. It was found that treatment of PBI with a phosphoric acid solution (27 mass %) improved the thermal stability of the polymer.¹¹⁰ This was associated with the formation of benzimidazonium cations. Samms *et al.*¹⁰⁴ studied the thermal stability of polymer complexes **10** and showed that these complexes are promising for use as polymer electrolytes in the hydrogen–air and methanol fuel cells. To simulate the operating conditions in a high-temperature PEMFC, the polymer complexes **10** were coated with platinum black, doped with phosphoric acid (4.8 H₃PO₄ molecules per repeating unit of PBI) and heated in an atmosphere of nitrogen and 5% hydrogen or in air in a TGA analyser. The degradation products were identified by mass spectrometry. In all cases the mass loss below 400 °C was found to be due to the loss of water. In addition, it was found that polymer complexes **10** coated with platinum black are thermally stable up to 600 °C.

Variation of the conductivity of polymer complexes **10** as a function of water vapour activity, temperature and acid doping level was studied.¹⁰⁶ It was shown that the conductivity of heavily doped complexes (500 mol.%) is nearly twice as high as that of the film doped to 338 mol.% at the same temperature and humidity. For instance, the conductivity of PBI doped with 500 mol.% H₃PO₄ (5 H₃PO₄ molecules per repeating unit of PBI) is 3.5×10^{-2} S cm⁻¹ at 190 °C and a water vapour activity of 0.1.

Raising the temperature and water vapour activity causes an increase in the conductivity of the polymers irrespective of the doping level of PBI with phosphoric acid. In addition, it was found that crossover of methanol molecules through the polymer complexes **10** is by an order of magnitude smaller than in the case of

perfluorinated polymer electrolytes and that the mechanical strength of such complexes is three orders of magnitude higher compared to that of Nafion membranes.

The proton conductivity of PBI polymer complexes prepared by the interaction of PBI with methanol solutions of strong acids was studied.⁷ The temperature dependences of the conductivities of anhydrous PBI–strong acid polymer complexes are shown in Fig. 17a.

Figure 17. Temperature dependence of proton conductivity of anhydrous (a) and hydrous (b) PBI complexes with H_3PO_4 (1), H_2SO_4 (2), EtSO_3H (3) and MeSO_3H (4);⁷ (a): doping level, acid molecules per PBI unit: 2.0 (1), 1.8 (2), 2.0 (3), 1.9 (4); (b): water uptake (mass %): 13 (1,4), 19 (2) and 26 (3).

All anhydrous polymer complexes of PBI with strong acids possess a proton conductivity of the order of 10^{-6} – 10^{-9} S cm^{-1} at 100 °C. The conductivity of polymer complexes **10** can be as high as 10^{-5} S cm^{-1} at 160 °C, whereas other PBI–acid complexes showed a decrease in the conductivity at temperatures above 80 °C. These results point to high thermal stability of polymer complexes **10**.

To prepare hydrated systems, the films of PBI–strong acid polymer complexes were placed in a desiccator with a relative humidity of 90% for 72 h. The water uptakes of the complexes were 13 mass %–26 mass %. The proton conductivity of the hydrous PBI–strong acid polymer complexes was found to be nearly an order of magnitude higher than the conductivity of anhydrous polymer complexes (Fig. 17b). This difference can be explained by the improvement of charge carrier generation in the absorbed water. Changes in the proton conductivity at room temperature are especially remarkable. Figure 18 presents the temperature dependences of the conductivity of anhydrous complexes **10** with different acid contents. As can be seen, the conductivity of polymer complexes **10** increases with the concentration of H_3PO_4 .

The temperature dependence of the conductivity of polymer complexes **10** is quite different: in this temperature range the conductivity is low. This suggests that two H_3PO_4 molecules quantitatively react with the PBI units containing two imidazole groups. As a consequence, an excess of H_3PO_4 determines the necessary proton conductivity. A study of PBI/ H_3PO_4 polymer complexes by FT-IR spectroscopy showed that the spectra exhibited three characteristic absorption maxima near 1090 cm^{-1} (HPO_4^{2-}), 1008 cm^{-1} (POH) and 970 cm^{-1} (H_2PO_4^-).^{111–114} As

Figure 18. Temperature dependences of proton conductivity of anhydrous PBI/ H_3PO_4 complexes containing 1.4 (1), 2.0 (2), 2.7 (3), 2.3 (4) and 2.9 (5) H_3PO_4 molecules per PBI unit.⁷

the concentration of H_3PO_4 increases, the intensity of the absorption maxima of HPO_4^{2-} and H_2PO_4^- increases. This suggests that proton conductivity can occur by the Grotthuss mechanism¹¹⁵ involving an exchange of protons between H_3PO_4 and PO_4^{3-} or H_2PO_4^- .

V. Fuel cell applications of proton-conducting membranes based on aromatic condensation polymers

Two blend polymer electrolytes containing acid and basic functional groups (90 mass % PEEK and 10 mass % PBI or 95 mass % PES and 5 mass % PBI) were applied in H_2/O_2 fuel cells. The current-*vs.*-voltage curves of the membranes in the fuel cells were comparable with that of Nafion 112 membranes.¹⁰⁹

Fuel cell tests of membranes based on sulfonated PES showed⁷ a cell voltage of 550 mV at a current density of 700 mA cm^{-2} (atmospheric pressure, humidified gases, 70 °C). No significant loss of membrane performance was observed after long-term operation (1000 h) under fuel cell conditions.

The maximum power of fuel cells with S-PPBP membranes reaches 0.3 W cm^{-2} at a current density of 800 mA cm^{-2} . The conductivity of the electrolyte membranes was 3×10^{-3} S cm^{-1} ; the membrane thickness and surface area were 0.01 cm and 3.15 cm^2 , respectively.

The maximum power of fuel cells H_2/O_2 and $\text{CH}_3\text{OH}/\text{O}_2$ with membranes based on polymer complexes **10** (see Ref. 7) was as high as 0.25 W cm^{-2} at a current density of 700 mA cm^{-2} . The electrical resistance of electrolyte membranes was 0.4 Ω , the thickness and surface area of the membranes were 0.01 cm and 1 cm^2 , respectively, and the doping level was 500 mol.%. The measured electrical resistance of the cell was equivalent to a conductivity of 0.025 S cm^{-1} . It was found that the electrical resistance of the fuel cell is independent of the water content in the gas (water produced at cathode is sufficient for maintaining the necessary conductivity of the electrolyte). This type of fuel cells was characterised by continuous operation at a current density of 200 mA cm^{-2} over a period of 200 h (and for longer times) without reduction of the membrane performance.

The power of $\text{CH}_3\text{OH}/\text{O}_2$ fuel cells at 200 °C and atmospheric pressure reached 0.1 W cm^{-2} at a current density of 250–500 mA cm^{-2} . The conductivity of membranes operating under these conditions remained constant in the temperature range 30–140 °C.

* * *

To summarise, the aforesaid shows that the aromatic condensation polymers can be thought to be candidates for fuel cell

applications: the structure of ACP-based polymer electrolytes can be modified with ease; these polymer electrolytes possess large water uptakes and high proton conductivities at high temperatures and low humidities, as well as sufficient thermal and chemical stability. Further investigations to design proton-conducting materials exhibiting long-term thermal stability and mechanical strength, capable of operating at high temperatures without humidification and further improvement of fuel cells are required.

Chemical modification of electrolytes for lithium batteries

V N Afanas'ev, A G Grechin

Contents

I. Introduction	775
II. Liquid-phase electrolytes	776
III. Polymeric electrolytes	781
IV. Electrolytic solvosystems for lithium batteries and mechanisms of charge transfer in solutions	783

Abstract. Modern approaches to modifying chemically electrolytes for lithium batteries are analysed with the aim of optimising the charge-transfer processes in liquid-phase and solid (polymeric) media. The main regularities of transport properties of lithium electrolyte solutions containing complex (encapsulated) ions in aprotic solvents and polymers are discussed. The prospects for the development of electrolytic solvosystems with the chain (ionotropic) mechanism of conduction with respect to lithium ions are outlined. The bibliography includes 126 references.

I. Introduction

Direct energy conversion from chemical to electrical forms is a central problem of modern science and technology. At present, active research is carried out on the development of primary and secondary lithium cells with characteristics (high energy density, low self-discharge rate, applicability at low temperatures, high reliability, *etc.*) that should surpass those of traditional electrochemical systems^{1–6} and displace them in future. The research on lithium chemical power sources (CPS) was, first of all, stimulated by the progress in such industrial fields as electronics, new communication systems and transport (electrical vehicles). Lithium cells and rechargeable batteries are increasingly applied as autonomous power sources in various domestic, medical and computer devices. Special-purpose lithium CPS are used in night-vision devices, guidance systems, space equipment, and new weapon systems. At present, the yearly production of lithium CPS for special equipment and military branches is ~ 30 million cells, which is 3–4 times higher compared with other industrial branches.⁷

Elaboration of highly efficient lithium CPS is largely aimed at the development of electrolytic systems with high conductivities (10^{-3} – 10^{-2} S cm⁻¹) in a wide temperature range (from –50 to +70 °C) and chemical and electrochemical stabilities with respect to lithium and cathodic materials. Such systems should also enable sufficiently fast and reversible electrode processes. Insufficient conductivity of liquid-phase and, particularly, solid poly-

meric lithium electrolytes is a key factor impeding the development of CPS with lithium electrodes.^{8–11} The importance of solving this problem is determined by the fact that the internal resistance of a power source directly governs its main performance characteristics such as the power density and the discharge current.

Most approaches to choosing optimum electrolytic compositions for lithium CPS were based on theoretical concepts of the ion-migration mechanism of charge transfer.^{12–14} Hence, the aim of the latest studies was to create such conditions that would both enhance the migration rates of electrolyte ions as the main charge carriers in solution and in polymers and increase their concentrations. For this purpose, mixed low-viscosity solvents with sufficiently low dielectric constants were used as the electrolytic systems, macrocyclic ligands which can encapsulate lithium cations and different anions were added, lithium salts with low lattice energies which involve large anions with delocalised charges were synthesised, *etc.* It is known that a chain (prototropic) mechanism of conduction is brought about in aqueous solutions of acids and bases used as the electrolytes for traditional CPS, which is responsible for the conductivities of these solutions being 1–2 orders of magnitude higher as compared with solutions with the migration mechanism of charge transfer. It is also known that the ionotropic mechanism of charge transfer can involve not only protons in water and protic solvents but also some other ions in aprotic media. In this connection, the latest studies have considered a possibility of developing highly conductive nonaqueous electrolytes with a conduction mechanism different from the ion-migration one, as well as designing CPS based on such electrolytes with improved performance characteristics.

This survey analyses and generalises the results of studies published in the past 10–15 years and devoted to modifying chemically the conventional electrolytes applied in lithium CPS with the aim of optimising the charge transfer processes in liquid-phase and solid (polymeric) media. The analysis was carried out from the standpoint of dividing the electrolytes according to their phase compositions, *viz.*, liquid-phase and solid (polymeric) electrolytes. The latter type traditionally involves biphasic electrolytes, *i.e.*, gels, composites, *etc.* The survey also includes new systems which do not fit the traditional classification (*e.g.*, electrolytes with polymeric anions and ionic liquids). That is why it seemed reasonable to analyse the results of studies of different polymeric electrolytes according to the examples of concrete chemical modifications that were most interesting from our viewpoint, rather than to consider in detail the classes of electrolytes.

II. Liquid-phase electrolytes

The main factors that affect the charge migration rate in electrolytes are the solvent viscosity and the processes of solvation and association. One of the first approaches to optimising electrolytic systems in lithium CPS consisted in the use of complex lithium compounds with low lattice energies, which involve weakly solvated and easily polarisable anions. This provided solutions with enhanced conductivities and higher concentrations of electrolyte ions. Within this approach, lithium electrolytes with coordinatively saturated fluorine-containing anions AsF_6^- , PF_6^- , BF_4^- and also with ClO_4^- , Ph_4B^- , all of which exhibited sufficiently high electrochemical stability, were extensively used.^{2, 8–11, 15–17} Moreover, the use of fluorine-containing salts allowed one to reduce the corrosion of cathodes with aluminium current leads at high positive potentials. However, the performance of power sources with the electrolytes mentioned entailed quite a number of problems. For example, lithium perchlorate is thermally unstable, and its solutions are explosive, especially, in ether-like solvents; lithium hexafluorophosphate can decompose in solution to give poorly soluble lithium fluoride and a Lewis acid PF_5 , which initiates polymerisation of cyclic ethers; hexafluoroarsenate ions are reduced electrochemically to give AsF_5 and As^0 which are environmentally hazardous; lithium tetrafluoroborate solutions do not provide a sufficient conductivity level and, moreover, BF_4^- ions initiate polymerisation of cyclic ethers. Therefore, the search for new lithium electrolytes which would exhibit better compatibility with solvents and electrode materials is still in progress.

Lithium salts with anions such as CF_3SO_2^- , $\text{B}_{10}\text{Cl}_{10}^-$, $\text{B}_{12}\text{Cl}_{12}^-$ and BMe_4^- turned out to be more stable but their solutions possessed low conductivities. Recently, new lithium electrolytes with large anions and minor polarisability have been proposed: $\text{Li}[(\text{CF}_3\text{SO}_2)_2\text{N}]$ (**1**) and the corresponding cyclic imides $\text{Li}[\text{N}(\text{SO}_2)(\text{CF}_2)_n(\text{SO}_2)]$ ($n = 1–3$) (**2**), lithium methanide $\text{Li}(\text{CF}_3\text{SO}_2)_3\text{C}$ (**3**), the family of lithium chelatoborates of the general formula $\text{Li}[\text{BR}_2]$ (**4–6**) (where bidentate ligands **R** are aliphatic or aromatic diols), and the corresponding lithium phosphates $\text{Li}[\text{PR}_3]$ which are highly stable chemically and electrochemically, well soluble ($> 1 \text{ mol litre}^{-1}$) and weakly associated.^{9, 18–25} The charge distribution in anions strongly affects the electrolyte association. With addition of electron-acceptor substituents such as F, CF_3 , COOR, SO_2OR and nitrogen atoms, which can delocalise the negative charge in anions, the association constants of lithium electrolytes decreased by several orders of magnitude. The effects mentioned favour the increase in the conductivity and extend the electrochemical window of solvents. Thus the specific conductivity of 1 M solutions of lithium

chelatoborates $\text{Li}[\text{B}(\text{C}_6\text{H}_x\text{F}_{4-x}\text{O}_2)_2]$ ($1 < x < 4$) in 1,2-dimethoxyethane (DME) increased by a factor of 4.4 at 25 °C and by a factor of 2.4 at –45 °C with substitution of fluorine atoms for four hydrogen atoms. A linear correlation between the limiting potentials of anodic oxidation of lithium borates and the energies of higher occupied molecular orbitals of anions, which was estimated using semiempirical quantum-mechanical methods AM1 and MNDO,^{9, 19} indicates that the electrochemical stability of these electrolytes depends on the degree of delocalisation of the negative charge in anions.

Lithium CPS most often employ cyclic and linear ethers and esters, *viz.*, DME, propylene carbonate (PC), γ -butyrolactone (γ -BL), tetrahydrofuran (THF) and inorganic sulfur compounds (SO_2 , SOCl_2 , SO_2Cl_2) as the solvents.^{2, 26–28} Solutions of lithium salts in such solvents demonstrated sufficiently high conductivities but often exhibited an enhanced activity with respect to both the lithium anode and cathodes. To enhance the stability of electrode materials, it was proposed to add dialkyl carbonates to solutions. In this case, due to a protective film formed on the anode and consisting mainly of solvent oxidation products, the cycling stability substantially increased. At present, the electrolytes for lithium power sources involve, as a rule, binary and ternary compositions based on PC or ethylene carbonate with addition of a certain low-viscosity solvent (DME, THF, *etc.*). At low temperatures, mixed solvents with low viscosities and sufficiently high dielectric constants proved to be most efficient.^{9, 10} Moreover, the possibility of using certain strongly associated and sufficiently viscous liquids, *viz.*, sulfones,^{29–31} sulfamides $\text{R}^1\text{R}^2\text{NSO}_2\text{NR}^3\text{R}^4$ and glymes (dimethyl ethers of polyethylene glycol) $\text{CH}_3\text{O}(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_3$ (see Refs 32–34), which allow preparing solutions of lithium salts with conductivities of an order of magnitude of $(0.8–2.5) \times 10^{-3} \text{ S cm}^{-1}$, was discussed.

1. Electrolytes with molecularly encapsulated lithium ions

The maximum conductivity and prevention of concentration polarisation during the discharge, were achieved if concentrated (1.5–3 M) electrolyte solutions were used in lithium CPS. However under these conditions, many lithium salts in solvents of low and medium dielectric constants dissociated incompletely to form ion pairs and other associates which cannot conduct current.³⁵ Insufficient solubility of lithium electrolytes also limited their practical application. The solubility and conductivity of lithium electrolytes could be enhanced by introducing macrocyclic compounds which contain oxygen or nitrogen atoms possessing appreciable affinity towards lithium ions into solutions. Several groups of mono- and bicyclic oxo- and aza(oxo)-ligands which form stable lithium complexes with the 1:1 composition are known. These comprise crown ethers: 12-crown-4 (**7**), 15-crown-5 (**8**), 18-crown-6 (**9**), 1,4,7-trioxo-10-azacyclododecane (**10**), *N*-benzyl-1,4,7-trioxo-10-azacyclododecane (**11**), *etc.*; cryptands: cryptand 211 (**12**), cryptand 221 (**13**), cryptand 222 (**14**); cryptand 222D (**15**), cryptand 221D (**16**), *etc.*; calixarenes: 25,27,26,28-bis[1,4,7,10,13,16-hexaoxa(hexadecamethylene)]calix-[4]arene (**17**), 4,10,16,22-tetra-*tert*-butyl-25,26,27,28-tetrakis-(ethoxycarbonylmethoxy)calix[4]arene (**18**), *etc.*^{36–43} Tricyclic ligands with cylindrical cavities can also form binuclear complexes with the composition 2:1 at high $\text{Li}^+ : \text{L}$ ratios.⁴²

Among all macrocyclic compounds known, cryptands form the most stable inclusion complexes (cryptates) with alkali metal ions. Such ligands have a spheroidal cavities that can encapsulate cations of suitable sizes, virtually screening the latter from interactions with solvent molecules and counterions.^{36, 37, 43–63} Due to their unique complexing properties, cryptands and crown-ethers favour the dissolution of metal salts and weaken their association in low-polarity media. The solubility increases due to a decrease in the free energy of ions as a result of their encapsulation in the ligand's internal cavity

This effect and the solvation of hydrophobic groups of the ligand by organic solvent molecules compete with the increase in the free energy of ions as their radii increase upon complexing. By the example of cryptand **14**, it was shown that complexing of salts with macrocyclic ligands results in a decrease in the solubility of salts well soluble in this solvent and its increase for poorly soluble salts. For a given cryptate salt, the solubility increased with the transition to less polar media in which this salt is more strongly associated.

Table 1. Standard enthalpies of formation for lithium electrolytes in acetonitrile (AN) and propylene carbonate (PC) at 298.15 K.^{45–49}

[Li(11)]AsF ₆	8.75	13.91
[Li(18)]AsF ₆	−22.5	—

The strategy of choosing complex electrolytes for lithium CPS, which has been put forward in Refs 45–49, is based on studying the processes of complex formation and solvation in lithium salt solutions. The experimentally determined enthalpies of dissolution ΔH° for a number of lithium electrolytes in acetonitrile and PC (Table 1) showed that, as a rule, a lithium ion in the free state is much more strongly solvated ($\Delta H^\circ < 0$) than that incorporated into a complex with macrocyclic ligands ($\Delta H^\circ > 0$). A decrease in the degree of solvation due to complexing, which leads to an increase in the conductivity, was observed in less polar media. A number of lithium electrolytes with complex cations involving crown ethers, cryptands and calix[4]arenes as the ligands were isolated as solids. Studies of solvation of simple (M^+X^-) and complex ($[ML]^+X^-$) electrolytes as well as ligands (L) allowed the estimating of the changes in the enthalpy for solid-state complexing processes

These values can be considered as the characteristics of complex formation in media with low dielectric constants.^{45–49} As was shown, the association of a complex cation with an anion in cryptand-containing solid electrolytes is weaker as compared with electrolytes containing crown ethers and calixarenes. For lithium salts (LiX), the coordination process becomes less exothermic with a decrease in the polarisability in the following sequence of anions: $I^- > ClO_4^- > Br^- > CF_3SO_3^- > AsF_6^- > BF_4^-$. In propylene carbonate at 298.15 K, the complexing of Li^+ with crown ethers resulted in a substantial increase in the ionic mobility (Table 2). Similar results were obtained for lithium complexes with **9** in PC and 2-cyanopyridine and complexes with **9** and **14** in a PC–dichloromethane mixed solvent.^{50,51}

Studies of the molar conductivity (Λ) of a 1 M LiBF₄ solution in γ -BL as a function of the [L]:[LiBF₄] ratio [L designates crown ethers **8** and **9** and dibenzo-18-crown-6 (**19**)] have shown⁵² that Λ increases with an increase in the crown ether content and reaches its maximum at the equimolar ratio. An electrolyte based on crown ether **8** which forms the most stable complex with a lithium

ion exhibited the maximum conductivity ($1.1 \times 10^{-2}\text{ S cm}^{-1}$). The use of **8** enhanced the battery power. A possibility of using substances capable of forming charge-transfer complexes (CTC) as the functional additives to electrolytes was also considered.⁵² It was found that for solutions containing CTC of metal lithium with hexamethylphosphoric triamide (HMPA) $\text{Li}^+[(\text{CH}_3)_2\text{N}]_3\text{PO}^-$ in γ -BL (lithium was added in excess, the ratio $[\text{HMPA}]:[\gamma\text{-BL}] = 1:2$), the conductivity increased by three orders of magnitude as compared with the initial solution without CTC and reached $4.2 \times 10^{-2}\text{ S cm}^{-1}$. The potential drop vs. current density dependence has shown that the transport properties of a complex electrolyte are better compared with the ordinary one. It was assumed that in the presence of CTC in solution the charge transfer can be realised by the chain mechanism, where the discharge of an ion is not preceded by its desolvation.

Most of the studies observed a correlation between the stability of complex lithium ions and the increase in the conductivity of the solution. Thus it was found⁵³ that the addition of crown ethers **7** and **9** to LiAsF_6 solutions in DME and **9** to LiClO_4 solutions in DME has practically no effect on the conductivity in the range of salt concentration from 10^{-4} to $5 \times 10^{-2}\text{ mol litre}^{-1}$. The result obtained can be explained by the weak interaction between lithium ions and ligands due to strong solvation of ions by the solvent molecules with the chelate structure. The addition of crown ethers to NaClO_4 solutions in DME resulted in formation of more stable complexes of sodium ions with ligands, thus decreasing the electrolyte association and increasing its conductivity. For more strongly associated electrolytes, the addition of macrocyclic ligands led to a greater increase in conductivity as compared with less associated electrolytes. For instance, the molar conductivity of a LiClO_4 solution in a cyclic ether, namely, 1,3-dioxolane, in the absence of macrocyclic compounds was lower as compared with its solutions in DME due to the stronger association of the salt in the former case. At the same time, the conductivities of 1,3-dioxolane solutions of LiClO_4 containing equimolar additions of **7–9** with $c_{\text{LiClO}_4} > 10^{-3}\text{ mol litre}^{-1}$ were substantially higher compared with DME solutions. The greatest increase in conductivity was observed upon addition of crown ether **8** (Fig. 1). It was concluded⁵⁴ that the extent of the complex-

**Figure 1.** Dependence of the molar conductivity of LiClO_4 and LiClO_4 + crown-ether (1 : 1) solutions in 1,3-dioxolane on the salt concentration at 298 K:⁵⁴ (1) LiClO_4 , (2) LiClO_4 + **7**, (3) LiClO_4 + **9**, (4) LiClO_4 + **8**.

ing-induced increase in conductivity should be directly proportional to the increase in the solution dielectric constant (ϵ) observed in low-polar media due to the higher dipole moments of ion pairs comprising complex cations as compared with ordinary ion pairs.

Conductometric and spectroscopic studies of dissociation of salts $[\text{LiL}]^+[\text{ZPh}_3]^-$ and $[\text{LiL}]^+[\text{A}]^-$ ($\text{Z} = \text{C, Ge and Sn}$, **L** is cryptand **12** and **A** is an anion of a CH-acid) in solvents of low polarity have shown that the introduction of a cryptand to solutions of organolithium compounds resulted in the formation of 'cryptand-separated' ion pairs with light absorption maxima independent of the solvent nature.^{55,56} In nonpolar solvents, the ion pairs comprising anions with strongly delocalised charges (Ph_3C^-) were less strongly associated. In more polar media, the inverse order of anion stability (with respect to ion pairs) due to the stronger ion–dipole interaction of localised charges with solvent molecules was found. Thus, in polar solvents, the electrolytes with charges localised on anions are associated to a lesser degree.

For lithium salts containing anions of CH-acids with strongly delocalised charges, the dissociation constants (K_d) remained virtually unchanged with the formation of cryptates. The degree of association changed only for salts containing anions with localised charges. On going from THF ($\epsilon = 7.6$, $K_d = 10^{-6}\text{ mol litre}^{-1}$) to cyclohexylamine ($\epsilon = 4.7$), and *N*-methylmorpholine, the dissociation constants of cryptate-containing ion pairs decreased by 3–4 orders of magnitude, whereas the transition to benzene ($\epsilon = 2.3$) resulted in their decrease by 9 orders of magnitude. Moreover, the constants depended linearly on the reciprocal dielectric constant of the medium.

A series of studies^{57–64} dealt with conductivity of lithium salts in media with similar dielectric constants, viz., acetonitrile (AN) and dimethylformamide (DMF), methanol and nitromethane (NM), with the aim of elucidating how the molecular structure of the solvent and the presence of macrocyclic ligands affect the transport properties of solvents. It was shown that the limiting

molar conductivity (Λ_0) of a complex electrolyte [LiL]Pi [L is diaza-18-crown-6 (**20**), Pi is picrate ion] in AN is smaller than Λ_0 of a simple LiPi salt. However, with an increase in the LiPi concentration (at the constant L concentration of 10.2×10^{-3} mol litre $^{-1}$), the molar conductivity of an electrolyte containing **20** became higher than without this additive. At a constant salt concentration, the molar conductivity increased with an increase in the L concentration. At the same time, the molar conductivity of KPi in AN with addition of **20** ($c_{20} = 5.2 \times 10^{-3}$ mol litre $^{-1}$) was lower and decreased with an increase in the ligand content.⁵⁷ The results obtained were analysed with account of the following equilibria:

where C is the solute, A is a counterion, S is a solvent molecule and L is a ligand.

Assuming that $K_2 > K_5$ and taking into account the strong association of LiPi in acetonitrile ($K_5 = 10^3$ kg mol $^{-1}$), the increase in conductivity can be explained by dissociation of nonconducting ion pairs, which is caused by complex formation (K_2). For KPi, it was concluded that equilibria 3, 4 and 5 weakly affect equilibria 1 and 2 due to insignificant association of the salt ($K_5 = 77$ kg mol $^{-1}$). It was also found that the addition of L to solutions of KPi and LiPi in MeOH did not affect the value of Λ due to the specific solvation of the ligand by solvent with the formation of H bonds. However, upon addition of an alkyl-substituted diazacrown ether RL (R = Alk), which can form complexes with cations, the conductivity of solutions decreased. The addition of crown ether **8** to LiPi and LiClO $_4$ solution in MeOH and DMF, in which these electrolytes are weakly associated, did not affect the value of Λ . For strongly associated LiPi and LiClO $_4$ in AN and NM (Fig. 2), the introduction of macro-

cyclic ligand **8** enhanced the conductivity, decreased the association constants, and made the decay in Λ which occurs with an increase in electrolyte concentration less pronounced.^{58, 59} In an AN + NM mixed solvent, the association constants were practically independent of its composition (as might be expected for isodielectric systems); in the absence of **8**, the values of constants substantially differed from one another and depended nonlinearly on the mixed solvent composition.⁶⁰

Studies of the molar conductivity of solutions of lithium, sodium and potassium perchlorates in MeOH and AN containing crown ethers **7**, **8** and cryptands **13**, **14** have shown that the association constants, mobilities and Stokes radii of [ML] $^+$ complex ions are practically independent of the nature of the metal ion involved. As a rule, the association constants for complex ions were lower compared with 'free' ions; however, $\Lambda_0([ML]^+X^-) \leq \Lambda_0(MX)$ (Table 3).^{61–64} It was assumed that the formation of complexes levels off the differences in the degrees of solvation, charge densities and sizes of complex ions, so that their mobilities depend solely on the size of the ligand attached. A deviation from this rule observed for large cryptate ions was attributed to the changes in their degrees of solvation, because for 'free' alkali ions Λ_0 increases as their solvation weakens

Table 3. Molar conductivity values at infinite dilution and association constants for lithium electrolytes at 298.15 K.

Figure 2. Dependence of the molar conductivity of lithium picrate LiPi solutions in (1, 2) acetonitrile and (3, 4) nitromethane on the salt concentration at 298.15 K.^{58, 59} Concentration of additive **8**: (1) 46.43×10^{-4} (3) 89.05×10^{-4} mol litre $^{-1}$, (2, 4) in the absence of **8**.

($\text{Li}^+ < \text{Na}^+ < \text{K}^+$) and Stokes radii increase. Similar results were reported in Ref. 65. The addition of dicyclohexyl-18-crown-6 to ethanol solutions of NaCl, KCl and RbCl ($c = 10^{-4}$ – 10^{-3} mol litre $^{-1}$) resulted in complete dissociation of the electrolytes. At the same time, the values of A_0 decreased. For the system KI + crown ethers in AN, the A_0 values were lower than in solutions without ligands, decreasing with a decrease in the r_1/r_2 ratio, where r_1 is the ionic radius and r_2 is the cavity radius. It is of note that electrolytes based on [K(12-crown-4)]I and [K(15-crown-5)]I ($r_1/r_2 > 1$) in AN exhibited association constants of 28 ± 4 and 23 ± 5 litre mol $^{-1}$, respectively, whereas the original electrolyte KI was completely dissociated. The explanation of this effect invokes the fact that the effective radii of complex ions are smaller than those of solvated ('free') ions. It is known that an increase in association constants due to complex formation is most pronounced for multicharged strongly solvated ions, e.g., halides of rare-earth elements with the cations strongly bound with organic ligands partially substituting their solvate shells.⁶⁶

The effect of the addition of crown ethers **9** and **19** and cryptand **14** on the thermodynamics of electrolytic dissociation and the conduction of KSCN in such solvents as AN, DMSO, PC and their binary mixtures with chlorobenzene was also studied.^{67,68} It was found that throughout the range of mixed solvent concentrations ($\varepsilon = 5$ –66), the association constants are smaller for electrolytes with complex cations than for simple salts. However, the conductivity in the systems studied ($c_{\text{KSCN}} = 10^{-3}$ – 10^{-4} mol litre $^{-1}$) increased with the addition of macrocyclic compounds as a result of a decrease in the degree of electrolyte association only for mixed solvents enriched with the nonpolar component. In individual solvents with relatively high dielectric constants (AN, DMSO and PC) and binary mixtures with high contents of these solvents, the degree of electrolytic dissociation of potassium thiocyanate was high; however, the conduction decreased upon addition of crown ethers and cryptands. This effect was attributed to the increase in the cation size with the formation of complexes comprising macrocyclic ligands, which reduced the cation mobility. In addition to the change in the ion size, the nature of the ligand attached also plays a certain role. It was shown⁶⁹ that, as compared with A_0 of free ions in AN, a decrease in $A_0(\text{ML}^+)$ ($\text{M}^+ = \text{Na}^+, \text{K}^+$) is more pronounced for complex ions containing macrocyclic ligand **9** with two *tert*-butyl substituents than for complex ions with similar but larger ligands with four *tert*-butyl substituents. The explanation of these results invoked the fact that in the latter case complex cations $[\text{ML}]^+$ were less stable and retained their association with anions.

The molar conductivity of potassium chloride solutions with additions of cryptand **14** was calculated for different interaction potentials using the Monte-Carlo method.⁷⁰ For KCl solutions with concentrations of 0.10 and 0.15 mol litre $^{-1}$ at 298 K, the values of Λ were found to be 128.82 and 126.52 S cm ^{2} mol $^{-1}$, respectively, whereas for the same solutions with additions of cryptand **14** the Λ values turned out to be substantially smaller, viz., 71.5 and 65.9 S cm ^{2} mol $^{-1}$, respectively. For a constant cryptand-to-salt concentration ratio, the molar conductivity decreased as the concentration increased in the range from 0.03 to 0.15 mol litre $^{-1}$. If the overall interaction potential took into account the hydrodynamic component in addition to the Coulomb attraction and repulsion forces, an adequate agreement of calculated and experimental Λ values was observed. However, the authors failed to derive a generalised interaction potential which would allow one to adequately simulate both the structural (neutron diffraction spectra) and dynamic (conduction) properties of the system studied.

2. Lithium electrolytes with molecularly encapsulated anions

By binding anions of lithium salts into complexes, it is possible to reduce not only the conductivity of a solution (due to a decrease in the degree of ion association), but also the transport number of lithium. Most of the known ligands capable of forming anionic

complexes cannot be used in lithium CPS, because they either coordinate anions by forming hydrogen bonds or comprise positively charged fragments (or metal atoms) acting as Lewis acids. Recently, new neutral ligands, viz., cyclic and linear azacompounds, in which the electron-acceptor groups CF_3SO_2 were substituted for hydrogen atoms in NH groups [octakis(trifluoromethylsulfonyl)pentaethylene hexamine (**21**), hexakis(trifluoromethylsulfonyl)hexacyclene (**22**), etc.] were studied.^{71–73} Nitrogen atoms of nonsubstituted polyamines display electron-donor properties, which favour the formation of complexes with cations. Upon introduction of electron-acceptor groups, these ligands become the receptors of anions due to the local positive charge that appears on the nitrogen atoms as the electronic density shifts to the substituent. The formation of complexes by linear ligands and anions was confirmed by the NEXAFS method (X-ray absorption spectra in solution). For complexes with cyclic ligands isolated in the solid state, this was confirmed by X-ray diffraction technique. It was shown that, for an equimolar concentration ratio of ligands and lithium halides (LiCl, LiBr, LiI, $c = 0.1$ or 0.2 mol litre $^{-1}$), the conductivity of THF solutions increased by 1–3 orders of magnitude (Table 4). The conductivity also increased with an increase in the number of sulfonamide groups NSO_2CF_3 for both cyclic and linear ligands. For LiBr and LiCl solutions in THF, the conductivity increased with an increase in the ligand concentration, however, to a lesser extent; the conductivity of a THF solution of lithium iodide remained virtually unchanged as the ligand-to-salt concentration ratio changed from 1:1 to 1:2. The greatest increase in conductivity with the introduction of macrocyclic ligands was observed for solutions of the most strongly associated salt, viz., lithium chloride, which exhibited the lowest conductivity. It was noticed that, upon introduction of macrocyclic ligands comprising six and seven sulfonamide groups in a ring, the conductivity of lithium halide solutions in THF increased to practically the same value ($\sim 1.6 \times 10^{-3}$ S cm $^{-1}$), although their solutions without additives exhibited quite different conductivities.

Yet another group of anionic receptors comprises boron-containing ligands with fluorinated aryl and alkyl groups: boranes $[(\text{C}_6\text{F}_5)_3\text{B}$ (**23**), etc.], borates $[(\text{C}_6\text{F}_5\text{O})_3\text{B}$ (**24**), etc.], boronates $[(\text{C}_6\text{H}_3\text{F})\text{O}_2\text{B}(\text{C}_6\text{H}_3\text{F}_2)$ (**25**), etc.].^{74–77} As compared with borane (**23**), borate (**24**) has a higher solubility in solvents of low polarity

Table 4. The effect of the addition of equimolar amounts of boron- and nitrogen-containing anionic receptors on the conductivity of lithium electrolytes at 298.15 K.^{71–77}

Electrolyte	σ / S cm $^{-1}$

0.1 M LiCl + 0.1 M (21)	1.6×10^{-3}
0.2 M LiCl	1.6×10^{-6}
0.2 M LiCl + 0.2 M (22)	1.4×10^{-3}
0.1 M LiBr	2.9×10^{-5}
0.1 M LiBr + 0.1 M (21)	1.8×10^{-3}

(*e.g.*, their solubilities in dimethyl carbonate at room temperature were > 1 and $0.3 \text{ mol litre}^{-1}$, respectively). The complexing of these ligands with halide ions was also confirmed by X-ray absorption spectra of solutions (NEXAFS). The addition of boron-containing ligands to lithium halide solutions in DME substantially increased the conductivity and solubility (see Table 4). For example, lithium fluoride was practically insoluble in solvents with low dielectric constants; however, the addition of a compound **23** or **24** (1 : 1) to its 1 M solution in DME yielded solutions with conductivities of $(6.2\text{--}6.8) \times 10^{-3} \text{ S cm}^{-1}$. The conductivity was shown to increase with an increase in the number of fluorine atoms in the ligand molecules. Boron-containing ligands, especially boranes, are electrochemically stable and compatible with the lithium anode. Thus for the 1 M LiF + 1 M **23** solution in a mixed PC–ethylene carbonate–dimethyl carbonate (1 : 1 : 3) solution, the range of working potentials reached 5.0 V. Compared with such electrolytes as LiPF₆ and LiAsF₆, lithium halides are cheaper and less toxic. Taking into account that the starting reagents for the synthesis of boron-containing anionic receptors are also inexpensive and of a low toxicity, electrolytes with complex anions have the prospects of gaining a wide use in future.

III. Polymeric electrolytes

Currently, keen attention is drawn to the safety of application and utilisation of waste power sources. In this respect, metallic lithium is an environmentally clean material as compared with lead and cadmium. The safety of lithium CPS for the environment and human beings is ensured by the correct choice of nonaqueous electrolyte solutions.

Numerous studies in the field of polymeric lithium electrolytes were largely aimed at solving the problems of enhancing the stability of the electrolytic system with respect to the lithium anode and increasing the safety and reliability of the performance of lithium batteries used for energising domestic devices.⁷⁸

The main drawback of polymeric electrolytes is their low conductivities at room temperature. Under the conditions mentioned, these electrolytes are mostly in a quasicrystalline state ($\sigma = 10^{-6}\text{--}10^{-7} \text{ S cm}^{-1}$). The conductivity increases only with the transition to the amorphous state (as the temperature rises). To improve the characteristics of polymeric electrolytic systems, different additives were extensively used, along with the procedures of modifying the polymer structure itself (which allows, *e.g.*, the reduction of the glass transition temperature). The addition of

plasticisers that, as a rule, represent electrolyte solutions in low-molecular aprotic solvents led to formation of hybrid biphasic gel-electrolytes with acceptable conductivities. However, they were highly active with respect to lithium electrodes. Additions of macrocyclic compounds weaken the association of ions in non-polar polymeric matrices, thus increasing the conductivity.

The effect of cryptand **14** additives on the conductivity of sodium salt of an oxysiloxane polymer was studied.⁷⁹ It was found that with addition of the cryptand, the conductivity increased by a factor of 15 irrespective of temperature and concentration and was $1.7 \times 10^{-5} \text{ S cm}^{-1}$. It was concluded that, in the general case, the conductivity should increase with an increase in the equilibrium constant of the formation of cation–cryptand complexes and an increase in the association constant of the polymeric electrolyte. This agrees with the conclusions made in the studies of solutions of liquid-phase lithium electrolytes. Cations are free charge carriers despite their sufficiently strong solvation by the polymer, and a cryptand additive should not cause any substantial conductivity rise. This was confirmed in several studies.^{80–84} Additions of cryptand **14** or crown ether **8** to polymeric electrolytes based on NaSO₃CF₃, NaBF₄, NaI and NaSCN solutions in amorphous polyethylene oxide were shown to reduce their solubilities and conductivities.^{80,81} Using spectroscopic methods, it was shown that association of these salts is insignificant and all polymer–salt complexes studied were amorphous. At the same time, the solubility and conductivity of NaSO₃CH₃ which is poorly soluble in the polymer increased with the addition of the crown ether and cryptand but did not reach the values observed for the other electrolytes of this system. An analysis of parameters of the Vogel–Tamman–Fulcher (VTF) equation which describes the temperature dependence of conductivity showed that the addition of the cryptand decreases the number of charge carriers for electrolytes with weakly associated NaSO₃CF₃, NaBF₄, NaI and NaSCN salts, increasing it only for electrolytes containing the more strongly associated salt NaSO₃CH₃.

Solid electrolytes based on Li[CF₃SO₂N(CH₂)₃OCH₃] complexes with cryptands **12–14** and crown ethers **7–9** and Li[(CF₃SO₂)₂N] complexes with **9** were also studied (Fig. 3).^{83,84} It was assumed that amorphous phases are formed due to the difference in the radii of the macrocycle cavity and the cation. The method of differential scanning calorimetry has shown that the most stable macrocycle–salt complexes [ML]⁺X[−] (M is an alkali metal, L is a crown ether or cryptand), in which the sizes of the cation and the ligand's (**7**, **12**) cavity match most closely one another, form only crystalline phases. A series of amorphous complexes of macrocyclic compounds and lithium salts were

Figure 3. Temperature dependence of the specific conductivity (σ) of amorphous complexes: (1) [Li(**14**)]CF₃SO₂N(CH₂)₃OCH₃, (2) [Li(**13**)]CF₃SO₂N(CH₂)₃OCH₃, (3) [Li(**12**)]CF₃SO₂N(CH₂)₃OCH₃, (4) [Li(**9**)]CF₃SO₂N(CH₂)₃OCH₃, (5) [Li(**8**)]CF₃SO₂N(CH₂)₃OCH₃ and (6) [Li(**7**)]CF₃SO₂N(CH₂)₃OCH₃.⁸¹

synthesised where the size ratio mentioned was violated. Complexes with cryptands passed into the amorphous state at lower temperatures as compared with complexes with crown ethers. The presence of asymmetric anions favoured the glass transition.⁸⁴ Amorphous samples with the lowest glass transition temperature exhibited the greatest conductivity ($10^{-4.5}$ S cm⁻¹). An analysis of IR and Raman spectra has shown that cryptands most effectively screen lithium cations. The parameters of the VTF equation have shown that cryptate complexes exhibit higher concentrations of charge carriers as compared with complexes with crown ethers (see Fig. 3).

An increase in conductivity at room temperature by 2 orders of magnitude (up to 10^{-4} – 10^{-3} S cm⁻¹) for polymeric electrolytes based on LiClO₄ and polyethylene oxide observed upon introduction of crown ether **8** was explained⁸⁵ by the formation of stable complexes of crown ethers with lithium ions. However, the addition of 1,4,7,10,13-pentaoxa(13)orthocyclophane(benzo-15-crown-5) had practically no effect on the conductivity in the system mentioned, because the formation of complexes with lithium ions was complicated. The solid polymeric electrolytes synthesised were well compatible with the lithium anode and stable during long-term storage.

New synthetic methods for polymeric and liquid electrolytes of the series of nitrogen-containing compounds, *viz.*, aromatic amines, diarylamines and organosilicon compounds with ammonium groups and their practical applications as the additives have been reported.⁸⁶ Organosilicon derivatives of 4,4'-bipyridyl were referred to as most promising. The additives mentioned almost double the conductivity of polymeric electrolytes and prevent the capacity fade during cycling.

The mobility of ions in polymeric electrolytes is directly associated with the mobility of polymeric chain fragments, which is the main factor limiting the conductivity. An approach to enhancement of the conductivity and simultaneous increase in the transport number of lithium ion is the use of compounds which act as Lewis acids and can interact with anions. For example, good results were obtained where cyclic boron-containing compounds **26** ($n = 1-3, 7.2$), particularly, 2,4,6-tris(2-methoxyethoxy)boroxine were introduced into polymeric electrolytes based on LiSO₃CF₃ and poly(methyl methacrylate).⁸⁷ This was explained by the effective interaction of oligoether oxygen-containing fragments with lithium ions and the anion-acceptor nature of boroxine rings. Introduction of 11-acryloyloxy-3,6,9-trioxaundecyl biphenyl-2,2'-diyl borate (**27**) into solutions of strongly associated electrolytes of LiCl and CF₃CO₂Li in both polar and low-polar media, as well as of electrolytes formed by LiBF₄ and **1** in DME and dimethyl carbonate (DMC) increased the conductivity.⁸⁸ In contrast, introduction of the same additive to solutions of well dissociated salts, namely, LiBF₄ and **1** in polar solvents resulted in a decrease in the ionic conduction, which was explained by a decrease in viscosity (Table 5). It is of note that the conductivity increased for all gel-polymeric electrolytes, because the additive introduced was built-in into the polymer structure in such a way that the microviscosity of the solution surrounding the ions remained unchanged.

Table 5. The effect of the addition of equimolar amounts of **27** on the conductivity of lithium electrolyte solutions ($c_m = 0.2$ mol kg⁻¹) at 298.15 K.⁸⁸

Salt	Electrolyte	Conductivity (mS cm ⁻¹) in a medium of			
		PC	γ-BL	DME	DMC
LiCF ₃ COO	without addition	0.33	5.2	0.024	$< 5 \times 10^{-4}$
	with addition	0.82	1.2	0.19	2.8

	with addition	2.2	3.1	2.5	0.027
Li(CF ₃ SO ₂) ₂ N	without addition	3.0	4.3	3.0	0.25
	with addition	2.4	3.3	6.9	0.42

In a number of studies, it was suggested to use lithium salts with polymeric anions. Thus for electrolytes based on acrylates of a co-polymer of ethylene oxide and propylene oxide and containing a lithium salt with a polyimide anion, *viz.*, lithium poly(5-oxo-3-oxa-4-trifluoromethyl-1,1,2,2,4-pentafluoropentamethylene-sulfonimide) (**28**), the conductivity was of an order of magnitude of 10^{-5} S cm² and the transport number of lithium > 0.7 substantially exceeded the value obtained for polymeric electrolytes with a 'monomeric' lithium salt **1**.⁸⁹ Polyanionic electrolytes prepared by introducing Lewis bases (imidazole) into the polymeric structure (the 'base in chain' method) were studied.⁹⁰ Plasticisation of the corresponding lithium polyimide salts (**29a, b**) by chloroaluminates (1 : 1) and AlCl₃ made it possible to substantially decrease the glass transition temperature (< -20 °C) and obtain liquid-phase systems with the electrolyte conductivity values currently best for polyanionic electrolytes. Thus the conductivity of lithium poly(carbamate sulfonylimide) (**29a**) reached the maximum value upon addition of 20% LiAlCl₄ ($10^{-2.9}$ S cm⁻¹ at 25 °C) (Fig. 4), whereas, for a similar complex with the 1,3-dichlorosulfonyl-1,3-dithiocarbamide (**29b**), the maximum conductivity value obtained upon introduction of 40% LiAlCl₄ did not exceed $10^{-3.3}$ S cm⁻¹. However, the presence of Lewis acids (AlCl₃, BF₃) in the system can initiate corrosion of the power source materials and other undesirable electrochemical processes. In this connection, it was proposed to 'fix' a Lewis acid directly in the polymer chain. For this purpose, the $-\text{O}-\text{B}-(\text{Ph})-\text{O}-([\text{CH}_2]_2\text{O})_n$ ($n = 2-23$) polymers synthesised by the 'acid in chain' method were transformed into polymeric anions by complexation with lithium salt anions representing Lewis acids (*e.g.*, Ph⁻, CN⁻).⁹¹ The largest conductivity values were obtained for short polyether chains $([\text{CH}_2]_2\text{O})_n$ which separated the anionic centres in the polymer. The polymers thus synthesised were reported to exhibit lower chemical activities and better compatibility with cathodic and anodic materials as compared with their analogues obtained by the 'base in chain' method. It is expected that higher values of ionic conduction can be reached by using lithium compounds with anions of a higher basicity, such as methoxide and formate ions, as well as with the methyl anion (CH₃⁻).

Figure 4. Temperature dependence of the specific conductivity of polymeric electrolytes based on lithium complexes with polyanions, *viz.*, $(1-x)\mathbf{29a}-\text{AlCl}_3$ (1:1)– $x\text{LiAlCl}_4$ (see Ref. 90). Arrows designate the conductivity of (I) an electrolyte without LiAlCl_4 at 298.15 K and (II) an electrolyte containing 20 mol.% LiAlCl_4 at the glass transition temperature; x : (I) 0, (2) 0.1, (3) 0.2, (4) 0.3, (5) 0.4, (6) 0.5.

Polymeric electrolytes with relatively high conductivities can be obtained not only in the amorphous state but also in the crystalline state. The following ‘rigid’ polymers were synthesised: poly(vinylene carbonate) (**30**) and poly(2-oxo-1,3-dioxolane-4,5-diyl oxalate) (**31**).⁹² In contrast to most polymeric electrolytes known, the addition of a lithium salt (LiCF_3SO_3) to these polymers decreased the glass transition temperature and the maximum conductivity was reached at a higher salt concentration (the molar concentration ratio of the salt to the monomeric units of polymers was 1:1). The crystalline structure of these polymers did not prevent the ionic transport, because the mobility of ions in the polymer is independent of the segmental mobility of polymeric chains.

30

31

In a number of cases, solid polymeric electrolytes based on amorphous co-polymers of acrylonitrile with the maximum concentration of lithium salt were found⁹³ to exhibit unusually high conductivity, *viz.*, $\sim 10^{-3} \text{ S cm}^{-1}$. Moreover, the conductivity of systems studied was shown to be either virtually independent of the temperature or have a weakly pronounced inverse temperature dependence as compared with the Arrhenius-type dependence. Measurements of charge transfer numbers showed that it is mainly cations that are involved in the ionic transport. An analysis of IR spectra of electrolytes confirmed the presence of substantial amounts of ion pairs, triplets and more complex associates of lithium salts. Based on these results, the authors proposed that highly concentrated macromolecular polymeric solutions have a special structure which involves ionic clusters interacting with one another. The ionic transport in such solutions proceeds by an unusual, low-energy mechanism. The use of extremely high (close to the solubility limit) concentrations of lithium salts in polymeric matrices was assumed to be promising for the development of highly conductive solid polymeric electrolytes.

Recently, great success was achieved in studying the so-called ionic liquids, *viz.*, salts with unusually low melting points, which remain in the liquid state even at room temperature. Such systems are of great interest as the electrolytes for lithium CPS. Based on lithium salts and Lewis acids (AlCl_3), the following liquid electrolyte systems with conductivities of $> 10^{-3} \text{ S cm}^{-1}$ at room temperature were synthesised: $0.33 \text{ LiCF}_3\text{SO}_3 - 0.67 \text{ AlCl}_3$,⁹⁴ $0.4 \text{ LiSCN} - 0.6 \text{ AlCl}_3$.⁹⁵ It was assumed that, due to ion–molecule interactions, the following complex anions are formed in these systems: $[\text{Al}_n\text{Cl}_{3n+1}]^-$, $[\text{Al}_n\text{Cl}_{3n-m+1}(\text{SCN})_m]^-$, *etc.*, and the melt structure changes, which makes crystallisation difficult and is favourable for the system to retain its liquid or glassy state. Moreover, the charge transfer mechanism is virtually independent of the structural relaxation of the medium (the charge is transferred preferentially by cations).

The above methods for modifying chemically the electrolytic systems are different; however, they have a common theoretical basis determined by the ion-migration (Stokes) mechanism of charge transfer. These methods were largely applied to dilute solutions of lithium electrolytes in aprotic solvents and polymers. Concentrated electrolyte solutions in aprotic solvents, which are used in lithium CPS, still remain insufficiently studied. The results obtained to date^{9,53,54} suggested that, in low-polar solvents, the greatest increase in conductivity upon addition of macrocyclic compounds takes place at concentrations below the molar conductivity minimum point, *i.e.*, where ion pairs prevail in solution. For higher concentrations (in the ‘anomalous’ range), the conductivity increased to a lesser extent, apparently, due to the changes in the nature and composition of ions.

For strongly associated electrolytes in solvents with low and moderate dielectric constants and polymers, the conductivity increases mainly due to the weakened association and increased solubility. The most pronounced weakening in the ion association was observed with the formation of lithium–cryptand complexes as compared with lithium–crown ether complexes. As a rule, an increase in conductivity in these media is proportional to the increase in the stability constant of the complex ions formed. With an increase in ligand concentration, conductivity increases and reaches a maximum at the equimolar $\text{Li}:\text{L}$ ratio. In more polar solvents, where the electrolyte is sufficiently soluble and weakly associated, and the size of the ligand attached exceeds that of the solvating shell, the mobility of ions can decrease due to an increase in their Stokes radii. For electrolytes in polar media, in which the ions are strongly solvated (*e.g.*, for lithium salt solutions in propylene carbonate, $K_a \approx 0$), the conductivity can increase as a result of weakening in solvation, and, correspondingly, a decrease in the ‘free’ (solvated) ion radius with the formation of a complex with a macrocyclic ligand. At the same time, in certain cases, a substantial weakening in the lithium ion solvation upon its complexing can increase the association constants for the electrolytes involving complex cations as compared with ordinary electrolytes.

IV. Electrolytic solvosystems for lithium batteries and mechanisms of charge transfer in solutions

To understand the reasons for the electrochemical behaviour of electrolytic systems of different nature in wide ranges of electrolyte concentrations and temperatures, it is necessary to gain an insight into the nature of charge carriers and the mechanism of charge transfer. It is known that the high conductivity typical of concentrated aqueous solutions of bases and acids used as the electrolytes in conventional CPS is caused by the chain mechanism of conduction.^{13,96,97} This mechanism is distinguished by the exchange interaction between the electrolyte ions which correspond to the lyonium and lyate ions of the solvent and the solvent molecules (H_2O , H_2SO_4 , H_2SeO_4 , H_3PO_4 , HF). Thus in an aqueous solution, hydroxonium ions (hydrated protons) and water molecules exchange protons

Several approaches were proposed for estimating different contributions to the charge-transfer mechanism in solutions.^{13, 66, 98–103} However, to date, no sufficiently reliable criteria and methods were proposed for elucidation of the nature of charge carriers, which makes the studies of the conduction mechanism in nonaqueous media quite difficult.¹⁰⁴ The greater complications arise for concentrated electrolyte solutions for which the concepts of the Debye–Hückel–Onsager theory and the law of independence of ions' motions (the Kohlrausch law) are not fulfilled. One of the approaches to assessing the conduction mechanism in electrolyte solutions consists in comparing the activation energies of the conduction and viscous flow processes. For example, within the framework of this approach, it was assumed that the charge transfer in the $\text{LiCl}–\text{AlCl}_3–\text{CH}_3\text{NO}_2–\text{SOCl}_2$ system (see Refs 27, 28) with the electrolyte concentration $> 1 \text{ mol litre}^{-1}$ occurs by both the ion-migration and chain mechanisms. The latter mechanism provided high conductivity values during the lithium battery discharge irrespective of the observed increase in the solution concentration and viscosity.

The conduction mechanism may be characterised by the transport number of ions (t_i), which however is insufficient to confirm the chain mechanism of conduction. Transport numbers of ions for most binary aqueous solutions of salts insignificantly deviate from the average value of 0.5; in aqueous solutions of acids and bases, t_{H^+} and t_{OH^-} are substantially higher, *viz.*, from 0.75 to 0.85. In nonaqueous solvents, transport numbers strongly depend on the differences in the degrees of solvation for cations and anions. For example, the greatest part of solvation energy for lithium salts in PC (up to 80%) falls to cations.¹⁷ Hence, as a rule, t_{Li^+} is smaller than the transport number of the corresponding anion and is equal to 0.3–0.5. The known attempts to analyse the experimental results on conductivities and the solution structure ambiguously assessed these data and often led to unorthodox conclusions. Thus it was suggested^{105, 106} that electrolyte solutions be considered as impurity conductors in which the charge is transferred by electrons and holes rather than by ions. Based on high-frequency studies, electrolyte solutions were concluded to have ionic lattices like those in crystals and the presence of a long-range order was assumed to be a key condition for enhancing the mobility of charge transfer in condensed media.

The possibility of realising the chain mechanism of conduction in solutions is largely determined by the structure and the degree of self-ionisation of the solvent, which depends (in protic solvents) on the strength of bridging hydrogen bonds between molecules.^{96, 97} For instance, in liquid ammonium the constant of self-ionisation (at -50°C) was found to be $\sim 10^{-23}$ due to a weak $\text{N}\cdots\text{H}\cdots\text{N}$ bond and a low ϵ , and the mobility of ions formed upon autoprotolysis was not anomalously high.^{107, 108} Such an order of magnitude is typical of self-ionisation constants of most nonassociated aprotic solvents. Nonetheless, the charge transfer by the chain mechanism can also occur in aprotic media. In this case, anomalous mobility values were observed for lyonium and/or lyate ions formed upon self-ionisation of solute associates.

In binary liquid systems formed by protic (H_2SO_4 , H_3PO_4) acids and proton-containing organic bases (RH) (such as acetamide, *N*-methylacetamide, *N,N*-dimethylacetamide, *etc.*), in the range of high acid concentrations, the charge was shown to be transferred by the chain mechanism as in individual acids.^{109–113} Bearing in mind that, for binary systems of organic bases with strong aprotic acids (MX_n) (SbCl_3 , FeCl_3 , SnCl_4 , SbCl_5), the conductivity isotherm has a maximum, it may be assumed that the charge transfer in these systems also occurs by the chain mechanism in the range of high acid concentrations. The components of these systems are prone to autoionisation; hence, the acid–base interaction occurs between the lyonium ion MX_{n-m}^+ of the acid and the lyate ion R^- of the base to give a nonelectrolyte $\text{MX}_{n-m}\text{R}_m$. This results in the increase in the concentration of the

lyate ions of the acid MX_{n+1}^{p-} and the lyonium ions of the base RH_2^+ in the solution. It is the mobility of these ions that determines the conduction of solutions.

For chlorides (solvated chloride-containing ions, *e.g.*, SbCl_4^- or AlCl_4^-) in ultra-concentrated solutions based on antimony trichloride and aluminium chloride, the following halogenotropic mechanism of conduction was postulated:^{109–111, 114, 115}

For bromides and iodides (polyiodides, I_3^- , Br_3^-), PCl_5 and PBr_5 in liquid bromine and iodine, the same mechanism was suggested.^{116–118}

It was shown¹¹⁹ that the conduction of salt solutions in low-polar solvents in a wide range of concentration (from $0.1 \text{ mol litre}^{-1}$ to fused salts) is largely determined by self-ionisation (autosolvation) of the electrolyte

where $\text{K}(\text{AK})_m^+$ and $\text{A}(\text{AK})_{n-1-m}^-$ are the autosolvated cation and anion, respectively.

According to concepts put forward,^{116–118} ions in concentrated solutions form aggregates which are involved in the charge transfer. Moreover, with an increase in electrolyte concentration, upon passing its minimum at $0.01–0.1 \text{ mol litre}^{-1}$, the molar conductivity of low-polar solutions was shown to increase due to the increased number of such aggregates, irrespective of the simultaneous increase in the solution viscosity. A hypothesis that an electrolyte in a concentrated solution passes into a state similar to that of a melt, which was put forward in the studies under discussion, was confirmed by the results of studying the molten $\text{ZnBr}_2–\text{AlBr}_3$ and $\text{SbBr}_3–\text{AlBr}_3$ systems. With an increase in salt concentration, the molar conductivity values of these melts (with a correction made for viscosity) increased up to a point where the conductivity of the individual liquid electrolyte is reached. According to this hypothesis, for any concentration of an electrolyte solution, its molar conductivity (with a correction made for its viscosity) cannot exceed the corresponding value of a hypothetical molten individual electrolyte under equal conditions. The anomalous conductivity can be observed not only for solvents with low dielectric constants but also in polar solvents at sufficiently high electrolyte concentrations. For both cases, a similar type of the dependence of the molar conductivity on the concentration was suggested.

Similar conclusions were drawn in Refs 32–34. Based on the results of studying thermodynamic and transport properties of lithium electrolytes in a wide range of concentrations in solvents of different types (glymes, sulfamides, AN, γ -BL, PC and their mixtures), it was concluded that at least two conduction mechanisms should be taken into account, *viz.*, the ion-migration mechanism, which occurs at low electrolyte concentrations, and the chain mechanism (charge transfer accompanied by rotation of complexes-associates), which occurs at high concentrations. It was assumed that the state of a highly concentrated electrolyte solution is similar to that of a fused salt. The chain mechanism of conduction can occur in both low-polar and polar aprotic solvents with sufficiently high electrolyte concentrations. In highly concentrated solutions, as the distance between ions decreases, the chain mechanism prevails and the difference in the conductivity values for solvents with low and high ϵ values decreases. A low viscosity of the medium and a high solvation power of the solvent, which weaken the ion association and facilitate reorientation of dipoles in the electric field, favour the charge transfer to occur by the chain mechanism.

However, for the chain mechanism (in contrast to the ion-migration mechanism), many properties of electrolytic systems (viscosity, solvation, association) can exert the opposite effects on the conduction. For example, despite the high viscosity of anhydrous sulfuric acid, the mobilities of the lyonium H_3SO_4^+ and the lyate HSO_3^- ions are comparable with the mobilities of H^+ and OH^- ions in water; in aqueous solutions, the mobility of protons substantially exceeds those of other ions, even if the hydration energy of H^+ is the highest; among the large number of electrolytes completely dissociated in aqueous solutions, only acid and base solutions, *i.e.*, electrolytes that comprise the ions formed by the self-ionisation (autoprotolysis) of the solvent have anomalously high conductivity values. The prototropic conduction decreases with an introduction of both electrolytes and non-electrolytes into these solutions,⁹⁷ which is usually attributed to the hydration of ions and molecules accompanied by the changes in the water structure built by hydrogen bonds. Such a structure is best suited for the chain transfer of protons. At the same time, it was found¹²⁰ that the additivity of the molar conductivity is typical of the whole composition range of an isomolar $\text{HCl} + \text{KCl}$ mixture in methanol. A similar Λ vs. composition dependence was also observed for an aqueous $\text{HCl} + \text{LiCl}$ system ($c_{\text{Li}} \leq 8 \text{ mol litre}^{-1}$). Taking into account these results, it was concluded that the prototropic mechanism of proton transfer is retained even for high concentrations of aprotic electrolytes.

It should be also noted that, in contrast to other ions, the mobilities of H^+ and OH^- increase with an increase in the pressure.⁹⁶ The temperature coefficient of conduction is positive for both aqueous solutions of acids and bases and other electrolytes with the usual ion-migration mechanism of conduction. The effect of the temperature on the structure of hydrogen bonds in water is apparently less significant compared with the effects of pressure and chemical factors (solvation). A comparison of different physicochemical parameters of water and other liquids in a wide temperature range have shown that water retains a sufficiently distinguishable structure up to the critical point.¹²¹

An analysis of the conduction data for different kinds of aqueous and nonaqueous electrolyte solutions have shown that the chain mechanism of conduction is realised in aprotic media if, first, the chemical nature of the electrolyte is similar to that of the solvent (solutes comprise lyonium or lyate ions of the solvent) and, second, at high concentrations, the solvent and/or the electrolyte form a polymeric structure with intermolecular bonds.

The presence of a certain solution structure is often characterised by high viscosity values (*e.g.*, H_2SO_4 , H_3PO_4 , H_2SeO_4 , concentrated electrolyte solutions). On the other hand, such associated liquids as water, $(\text{HF})_n$, SbCl_3 , *etc.*, in which the charge is transferred by the corresponding ions by the chain mechanism, exhibit relatively low viscosities. Evidently, under conditions necessary for the chain mechanism to occur, an additional decrease in the viscosity should facilitate the charge transfer.

To develop nonaqueous electrolytic solvosystems with the chain mechanism of conduction, it is necessary to carry out a quest for new-in-principle lithium electrolytes and nonaqueous media which will match the requirements described above. One of the approaches in such a research is to develop electrolytic solvosystems based on organolithium compounds. Organolithium compounds pertain to the group of the so-called electron-deficient structures, like organoelement compounds of the Groups II and III on the Periodic System (R_2Be , R_3B , R_3Al).^{122, 123} At the same time, organolithium compounds behave in reactions as the reagents with a deficit of electrons and react in the same manner as carbanions. The deficit of electrons manifests itself in a strong association of molecules $n\text{RLi} \rightleftharpoons (\text{RLi})_n$ ($n = 2-6$) by means of bridge bonds formed by the electrons of the $\text{C}-\text{Li}$ bond and free $2p$ orbitals of the lithium atoms. It was assumed¹²⁴ that the nature of $\cdots\text{Li}-\text{C}\cdots\text{Li}-\text{C}\cdots$ 'lithium' bonds in the associates of organolithium compounds is similar to that of hydrogen bonds.

A possibility that lithium ions of an electrolyte Li^+X^- and a solvent LiR are transferred by a mechanism similar to that of proton transfer in water, *i.e.*,

should be attributed to dissociation (self-ionisation) of the associate $(\text{RLi})_n$ (a dimer, in the simplest case)

The compound LiR should preferentially be of the nucleophilic nature, *i.e.*, have the affinity to lithium ions, and the lithium salt should contain a weakly basic anion (X^-) for these processes to be realised.

It is known that the complexes formed by aliphatic and aromatic organolithium compounds with lithium halides, which are less reactive than the original organolithium compounds, are stable in air and more handy in applications. The ability to form complexes depends on the nature of the radical (R), the lithium salt anion and the solvent. It is also of note that polyacetylene films ($\sigma = 10^{-12} - 10^{-9} \text{ S cm}^{-1}$) doped with organolithium compounds had an anomalously high conductivity ($20 - 160 \text{ S cm}^{-1}$)¹²⁵ typical of electron-conducting polymers and charge-transfer complexes.¹²⁶ In this connection, it seems interesting to explore the possibility of using organolithium compounds as one of the components of the medium (solvent) for electrolytes in lithium CPS.

* * *

In the past decade, the main research on electrolytic systems for lithium power sources was directed to modifying chemically the electrolytes and solvents traditional for this field. A key problem for these studies is the enhancement of conductivity of lithium salt solutions in aprotic solvents and polymers in order to optimise the electrochemical processes and improve the performance of lithium CPS. The advances in the field of physics and chemistry of solutions, chemistry of polymers and coordination chemistry allow one to understand and explain the specific features of charge transfer in condensed media and serve as the theoretical basis for the development of new electrolytic systems.

The most promising research directions involve the studies of highly concentrated solutions (including ionic liquids), the use of principles of molecular encapsulation of ions by macrocyclic ligands, and the quest for systems with nontraditional mechanisms of ionic transport. However, it is clear that the possibility of enhancing the conductivity within the framework of the approaches based on the ion-migration charge-transfer mechanism, *e.g.*, by reducing the solvent viscosity and the degree of ionic solvation (increasing their mobility), or decreasing the degree of association of the electrolyte (increasing the number of charge carriers) are limited.

This review was financially supported by the Commission of the Russian Academy of Sciences on the research carried out by junior scientists (the 6th competition-expertise, Project No. 160) and by the Russian Foundation for Basic Research (Project TsKP No. 00-05-401-31).

Abstract. Modern physicochemical applications of NMR tomography, or magnetic resonance imaging (MRI), to the investigation of mass transfer processes are described. The mass transfer involved in the sorption of gases, fluids and solutes, swelling of polymers and coal and drying of various materials is considered. Various methods of studying isotropic, anisotropic and restricted diffusion in porous media are discussed. The approaches to the investigation of filtration and the flow of fluids, gases and granulated materials are presented. The bibliography includes 373 references.

I. Introduction

This review concerns a number of the most widely used modern physicochemical applications of the method of NMR tomography, or magnetic resonance imaging (MRI), which mainly concern the studies in the field of the transfer (transport, flow) of fluids, gases and granulated materials. The studies devoted to the obtaining of spectral data and the NMR experiments carried out without spatial resolution are covered fragmentarily. The exception are the investigations involving the use of the pulsed magnetic field gradients for studies of the spatial molecular displacements due to diffusion, to the flow of fluids and other types of motion. These communications were covered in the review because of their great value and also for yet another reason, namely, because the corresponding experiments are often considered as the MRI studies in the molecular displacement space rather than in the conventional coordinate space. The title field of research is so broad that the published data are covered only partially. The salient features of the MRI techniques and their applications to studies of liquid-containing materials have been reported in a recent review.¹

II. Sorption into porous materials

1. General remarks

Sorption has found a very broad spectrum of technological applications including, in particular, the drying and separation of chemical substances. Transport of fluids and gases through porous materials also plays an important role in catalysis. Permeability of building materials is critical to the development and use of engineering protective structures and containers for nuclear waste. Water and brine ingress into building materials can cause their accelerated degradation following different mechanisms including freezing, uptake of ions and corrosion and affects the gas permeability and thermal conductivity of materials.

The problem of how the structure of the pore space influences the transport processes in porous media is also topical. Application of the MRI technique to studies of this interrelation offers considerable prospects, since the method allows investigation of both structural and transport features for the same sample under the same conditions. Mass transfer can be strongly affected by not only microscopic inhomogeneities with the characteristic sizes lying in the pore size length scale, but also by macroscopic structural inhomogeneities inside porous materials including those due to specific features of the preparation procedure; therefore, MRI is widely used in the studies of transport processes.

Most modern building materials, as well as soil and many catalysts contain large amounts of paramagnetic ions, predominantly, Fe ions, which are responsible for appreciable shortening of the spin relaxation times of the fluids confined within the pores of such materials and for the appearance of local inhomogeneities of the magnetic field due to different magnetic susceptibilities of the chemical substances at the interfaces (if the experiments are carried out in strong magnetic fields). For instance, the T_2 time of water present in the fired-clay red brick containing a large amount of iron was found to lie between 180 and 360 μs .^{2–4} Correspondingly, the MRI studies are often carried out in relatively weak fields ($< 1\text{--}2\text{ T}$) using strong amplitudes of the applied field gradients and appropriate experimental techniques that provide a short effective echo time.^{5,6}

Large variations of the fluid content in the sample usually cause substantial changes in the relaxation times (see Section IV.2 in Ref. 1). Short T_2 times make a complete elimination of the relaxation weighting of MRI images virtually impossible; therefore, variations of the signal amplitudes are not in proportion to variations of the fluid content in the sample. In addition, adsorption can be accompanied by pronounced variation of the temper-

ature, which also affects the relaxation time values. Therefore, quantitative measurements require the use of some references and calibration curves.

Sorption of water usually causes large variations of the dielectric losses in the sample, while the presence of paramagnetic ions affects the electrical conductivity of the sample. This can be responsible for substantial variations of the sensitivity of the NMR spectrometer as a result of detuning the resonant circuit, which additionally complicates the quantitative interpretation of experimental data and in some instances makes it ambiguous due to nonmonotonic variation in the signal amplitudes upon a monotonic change in the water content.^{7,8} For this reason, a number of experiments were carried out on a tailor-made instrument designed to study the processes accompanied by substantial variations of the water content in the samples.³

2. Sorption studies

Investigations of one-dimensional (1D) capillary sorption of water into different building material bars showed⁹ that transport of water can be described using a nonlinear 1D diffusion equation in which the effective capillary diffusion coefficient, $D(C)$, depends on the water concentration, C . For gypsum and mortar bars⁹ and for some limestone rock bars^{9,10} the D value exponentially increases with the local concentration of water. Sorption of water into cylindrical hardened mortar samples¹¹ is described by an analogous equation with exponential dependence of D on C . Transfer of water in the sample dried at 105 °C was found to occur much faster than in the sample dried under milder conditions by extraction in isopropyl alcohol followed by drying at 40 °C. This can be due to the formation of a system of interconnected larger pores in the high-temperature drying. Shortening of the T_2 time of the adsorbed water in the region behind the adsorption front with time indicates a gradual redistribution of water from capillary pores into smaller gel pores that are formed around the cement grains upon hardening of the mortar.¹¹ Capillary sorption of water into different materials is characterised by the presence of a sharp front of water. In the case of 1D diffusion the front moves in proportion to the square root of time and the amount of the adsorbed water behaves analogously.^{5,9–11} Adsorption of D_2O into samples with large initial water content was studied using the ^2D NMR signals.⁵

Often, the results of the sorption dynamics studies are presented as the $C = C(x/t^{1/2})$ dependence using the Boltzmann coordinate transformation. In these coordinates, e.g., the 1D water distribution profiles obtained^{2–4} for water in the fired-clay red brick at different times that passed after the beginning of the adsorption process fall on the same curve.⁴ Numerical simulation of adsorption using the 1D diffusion equation and exponential dependence of D on the water content

$$D = D_0 \exp(\beta C),$$

where β is the fitting parameter, led to good agreement between the calculated and experimental data.

Absorption of aqueous NaCl solution into a cylindrical calcium silicate sample was studied by simultaneously recording the 1D water distribution profiles and sodium concentration profiles.¹² Similarly to the data obtained for water, the sodium concentration profiles fall on the same curve in the $C(x/t^{1/2})$ coordinates. However, the system exhibits no sharp sodium concentration front. Virtually no sodium is present in the vicinity of the water front; sodium falls far short of the water front, being adsorbed into the pore space. It was recognised that the profiles obtained using the ^{23}Na NMR signals correspond to the sodium ions present in solution, whereas the concentration of the adsorbed sodium can be found from the adsorption isotherm measured in that study. The results obtained for sodium cannot be described by the diffusion equation in the $C(x/t^{1/2})$ coordinates even assuming that the equilibrium local concentration of the adsorbed sodium (determined from the adsorption isotherm) is reached following an exponential dependence some time after the

beginning of the process rather than instantaneously. All calculations predict the presence of a more or less sharp sodium concentration front, which contradicts the experimental results.¹² Good agreement between the calculated and experimental data for water was obtained using an exponential dependence of D on C .

To reduce the water permeability of building materials, they are impregnated with some agents based on hydrophobic polymers and other compounds. An impregnation study of a hardened mortar sample with 5% solution of alkyltrialkoxysilane in methanol showed⁶ that the impregnating agent penetrates only a short distance (1.5 mm from the surface). After drying the sample water poured on its surface did not penetrate the material, in contrast to non-impregnated blank sample. Water uptake by hardened cement samples containing both clay (sodium aluminosilicate, 2%) and polyvinyl alcohol (4%) additives was much smaller as compared to the samples containing only one additive.¹³ This behaviour was explained by the formation of a hydrophobic material (as a result of cross-linking of the aluminosilicate particles and alcohol molecules), which fills the pores, thus preventing water ingress.

MRI allows visualisation of the spatial distribution of water and hydrocarbons in rock samples, which is necessary for the development of efficient procedures for improved petroleum recovery from petroleum pools based on the results of numerical simulation of the fluid diffusion in rocks (see also Section V). In particular, adsorption of water vapour into sandstone cores of various compositions, porosities and permeabilities has been studied.¹⁴ The 1D water distribution profiles recorded at relatively low saturations allowed visualisation of the ingress of water vapour into the core through its open end. Simulation of the results obtained was carried out based on the assumption of simultaneous diffusion transport of water vapour and the adsorbed water with inclusion of the local equilibrium between them and led to good agreement between the calculated and experimental data. Assuming an exponential dependence of the vapour pressure on the concentration of the adsorbed water, it was found that D exponentially increases with an increase in the water content in the sample until the vapour filtration threshold is reached at times longer than 100 h. At even longer times, the distribution of water along the core axis became relatively homogeneous and varied only slightly upon further keeping the sample over a water bath, which was due to blocking of narrow inter-pore channels with the liquid that prevented free diffusion of vapour. Carrying out a series of experiments at different temperatures allowed the determination of the activation energy for surface diffusion.¹⁴

Selective water sorbents (SWS)^{15–17} represent porous matrices impregnated with hygroscopic salts. The ability of such materials to efficiently absorb water vapour and alcohol vapours and release a great deal of energy offers considerable prospects for versatile applications of these materials, in particular, for dehumidification of gases, in heat pumps and in chemical heat accumulators. Adsorption of water vapours by individual $CaCl_2$ -impregnated silica gel granules exposed to a humid air stream leads to the appearance of a sharp front of the adsorbed water inside the granule^{7,8,18} (Fig. 1). Therefore, the presence of salt inside the millimetre-size granules makes capillary transport inefficient. The limiting stage of the process is transport of the adsorbed water into the interior of the granule. The results of numerical simulation of the process using the diffusion equation are in satisfactory agreement with the experimental data if one assumes an exponential increase in D with an increase in the water content.^{8,18,19} The use of $CuCl_2$ allows one to follow the salt redistribution as a result of successive sorption–drying cycles for the granules prepared with inhomogeneous salt distribution.^{7,18} Granules with large initial water content were characterised by the absence of a sharp water front during the adsorption process.¹⁸

Sorption of water vapour by a cylindrical pack of SWS granules exposed to a humid air stream has been studied.^{7,8}

Figure 1. Visualisation of the adsorption of water vapours into a cylindrical silica gel granule impregnated with CaCl_2 (granule diameter: 6 mm).

Sixteen successively recorded two-dimensional images (acquisition time: ~ 15 min per image; the dark ring corresponds to the region containing the adsorbed water) (a); one-dimensional water distribution profiles along the diameter of the granule (acquisition time: 34 s per profile, the time taken to complete the experiment: nearly 5 h) (b).

Mention has been made that numerical simulation of the longitudinal movement of the sorbed water front requires the inclusion of (i) the effect of intragranular transport on the adsorption efficiency, (ii) flow dispersion effects in the porous medium and (iii) the character of the adsorption isotherm. Adsorption of water vapours by individual SWS granules and pellets and by SWS packs under vacuum has also been reported.^{8,20} It was found that transport of adsorbed water under vacuum is, by and large, much more efficient; however, it is to a great extent determined by the granule (pellet) composition and morphology.

Interest in mass transfer in zeolites is due to the wide use of these materials in separation processes, drying and catalytic reactions. MRI was used for studying adsorption of different gases and vapours by zeolites. The movement of the adsorbed

water front into the interior of the adsorbent (small crystals of zeolite 4A) has been studied in detail.^{21,22} The shape of the front and the character of its movement were found to be strongly dependent on the relative efficiency of transport in the intercrystalline space and intracrystalline transport within the adsorbent layer. For tiny crystals (several micrometres in size) one can expect that the limiting stage of transport process is the diffusion of water vapour in the intercrystalline space, while the equilibrium between the adsorbate concentration in the crystal and the vapour pressure above the surface of the crystal is described by the adsorption isotherm. In this case the process can be described using one nonlinear diffusion equation while the diffusion coefficient, D , depends on the amount of the adsorbed water and is expressed by a combination of constant diffusion coefficients of the water vapour and adsorbate inside individual crystals. When exponential adsorption isotherm is used, the D value increases as the water content increases and can be represented as the sum of a constant and an exponential term.^{21,23} Analogous experiments were carried out at different temperatures for two contacting layers comprised of 3 μm zeolite 4A granules with different initial water content.²³ Simulation of the results obtained showed that a decrease in the water content and an increase in temperature make the role of intragranular transport more significant. Equilibration of two contacting layers saturated with the light and heavy water occurs at a high vapour pressure and much faster, while the apparent (constant) diffusion coefficients of the adsorbed water and water vapour are somewhat higher than the corresponding values obtained in the equilibration experiments with a water-saturated layer contacting a dry layer. This difference becomes significant at higher temperatures and is probably due to the drawbacks of the mathematical model employed to describe the transport process. In particular, the intracrystalline vapour diffusion coefficient can also be strongly dependent on the vapour concentration. For instance, adsorption of *n*-hexane by a NaX zeolite layer is accompanied by a decrease in the intracrystalline diffusion coefficient with an increase in the adsorbed *n*-hexane.²⁴

In the beginning of adsorption process the concentration of adsorbate in the surface layer rapidly reaches a maximum value, which is followed by the movement of the sharp concentration front into the interior of the adsorbent.²² The concentration front is likely to move proportionally to the square root of time. In the later stages of the process the concentration front becomes somewhat diffuse and a wing appears in the region of low adsorbate concentration. The T_1 times obtained for water in the vicinity of and behind the adsorption front are different, which was associated with the changes in the mobility of water molecules that cannot be instantaneously located inside zeolite cavities.²² The gradual movement of a sharp adsorption front was also observed in studies of the adsorption of water or butane vapours by a layer comprised of tiny crystals (4 μm in diameter) of zeolite NaX (Ref. 25) and of the adsorption of *n*-hexane vapours by zeolite NaX layer.^{24,26} In contrast to this, experiments with zeolite NaX crystals 40 μm in diameter showed that intercrystalline transport is no longer the limiting factor and that butane remains uniformly distributed within the layer, whereas the overall amount of the adsorbed butane gradually increases.²⁵

The MRI technique can be used for studies of adsorption from solutions. For instance, the chemical shift of 1,3,5-*tert*-butylbenzene adsorbed on $\gamma\text{-Al}_2\text{O}_3$ differs from that of the bulk phase of 1,3,5-*tert*-butylbenzene. This allowed the determination of the variation of the adsorbate concentration with time and estimation of the effective diffusion coefficient for a CDCl_3 -filled granule from the NMR signal intensities.²⁷ Moreover, the chemical shift of the adsorbate can be pore size dependent. For instance, NMR studies of the samples of a carbon adsorbent characterised by a broad multimodal pore size distribution (from micropores to macropores) and saturated with solutions of acetonitrile, dichloromethane or benzene in CCl_4 revealed that the NMR spectra exhibit a superposition of several broad lines, each of them corresponding to the fluid confined inside pores of

different size. The chemical shift difference between the pore-confined and bulk-phase fluids varied from 1.4 ppm (large pores) to 9.6 ppm (small pores) for the three compounds studied. This indicates that the difference in the chemical shifts of the molecules inside pores of different size is due to different diamagnetic susceptibilities in the vicinity of the interfaces rather than donor–acceptor interactions. The ‘dips’ in the pore size distribution plot and slow inter-pore molecular exchange are two prerequisites for this conclusion. The linewidth is determined by intra-pore processes and is temperature independent in the range between 20 and 60 °C. From the surface areas of the signals in the NMR spectrum one can determine the fraction of the adsorbate inside the pores of different size (determination of absolute values requires the use of other measuring techniques). The method allows investigations of the role played by the pores of different size in the course of adsorption. As the adsorbate concentration increases from 0.2 to 1.2 mol litre⁻¹, the total amount of the adsorbate inside the micro- and mesopores is ‘saturated’, whereas the amount of the adsorbate in the large pores increases. Hence, preferred adsorption in micropores occurs initially. The T_1 and T_2 relaxation times of the peaks corresponding to different chemical shifts are also different. The T_2 times of the fluids confined in micropores remain constant as the adsorbate concentration varies, since the micropores are completely filled at a concentration of 0.2 mol litre⁻¹. At the same time, the T_2 times of the fluids confined in larger pores are lengthened as the concentration of adsorbate increases, since the fraction of the adsorbed molecules in these pores decreases. The amount of adsorbate in meso- and macropores increases with time, which is accompanied by displacement of the solvent molecules from the pores. The results obtained allowed construction of the isotherms of acetonitrile and benzene adsorption from CCl₄ separately for large, small and intermediate pores in the sample. Variation of the adsorbate concentration is accompanied by some variation of the chemical shifts of the NMR signals, which is consistent with their assignment to pores of different size.²⁸

Transport of fluids in soil is critical to soil contamination studies. Equilibration of soil and water after placing a sample of dried soil (humus) in water has been studied over a period of 50 days.²⁷ 2D spin density maps and the T_2 time maps of water were obtained. The sample was found to be inhomogeneous and characterised by a bimodal T_2 distribution and by the shift of the short- T_2 mode towards the short-time region. This is probably due to either a gradual filling of micropores with water or to gelation.

III. Swelling of polymers and coal during sorption of solvents

1. General remarks

The interactions between polymers and fluids or gases accompanied by swelling and dissolution of the polymers are of great practical value for fabrication, processing and use of polymeric materials as well as in the physical chemistry of coal. Swelling of polymers is often accompanied by gelation.

The polymer–solvent systems can exhibit various types of mass transfer. If the rate of solvent diffusion into the polymer is much lower than the segmental relaxation rate of the polymer, the diffusive transport of the solvent is usually observed, which obeys Fick’s laws (the so-called Case I transport). This type of transport is characterised by a gradual change in the solvent concentration along the direction of the solvent diffusion, movement of a diffuse solvent concentration front in proportion to the square root of time ($t^{1/2}$) and by nearly constant spin–spin relaxation time, T_2 , of the solvent in the solvent-filled regions of the polymer. A quite different behaviour is characteristic of Case II transport, which occurs if the solvent diffusion rate is higher than the segmental relaxation rate of the polymer. In this case, a clearly visible front of the solvent permeating into the polymer is observed, the solvent concentration front moves linearly with time, the solvent concentration behind the front is constant and the T_2 time is shortened

with the distance from the polymer surface contacting the solvent. The contour of the solvent front in 2D images matches that of the outer surface of the sample, through which the solvent ingress occurs, whereas in the case of Fickian transport the solvent contour acquires a circular shape after passage of a short time.

Fickian transport is usually observed in amorphous polymers characterised by the glass transition temperature lying below the temperature of the experiments. In contrast to this, realisation of Case II transport requires that the polymer be (initially) in the glassy state. Swelling of a polymer is usually accompanied by a decrease in the glass transition temperature, T_g , which can lead to transition of the polymer to the rubbery state. In addition to the two limiting cases, an intermediate type of transport (Case III transport) occurs. Often, the character of transport and its features can be revealed only using spatially resolved measurements.

Solvent transport into the interior of the polymer is often accompanied by cleavage of hydrogen bonds, weakening of other intermolecular interactions and by disentangling and moving apart the polymer chains. Infinite swelling leads to dissolution of the polymer.

Impregnation of polymeric materials with various solvents can be studied either by periodically interrupting the process to acquire MRI images or using real-time monitoring. The use of conventional techniques employed in the liquid-phase NMR allows selective monitoring of solvent transport,²⁹ whereas the signal of the solid matrix is often not observed due to short T_2 relaxation times. However, sometimes the mobility of the macromolecules becomes so high due to swelling that MRI imaging of the polymer is possible without using solid-state NMR techniques.^{30,31} It should be noted that MRI allows one to obtain separate images of the solvent and the polymer, as well as the images of individual solvents if their mixtures are used in the experiments (see Section III.1 in Ref. 1). Swelling of polymers and coal in solvents occurs at relatively low rates; therefore, corresponding experiments may take times from tens of minutes to tens of days.

2. Swelling of polymers and coal

Periodic recording of the 1D acetone distribution profiles in a vulcanised rubber sheet revealed³² a Fickian transport of the liquid. The acetone front moves from the surface into the interior of the sample in proportion to the square root of time ($t^{1/2}$), since the glass transition temperature of the polymer under study is below the room temperature (the experiment was carried out at room temperature). Nevertheless, no substantial dispersion of the acetone front was observed, which indicated an (exponential) increase in the diffusion coefficient with an increase in the acetone concentration (C) in the polymer. Transport of boiling water in a nylon-6,6 block also obeys Fick’s laws (the results obtained were described using an exponentially increasing dependence of D on C).³³ More recently,³⁴ transport of water in nylon-6,6 was studied at different temperatures between 20 and 100 °C; in this case, a linear dependence of D on C was used. The activation energy, E_a , for water diffusion in the polymer, extracted from the experimental data, was found to be 15 kcal mol⁻¹. This value is only slightly dependent on the water content. The temporal evolution of both the water distribution profiles and the spin relaxation times of water was described by the two-phase model, which implies the presence of two types of water molecules differing in degree of binding to the polymer. An increase in pressure caused an increase in both the diffusion coefficient and the maximum content of water in the polymer.³⁴

Analysis of the 2D MRI images of radial transport of 1,4-dioxane in a poly(vinyl chloride) rod showed³⁵ that the system is characterised by Case II transport and the movement of the 1,4-dioxane front into the interior of the rod is proportional to $t^{0.91}$. At the same time, the swelling-induced variation of the rod diameter was proportional to $t^{1/2}$, since the increase in the volume occurs in the polymer region that is behind the liquid front and is

in the rubbery state for which transport of liquids obeys Fick's laws.³⁵ The solvent region behind the front is characterised by a constant spin density and by lengthening of the T_2 time with the distance from the surface. A more complex picture was observed for swelling of a bisphenol A polycarbonate rod in acetone. The movement of the solvent front was proportional to $t^{1/2}$, thus indicating Fickian transport. The solvent concentration decreased from the surface towards the core of the rod, while the T_2 time was nearly constant. At the same time, the 2D images exhibited a contracting, high-intensity ring-shaped zone of the NMR signal around the core; the concentration and the T_2 time (mobility) of the solvent inside this zone were higher than outside.³⁵ This was associated with crystallisation of the polymer, accompanied by the displacement of the solvent into the interior of the sample, which causes the solvent front to move in proportion to the square root of time. Crystallisation of the sample leads to the appearance of wedge-like cracks oriented from the surface into the interior of the cylinder; on further swelling, stress cracking is developed and the cracks become larger.

The butadiene rubber–toluene,³⁶ isobutyl rubber–toluene³⁷ and methylsiloxane rubber–hexafluorobenzene³⁶ systems exhibit Fickian transport while the poly(ethyl methacrylate)–methanol and bituminous coal–pyridine systems are characterised by Case II transport (a sharp solvent front is clearly visible in the corresponding 2D MRI images and moves at a constant velocity).^{36,37} It was found that, due to attenuation of the signals characterised by short T_2 times, the solvent front in the MRI images can appear to be sharper than that which actually exists.³⁶ A relatively simple model proposed for the description of the kinetics of the process couples the solvent diffusion and the polymer network relaxation upon transition from the glassy state to the rubbery state.³⁶ The experimentally measured solvent front velocities were used for calculations of the constant solvent diffusion coefficient in the glassy polymer and the polymer relaxation rate constant. The poly(methyl methacrylate)–methanol system exhibits Case II transport, which is probably due to the presence of the initial Fickian induction period.³⁸ The 2D images of poly(methyl methacrylate) rods partially saturated with deuteromethanol (CH_3OD) or acetone and the 2D maps of both the spin relaxation time distribution and the diffusion coefficient of the solvent were also obtained using the NMR signal of the solvent.³⁹ The presence of a sharp solvent front and a constant solvent concentration in the region behind the front are indicative of Case II transport. When moving from the glassy core into the interior of the swollen region, the T_1 and T_2 times and the diffusion coefficients of both solvents increase and then reach a plateau. This behaviour can be due to gradual increase in the polymer mobility along the polymer chain that is fastened at one end (in the glassy domain of the sample) and to the effect of the polymer mobility on the mobility of the solvent molecules. In practice, the behaviour of the system can strongly depend on the presence of residual amounts of the monomer or water in the polymer. For instance, an increase in the initial water content in poly(methyl methacrylate) increased the diffusion rate of methanol during the absorption process. If the water content exceeds 1 mass %, a passage from the Case II transport to Fickian transport of methanol occurs.⁴⁰ The absorption–desorption cycling of water and methanol followed by drying of the polymer also accelerate the diffusion of methanol in poly(methyl methacrylate) and the diffusion kinetics alters from Case II diffusion to Fickian diffusion. In all cases the initial period of absorption was characterised by a specific type of methanol diffusion, intermediate between the Fickian diffusion and Case II diffusion.⁴⁰

Studies of the swelling of a poly(vinyl chloride) rod in toluene for 15–50 h revealed^{41,42} a sharp solvent front characteristic of Case II diffusion. The solvent front contour matched the cross-sectional shape (round or square) of the sample. When toluene penetrated into the rectangular rod through two oppositely lying surfaces, two parallel solvent fronts moved to meet each other.⁴² At the same time the high-density polyethylene–n-pentane system

exhibited a diffuse circular n-pentane front⁴¹ typical of Fickian diffusion. The sample of stretched poly(vinyl chloride) used in yet another study⁴¹ was prepared as follows. A poly(vinyl chloride) pipe was heated above the glass transition temperature of the polymer and expanded in a radial fashion. Then, slices were cut from the pipe, parallel to the pipe symmetry axis. Investigation⁴¹ revealed strong anisotropy of solvent diffusion during the swelling process. In this case, the diffusion of toluene or trichloroethylene in the polymer occurred only in the direction corresponding to the radial direction for the initial pipe and was accompanied by elongation of the sample in the same direction and by contraction of the sample along the axis orthogonal to the direction of solvent diffusion. The anisotropy of the properties of the polymer was found to be hard to detect by high-resolution solid-state NMR techniques irrespective of the presence or absence of solvent in the sample.

Swelling of a copolymer of 2-hydroxyethyl methacrylate (HEMA) and tetrahydrofurfuryl methacrylate (THFMA) in water has been studied.²⁹ The diffusion coefficient of water ($D_{\text{H}_2\text{O}}$) in polyHEMA is $(1.5\text{--}2) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$; in the copolymer the $D_{\text{H}_2\text{O}}$ value decreases with an increase in the THFMA content due to the lower polarity of THFMA. The NMR images obtained revealed a Fickian diffusion and the peaks corresponding to increased content of water in the region between the diffusion front and the glassy core of the sample at the mole fractions of HEMA greater than 0.6. The peaks are thought to be due to the formation of small cracks appeared in peripheral regions of the glassy core owing to stress induced by swelling of the outer part of the sample; the cracks are filled with water. Further swelling of the polymer leads to closure of the cracks, while the region with the increased water content moves through the sample along with the diffusion front. As the diffusion front reaches the core of the sample, the peaks in the MRI images disappear along with the glassy core.

The character of diffusion for the same polymer–solvent pair can change appreciably with temperature. For instance, the diffusion of methanol in poly(methyl methacrylate) is Fickian at temperatures above 60 °C and Case II diffusion at temperature below 30 °C, whereas in the temperature range between 30 and 60 °C one can expect a combination of the two diffusion mechanisms.^{43,44} The character of diffusion can also strongly depend on the degree of cross-linking of the polymer. For instance, the diffusion of dioxane in a material prepared by polymerisation of styrene with divinylbenzene (DVB) additives can obey Fick's law (5% DVB), be Case II diffusion (1% DVB) or exhibit an intermediate diffusion type (2.5% DVB).⁴⁵ An increase in the degree of cross-linking of the polymer chains is accompanied by substantial reduction of the velocity of the movement of the dioxane front into the interior of the polymer sample.

Ageing of polymers strongly affects the diffusion processes. This was shown,⁴⁶ in particular, in the study of swelling of natural rubber exposed to high-temperature ageing at 170 °C in C_6D_6 . At the ageing times of the order of 50–100 min, the diffusion and swelling rates in the surface layer, in which the ageing occurs most intensely, increase. At prolonged ageing, radical polymerisation in the presence of oxygen induces cross-linking of the polymer chains, which precludes the changes in the size of the sample due to swelling, but has no effect on diffusion. The anisotropy of the polymer structure strongly affects its swelling behaviour, *e.g.*, the change in the size of the sample.

Swelling of a polymer proceeds differently when a mixture of two or more liquids is used instead of the individual liquids. Swelling of a bisphenol A polycarbonate rod in a mixture of acetone and methanol (a good and a poor solvent for the rod material, respectively) has been studied using the difference between the chemical shifts of the solvents.³⁵ It was shown that the presence of methanol reduces the rate of acetone diffusion in the polymer, whereas the diffusion coefficient of methanol increases in the presence of acetone. Analogous studies of the diffusion of individual components of acetone–methanol mix-

tures with different component ratios were carried out using deuterated compounds.⁴⁷ A square-root-of-time dependence of the movement of the solvent front and a constant T_2 time of acetone in the region behind the solvent front were interpreted as manifestations of Fickian diffusion. In mixtures with the mole fraction of acetone being less than 50% both solvents diffuse with the same rate, whereas diffusion of acetone in the mixtures with higher content of this component occurs faster. Swelling of a cylindrical vulcanised rubber sample in an acetone–methanol mixture has been studied based on large difference between the chemical shifts of the mixture components.⁴⁸ It was found that both liquids diffuse in the mixture with the same rate equal to 80% and 250% of the diffusion rates of benzene and acetone, respectively, in the case of single-component impregnation. The creation and recording double-quantum coherence of the nuclear spins allowed one to follow isooctane diffusion in identical cylindrical sample impregnated with cyclohexane.⁴⁸ Swelling studies of cross-linked polystyrene in C_6F_6 revealed the presence of the absorption front. However, no clearly visible absorption front was observed for polystyrene initially saturated with C_6H_6 ; structural inhomogeneities favoured diffusion transport of liquid.⁴⁹

A polymer gel based on poly(*N*-isopropylacrylamide) and H_2O/D_2O with CH_3OD additive, in which cross-linking of the polymer chains occurs in the presence of different amounts of *N,N'*-methylenebisacrylamide, is known to have the lower critical solution temperature.⁴⁶ As the temperature exceeds the critical value or as the concentration of the organic component of the solvent increases, the gel undergoes a transition from the swollen to the 'compressed' state. This behaviour can be used for fabrication of automatic chemomechanical valves. The 2D NMR images of a cylindrical sample revealed a decrease in the diameter of the sample with an increase in the temperature of water. The process was accompanied by the change in the T_2 -contrast due to the variation of the mobility of the polymer and water molecules. Experiments with a D_2O-CH_3OD mixture showed that the initial stage of CH_3OD diffusion in the polymer gel obeyed Fick's laws. Since the degree of swelling of the polymer gel depends on the local component ratio in the solvent, this causes some changes in the polymer gel structure, followed by deviation of the diffusion mechanism from Fickian diffusion. Sometimes the formation of a surface layer was observed, which slowed down or precluded further ingress of the solvent into the polymer gel.

Not only the solvent behaviour, but also the changes in the properties of polymers have been studied. In particular, a study of the swelling of the peroxide vulcanised natural rubber in decane^{21, 50} revealed a correlation between the T_2 time of the polymer and the local concentration of decane in the sample. An empirical relationship was suggested to describe the correlation. It was also found that the diffusion coefficient of decane exponentially increases as its local concentration increases. The study⁵¹ of swelling of poly(ethylene oxide) in water showed that both diffusion of water in the swollen hydrogel and the swelling process are diffusion controlled and not accompanied by the change in the overall volume of the polymer and water. It was also found that monitoring simultaneous ingress of H_2O and D_2O into the polymer from the opposite ends of the sample allows one to observe the redistribution of the light and heavy water in the sample even after the two solvent fronts meet. The use of CD_2Cl_2 as solvent permitted the observation of the ^1H NMR signal of the polymer prepared by cross-linking the liquid-crystalline nematic prepolymer chains.⁴⁶ The ^1H NMR signal of the polymer was shown to increase with the degree of swelling of the sample. In this case, solvent diffusion along the polymer chains occurs much faster than lateral diffusion, the latter being jumpwise.

Sodium polyacrylate is a hydrophilic polymer capable of absorbing large amounts of water (several hundred times its own mass).⁵² The 1D H_2O profiles obtained in the course of swelling of the polymer in water indicate a Fickian diffusion of water. Swelling was accompanied by shortening of the T_2 time of water due to gelation. By recording the NMR signal of the polymer it

was shown that the swelling of the polymer followed by gelation occurred nearly two times faster than the movement of the water front into the interior of the polymer. It was found that distilled water diffuses faster than water containing salts and other impurities due to different chemical potential gradients.

Swelling of polymers occurs not only when the polymers contact liquids, but also when they are exposed to vapours. For instance, the ionic conductivity of polymer electrolytes $(Pb,Zn)(CF_3SO_3)_2(PEO)_n$ [PEO is poly(ethylene oxide)] is enhanced by several orders of magnitude upon adsorption of water vapours.⁵³ The 1D spin density and T_2 profiles for the adsorbed water and for the water-soaked polymer were obtained. In a number of experiments the contributions of water and polymer were separated using D_2O . The experiments confirmed that the adsorbed water exhibits a Fickian diffusion despite the presence of a sharp front. At the same time, the results obtained using the NMR signal of the polymer are quite different, namely, the signal amplitude is constant in the region behind the water front, while the T_2 time is shortened along the direction from the adsorbing face into the interior of the sample. The apparent velocity of the H_2O front movement was much higher than in the case of D_2O ; this was explained by different dynamic properties of water and the polymer. An amorphous film with high content of poly(ethylene oxide) contained crystalline domains of the pure polymer with characteristic sizes from 500 to 800 μm . The 2D NMR images of the films totally exposed to water vapours showed that adsorption of water by the sample occurred due to the amorphous phase and caused a transition of the crystalline domains to the amorphous state.⁵³

Similar discrepancies between the results obtained using the NMR signals of the solvent and polymer were also observed during adsorption of acetone vapours by poly(vinyl chloride) samples.⁵⁴ In this case, the solvent exhibited a Case II diffusion with a constant acetone concentration behind the liquid front; however, a 'Fickian precursor', that is, a long wing of low intensity and substantial extension into the interior of the polymer, was observed ahead of the solvent front. Variation of the signal behind the liquid front was rationalised by gradual softening of the swollen polymer. Another possible explanation is low segmental mobility of the polymer chain in the glassy region of the sample and gradual increase in this parameter with an increase in the depth of penetration into the rubbery swollen region.³⁹ The acetone and polymer signals were distinguished⁵⁴ using both deuterated acetone and the difference in the T_2 times. Despite the fact that the samples studied were synthesised in the United Kingdom while studied in Germany, it was stated that no errors were introduced. The charge carrier distribution in the polyelectrolyte-based electrochemical cells has been studied.⁵⁵

Analysis of the profiles acquired using the NMR signals of polymers characterised by high segmental mobility [experiments on adsorption of the deuteriochloroform or carbon tetrachloride vapours by poly(methyl methacrylate) or polystyrene bars] revealed⁵⁶ a Fickian diffusion in these systems. This conclusion is based on the assumption of proportionality of the local concentration of the mobile polymer to the local concentration of the adsorbed solvent. However, the T_1 profiles showed that the T_1 time of the polymer varies along the length of the sample even after establishment of homogeneous swelling after long-term impregnation with the liquid. This was interpreted as a consequence of the polymer mobility gradient.

Water diffusion is of great importance for food polymers since the presence of water affects the quality and the shelf life of food products. Studies of amylose pellets prepared from corn starch revealed⁵⁷ a Fickian diffusion of water in the sample exposed to water vapours and a Case II diffusion of water in the polymer sample contacting liquid water; in addition, polymer swelling in the latter case occurred much faster than in the former. The signal amplitudes were converted into actual water content using an empirical calibration relationship.

The 2D NMR images obtained in the course of swelling of bituminous coal in deuterated solvents (pyridine, acetone) exhibited⁵⁸ a gradual increase in the concentration of proton-containing substances in solution, which was attributed to the removal of loosely bound solvent molecules from coal. The NMR signal of protons inside the coal sample was detected only after 48 h monitoring, thus reflecting the appearance of mobile proton-containing components. A sample of another type of coal exhibited conventional swelling; however, only the NMR signal of the surrounding liquid was observed.⁵⁸

In a number of studies the NMR images of polymers and coals partially saturated with a certain solvent were presented 'as is' without reporting the swelling dynamics data. Rod-like samples of bisphenol-acetone epoxy resin reinforced with a glass fibre swell in water at 93 °C in different manners depending on the character of the curing agent used in the sample preparation.⁵⁹ The difference is first of all due to the character of the microcracking of the sample. The distribution of water in the samples remains inhomogeneous even after swelling over a period of 90 days. The surface swelling occurs mainly in the vicinity of the glass fibre bundles.⁵⁹ The 2D images of the signal intensity and T_2 time distributions obtained for a rod-like sample of polybutadiene rubber completely saturated with 1,4-dioxane⁶⁰ revealed inhomogeneity of the polymer structure, which is due to, *e.g.*, poor mixing of the components or nonuniform heating in the course of the preparation and vulcanisation of the polymer. Saturation of a sample of natural rubber with hot water allowed visualisation of pores connected to the outer surface while the NMR images of a sample of vulcanised rubber completely saturated with cyclohexane allowed one to find the regions characterised by increased degree of cross-linking of the macromolecular chains.⁶¹

In spite of very broad NMR signals (300–800 Hz), the B₁-imaging technique¹ was successfully employed to acquire the 2D images of cellulose exposed to acetic acid vapours for 48 h and polystyrene swollen in liquid n-pentane for 72 h.⁴² The images of coal samples swollen in acetone, DMSO or pyridine over a period of several hours allowed studies of the coal morphology and its changes caused by swelling.⁶² It was found that permeation of solvents into coal was essentially inhomogeneous. The presence and arrangement of microcracks, cavities, mineral inclusions and other coal structure peculiarities was found using pyridine and pyridine-d₆.⁶³

Studies of solvent desorption from a polymer are also of interest. If swelling of a polymer exhibits a Case II diffusion, one can expect a transition of the polymer from the rubbery state to the glassy state in the course of desorption, which must affect the efficiency of solvent transport. The dynamics of changes in the NMR images of a poly(methyl methacrylate) rod in cyclohexane-d₁₂ at 30 °C (the sample was preliminarily kept in CH₃OD at the same temperature) has been studied.⁶⁴ During the first 60 min period the concentration of methanol in the surface layer of the sample substantially decreased and then varied only slightly over a period of 100 h. The results obtained suggested that the near-surface layer of the polymer undergoes a glass transition faster than other regions of the sample, which strongly hampers transport of the desorbing methanol.

Studies of infinite swelling resulting in dissolution of polymers are of interest from the standpoint of, *e.g.*, the development of controlled drug release systems based on dissolution of polymeric supports. For instance, water diffusion in a polyvinyl alcohol pellet (the molecular mass of the polymer lies between 35 740 and 133 000) causes a transition of the polymer to the rubbery state under normal conditions.⁶⁵ The 1D water content profiles exhibit a steep liquid front, thus indicating a relaxation-controlled (Case II) transport. For the rubbery domain, the water distribution profiles have a plateau and suggest a low diffusion resistance. As the molecular mass of the polymer increases, the diffusion rate decreases. Numerical simulation showed that the diffusion coefficient of water decreases with the distance from the pellet surface, since restricted mobility of the polymer chains in the vicinity of the

glassy core hampers transport of water. As time passes, the diffusion coefficient in the vicinity of the pellet surface contacting the solid surface increases while remains constant near the free surface contacting the solvent.

A gel layer surrounding the pellet reduces the rates of dissolution and outward diffusion of drugs.^{66,67} Swelling of a hydroxypropylmethylcellulose (HPMC) pellet in water was characterised⁶⁶ by gradual permeation of water into the pellet and by swelling-induced movement of the interface. The penetration depth of water is a function of the square root of time, $t^{1/2}$. The T_2 relaxation times of water were converted into the 1D polymer concentration profiles along the direction of swelling using the results of NMR calibration experiments. After swelling for 37 h the pellets became four-fold thicker. The regions with the HPMC content greater than 30% remained solid; reduction of the HPMC fraction to 10%–30% was accompanied by gelation, while in the regions with the HPMC content less than 10% the polymer slowly dissolved and diffused into the bulk water phase.

Osmosis-based substance release mechanisms were found to act for water in a silicon matrix containing NH₄F.⁶⁸ In the presence of salt the T_1 and T_2 times of water are shortened and the ability of the cylindrical polymer sample to absorb water is enhanced considerably. Water diffusion in the matrix was accompanied by the formation of concentrated brine droplets that grew under the action of osmotic pressure. The process was monitored over a period of three months. The spatial distribution of water in a cylindrical sample containing 1% NH₄F was more or less homogeneous during the observation time. At 5% NH₄F, after swelling for seven days the content of water in the inner region of the sample was lower than in the outer region. After swelling for 35 days at the same concentration of NH₄F the content of water in the outer region of the sample decreased. This is due to the development of stress cracking in the matrix and to release of the content of brine 'pools'. Cracking of the sample was initiated at the surface and gradually moved into the interior.

Poly(hydroxyalkanoates) form a family of semicrystalline biopolymers. They are of interest because of biocompatibility and the ability to undergo biodegradation under the action of enzymes released by microorganisms. Enzymatic degradation of thin polymer films (0.2 mm) has been studied.⁶⁹ Since the crystalline domains do not contribute to the NMR signal, the signals observed in the experiments carried out at 50–60 °C after washing and drying the sample corresponded to the spin density in the amorphous domains. At the beginning of the process the content of amorphous polymer exponentially decreased and after some time became a linear function of time. In the deeper stages of the process enzymatic degradation of both the amorphous and the crystalline polymer occurred, which was confirmed by comparing the results of NMR imaging experiments and mass loss measurements.

IV. Drying

1. General remarks

Drying has found numerous technological applications. For instance, quality of cement and concrete articles depends on the water content in set and dried materials. Drying is used in film technologies (adhesives, binders, paints, coatings, *etc.*), synthesis of catalysts and treatment of food products and vegetable materials.

Violation of the drying regimes is often accompanied by deformation and cracking of articles and coatings. Because of this, the development of methods for controlling the water content in the samples in the course of the drying process is of great importance. MRI allows one to obtain necessary information and real-time monitoring makes it reliable.

The spin relaxation times of water in many porous materials are short due to the presence of paramagnetic impurities, reduction of molecular mobility owing to binding H₂O molecules and to the interactions of water molecules with the developed surface of

solids. This situation occurs, in particular, in the studies of cement and concrete. For instance, the relaxation times of hydrated white Portland cement are as follows: $T_2 = 320 \mu\text{s}$, $T_2^* = 170 \mu\text{s}$ and $T_1 = 1.2 \text{ ms}$.⁷⁰ Therefore, quantitative studies require the use of solid-state NMR techniques.^{71–77} For instance, the use of strong gradients of the stray fields of a superconducting magnet in the STRAFI technique¹ allows the recording of the proton signals even for the hydrated and gel phases during hydration of cement.⁷⁸ The single-point imaging (SPI) technique is also promising,^{1,70} though these methods do not allow the imaging of the whole amount of water in hydrates^{78,79} [this water has a T_2^* time of $20 \mu\text{s}$ (Ref. 79)]. Samples tens or hundreds of micrometres thick are studied using the GARField device, which produces a homogeneous magnetic field in the plane of the sample and a strong static gradient in an orthogonal direction.^{80,81} The advantage of the design is that the sample is placed on the surface of the probe rather than inside it.

It should be noted that the relaxation times are usually shortened as the water content decreases; therefore, the signal amplitude is not proportional to the actual water content in the sample. Often, the signal amplitudes are corrected using some calibrations obtained by independent methods of water content determination.⁸² This allows one to exclude, in particular, the influence of other factors on the amplitude of the NMR signal. For instance, large variations of the water content in the sample cause detuning of the resonant circuit and change the sensitivity of the NMR probe.

2. Drying of materials and films

As mentioned above, MRI allows one to monitor the processes associated with the presence of water in cement, mortar and concrete. Hydration of cement during the first 48 h after the preparation of the cement paste has been studied by periodically recording the 1D water content profiles along the axis of the sample placed in a glass ampoule.⁷⁸ The experiments showed that water displaced from the bulk of the sample is present above the cement surface and the linear dimensions of the sample are reduced owing to shrinkage. The appearance of hydrates caused appreciable shortening of the T_2 time of a fraction of the H_2O molecules; therefore, even with an echo time of $30 \mu\text{s}$ the signal amplitude is attenuated and does not correspond to the actual content of water. Gypsum and lime additives cause a decrease in the degree of shrinkage of the samples and a faster attenuation of the signal amplitude.

The drying of cement^{70,79,83} and concrete^{79,83,84} after long-term moist curing has been studied. The samples were of different compositions and had different initial water content, the drying time being also different. During the first 24 h of drying, the water content in the sample decreased appreciably in the region near the open surface and to a lesser extent along the full length of the sample up to its closed end (due to capillary flow).⁷⁰ Capillary transport plays a more important role in the samples with high initial water content, since in this case the amount of hydrate formed is insufficient for filling the volume that was initially filled with water.⁸³ As the water-to-cement mass ratio decreased to 0.3–0.4, almost the whole amount of water was involved in the hydrate formation. For longer moist curing periods the porosity and permeability of the samples decreased, thus substantially reducing the efficiency of capillary transport of water in the course of drying.^{79,83} In the deeper stages of the drying process, capillary transport of water changed to diffusion transport, which was accompanied by the movement of the drying front into the interior of the sample.^{83,84} Compared to cement, the loss of water in concrete occurred faster in the early stages of the drying process, while in deeper stages the loss of water occurred more slowly. The presence of large aggregate particles in concrete prevented the material from cracking under the action of the surface tension forces due to the presence of the residual water in the pores of size 2.5 to 50 nm.

Interpretation and quantitative analysis of the data on the drying of cement and concrete first of all require detailed analysis of the relaxation behaviour of water in order to elucidate the correspondence between the NMR data and the actual water content in the sample. Probably, sometimes the signal amplitude reflects the distribution of only that fraction of water, which can be removed by drying,⁷⁹ and does not reflect the water in the gel pores.⁸⁴ For concrete samples moist cured for a long time (28 and 90 days), variation of the amplitude of the MRI profile was proportional to the change in the water content, whereas for the samples moist cured for no longer than 24 h this proportionality was observed only after drying over a period of a week.⁷⁹ This is probably due to the presence of at least three types of water molecules characterised by different (and variable) T_1 and T_2 times and, hence, by different (and variable) relative contributions. At the same time, in some instances the T_2^* time is independent of the water content, *i.e.*, the amplitude of the MRI profile is proportional to the water content.⁷⁰ When the T_1 times are analysed using the stretched exponent

$$M_z(t) = M_0 \left\{ 1 - 2 \exp \left[- \left(\frac{t}{T_1} \right)^\alpha \right] \right\} \quad (1)$$

(M_z is the longitudinal magnetisation of the nuclear spin system), the parameter α characterises the size distribution of the filled pores, which allowed the detection of the onset of microcracking 28–90 days after the beginning of the drying process.⁸³ The T_1 , T_2 and T_2^* maps for mortar and partially dried concrete were obtained.⁸⁵

Analysis of the 2D images and relaxation parameters of water in cylindrical samples of cement at low temperatures showed that the addition of superplasticiser favours a decrease in porosity, reduction of the pore sizes and precludes the formation of macropores in which water freezes at relatively high temperatures.⁸⁶ The variation of T_1 [determined according to Eqn (1)] during the hydration process revealed that the addition of the superplasticiser causes an increase in the setting time of cement and the rate of subsequent hydration. The fact that the parameter α reaches the maximum value at long times is thought to be associated with the formation of microcracks.

Drying of fired clay brick, lime-and-sand brick and gypsum by blowing air with a relative humidity of 45% (at 20°C) over the open end of cylindrical samples has been studied by periodically recording the 1D water distribution profiles along the axis of the samples.^{3,87} In all cases, a relatively homogeneous decrease in the water content along the full length of the sample was initially observed. As time passed (7 to 20 h), the drying front moving into the interior of the sample was observed. The gypsum and lime-and-sand brick samples exhibited a nonzero residual water content in the region behind the drying front. Transport processes were simulated using the diffusion equation, which allowed one to obtain the dependence of the effective diffusion coefficient on the water content for the materials under study. Namely, for all the samples the D value decreased with decreasing C (for C lying in the range from 5% to 20%), was minimum at $C = 2\%–5\%$ and increased again on further decreasing the water content. The last-named feature is associated with increasing importance of the diffusion transport of water vapour at low water content and with the presence of a plateau in the adsorption isotherm.⁸⁷ To obtain a more reliable $D(C)$ dependence in this range of water contents, the movement of the drying front was simulated using a constant velocity model. The velocity of the front movement was strongly dependent on the type of the material and inversely proportional to the length of the sample.

Drying of a cubic limestone block at 105°C was studied by periodically interrupting the drying process to acquire the NMR images.⁸⁸ It was found that the completely dried block exhibits an NMR signal of unknown nature, which is characterised by rather long relaxation times ($T_1 = 300 \text{ ms}$, $T_2 = 30 \text{ ms}$). If the water content exceeds 15% of the maximum value, drying is accompa-

nied by a relatively homogeneous decrease in the water content in the entire block; at lower water content, the drying front moving into the interior of the sample was observed. In this stage, the water present in the sample was confined in a spherical 'pool' contracting in the course of the drying process.⁸⁸

Drying of liquid-saturated porous cylindrical granules (Al_2O_3 , SiO_2 , TiO_2) by blowing dry air has been studied.^{7, 8, 89, 90} Due to the fact that the acquisition time of the 2D images was much longer than the complete drying time of the sample (< 1 h), attempts at obtaining time-resolved profiles for quantitative data analysis failed.⁸⁹ Recording the 1D water content profiles along the diameter of a cylindrical granule allowed substantial reduction of the time taken to complete a single experiment (0.5–1 min), thus providing a way of studying radial transport of liquid inside the granules in the course of the drying process.^{7, 90, 91} A special series of experiments was carried out to plot a calibration curve relating the amplitude of the experimental profile to the actual water content. The results obtained and their numerical simulation^{91, 92} showed that in the early stages the drying process proceeds at a constant rate, the slow drying regime being maintained due to efficient capillary transport of the liquid inside the granule. This was confirmed by nearly homogeneous dehumidification of the sample. Only after removal of nearly the whole amount of water the drying rate decreases, which is accompanied by creation of strong water content gradients within the sample. The effective 'capillary diffusion' coefficient, D , depends on the concentration, C , of water in the sample and much exceeds the self-diffusion coefficient of water at high C . The $D(C)$ dependence is closely related to the pore size distribution and can exhibit local extrema against the trend towards decreasing D with a decrease in the water content for the samples with complex pore size distribution patterns (e.g., bimodal). Experimentally, this manifests itself in nonmonotonic variation of the curvature of the water content profile during the drying process. The character of the profile transformations is related to the degree of homogeneity of the granules.⁷ In particular, the granules having small pores in the near-surface region are characterised by higher water content near the surface in the course of the drying process compared to the interior of the granules, though evaporation of water occurs from the surface. Inhomogeneities inside the granules cause significant distortion of the shape of the profiles. Experiments with organic liquids (acetone, cyclohexane or benzene) showed that redistribution of the liquid due to capillary flow is much less efficient and the liquid content profiles acquired during the drying process have a clearly visible dome-like shape.^{7, 90}

Drying of the monolithic alumina catalysts saturated with water by passing a stream of dry air through their transport channels has been studied. The apparent uniform decrease in the water content along the length of the monolith is due to redistribution of water owing to the action of capillary forces.^{7, 8, 93} A modified catalyst sample of identical shape, in which longitudinal transport of water in the transport channel walls was impossible, exhibited a decrease in the drying rate with the distance from the inlet flat wall of the monolith.^{8, 20} Slow drying of the monolithic catalyst in the absence of air circulation and adsorption-contact drying of a monolithic catalyst using fine-grained alumina or zeolite powders has also been studied.

A number of studies have been concerned with the drying of various water-saturated granular packs, such as glass bead packs (bead size: 0.3–1 mm),^{94, 95} sand packs (grain size: 50–100 μm), potato starch packs (granule size: 20–50 μm), silica gel packs (granule size: 40–60 μm)⁹⁵ by blowing the pack surface with dry air. The NMR images obtained exhibit inhomogeneous patterns of drying inside the packs.⁹⁴ Investigations of the effect of surface tension on the drying process were carried out with an aqueous detergent (sodium dodecylsulfate) solution.⁹⁵ The experimental results were discussed using a model, which included the diffusion transport of water and the influence of the capillary and gravity forces that play a significant role in the case of packs of larger particles.⁹⁵ Drying of (i) packs comprised of water-saturated

Figure 2. Two-dimensional MRI images obtained in the course of drying water-saturated alumina granules by blowing dry air through a cylindrical pack.

A pack of alumina granules 2.8 mm in diameter and 3.2 mm long (slice selective imaging technique; a slice 5 mm thick) (a); a pack comprising non-porous glass granules 2.4 mm in diameter and 2.2 mm long (invisible in the images) and a total of ten alumina granules (imaged without slice selection) (b).

porous alumina granules and (ii) mixed packs of non-porous and liquid-saturated porous granules^{7, 8} (Fig. 2) has been studied. These experiments allow studies of the details of mass transfer processes for grains located at different distances from the reactor walls.

A sample comprising a number of parallel, constant-diameter capillaries closed at one end is characterised by inefficient capillary transport. Exposure of the open end of a water-saturated sample to air stream led to establishment of fast drying regime, which was characterised by the movement of the sharp evaporation front along the capillaries towards the closed end.^{7, 96} The propagation of the evaporation front was proportional to the square root of time, while the estimate of the diffusion coefficient ($D = 0.24 \text{ cm}^2 \text{ s}^{-1}$) coincided with the diffusion coefficient of water vapour in air.

Evaporation of water from sodium silicate based films was studied by recording the 1D water content profiles in the direction normal to the film surface.⁸² Experiments on drying of the films at 22–62 °C showed that water is faster removed from the near-surface region and that strong humidity gradients appear inside the films. Analysis of the T_2 distribution suggested a decrease in the molecular mobility in the course of the drying process, the molecular mobility at a particular water content being independent of the drying regime. Despite the introduction of corrections for short relaxation time, the hydration values calculated for the most dry films were found to be nearly twofold underestimated. Therefore, quantisation was performed using a calibration obtained by weighing the samples with homogeneous water content. The spatial resolution of the technique (100 μm) was determined by the accuracy of orientation of the film plane normal to the direction of the (static) magnetic field gradient and by the magnitude of stepwise displacement of the sample in the course of the measurements.

The deposition of solid colloidal particles onto a surface *via* the drying of waterborne dispersions is an important process in nature and in many technologies. Recently, this process has attracted increased interest due to ecological problems. The drying of thin colloidal films occurs in the horizontal direction. Changes in the water distribution in the films are accompanied by transport of the solute molecules. Horizontal drying of the dispersions of acrylic latex and polystyrene latex with systematic variation of the particle size, film thickness and evaporation rate has been studied.⁹⁷ For relatively large particles, low evaporation rates and small film thickness the film edges are not completely dried over a rather long time and the central region of the film remains more wet than the peripheral zones. Then, the drying

front comes into play, moving inward from periphery, the interface between the dry and wet regions being diffuse. Ahead of the drying front, a clearly visible particle-packing front moves. In the second limiting case, the drying and particle-packing fronts overlap and move inward from the periphery just after the beginning of the drying process.⁹⁷ If a droplet of aqueous dispersion of acrylic latex is dried by exposing to air stream, a 'skin' is formed on its surface.⁹⁸ The formation of a film upon simultaneous drying and photo-induced cross-linking of the aqueous dispersion of (vinyl acetate)-*co*-ethylene copolymer based latex indicates a complex picture of changes in the concentrations and molecular mobility with the thickness of the sample. This is due to different processes, such as diffusion of water, oxygen and cross-linking agent, transmission of light and free-radical polymerisation.⁹⁹

Alkyd polymers prepared from natural substances (*e.g.*, fatty acids and oil) have found increasing use as paints. Unlike solid particles of colloidal dispersions, alkyd droplets are readily deformable in emulsion, which can affect the drying process. Therefore, drying of aqueous emulsions of an alkyd resin has been studied.^{81, 98} The difference between the chemical shifts of oil and water is sufficiently large to obtain separate NMR images.¹ It was shown that drying of a droplet deposited onto a solid surface and exposed to either stationary air or air stream was accompanied by a decrease in the size and thickness of the droplet.⁹⁸ The water loss rate was minimum at the edge and maximum at the centre of the droplet due to horizontal outward transport of water. The total amount of water decreased linearly with time over the whole observation time.^{81, 97} No increase in the alkyd resin concentration at the edge of the droplet was observed. The experimental data were compared with the results of model calculations. When the film was dried in stationary air, the film thickness linearly decreased with time during the first 13 min.⁸¹ The 1D T_2 distribution profiles obtained after 18 min exhibit a clearly visible near-surface layer, or a 'skin', characterised by much shorter T_2 time and by an increase in the thickness with time, while the underlying region of the film remains wet. The presence of a sharp interface indicates a strong dependence of the diffusion coefficient on the water content. After 190 min, the 'skin' extends throughout the full thickness of the film and the sample is characterised by one T_2 value.⁸¹ In auto-oxidative cross-linking of an alkyd resin film in the presence of a cobalt catalyst, a decrease in the amount of solvent is accompanied by shortening of the T_2 time as a result of cross-linking.⁸⁰

Drying of composite liquid packaging cardboard by exposing both surfaces to air flow (20.5–60 °C) has been studied.¹⁰⁰ The air flows were of different rates and humidities. The 1D water content, T_1 and T_2 profiles were acquired. Initially, the concentration of water in the two outer layers was higher than in the middle layer. During drying the profiles became narrower due to shrinkage of the cardboard sheet. Under faster drying conditions the water loss was predominantly from the near-surface regions, while with slower drying conditions the water loss occurred uniformly throughout all layers. Initially, the drying rate was nearly constant, and then decreased.

Knowledge of water distribution in wood is of great importance for wood-working industry. Drying of white oak lumber samples has been studied by periodically recording the cross-sectional 2D NMR images over a period of two weeks.¹⁰¹ The drying rate was found to be strongly dependent on the thickness of the sample and on the orientation of the wood rays and the growth rings with respect to the outer surface. Water loss from the surface of the wood was accompanied by the formation of a more dry near-surface region and more wet inner region, while outward transport of water could occur through wood rays.¹⁰¹ Polyexponential analysis of the spin relaxation times in different stages of the drying of cedar and fir samples allowed one to distinguish and follow the behaviour of different types of water molecules (water on the walls and inside the walls of the earlywood tracheids, latewood tracheids and wood rays) for the sap-wood and heart-wood regions.¹⁰² The T_2 time is determined by exchange of water

molecules between the surface and the bulk water phase, and the experimental values were consistent with the cavity sizes typical of tracheids and wood rays. Acoustic drying of wood has also been studied.^{103, 104} The acoustic field was shown to induce a substantial redistribution of water in the sample, which favours water recession.

Drying of food products and vegetable materials has been studied. For instance, the cross-sectional 2D NMR images of a corn spadix exposed to air flow at 60 °C exhibited a decrease in the water content inside the corn grains and reduction of the grain sizes.¹⁰⁵ A drying study of individual grains has been reported.¹⁰⁶ Drying of textile articles provides an example of drying of synthetic fabrics.¹⁰⁷

V. Diffusion

1. General remarks

NMR diffusion studies have been carried out for more than five decades.^{108, 109} One of the modern NMR applications, the multi-dimensional DOSY (diffusion ordered spectroscopy) technique, provides a tool for the analysis of the NMR spectra of complex mixtures based on the differences between the diffusion coefficients of different molecules, for estimation of the molecular sizes and for detection of molecular aggregates.^{110–114} MRI also allows spatially resolved diffusion studies.

Recently, considerable attention has been given to investigations of restricted diffusion of fluids and gases in porous materials (in this case, the presence of some obstructions/barriers imposes restrictions on the molecular displacements and, in particular, diffusion transfer).^{115, 116} Observation of the diffusive motion of the molecules in a porous medium permits extraction of information on the structure of the pore space. Generally, the apparent diffusion coefficient of the molecules in the pore space, $D(\Delta)$, depends on the observation time, Δ . At short Δ , the $D(\Delta)$ value is independent of the morphology of the porous structure and is defined as follows^{117–119}

$$\frac{D(\Delta)}{D_0} = 1 - \frac{4}{9\sqrt{\pi}} \frac{S}{V} \sqrt{D_0 \Delta} + O(D_0 \Delta). \quad (2)$$

Thus, diffusion studies at short Δ allow the determination of the pore surface-to-volume ratio, S/V . In addition, in the limiting case ($\Delta \rightarrow 0$) the molecules have no time to 'sense' the presence of barriers (see below) and the measurements give the self-diffusion coefficients of fluids.

In the long-time limit ($\Delta \rightarrow \infty$), one gets

$$\lim_{\Delta \rightarrow \infty} \left[\frac{D(\Delta)}{D_0} \right] = \frac{1}{T}, \quad (3)$$

where T is the tortuosity factor of the pore space.^{117, 118} There are also some interpolation formulae,^{117, 120} which make it possible to calculate the $D(\Delta)/D_0$ ratio at intermediate Δ values in the range between ~ 0 and $\sim \infty$.

Determination of the tortuosity factor of the pore space from the asymptotic behaviour of the diffusion coefficient requires that the molecule migrate over a distance of the order of the characteristic inhomogeneity size in the sample during the observation time. At the same time, pore size distribution measurements based on the results of analysis of the spin relaxation behaviour of a fluid assume an insignificant role of the inter-pore migration of the molecules. As can be seen, the two types of measurements are in some sense mutually exclusive.¹²¹ Gases usually diffuse much faster than fluids. Therefore, the short-time limit is hard to study for gases; however, the long-time limit can be investigated with ease.^{122–124} This can be of use in, *e.g.*, the studies of the samples with extended structural inhomogeneities.

In studies of the properties of the pore space considerable advances can be achieved using an analogy between diffusion and hydrodynamic (or gasodynamic) dispersion of flow through a

porous medium (see Section VI.4), since the dispersion coefficient can be much larger than the effective diffusion coefficient.¹²⁵

For the molecules in voids (in contrast to the interconnected pore space) the maximum migration length is limited to the void size and the product $D(\Delta)\Delta$ reaches a plateau while the $D(\Delta)$ coefficient tends to zero as Δ increases.^{117, 126} This can be used for the determination of the characteristic volume of droplets, cells, *etc.*, which imposes restrictions on the diffusion. At the same time, in contrast to relaxation porosimetry data (this technique is sensitive to the smallest characteristic size of essentially non-spherical pores, such as long cylinders and slits), the results of diffusion coefficient measurements obtained in the long-time limit depend on all characteristic pore sizes; therefore, it is not necessarily true that the asymptotic limit for $D(\Delta)$ is reached over the observation time [$\Delta < (3-5)T_1$].¹²⁷

Multiple-quantum coherence (MQC) technique with $n > 1$ is known to be more sensitive to inhomogeneities of the magnetic field than the NMR signal ($n = 1$).^{128, 129} This can be useful in measuring small diffusion coefficients. Intramolecular MQC can be created for both single quadrupolar nuclei¹³⁰ and for the system of interacting spins within the same molecule.¹³¹ If the samples have strong NMR signals, the intermolecular MQC can be created using the nonlinear echo technique¹³² based on the long-range intermolecular dipolar interaction between the nuclear spins, or the dipolar demagnetising field (DDF) technique. Experiments with a number of fluids showed¹³³ that for intermolecular multiple-quantum coherence one gets $D_{\text{ap}} \approx nD$, where D_{ap} is the apparent value (*cf.* $D_{\text{ap}} = n^2D$ for intramolecular n -quantum coherence).

The methods described below allow one to obtain information on the molecular diffusion over distances of the order of 0.1 μm , which is much better than the spatial resolution of the MRI technique. Thus, by considering the 'displacement space' it is possible to substantially improve the spatial resolution of the NMR experiments.¹³⁴

2. Methods of diffusion studies

One approach to the investigation of diffusion processes with the NMR technique involves the use of the concentration gradient of tracers or labelled compounds. In the presence of stable radicals and paramagnetic metal ions the relaxation times of the fluid or gas molecules contacting the unpaired electron spin are shortened. Diamagnetic compounds containing different nuclei and their isotopes, including mixtures of proton-containing compounds and their deuterated analogues, are also used. These experiments are most often carried out using the spatially resolved NMR imaging techniques in order to follow the temporal and spatial redistribution of tracers and then to determine the diffusion coefficient using numerical simulation methods.

A simple 'null-point' technique^{135, 136} proposed for the studies of diffusion of paramagnetic substances involves the observation of the displacement of the concentration front of the paramagnetic tracer over relatively short distances, with the concentration variation being small compared to the average tracer concentration in solution. This allows reduction of the time taken to measure the diffusion coefficients to tens of minutes instead of much longer time (*e.g.*, several days) required when using the methods based on the recording of variations of the total concentration profiles with time. Experimentally, the 1D concentration profile is acquired some time after inversion of the equilibrium magnetisation. The delay time is chosen in such a way that the desired concentration of the paramagnetic tracer corresponded to the passage of the magnetisation through zero when the signal is acquired. After calculations of the absolute values of the signal the profile exhibits a clearly seen, sharp minimum corresponding to the position of a given concentration of the diffusing paramagnetic tracer. A 2D version of the technique was also proposed.¹³⁷

MRI also allows diffusion studies without creating the gradient of the diffusing substance. In this case, selective inversion or saturation of the signal from a certain region of the sample can be

used as 'marker'. If no convection occurs, the 'dip' in the signal amplitude curve is recovered as a result of diffusion and spin-lattice relaxation.

Diffusion displacements of various molecules can be studied using the well-known¹⁰⁹ pulsed magnetic field gradient NMR techniques (pulsed field gradient, or PFG, and pulsed gradient spin echo, or PGSE). By modifying the conventional echo pulse sequence and by using strong pulsed field gradient amplitudes (up to 2500–5000 G cm⁻¹)^{138, 139} one can measure the diffusion coefficients of the order of 10⁻¹⁰ cm² s⁻¹. The measurement error is usually 5% to 10% of the measured values and depends on many factors^{140, 141} including finite duration of the gradient pulses^{142–144} and gradient-induced eddy currents,^{112, 145–147} local field gradients due to the presence of interfaces between materials with different magnetic susceptibilities,^{148–151} convection,¹⁴⁷ temperature errors and radiation damping effects.¹⁴⁸ Thorough consideration of these factors allows¹⁴⁰ the experimental error to be reduced to less than 1%. Diffusion studies can also be carried out using (quasi-)static field gradients.

The PFG technique is based on analysis of the dependence of the spin-echo signal amplitude on the magnitude of the applied field gradient. For a system of immobile spins the dephasing of precession of the nuclear spins experiencing different magnetic fields is reversible. However, random molecular displacements in inhomogeneous magnetic fields lead to incomplete rephasing of the NMR signal when the spin echo signal is created. Currently, the pulse sequences employed in PFG experiments utilise a pair of gradient pulses applied to the spin system after the transverse magnetisation is created. The gradient pulses have the effective amplitudes $-g_i$ and g_i ($i = x, y, z$), the same duration δ and are delayed by the time Δ [if a 180°-radiofrequency (RF) pulse is applied between the gradient pulses in order to rephase the transverse magnetisation, the gradient pulses must be of the same sign]. In this case, the expression for the spin-echo signal amplitude derived in the short gradient pulse approximation assuming unrestricted diffusion has the form¹⁰⁹

$$E(b) = \exp(-Db), \quad (4)$$

where

$$b = \gamma^2 g^2 \delta^2 \Delta_{\text{ef}} \quad (5)$$

(γ is the gyromagnetic ratio for the nuclei under study).

For the normal distribution of diffusive displacements one gets

$$\Delta_{\text{ef}} = \Delta - \frac{\delta}{3}. \quad (6)$$

Thus, the plot of the $-\ln[E(b)]$ dependence is a straight line with the slope D (see Ref. 109)

$$-\ln[E(b)] = Db. \quad (7)$$

Since varying the durations of the gradient pulses and delay times in the pulse sequence can affect the signal amplitude due to relaxation effects, the experiments usually involve variation of the gradient amplitudes g_i by using multiple repetition of the pulse sequence. Often, these measurements take a long time (see Section II.2 in Ref. 1); therefore, a number of fast techniques for diffusion studies have been developed.^{123, 152} In the case of multi-component solutions or mixtures the measurements can be performed for each component.

The experiment in question involves measurements of the projections of the molecular displacements on the direction of the field gradient. Often, diffusion is spatially anisotropic. The diffusion anisotropy can be detected by projecting the diffusion displacements on different spatial coordinates, which can be achieved by judicious choice of the direction of the field gradient. However, obtaining more detailed information on the diffusion anisotropy requires the determination of the 3×3 -diffusion tensor rather than scalar D_i values ($i = x, y, z$). Different elements of the diffusion tensor (including off-diagonal elements) can be deter-

mined from a special-purpose experiment in which the gradient pulses are applied along different directions (i, j) and the scalars b_i are replaced by a tensor with the elements

$$b_{ij} = \gamma^2 g_i g_j \delta^2 \Delta_{\text{ef}}, \quad (8)$$

which determine the contribution of each element of the diffusion tensor D_{ij} to the signal attenuation.^{152, 153} In principle, carrying out a total of six experiments with different orientations of the gradient vectors and one experiment without diffusion weighting (at $g = 0$) is sufficient for the determination of the elements of symmetrical diffusion tensor.

Sometimes, it is sufficient to know, *e.g.*, the spur of the anisotropic diffusion tensor, which is equivalent to the orientation average of the diffusion coefficient tensor. This can be achieved by performing one experiment with non-zero gradients (and one experiment with $g = 0$), in which the spin echo signal amplitude is proportional to the spur of the diffusion tensor.¹⁵⁴ However, the obtaining of an NMR image, in which the signal amplitude is proportional to any characteristic of the anisotropy of the diffusion tensor, *e.g.*, the dispersion and asymmetry coefficients (the second and the third moments, respectively), requires the same number of measurements ($6 + 1$) as that needed for the determination of all elements of the symmetrical diffusion tensor.¹⁵⁴

Diffusion is strongly affected by the presence of impermeable barriers (pore walls) to molecular motions. In this case, the $E(b)$ dependence cannot be described by the simple expression (4) and can also be nonmonotonic. This makes it possible to use the NMR technique in studies of the morphology of the materials in which restricted diffusion occurs.

The effects accompanying diffusion between two impermeable barriers were described¹⁵⁵ using three characteristic sizes [characteristic diffusion length l_d , pore size l_p and the parameter $l_g = (D_0/\gamma g)^{1/3}$]. Three limiting cases were considered, where one size was much smaller than the other two sizes. Since at $l_d \ll l_p$ most of the molecules do not ‘sense’ the barriers, one can expect that the corresponding experiments must give a correct value of the self-diffusion coefficient of the fluid, D_0 . However, the unrestricted diffusion regime can be attained only if the condition $l_d \ll l_g$ is simultaneously met. Then the spin-echo signal amplitude is given by expression (4). If $l_g \ll l_p$, l_d , a ‘localised’ diffusion regime is realised. In this case, the largest contribution to the observed NMR signal comes from the spins located in the near-wall region. In MRI, this leads to the so-called ‘edge enhancement’ effect and to a decrease in the observed D value. The third regime (at $l_p \ll l_g$, l_d) corresponds in MRI to the collapse of an image to a single-peak. Experimentally, the three regimes can be distinguished based on the shape of the $E(b)$ dependence. The first and second regimes were demonstrated taking the diffusion of water in a slit 160 μm wide between parallel glass plates (the slit is too wide to allow realisation of the third regime). The geometry of the experiment permits comparison of the results obtained for unrestricted and restricted diffusion by applying the field gradient parallel or normal to the plates.¹⁵⁵

Consideration of molecular diffusion in a regular system of voids or in an interconnected pore system exhibits an analogy between the PFG NMR and diffraction in optics.^{116, 134, 156, 157} As the observation time (Δ) passes, the diffusion-‘diffraction’ effects cause the appearance of extrema on the $E(q)$ dependence ($q = \gamma g \delta / 2\pi$) for a void of diameter a . Positions of the minima are close to the integer values of the product aq , which can be used for estimating the pore size. The situation becomes more complicated in the case of non-spherical pores. Numerical experiments on the diffusion in a cylindrical pore at arbitrary orientation of the axis of the cylinder with respect to the direction of the field gradient show the presence of two systems of minima on the plot of the dependence of the echo amplitude on q . These minima correspond to the motion along and normal to the axis of the cylinder, their amplitudes increasing with the increase in the $D\Delta$

product.¹⁵⁸ In one limiting case (large molecular displacements and small q values) the effective diffusion coefficient, $D = D_{\text{ef}}$, equals $L^2/12\Delta$ and $R^2/4\Delta$ if the field gradient is applied along and normal to the axis of the cylinder, respectively (L is the length and R is the radius of the cylinder). In the small-displacement limit, the $E(q)$ dependence in the form

$$E(q, \Delta) = E_A(q) = \exp(-4\pi^2 q^2 D \Delta_{\text{ef}}) \quad (9)$$

is observed only at small q ; at large q , the $E(q)$ dependence obeys a power law. An ensemble of randomly oriented non-spherical pores and the system of aligned pores are characterised by different functions $E(q)$. However, the pore orientation distribution and the pore size distribution can be distinguished only using a special-purpose experiment involving two successive ‘scattering’ acts, as was used in studies of the shape of the yeast cells.¹⁵⁹

The effect of the pore space geometry is of particular interest when following the spin motion in interconnected pore systems.^{125, 134, 160} For a regular system of pores interconnected by narrow channels the coherence effects are also manifested as extrema on the $E(q)$ plot in the $\Delta \rightarrow \infty$ limit. If the regularity of the pore space is not perfect, the $E(q)$ plot will exhibit a diffuse peak at $q \approx 1/b$ corresponding to the nearest environment, similarly to X-ray diffraction in liquids (b is the distance between the adjacent pores). The coherence effects are also substantially weakened due to orientational disordering of the pore necks; however, the effect of the structure of the pore system on the $E(q)$ dependence is still retained. Meeting the condition $2D_{\text{ef}}\Delta \approx b^2$ is optimal for obtaining information on the structure of the pore space. At $D_{\text{ef}}\Delta \gg a^2$ (a is the pore diameter) one can distinguish three regimes, *viz.*, $q \ll 1/b$, $q \sim 1/b$ and $q \sim 1/a$. The case $q \ll 1/b$ [initial portion of the $E(q)$ dependence] corresponds to large molecular displacements and allows the determination of the D_{ef} value, the D_{ef}/D_0 ratio tending to $1/T$ at $\Delta \rightarrow \infty$ (T is the tortuosity factor of the pore space). At $q \sim 1/b$, the $E(q)$ dependence for a regular pore structure exhibits a peak. This is true assuming equilibration of the situation inside the pore, when the characteristic time of migration over a distance of the order of the pore size is shorter than the characteristic time of inter-pore migration. At $q \sim 1/a$, the $E(q)$ dependence passes through a minimum, as in the case of isolated pores. At short diffusion times, Δ , the D value is independent of the morphology of the pore space, being determined by the S/V ratio for the pore space [see formula (2)].

Integration of the $E(q)$ dependence over q gives the probability for a particle to return to (or remain in) the vicinity of its initial position after a given diffusion time Δ .^{144, 161} This parameter can be used in studies of the pore space in materials with the broad size distributions of pores and solid grains constituting the material. For instance, the studies of rock cores revealed a correlation between the above-mentioned probability and hydraulic permeability of the samples.

NMR imaging in the displacement space (q -space, in contrast to NMR imaging in the k -space, or coordinate space) allows one to obtain not only the averaged diffusion characteristics (*e.g.*, the diffusion coefficient), but also complete information on the molecular displacement distribution over the observation time. Diffusion displacements can be characterised by the function $P(\mathbf{r}|\mathbf{r}', \Delta)$, which represents the probability density for a molecule initially located at the point $\mathbf{r}$ to appear at the point $\mathbf{r}'$ after time Δ .^{116, 141} The quantities measured in the NMR experiments are inevitably averaged over a large molecular ensemble present in the entire sample or in its macroscopic region. In addition, the $P(\mathbf{r}|\mathbf{r}', \Delta)$ parameter can vary in the microscopic length scale. Averaging of $P(\mathbf{r}|\mathbf{r}', \Delta)$ allows passage to the formalism of the averaged propagator $P(\mathbf{R}, \Delta)$, which gives the probability density for a molecule to migrate (or to be displaced) over the distance $\mathbf{R} = \mathbf{r}' - \mathbf{r}$ over time Δ irrespective of its initial position $\mathbf{r}$. At long observation times, Δ , the propagator can be considered as the autocorrelation function of the molecular displacements^{143, 156} or

as the autocorrelation function of the pore shape in the direction of the applied field gradient;^{159, 162} this allows the determination of the pore size as the half-width of the $P(\mathbf{R}, \Delta)$ peak, which describes the shape of the propagator as a function of $\mathbf{R}$.

The averaged propagator $P(\mathbf{R}, \Delta)$ is often measured using the above-mentioned pulse sequence with two pulsed gradients. In this case, the spin-echo signal amplitude is represented as a function of the following parameter

$$\mathbf{q} = \frac{\gamma \mathbf{g} \delta}{2\pi}. \quad (10)$$

The vector $\mathbf{q}$ is analogous to the wave vector $\mathbf{k}$; however, the $\mathbf{q}$ space is the reciprocal of the displacement space $\mathbf{R}$ rather than the coordinate space $\mathbf{r}$. If the gradient pulses are short, the spin-echo amplitude $E(\mathbf{q}, \Delta)$ and the averaged propagator are mutually conjugate:^{116, 141, 163}

$$E(\mathbf{q}, \Delta) = \int P(\mathbf{R}, \Delta) \exp(i 2\pi \mathbf{q} \mathbf{R}) d\mathbf{R}, \quad (11)$$

$$P(\mathbf{R}, \Delta) = \int E(\mathbf{q}, \Delta) \exp(-i 2\pi \mathbf{q} \mathbf{R}) d\mathbf{q}. \quad (12)$$

In the new notations, expression (4), which holds for unrestricted diffusion, takes the form of Eqn (9). The corresponding propagator describes a Gaussian distribution of diffusive molecular displacements centred at $\mathbf{R} = 0$:

$$P(\mathbf{R}, \Delta) = \frac{1}{\sqrt{4\pi D_{\text{ef}} \Delta}} \exp\left(-\frac{R^2}{4D_{\text{ef}} \Delta}\right). \quad (13)$$

q -Spectroscopy experiments involve multiple repetitions of the pulse sequence upon stepwise variation of the q parameter (as a rule, using a constant increment of the gradient amplitude). Some advanced techniques with variable q increment (in particular, this permits shortening of the measurement time) have also been developed.^{164, 165}

Dynamic q -space NMR imaging allows the determination of the spatially resolved averaged propagator $P(\mathbf{r}, \mathbf{R}, \Delta)$ and extraction of information on the displacements $\mathbf{R}$ that can be much smaller than the spatial resolution of the imaging experiments. In dynamic NMR imaging the signal amplitude, $S(\mathbf{k}, \mathbf{q})$, is experimentally measured as function of the $\mathbf{k}$ and $\mathbf{q}$ vectors at fixed Δ values

$$S(\mathbf{k}, \mathbf{q}, \Delta) = \iint \rho(\mathbf{r}) P(\mathbf{r}, \mathbf{R}, \Delta) \exp 2\pi i (\mathbf{k} \mathbf{r} + \mathbf{q} \mathbf{R}) d\mathbf{R} d\mathbf{r}, \quad (14)$$

where $\rho(\mathbf{r})$ is the spatial distribution of the spin density.

The multidimensional Fourier transformation technique makes it possible to derive the averaged propagator $P(\mathbf{r}, \mathbf{R}, \Delta)$ as a function of the coordinate $\mathbf{r}$ and to separately measure the propagator for each pixel of the NMR image using the formula^{116, 141}

$$\rho(\mathbf{r}) P(\mathbf{r}, \mathbf{R}, \Delta) = \iint S(\mathbf{k}, \mathbf{q}, \Delta) \exp(-2\pi i (\mathbf{k} \mathbf{r} + \mathbf{q} \mathbf{R})) d\mathbf{k} d\mathbf{q}. \quad (15)$$

Like usually, in this case the direction of the measured molecular displacement component is determined by the applied field gradient, *i.e.*, the $P(\mathbf{R}_i, \Delta)$ value is measured experimentally, where $\mathbf{R}_i$ is the projection of the displacement vector on the direction of the applied field gradient. However, independent stepwise variation of two or three orthogonal field gradients allows the determination of the probability $P(\mathbf{R}, \Delta)$, where $\mathbf{R}$ is the displacement vector in the 2D or 3D space, though these experiments are time-consuming and, hence, rare.

The averaged propagator formalism is applicable to the description of the experiments with short gradient pulses. Experiments with the gradient pulses of arbitrary duration and shape can be described using the formalism which is not based on the

averaged propagator and thus can also be applied to the description of non-Markovian processes.¹⁶⁶

The maximum observation time in the PFG NMR experiments is determined by the T_2 time or by a combination of the T_1 and T_2 times of the diffusing molecules. To increase the observation time, the stimulated echo sequence is often employed instead of the spin echo sequence, which makes it possible to extend the time Δ up to the times of the order of T_1 rather than T_2 or T_2^* . Experiments with inert gases can also be useful, since their spin relaxation times are much longer than those of fluids. However, the relaxation times can be substantially shortened upon pore filling with a fluid or a gas. The relaxation times also impose restrictions on the observation time in the experiments with the diffusion recovery of the NMR signal after local disturbance by the RF pulses. In the tracer concentration gradient experiments the observation time is limited to the time taken to equilibrate the tracer concentration over the sample. It should be noted that these types of experiments are inequivalent in the sense that the corresponding diffusion coefficients can be different since different measuring techniques are sensitive to the structure of the pore space in different length scales.¹⁶⁷

Another approach to the description of displacements of molecules is to use the velocity autocorrelation function.¹⁶³ The frequency analysis of this function can be performed by judicious choice of the frequency spectrum for the time integral of the effective field gradient. A study of the gradient sequences that allow one to determine the spectral densities of the velocity autocorrelation function in the frequency range (ω) from 10 Hz to 100 kHz has been reported.¹⁶³ The $D(\omega)$ coefficient of bulk water was shown to be constant in the frequency range studied (210–1670 Hz).

Due to a finite switch on–switch off time of the pulsed field gradients the molecular displacements are hard to measure at times of the order of 100 μs . In this case, the oscillating field gradients are sometimes employed.¹⁶⁸ A single field gradient pulse diffusion study technique based on the effects of long-range dipolar interaction in liquids has been proposed.¹⁶⁹ Diffusion and relaxation time studies (including spatially resolved ones) can also be carried out with the gradients of the radiofrequency field B_1 instead of the gradients of the static magnetic field B_0 .^{129, 170, 171}

As mentioned above, a feature of porous materials placed in a magnetic field is the appearance of internal field gradients due to the presence of interfaces with different magnetic susceptibilities. Diffusion in the presence of local field gradients also causes attenuation of the NMR signal; however, an increase in the observation time causes the signal amplitude to reach some constant level rather than to decrease down to zero. The characteristic time taken to reach the asymptotic limit is determined by the time of diffusive displacement of a molecule over a distance of the order of the pore size.¹⁷² If the pore system exhibits a pore size distribution, the decay of the signal is characterised by a set of characteristic times. The inverse Laplace transform allows the determination of the characteristic decay times and the pore size distribution for the sample under study.¹⁷³

3. Use of tracer concentration gradients

Diffusion in a cylindrical zirconia granule pre-saturated with water and placed in an ampoule with D_2O was studied¹⁷⁴ using the ^1H NMR signal of the 1D projections of the sample on the direction normal to the axis of the cylinder. The radial distribution of water was reconstructed using the Abel transform. The use of the 1D technique allowed the recording of a large number of profiles over the complete diffusion mixing time of two liquids. The effective diffusion coefficient and the tortuosity factor of the pore space ($T = 1.98$), which appeared to be close to the reciprocal of the sample porosity, were determined using numerical simulation of diffusion in a cylinder.

Diffusion of water in Laponite gel (synthetic smectic clay) was studied by recording the 1D profiles along the same axes of two cylindrical samples placed in contact through the flat walls to

initiate diffusion.¹⁷⁵ One of the two samples was prepared using heavy water (D₂O). Fitting of the experimental profiles was performed with inclusion of fast H/D exchange and corrected for the dependence of the NMR signal amplitude on the local light/heavy water ratio, which causes appreciable changes in the T_2 -weighting degree of the NMR signal. The (macro)diffusion coefficient of light water ($1.50 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$) was found to be close to the (micro)diffusion coefficient obtained using the PFG technique ($1.75 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$); both values are only slightly smaller than the self-diffusion coefficient of bulk water ($2.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$) under these conditions. This is thought to be due to the 'open' structure of the gel consisting of platelets.¹⁷⁵

Fractal systems exhibit anomalous self-diffusion and the mean square of molecular displacements is time dependent

$$\langle r^2 \rangle \sim t^{2/d}. \quad (16)$$

For unrestricted diffusion, $d = 2$; visualisation of light water diffusion in the pores of a percolation model object pre-saturated with D₂O gave a d value of 2.6.¹⁷⁶

Low-temperature conservation of *in vitro* grown living tissues requires the use of cryoprotective agents. Cryoprotective solutions are usually introduced at a low temperature to prevent the development of osmotic stress and to reduce the toxic action on the tissues. A study¹⁷⁷ of DMSO/D₂O mixture ingress into artificial dermal replacement saturated with H₂O revealed a decrease in the rate of water diffusion with an increase in the DMSO concentration due to the strong interaction between the DMSO and water molecules, which leads to higher ultimate (equilibrium) concentrations of H₂O. Analysis of the behaviour of two samples (one of them was freeze dried) showed that the presence of living cells causes acceleration of water diffusion due to osmosis effects. As the temperature decreases below room temperature, diffusion slows down. Permeation of aqueous solutions of three cryoprotective agents into a dechorionated fish embryo has also been studied.¹⁷⁸ Methanol was found in the embryo after 15 min, whereas no DMSO and propylene glycol were detected even after 2.5 h. It was concluded that the syncytial layer of yolk is impermeable for DMSO and propylene glycol and prevents them from being transferred into the interior of the embryo.

Measurements of the diffusion coefficients of copper ions or 4-amino-TEMPO[†] nitroxyl radical from aqueous solution into various gels along the axis of cylindrical samples have been reported.¹³⁵ Due to the more 'open' gel structure with larger pores, diffusion of copper ions in agarose gel ($D = 4.8 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$) occurs faster than in acrylamide gel ($D = 3.3 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$) and silica gel ($D = 3.5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$). The diffusion coefficients of nitroxyl radical in gels were found to be nearly 80% of the corresponding values for the copper ion due to the larger size of 4-amino-TEMPO. Diffusion of Fe(II) and Fe(III) ions in a cylindrical sample of agarose gel has been studied by simulating the 1D diffusion process and led to $D = 2.7 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ for Fe(III) and $D = 3.3 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ for Fe(II) at room temperature.¹³⁶ Radial diffusion of copper ions in a hollow cylinder made of polyacrylamide gel, whose cavity was filled with an aqueous CuSO₄ solution ($D = 3.5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$), has also been studied.¹³⁷ The acquisition time was less than 3 min per 2D NMR image, which is shorter than the time taken to move the diffusion front over a distance of the order of the characteristic spatial resolution achieved in the experiment (0.15–0.5 mm). Diffusion of Mn²⁺ ions from aqueous solution into agarose gel has been reported.¹⁷⁹ The radical 4-hydroxy-TEMPO was used¹⁸⁰ to investigate diffusion from aqueous solution into silk fibroin gel ($D = 8.1 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$). The NMR images obtained were both T_1 - and T_2 -weighted;¹ because of this, an increase in the local

concentration of the radical in gel initially caused an increase and then a decrease in the water signal amplitude.

Diffusion of paramagnetic tracers in liquid-saturated porous media has been studied¹⁸¹ using a tailor-made cell with an impermeable horizontal barrier between two sand layers (grain size: 250 μm). In the first experiment the upper layer was saturated with an aqueous NaCl solution while the lower layer was saturated with the same solution to which NiCl₂ (5 mmol litre⁻¹) was added. The experiment started with removal of the partition and the 2D images were obtained by acquiring the NMR signal of water, which was directly proportional to the concentration of the Ni²⁺ ions in the concentration range studied (0–5 mmol litre⁻¹) due to judicious choice of the experimental parameters. In the second experiment the upper (lower) sand layer was saturated with aqueous KCl (NaCl) solution and the 1D fluid distribution profiles were obtained by directly acquiring the ²³Na NMR signal. The diffusion coefficients obtained after fitting the experimental data were $2.7 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ for Ni²⁺ and $1.04 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ for Na⁺. The difference between these and actual values can be due to the effect of the Cl⁻ ions present in solution on the diffusion process. Despite the thin barrier (200 μm), the apparent diffusion coefficients for the lower layer were found to be substantially (by a factor of 3.5) overestimated due to a non-ideal contact between two sand layers.¹⁸¹

4. Diffusion studies without use of tracers

As mentioned above, an extensive literature has evolved, concerning the studies of fluid diffusion in various materials. Measurements of the D and S/V values for water diffusion in a glass bead pack,¹⁶⁰ of the D value and the pore space tortuosity factor for porous granules and catalyst powders^{182–184} and of the temperature dependence of D for anions and cations diffusing in concentrated electrolyte solutions¹⁸⁵ can serve as examples of these studies. The diffusion coefficients of hexadecane in silica and of MgO/n-octanol paste have been measured.¹⁸⁶ The experiments aimed at investigating the effects of the local field gradients were carried out using a Fe₂O₃ powder additive to MgO/n-octanol paste. Studies of water and brine diffusion in carbonate and sandstone rock cores have been reported.^{117, 121, 187} It was shown¹¹⁷ that in the short-time limit ($\Delta \rightarrow 0$) the D value tends to the self-diffusion coefficient, D_0 , of the bulk fluid. Measurements carried out at short Δ allowed the determination of the S/V ratio [formula (2)] and the surface relaxivity. At long Δ , the D/D_0 ratio decreases^{117, 187} and tends to $1/T$; however, this limit was reached for none of the samples studied.¹¹⁷ In some experiments, the expected monotonic decrease in D/D_0 with an increase in Δ was not observed at all.¹²¹ Analysis of the relaxation data showed that the samples exhibiting an anomalous behaviour were characterised by a complex pore size distribution pattern. Macroscopic structural heterogeneities of the porous medium can strongly affect transport of fluids and, in particular, be responsible for an increase in the apparent tortuosity factor.¹⁸³

For water in kraft cellulose¹⁶² at short Δ the propagator has a Gaussian shape and allows the determination of the S/V ratio. For cellulose with a reduced water content the distance between the diffusion barriers estimated from the propagator peak width at long Δ was 7 μm . The possibility of separating the contributions of free diffusing water in the inter-fibre space and of restricted water diffusing inside the fibres was recognised. Experiments showed that intra-fibre diffusion of water is anisotropic. In particular, the D values of water in a three-layer composite cardboard sheet were found to be the same for all layers at different water contents; however, the diffusion coefficient along the direction parallel to the surface of the cardboard sheet is larger than in the cross fibre direction due to the corresponding fibre orientation.¹⁰⁰ Drying of cardboard is accompanied by demonstrated shrinkage (a decrease in the pore size) and the D value also decreases. Numerical simulation was based on the model which included an exchange between two ensembles of water molecules with different D . Experiments¹⁴⁷ with a celery stalk also demon-

[†] TEMPO — 2,2,6,6-tetramethylpiperidine-1-oxyl, stable nitroxyl radical.

strated the anisotropy of water diffusion, especially in the vascular tissues. The measured D values were found to be 1.6×10^{-5} for longitudinal and $8.3 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ for lateral diffusion. The experimental diffusion coefficient of water in a developing wheat grain is $8.3 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$.¹⁸⁸

The orientation of fibres in living tissues can be determined by, *e.g.*, measuring the diffusion tensor. Functional disorders are often accompanied by changes in the tissue structure, which is intimately related to the diffusion tensor.¹⁸⁹ For instance, a MRI evaluation of post-stroke patients by constructing the 3D diffusion tensor maps showed that the greatest changes in the diffusion tensor are observed for the white matter of human brain.

Measurements of the diffusion coefficient in voids can be used for sizing the droplets of the dispersed phase in emulsions.^{190, 191} Though the inverse problem (reconstruction of the size distribution from the NMR data) belongs to the class of ill-posed problems, the use of regularisation methods provides a tool for solving this problem in the absence of *a priori* information on the type of the size distribution. By employing flow-compensated PFG NMR techniques one can determine the size of emulsion droplets under flow. Measuring the $E(q)$ dependence also permits calculations of the diffusion coefficients and size distribution of molecular aggregates (*e.g.*, micelles and phospholipid vesicles).¹¹⁴ The contributions of the entire molecular aggregates, individual molecules in them and individual molecules in solution to the NMR signal can be separated based on the difference between their diffusion coefficients.

For a number of systems the $E(q)$ dependence exhibits extrema due to diffraction-like diffusion effects in the quasi-periodic porous systems. In particular, a coherent peak was observed for water in a polystyrene bead pack.^{161, 192} The $E(q)$ curves obtained for suspensions of human erythrocytes with different hematocrit exhibited some features (extrema and shoulders) due to both intra- and intercellular diffraction-like diffusion effects.¹⁹³ Cell death during the freeze–thaw cycles leads to disappearance of these features. Position of the ‘intracellular’ peak depends on the rate of transmembrane water exchange between the cell and its environment, which was confirmed experimentally by varying the temperature and by adding a transmembrane exchange inhibitor. Application of the pulsed field gradients parallel or perpendicular to the external magnetic field led to observation of different $E(q)$ dependences. This suggested that the diffusion anisotropy in the samples, which were in equilibrium with dioxygen, is a result of alignment of erythrocytes in the magnetic field (7 T) due to the difference between the diamagnetic susceptibilities of the suspension and the erythrocytes bearing oxygen-containing hemoglobin. In this case, a disk-shaped erythrocyte is aligned in such a way that the axis of the disk is directed normal to the external magnetic field. The addition of NaNO_2 to the suspension is accompanied by transition of hemoglobin to the paramagnetic state, which causes alignment of the axis of erythrocyte along the magnetic field. This was indirectly confirmed by the change in the shape of the $E(q)$ dependence. This mechanism was assumed to be responsible for the effect of the magnetic field on the blood flow in living organisms. (The experiments were carried out at 25 °C.)

When studying diffusion in porous media, spin relaxation induced variations of the NMR signal cannot be correctly included by simply multiplying the signal amplitude by the corresponding coefficient because of the effects of coupled restricted diffusion and surface relaxation.^{183, 194} In this case carrying out relaxation measurements allows a correct determination of the diffusion coefficients, relaxation times and the contributions of the components experiencing different environments.^{195, 196} Such experiments have been performed for water in a glass bead pack¹⁹⁴ and other fluids, for plants^{195, 196} and for the cat brain *in vivo*.¹⁹⁵ The authors of the last-mentioned study succeeded in separating the contributions of brain tissues and cerebrospinal fluid and in observing a decrease in the D value in an artificially created ischemic region.

Gas diffusion measurements have also been reported. For instance, the diffusion coefficient of a xenon–dioxygen mixture was determined by recording a time profile of the changes in the 1D signal projections after inversion of the magnetisation in a slice 12–24 mm thick oriented normal to the spatial coordinate of the 1D NMR image.¹⁹⁷ The diffusion coefficient of ^3He in a porous slice at a pressure of several atmospheres was determined in analogous experiments involving inversion or saturation of the signal followed by simulation of the results.^{198, 199} The spin–lattice relaxation time, T_1 , of the gas was calculated from the changes in the area under the curve of the 1D NMR signal profile.¹⁹⁸

Diffusion of xenon from the bulk gas phase into an aerogel sample causes attenuation of the NMR signal from peripheral regions of the sample after selective inversion of the signal of the bulk Xe phase.²⁰⁰ If the amplitude of the field gradients employed to obtain the image is increased, the signal of the bulk gas phase becomes weaker which allows the selective visualisation of the occluded xenon phase characterised by a relatively low diffusion rate.²⁰¹ The D values for the mixture of thermally polarised xenon with oxygen²⁰² and for hyperpolarised xenon^{123, 202} were determined using the $E(q)$ dependences. Diffusion of thermally polarised xenon in a glass bead pack has been studied.²⁰² The diffusion coefficient of xenon decreases with the observation time (12.5–1000 ms) and reaches the asymptotic limit. Measurements of the asymptotic behaviour of D values in the long-time limit in the experiments with fluorinated gases permitted the determination of the tortuosity factor of the pore space for partially sintered Y-stabilised tetragonal zirconia polycrystals.¹²²

Considerable attention has been given to diffusion of adsorbates in zeolites (*e.g.*, diffusion of water, acetone, isopropyl alcohol, propane and propene in the NaX and CsNaX zeolites,²⁰³ diffusion of alkanes in NaCaA zeolites¹³⁹) under different conditions.¹¹⁵ Since zeolites are most often used in the form of fine crystalline powders, transport of adsorbate is affected by both intracrystallite molecular diffusion and diffusion in the intercrystallite space.

Diffusion of ethane adsorbed into NaX and NaCaA zeolite powders at different observation times, temperatures, average crystallite sizes and adsorbate concentrations has been studied.²⁰⁴ The experimental conditions were chosen in such a way that the fraction, p , of the ethane molecules in the intercrystallite space was small. Therefore, at short observation times the diffusion (average) propagator had a Gaussian shape. At long observation times, when the average molecular displacement exceeds the crystallite size, the shape of the propagator depends on the ratio of D_1 and pD_2 , where D_1 is the intracrystallite diffusion coefficient of ethane and D_2 is the diffusion coefficient of ethane in the intercrystallite space. A feature of the ethane–NaCaA zeolite system is equality of the D_1 and pD_2 values at 173 K. Since the parameter p exhibits the most pronounced temperature dependence, at lower temperatures the propagator is mainly determined by intracrystallite diffusion even at long observation times; in addition, the smaller the crystallite size, the narrower the propagator peak. At higher temperatures, the propagator exhibits a wing extended towards large molecular displacements ($\mathbf{R}$), since a fraction of molecules has time to diffuse out of the crystallites. Therefore, the smaller the crystallite size, the broader the propagator peak. The average propagator observed on further extension of the observation time is due to exchange of the gas molecules between the inter- and intracrystallite space.

A study²⁰⁵ of ethane diffusion in H-ZSM-5 zeolite powder and of methane and butane diffusion in silicalite crystals and ZSM-5 zeolite at 123–383 K (see Ref. 206) revealed a decrease in D with an increase in the observation time Δ .²⁰⁵ The effect becomes less pronounced on raising the temperature and is virtually independent of the displacement $\mathbf{R}$ for methane at high temperatures. Variations of D on changes in the root-mean-square molecular displacements are due to the presence of intracrystallite barriers to diffusion (*e.g.*, intergrowth). The results obtained were

simulated using the Monte Carlo technique.²⁰⁶ The limiting stage of diffusion of benzene adsorbed into loose or compressed zeolite H-ZSM-5 is intraparticle diffusion.²⁰⁷ The D value was found to be $10^{-10} \text{ cm}^2 \text{ s}^{-1}$. The effect of coke formation in zeolite on the diffusion process was also studied.

Nitrogen ($^{15}\text{N}_2$) diffusion in CaNaA and NaX zeolites at different pressures and temperatures has been reported.¹²⁴ Small crystallite sizes and large diffusion coefficient of the gas permit only the D value for large molecular displacements to be experimentally determined, thus allowing calculations of the D_2 value.

Many technological applications of zeolites involve multi-component adsorption, which gives an impetus to research in the field of simultaneous diffusion of several adsorbates. For instance, diffusion of ethane–ethene mixture in zeolite NaX has been studied.²⁰⁸ Compared to the single-component systems, the diffusion coefficient of ethane in the binary system becomes much smaller and approaches the diffusion coefficient of ethene, which was found to be nearly constant in the single-component and binary systems.

Reagent and product diffusion during catalytic conversion of cyclopropane into propene on zeolite NaX has been investigated.²⁰⁹ In the binary system the diffusion coefficients of the two compounds were found to be equal and constant throughout the process, being coincided with the value obtained by extrapolating the results obtained when no reaction occurred. Catalytic conversion of ethene on silicalite or zeolite H-ZSM-5 was studied with CF_4 as an inert probe.²¹⁰ A three-fold decrease in the diffusion coefficient of CF_4 was observed after 240 min from the beginning of the reaction. No further decrease in D was detected; however, regions with different mobility of the probe molecules appeared in the sample. It was found that ‘short’ alkanes are mainly formed at 370 K, whereas aromatic compounds are mainly formed at 575 K. After conducting the reaction under the above-mentioned conditions the D value of CF_4 changed by an order of magnitude. The same differences were also observed for the CF_4 –hexane and CF_4 –benzene systems in the same zeolites without carrying out the reaction.

Experiments with zeolite single crystals allow one to reveal correlations between different components of the diffusion tensor, associated with the structure of the zeolite cavities and transport channels. To this end, water diffusion in natural chabazite has been investigated.¹³⁸ Diffusion anisotropy studies can also be performed with powders; however, this requires simulation of the $E(q)$ dependence.

MRI allows the determination of the dimension of the space in which diffusion occurs. For instance, one-dimensional diffusion can be established even for a sample comprising randomly oriented crystallites. A diffusion study of ethane in large crystals of $\text{AlPO}_4\text{-5}$ molecular sieves has been reported.²¹¹ The $\text{AlPO}_4\text{-5}$ crystals have a system of parallel cylindrical channels 7.3 Å in diameter and no interconnections. The mean square displacements depends on the square root of the observation time ($t^{1/2}$), which indicates a ‘single-file’ diffusion when the molecules cannot ‘bypass’ one another. At the same time, both ‘single-file’²¹² and unidirectional (rather than ‘single-file’) diffusion of methane in $\text{AlPO}_4\text{-5}$ were observed.²¹¹ A continuous-flow generation system of hyperpolarised gas was employed in studies of xenon diffusion in the 1D channels of porous nanocrystallites.²¹³ The amplitude of the NMR signal acquired using the saturation–recovery technique was used as a direct measure of the average penetration depth of the xenon atoms in the interior of the crystallites. The time dependence of the NMR signal corresponded to ‘single-file’ diffusion. The advantage of the technique is the possibility of studying molecular displacements at times from hundreds of milliseconds to tens of seconds.

5. ‘Edge enhancement’ effect

One interesting and useful consequence of the attenuation of the NMR signal in the case of diffusion in inhomogeneous magnetic field is the so-called ‘edge enhancement’ effect. The molecules

located in the vicinity of impermeable barriers migrate over shorter distances compared to the molecules present far from the barriers; therefore, they are less sensitive to signal attenuation, which is equivalent to extension of the decay time, T_2^* of the transverse magnetisation. As a result, the signal from the near-wall region will be more intense in the images. Indeed, reconstruction of the 2D diffusion coefficient maps of water and octanol in glass capillaries provided an experimental proof of the reduction of the diffusion coefficient of water in the near-wall layer up to 150 µm thick at an observation time of 0.8 s.²¹⁴ Often, reduced signal attenuation in the near-wall region compared to the bulk of the sample was experimentally observed in the diffusion-weighted NMR images of different dimension, *e.g.*, in the 1D and 2D images of water in glass capillaries 600 and 190 µm in diameter (see Ref. 215) and in the 1D images of water in a slit 2.6–2.8 mm wide.²¹⁶ The effect of the amplitude and duration of the gradient pulses²¹⁵ and of the observation time²¹⁶ on the ‘edge enhancement’ effect has been investigated. The characteristic range of the molecular displacements over the observation time under the experimental conditions was found to be 12–22 µm.²¹⁶

Rather large diffusion coefficients of gases can cause significant distortions of the NMR images. The character of these distortions strongly depends on the sample size, the field gradient amplitude and the diffusion coefficient. The possibility of attenuation of the signal from the bulk gas phase compared to the signal of gas in the near-wall region was demonstrated in experiments with xenon.^{217,218} As the relative efficiency of diffusion increases due to decrease in the field gradient or reduction of the sample size, the near-boundary peaks are broadened, approach each other and then coalesce into one peak.²¹⁸ In this case, the MRI ‘image’ does not correspond to the spatial structure of the object under study. The experimental mean diffusive displacement of gas molecules in a rectangular ampoule differs from zero at the sample boundaries and is of different sign near the oppositely lying boundaries, while the root-mean-square diffusive displacement near the boundaries is smaller than inside the ampoule. Combining these effects and diffusion weighting provides a tool for implementation of selective edge imaging; however, a drawback of this technique is a substantial reduction of the signal-to-noise ratio. The edge distortion of the 1D NMR images of gas confined between impermeable parallel walls of a rectangular ampoule has also been observed in the experiments with hyperpolarised ^3He .^{199,219} Possible reasons for distortion of the NMR images include the ‘edge enhancement’ effect and the magnetic field disturbance near the tube walls due to different diamagnetic susceptibilities of materials. In the case of hyperpolarised gas, the long-range dipolar demagnetising field produced by the spin ensemble at the location of an individual spin also causes the ‘edge enhancement’ effect.²¹⁹ Helium also exhibits a lower diffusion coefficient in the vicinity of the tube walls;¹⁹⁹ however, this was thought to be unrelated to the restricted diffusion mechanism, since the diffusive displacement over the measuring time (0.1 mm) is much smaller than the spatial resolution achieved in the experiment (0.8 mm).

On the one hand, the ‘edge enhancement’ effect can find some useful applications in, *e.g.*, the experiments involving selective NMR spectroscopy of the near-wall regions,²¹⁵ enhancing the NMR signal in the regions of impermeable boundaries and revealing partitions that would be invisible otherwise.²²⁰ On the other hand, this effect can cause significant distortions of the NMR images of microscopic objects. Broadening of spectral lines due to fast near-wall relaxation and partial penetrability of the barriers can suppress this effect.²²⁰

The ‘edge enhancement’ effect on the 1D, 2D and 3D images in linear and spherical geometries has also been the subject of theoretical studies.²²⁰ Calculations for objects with a characteristic size of 40 µm showed that an increase in the diffusion coefficient causes averaging of the ‘edge enhancement’ effect due to faster molecular motions and leads to the appearance of a single peak with the maximum at the centre of the model object.

Calculations for two hollow spheres filled with water (one sphere was placed inside the other) showed that the 'edge enhancement' is observed only inside each sphere but not at the outer surface of the smaller sphere.²²⁰

An expression for the description of the 'edge enhancement' at an arbitrary shape and duration of the pulsed field gradients has been derived.²¹⁶ The echo amplitude was expressed through the molecular motion correlation function while the inhomogeneous spatial distribution of the magnetisation phase was expanded into a plane-wave series. In this approach incoherent molecular displacements cause a discord of plane waves, thus leading to improvement of the signal-to-noise ratio in the near-wall region. The maximum signal amplitude (or minimal root-mean-square molecular displacement) is observed at some distance from the walls rather than in the immediate vicinity of the walls. This distance, as well as the width of the peak, is independent of the amplitude of the applied field gradient but increases with the observation time. The Monte Carlo simulations lead to 'sharper' near-wall peaks compared to those observed in the experiments.²¹⁵

VI. Application of magnetic resonance imaging to flow studies

1. General remarks

This Section concerns flow studies including filtration; however, one should keep in mind that the experimental methods considered here also allow investigation of other types of motion, *e.g.*, a translational or rotational motion of the entire body, deformation, *etc.* Therefore, we use the term 'flow' in a wider sense.²²¹ In addition to studies of the motion of individual molecules and molecular aggregates (by measuring the nuclear spin relaxation times and magnetisation transfer processes) and diffusion, MRI allows investigations of the transport of macroscopic mass quantities of, *e.g.*, liquids, gases and solids.^{116, 222, 223} The technique does not require introduction of tracers into the flow, imposes no limitations on the refraction indices of the media under study and provides a tool for studying optically opaque flows, *e.g.*, multiphase flow and flow of granulated solid materials through the entire volume of the flowing substance. Usually, the results of MRI studies are in good agreement with those obtained using other flow investigation techniques including optical methods.^{221, 224, 225} In contrast to many conventional methods, MRI also allows reliable visualisation of unstable flow regimes²²⁶ and investigation of transverse velocity dispersion.

The minimum flow velocity measured in the experiments is limited to diffusive molecular displacements (nearly $10 \mu\text{m s}^{-1}$ for unbound water and $1 \mu\text{m s}^{-1}$ for macromolecules²²⁷). The maximum velocity is determined by the outflow of the sample from the RF coil during the measuring time. The relative accuracy of the velocity measurements is usually several per cent. Knowledge of the velocity field allows, in particular, mapping the deformation rates of the medium and calculations of the volumetric flow of the fluid, which can be compared with the experimental results.²²⁸ It should be noted that the quantities measured by the MRI technique are statistically averaged over space and time and that the averaging scale can be varied; this provides a way for comparing the experimental data with the predictions of the theories based on the averaged quantities.²²¹ For instance, in most cases the experimental data were found to be in satisfactory agreement with the results of hydrodynamic calculations for different fluids and flow geometries.^{224, 229–240}

In studies of, *e.g.*, the flow of fluids the results are often represented as the spatial velocity distribution maps; however, the experimental techniques discussed below involve measurements of the molecular displacements over the observation time. These measurements are equivalent to the velocity measurements provided that the velocity remains constant over the observation time. This should be kept in mind, in particular, in the molecular diffusion or hydrodynamic dispersion studies.

This review concerns only a few applications of the MRI technique to flow studies in biology and medicine. At the same time, there is a wealth of such applications and a number of problems can be solved using the NMR imaging techniques employed in medical MRI evaluation. For instance, MRI has long and successfully been used in transport studies of blood and other fluids in living organisms.^{241–243} For instance, it was established that the arterial blood flow velocity can be as high as 150 cm s^{-1} (see Ref. 244) at the Reynolds numbers of up to 12 000. It should be noted that the demand to study the pulsatory flows in elastic branching vessels in the presence of spiral, vortex and reversible (in particular, valvular regurgitation induced) flows led to the development of special techniques.^{228, 245–248}

2. Methods of flow studies

The method of spatial tagging is based on the creation of tags (magnetic stripes) by changing the NMR signal in a particular region of the sample followed by tracing the movement and change in the shape of the markers in the NMR images.^{221, 249} A tag can be created using, *e.g.*, inversion or saturation of the NMR signal. In particular, the use of selective pulses and field gradients allows local manipulation of the signal in the specified slice. If the tag plane is not parallel to the image plane, the tag looks like a contrast stripe in the NMR image (Fig. 3*a*). With an increase in the delay time between the instant at which the tag is created and the instant at which the image is acquired the relative and absolute displacements of different parts (regions) of the sample will be followed by displacement and change in the shape of the tag (Fig. 3*b,c*). The lifetime of the tag is determined by the longitudinal relaxation time, T_1 , of the nuclear spins.

Creation of a single tag is usually sufficient to study low-dimensional flows. For instance, creation of a tag in the plane orthogonal to the developed flow in a straight tube and imaging the tag shape after some time immediately gives the flow velocity field (see Fig. 3*b,c*). Studies of more complex flow patterns involve creation of many tags. One can, *e.g.*, simultaneously create a number of parallel stripe-like (or planar) tags and then to create the second set of perpendicular tags.^{226, 237, 250–254} In this case the displacement of the tag cells in the NMR image permits the determination of the local flow velocity while distortion of the cell shape is related to the shear deformation.²²¹

The time-of-flight technique is also based on disturbance of the NMR signal in a particular region of the sample by the RF pulses using the signal inversion or saturation techniques. However, this approach usually involves observation of subsequent changes in the NMR signal amplitude due to displacements of the disturbed and undisturbed spins in the sample. NMR signal

Figure 3. MRI images of water in a tube of 7.6 mm i.d. Stagnant water, $Re = 0$, the delay between the tag creation and image acquisition is 4.1 ms (*a*); laminar flow, $Re = 250$, the delay is 83.1 ms (*b*); and turbulent flow, $Re \approx 8300$, the delay is 7.1 ms (*c*). The tag was created using the spin saturation technique in the slice 1.4 mm thick and perpendicular to the plane of the two-dimensional image obtained without slice selection. Image size: 1 cm (horizontal dimension) $\times$ 3.1 cm (vertical dimension).

recovery in the disturbed region occurs due to inflow of the spins with equilibrium polarisation from undisturbed upstream regions. Simultaneously, the signal amplitude in the undisturbed downstream regions will decrease due to replacement of the undisturbed spins by the disturbed ones. In this case, variation of the signal amplitude will depend on the flow velocity (the time of flight) in a given region of the sample.

The time-of-flight technique can also be implemented without disturbance of the NMR signal by the RF pulses, since the initial magnetisation of a fluid inflowing into the magnet is close to zero and the spin relaxation rate of the fluid will depend on the time of flight taken to reach the RF detection coil, *i.e.*, it will be different for the spins experiencing different flow velocities.²⁵⁵ Signal inversion can be achieved by adiabatic passage through resonance if the fluid flows along the direction of the field gradient. The use of time-of-flight technique without spatial resolution gives the average flow velocities.²⁴² The spin disturbance and signal acquisition regions can be different. For instance, one RF coil can be used for signal disturbance while the second (detection) coil can be placed downstream.^{242, 255} It should be noted that in the literature the names of the two methods considered above are often used as synonyms since they involve creation of a spin disturbance in a particular region of the sample followed by observation of variations of the NMR signal.

Quantification of the molecular velocities and mapping the fluid velocity fields are often carried out using the phase (phase contrast) technique.^{253, 254, 256–258} In this case the pulse sequence is designed in such a way that the phase of the signal to be acquired be proportional to the spin motion velocity. For instance, if the pulse sequence includes two field gradients with the effective amplitudes $-g_i$ and g_i , duration δ and the time delay Δ between them, the phase of the transverse magnetisation will change by

$$\phi = \gamma v_i M_1 = \gamma v_i \int t g_i(t) dt = \gamma v_i g_i \Delta \delta, \quad (17)$$

where M_1 is the first moment of the gradient sequence. As can be seen, variation of the signal phase is independent of the spin location and proportional to the velocity component (v_i) parallel to the applied gradient g_i .

Flow velocity induced variation of the magnetisation phase must lie between $-\pi$ and π to exclude ambiguity of the dependence between the phase and velocity.²⁵⁹ However, sometimes this limitation is deliberately violated. If the signal-to-noise ratio and the spatial resolution of the experiment are sufficiently high, this ambiguity can be corrected for by adding a value of $\pm 2\pi n$ to the measured phase to eliminate the phase discontinuities ($\pm 2\pi$) between the signals from adjacent pixels.²⁶⁰ At the same time, if the maximum phase variation is much larger than π , the NMR image represents a map of isovelocity lines.²⁶¹

Since the phase of the NMR signal depends on many factors, measuring the molecular velocities requires separation of the flow-related contribution, which can be done in a number of ways.²⁵⁶ Often, an experiment is repeated twice and thus, and in one of the repetitions expression (17) is set to zero by either turning off the flow ($v_i = 0$) or by setting M_1 equal to zero (by *e.g.*, setting $g_i = 0$). Mapping the projection of the velocity vector on the direction of the applied gradient is achieved by calculating the phase difference for each pixel followed by calculating the velocity using expression (17). Phase modulation of the NMR signal can be readily converted into amplitude modulation using the RF pulses; therefore, the NMR signal amplitude is sometimes used as a measure of the velocity.^{261–263} In this case, the Fourier transformation of the experimental data immediately gives the velocity map without performing additional calculations.²⁶² Imaging techniques with the signal amplitude depending on, *e.g.*, flow velocity gradient have been reported.²⁶⁴

Partial outflow of the fluid from the detection coil in the phase contrast experiments does not disturb the observed flow pattern since the phase rather than amplitude of the NMR signal is

measured. At the same time, if a substantial fraction of the fluid leaves the RF coil over the acquisition time, this can lead to loss of the signal against the noise background, thus preventing the determination of the signal phase and, hence, of the flow velocity for a given image pixel.

It should be noted that NMR imaging of a moving object or its parts faces some difficulties, *e.g.*, image distortions due to variation of the spin precession frequency caused by the spin motions in the presence of the field gradient. In addition, dephasing of the magnetisation within the same pixel due to different spin velocities leads to loss of the signal in the NMR image. To avoid these undesired effects, the so-called flow-compensating technique is employed. Namely, the gradient sequence is designed in such a way that the first moment of the sequence, M_1 [see expression (17)], be zero; in this case, the phase of the signal to be acquired is the same for particles moving with different velocities, thus precluding image distortions. The condition $M_1 = 0$ is realised, in particular, for even echo signals at multiple refocussing of the transverse magnetisation in the constant field gradient. Therefore, the even echo partially prevents the loss of the signal intensity even in the case of turbulent flow.²⁶⁵

The phase encoding technique can also be used for measuring higher derivatives of the molecular coordinates with respect to time. For instance, setting M_1 to zero allows the molecular acceleration to be determined. In this case, the phase of the transverse magnetisation is proportional to the product of the projection of the acceleration vector on the direction of the field gradient by the second moment of the gradient sequence

$$M_2 = \int t^2 G(t) dt.$$

The sources of possible difficulties and errors in the phase encoding of flow have been analysed.²²⁸

An image of a fluid flow can be obtained by visualisation of streamlines by creating multiple tags. For steady-state flows the tags in the form of stripes parallel to the streamlines remain unchanged. The tags are created in the form of stripes parallel to streamlines in the upstream regions with respect to the flow region under study. Curved streamlines (if, *e.g.*, a fluid flow in a tube with a diaphragm is studied) inside the flow region under study initially are not in parallel to the straight tag stripes. However, after some time the tags adopt the shape of the streamlines as a result of replacement of the fluid in this region by the fluid from the upstream region.²⁶⁶ Streamline images can also be calculated using information on the three spatial fluid velocity components.²⁶⁷

For non-steady-state flows (*e.g.*, pulsatile intracardiac blood flow), realistic flow patterns can be obtained by visualising the trajectories of the movement of an ensemble of phantom particles that were mentally 'introduced' into the flow at some instant.²⁶⁷ Combining trajectory visualisation technique with animation and with overlay of the trajectory images²⁶⁷ or a colour velocity map²⁴⁶ on the 2D images of anatomic sections gives a complete image of such a flow.

NMR angiography is widely used^{241, 268, 269} in medical evaluation to provide a maximum contrast between the vasculature and surrounding tissues (usually, images of bright vessels against dark background are obtained). This is achieved using various versions of the time-of-flight technique. The most widely used approach involves predominant saturation of immobile spins by imaging at fast repetitions of the gradient echo sequence. The phase techniques and some magnetisation transfer based approaches are also employed in angiography. The quality of angiograms can be improved using some contrast agents that are introduced into blood to shorten the spin relaxation times.^{241, 242} NMR angiography allows studies and characterisation of blood flow and, in particular, establishment of the presence of obstacles and the determination of conditions under which the blood flow favours the appearance of plaque depositions.^{234, 244}

As mentioned above, diffusive molecular displacements can be studied by q -spectroscopy. This method is also widely used in the flow studies. For instance, if isotropic molecular diffusion with the diffusion coefficient D is superimposed on the flow characterised by the velocity $\mathbf{u}$, the expression for the echo amplitude, $E(\mathbf{q}, \Delta)$, has the form

$$E(\mathbf{q}, \Delta) = \exp(-4\pi^2 q^2 D \Delta_{\text{ef}} + i 2\pi \mathbf{q} \mathbf{u} \Delta). \quad (18)$$

As can be seen, diffusion leads to attenuation while flow causes modulation of the NMR signal. By applying the Fourier transformation of the signal one gets

$$\begin{aligned} P(\mathbf{R}, \Delta) &= \frac{1}{\sqrt{4\pi D \Delta_{\text{ef}}}} \exp\left(-\frac{R^2}{4D \Delta_{\text{ef}}}\right) \otimes \delta(\mathbf{R} - \mathbf{u} \Delta) = \\ &= A \exp\left[-\frac{(R - \mathbf{u} \Delta)^2}{4D \Delta_{\text{ef}}}\right]. \end{aligned} \quad (19)$$

Here δ is the delta function, the symbol $\otimes$ denotes convolution and A is a constant. As in the case of diffusion [see expression (13)], the propagator (19) has a Gaussian shape; however, in the presence of a flow the maximum of the propagator is shifted from the point $\mathbf{R} = 0$ to $\mathbf{R} = \mathbf{u} \Delta$.²⁷⁰ If the diffusive molecular displacements over time Δ are small, the propagator $P(\mathbf{R}, \Delta)$ characterises the flow velocity distribution (histogram).^{271, 272} The direction of the displacement component to be measured, $\mathbf{R}_i$, is determined by the direction of the field gradient g_i .

Since measurements of the average propagator are based on measurements of the NMR signal amplitude, outflow of the fluid from the RF coil can lead to underestimation of the measured $P(\mathbf{R}, \Delta)$ value. This underestimation usually increases with an increase in $\mathbf{R}$, since higher flow velocity corresponds to a larger number of spins that have time to escape from the RF coil during the observation time Δ . Partial suppression of this effect can be achieved by measuring the propagator using the slice-selective normal to the direction of the net flow rather than for the entire sample placed in the RF coil. Obtaining reliable results requires detailed analysis of artifacts and measurement errors.¹⁴¹

Similarly to diffusion studies, the use of an extra module in the pulse sequence to encode the spatial information (the so-called dynamic MRI) allows spatially resolved measurements of the average propagator $P(\mathbf{r}, \mathbf{R}, \Delta)$ [see formulae (14) and (15)]. The use of the dynamic MRI is of crucial importance in the presence of a velocity distribution within the same pixel (low spatial resolution, thin capillaries, *etc.*).^{270, 273, 274} In this case other methods for obtaining the flow velocity map only allow the effective velocity for each pixel to be determined, whereas measurements of the spatially resolved propagator make it possible to avoid this undesired averaging. Dynamic MRI with high spatial resolution can be useful in, *e.g.*, obtaining rheological information on non-Newtonian fluids, in studies of dynamic processes in plants and for the determination of the diffusion coefficient and average flow velocity for each image pixel.¹⁴¹

The above-mentioned methods can be used for imaging of the motions characterised by coherence in the measuring time scale, *e.g.*, in studies of steady-state flows. Diffusion, hydrodynamic dispersion and turbulence cause the loss of coherence and attenuation of the NMR signal.²⁷⁵ These processes can be best studied by the methods based on recording the signal amplitude variations (in particular, by measuring the propagator). Nevertheless, in the case of a developed turbulent flow both the phase encoding and the tagging technique can be used to study the average molecular displacements over the measuring time. In principle, the amplitude of the signal in the NMR images allows one to extract information on the incoherent component of the motion (turbulent or periodic pulsations, diffusion, dispersion);^{251, 252, 276} however, this problem is hard to solve. Non-steady-state processes (including aperiodic, transient and turbulent flows) can be studied by fast (10–100 ms) imaging techniques. In the case of periodic

flows the use of synchronisation of the pulsatory flow and the NMR signal acquisition allows relatively slow imaging techniques to be employed to determine the flow pattern at different instants of the pulsation period. Medical experiments concerning blood flow in organisms usually involve synchronisation of the NMR measurements with the electrocardiogram signal.

By measuring the spin echo amplitude with varied pulse sequence parameters one can determine the quantities employed in the statistical description of a random fluid motion^{265, 275, 277–279} including the correlation time of velocity fluctuations, τ :

$$\tau = \int_0^\infty \frac{R_u(t) dt}{R_u(0)}. \quad (20)$$

Here, $R_u(t)$ is the velocity autocorrelation function

$$R_u(\tau) = \langle u(t)u(t+\tau) \rangle, \quad (21)$$

while the particle velocity, $v(t)$, is represented by the sum of the average velocity, U , and the fluctuating component, $u(t)$

$$v(t) = U + u(t). \quad (22)$$

If τ is much longer than the duration of the pulsed field gradients and the time delay between them, a turbulent flow can be correctly described in terms of the mean square of velocity fluctuations, $\langle u^2 \rangle$, or turbulence intensity, I

$$I = \frac{\sqrt{\langle u^2 \rangle}}{U}. \quad (23)$$

Otherwise, in the short correlation time limit, a turbulent flow can be characterised by the eddy diffusivity, D_e

$$D_e = \langle u^2 \rangle \tau. \quad (24)$$

MRI allows measurements of both quantities, I and D_e , as well as studies of spin exchange processes in the coordinate and velocity space.^{280–282} In particular, by independently varying the amplitudes of two gradient pulses one can obtain a 2D NMR spectrum with the axes corresponding to the spatial coordinate of the spin at the instants t and $t + \Delta$ (x_1 and x_2), while the signal amplitude is proportional to the probability density of the spin displacement from x_1 to x_2 over time Δ (position exchange spectroscopy, or POXSY). The 1D sections of such a 2D spectrum characterise the probability distribution of spin migrations over different distances over a specified time. At small spin displacements (*e.g.*, at short times Δ), the 2D POXSY spectrum exhibits a signal (ridge) along its diagonal. As the spin displacements increase, the diagonal ridge is broadened until complete loss of correlation between the initial and final coordinates. It is noteworthy that the diagonals of such a 2D spectrum correspond to the average coordinate ($\langle x \rangle$) and the average velocity ($\langle v \rangle$); therefore, the same 2D spectrum rotated by -45° characterises the correlation between the average particle coordinate and average particle velocity (the probability density for a particle located at position $\langle x \rangle$ to have the velocity $\langle v \rangle$).

Analogously, independent variation of two pairs of gradients in the four-gradient experiments allows exchange studies in the velocity space,^{238, 280, 281} *i.e.*, the probability density for the spin velocity to change from v_1 to v_2 over time Δ irrespective of the spin position (velocity exchange spectroscopy, or VEXSY). The same VEXSY spectrum rotated by -45° characterises the correlation between the average velocity and average acceleration of particles. For unrestricted diffusion the correlation spectrum has a shape of a 2D Gaussian with the standard deviation $\sigma = (2D\Delta)^{0.5}$, where D is the self-diffusion coefficient of water.²³⁸ The SERPENT (sequential rephasing by pulsed field gradients encoding N time intervals) experimental technique^{283, 284} allows studies of the spin velocity or spin displacement correlations for two time intervals measured from a common initial time instant.

3. Fluid flow in various geometries

A developed laminar flow of a Newtonian fluid in a circular cross-section tube or capillary is characterised by a parabolic longitudinal velocity distribution along the tube diameter with a maximum at the tube axis and a zero flow velocity at the tube wall

$$v = v_{\max} \left[1 - \left(\frac{r}{R} \right)^2 \right], \quad (25)$$

where R is the tube radius, r is the distance from the tube axis to the observation point and $\beta = 2$. These distributions were obtained by both MRI tagging technique (see Fig. 3b) and using the maps of longitudinal velocity.^{93, 141, 227, 261, 272, 285–288}

The motion of water flowing through a narrow tube into a cell containing a fragment of a monolithic catalyst with transport channels of different shape and cross section dimensions have been studied.^{8, 20, 93} Mapping the three velocity components at different distances from the inlet edge of the monolith allowed detailed visualisation of a complex flow pattern and a transition to the fully developed flow in the inlet portion of each transport channel. Experiments revealed the presence of counterflows both inside and upstream of the monolith as well as jets flowing out of the transport channels and a vortex motion of water in the immediate vicinity downstream the block.⁹³ A film flow through the channels of a monolithic catalyst at different fluid flow rates has been investigated.²⁸⁹ The flow of a silicon oil film ~ 1 mm thick on the surface of a vertical plate made of poly(methyl methacrylate) has been studied by mapping the velocity and spin density distributions.²⁹⁰ The flow velocity was found to be higher near the plate edges, where the film was thicker due to wetting effects. This velocity increases quadratically with the distance from the plate surface. An increase in the Reynolds number causes the appearance of surface waves on the film surface. The appearance of standing waves was observed with pulsatile supply of silicon oil when the system was isolated from the atmosphere.

Spatially resolved MRI was employed in studies of a developed turbulent flow of water in a tube. The experiments revealed a large average velocity gradient near the tube walls and a nearly planar velocity distribution profile for the rest of the tube cross-section²⁷² (see Fig. 3c).

However, sometimes measuring the velocity for each image pixel is insufficient. Even in the studies with high spatial resolution the molecules within the same image pixel are characterised by different displacements due to, *e.g.*, molecular diffusion. Dynamic NMR microimaging provides a tool for measuring the displacement distribution within each image pixel.^{287, 291} At high spatial resolution, the average propagator for an image pixel is a Gaussian curve [see expression (19)]. The width of the propagator peak is determined by the diffusive molecular displacements while the shift of the maximum position is determined by the average molecular displacement due to the fluid flow.^{141, 270} At small diffusion coefficients (*e.g.*, for polymer solutions), the distribution of the molecular velocities within the same image pixel leads to overestimation of the apparent D value. In the case of a laminar flow this can be avoided by using flow-compensating technique. A feature of flows in thin capillaries is the possibility of overestimating the apparent D values for the near-wall region due to the presence of small air bubbles on the capillary walls, which disturb the flow pattern.

If the spatial resolution is low, the molecular velocity distribution within the same pixel can be rather broad.²⁹² Moreover, for thin capillaries surrounded with a stagnant fluid each image pixel can reflect both the flowing and the stagnant fluid, which leads to incorrect measurement of the average velocity and fluid flow rate in the capillary.²⁹³ In this case, measurements of the propagator for each image pixel allow one to obtain complete information on the fluid flow and to separate the contribution of the stagnant fluid to the NMR signal.^{270, 273}

Fluid flow in a tube can also be studied by measuring the propagator without spatial resolution.^{93, 272, 280} In the case of a

Figure 4. Averaged propagator for axial molecular displacements in flowing water.

Laminar flow ($Re = 285$) in a tube with circular cross-section (a); flow in a cylindrical glass bead pack (b). Bead diameter: 3.2 mm; bead pack diameter: 21 mm; observation time: $\Delta = 306$ ms.

laminar flow of a Newtonian fluid in a cylindrical tube the propagator considered as a flow velocity function is nearly constant in the v range from zero to $v_{\max}$ and equals zero at $v > v_{\max}$ (Fig. 4a). If we go to a turbulent flow at $Re > 2300$, the probability density becomes an increasing function of the flow velocity up to $v = v_{\max}$. Noteworthy is that an analogous propagator can also be observed in the case of a laminar, but not completely developed, flow⁹³ or a laminar flow of non-Newtonian fluid (*e.g.*, blood).²⁷² Studies of spin exchange in the coordinate and velocity space for a laminar²⁸¹ and turbulent²⁸⁰ flow of water in a tube and for a water flow in a converging tube²⁸¹ were carried out using the POXSY and VEXSY techniques.

A feature of a model of a real dialysis cell (artificial kidney) is counterflow of water inside hollow cellulose fibre membranes ('blood') and in the outer jacket ('dialysis solution').^{73, 287} An increase in the cell packing density due to the use of textile fibres leads to a more homogeneous flow distribution of the 'dialysis solution'. The regions near the ends of the dialysis cell are characterised by increased maximum water flow velocity (by a factor of 1.4) compared to the velocity in the bulk of the cell due to swelling of the membranes surrounded by rigid polyurethane shell used for cell hermetisation.²⁸⁷ Unfortunately, the 2D VEXSY spectra revealed no cross-peaks that could be indicative of the reversal of the direction of the molecular motion.²⁸⁰

Considerable attention has been given to the NMR studies of convective motion of various nature. Fluid flow inside a porous hollow-fibre membrane is known to induce slow convective flows in the surrounding fluid. For instance, an NMR imaging study of a reactor with 40 parallel membranes revealed an increased flow velocity in the narrow gaps between adjacent membranes.²³¹

Convection can arise even at relatively small temperature gradients (*e.g.*, 0.05 K cm^{-1} for convection in chloroform). In particular, the temperature gradient in the bore of a magnet of an NMR spectrometer is sufficient to induce a convective flow of water with a velocity of up to 0.5 mm s^{-1} (see Ref. 261). Such a flow in a liquid-containing ampoule 5 mm in diameter was also induced by temperature gradients during thermal regulation or as a result of absorption of the RF radiation. The flow velocity was $\sim 0.5 \text{ mm s}^{-1}$ for water or DMSO and reached up to 5 mm s^{-1} for chloroform.^{262, 294} The 2D NMR images exhibited the presence of numerous convection cells and 'twisting' of the nodal plane in the ampoule.²⁶²

Rayleigh convection with velocities of up to $600 \mu\text{m s}^{-1}$ was observed in a bottom-heated silicon oil layer 1 cm thick.²⁹⁵ The study revealed the presence of four convection cells whose pattern and relative sizes were in agreement with the results of visual observations. A 5% polystyrene solution in cyclohexane in a bottom-heated ampoule exhibited the presence of a convection cell and a steady-state character of convection.²⁹⁶

A convective fluid flow in a freely falling droplet has been studied as a model system with two interacting phases.²⁹⁷ Because of the short residence time of the droplet inside the RF coil recording a 3D NMR image required a total of 33 800 droplets to fall. The droplet size reproducibility was better than 99%. Large-scale water circulation in droplets was mapped and it was shown that the addition of surfactants causes reduction of the droplet diameter, improves reproducibility of the droplet size and shape and shifts the convection pattern towards much smaller length scale.

If a fluid has some regions with locally different concentrations of oppositely charged particles, application of an external electric field induces electro-osmotic transport. For instance, placing a closed capillary with charged walls filled with aqueous KCl solution ($1 \text{ mmol litre}^{-1}$) in an axial electric field causes the fluid in the near-wall region to move, which is due to the increased concentration of the counterions in the near-wall layer.²⁹⁸ This induces a neutral fluid flow with parabolic velocity distribution along the tube diameter; however, in contrast to conventional flow in the tube, the flow velocity on the walls differs from zero and is reversed with respect to the flow velocity direction at the capillary axis.^{235, 298} The characteristic flow velocity was found to be 0.1 mm s^{-1} while the settling time of the steady-state flow with pulsed switching on the electric field was of the order of 100 ms.²⁹⁸ The use of coatings neutralising the surface charge reduces the electro-osmosis effect.²³⁵

A nitrobenzene– C_6D_6 mixture also exhibited electroconvection, which can be due to the appearance of the space charge as a result of association of the polar molecules around the ions.²⁸² In this case, the expression for the effective diffusion coefficient at room temperature has the form

$$D = 1.08 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1} + (3.33 \times 10^{-5} \text{ cm}^4 \text{ kV}^{-2} \text{ s}^{-1}) E^2,$$

where E is the strength of the applied electric field.

The flow of fluids in curved channels is strongly different from the flow in straight tubes. The pressure gradients directed normal to the net flow are responsible for the appearance of complex secondary flows, which lead to significant changes in the flow pattern. A laminar flow of water in a tube with abrupt contraction and/or expansion exhibits large deviations from the parabolic longitudinal velocity distribution and rather high radial velocities. It was found that the flow velocity increases (decreases) as water flows in (flows out of) the narrow region of the tube. Recirculation flow has also been observed in the immediate vicinity downstream

the expansion.^{232, 233} The flow of water in branching tubes has been studied.²⁵⁶

Fluid flow in a tube with an U-shaped bend exhibited parabolic longitudinal velocity profiles before the bend²⁹⁹ and an acceleration of the flow near the inner wall of the tube just after the curved section, which induced a displacement of the rapidly moving molecules and the maximum flow velocity towards the outer wall.^{236, 239, 263, 299} Rather fast flow produced rotating, spiral Dean vortices that were clearly seen in the transverse velocity maps.²⁹⁹

To obtain the velocity distribution maps at different instants of the pulsation period, studies of pulsatile flow in straight²⁴⁰ and U-shaped tubes^{236, 239} were carried out with synchronisation of the pulse sequence with flow pulsations.

Studies of aperiodic flows require the use of fast NMR signal acquisition techniques. For instance, imaging over a period of 20 to 50 ms allowed one to obtain an 'instantaneous' velocity distribution map for a turbulent flow of water in a tube.^{251, 264, 300} In particular, a transition to turbulence with alternation of turbulent and laminar flow regions in the flow pattern was detected in the Re range between 1500 and 3000. The 1D temporal autocorrelation function of the signal amplitude and the 2D spatial autocorrelation function of the signal amplitude corresponding to the transition to turbulent flow were calculated.²⁶⁴ It was found that the correlation time is maximum (0.45 s on the tube wall and 0.8 s at the tube centre) at $\text{Re} = 2000$ and decreases with an increase in the Re value due to the appearance of progressively faster and smaller vortices. The correlation length was maximum (4 mm) at $\text{Re} = 3000$ and also decreased as the Reynolds number increased. Transition to a turbulent flow and recirculation flows in a tube with a contraction have been studied at different Reynolds numbers^{244, 301} and the appearance of a Karman vortex street behind the rod placed in the tube normal to the direction of the net flow ($\text{Re} = 39 - 200$) has been explored.²⁴⁴ At $\text{Re} \geq 82$, the vortices rotating in the opposite direction alternately separated from different sides of the rod at a frequency of 1.7 Hz. The use of fast NMR imaging techniques also allows studies of transient flows, *e.g.*, establishment of a steady-state regime in the system after starting the flow.²³³

Statistical characteristics of a flow at long correlation times, τ , of velocity fluctuations have been measured for a turbulent flow of water in a tube and for grid-generated turbulence using grids of different cell size.²⁷⁷ For the flow in a tube at $\text{Re} > 2000$ the mean square velocity fluctuation rapidly increases as the Re value increases, whereas the flow turbulence intensity remains nearly constant. Measurements in the opposite, short τ limit allowed one to obtain the spatial τ distribution maps and the eddy diffusivity (D_e) distribution maps for the fluid flowing in the region behind the tube contraction/expansion²⁷⁸ and for a jet flowing through a tube into the flat wall of a right liquid-filled cylinder.³⁰² In the last-mentioned experiments the D_e values reached $0.7 \text{ cm}^2 \text{ s}^{-1}$.

The Taylor–Couette flow, *i.e.*, the flow of a viscous fluid in the gap between two coaxial cylinders rotating at different rates, is of great practical value. Mapping the spatial velocity distribution using the NMR imaging technique allows characterisation of the flow of the fluid in the gap.^{226, 303} At low rotation rates, a cylindrical fluid flow occurs, which is employed, in particular, in conventional Couette viscometers. As a critical combination of the cylinder rotation frequencies is reached, a flow instability appears, leading to the appearance of Taylor vortices in the form of toroidal cells in the longitudinal direction.²²⁶ This effect is used in separators and mass transfer reactors. The size and behaviour of the Taylor cells for the spiral Poiseuille flow (a combination of the Couette flow and longitudinal fluid flow) has been studied.²²⁶

Rotational motion including the Couette flow can be studied using the oscillating (rotating) field gradients. Varying the rotation frequency of the field gradient allows selective observation of the signal of a cylindrical fluid volume element for which the rotation frequency coincides with the gradient rotation frequency.³⁰⁴ The 2D correlation spectra of the Couette flow

obtained using the VEXSY exchange spectroscopy exhibit a complex 'ridge' pattern, which is to some extent similar to the Pake structure in the 2D dipolar correlation spectroscopy.²³⁸

Information on the flow of fluids in extruders is useful for optimisation of extrusion process. The velocity distribution maps of a 1.5% aqueous carboxymethylcellulose solution in an extruder with open or closed discharge with immobile cylinder and a rotating straight or tapered screw, obtained using the MRI technique were compared with the results of model calculations.²³⁰

MRI is also widely used in the investigations of multicomponent flow systems; the technique allows studies of the flow of individual components of complex mixtures. The contributions of different components can be separated in a variety of ways.^{1,288} Application of the chemical shift selective NMR imaging was demonstrated taking the oil-in-water emulsions as examples. This type of emulsions is of great importance for food and petrochemical industries.^{288,305} It was found that the radial distribution profiles of the longitudinal velocity²⁸⁸ and the maximum velocity³⁰⁵ for water and oil are identical. At the same time, profile-shape analysis showed that the emulsion viscosity decreases as the shear rate increases.²⁸⁸ Partial separation of the emulsion due to shear-induced migration of the dispersed phase allowed one to observe the flow of neat oil, water and emulsion as well as a recirculation flow in front of the tube contraction.²⁸⁸

Complex fluids, such as polymer solutions and melts, emulsions, suspensions, gels and micellar solutions exhibit viscoelastic properties under mechanical stress. Rheology studies the mechanical properties of such viscoelastic fluids, usually under conditions of a steady-state flow accompanied by shear deformation. The rheological properties of non-Newtonian fluids should be taken into account in the design of various technological processes. Online measurements of the rheological properties of materials in the course of a technological process are of importance for control purposes. MRI can be used as a technique for fast contactless determination of the rheological properties of materials.

In contrast to conventional methods, a single NMR flow imaging experiment with a viscoelastic fluid can provide information on the fluid viscosity over a broad range of shear rates. Information on the shear rate is extracted from the spatial flow velocity distribution maps.^{306,307} For instance, for a laminar fluid flow in a capillary [expression (25)] the shear rate,

$$\dot{\gamma}(r) = \left| \frac{dV(r)}{dr} \right|, \quad (26)$$

continuously changes from zero at the centre of the capillary to the maximum value on the capillary walls. Given the pressure drop, the expression for the shear stress has the form

$$\sigma(r) = -\frac{\Delta P}{2L}r, \quad (27)$$

where r is the current radius and $\Delta P/L$ is the pressure gradient. Shear viscosity can be found as

$$\eta(\dot{\gamma}) = \frac{\sigma(\dot{\gamma})}{\dot{\gamma}}, \quad (28)$$

which allows extraction of information on the shear viscosity for a range of shear rates from one map.³⁰⁶

A number of rheometer designs and features have been reported.^{308,309} These devices can be placed inside the probe of an NMR microimager to perform rheo-NMR microimaging studies of the properties of various fluids. The flow velocity distribution maps of water and polydimethylsiloxane in such rheometers have been obtained.³⁰⁸ Rheometers are small devices and require small amounts of fluids to be studied; hence, one can produce high shear rates.^{308,309} It was found³⁰⁸ that combining rheo-NMR microimaging and NMR spectroscopy allows one to

relate the mechanical properties of fluids to their molecular properties. For instance, the ^2H NMR spectrum of a CTAB/ D_2O micellar solution (CTAB is cetyltrimethylammonium bromide) was studied as function of the radial coordinate in the gap between two cylinders in the Couette geometry. Line splitting in the NMR spectrum measured in the region of the maximum mechanical stress near the internal cylinder walls indicated the formation of a nematic phase in this region of the sample. In a study of polyacrylamide in D_2O it was found that the shear rate correlates with the spin relaxation times of the polymer.

The rheological behaviour of polymer melts, including the shear viscosity, is of great importance in many technological processes. For instance, the molecular mass distribution of linear polymers correlates with the dependence of their shear viscosity on the shear rate.³⁰⁶ Velocity profile measurements for a low density polyethylene melt flowing at 232°C along a cylindrical tube showed that the fluid exhibits a nearly Newtonian behaviour; a slight decrease in viscosity was observed only at shear rates higher than 1 s^{-1} .³⁰⁷

A markedly decreasing dependence of the shear viscosity on the shear rate (the minimum and maximum values differ by two orders of magnitude) was obtained for the flow of a 1% carboxymethylcellulose solution in a tube.³⁰⁶ This dependence is in agreement with the results of conventional measurements performed at shear rates exceeding 10 s^{-1} .

A feature of the motion of suspensions and pastes under conditions of inhomogeneous shear distribution is particle migration towards the region of low shear rate,³¹⁰ which results in strong concentration gradients in the initially well-mixed suspensions and has a negative effect on their heat exchange properties. Simultaneously, this causes essential changes in the rheological properties, since the effective viscosity is strongly dependent on the particle concentration.

A number of studies has been devoted to the investigations of particle migration and its influence on the velocity distribution and concentration profiles for suspensions of microspheres immersed in viscous fluids in different flow geometries. For instance, a suspension of monodispersed spherical particles in a Newtonian fluid of the same density was plunger pumped³¹¹ along a cylindrical tube with abrupt contraction and expansion. The velocity distribution along the diameter was described by the function (25) with $\beta = 2.8$. Analogous experiments were carried out for a suspension of poly(methyl methacrylate) microspheres in polyalkylene glycol in the Couette flow and in a single-screw extruder with a closed outlet.²³⁷

Separation into phases with substantially different viscosities was observed for an aqueous micellar solution and tomato sauce in a plate-and-cone rheometer. Tomato sauce was found to separate into two phases with different rheological properties in Couette geometry.³⁰⁸

Blood can be considered as a complex heterogeneous suspension. Probably, a nonlinear relationship between the mechanical stress, σ , and the shear rate $\dot{\gamma}$

$$\sqrt{\sigma} = 0.33 + 0.16\sqrt{\dot{\gamma}} \quad (29)$$

can be explained by blood erythrocyte migration towards the region with minimum shear stress at the centre of the tube.²⁷² 'Stacking' of erythrocytes at low shear rates equalises the flow velocity along the cross-section of the capillary, thus flattening the maximum of the velocity distribution profile even at small Reynolds numbers (10–50); in addition, some indications of flow disturbance and the presence of the transverse velocity components have been reported. After transition to a turbulent flow (at $\text{Re} \approx 2300$) the experimental blood velocity profile was less flattened than the velocity profile of a water–glycerol mixture of the same viscosity, which can be associated with the elastic properties of erythrocytes.²⁷²

Water flow at the centre of a developing wheat grain¹⁸⁸ and a rising water flow in plant stems^{227,270} (from $45\text{ }\mu\text{m s}^{-1}$ to

3 mm s⁻¹) have been studied. A downflow of nutrients towards the roots of the plant in a castor bean seedling has been reported.²⁷³ Since the pixel size in the NMR images is much larger than the wood tracheid diameters, reliable determination of the velocity in most cases was achieved using the dynamic MRI technique.^{188, 270, 273, 291} This approach permits simultaneous measurements of the velocity distribution maps and the diffusion coefficient. For instance, the experimental diffusion coefficient of water in a wheat grain was found to be 8.3×10^{-6} cm² s⁻¹.¹⁸⁸ In studies of water flow in developing quail and bantam eggs the fluid flow was detected only after a four-day incubation period,²⁵² the maximum flow velocity being 1 mm s⁻¹. In addition, a pulsatile flow at a frequency of 0.4 Hz was detected in the quail egg after a 167 h incubation period.

Studies of other types of motion have been reported, *e.g.*, rotation of a gelatin sample in a tube at rates up to 60 rpm (see Ref. 300) and the transverse expansion of a gel cylinder at axial compression at a constant velocity.²⁸⁶ A combination of static and quasi-static deformation of materials with phase encoding of the molecular displacements can be used for the determination of a material's response to mechanical strain followed by reconstruction of Young's modulus maps by solving the corresponding model equations.³¹²

The distribution of dynamic deformations associated with the propagation of the compression and shear waves in a medium is studied by magnetic resonance elastography.^{313, 314} The technique involves creation of transverse acoustic waves with frequencies ranging from 10 to 2000 Hz in tissues or materials. In this case, the wave attenuation in the medium is much smaller than the ultrasound damping, while the wave propagation velocity is low. In addition, the shear modulus varies over a range of several orders of magnitude.³¹⁵ The waves are created using mechanical or electromechanical (*e.g.*, piezoelectric) devices or a modulated ultrasonic beam. The modulated magnetic field gradients applied synchronously with the oscillations of the medium change the phase of the NMR signal, which is proportional to the spin displacement amplitude and to the amplitude, period and number of the field gradient cycles. This can be used for improving the sensitivity of the experiment to the small-amplitude oscillations of the medium.^{313, 315} The technique allows the detection of displacements smaller than 100 nm. By processing the NMR images one can obtain the spatial molecular displacement amplitude maps, as well as the wave propagation velocity maps in the medium and the elastic modulus maps.³¹⁶ Observation of wave reflection from the boundaries and wave refraction at the interface between the soft and rigid regions of the medium, accompanied by variations of the wave propagation velocity, is also possible.^{314, 315} The wave propagation dynamics can be visualised by combining variation of the phase shift between the magnetic field gradient and the wave with animation.^{315, 317} The possibility of studying single waves or short deformation wave trains in the media³¹⁵ and observing the interference pattern for two point sources have been demonstrated.³¹⁴ Wave propagation velocity and wave attenuation measurements at different temperatures were carried out for phantoms as well as animal and human tissues.³¹⁷

4. Filtration

Fluid flow in porous materials (filtration) often occurs in nature and technology (*e.g.*, in perfusion in biological tissues, petroleum recovery and in catalysis). Dispersive character of the flow is critical to filtration. Flow velocity dispersion is due to several mechanisms.^{157, 318} For a laminar fluid flow in a tube the flow velocity dispersion is due to different particle velocities [see formula (25)]. In this case, the dispersion is to some extent reversible (this can be achieved by reversal of the flow direction). Taylor dispersion is due to random velocity modulation as a result of lateral diffusion. Mechanical dispersion is due to the velocity modulation when moving through a complex system of channels

in the pore space. The presence of stagnant regions (*e.g.*, dead-ended pores) causes dispersion due to partial fluid retention.

Application of the MRI technique to studies of filtration processes has some advantages over other methods, since it allows characterisation of not only the flow properties, but also the medium structure, porosity and saturation level, which can be used for, *e.g.*, estimating the medium permeability and the capillary pressure.³¹⁹ The NMR-porosimetry technique¹ permits the pore size distribution to be determined and even the structure of the pore space to be visualised by recording the 3D images if the pores are relatively large.^{318, 320, 321} The results obtained can then be used in simulation of the fluid flow. Selective detection of the NMR signals of different fluids¹ allows studies of the processes occurring in multicomponent systems.

The MRI techniques employed in the flow studies in porous media have some salient features. When determining the content of a fluid in a porous sample using the NMR imaging technique, one should take into account the fact that the T_1 and T_2 relaxation times of the fluid inside the pores are usually much shorter than those of the bulk liquids, which affects the amplitude of the NMR signal. In addition, the relaxation times depend on the saturation level of the sample.^{322, 323} The relaxation behaviour is complicated in the presence of fluid mixtures. For instance, a surface film of the wetting fluid (water) prevents the T_1 time of oil (in contrast to the T_1 time of water) from 'sensing' the surface, while the transverse relaxation rate can decrease with a decrease in the oil content due to concentration of oil inside larger pores.³²⁴ Therefore, quantitative measurements require analysis of the relaxation behaviour^{322–324} and/or using the calibration curves for the signal amplitude.³²⁴

Placing a sample with numerous interfaces between phases with different magnetic susceptibilities in a magnetic field produces strong local field gradients, which can affect the accuracy of the results obtained, especially if the flow velocities to be measured are low.³²⁵ Fluid flow in an inhomogeneous magnetic field causes further shortening of the decay time of the transverse magnetisation, T_2^* . Therefore, the pulse sequences based on the spin echo or stimulated echo are most often employed, which include the 180°-pulses for refocussing of the transverse magnetisation in the local field gradients.^{326, 327} Usually the condition $T_1 \gg T_2^*$ is met; hence, the stimulated echo technique is preferable. It allows one to perform measurements at the longest observation times, Δ , since in this case the NMR signal decay is determined by the T_1 rather than T_2^* time.

In most cases the pore size of the medium is less than or comparable with the spatial resolution of the NMR images.³²⁶ This leads to a limited use of the imaging techniques involving the averaging of the fluid velocity over the volume element corresponding to a particular pixel of the NMR image.³¹⁸ In particular, calculations of the mass flow rate and the flow velocity distribution should be carried out with inclusion of partial-volume correction.³²⁸ Therefore, often preference is given to the measurements based on the average propagator (corresponding to the number of the molecules with a given velocity, averaged over the measuring time rather than volume)³²⁵ rather than the velocity histogram construction.^{321, 325, 326, 329, 330}

By measuring the propagator one can study the molecular migrations over distances that either are shorter than the characteristic pore size or are of the order of several pore sizes.^{331, 332} At short Δ , the propagator corresponds to the molecular motions inside individual pores³³³ and characterises the instantaneous velocities of a random, steady-state fluid flow^{331, 334} as well as diffusive molecular displacements.¹⁸² In the short-time limit (at $\Delta \rightarrow 0$) the contribution of the diffusive displacements is predominant. In contrast to this, at long Δ , where the fluid flow causes the molecules to be displaced over distances of the order of several pore sizes, measurements of the propagator allow the determination of the average molecular displacements and studies of the hydrodynamic dispersion.³¹⁸

The effective dispersion coefficient can also be defined at short Δ . For an exponential velocity correlation function of the form

$$R_u(t) = \langle u(0)u(t) \rangle = \langle u^2 \rangle \exp\left(-\frac{t}{\tau}\right), \quad (30)$$

the effective dispersion coefficient, D' , is given by the formula

$$D' = \frac{1}{2} \langle u^2 \rangle \Delta \text{ at } \Delta \ll \tau, \quad (31)$$

$$D' = \langle u^2 \rangle \tau \text{ at } \Delta \gg \tau. \quad (32)$$

Thus, the dispersion coefficient D' measured along the direction of the net flow ($D_{||}$) initially increases and then reaches the asymptotic limit as Δ increases.³¹⁸ Generally, there is no need to assume a Gaussian shape of the propagator. The average molecular displacement and the dispersion coefficient only correspond to the two lowest moments of the displacement distribution, whereas the propagator provides a complete displacement distribution.³³⁵

By carrying out experiments with modulation of the field gradient one can determine the frequency spectrum of the fluid velocity autocorrelation function in the frequency range from 10 Hz to 100 kHz. This spectrum is defined as

$$D'(\omega) = \int_0^\infty \langle u(0)u(t) \rangle \exp(i\omega t) dt \quad (33)$$

and describes the dependence of the hydrodynamic dispersion coefficient (tensor) on the fluid particle motion frequency, ω .^{163, 255, 318, 336} The approach allows studies of the frequency spectrum of the particle motions and separation of the contributions of the motions corresponding to different time scales.¹⁶³

The propagator is usually obtained by using the Fourier transform of the echo amplitude, $E(\mathbf{q}, \Delta)$, measured at different $\mathbf{q}$ values [see expression (19)]. However, the dispersion coefficient can also be obtained in another manner, by analysing the $E(\mathbf{q})$ dependence in the small $\mathbf{q}$ region (analogously to the diffusion coefficient).³¹⁸ In contrast to other methods, dispersion measurements with NMR directly provide the necessary information and do not require solving model equations. They also permit the dispersion coefficient to be measured both along the net flow (pressure gradient) and in the transverse direction.

When measuring the propagator, there is no need of introducing any tracers into the flow since their role is played by the phase of the transverse magnetisation. Another approach to the dispersion studies involves the use of paramagnetic compounds (tracers) and recording the relaxation-weighted NMR images.^{137, 337–340} The local concentration of the paramagnetic tracer can be determined from the nuclear spin relaxation time of the fluid.^{337, 339}

The most widely used model of filtration is water flow through a cylindrical bead pack. If the beads are sufficiently large, the NMR images of stagnant water in the bead make it possible to visualise individual pores and the inter-pore channels and to analyse the structure of the pore space.^{320, 321} Mapping different velocity components allowed one to establish the character of the correlation between the average flow rate (F) through the pore 'neck' and the 'neck' surface area (S). All experimental dependences were found to be intermediate between linear $F \sim S$ (plug flow) and quadratic $F \sim S^2$ (viscous flow).³²¹ The maximum flow velocities in bead packs much exceed the average velocity,^{321, 328} while a large fraction of the fluid flow is confined within a small region of the pore space.³²⁰ Transition to a diffuse fluid flow inside the bead pack occurs at a distance of the order of the bead diameter from the inlet edge.³²⁸ Some indications of reverse flows have been reported.³²¹ Peculiarities of water flow in a tube in the regions upstream and downstream the plastic bead pack have been studied.³²⁸

At $d_c/d < 10–15$ (d_c is the diameter of the bead pack and d is the bead diameter), the edge effects play a significant role.³³¹ The dependences of the average bed porosity and the average flow velocity on the distance from the cylinder wall have been plotted based on the experimental data. The porosity is maximum on the cylinder walls (due to ordering of beads), whereas the flow velocity is maximum at a distance approximately one particle radius thick.^{318, 320} Capillary electrochromatography and pressure-driven filtration experiments with bead packs with a small d_c/d ratio confirmed the higher velocity in the near-wall region.³⁴¹ Bead packing inhomogeneities were found to affect the fluid flow.

Both versions of measurements of the average propagator (with or without spatial resolution) are widely used in studies of water flow through bead packs. Judicious choice of the field gradient allows one to obtain the propagator for both longitudinal and transverse molecular displacements, while variation of the observation time permits flow studies in different characteristic length scales. If the average molecular displacements are smaller than the characteristic pore size, the longitudinal propagator is asymmetric, centred at zero displacement^{187, 331} and exhibits an exponentially decaying wing towards larger displacements.^{182, 331} As the observation time increases, the amplitudes of the near-zero peak¹⁸⁷ and of the exponential wing³³¹ decrease; this is accompanied by the formation of a Gaussian propagator centred at the average longitudinal molecular displacement (see Fig. 4b).^{182, 187, 318, 331} At the same time, the average transverse molecular displacements are equal to zero; therefore, the corresponding transverse propagator is centred at zero at any observation time³³¹ and usually has a Gaussian shape, though a propagator represented by the sum of two Gaussians was observed for an bed of glass beads 290 μm in diameter at small molecular displacements.³³¹ The first Gaussian curve corresponded to the hydrodynamic dispersion coefficient, which is four-fold greater than the self-diffusion coefficient of water. The amplitude of this curve decreased with an increase in the observation time. The second curve continuously broadened with increase in the average longitudinal displacement.³³¹ The longitudinal and transverse propagators were also represented as the sums of three curves corresponding to diffusion/dispersion in different length scales and characterised by different diffusion/dispersion coefficients (and different average displacements for axial propagator) and by the observation time dependent relative contributions.¹⁶⁰

The longitudinal ($D_{||}$) and transverse ($D_{\perp}$) dispersion coefficients are much larger³⁴² than the self-diffusion coefficient of the bulk fluid, D_0 , with $D_{||}$ being more than an order of magnitude larger than $D_{\perp}$.¹⁸² For instance, water flow through a pack of glass beads 3 mm in diameter at $\text{Pe} = 1570$ ($\text{Pe} = v l / D_0$ is the Peclet number, where v is the average velocity and l is the characteristic pore size) and $\text{Re} = 3$ is characterised by $D_{||} = 3000 D_0$ and $D_{\perp} = 80 D_0$.¹⁸⁷

The experimentally measured values were found to be dependent on the time³³¹ and spatial³⁴³ averaging scales. The average molecular velocity and $D_{||}$ reach the limiting values at $\Delta \sim 20 d/v_z$, while for $D_{\perp}$ this occurs¹⁶⁰ at $\Delta \sim (5–10) d/v_z$, the D' value increasing with the average velocity.^{125, 318} As the volume (layer thickness) included in the averaging increases, a predicted fluctuation of $D_{||}$ occurs.³⁴³ The calculations also predict a decrease in $D_{||}$ on further increase in the layer thickness. Spatially resolved measurements of the propagator for inhomogeneous samples exhibit the spatial inhomogeneity of the velocity and dispersion distribution.³¹⁸ A number of models for the description of the propagators measured in the filtration experiments have been proposed.^{333, 343, 344}

Slowing down the net mass transfer due to diffusive mass transfer inside porous granules is an important dispersion mechanism for the beds comprised of porous beads.¹⁸² Here, the longitudinal and transverse propagators are described by the sum of two Gaussian curves. One curve is centred at zero displacement and corresponds to diffusion in the bead pores, which allows the determination of the tortuosity factor of the pore

space.^{182, 342, 345} The other curve corresponds to the fluid moving in the intergranular space,^{342, 345} which makes it possible to calculate the average flow velocity (for the longitudinal propagator). With the known fluid flow rate one can find the porosity of the bed if the observation time is not too long.^{182, 345}

In the experiments with beds comprised of porous beads the variations of the average flow velocity and observation time affect variations of the propagator in different manners. An increase in the flow velocity has virtually no effect on the contribution of the fluid confined inside the pores.^{331, 342, 345} At the same time, an increase in the observation time causes the amplitude of the first Gaussian curve to decrease due to water exchange between the pore volume and the intergranular space, thus allowing the exchange dynamics to be studied.^{182, 331, 342, 345, 346} In the long-time limit, the average longitudinal and transverse propagators characterise only the flow contribution; which allows the determination of the overall porosity of the system (layer + beads).¹⁸²

Sometimes, an analogous picture was also observed for water flowing through a non-porous bead (granule) pack (see Fig. 4b).³¹⁸ The component of the propagator centred at zero molecular displacement is thought to correspond to stagnant water present at intergranular contacts. For smaller granules, the characteristic size of these 'pools' is also smaller and the contribution of the immobile fluid decreases faster with increasing the observation time.

Studies of the frequency spectrum $D(\omega)$ of transverse molecular motions for a fluid flowing through a bead pack revealed the presence of three components of the molecular displacements: (i) Brownian motion, (ii) coherent oscillatory motion relative to the bead pack axis due to curvilinear flow around the beads and (iii) random perfusive walks. The experimental spectra, $D(\omega)$, exhibit a characteristic maximum, which is shifted towards higher frequencies with increasing the flow velocity and corresponds to coherent oscillations. A high-frequency plateau $D(\omega) = D_0$ corresponds to diffusive motions, while the low-frequency plateau, which decreases with increasing the flow velocity, corresponds to random perfusive motions.¹⁶³

Measurements of the propagators $P(\mathbf{R}_1, A_1; \mathbf{R}_2, A_2)$ characterising the mutual probability density of a molecular displacement over distance $\mathbf{R}_1$ over time A_1 and over distance $\mathbf{R}_2$ over time A_2 (including the VEXSY and SERPENT experiments) permit studies of the spatial and time correlations of flow velocity fluctuations.^{283, 318, 347} In particular, this approach was employed in comparing fluid flows in disordered and ordered porous media.³⁴⁷ In some instances the spatial velocity correlation can also be calculated from the spatial velocity distribution maps.³³⁷

Molecular motions in a periodic system of identical pores can be accompanied by the appearance of coherence effects. For instance, experiments with water flow through a bead pack revealed flow-dependent diffraction-like effects manifested as a maximum in the plot of the dependence of the echo amplitude, E , on q near $q = 1/d$ (d is the bead diameter). Simulation of the results obtained allowed the determination of the longitudinal hydrodynamic dispersion coefficient, average inter-pore distance and the pore sizes. The peak indicates that the molecular displacements are correlated in the bead-diameter length scale.^{125, 318}

Interest in the flow of gases, fluids and suspensions through porous rocks is first of all related to the gas and oil recovery. For most of rocks mapping the pore space using the MRI technique is impossible. At the same time, the amplitude of the NMR signal from a fluid-filled core depends on the local porosity of the core.³²⁵ The Darcy relation connects the flow velocity to the medium permeability, thus allowing establishment of a correlation between the local porosity and permeability.³³⁰

The flow velocity distribution maps obtained for water, brine^{326, 329, 330} or a mixture of aliphatic hydrocarbons³²⁵ in sandstone cores were converted into corresponding velocity histograms and it was found that the flow velocity increases almost linearly with the medium porosity.³³⁰ The velocity distribution

obtained for a layered core with bimodal pore size distribution was found to be nearly Gaussian.³³⁰ A correlation between the hydrodynamic dispersion coefficient and the average flow velocity has been observed.³²⁹

The flow velocity maps obtained for identical flow rates were shown to be different if the flow rate was altered in between the measurements.³²⁹ To explain this, a stochastic theory of flow through a porous medium has been proposed.³²⁹

Similarly to model bead packs, at short observation times the longitudinal (along the pressure gradient) propagator obtained for the fluid in the sandstone core is centred at zero displacements and exhibits a wing decaying towards larger displacements; as the observation time increases, the propagator approaches a Gaussian curve.^{333, 334} The transverse propagator has a Gaussian shape, is centred at zero displacement and broadens with the delay time.³³³ Measurements of the 2D propagator revealed correlations between the longitudinal and transverse molecular displacements.³³⁴

Filtration of colloidal suspensions are of great practical value for borehole drilling. When using drilling fluids, clay permeates the pores of the surrounding rock, which affects the drilling efficiency and the operating performance of the borehole. Large surface area of suspended clay causes substantial variations of the T_1 time of the fluid, which allows one to follow the clay accumulation in the pores.^{348–350} The maximum penetration depth of clay into the core is less for the cores with lower permeability^{348, 350} and is reached after relatively short times. Further injection of clay suspension has no effect on the penetration depth.^{348–350} For highly permeable limestone the process is accompanied by substantial porosity reduction.³⁵⁰

Filtration is accompanied by deposition of a layer of increased concentration of retained molecules, particles or droplets on the filter surface. Measuring the dependence of the spin relaxation time of the fluid on the pore size allowed the determination of the spatial porosity distribution in the dense deposit layer during pressure-driven filtration of aqueous clay suspension.³⁵¹

Considerable attention has been given to the multicomponent flows and displacement of particular components. These processes occur when cleaning contaminated soils and are of interest from the standpoint of improving the extraction of petroleum content from rocks. By selecting the contribution of a particular component to the NMR signal one can obtain, *e.g.*, the distribution of water (brine) and oil in the sample throughout the displacement process.

A number of studies on the displacement of oil (hydrocarbon) by pumping water through oil-saturated cores^{322, 323, 352–354} or granular beds³⁵⁵ has been reported. Water ingress into cores occurs in the form of jets, the characteristic size of which is much less than the spatial resolution achieved in the experiments.³⁵³ As a result, water rapidly permeates into the sample; however, the process is not accompanied by substantial displacement of oil and the formation of a sharp interface between the two fluids. As time passes, a gradual displacement of oil by water occurs uniformly throughout the sample. A fraction of oil is retained within the sample after pumping a large amount of water, which was confirmed by recording the water and residual oil distribution profiles.^{352, 353, 355} Water poured in a cavity of a porous thimble-shaped ceramic sample pre-saturated with C_6F_6 causes the hydrocarbon to be displaced uniformly across the sample section,⁴⁹ which was confirmed by recording 2D NMR images using the ^{19}F NMR signals.

Displacement of water from various cores^{323, 324, 353, 356} or a granular bed³⁵⁵ by pumping oil has been studied. The process is accompanied by the formation of a clearly visible interface between the two liquids.^{353, 355} The residual water content in the core strongly depends on the oil flow rate.³²⁴ For a sample with the axial bedding planes different porosity and permeability of different layers led to different displacement rates.³²³ Displacement of oil and water by isopropyl alcohol has been studied.³⁵²

The propagators for flowing water or oil at different residual content of oil (water) in the core³³⁴ and for two-phase flow of water and dodecane^{334, 357} have been measured.

The presence of a contaminant (residual content of a poorly soluble fluid) confined inside the pores of a medium can be responsible for prolonged poisoning of water pumped through the medium. Displacement of *n*-hexanol by water from a sand layer was studied by recording the *n*-hexanol distribution profiles.³⁵⁸ The behaviour of individual octanol droplets during the displacement process was followed by using a pack of large beads (3–5 mm).³⁵⁹ Recording the velocity distribution maps showed that a fraction of droplets distant from the fast jet flow is removed very slowly. An increase in the water pumping rate and a decrease in the droplet size led to faster removal of the contaminant. A number of numerical simulations of the process has also been reported.^{358, 359}

Experiments on simultaneous filtration of water and air through a bead pack showed that their distribution in the layer remains inhomogeneous for a rather long time after starting the flow (2 h). It was also found that a nine-fold increase in the water flow rate after establishing the steady-state flow leads to a redistribution of the fluid and gas in the layer, whereas an eight-fold increase in the gas flow rate causes only insignificant changes.^{320, 360}

Filtration induced dispersion can also be studied by introducing paramagnetic tracers into the flow and following the movement of the tracer concentration front in the porous medium. The presence of inhomogeneities in the bead pack or core cause a significant increase in dispersion of the tracer concentration front.^{137, 337, 338} A study of the dispersion coefficient in a pack comprised of large beads showed that the tracer concentration front oscillates with a spatial period equal to the bead size due to the flow velocity fluctuations occurring with the same spatial period. This behaviour was confirmed by model calculations using a 2D grid of cylindrical pores with variable cross-sections.³³⁹

Secondary convective flows due to the gravity force are of significant importance if the bead pack is arranged vertically and the fluids to be mixed have different densities.³⁴⁴ Bottom feed of a more concentrated $\text{Mn}_2(\text{EDTA})$ solution (EDTA is ethylenediaminetetraacetic acid) causes a uniform movement of the concentration front along the flow direction. The injection of the solution from the top leads to a parabolic front accompanied by its convective spreading. Flow direction reversal experiments showed that dispersive spreading of the concentration front is fully irreversible in the former case and partially reversible in the latter (a pack of 2 mm beads was studied). When 8 mm beads were used, a flow instability was observed, accompanied by fast dispersion of the concentration front along the full length of the bead (22 cm).³⁴⁴ It was found that a density gradient causes convection in stagnant fluid. A study of inhomogeneous bead pack with the top part filled with brine and the bottom part filled with water showed that advective fingering is observed first in the region with a higher permeability and later — in the rest of the bead pack.³³⁸

The movement and transformations of the concentration front in chromatographic and ion-exchange columns have been studied.^{340, 361, 362} Because of the high velocity of movement of the concentration bands, investigations of high-pressure chromatography processes require the use of fast NMR imaging techniques. This allowed visualisation^{340, 361} of the movement of $\text{Gd}(\text{DTPA})$ solution (DTPA is diethylenetriaminepentaacetic acid) with a velocity of up to 1 mm s^{-1} at an external pressure of nearly 55 atm. At pH 6 of the liquid phase, a compact concentration band was found to move through a column filled with silica gel without changes in its shape with time. However, an analogous process at pH 7 was accompanied by appreciable band broadening and a change in the shape. NMR images also allow one to assess the packing character of the stationary phase in the column. In particular, in columns with the slurry packed stationary phase the packing gradient of the solid phase induced a gradient of the

spin relaxation times of the fluid throughout the height of the column.

Experiments with a chromatographic column in the form of the bed of polystyrene beads swollen in THF (bead diameter: 100 μm) showed⁴⁹ that a fluoro derivative of glycine poured onto the bead pack surface moves down the column right to the bottom without retention in the polystyrene microcavities.

Processes in a column loaded with ion-exchange resin (Na^+ form) were studied by recording the NMR images using the ^{23}Na NMR signal. The movement of the free Na^+ ion concentration front down the column during successive elution with aqueous HCl solution, aqueous NaCl solution and water was followed.^{340, 361}

5. Motion of granulated materials

The NMR imaging technique is also used in the investigations of the motion of solid granulated materials, when optical methods are inapplicable because of opaqueness of the objects under study. Experiments are carried out with liquid-containing solid particles, such as liquid-containing pharmaceutical pills, mustard and poppy seeds and porous granules partially saturated with liquid. Segregation of granulated materials can be studied using their mixtures with solid particles that are 'invisible' to NMR.

The motion of solid particles in rotating cylinders is widely used in grinding, granulation, mixing and drying of solid granulated materials and in coating processes. When the cylinder is full, rotation of the entire sample allows estimation of the accuracy of the particle concentration and particle velocity distributions obtained in the experiments.²⁵³ The NMR images of a half-filled horizontal cylinder show different regimes of the particle motion depending on the rotation rate.²⁵³ The oblique surface of the granular bed exhibits a clearly visible layer with a reduced average density of the 'flowing' particles, the layer thickness being dependent on the rotation rate. A density gradient due to the dynamic particle packing effects was also observed in other regions of the granular bed.²⁵³ The dynamic angle of repose at different rotation rates was measured²⁵⁴ and the spatial particle velocity distribution maps in the cylinder were obtained.^{253, 254, 265}

Experiments aimed at determining the correlation time of the particle motion, τ , the autocorrelation velocity function [expressions (20) and (21)] and the diffusion coefficient D for the axial motion of particles in a rotating cylinder have been carried out.^{265, 279} It was found that the effective axial diffusivity is maximum near the foot of the sliding particle layer^{254, 279} and is different at different distances from the surface.²⁷⁹ The characteristic τ values lie in the millisecond range, the D are three orders of magnitude higher than the self-diffusion coefficient of water²⁶⁵ and the mean square of velocity fluctuations, $\langle u^2 \rangle$, exceeds $10^{-3} \text{ m}^2 \text{ s}^{-2}$ (see Ref. 279). The experimental values of the dynamic angles of repose, and the spatial maps of concentration, velocity and diffusivity values obtained for solid granules are in good agreement with the results of calculations.²⁵⁴

Often, relative motion of particles with different properties (size, density, shape) causes spontaneous segregation of mixtures. Nearly immediately after a cylinder filled with a well-mixed mixture of particles of different sizes starts to rotate, radial segregation occurs, accompanied by an increase in the concentration of smaller particles near the axis of rotation.³⁶³ As the cylinder continues to rotate, radial segregation evolves into an axial segregation until complete segregation of the mixture into several layers comprised of the particles of different size, which follow one another in the axial direction.³⁶³ For a binary mixture the trends to segregation due to different particle size and density can be mutually compensated.³⁶⁴ If the system is described in the 'particle size' – 'particle density' coordinates, there is a boundary corresponding to good mixing, whereas moving away from the boundary causes greater segregation.

To intensify the motion of solid particles, vibration is often used. For instance, a study has been reported of the motion of beads 2 mm in diameter placed in a container attached to a lever,

the long arm of which was connected to a loudspeaker.³⁶⁵ The amplitude of the oscillations of a specified frequency (20–25 Hz) supplied to the loudspeaker increased until a value at which arching was observed using a stroboscope. The amplitude of container displacements was ~ 0.5 cm. Alternating left-right arching has been studied. The 2D NMR images of the vibrating layer at different instants of the oscillation period exhibited the effect of doubling the oscillation period. The layer edges execute an out-of-phase motion: when one edge is at the top, the other is at the bottom, and *vice versa*. The largest shear deformation was observed in the middle region of the layer, which always moves from the elevated towards the lowered edge of the layer.

Convection in a particle layer placed in a periodically shaken cylindrical container has been studied by recording the NMR images.³⁶⁶ Transformation of the shape of spatial tags illustrated an upward motion of the particles near the axis of the cylinder and a downward motion near the walls, the velocity on the walls being maximum in absolute value. Except for the near-surface region, the velocity of the motion exponentially decreases with increase in the depth.³⁶⁶ The propagators for the vertical particle displacement at different shaking frequencies and amplitudes have been obtained.³³⁵

The gravity driven filtration of a fine-grained granulated material through a pack of larger beads, simulating a catalytic reactor, has been studied.⁸ The 2D NMR flow velocity maps of the material exhibited a flow not only near the walls, but also in the bulk of the bead pack. The propagators characterising the flow velocity distribution of small granules have also been obtained.

6. Gas flow

Gases have large diffusion coefficients as compared to liquids. Because of this, one can expect that the diffusive displacements of gas molecules contribute largely to the net displacement over the observation time. This seems to be the reason for weak interest in the application of the MRI technique to gas flow studies until recently. However, recent advances in this field^{93, 217, 367, 368} are thought to give an impetus to intensive research on gas flow. In particular, visualisation of the flow of gaseous hydrocarbons^{93, 367} can be useful in the MRI studies of heterogeneous catalytic processes.

The potentialities of the NMR imaging technique in the studies of the flow of gases with equilibrium spin polarisation in moderately strong magnetic fields (7 T) have been illustrated taking acetylene, propane and butane flowing in a circular cross-section tube or in transport channels of a monolithic catalyst as examples.^{93, 367} The longitudinal velocity distribution maps obtained for a developed laminar butane flow in a tube exhibit a parabolic radial velocity distribution (Fig. 5a). The propagator measured under the same conditions virtually coincides with the velocity histogram constructed based on the velocity distribution maps. As the observation time becomes sufficiently long for diffusive molecular displacements over a distance of the order of the tube diameter to occur, the rectangular propagator changes into a Gaussian one due to the Taylor dispersion.

It was also found that laminar gas flow can be visualised using the spatial tag technique, which exhibits transformation of a linear tag created normal to the flow direction into a parabolic tag. At the same time, as the Reynolds number approaches the critical value, the NMR signal amplitude rapidly attenuates below the noise level, which precludes investigations of the transition to turbulent flow and a developed gas turbulence.

Nevertheless, the MRI technique can be applied to studies of not only developed laminar flows, but also establishment of a developed gas flow through the entrance region of a tube or channel. The MRI velocity distribution maps for the gases flowing through a tube into a cylinder of a larger diameter, containing a fragment of a monolithic catalyst, at $Re = 190$ –570 have been obtained (see Fig. 5b). In this case the velocity distribution across the transport channels is significantly different from analogous

Figure 5. Visualisation of butane flow by the phase contrast technique.² Two-dimensional velocity map (1) and its one-dimensional cross-section (2) for a laminar gas flow in a tube with a circular cross-section; the velocities for the two-dimensional map are given at the right, those for the one-dimensional cross-section are given at the left (a); velocity map for butane flowing into a cell of a monolithic catalyst (cell diameter: 21 mm) with 4 mm square channels (b).

distribution for a completely developed laminar flow. In particular, inhomogeneous shear rate distributions across the channel cross-sections are observed. This is in agreement with the estimates of the entrance length, which exceeded the distance from the inflow edge of the monolith to the NMR image plane.^{93, 367}

Studies of gas filtration through porous materials are of considerable interest. As mentioned above, spatially resolved MRI techniques are of limited use even for liquids. Typical of gases with equilibrium polarisation is a low signal-to-noise ratio, which makes this approach of little promise. In this connection, it is of interest to use the average propagator approach in gas filtration studies. For instance, the propagators for longitudinal and transverse displacements of gas molecules in a porous medium have been obtained for a cylindrical glass bead pack (Fig. 6). By and large, transformation of the propagators with increasing Δ is similar to those observed for the filtration of liquids. At short Δ , a broad (due to high gas diffusion coefficient) Gaussian propagator centred at zero displacement is observed. As Δ increases, a wing appears in the large displacement region and then a Gaussian propagator is formed, which is centred at the average molecular displacement. The width of the propagator is determined by the gasodynamic dispersion coefficient. Despite high gas diffusion rates, the experimental longitudinal and transverse dispersion coefficients are much larger than the self-diffusion coefficient D_0 ($D_0 = 0.03$ cm² s⁻¹ for butane at a pressure of

Figure 6. Averaged propagator for axial displacement of butane molecules flowing through a cylindrical glass bead pack (bead diameter: 3.2 mm; bead pack diameter: 21 mm). Observation time: $\Delta = 1, 2, 5, 10, 20, 40, 80, 150$ ms (the corresponding curves are plotted from top to bottom).

The inset presents the data for $\Delta = 40, 80, 150, 300$ and 600 ms.

1 atm and room temperature). The dependence of the dispersion coefficient on the observation time, flow velocity and bead size has been studied. The VEXSY experiments were also carried out, which allowed one to follow the loss of molecular velocity correlation in the pack with increasing the observation time in spite of a rather large diffusive contribution.

Experiments with hyperpolarised gases^{369–372} permit substantial improvement of the signal-to-noise ratio compared to that obtained for gases with equilibrium polarisation. In particular, this makes it possible to achieve a rather high spatial resolution when recording the NMR images using the NMR signal from the gas molecules in macroporous materials. However, acceleration of the spin relaxation of the gas in the pores of the medium can sacrifice the advantages of using hyperpolarised gases in the studies of filtration through many materials.

Xenon flow was investigated using a system with continuous circulation of polarised ^{129}Xe , which allowed enhancement of the magnetisation by more than three orders of magnitude compared to the equilibrium ^{129}Xe polarisation at the same magnetic field (4.2 T).^{217,368} The 2D images in the mixed k, q -space (propagator

with spatial resolution along one coordinate) were obtained in dynamic MRI experiments. Studies of xenon flow in a round tube²¹⁷ at different observation times Δ revealed that Taylor dispersion due to lateral molecular diffusion causes the gasodynamic dispersion coefficient initially to increase with increase in the delay time and then to reach a plateau at delay times that are longer than the characteristic time of molecular diffusion over a distance of the order of tube diameter.

A feature of xenon flow in a tube with a diaphragm having a small opening at the centre is flow acceleration at the tube axis and the reverse flow in the near-wall regions as a result of flow turbulence.³⁶⁸ Analogous studies were also carried out for parallel xenon flow through two polyurethane foam samples with pores 400 and 200 μm in diameter. The velocity distribution maximum was found to be shifted towards higher velocities for the material with a lower density and larger pores.

Application of MRI to gas filtration studies allows the local permeability of porous samples to be determined. If the porous material does not adsorb a gas, the signal amplitude in the NMR image is proportional to the local gas pressure, whereas the viscosity of an ideal gas is pressure independent. Knowledge of the velocity field permits calculations of the spatial distribution of material permeability using the Darcy equation. In this case, carrying out the 1D experiments does not require gas velocity measurements.³⁷³

* * *

When studying various mass transfer processes, a detailed picture of a particular process can be obtained only when using modern physicochemical methods that allow spatially resolved measurements. Numerous examples presented in this review demonstrate that MRI is an efficient tool for studying such processes. The authors hope that this information will be of use to those dealing with mass transfer problems in various fields of science and technology.

This review has been written with the financial support by the Russian Foundation for Basic Research (Project Nos. 02-03-32770 and 00-15-97450) and the Siberian Branch of the Russian Academy of Sciences (the ‘Integration’ Programme Project No. 46).

VII. Supplement

In Table S.1 we present additional information on the MRI studies of mass transfer processes.

Table S.1. Applications of the MRI techniques.

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
0.78	water in fired clay	spin echo	1D	0.17–1 mm, a cylinder 20 mm in diameter	—	^1H	2–4
4.7	H_2O or D_2O in concrete of various composition	spin echo or SPI	2D	64×128 ; a slice 25 mm thick (spin echo)	6 min (SPI)	^1H (SPI), ^2H (echo)	5
5.5	5% methanolic solution of alkylalkoxysilane in hardened mortar	STRAFI + dipolar (solid-state) echo	1D	100 μm	—	^1H	6
0.7	water in gypsum, limestone and mortar	—	1D	< 2 mm	5 min	^1H	9
2	water in limestone	spin echo	2D	128×128	40 s	^1H	10
0.8	water in hardened mortar prepared from Portland cement and silica sand	the same	1D	0.9 mm, a cylinder 20 mm in diameter	—	^1H	11

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
0.78	aqueous NaCl solution in a calcium silicate brick	spin echo	1D	0.25 mm (2 mm), a cylinder 20 mm in diameter	—	^1H , ^{23}Na	12
2.35	water in hardened cement with clay additive (sodium aluminosilicate) and PVA	—	2D	40 μm , a slice 0.35 mm thick	—	^1H	13
0.7	water in sandstone cores	gradient echo with oscillating gradients	1D	0.4 mm, a cylinder 25 mm in diameter	5.5 s	^1H	14
0.5	decane in peroxide vulcanised natural rubber	the same	2D	250 (400) μm for decane, 600 μm for rubber, a slice 5 mm thick	20 min	^1H	21
2.4	water in zeolite 4A	SPRITE	1D	64 points, 0.55 mm	< 2 min	^1H	22
0.7	the same	gradient echo with oscillating gradients	1D	—	few seconds	^1H	23
2.0	n-hexane in zeolite NaX	stimulated echo	1D	0.3 mm	2 min	^1H	24
1.4	butane in zeolites NaCaA, water in zeolite NaX	FID	1D	0.5 mm	—	^1H	25
2.0	n-Hexane in zeolite NaX	stimulated echo	1D	0.3 mm	2 min	^1H	26
2.35	water in soil (humus)	spin echo	2D	128 $\times$ 128 or 256 $\times$ 256, (0.47 mm) ^{2} or (0.35 mm) ^{2} , a slice 20 mm thick	—	^1H	27
7.05	acetonitrile, benzene, dichloromethane and CCl_4 in carbonaceous adsorbent	FID	—	WSR	—	^1H	28
7.05	water in copolymer of 2-hydroxyethyl methacrylate and tetrahydrofurfuryl methacrylate	spin echo	3D	128 $\times$ 128 $\times$ 8, 78 μm $\times$ 78 μm $\times$ 3.75 mm	35 min	^1H	29
7.05	vulcanised <i>cis</i> -1,4-polybutadiene + cyclohexane- d_{12}	the same	2D	256 $\times$ 256, (37 μm) ^{2} or (58 μm) ^{2} , a slice 1 mm thick	—	—	30
7.05	vulcanised polybutadiene rubber + deuterocyclohexane or cyclohexane- d_{12}	"	2D	256 $\times$ 256, (39 μm) ^{2} or (32 μm) ^{2}	—	—	31
2	acetone in vulcanised rubber	"	1D	128 points, 100 μm a slice of 0.5 cm^2 surface area	32 s	^1H	32
—	hot water (100 $^\circ\text{C}$) in nylon-6,6	steady-state free spin precession (SSFP)	1D	240 μm	—	^1H	33
9.4	1,4-dioxane in PVC	spin echo with inversion – recovery	2D	(70 μm) ^{2} , a slice 4 mm thick	—	^1H	35
9.4	acetone or acetone + methanol in bisphenol A polycarbonate	the same	2D	(70 μm) ^{2} , a slice 4 mm thick	—	^1H	35
2.35	toluene in butadiene rubber, hexafluorobenzene in methylsiloxane rubber, methanol in PEMA, pyridine in bituminous coal	spin echo	2D	128 $\times$ 128, (70 μm) ^{2}	10 min (^1H), 30 min (^{19}F)	^1H , ^{19}F	36

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
2.35	pyridine in bituminous coal, methanol in PEMA, toluene in isobutyl rubber	—	2D	$128 \times 128, (40 \mu\text{m})^2$	10 min	^1H	37
7	CH_3OD in PMMA	gradient echo (FLASH)	2D, 3D	$200 \mu\text{m}$	—	^1H	38
7	acetone or CH_3OD in PMMA	spin echo	2D	256×256 , a slice 2 mm thick	—	^1H	39
7	CH_3OD in water-soaked PMMA	gradient echo (FLASH)	2D	$256 \times 256, (100 \mu\text{m})^2$, a slice 1 mm thick	10 min	^1H	40

7.05	water in Portland cement with or without superplastifier	SPI	2D	64 $\times$ 64 or 124 $\times$ 64, 101 μ m $\times$ 140 μ m	—	¹ H	86
0.75	water in clay brick, lime-and-sand brick or gypsum	spin echo	1D	0.15 mm	40 min	¹ H	87
0.1	water in limestone	gradient echo	3D, 1D	128 $\times$ 128 $\times$ 16, 2 $\times$ 2 $\times$ 8 mm (3D); 2 mm, a slice of surface area 10 $\times$ 10 cm (1D)	26 min (3D)	¹ H	88
4.7	water in alumina or silica	the same	2D	a slice 1 mm thick	—	¹ H	89
4.7	water in glass bead pack	spin echo (Hahn echo, EPI or PEPI)	2D, 3D	128 $\times$ 128; (94 μ m) ² , a slice 0.5 mm thick (2D); 128 $\times$ 128 $\times$ 128, (117 μ m) ³ (3D)	51 min or 24 s (2D); 9 h or 15 min (3D)	¹ H	94
2	water or aqueous solution of sodium dodecylsulfate in glass bead pack, sand, silica gel, potato starch	spin echo	1D	a slice 5 mm thick	—	¹ H	95
9.4	dispersion of acryl or polystyrene latex in water	the same	2D	512 $\times$ 512, (43 μ m) ² , a slice 2 mm thick	8.5 min	¹ H	97
9.4	emulsion of alkyd resin in water, aqueous dispersion of acryl latex	"	2D	512 $\times$ 512, (20 μ m) ² , a slice 0.5–1 mm thick	7–51 min	¹ H	98
9.4	water in composite liquid packaging cardboard	"	1D, 2D	128, 15.6 μ m, a slice 2 mm thick (1D); 128 $\times$ 16, 15.6 $\times$ 500 μ m, a slice 8 mm thick	24 s (1D); 2 min (2D)	¹ H	100
0.5	water in white oak wood	"	2D	256 $\times$ 256, (1.2 mm) ² , a slice 8 mm thick	12.8 min	¹ H	101
4.7	water in corn grains	"	2D	(234 μ m) ² , a slice 1.3 mm thick	640 s	¹ H	105
2	brine in sandstone or limestone	stimulated echo	—	WSR	7 h	¹ H	117
2	water in glass bead pack, in limestone, chalk and sandstone cores	inversion–recovery signal or stimulated echo	—	WSR	—	¹ H	118

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
2	brine in carbonate rocks and sandstone	stimulated echo	—	WSR	—	^1H	121
1.9	C_2F_6 or C_4F_8 in ceramics (yttrium-stabilised zirconia)	spin echo	3D	—	2 h	^{19}F	122
4.7	^{129}Xe (3 atm) in glass cylinder	stimulated echo	—	WSR	—	^{129}Xe	123
8.5	N_2 in zeolites NaCaA and NaX	spin echo	—	WSR	—	^{15}N	124
—	water in polystyrene bead pack	the same	2D, WSR	$(31.5\text{ }\mu\text{m})^2$, a slice 200 μm thick or WSR	—	^1H	125
1.5	human brain, rat brain <i>in vivo</i>	intermolecular two-quantum coherence + EPI	2D	64×64 ; $(3.8\text{ mm})^2$, a slice 15 mm thick (<i>Homo</i>) or $(0.48\text{ mm})^2$, a slice 4 mm thick (rat)	—	^1H	133
2	copper ions or 4-amino-TEMPO in water-containing gels	spin echo with inversion – recovery	1D	0.1 – 0.2 mm	—	^1H	135
0.2	Fe(II) and Fe(III) ions in agar gel	the same	1D	512, 0.11 mm	28 – 112 s	^1H	136
2	copper ions in water-containing polyacrylamide gel	"	2D	256×256 (128×256), $(0.15\text{ mm})^2$	150 s	^1H	137
2	copper in water-saturated limestone core	"	2D	256×128 , $(0.47\text{ mm})^2$	2.3 min	^1H	137
2.35	D_2O in lyotropic liquid crystal	spin echo	—	WSR	—	^2H	140
1.4	0.1% CuSO_4 + water in capillary	spin echo + PRI	2D	$(20\text{ }\mu\text{m})^2$, a slice 1 mm thick	—	^1H	141
5.9	5% polyacrylamide gel in D_2O	stimulated echo	—	WSR	—	^1H	145
2	water, acetonitrile, DMSO and n-butanol in ampoules; celery stalk	spin echo	2D	128×128 ; $(0.34\text{ mm})^2$, a slice 5 mm thick	—	^1H	147
7.05, 11.7	$\text{H}_2\text{O}/\text{D}_2\text{O}$ or ethanol/ $\text{H}_2\text{O}/\text{D}_2\text{O}$ in ampoule	spin echo or stimulated echo	1D, WSR	—	—	^1H	148
4.7	water in glass or polystyrene bead pack	stimulated echo	—	WSR	—	^1H	149
4.7	water or polyacrylamide gel	spin echo	2D	64×64 ; $(0.63\text{ mm})^2$, a slice 4 mm thick (water) or $(1\text{ mm})^2$, a slice 10 mm thick (gel)	—	^1H	152
4.7	water, pork loin <i>in vitro</i>	the same	—	WSR	—	^1H	153
2.0	water between glass plates	"	—	WSR	—	^1H	155
—	various liquids in rocks or alumina	stimulated echo	—	WSR	—	^1H	156
14.1	yeast cells	the same	—	WSR	—	^1H	159

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
2	water + CuSO ₄ in glass bead pack	stimulated echo	—	WSR, a slice 3.6 cm thick	1040–2080 s	¹ H	160
2	water in a polystyrene bead pack or brine in calcium carbonate	the same	—	WSR	—	¹ H	161
4.7, 7	water in kraft cellulose	"	—	WSR	—	¹ H	162
7	water in ampoule or in granular ion-exchange resin pack	spin echo	—	WSR	—	¹ H	163
2	1 mM CuSO ₄ + water in a tube	gradient echo	2D	128 × 64, a slice 5 mm thick	—	¹ H	164
4.7	water or H ₂ O/D ₂ O in alumina or silica	spin echo	2D	128 × 128, (40 μm) ² , a slice 0.3–1 mm thick	—	¹ H	167
1.89	H ₂ O/D ₂ O in zirconia	the same	1D	128 points, 184 μm	17 s	¹ H	174
2.35	H ₂ O/D ₂ O in laponite gel	—	1D	—	—	¹ H	175
—	water in porous polystyrene, natural sponge, pumice stone or glass bead pack	spin echo or gradient echo	3D	—	—	¹ H	176
5	DMSO + NaCl + H ₂ O + D ₂ O in artificial dermal replacement	gradient echo	2D	128 × 128, (67 μm) ² , a slice 2 mm thick	20 or 40 s	¹ H	177
8.5	DMSO, propylene glycol, methanol in fish embryo	spin echo	2D	128 × 128, (40 μm) ² –(17 μm) ² , a slice 100–600 μm thick	—	¹ H	178
6.3	4-hydroxy-TEMPO in water-containing silk fibroin gel	the same	2D	(0.2 mm) ² , a slice 2 mm thick	5 min	¹ H	180
4.7	Ni ²⁺ ions in water-saturated sand pack	—	2D	—	2 min	¹ H	181
4.7	Na ⁺ ions in water-saturated sand pack	spin echo	1D	256 points, 0.5 mm without slice selection	7 min	²³ Na	181
0.5	water in porous silica bead pack	stimulated echo	—	WSR	—	¹ H	182
4.7	water in alumina or silica	the same	—	WSR	—	¹ H	183
9.4	hexadecane in silica bead pack or MgO/n-octanol paste with or without Fe ₂ O ₃ additive	"	—	WSR	—	¹ H	186
2	water or aqueous NaCl solution in glass bead pack or sandstone	"	—	WSR	—	¹ H	187
1.4	water in wheat grain	stimulated echo + PRI	2D	64 × 64, (100 μm) ²	1.6 h	¹ H	188
3	white matter of human brain	spin echo	2D	128 × 128, (2 mm) ² , a slice 5 mm thick	—	¹ H	189
7.5	xylene (or toluene) + non-ionic detergent + water	stimulated echo	—	WSR	—	¹ H	190

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
7.05	suspension of human blood erythrocytes	spin or stimulated echo	—	WSR	25 min	^1H	193
7.05	water in glass bead pack	stimulated echo	—	WSR	—	^1H	194
4.7	water and 20% gelatin solution; cat brain <i>in vivo</i>	spin echo	2D	$128 \times 128, (0.55 \text{ mm})^2$	—	^1H	195
0.5	water + CuSO_4 , polyethylene glycol, cyclohexane; apple, seedling of a plant	the same	—	WSR	—	^1H	196
1.5	Xe (0.78 atm) + O_2 (0.15 atm) in glass sphere	FID after selective inversion	1D	1024 points, 0.5 mm (2 mm)	—	^{129}Xe	197
2	^3He (9 atm) + O_2 (2 atm) in glass sphere	spin echo	1D	1024; 0.1 mm, a slice 16 mm thick	—	^3He	198
1.9	^3He (7 atm) in cylinder	gradient echo	1D	0.8 mm	—	$^3\text{He}^*$	199
9.4	Xe (30 atm) and O_2 in aerogel	chemical shift selective spin echo	3D	$(420 \mu\text{m})^2$, a slice 1 mm thick	—	^{129}Xe	200
7	C_2F_6 (5 atm) in ceramic composite	spin echo	2D	$(100 \mu\text{m})^2$, a slice 0.5 mm thick	12 h	^{19}F	201
4.7	Xe (1–3 atm, 90% ^{129}Xe) + O_2 or Xe* (3 atm) in a glass cell or glass bead pack	gradient echo, spin echo or stimulated echo	—	WSR	—	$^{129}\text{Xe}^*, ^{129}\text{Xe}$	202
1.4, 9.4	propane, propene, water, acetone or isopropanol in CsNaX zeolites	spin echo	—	WSR	—	^1H	203
1.4	ethane in NaX and NaCaA zeolites	stimulated echo	—	WSR	—	^1H	204
4.7, 9.4	ethane in zeolite H-ZSM-5	spin echo	—	WSR	—	^1H	205
9.4	n-butane or methane in zeolites	stimulated echo	—	WSR	—	^1H	206
7.05, 9.4	benzene (+ Xe) in zeolite powder, 2,3-dimethylpentane or Xe in zeolite with coke	spin echo	1D, 2D	—	—	$^1\text{H}, ^{129}\text{Xe}$	207
2.1	ethane and ethene in zeolite NaX	the same	—	WSR	—	^1H	208
2.1	cyclopropane and propene in zeolite NaCdX under reaction conditions	"	—	WSR	—	^1H	209
9.4	ethene + CF_4 in silicalite or H-ZSM-5	"	—	WSR	15 min	$^1\text{H}, ^{13}\text{C}$ or ^{19}F	210
—	ethane or methane in AlPO_4^{3-} molecular sieves	stimulated echo	—	WSR	—	^1H	211
9.4	CH_4 or CF_4 in zeolites	spin echo	—	WSR	—	^1H	212
11.75	Xe + He in tris-(<i>o</i> -phenylenedioxy)cyclophosphazene crystallites	broad-line NMR	—	WSR	—	$^{129}\text{Xe}^*$	213

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
2.1	water + CuSO ₄ and octanol in glass capillaries	B ₁ -tomography with recording of pseudo-echo and PRI	2D	60 projections, (11 μm) ²	—	¹ H	214
8.5	water in capillaries	spin echo + gradient echo	1D, 2D	128, 9.4 μm, a slice 0.6 mm thick or without slice selection (1D); 128 × 128, (9.4 μm) ² (2D)	2 s (1D)	¹ H	215
3	water in a narrow slit (plastic)	spin echo	1D	512, 25 μm	—	¹ H	216
4.3	Xe flow at 0.8–1.3 atm in a tube 4 mm in diameter	dynamic NMR microscopy (PGSE, PGSTE)	2D in mixed <i>k</i> – <i>q</i> -space	512 × 256(<i>q</i>) (256 × 32) or 1024 × 32(<i>q</i>) (512 × 16), 100 μm, without slice selection	—	¹²⁹ Xe*	217
4.3	Xe (2 atm, 80% ¹²⁹ Xe) in an ampoule with rectangular cross-section	FID gradient echo	1D, 2D 1D	—	—	¹²⁹ Xe*	218
0.0031	Rb (10–100 mg) + N ₂ (10–200 Torr) + ³ He (0.2–2.5 atm) an ampoule with rectangular cross-section	FID	1D	—	—	³ He*	219
—	water in a bent tube with square cross-section	—	—	—	—	—	221
1.5	water in a tube with a cylindrical flow obstruction	gradient echo (EPI)	2D	1.9 × 1.8 mm, a slice 2 mm thick	64 ms	¹ H	224
4.7	water in gap between two coaxial cylinders	gradient echo (FLASH)	2D	512 × 512, 195 × 117 μm or (107 μm) ² , a slice 2 mm thick	0.5 s	¹ H	226
1.4	water + CuSO ₄ in a capillary, water in a plant stem <i>in vivo</i>	stimulated echo + PRI	2D	128 × 128; (12 μm) ² , a slice 1 mm thick (capillary), (75 μm) ² , a slice 3 mm thick (plant)	—	¹ H	227
—	water + 1 mM CuSO ₄ in a tube	gradient echo (FEER)	—	—	—	¹ H	228
—	1.5% solution of carboxymethylcellulose in extruder	spin echo	2D	128 × 128, (0.39 mm) ² , a slice 10 mm thick	—	¹ H	230
2.1	water + CuCl ₂ in membrane bioreactor	the same	2D	—	—	¹ H	231
1.4	water + 0.1% CuSO ₄ in a tube with abrupt contraction (expansion)	spin echo + PRI	2D	64 × 64, a slice 0.33 mm thick	—	¹ H	232
4.7	water + CuSO ₄ in a tube with contraction	spin echo + gradient echo (EPI)	2D	64 × 64, 1.25 × 0.625 mm or 1.5 × 0.5 mm, a slice 2 mm thick	105–115 ms	¹ H	233
1.5	water + glycerol in a tube with branching	gradient echo	2D	256 × 256, (0.5 mm) ² , a slice 4 mm thick	—	¹ H	234
11.9, 14.1	1 mM KCl + water in a tube filled with glass spheres or without glass spheres	spin echo	2D	128 × 128, (78 μm) ² , a slice 100 μm thick	—	¹ H	235
1.5	water in U-shaped tube	gradient echo	2D, 3D	128 × 256 (2D); 192 × 256 × 16, 1 × 0.8 × 1.2 mm (3D)	2 or 10 min (2D)	¹ H	236

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
0.6, 2	polyalkylene glycol (PG) or PMMA microspheres in PG	—	2D	128×128 or 256×256 , a sample 1 cm thick	—	^1H	237
7, 1.4	water, water + 0.1% CuSO_4 , or water + 0.5% high-molecular mass PEO	stimulated + spin echo (VEXSY)	—	WSR	140 min or 4.5 h	^1H	238
0.5	water + CuSO_4 in U-shaped tube	—	2D	256×256 , $(0.78 \text{ mm})^2$, a slice 2 or 3 mm thick	36 min	^1H	239
1.9	fluid in tube	gradient echo	2D	256×256 , $(0.5 \text{ mm})^2$, a slice 4.2 mm thick	—	^1H	240
2.35	water in a tube with contraction/expansion	FID + PRI or spin echo	2D	256×256 , $(118 \mu\text{m})^2$, a slice 2 mm thick (echo); 128×32 or 256×64 , 0.7, 0.8 or 1.6 mm, a slice 0.5 cm thick (FID)	8 or 23 ms (FID)	^1H	244
0.5	blood in thoracic aorta	spin echo or gradient echo	2D	256×256 , $(1.6 \text{ mm})^2$, a slice 10 mm thick	15–20 min	^1H	245
1.5	water + MnCl_2 or water + human albumin in tube	spiral trajectories	2D	$(1.46 \text{ mm})^2$ – $(2.4 \text{ mm})^2$, a slice 5–7 mm thick	180 ms (60 ms)	^1H	246
7.05	water + CuSO_4 in a tube or cylinder	spin echo	2D	256×128 , $(0.27 \text{ mm})^2$, a slice 2 mm thick or 1024×64 , $0.078 \text{ mm} \times 0.23 \text{ mm}$, a slice 0.4 mm thick	17 or 2 min	^1H	249
2	water in a tube with partitions	the same	2D, 3D	$128 \times 64 \times 64$ (3D)	137 min	^1H	250
1.0	water + CuSO_4 in a tube	gradient (EPI) or spin echo	2D	64×64 , $(375 \mu\text{m})^2$ (EPI) or 256×256 , $(94 \mu\text{m})^2$ (spin echo); a slice 2.5 mm thick	21.12 ms (EPI)	^1H	251
4.7	fertilised bird eggs	gradient echo	1D, 2D	$(200 \mu\text{m})^2$ or $(300 \mu\text{m})^2$, a slice 2.7 mm thick	—	^1H	252
1.9	mustard seeds in horizontal rotating cylinder	spin echo	2D	128×128 ; $(0.8 \text{ mm})^2$, a slice 8 mm thick	15 min	^1H	253
1.9	the same	the same	2D	a slice 8 mm thick	—	^1H	254
1.9	water in straight tube or a tube with branching	gradient echo or spin echo	1D, 2D	—	—	^1H	256
4.7	water in a tube	spin echo	2D	256×256 , $(78 \mu\text{m})^2$ or $(65 \mu\text{m})^2$, a slice 1 mm or 3 mm thick	6.5, 13 or 80 min	^1H	261
7.05, 14.1	DMSO or water in an ampoule 5 mm in diameter	stimulated echo	2D	32×256 ; a slice 1.4 mm thick	10 min	^1H	262
2.35	water in a tube with U-shaped bend	FID, radial trajectories (RUFIS); spin echo	2D	0.6–1.2 mm (RUFIS)	8–11 ms (RUFIS)	^1H	263
2	water + CuSO_4 , turbulent flow in a tube	spin echo (EPI)	2D	64×64 , $(1.2 \text{ mm})^2$, a slice 3 mm thick	33 ms	^1H	264
1.9	oil-filled plastic beads in horizontal rotating cylinder	spin echo	2D	$(1 \text{ mm})^2$, a slice 20 mm thick	—	^1H	265

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
1.9	water + glycerol in a tube with diaphragm (stenosis)	spin echo	2D	128×256 , $(0.39 \text{ mm})^2$	—	^1H	266
1.5	intracardiac blood flow	gradient echo	3D, 2D	$256 \times 256 \times 16$, $1.2 \times 1.2 \times 8 \text{ mm}$ (3D); 256×128 , $1.25 \times 2.5 \text{ mm}$, a slice 7 mm thick	29 min (3D), 2 min/a slice (2D)	^1H	267
0.47	water + CuSO_4 in a tube, water in tomato stem	spin echo (turbo)	2D	128×128 , $(315 \mu\text{m})^2$ or $(117 \mu\text{m})^2$, a slice 3 mm thick	31 or 64 s	^1H	270
7	water + glycerol + CuSO_4 or pig blood in tube	spin echo	1D	$78 \mu\text{m}$ or $23 \mu\text{m}$, a slice 1 mm thick or WSR	20 min (1D)	^1H	272
7.05	0.1% aqueous solution of PEO in tube, water and nutrients in castor-oil plant stem	the same	2D	128×128 , $(54.7 \mu\text{m})^2$; 64×64 , $(469 \mu\text{m})^2$ or $(1.4 \text{ mm})^2$ (tube); 128×128 , $(47 \mu\text{m})^2$ (stem)	—	^1H	273
—	water + CuSO_4 in a coiled tube	gradient echo	2D	64×64	1 min	^1H	274
1	water in a tube	spin echo + gradient echo	2D	32×32 , $(0.75 \text{ mm})^2$, a slice 4 mm thick	20.5 ms	^1H	276
2	water + CuSO_4 in a tube with grid-generated turbulence or without it	gradient echo	1D	256 or 128 , 0.29 or 0.58 mm , a slice 3 mm thick	—	^1H	277
1.5	water + MnCl_2 in a tube with contraction–expansion	the same	2D	256×256 , $(590 \mu\text{m})^2$, a slice 5 mm thick	—	^1H	278
1.9	oil-filled plastic beads in horizontal rotating cylinder	spin echo	2D	$(1 \text{ mm})^2$, a slice 20 mm thick	—	^1H	279
7	water in a tube or in a dialysis cell	spin echo or stimulated echo	—	WSR	—	^1H	280
7.05	water + CuSO_4 in a tube or conical converging tube	spin echo	—	WSR	—	^1H	281
7	$\text{C}_6\text{D}_5\text{NO}_2$	the same	1D	$90 \mu\text{m}$	—	^2H	282
2	water + CuSO_4 in glass bead pack	spin echo + stimulated echo	—	a slice 10 mm thick	—	^1H	283
11.75	water in a tube	spin echo	2D	128×128 , $(39 \mu\text{m})^2$, a slice 500 μm	—	^1H	285
7	water in a tube, gel during compression	spin echo (PEPI)	2D	32×32 , $125 \times 250 \mu\text{m}$	80 ms	^1H	286
7	0.1% CuSO_4 + water in a tube or hemodialysis cell	spin echo	2D	128×64 , $94 \times 190 \mu\text{m}$ a slice 1.6 mm thick	—	^1H	287
2	flow of water, sunflower oil or oil-in-water emulsion in a tube	gradient echo	2D, 3D	64×64 , $(850 \mu\text{m})^2$ or $(780 \mu\text{m})^2$, a slice 2 or 2.5 mm thick; $64 \times 64 \times 64$, $(710 \mu\text{m})^3$ (3D)	20–60 s (2D); 23 min (3D)	^1H	288
0.47	water + MnCl_2 on walls of a monolithic catalyst	—	—	128×128 , $(0.4 \text{ mm})^2$ or 192×192 , $(78 \mu\text{m})^2$, a slice 4 mm thick	13–17 min	^1H	289
4.7	polydimethylsiloxane film on vertical surface	spin echo	2D	—	—	^1H	290
0.7	water + MnCl_2 in a tube, corn stem, tomato pedicel	stimulated echo + (turbo) spin echo	2D	128×128 , $(0.16 \text{ mm})^2$ or $(0.12 \text{ mm})^2$, a slice 3 or 4 mm thick	17–19 min	^1H	291

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
1.5	water + MnCl_2 in a tube, blood in human femoral artery	gradient echo or spiral trajectories	2D	256×256 , $(0.63 \text{ mm})^2$ or 205×205 , $(0.88 \text{ mm})^2$, a slice 10 mm thick	—	^1H	292
1.5	water in a tube placed in agar gel	gradient echo	2D	256×256 , $(2.44 \text{ mm})^2$, a slice 5 mm thick	—	^1H	293
7, 11.7	convection in DMSO, water or chloroform	stimulated echo	—	WSR	—	^1H	294
7, 11.7	DMSO, water or chloroform	FID	1D	$170 \mu\text{m}$	—	^1H	294
2	convection in silicon oil	spin echo	2D	256×256 , a slice 1 cm thick	4 min	^1H	295
7.05	5% polystyrene in cyclohexane	the same	2D, WSR	—	—	^1H	296
4.7	falling droplet of water or water + surfactant	—	2D, 3D	—	10 h (3D)	^1H	297
7	1 mM KCl + water in a tube	stimulated echo	2D	128×128 , $(78 \mu\text{m})^2$, a slice 4 mm thick	—	^1H	298
2	water + CuSO_4 in U-shaped tube	spin echo	2D	256 , a slice 5 mm thick	—	^1H	299
1	gelatin in a rotating tube, water in a tube	gradient echo + spin echo	2D	32×32 , $(0.75 \text{ mm})^2$	20.48 ms	^1H	300
2.35	water in a tube with contraction	FID + PRI or spin echo	2D	24 mm FOV (32 projections per 180° sector), a slice 5 mm thick (FID); a slice 2 mm thick (echo)	11 ms (FID)	^1H	301
1.5	water + GdCl_3 (EDTA) in a tube or in a tube with expansion	gradient echo	2D	256×256 , $(1.25 \text{ mm})^2$ or $(0.94 \text{ mm})^2$, a slice 1 cm thick	263 s	^1H	302
2	5 mM CuSO_4 + water in gap between two coaxial cylinders	gradient echo, spin echo	2D 1D	512×512 , $(50 \mu\text{m})^2$, a slice 5 mm thick (2D); 512 , $50 \mu\text{m}$, a slice of surface area $1 \text{ mm} \times 1 \text{ cm}$	2 min (2D); 3.2 s (1D)	^1H	303
4.7	50% $\text{H}_3\text{PO}_4/\text{D}_2\text{O}$ in gap between two coaxial cylinders	spin echo	1D	—	—	^{31}P	304
4.7	oil-in-water emulsion (5% or 20%) + detergent and CuSO_4 in a tube or hollow-fibre membrane filter	spin or stimulated echo	2D	128×128 , $(94 \mu\text{m})^2$ or 256×256 , $(47 \mu\text{m})^2$, a slice 1 mm thick	—	^1H	305
0.6	1% solution of carboxy-methylcellulose in a tube	spin echo	1D	$147 \mu\text{m}$	192 s	^1H	306
0.6	low-density polyethylene melt in a tube	the same	1D	256 ; 0.25 mm	—	^1H	307
7.05	water or polydimethylsiloxane in NMR rheometers of different design	"	2D	128×128 , $(20 \mu\text{m})^2$, $35 \times 78 \mu\text{m}$ or $96 \times 32 \mu\text{m}$, a slice 2 mm thick or without slice selection	30 min	^1H	308
7.05	aqueous solution of cetylpyridinium chloride + sodium salicylate, tomato sauce, CTAB/ D_2O micellar solution, polyacrylamide/ D_2O	"	2D	—	—	^1H , ^2H	309

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
1.9	PMMA beads + a mixture of fluids in a tube with contraction and expansion	spin echo	2D	128×128 or 256×128 , $(200 \mu\text{m})^2$, a slice 0.5 cm thick	2 or 4 min	^1H	311
2	urethane rubber based composite or dog kidney in gelatin	stimulated echo	2D	128×128 or 256×256 ; $(0.8 \text{ mm})^2$ or $(0.6 \text{ mm})^2$, a slice 5 or 10 mm thick	—	^1H	312
1.5	agar gel	gradient echo (FLASH)	2D	256×256 ; $(0.55 \text{ mm})^2$	12 s	^1H	313
1.5	agar gel or pig kidney in gel	gradient echo or spin echo	2D	128×128 or 256×256 , a slice 10 mm thick	10–120 s	^1H	314
1.5	agar gel	gradient echo (FLASH)	2D	128×128 or 256×256	20–120 s	^1H	315
1.5	tissues <i>ex vivo</i> , agar gel, female breast	gradient echo or spin echo	2D	256×128 ; $0.63 \times 1.25 \text{ mm}$, a slice 10 mm thick	—	^1H	317
7	water in latex microsphere pack	spin echo	2D	128×128 , $(31.5 \mu\text{m})^2$, a slice 200 μm thick or 64×64 , $(63.5 \mu\text{m})^2$, a slice 1 mm thick	—	^1H	318
2	D ₂ O + hexadecane in limestone	—	1D	—	—	^1H	319
4.7	water or water + air in granular alumina pack	spin echo	3D	$256 \times 256 \times 32$, $(156 \mu\text{m})^3$	—	^1H	320
4.7	water in glass bead pack	the same	2D, 3D	256×256 , $(195 \mu\text{m})^2$, a slice 1 mm thick; $256 \times 256 \times 256$, $(195 \mu\text{m})^3$ (3D)	—	^1H	321
2	water or n-hexadecane + D ₂ O in sandstone or limestone	"	1D	0.6 mm	—	^1H	322
2	water or D ₂ O + n-octadecane or n-hexadecane in sandstone or limestone	"	1D	0.42 or 0.19 mm, a slice 4 mm thick	2 min or 16 s	^1H	323
2	D ₂ O and n-dodecane in limestone	"	1D, 2D	128 points, 783 μm (1D)	—	^1H	324
1.9	mixture of aliphatic hydrocarbons in sandstone	stimulated echo	2D	$(1.2 \text{ mm})^2$, a slice 14 mm thick	—	^1H	325
0.5	water in a tube, water or 3% brine in sandstone	spin echo	2D	$(1 \text{ mm})^2$ or $(3 \text{ mm})^2$, a slice 1 cm thick	—	^1H	326
0.5	water in a tube or water in glass bead pack	stimulated echo	—	WSR	—	^1H	327
1.9	water + contrast agent in plastic bead pack	spin echo	2D	128×128 or 128×256 , $(0.4 \text{ mm})^2$, a slice 5 or 20 mm thick	4 min	^1H	328
—	water in sandstone	spin echo (PEPI)	2D	a slice 18 mm thick	—	^1H	329
2	1% KCl + water in sandstone	spin echo	3D	$64 \times 64 \times 16$, $1 \times 1 \times 8 \text{ mm}$	—	^1H	330
0.5	water in bead pack	spin echo or stimulated echo	—	WSR	—	^1H	331

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
2	3% aqueous NaCl solution in sandstone	stimulated echo	—	WSR	—	^1H	333
2	water or 3% NaCl + dodecane solution in sandstone	the same	—	WSR	—	^1H	334
—	water in polystyrene bead pack	spin echo	—	WSR	—	^1H	336
1.89	water + Gd-based contrast agent in glass bead pack	spin echo, modified stimulated echo	1D 2D	128 (1D), 1.39 mm; 128 × 128, 0.91 mm × 1.16 mm, a slice 5 mm thick	300 ms (1D)	^1H	337
1.5	water + CuSO_4 or water + CuSO_4 + NaCl in fused quartz bead pack	spin echo	2D	128 × 128, (2.36 mm) ² , a slice 5 or 10 mm thick	0.5–3 min	^1H	338
5	GdCl_3 in glass bead pack filled with water	spin echo, stimulated echo	2D	128 × 16, 1 × 3 mm, a slice 4 mm thick	—	^1H	339
1.5, 4.7	aqueous Gd(DTPA) solution in chromatographic column (^1H); free Na^+ ions in ion-exchange column	gradient echo (FLASH)	2D (^1H), 3D (^{23}Na)	256 × 256 or 128 × 128, (300–1000) × (300–1000) μm , a slice 2–5 mm thick (^1H)	0.4–6 s (^1H), 4 min (^{23}Na)	^1H , ^{23}Na	340
0.5	water in porous silica bead pack	stimulated echo	—	WSR	—	^1H	342
—	water in glass bead pack	spin echo (PEPI)	2D	16 × 32, a slice 10–50 mm thick	—	^1H	343
0.1	$\text{Mn}_2(\text{EDTA})$ complex in glass bead pack filled with water	spin echo	3D, 1D	256 × 128 × 32, 1 × 2 × 3 mm (3D); 256 points, 1 mm (1D)	13 min (3D), 9 s (1D)	^1H	344
0.5	water in porous silica bead pack	—	—	WSR	—	^1H	345
2	3% brine or water + CuSO_4 in glass bead pack, glass or polyamide fibres or in sandstone	stimulated echo	—	WSR	—	^1H	347
348	drilling fluid (suspension of bentonite in water with additives) in limestone or sandstone	spin echo	1D	128; 0.48–2.4 mm	—	^1H	2
2	aqueous clay suspension (bentonite) in limestone	gradient echo (FLASH) or spin echo	2D	128 × 64 or 128 × 128, a slice 5 or 10 mm thick	1.9 s (FLASH)	^1H	349
2	bentonite + water + NaOH + lignosulfonate dispersant (+ barite) in sandstone or limestone	spin echo	1D	128	—	^1H	350
2	clay suspension in water	spin echo with inversion – recovery	1D	0.54 mm	—	^1H	351
1.5	oil + aqueous CaCl_2 solution + isopropanol- d_8 in sandstone, oil + aqueous NaI solution in dolomite	chemical shift selective spin echo	2D	128 × 256, (0.5 mm) ² , a slice 5 mm thick	20 min	^1H	352

Table S.1 (continued).

Field /T	Object, process	Technique	Dimension	Spatial resolution characteristics	Recording time	Nucleus	Ref.
1.89	oil + water in dolomite	chemical shift selective spin echo	1D, 2D	128 points, 0.8 mm (1D), 128 × 128, 0.3 × 0.8 mm (2D)	5 min (1D), 2.5 h (2D)	¹ H	353
2	n-octadecane + D ₂ O in limestone	spin echo	1D	—	7.5 s	¹ H	354
1.9	water + NiSO ₄ or mixture of hydrocarbons in crushed glass pack	the same	2D	256 × 256, (0.45 mm) ² , a slice 1.7 mm thick	26.5 min	¹ H	355
—	hexadecane and D ₂ O in sandstone	—	1D	—	—	¹ H	356
4.7	n-hexanol and water in sand	spin echo	1D	400 μm	—	¹ H	358
4.7	octanol and water in glass bead pack	the same	2D, 3D	256 × 256 × 256, 195 × 195 × 195 μm or 128 × 128 × 128, (390 μm) ³ (3D), 256 × 256, (195 μm) ² , a slice 1 mm thick	—	¹ H	359
1.9	water + Cu(II) in ion-exchange column	gradient echo	3D	16 × 16 × 512, a slice 0.13 mm thick	20 min	¹ H	362
1.9	pharmaceutical granules in horizontal rotating cylinder	spin echo	2D	(0.8 mm) ² , a slice 8 mm thick	—	¹ H	363
2	mustard seeds + glass or sugar beads in rotating cylinder or narrow cylinder	—	3D	128 × 128 × 128	—	¹ H	364
1.9	oil-filled plastic beads rotated in a container	gradient echo	1D (2D)	a slice 4 × 2.5 mm	—	¹ H	365
2	poppy grains in shaken vertical cylinder	—	2D	a slice 1 or 2 mm thick	—	¹ H	366
4.2	Xe (0.4 atm) + N ₂ (0.27 atm) + He (total pressure of the gas mixture 4 atm) in capillaries, in a tube, flow through a tube with diaphragm or polyurethane foam	gradient echo (PGSE)	2D 2D in mixed <i>k-q</i> -space	256 × 128, 110 × 340 μm, a slice 5 mm thick 256 × 32, a slice 4 mm thick	51 min —	¹²⁹ Xe* ¹²⁹ Xe*	368 368
4.3	Xe (1–3 atm, 80% ¹²⁹ Xe) in coaxial tubes or in capillary bundle	gradient echo (FLASH)	2D	128 × 64, 0.1 mm	—	¹²⁹ Xe*	370
4.3	Xe (1–3 atm, 80% ¹²⁹ Xe) in aerogel	the same	1D	0.1 mm	—	¹²⁹ Xe*	370
9.4	Xe (10 ¹⁹ cm ^{−3} , 70% ¹²⁹ Xe) in mice lungs <i>in vitro</i> in an ampoule	"	2D	128 × 128, (0.37 mm) ²	600 ms	¹²⁹ Xe*	371
2.35	C ₃ F ₇ H (2 atm) in phantom or sandstone	gradient echo	1D	0.5 mm	21 min	—	373

Notes: PVA is poly(vinyl alcohol), PVC is poly(vinyl chloride), PEMA is poly(ethyl methacrylate), PMMA is poly(methyl methacrylate), PEO is poly(ethylene oxide), DMSO is dimethyl sulfoxide; PRI is projection reconstructed imaging, WSR is without spatial resolution, FID is free induction decay; EPI is echo-planar imaging, PEPI is echo-planar imaging with PI-pulses, STRAFI is stray field imaging and FLASH is fast low-angle shot.

Electrocatalysis on polymer-modified electrodes

B I Podlovchenko, V N Andreev

Contents

I. Introduction	837
II. Modification of electrode surfaces by polymers	838
III. Electrochemical reactions on polymer-modified electrodes	841
IV. Electrodes coated with polymeric films with incorporated metal-catalyst particles	843
V. Conclusion	847

Abstract. The procedures for applying polymeric films onto conductive supports and doping them with active microparticles of metal-catalysts or functional redox groups are considered. General principles of the electrocatalytic action of these systems are discussed. Experimental results on the electrocatalysis on electrodes modified by polymeric films are analysed. Attention is drawn to systems involving particles of platinum-group metals incorporated into polymeric matrices. The properties of electrodes modified by ion-conducting and electron-conducting polymers are compared. Certain problems to be solved in future studies of the electrode systems under discussion are formulated. The bibliography includes 265 references.

I. Introduction

The development of new types of electrode materials pertains to important problems of electrochemistry. The electrodes the surfaces of which have been formed with involvement of polymeric films are the promising subject of studies aimed at solving this problem.[†] The attention of scientists to these electrode materials is determined by the fact that their adsorption, electrochemical, photoelectrochemical, corrosion and electrocatalytic properties can be changed by varying their surface composition and structure. The progress in solving this problem requires the knowledge of the structure and electrochemical properties of the support-modifying layer system and an insight into the mechanisms of the processes in this system.

Polymers used in electrochemical systems may be divided into two groups, *viz.*, ion-exchange (without electron conduction) and electron-conducting polymers. The polymeric films with solely ionic conduction applied onto conductive supports should be, as a rule, functionalised by redox groups to find catalytic (electrocatalytic) applications (this is the reason for the frequently used term 'redox polymers'). The latter act as mediators, so that the

polymer-support system can accelerate certain electrode processes.

The structures of electron-conducting organic polymers are characterised by the presence of conjugated bonds between electroactive groups in the chains, which is the reason for their high electron conductance in a certain potential range. The possibilities of the mediator catalysis by electron-conducting polymers can substantially be widened by additional introduction in them of functional groups through chemical bonding or Coulomb interaction between multicharge ions sorbed from a solution and charges of the polymeric matrix.

The use of polymeric films as the matrices for classical electrocatalysts, *viz.*, platinum-group metals, opens up wide prospects. The development of such systems increases substantially the number of electrode processes where the use of polymers can be very effective. Particularly, this will allow the use of M-polymer-support systems (M is the metal-catalyst) in the electrooxidation of hydrogen and simple organic compounds, electroreduction of oxygen, *etc.*, which attracts the keenest attention in the context of the fuel cell problem. It is those chemical reactions, which are accompanied by strong adsorption (chemisorption) of initial and/or intermediate species, that are frequently called 'electrocatalytic' in the electrochemical literature.^{1,2} At the same time, in many studies, the term 'electrocatalysis' is used in a more broad sense, embracing acceleration of electrode reactions and/or enhancement of their selectivity due to the mediator catalysis.

This review surveys the current directions of research in the field of using polymers for fabricating highly active electrodes. The main advances and problems in this field of electrochemistry are considered. Despite the abundance of reviews on electrochemistry of polymers (*e.g.*, see Refs 3–16), quite a limited number of publications generalising the results on electrocatalysis on polymer-coated electrodes are available: certain reports comprehensively discussed the problems of synthesis, structure and physicochemical and electrocatalytic properties of a single polymer or a group of polymers similar in composition (*e.g.*, Refs 9, 11, 12), other reviews delving deeply into the theory of electrochemistry of polymers and the principles of their use for electrocatalysis merely listed the electrode systems and electrocatalytic processes studied (*e.g.*, see Refs 6, 13, 16).

[†] In the scientific literature, these electrode systems are shortly called the polymer-modified electrodes, because it is by the polymeric coatings that their electrochemical behaviour is often determined virtually totally. It is not without purpose that along with the term 'polyaniline-modified electrodes', the term 'polyaniline electrode' is frequently used.

This review cannot also pretend to comprehensively cover all the problems on the subject and give an exhaustive bibliography, otherwise this would contain over thousand references. The questions concerned with the main procedures of the preparation of electrodes with polymeric coatings, the principles of using them for the catalysis of electrochemical processes, the specific and/or general features of the behaviour of systems with ion-exchange and electron-conducting coatings, the main developments and problems in the promotion of a number of important electrode reactions are considered. Among the latter reactions, preference is given to the processes occurring in aqueous solutions and vital for the development of fuel cells and electrosynthesis. Nafion and poly(vinylpyridine) are chosen as the typical representatives of ion-exchange polymers, and polyaniline and polypyrrole represent the electron-conducting polymers. Attention is drawn to the systems with electrocatalytically active surfaces formed by incorporation of microparticles of noble metals into polymeric matrices. An attempt is undertaken to analyse the reasons for such a wide scatter and discrepancy in the experimental results on the electrocatalytic activity of these systems.

II. Modification of electrode surfaces by polymers

Of the various methods for applying polymeric coatings onto conductive supports, here we consider only those used most frequently in fundamental studies for fabricating the support–polymeric matrix systems. As a rule, films of ion-exchange polymers are ‘attached’ to the surface by chemical bonding or through adsorption interaction.^{17–32} Both chemical and electrochemical methods are used for synthesising conducting polymeric films on the surfaces of solid supports.^{3, 7, 9, 14, 33} Solubility of the polymer is the important factor determining the adhesion of the film.

1. Methods of application of modifying polymeric coatings

a. The immersion method

The immersion method is based on the exposure of an electrode (support) to a polymer solution for a certain time sufficient for the adsorption of molecules and the formation of a film on the surface.^{17–21} Due to chemisorption and low solubility of coatings formed in the solutions used, the films obtained by this method well adhere to the surface. The formation of coatings can proceed as a result of chemical reactions of the polycondensation type. A typical example is the formation of polymeric layers from organosilanes X_3SiR ($X = Cl, OCH_3$, etc., R is the substituent involving a certain functional group) on oxidised surfaces.^{14, 20, 21} The formation of molecular networks occurs due to a sequence of reactions presented by the following scheme:

where Z is the supporting surface.

b. ‘Drop evaporation’

The method of drop evaporation was used for modifying electrodes of small areas. Dropwise application of several microlitres of a polymer solution of a given concentration followed by evaporation of the solvent allowed one to obtain films well characterised with respect to both the amount of the polymer and its composition.^{22–25} The structural uniformity of the films depended to the greater extent on the evaporation procedure, namely, the latter should occur sufficiently slowly. The composition of the original film (including its functional groups) can be changed by treating it with the corresponding reagent using the same method of ‘drop evaporation’. Thus the stability of a poly(ethylene imine) film in acidic solutions is increased upon treatment with a solution of dibromobutane in propan-2-ol, which resulted in cross-linking of the polymer^{26–28} and a decrease in its solubility in aqueous solutions with low pH.

c. Oxidative and reductive deposition

Solubilities of certain compounds in their oxidised and reduced forms are different. This can be used for the deposition of modifying (including polymeric) films on electrodes.^{29–32} For example, it was found^{29, 30} that viologens with more than four carbon atoms in the alkyl substituent and certain polymeric viologens form stable films of radical cations upon their chemical or electrochemical reduction. The same principle was also applied for the deposition of poly(vinylferrocene) films.^{31, 32}

The methods discussed of deposition of polymeric coatings and their versions were used for the deposition of redox polymers and, in certain cases, for modifying electrodes by electron-conducting polymers. However, the common practice for the preparation of electron-conducting polymeric films is electrochemical polymerisation.

2. Redox polymers as the mediators of redox processes

Ion-conducting polymeric films with incorporated redox groups were used as the charge carriers from the substrates in a solution to the support.^{7, 10, 14, 17–20} If the substrate is oxidised or reduced faster on electrodes modified by redox polymers as compared with unmodified electrodes (support), one can speak of the catalytic effect of the film. A scheme in Fig. 1 illustrates the process of charge transfer in the reduction of species A to species B ($A + e^- \rightarrow B$) through redox centres (Red/Ox) in the polymeric film.

In the general case, the reduction rate is determined by the rates of the following processes: diffusion of species A from the solution bulk to the film surface, the reaction

in the film surface layer, the charge transfer in the film and the reaction

A specific and the most important process in the systems of the type discussed above is the charge transport in the film, which is characterised by the formal diffusion coefficient D_f . Despite the absence of the self-conduction of the polymer, the charge transfer through the film is possible by either physical diffusion of Red and/or Ox in the film or the step-by-step electron exchange between neighbouring redox centres (see Fig. 1).^{34–41} These processes are accompanied by the motion of polymeric chains, the solvent and counter-ions. The redox centres frequently represented polycharge ions [$Fe(CN)_6^{3-/4-}$, $Mo(CN)_8^{3-/4-}$, $IrCl_6^{2-/3-}$, etc.] which are strongly bound to ion-exchange polymers due to the Coulomb interaction.

Figure 2 exemplifies the voltammograms of a smooth platinum electrode and the electrode modified by a poly(ethylene

Figure 1. A scheme of reduction of a substance on the electrode modified by a redox-polymer film.

D_A is the diffusion coefficient of A particles in solution; c_A is the concentration of A in the solution bulk; D_i is the formal coefficient of charge diffusion in the polymeric film.

imine) film.[‡] It is seen that before the introduction of a redox group into the ion-exchange polymer (curves 1), the system was characterised by a very low polarisation capacity I/v (lower than that of the support, *i.e.*, smooth platinum). With the accumulation of $\text{Fe}(\text{CN})_6^{3-/4-}$ ions in the film, the system acquires the gradually increasing redox activity due to the following reaction:

Figure 2. Cyclic voltammograms of a platinum electrode modified by a poly(ethylene imine) film.

Measured in solutions: (1) 0.5 M H_2SO_4 ; (2) 0.2 mM $\text{K}_3\text{Fe}(\text{CN})_6$ + 0.5 M H_2SO_4 every 5 min (2) and 60 min (3) after the immersion of the electrode into solution. The potential scan rate $v = 50 \text{ mV s}^{-1}$.

3. Electrochemical polymerisation

Synthesis of polymeric films by electrochemical polymerisation shows a number of advantages over the method of chemical polymerisation. First, the films are formed directly on the electrode surface, and the reaction product, *viz.*, an electroactive film, exhibits a high conductivity. Second, the electrosynthesis provides a good current efficiency and a strict stoichiometry of the process; hence, the films of desired masses and thicknesses can be obtained. Third, the properties of the polymeric film can be controlled in the course of the synthesis. Possible electrochemical and chemical

reactions occurring during the syntheses of polyaniline^{3, 4, 42, 43} and polypyrrole^{11, 12, 43–46} were described in detail in the literature.

Electrochemical properties of the support–electron-conducting polymer system depend strongly on the conditions of the polymer synthesis. Below, we consider the effects of some of these conditions.^{3–9, 11, 42, 43, 47, 48}

a. The effect of the support material

In the synthesis of electron-conducting polymers, different materials were used as the supports, *viz.*, platinum,^{49–53} gold,^{53–55} metal oxides,^{49, 55, 56} glassy carbon,^{51, 52} pyrographite,⁵³ stainless steel^{49, 57} and iron^{58–61} for polyaniline; noble metals,⁶² conductive glass,^{43, 62} carbon materials,^{11, 63} aluminium, tantalum and copper,^{62–66} steels^{63–67} and semiconductors⁶⁸ for polypyrrole. From these studies, it can be concluded that the nature of the support material had virtually no effect on the synthesis and properties of conductive polymeric films with the thicknesses exceeding tens of monolayers. The exception is provided by the metals with surface oxide films.^{11, 45}

On the other hand, the formation of first layers initiated by the formation of radical cations^{3, 47} is determined largely by the nature and the structure of the support. However, in such systems the electrochemical effects caused, on the one hand, by the adsorption-induced surface modification and, on the other hand, directly by the polymeric film can hardly be separated.

The process of film formation was shown to be ‘sensitive’ to the solution composition (see below); hence, to obtain reproducible results, it is desirable that the synthesis (not too lengthy) is carried out in a three-electrode cell with separate anodic and cathodic compartments.

b. The effect of the polarisation mode

Films of conducting polymers used in electrocatalysis are mainly prepared by electrooxidation of monomers (the anodic synthesis). This synthesis always proceeds at a potential exceeding those of anodic doping of polymers. The anodic doping is the reversible oxidation of a polymer resulting in its transition from the state of an insulator or semiconductor into the conductive state.^{3–11, 13, 47, 69} The electroneutrality of the oxidised polymer with positive charges on certain parts of its chain is achieved by incorporation of counterions, *i.e.*, anions into the polymeric matrix (P)

where n is the degree of polymerisation. The x/n ratio characterises the degree of doping of the polymer. Dedoping (cathodic reduction) of an anodically doped polymer results in the elimination of charges in its chains and the dissociation of the anions to the solution. The doping–dedoping processes are accompanied by

Figure 3. A cyclic voltammogram of a glassy carbon electrode modified by a polyaniline film.

[‡] Hereinafter, the potential values E are shown with respect to the reversible hydrogen electrode in the same solution, unless otherwise specified.

redox reactions, which determine the redox activity of electron-conducting polymers. The intrinsic redox activity of a polyaniline film (Fig. 3) is manifesting itself in the vicinity of two pairs of anodic–cathodic peaks in the cyclic voltammogram (at ~ 0.45 and ~ 0.95 V). In the potential range between these peaks, the film exhibited a high electron conductivity (up to 10^5 S cm $^{-1}$).

The films can be synthesised using different modes, *viz.*, potentiostatic, galvanostatic, potentiodynamic and pulsed modes. These modes were used in the synthesis of electron-conducting films of polyaniline^{43, 50, 70–78} and polypyrrole.^{11, 70, 79–82} An analysis of the experimental results obtained allowed the following conclusions to be drawn.

The number of aniline molecules incorporated into the polymeric film was roughly proportional to the charge passed through the system during the synthesis.

The mass of the polymeric film on the electrode, as a rule, was proportional to the charge consumed in its doping. However, the slopes of the corresponding linear dependences vary depending on the synthetic mode.

The results of measurements of these dependences for polyaniline have shown that, for a galvanostatic synthesis, the degree of doping decreases with a decrease in the current density. Under potentiostatic conditions, the maximum degree of doping was reached at the potential of 0.9 V. In the potential cycling mode, the dependence of the degree of doping on the potential scan rate also demonstrated a maximum.⁵⁰

The following explanation to the regularities observed was proposed.⁵⁰ At low current densities, the film growth involves a small number of nuclei, which can result in a polymeric structure with a low redox activity. Probably this is the reason for the decrease in the redox activity observed for the films synthesised at the potentials below 0.9 V. As the potential increased above 0.9 V, the redox activity of films decreased probably due to the degradation processes⁸ in the polymeric films.^{51, 83–85} The decrease in the redox activity of polyaniline at high potential scan rates was probably due to either the finite rate of recombination of radical cations or the adsorption of the monomer on the polymer.⁴⁷ Syntheses under galvanostatic (the current density > 0.1 mA cm $^{-2}$) and potentiostatic (the potential > 1.0 V) conditions were accompanied by noticeable exfoliation of polymeric films formed.

Of different deposition modes used, the cyclic potential scanning allowed polyaniline of the maximum redox activity to be obtained.^{50, 51} Films synthesised under such conditions also exhibited better adhesion to the electrode. The foregoing mainly concerns the films with thicknesses of ~ 300 – 400 nm.

c. The effect of solution composition ¶

Physicochemical properties of polypyrrole^{43, 46, 80, 81, 86, 87} and polyaniline^{88–114} films were shown to depend on the solution composition. This can be illustrated by several examples.

The polymerisation rate of aniline depends on the nature of an acid (supporting electrolyte) in the order $\text{HCl} < \text{HClO}_4 < \text{HBF}_4 < \text{HF} < \text{H}_3\text{PO}_4 < \text{H}_2\text{SO}_4$.⁴⁷

The effect of organic additives, benzene and its derivatives serving as examples,^{99–101} is defined by the character of their interactions with the polymer during the film growth, *viz.*, on the possibilities of formation of chemical bonds with elements of the polymer chain and of co-polymerisation. Thus in the presence of phenol, the synthesis of polyaniline decelerated and, for a certain phenol/aniline concentration ratio (1 : 2) in solution, the synthesis stopped. The presence of phenol in the deposition solution enhanced by 15% the susceptibility of polyaniline to doping and

prevented its degradation. The presence of phthalic acid in solution increased the porosity of the polymeric film, which was accompanied, on the one hand, by the increase in its susceptibility to doping and, on the other hand, a decrease in its stability towards degradation. The additions of salicylic acid had the opposite effect.

According to the results of other studies,^{50, 51} no polymeric chains were formed in a two-dimensional adsorption layer at the polymerisation potential. For a polymer to form, its monomer should be present in solution in a certain concentration. For example, for polyaniline, this concentration was $\geq 10^{-4}$ mol litre $^{-1}$ (see Refs 75, 76). Probably, the monomer can be adsorbed on the polymer and get incorporated into it under certain conditions.

d. Stability of film characteristics

Keen attention was drawn to the problem of stability of electrochemical parameters of modified electrodes.^{70, 72, 73, 84, 85, 94, 95, 99–101, 115}

For acidic media, cyclic voltammograms measured on films synthesised on supports by the electrochemical polymerisation method were shown to be stable only in a certain potential range. The extension of the potential cycling range into anodic and cathodic directions entailed a decrease in the area under the peak of polymer doping in the voltammogram and caused irreversible changes in certain characteristics of the polymer, *e.g.*, its conductivity. The limits of the potential range where a film exhibited stable electrochemical properties depended of many factors, *e.g.*, on the electrolyte composition.

These changes in the film characteristics were caused by the degradation of polymers. According to the features of the changes occurring in the polymeric film, two main types of degradation could be singled out.^{96, 97} For one of them, the specific doping ability of the polymer tended to decrease, whereas its mass remained constant; for the other, both the specific doping ability and the polymer mass decreased. Such processes of severe degradation resulting in disintegration of the film were also observed in the course of the polymer synthesis. For high potentials of the synthesis, the growth of the film bulk was accompanied by its exfoliation.

The radioactive tracer technique proved to be effective for studying polymer degradation.^{94, 96, 115} Using this method, it became possible to confirm the existence of the degradation types mentioned above and show that different electrochemical synthetic modes produced polyaniline films with different stabilities towards oxidative degradation.

The differential radioactive tracer method has shown that the processes of oxidative degradation of polyaniline films with thicknesses < 500 nm involve the whole mass of the polymer on the electrode. At the potentials of 0.7–0.75 V in 0.5 M H_2SO_4 , the third degradation type named ‘mild degradation’ was observed.⁹⁷ It was shown that under these conditions, the polymer mass and its susceptibility to doping (the area under doping peaks) remained constant, chemical bonds of certain polymer molecules with the surface were broken with retention of the electrochemical bonding due to the interaction between polymeric chains.

e. Composite polymeric films

Composite materials containing nonconducting and ion-conducting polymers along with electron-conducting ones were proposed to improve unsatisfactory mechanical characteristics of conducting polymeric films (polyaniline, polypyrrole). Many studies are aimed at the development of such composite materials.^{43, 105, 112, 116–129} These were synthesised in one or two steps. In one-step method, the electrode is immersed into a solution containing a matrix polymer and the monomer of a conducting polymer, and the electrosynthesis is carried out in this solution. Alternatively, a layer of an inert ‘matrix’ polymer which usually represents a nonconducting (ion-conducting) polymer with good mechanical properties, *e.g.*, Nafion, is formed in the first step. In

§ Irreversible redox processes which occur during potential cycling.

¶ This review considers the systems using water as the solvent. Hence, the term ‘solution composition’ means the monomer concentration and concentrations and compositions of the supporting electrolyte and different additives.

the second step, the electrode covered with the matrix polymer layer is immersed into a monomer solution, and the conducting polymer is synthesised. In the course of electropolymerisation, particles of the matrix polymer become incorporated into the conducting polymer. For the details of the syntheses of composite materials see Ref. 43.

It should be borne in mind that, in many cases, the formation of a composite implies the appearance of new qualities rather than simple 'summation' of the properties of its components. An illustration to the issues mentioned above is provided by the results obtained using radioactive-tracer and electrochemical methods for the formation of polyaniline–Nafion composite films on platinum and glassy carbon.^{128, 129} Particularly, for Nafion-covered electrodes, it was shown that aniline is first accumulated in the porous matrix polymer and only later transformed into polyaniline (the template synthesis^{130, 131}). The degradation of such a film proceeds more slowly; hence, a substantially smaller amount of polyaniline fragments is removed from the electrode. This can be associated with the complex and branched structure of the polyaniline formed in the porous Nafion matrix.

III. Electrochemical reactions on polymer-modified electrodes

1. Films of nonconducting polymers

Ion-exchange polymeric films with incorporated redox systems are promising for electrochemistry of organic substances. Their use often made it possible not only to decrease the electrolysis overvoltage but also to enhance the selectivity of the main electrode reaction.^{132, 133}

Thus manganese dioxide is known to selectively oxidise allyl alcohol to the corresponding aldehyde leaving the double bond intact. It was shown that the introduction of the $\text{Mn}^{2+}/\text{MnO}_2$ pair into the Nafion film provides the efficient electrolysis of cinnamyl alcohol to β -phenylacrolein.¹³⁴ The current efficiency in aldehyde increased from $\sim 70\%$ to $\sim 82\%$ with the changeover from the Pt–Nafion system to the Mn, Pt–Nafion one.

Figure 4 shows voltammograms of a glassy carbon electrode in an aqueous cysteine solution in the absence and in the presence of the Nafion– $\text{Os}(\text{bipy})_3^{2+/3+}$ (bipy is bipyridyl) film on the surface. As can be seen, the diffusion current of cysteine electro-oxidation reached its limiting value in the second case.¹³⁵

Dimethylferrocene immobilised together with glucose oxidase in an ion-exchange film on a graphite support was used as the charge-carrier from the reduced enzyme (obtained as a result of glucose oxidation) to the conducting support.¹³⁶ In this system too, the limiting diffusion currents of glucose oxidation were reached, which allowed an amperometric sensor for glucose to be developed.

The oxidation of Fe^{2+} cations to Fe^{3+} carried out on a cross-linked poly(4-vinylpyridine) (PVP) and PVP-poly(α -lysine) films containing the $\text{IrCl}_6^{3-}/\text{IrCl}_6^{2-}$ pair^{137, 138} can be cited as the

Figure 4. Voltammograms of cysteine oxidation on a rotating disk electrode of glassy carbon (1) in the absence and (2) in the presence of the surface of a Nafion film with the $\text{Os}(\text{bipy})_3^{2+/3+}$ redox system;¹³⁵ $v = 1 \text{ mV s}^{-1}$; cysteine concentration is $1.28 \text{ mol litre}^{-1}$, pH 4.

example of the mediator catalysis for inorganic reactions. These studies have also theoretically discussed the possibility of estimating the contributions by the mass transfer, the kinetics of interactions of particles and the charge transport in the films into the general mechanism of the electrode process involving a mediator.

2. Electron-conducting polymeric coatings

To date, a considerable number of electrochemical reactions which occur on electrodes with electron-conducting films were studied. However, the occurrence or the absence of the catalytic (electrocatalytic) effect for a particular process was debated more often than in the case of ion-exchange polymers. Apparently, this is largely caused by different conditions of film preparation and different compositions of supporting electrolytes used, because, as was shown above (see Section II.3), these factors strongly affect the physicochemical and electrochemical properties of electron-conducting coatings. The ambiguous interpretation of these results was due to the lack of a theory of electrocatalytic effects by such coatings, which would encompass the whole diversity of the occurring processes.^{6, 10}

A typical electrocatalytic reaction studied on electrodes modified by conducting polymers is the oxygen electroreduction. Studies of this process on a gold electrode covered with a polypyrrole film have established the promoting effect by the polymer.^{139, 140} Using the method of the rotating ring–disc electrode, the authors of these studies have shown that this effect is due to an increase in the selectivity to the oxygen electroreduction to give water.

It was also concluded^{139, 140} that polypyrrole films are permeable to oxygen and the reaction mainly proceeds at the metal/polymer interface. In another study,¹⁴¹ no promoting effect was observed for polypyrrole doped with perchlorate anions.

The promoting effect of polyaniline films on the oxygen electroreduction on glassy carbon electrodes in dilute acidic solutions was observed.^{142, 143} It was noted that in the course of this process the electrochemical characteristics of polyaniline remained stable for a long time, *i.e.*, the polymer did not degrade.

Studies of oxygen reduction on polyaniline and Nafion films have revealed the promoting effects of polymers on the electrochemical reaction.¹²⁴

The problems of organic reactions on electrodes modified by polymeric films were discussed.^{144–152} Particularly, the electro-oxidation of formic acid on polymer-modified platinum and gold electrodes was described in most detail.^{144–147, 152} The promoting effect of a platinum-supported polyaniline film on this process in the potential range below 0.5 V was found.¹⁴⁶ Presumably, the polymer prevented accumulation of the products of strong adsorption of formic acid on the electrode, which thus increases the number of active sites for the oxidation reaction.

By combining radioactive-tracer and electrochemical methods, the promoting effect of polyaniline films on the steady-state oxidation of formic acid on platinum and gold electrodes was also confirmed.^{144, 145} It was shown experimentally that the amount of products of strongly adsorbed formic acid on a polyaniline-film modified electrode was higher as compared with unmodified electrodes (Fig. 5). This result qualitatively agrees with the conclusions made earlier.¹⁴⁶ However, it was found^{144, 145} that an eightfold increase in the polymer-film thickness did not change the amount of strong-adsorption products accumulated on the electrode, which contradicts the conclusions drawn in Ref. 146. At the same time, the authors of these studies^{144–146} have agreed on the location of the oxidation process, *viz.*, that the reaction occurs on platinum areas unoccupied by the polymeric film. This conclusion was confirmed experimentally.^{144, 145} It was shown that if the polyaniline-free platinum areas are filled with CO adsorption products, then virtually no HCOOH oxidation occurs.

The promoting effect was explained^{144, 145} by assuming that polymers catalyse the oxidation of weakly bound adsorption products of formic acid just as it was shown in earlier studies

Figure 5. Kinetics of HCOOH adsorption at a potential of 0.2 V from a 10^{-2} M HCOOH + 0.5 M H₂SO₄ solution on (1) platinum electrode and (2) platinum electrode modified by a polyaniline film. Measurements were carried out by a radioactive tracer method.¹⁴⁴

(*e.g.*, see Ref. 153) dealing with oxidation of organic substances on platinum modified by thallium adatoms.

The electrooxidation of methanol on polyaniline-modified platinum was also shown to be accompanied by a substantial decrease in the amount of products of strongly adsorbed methanol on the electrode; however, in this case, the polymer inhibited the electrooxidation.¹⁵⁴ Thus, as would be expected, the nature of the polymer effect (promotion, inhibition) on the oxidation process depends on the nature of the organic substance to be oxidised.

Polyaniline films were shown¹⁴⁹ to catalyse the electrooxidation of hydroquinone in a wide potential range. This effect was also confirmed later.^{155–162} Figure 6 shows polarisation curves of electrooxidation of hydroquinone and reduction of benzoquinone on a film-free gold electrode and that covered with a polyaniline film. The half-wave potentials of these processes were shown to shift in the cathodic direction for the hydroquinone oxidation and in the anodic direction for the benzoquinone reduction. It was found¹⁶¹ that the exchange current of hydroquinone oxidation increased by two orders of magnitude on freshly prepared polyaniline films (supported on platinum). Most scientists associated the

Figure 6. Cyclic voltammogram of (2) Au and (1, 3) Au–polyaniline system in (3) 0.5 M H₂SO₄ and (1, 2) *p*-benzoquinone solution (10^{-2} mol litre⁻¹) in 0.5 M H₂SO₄.¹⁵⁹ Potential scan rate is 50 mV s⁻¹.

catalytic effect with the adsorption interaction between the polyaniline film and these compounds.^{159–161} Some convincing evidence (based on experimental results) for the specific adsorption of hydroquinone on the emeraldine form of polyaniline has been obtained.¹⁶² This case allows us to speak of ‘classical’ electrocatalysis directly by the conducting polymer. The effect of the polyaniline film morphology on the rate of hydroquinone oxidation was assumed¹⁶² to be associated with the changes in the film surface areas involved in the adsorption and oxidation of the substrate. Alkyl derivatives of polyaniline behaved like polyaniline in the benzoquinone–hydroquinone reaction.^{163–166} The differences in the kinetics of the hydroquinone–benzoquinone reaction on polyaniline and poly(*ortho*-phenylenediamine) films were explained¹⁵⁹ by the different distribution of equilibrium potentials at the polyaniline/solution interfaces.

The processes discussed above occurred in the potential range where the film was the electron conductor. In earlier studies (*e.g.*, see Ref. 167), it was assumed that in the ‘nonconduction’ potential range, electrode reactions should be entirely inhibited. However, this assumption turned out to be incorrect. Thus the reactions of hydrogen oxidation and oxygen reduction were shown to proceed (even if at much slower rates) in the potential region of ‘nonconducting’ films as well.¹⁶⁸ These processes were found to be strongly affected by the support nature. On nonconducting polyaniline films, the processes of reduction of oxygen¹⁶⁹ and naphthoquinonesulfonate¹⁶³ were observed to occur. To explain the occurrence of these processes, their rate-determining steps were assumed to be located at the metal/solution (due to porous structures of the films) and/or metal/polymer (for the mediator catalysis) interfaces¹⁶⁸ and the oxidant was supposed to inject positive charges into the polymeric matrix.^{6,163} Moreover, it should be borne in mind that sufficiently thin films (≤ 500 nm) across which the potential drop is small were used most often,¹⁷⁰ and that the relaxation from the conducting state to the nonconducting one is sufficiently slow.¹⁷¹

As is seen from the above examples, to date there is no agreement on the reasons for the appearance of catalytic effects in the systems containing electron-conducting films.^{6,172} Some authors favoured the mediator mechanism, the other (without any strong evidence) assumed the potential change in such systems to be associated only with the potential drop across the polymer/electrolyte interface. An analysis of thermodynamic equilibria in the metal–polymer–electrolyte system at different interfaces has shown¹⁷² that in the general case the potential drops across all the interfaces involved should be taken into account. For a more accurate elucidation of the role the polymer plays, additional information is required, particularly, on the exact location of the reaction and its rate-determining step. However, it is very difficult to obtain this information for electrodes with polymeric coatings.

Considerable progress has been achieved in modifying electron-conducting polymers by different redox groups and catalytic centres such as porphyrins, phthalocyanines, transition-metal complexes, biological molecules, *etc.*^{6,169,173–182} In most of such systems, the mechanism of mediator catalysis was realised. Thus it was found¹⁵² that electroreduction of oxygen on glassy carbon can be accelerated by covering it with a polyaniline film containing anions of heteropolyacids (SiW₁₂O₄₀)⁴⁻ and (PW₁₂O₄₀)³⁻. The possibility of using polythiophene and polypyrrole films modified by heteropolyacid anions for catalysing this process was also considered.^{183–187} On a polyaniline + cobalt tetra-2,3-pyridineporphyrin (CoTPP) composite film, the oxygen reduction potential shifted to more positive values as compared with its reduction potential on the electrosorbed CoTPP.¹⁶⁹ It is of note that even an increase in the currents was observed in the transition of polyaniline into the reduced state.

It was shown^{186,187} that modification of a glassy-carbon electrode surface by an [Os(bipy)(PVP)Cl]Cl coating [PVP is poly(vinylpyridine)] allowed the limiting diffusion currents of nitrite electroreduction to be reached. This makes this system promising for the development of a sensor for nitrite anions.

IV. Electrodes coated with polymeric films with incorporated metal-catalyst particles

From the foregoing it follows that modifying polymeric films play the role of charge carriers in electrocatalysis, and their catalytic activities manifest themselves in the processes free from destruction of substrate molecules. Platinum-group metals are the best electrocatalysts (catalysts) for the processes which involve cleavage of interatomic bonds (*e.g.*, oxidation of hydrogen, organic substances, *etc.*). It is possible to prepare highly dispersed deposits of these metals by incorporating them into polymeric matrices.

A specific feature of the systems thus obtained is that the polymeric matrix determines the conditions for the metal phase development. The properties of the matrix (film) itself can be changed by choosing a particular polymer and varying the conditions of the surface film formation.

Keen attention was drawn to the processes of deposition of platinum-group metals in ion-exchange polymeric matrices,^{188–201} because the latter are stable in different media and can be used as the solid polymeric electrolytes in electrochemical reactors. It was proposed in many studies to prepare deposits of platinum-group metals using electron-conducting polymers where the formation conditions and the behaviour of metal particles can differ substantially from those in ion-exchange films.^{54, 154, 202–222} This can result in a three-dimensional structure representing a conducting matrix with sufficiently uniformly distributed catalyst microparticles. The porous structure of such a matrix can make the metal-catalyst accessible for reactants and provide the exit of the products to solution.

For these systems, the practically important effect of the increase in the electrocatalytic activity calculated either per the geometrical surface of the electrode or per a mass unit of the noble metal could be achieved mainly due to an increase in the surface area of the deposit. However, of prime scientific interest is to increase the activity per the surface unit of the metal catalyst as compared with the compact metal. This can be associated with the structural peculiarities of microdeposits (*e.g.*, the size effect¹), the interaction of metal particles with the polymeric matrix and the changes in the reactant activities in the porous space of the matrix.

In theoretical studies, great attention was drawn to the electronic structure of microdeposits. Due to the high work function values for metals of the platinum group²²³ as compared with other materials, it could be expected that the electrons would be partially transferred from the matrix to the microdeposit and, as a consequence, the mean electron density in the deposit would increase. However, such an effect was detectable only where the sizes of microdeposit particles were commensurable with the thickness of the electrical double layer. According to the estimates,^{224, 225} even in the absence of their interaction with the matrix, the Fermi energy in small particles (the size $d \leq 3$ nm) should substantially differ from that in the compact metal.

1. Dispersion of particles of platinum-group metals in polymeric matrices

Different chemical procedures were developed for introducing metal particles into polymeric matrices.^{194, 226–231} For example, deposits of Pt, Pt + Ru, and Pt + Sn were obtained by reducing the corresponding salt solutions by reactants diffused from the other side of a membrane.^{226, 227} Membranes were often impregnated with solutions of platinum-group metal salts and then immersed into the reducing solution.^{228, 229}

However, those methods which use the electrodeposition of metals are most convenient (especially, for films) for incorporating metal particles into polymeric matrices.^{188–193, 195–222} By varying the potential, current and deposition time, one can control the accumulation rate and the amount of the metal deposited. Such methods can be divided into two groups, *viz.*, with single- and two-step deposition. In the former case, the film is first formed (by a chemical or electrochemical method), and then the metal is electrodeposited in it (often on it). In the latter method, the film is

formed electrochemically from a solution containing both a monomer capable of electropolymerisation and a salt of a metal-catalyst. By varying the electrodeposition conditions (supporting electrolyte concentration, components concentrations, modes of current and potential variations, *etc.*) it is possible to prepare films with diverse morphologies and various contents and depth-distributions of metal particles.

Two-step deposition was used for both ion-exchange and electron-conducting films. In the films devoid of intrinsic electron conduction [*e.g.*, Nafion and poly(vinylpyridine)], the formation of metal particles begins from the support, and their further growth occurs along the pores 'from one particle to another' with retention of contacts between the particles (Fig. 7). Gradually, the electrodeposition process reaches the film surface (this stage is not shown in the figure), which can occur before the whole porous space is filled, as a result of the difference in the rates of formation and growth of films in different pores. Later, the metal layers are deposited on the film surface, and this process is only indirectly controlled by the film. Evidently, the specific behaviour of metal particles incorporated into the polymeric matrix should be judged based on the analysis of the behaviour of systems in which the metal deposit, at least, its greatest part, has not yet 'escaped' to the film surface. According to the literature data, as might be expected, the mechanism of deposit growth and the sizes of metal particles formed strongly depend on the modes of the support polarisation.

During the formation of metal particles in electron-conducting polymers, the metal-catalyst can be deposited directly onto the polymer. Though it was suggested²²⁰ that during the deposition of metals on an electron-conducting polymer in the potential range where the polymer is dedoped and assumed^{9, 13} to become 'non-conducting', the mechanism of metal deposition in the films remains virtually the same as for ion-exchange polymers (see Fig. 7a). However, it was found^{211, 222} that the deposition of a metal directly on the polymer can also occur in the potential range of its 'nonconducting' state. Using the AFM method for the

Figure 7. A scheme of accumulation of metal particles in a polymeric matrix formed on a glassy carbon support for (a) ion-exchange and (b) electron-conducting polymers.

palladium deposition in sufficiently thick polymeric matrices where the metal volume was an order of magnitude lower than that of the porous space (estimated from the results of Ref. 232), palladium particles were observed on the film surface at the deposition potential of 0.14 V, *i.e.*, in the range where polyaniline is nonconducting. The appearance of metal particles was explained by the 'residual' conductivity which is retained after the polymer is dedoped²³³ and ensures sufficiently small potential drops across thin (~ 500 nm) polymeric films. The results of layer-by-layer Auger-spectroscopic studies²¹¹ of a polyaniline film[†] with palladium particles have shown that deposition of palladium preferentially occurs in the external regions of the film. Figure 7b shows the model for deposition of metal particles into an electron-conducting film. In this case, the contact between metal particles is not necessary: the most pronounced manifestation of the catalytic activity can be expected at the potentials of high conductivity of the polymer (especially, for thick films).

A single-step method of preparation of composite M – electron-conducting polymer films was used less frequently. Potential cycling in the range from sufficiently high positive values at which the monomer is preferentially polymerised, to the potentials close to that of the reversible hydrogen electrode, at which the metal is preferentially deposited, made it possible to provide a largely uniform distribution of metal-catalyst particles throughout the film.^{211, 222} Moreover, the formation of substantial amounts of metal on the film was ruled out. However, the single-step synthesis by periodic application of sufficiently high potential values to the electrode led to noticeable degradation of the polymer even during the formation of the electrocatalytic system,²²⁰ and the degradation became more pronounced in the presence of particles of platinum-group metals.²²²

The use of polymeric matrices (especially those of ion-exchange polymers) made it possible to obtain ultradispersed deposits of platinum-group metals (with the grain diameter of 3–5 nm) with larger specific surface areas. As a rule, the most dispersed deposits were formed at small metal-to-polymer mass ratios, *i.e.*, where the deposit fraction remained within the polymeric matrix is substantial.^{195, 200} For large amounts of deposited metals and/or small film thicknesses, the specific surfaces substantially decreased and, as would be expected, often approached those of individual metal deposits.^{200, 201, 203, 219, 233–235}

At attempt was made to deposit platinum in preformed polyaniline films from aqueous H_2PtCl_6 solutions.¹⁵⁴ The form in which platinum is accumulated in the film was concluded to be strongly dependent on the lower limit of the potential cycling interval, *viz.*, in the 0.1–0.7 V range, it was accumulated as two- and four-charged ions, whereas in the 0–0.7 V interval, platinum metal particles prevailed.

A comparison of the data shown in Table 1 allows one to assess the possibilities of increasing the catalyst surface area by using polymeric matrices. The table shows the maximum values of specific surface areas for several metals of the platinum group electrodeposited into Nafion and poly(vinylpyridine) (the results^{196–199, 220} were averaged) and similar values for electrodeposits of these metals on platinum. The greatest effect was observed for palladium. It is important that the polymeric matrix also favoured the stabilisation of particles. This made it possible, for example, to observe the size effect, *viz.*, a sharp decrease in the amount of absorbed hydrogen, for palladium particles of sizes < 7 nm [poly(vinylpyridine) matrix].¹⁹⁸

The attempts to achieve such a great development of the metal-catalyst surface area for electron-conducting polymeric films have failed.^{219, 120, 222} This indirectly confirmed that the metal deposit can grow on the film surface even for small metal-to-polymer mass ratios.

[†] The film was deposited by the two-step method, and palladium was deposited in the potential range of 'nonconducting' polyaniline.

Table 1. Maximum specific real surface areas ($\text{m}^2 \text{g}^{-1}$) for deposits obtained for metal–polymer–glassy carbon systems (S_1) and metal electrodeposits on platinum (S_2).^{196–199, 220}

Metal	Polymer	S_1	S_2
Pt	poly(vinylpyridine)	100	18–25
	Nafion	80	
Pd	poly(vinylpyridine)	100	10–15
	Nafion	90	
Rh	poly(vinylpyridine)	60	30–40

However, for palladium microdeposits in polyaniline, the specific surface areas of $35\text{--}45 \text{ m}^2 \text{g}^{-1}$ were reached (see Refs 220, 222).

2. Determination of the real surface area of metal-catalyst particles in polymeric matrices

The determination of the real surface area of metal-catalyst particles incorporated into polymeric matrices presented a serious problem for comparing correctly the specific electrocatalytic activities of deposits. Unfortunately, many studies of the electrocatalytic activity of metal-catalyst–polymeric matrix systems did not pay due attention to this problem and did not separate the contributions to the electrocatalytic activity into those caused by the surface development and by the changes in the intrinsic specific activity of the incorporated particles.^{54, 154, 212–218}

Determination of specific surface areas of metal deposits in polymeric films S ($\text{m}^2 \text{g}^{-1}$) also presented independent interest for estimating the degree of dispersion of the metal-catalyst. The use of a certain model allows the average sizes of metal particles to be calculated roughly from the S values. The modern physical methods such as the scanning tunnelling microscopy and atomic force spectroscopy made it possible not only to assess more accurately the average size of particles but also to determine their size distribution.²³⁶ However, the use of these methods for characterising the particles located inside the polymeric matrix is associated with considerable experimental difficulties.

The method for estimating the real surface areas from the hydrogen adsorption, which is commonly accepted for platinum group metals,^{237, 238} often gave insufficiently correct results and in many cases could not be used at all. Thus the 'hydrogen regions' of metal particles in polymeric matrices can be deformed due to the small sizes of these particles, their adsorption interaction with the polymeric matrix and the changes in the pseudo-capacity of the support.^{197, 239, 240} In systems with electron-conducting polymeric matrices such as polyaniline and polypyrrole, additional difficulties arose due to the severe overlapping of the potential ranges of hydrogen adsorption–desorption and those of the intrinsic redox activity of the polymer.^{154, 219, 220} The method for determination of the surface area by hydrogen adsorption cannot be used in principle for palladium particles, because the hydrogen absorption in the Pd(H) α -phase substantially exceeds the hydrogen adsorption.^{241, 242} Many of the difficulties noted above could be avoided if the real surface area was estimated by the underpotential deposition (upd) of copper.^{196, 220, 241–243} In the Pt–poly(vinylpyridine) system (a glassy carbon support), a 10% deviation between the specific surface areas of platinum determined from hydrogen adsorption and upd of copper appeared only for $S > 80 \text{ m}^2 \text{g}^{-1}$. The use of copper adatoms for determination of the real surface area of palladium particles deposited into poly(vinylpyridine) and Nafion films proved to be effective.^{198, 199} At present, this is the most correct electrochemical method for determination of real surface areas of palladium particles incorporated into polymeric matrices. Calculations of real surface areas of palladium electrodes by the oxygen adsorption^{241, 243} proved to be useless, because the polarisation of electrodes to high anodic potentials often caused irreversible changes in the M–polymer–support systems.^{83, 85, 98, 115, 196}

It was found²¹⁹ that due to many similar charges being consumed in the removal of hydrogen adatoms from incorporated platinum particles and in the polyaniline film oxidation, the real surface areas estimated in parallel experiments from the hydrogen adsorption differed twofold even for the platinum-to-polymer mass ratio of ~ 70 . According to experimental results,²²⁰ well reproducible real surface areas estimated from upd of copper could be obtained for platinum and palladium particles incorporated into polyaniline when the metal-to-polymer mass ratio was ~ 0.2 .

The formation of monolayer coverages by adatoms (Cu, Ag, *etc.*) with the subsequent removal of their ions from the solution bulk, allowed the surface areas of metal-catalysts to be determined by suppressing the hydrogen adsorption.

To determine the surface area of platinum particles in a polyaniline matrix, it was proposed¹⁷⁷ to use the CO adsorption. However, depending on the structures formed by adsorbed CO (bridge or linear), the real surface areas estimated can differ twofold. Moreover, carbon monoxide can be sorbed by the polyaniline film itself.²²¹

The possibilities of using physical methods for the estimation of the sizes of particles incorporated into polymeric matrices could be remarkably increased, if the film could be separated from the support. Thus composite films of polypyrrole with palladium particles were deposited on plates of In–Ti oxides and then separated from them and analysed using a transmission electron microscope.²⁴⁴ The average size of palladium particles was found to be ~ 5 nm.

3. Electrode processes on polymeric films with incorporated particles of metal-catalysts

The results on the electrode processes on polymeric films with incorporated metal-catalyst particles are discrepant and unequal with respect to their quality and scientific importance.^{245–265} This often means not only the quantitative discrepancies, but also concerns qualitative deviations in experimentally observed effects. This was caused by a number of factors, the main of which are as follows:

- (1) the difference in the procedures used for synthesising the metal-catalyst–polymeric matrix systems;
- (2) the wide scatter in the metal-to-polymer mass ratios; this can cause substantial differences in the behaviour of electrodes with essentially similar metal-catalysts and polymers (see Section IV.1);
- (3) different conditions of measuring polarisation curves;[‡]
- (4) uncertainty associated with the steady-state criteria;
- (5) the low ‘sample-to-sample’ reproducibility of the electrochemical reaction rates (like electrooxidation of organic substances) even for individual electrodes of platinum-group metals;[§]
- (6) in most studies, the specific currents were expressed per the geometrical surface area of the electrode, which dramatically reduced the fundamental importance of the results (see Section IV.2).

The difficulties mentioned above were caused by the complicated nature of both the electrode systems themselves and the electrocatalytic processes on them, as well as by different factors which could promote or inhibit the electrode reactions. Hence, the attempts to explain the results obtained for the modified electrodes under consideration have yet involved only phenomenological

interpretations. In connection with the aforesaid, when choosing the data for the discussion, we focused attention on the results of those studies in which the measurements were carried out under steady-state conditions on electrodes with small metal-to-polymer mass ratios and which provided the estimates of the metal-phase surface area. The literature data on the methanol and formic acid electrooxidation and oxygen electroreduction in acidic solutions well illustrate the variety of experimental results on the electrocatalysis by particles of platinum-group metals deposited in/on polymeric coatings (Table 2).

Most of the studies in which the promotion of the methanol electrooxidation was detected, measured non-steady-state currents calculated per unit of the geometrical surface area (with several exceptions^{196, 200, 201, 213, 219, 222, 247}), *i.e.*, considered the gross effect. (Sometimes, the oxidation rate increased only two- to three-fold, *e.g.*, in Refs 219 and 247.)

When the effect of Nafion and poly(vinylpyridine) matrices on the behaviour of platinum particles was studied for extremely small amounts of the metal deposited (no more than $21 \mu\text{g cm}^{-2}$), it was found^{196, 200} that the specific rates of CH_3OH electrooxidation (under steady-state conditions) decreased as compared with the oxidation rate on platinised platinum (Pt/Pt). A similar effect of the Nafion matrix for the platinum mass $< 60 \mu\text{g cm}^{-2}$ was mentioned.²⁰¹ In the Pt–poly(vinylpyridine)–glassy carbon system, with an increase in the metal-phase dispersion, the rate of CH_3OH electrooxidation decreased.^{196, 200}

At the same time, for platinum deposits incorporated into Nafion films with the platinum mass $< 60 \mu\text{g cm}^{-2}$, higher steady-state specific currents of CH_3OH electrooxidation as compared with the currents on Pt/Pt were found.²⁰⁰ The increase was explained by the changes in the binding energy of the products of CH_3OH adsorption with the surface due to the changes in the deposit structure. Inasmuch as small-mass deposits are much more dispersed as compared with large-mass ones, one can speak of the qualitative agreement between different estimates^{196, 200, 201} of the effect of the degree of platinum dispersion on the methanol electrooxidation rate.

For the electrooxidation of formic acid on platinum particles incorporated into poly(vinylpyridine) and Nafion, it was found that the specific rates increased with an increase in the degree of metal-phase dispersion.^{196, 200} Moreover, the activity of highly dispersed platinum deposits ($\geq 30 \text{ m}^2 \text{ g}^{-1}$) was higher as compared with electrodeposits of platinum on platinum. A similar effect was greater for the Pt–Nafion–glassy carbon system (Fig. 8).¹⁹⁹

The results discussed above show that the changes in the activity of metal particles incorporated into polymeric matrices largely depended on the nature of the substrate. Thus the effects of the degree of dispersion were found to be opposite for the

Figure 8. Stationary polarisation curves for electrooxidation of formic acid in the Pd/Pt (1), Pd–Nafion–glassy carbon (2) and Pd–polyaniline–glassy carbon (3) systems in a 0.5 M HCOOH + 0.5 M H_2SO_4 solution.^{199, 222}

‡ Unfortunately, the authors of the overwhelming majority of studies used the potentiodynamic method for recording relatively fast polarisation curves. As a rule, this involved measuring non-steady-state currents, the interpretation of which was especially difficult due to the uncertainty in the surface coverages by original particles, their products, solution ions, *etc.*

§ Naturally, as one passes to more complicated M–polymeric matrix systems, the reproducibility of the results is reduced. Hence, the comparative estimates of the activity based only on the experimentally observed two- to three-fold change in the currents should be considered with caution.

Table 2. Results on the electrooxidation of methanol and formic acid and electroreduction of oxygen in the M – polymer – support systems.

M – polymer – support system ^a	Film thickness / μm	M content / $\mu\text{g cm}^{-2}$	Substrate	Polarisation curves	Catalytic effect ^b	Ref.

^a Electrodeposition was used for incorporating metal into polymers unless otherwise specified. ^b Signs 'plus' and 'minus' designate the presence or absence (as assessed by the authors of the cited paper) of the catalytic effect; in the parenthesis, the surface area type (geometrical or real) used for calculating the currents is shown. ^c Chemical deposition was also used. ^d Three methods were used. ^e One-step method.

methanol and formic acid electrooxidation processes. A similar phenomenon was also mentioned for other catalytic systems, viz., not only for systems containing Pt particles, but also for those with Rh, Pd and Ir (see references in Ref. 240). This can be explained by assuming that particles involved in methanol electrooxidation occupy the greater number of surface sites than the sites required for the adsorption of HCOOH or CH₃OH.²⁴⁰

On the whole, the specific steady-state currents of methanol electrooxidation on platinum particles deposited in/on polyaniline films were found to be higher than the currents of its oxidation on Pt/Pt particles.^{219, 222} However, a substantial catalytic effect was observed²¹⁹ only for the platinum mass $> 60 \mu\text{g cm}^{-2}$. Inasmuch as only very thin films were studied (35–50 nm), it can be assumed that the effect was caused by the peculiarities of the structures of

platinum deposits formed on the surface of a polyaniline film (see Section IV.1).

The higher electrocatalytic activity of platinum particles in a polyaniline matrix as compared with Pt/Pt particles was also found²²² for the electrooxidation of formic acid and carbon monoxide. For CO, the effect was explained by the growth of its concentration in the polymeric film. The fact that CO is sorbed by the film was confirmed by a special study.²²¹ For platinum dispersed in polyaniline, the effect of promotion of formic acid electrooxidation was apparently of the same nature as for the aforementioned (see Section III.2) increase in its electrooxidation rate on platinum electrodes observed upon covering them with polyaniline films.

The greatest increase in the specific rates of formic acid electrooxidation was found for palladium particles incorporated into polyaniline (see Fig. 8). Moreover, the steady-state currents increased more than by an order of magnitude when both single-²²² and two-step¹⁷⁰ methods were used for synthesising Pd–polyaniline–glassy carbon systems. It is remarkable that the slope of polarisation curves remained virtually unchanged, although the process occurred in the potential range of polyaniline ‘nonconduction’. This suggests, first, that the mechanism of HCOOH electrooxidation of palladium remains unchanged²⁴⁸ and, second, that the electrode reaction rate can remain virtually unaffected by the ohmic potential drops in sufficiently thin films of electron-conducting polymers in the potential ranges of their ‘nonconduction’ (see also Section III.2).

According to the literature data, electrodes modified by composite Pt–polyaniline coatings can also be used for the oxidation of propan-2-ol,²⁴⁹ ethylene glycol,^{178,250} and D-glucose²⁵¹ (the latter can also be oxidised on a Pr–polypyrrole coating²¹⁸) at moderate anodic potentials. However, the authors of these studies have used the potentiodynamic method for measuring voltammograms and have not estimated the real surface area of the metal phase. Hence, even if certain ‘electrocatalytic effects’ were found in these studies, this is more likely to be attributed to the surface development of the metal-catalyst. A minor increase in the specific steady-state currents was found for ethanol electrooxidation on platinum particles incorporated into a polyaniline matrix by the chemical deposition procedure.²²⁹

Most authors associated the promoting effect of polymeric matrices on the electrooxidation of simple organic substances at moderate potentials (before the onset of oxygen adsorption) either with the deceleration of the appearance on the surface of metal-catalyst of strongly chemisorbed species, which are the ‘poison’ for the current-controlling reaction, or/and with an increase in the amount of weakly bound species.²⁴⁵ The ‘parallel mechanism’ of electrooxidation of organic compounds, which was first proposed in Refs 253, 254 for the reaction of methanol electrooxidation have gained substantial recognition.

Inasmuch as, as a rule, the sizes of metal-catalyst particles in polymeric matrices exceed 5 nm, the ‘pure’ size effect can hardly be considered. It is most probable that the catalytic effect is caused by the changes in the structure and/or the composition of the surface. Moreover, the changes in the latter can be caused not only by the adsorption of polymeric molecules and their fragments but also by the adsorbed impurities which could get into the metal phase from the deposition solution.^{197,222} The surface composition was shown to strongly affect the formation of adsorbed OH groups, which play an important role in electrooxidation of organic compounds.²⁴⁵

Only few interpretations of the results took into account that the activities of water and substrate molecules in the pores of the M–polymer–support system can differ from those in the solution bulk.^{194,222} However, the difference in these characteristics is quite probable, because, according to experimental results, *e.g.*, for Nafion¹⁹⁴ and polyaniline,²³² the polymers have channels with the mean size of ~ 1 nm, *i.e.*, approaching the thickness of the electrical double layer. Evidently, the effect of the triple metal/polymer/solution interface on the kinetics of electrocatalytic processes should also be taken into account.

A new in principle interpretation of the promotion of formic acid electrooxidation in the Pt–polyaniline–glassy carbon system was given for the case where the incorporation of platinum into the film was accomplished by the potential cycling in the 0.1–0.7 V range.¹⁵⁴ It was assumed¹⁵⁴ that under these conditions platinum is preferentially accumulated as complex ions (Pt^{2+} and Pt^{4+}) which catalyse the process. The effect was unsteady and decreased in time very quickly, because the complex ions were removed from the film being exchanged for solution ions. Methanol was not electrooxidised on such platinum complexes which confirms again the substantial differences between the electrooxidation mechanisms of methanol and formic acid.

The electrocatalytic activity of M–polymeric matrix systems in electrooxidation of organic compounds could be enhanced (as in the case of individual metal-catalysts^{240,245}) by the deposition of adatoms of foreign metals (*e.g.*, see Refs 251, 256, 257).

The high currents of hydrogen evolution on composite electrodes Pt–polymer [poly(vinylpyridine), Nafion, polyaniline]–glassy carbon and Rh–poly(vinylpyridine)–glassy carbon could be obtained for very small amounts of metal-catalysts ($\sim 20 \mu\text{g cm}^{-2}$).^{200,222,234} For small overvoltages, the parameters of polarisation curves with the currents calculated per 1 cm^2 of the geometrical surface area turned out to be similar to those for compact metal electrodes for which the hydrogen evolution was controlled by diffusion.^{258,259}

Some of these results^{200,222} correlated well with the results of studies^{189,202} which showed that the ‘hydrogen reaction exchange currents’ in the Pt–polyaniline and Pt–Nafion systems virtually coincide with those on smooth platinum. However, it is more likely that the currents measured in the latter studies^{189,202} were also of the diffusion nature rather than of the kinetic nature.

It was found^{200,222,234} that with an increase in the overvoltage, the hydrogen evolution current on Pt–polymer–glassy carbon electrodes became smaller than those observed on smooth platinum. This was explained by the earlier transition to the mixed-kinetics region. The potentials of the transition depended on the polymer structure; for the polymers under consideration they changed in the following order: polyaniline > poly(vinylpyridine) > Nafion. Indeed, this points to the decrease in the real exchange currents of the hydrogen reaction in composite electrodes due to the adsorption interaction between the metal-catalyst particles and the polymer and/or its destruction products.^{200,222} The results obtained for the Pt–Nafion–glassy carbon system, namely, that the diffusion currents estimated per 1 cm^2 of the geometrical surface area exceeded the specific currents on smooth platinum, are of special interest.²⁰⁰ This was explained by the more effective stirring of the near-electrode layer by hydrogen bubbles on the hydrophobised surface.

A number of studies^{126,260–263} have mentioned a possibility in principle of oxygen electroreduction on platinum particles incorporated into polyaniline or polypyrrole, but did not provide any correct comparison with the activity of platinum in this reaction. A lower activity was reported¹²⁶ for platinum deposited on a mixed polyaniline–Nafion film as compared with compact platinum. This was explained by the peculiarities of the formation of metal-catalyst deposits on such a film. Other scientists assumed the oxygen electroreduction rate to be largely controlled by the oxygen diffusion in the polymeric matrix. On the whole, the sufficiently fast degradation of electron-conducting polymers in the presence of oxygen and the catalysis of this process by incorporated particles of platinum-group metals were shown^{96,97,115,200,222} to have an adverse effect on the stability of properties of electrocatalytic systems involving these polymers and used in the oxygen electrode.

V. Conclusion

The results shown above suggest that the research carried out to date with polymer-modified electrodes is largely aimed at the elucidation of interrelations between the properties of support materials, polymeric coatings and incorporated metal-catalyst particles and/or certain functional groups. The fact that polymeric materials cannot provide the destructive chemisorption of substrate molecules gives the grounds to expect that the systems with polymeric matrices containing microparticles of catalytically active metals are more promising for a number of electrode reactions (particularly, those in fuel cells).

Inasmuch as the properties of polymeric matrices and microparticles are interrelated, the theoretical concepts describing the dependence of fine particles on the properties of phases in contact with them are of special importance. These studies are directly connected with the development of concepts on the structure of

different interfaces in the systems studied, including the three-phase interfaces, viz., support/polymer/solution and polymer/metal-catalyst/solution. Taking into account the polymer–solvent interaction and possible changes in the activities of solvent and substrate molecules in the polymeric matrix also appears to be very important.

The cited examples of polymer-containing electrode systems comprise only a small fraction of those available in the literature. However, at present, the development of theoretical concepts should be aimed at more comprehensive and deep experimental research to reveal more distinctly the catalytic effects for electrode reactions rather than at the increase in the number of systems studied. For this purpose, not only the complex use of modern experimental techniques (physical, physicochemical, analytical, etc.) but also the modernisation of experimental methods (see Section IV.3) are necessary.

This review only mentions certain examples of the use of polymer-covered electrodes in practice. Great interest to the new type of electrode systems was associated, first of all, with the great diversity of their practical applications, namely, the modernisation of present-day electrolyzers and electrochemical generators and development of their new types, synthesis of effective anti-corrosion coatings, the development of biosensors, the extension of the possibilities of electrocatalysis, the development of electrochromic devices, applications in micro- and nanoelectronics, etc.

Abstract. The main processes and phenomena (grain growth, phase transformations, relaxation, diffusion, and so on) in nanomaterials subjected to heat treatment are considered. Experimental data and theoretical views on the thermal stability of nanomaterials are analysed and generalised. Attention is drawn to unsolved problems. The bibliography includes 152 references.

I. Introduction

At present, the concept of nanomaterials (NM), the development of which has been substantially stimulated by a number of publications,^{1–3} is widely known. This is indicated, for example, by the fact that representative all-Russian and international conferences and seminars dealing with nanomaterials have been regularly held for many years; this subject is also actively discussed at the Symposia of the American Materials Research Society (MRS) and the NATO Advanced Study Institute (NATO ASI); monographs, collections of works, and reviews have been published (see, for example, Refs 4–24).

The main emphasis in the above-mentioned studies^{1–3} was put on the crucial role of numerous interfaces existing in NM. The properties of solids containing such interfaces can be changed appreciably both by structural and electronic modification and by using new doping resources irrespective of the type of bond, size factors, etc. When the grain or crystallite size (L) is several nanometers, the proportion of interfaces in the total bulk of the material is at least $\sim 50\%$. This value was approximately estimated from the $3s/L$ ratio, where s is the width of the near-boundary region; for a reasonable value $s \approx 1$ nm, a proportion of 50% is attained when $L \approx 6$ nm. Gleiter and coworkers^{1–3} proposed a method for producing nanomaterials, which included preparation of ultradisperse powders by vaporisation–condensation and subsequent *in situ* compaction at high pressures. This procedure gave disk-like specimens 10–20 mm in diameter with a height of up to 0.1–0.5 mm. In order to obtain high-purity specimens, it is necessary to eliminate contact of the highly reactive powders with the environment (although these specimens

usually contain up to 10%–20% of residual porosity). However, initially, this fact was ignored and gave rise to some erroneous inferences (see, for example, Ref. 21).

This method for the preparation of NM was assimilated by researchers in many countries, first of all, in the USA (Siegel's group in the Argonne National laboratory²⁵ and research groups in some other universities); this triggered an avalanche-like accumulation of data concerning the properties of NM.

The first Russian session devoted to the research of properties of consolidated NM was held in 1984 and called the first All-Union Conference on the Physical Chemistry of Ultradisperse Systems.[†]

In an earlier study of NM published in 1983,²⁷ it was shown that compaction of ultradisperse nickel powders at high pressures and moderate temperatures furnishes NM with a crystallite size of about ~ 60 nm with a hardness exceeding that of usual polycrystalline nickel by a large factor. Unfortunately, the publications cited^{26,27} have passed almost unnoticed by both Russian and foreign specialists. Meanwhile, these studies²⁷ demonstrated one more time, independently of the results obtained by Gleiter and coworkers,^{1–3} the validity of the known Hall–Petch relationship, which relates strength (hardness) to the grain size ($H \sim L^{-1/2}$) in the nano-size range, and the expediency of extending this relationship to NM. At present, the greatest L value is taken to be ~ 100 nm.^{17,20,21}

In view of the relatively small dimensions of NM crystallites (and, correspondingly, the numerous interfaces they contain), it becomes clear why it is important to study the nanostructure evolution, which is accompanied by changes in the properties of NM, upon heat treatment or other types of treatment. Naturally, these items attract attention of researchers; various aspects of the problem of NM stability have been considered in a number of papers, reviews, and monographs (see, for example publications^{14,18,20–22,28–31}); however, generally, this item does not appear to be adequately studied.

In terms of the fields of application, one can distinguish the following main functional types of NM for which thermal stability is especially significant: tool materials and materials for high-temperature friction units; thermal and diffusion barrier components; high-temperature semiconductors, catalysts, and sensors; porous, emission and filter component parts; and refractory materials of various types. The knowledge of thermal stability patterns is also important for NM manufacture technology. In particular, when selecting the optimal conditions for superplas-

ticity and when developing the conditions for controlled crystallisation from the amorphous state and for plasma sputtering of nanostructured coatings and high-energy methods for consolidation of ultradisperse powders, specialists should take into account conditions for nanostructure maintenance. The information outlined above accounts for both the theoretical and practical interest in the problems of thermal stability of NM.

II. The key types, structure, and general characteristics of nanomaterials

The concept of NM introduced by Gleiter and coworkers,^{1–3} mainly in relation to metal-like materials, has now substantially expanded. Twenty years later, Gleiter²² considered a broader spectrum of NM, apart from the above-mentioned objects, namely, semiconductors, polymers, diamond-like and supramo-

lecular structures, and biomaterials. This can be supplemented by ceramics, catalysts, nanoporous materials, and a large number of nanocarbon and, generally, nanotubular structures; the scope of investigations of these materials is swiftly extending.

The NM listed above have been prepared by different methods and have different types of microstructure. Table 1 and Fig. 1 present data concerning compact and nonpolymeric NM.^{21,22} Classification according to the composition, distribution, and the shape of structural components implies three kinds of structural shapes (layer-shaped, rod-shaped, and equiaxed forms) and four sorts regarding the chemical composition and component distribution, namely, single-phase compositions, statistical multiphase compositions with either identical or non-identical interfaces (*i.e.*, the possibility of segregation is taken into account), and matrix compositions. The number of structural types can be greater due to mixed variants, the presence of porosity and so on. One should

Table 1. Key methods for the preparation of compact NM.

Preparation technique	Main types	Objects
Powder technology	Gleiter method (gas-phase deposition and compaction) electric-discharge sintering hot pressure treatment high static and dynamic pressures at ambient and high temperatures	elements, alloys, compounds
Severe plastic deformation	equal-channel angular pressing high-pressure torsion pressure treatment of multilayer composites phase cold hardening	metals and alloys
Controlled crystallisation from the amorphous state	normal and high pressures	amorphous materials
Film technology	chemical vapour deposition (CVD) physical vapour deposition (PVD) electrodeposition sol–gel processes	elements, alloys, compounds

Figure 1. Sketch of single-phase (*a*) and multiphase NM with a statistical (*b*, *c*) and matrix (*d*) distribution of structural components.²² (*b*) identical interfaces; (*c*) non-identical interfaces.

also take into account the conditional character of the classification of production processes because the borders between particular technological expedients are often blurred. When comparing the thermal stability of different NM, one must bear in mind that the diversity of production techniques and types of macro- and microstructures has an influence on the NM behaviour during heating.

The most frequently encountered structural types are single-phase and multiphase matrix and statistical objects, rod-shaped and multilayer structures (so-called superlattices); the latter type is

Figure 2. Photomicrographs of the NM structure: (a) Ti(N,B) film prepared by magnetron sputtering;³² (b) multilayer TiN/NbN film prepared by magnetron sputtering (the overall thickness of individual monolayers is 4.6 nm);³³ (c) 'Finemet' magnetic alloy prepared by crystallisation from the amorphous state followed by annealing at 500 °C ($t = 1$ h); the arrows mark the grain boundaries.³⁴

typical of films. Figure 2 shows examples of some typical structures. High-resolution transmission electron microscopy is especially effective for elucidating the NM structure.^{32–34} Attention is drawn by the difference between the structures and thicknesses of interfaces for NM prepared by different procedures (see, for example, Figs 2 a and 2 c). Various opinions have been expressed concerning the nature of interfaces in NM (see, for example, Ref. 21); however, it is clear that the diversity of production methods also leaves a mark on the nature of the interfaces. X-Ray diffraction methods, which allow one to estimate the anisotropy of grain size and to obtain information on structure distortion, are also widely used to study nanostructure (this has been done most comprehensively in investigating the effect of annealing on the rutile nanostructure³⁵).

It is evident that the vast majority of NM, except for supramolecular structures (which was first noticed in the review by Gleiter²²), are non-equilibrium in their nature. A system can move away from equilibrium for several reasons. As regards NM, the most important of these reasons is the abundance of interfaces (grain and phase boundaries and triple junctions), which gives rise to excess free surface energy. Figure 3 sketches a triple junction and Fig. 4 shows the dependences of the overall fraction of interfaces and the fractions of proper grain boundaries and triple junctions on the grain size.[‡]

Figure 3. Triple junction formed by grains shaped like tetrahedral dodecahedra.

Figure 4. Effect of the grain size on the overall fraction of interfaces (1) and on the fractions of grain boundaries (2) and triple junctions (3) (boundary width 1 nm).³⁶

[‡] According to estimates,³⁶ the overall fraction of interfaces amounts to $V_1 = 1 - [(L-s)/L]^3 \sim 3s/L$, the fraction of proper grain boundaries is $V_2 = [3s(L-s)^2]/L^3$ and the fraction of triple junctions is, correspondingly, $V_3 = V_1 - V_2$.

As noted above, for grain sizes of less than 5–6 nm, these fractions are rather high and, hence, the excess free surface energy is also rather high; the fraction of boundary segregations also increases.

Note that the values of the interfacial and boundary surface energy can differ from those for usual coarse-crystalline materials; however, reliable experimental data are scarce (see, for example, Ref. 21). It is worth noting that the presence of free space in virtually non-porous NM has been noted in many publications. For example, this was found in densimetric measurements for nanocrystalline nickel³⁷ and gold³⁸ specimens (Table 2) and in a study of positron annihilation in palladium.³⁹ A possible constituent of the free space is the discontinuity of the grain boundaries.

The NM structure often contains non-equilibrium phases; therefore, phase equilibrium diagrams can markedly vary. Nanomaterials produced using film technology and high-energy treatment (static and dynamic high pressures, intensive plastic flow, *etc.*, see Table 1) occur inevitably under residual stress and contain crystal structure defects; this also influences their energy state.

Table 2. Density of nanocrystalline nickel³⁷ and gold³⁸ specimens (γ_t is the theoretical density).

Specimen	Preparation method	L /nm	γ_t /g cm ⁻³	γ /g cm ⁻³
Nickel	pulse electrodeposition	11 ± 1	8.897	8.34 ± 0.02
Gold	magnetron sputtering	18 ± 2	19.299	19.0 ± 0.5

Thus, heat treatment, exposure to force fields or radiation, or long-term operation of NM even at usual temperatures induce recrystallisation, segregation, homogenisation and relaxation processes; phase transitions; phase formation and destruction; amorphisation, sintering, and nanopore (nanocapillary) closing. For a long period, these processes have been the subjects of numerous studies related to material science and the physics and chemistry of solids. For example, the theoretical views on the stability of colloids and thin films have been surveyed in a monograph.⁴⁰ However, the mechanisms of many of these processes as applied to NM have not been adequately studied. Currently, it is still difficult to differentiate between them and to evaluate their role but, generally, almost all of the above phenomena have an appreciable effect on the properties and the service performance of NM. In the limiting case, degradation of NM is possible, although in many cases, an additional heat treatment of NM proves useful for stabilising their properties.

III. The main processes in nanomaterials during heat treatment

1. Grain growth
a. Experimental data

The experimental curves that illustrate the effect of temperature and duration of the annealing on grain growth in various types of NM are shown in Figs 5–12.^{41–53} The general regularities based on the data presented here and other data on grain growth in nanocrystalline specimens are outlined below.

1. The lognormal or normal grain size distributions remain virtually the same for the initial and annealed specimens. Numerous kinetic studies gave diverse results. For example, in the general case, a power law holds for grain growth (see Fig. 5) but it is often rather difficult to prefer either a relation like $L^2 \sim t$ or some other ($L^{1.3;4} \sim t$).⁴¹ Using experimental results (isothermal annealing) for NbAl₃ nanocrystals prepared by mechanical doping⁴⁷ and for Fe₃₃Zr₆₇ and (Fe,Co)₃₃Zr₆₇ alloys prepared by crystallisation from the amorphous state,⁴⁸ the relationship $L^3 \sim t$ was found.

Figure 5. Kinetics of the grain growth in nanocrystalline copper prepared with sliding friction.⁴¹ T/K: (1) 575, (2) 625, (3) 675.

Figure 6. Kinetics of the grain growth in nanocrystalline copper prepared by compacting an ultradisperse powder in a vacuum.⁴² Porosity (%): (1) 7, (2) 4, (3) 3; T = 298 K.

Figure 7. Kinetics of nanograin growth during annealing of RuAl powders prepared by mechanosynthesis.⁴³ T/K: (1) 873, (2) 973, (3) 1073, (4) 1173, (5) 1273.

Figure 8. Effect of temperature ($t = 1$ h) on the nanograin growth in iron (1) and iron–aluminium alloy (2–5) powders prepared by mechano-synthesis with attritor milling under nitrogen (1–4) or argon (5) at low temperatures.⁴⁴

Aluminium content in the alloy (mass %): (2) 2.6; (3) 10; (4) 10 (milling for a longer period); (5) 10.

The exponential quantity n can depend not only on the object of investigation but also on the temperature range ($1/n = 0.05–0.5$).^{20,22} The experimental data obtained in kinetic measurements of the growth of nanograins during annealing of ruthenium monoaluminide powders were found to be in good correspondence with the following expression:

$$\frac{L^2(t) - L_{\max}^2}{L^2(0) - L_{\max}^2} = \exp\left(-\frac{2qt}{L_{\max}^2}\right), \quad (1)$$

where indices t and 0 refer to the current and initial time, $L_{\max}$ is the maximum grain size at the given annealing temperature dictated by factors restricting the grain growth (for example, boundary segregations) (see Fig. 7), and q is a kinetic constant.⁴³

In a study of the grain growth ($L_0 \sim 8$ nm) in iron powders treated in a high-energy attritor and annealed at $350–600$ °C in a dynamic vacuum ($\sim 10^{-3}$ Pa, annealing time from 5 min to 142 h), a dependence of the exponential quantity on temperature was found and the correspondence of the experimental kinetic data to both the dependence of the $\sim t^n$ type and relation of type (1) was established.²⁹

Figure 9. Effect of the duration of deposition from a $[\text{Cd}(\text{CH}_3\text{COO})_2 \cdot 2\text{H}_2\text{O} + \text{H}_2\text{NCSNH}_2 + (\text{HOCH}_2\text{CH}_2)_3\text{N} + \text{NH}_4\text{OH}]$ solution at 75 °C on the CdS film thickness (1) and crystallite size (2).⁴⁵

Figure 10. Statistical size distributions of crystallites in ZrN films (a, b), a ZrN + TiN 20-layer film (c) and a doped (Zr,Ti)N film (d) annealed at different temperatures.⁴⁶ Film thickness μm : (a, c) 2, (b) 0.1, (d) 1.

Figure 11. Change in the microhardness of TiN/AlN multilayer films after annealing in an argon atmosphere for 2 h.⁵³ The total thicknesses of TiN and AlN individual layers are 16 (1) and 2.9 nm (2); the total film thickness is 300 nm.

2. When NM are kept for a long time even at room temperature, growth of grains takes place.^{22, 42, 49, 50} This so-called anomalous growth of grains occurs if the grain size distribution is inhomogeneous (in this case, large grains serve as seeds for the anomalous growth).²² The activation energies for grain growth in NM and for the grain-boundary diffusion are close.^{21, 22} Measurements over a broad temperature range showed an increase in the activation energy for boundary growth with temperature rise; for example, for RuAl nanocrystals, the activation energies were found to be 39, ~72 and 213.5 kJ mol⁻¹ for temperatures of 873–1073, 1073–1173 and 1073–1273 K, respectively. This dependence could be due to the progressive effect of the boundary segregation temperature on the retardation of grain growth.⁴³ The activation energy for grain growth in iron at low temperatures is 125 kJ mol⁻¹ (which is close to the activation energy of the boundary self-diffusion in iron), while at higher temperatures, this value is 248 kJ mol⁻¹ (which is approximately equal to the activation energy of bulk self-diffusion).²⁹ These results can be

Figure 12. Effect of the annealing temperature on the electrical resistivity at 4.2 K $\rho_{4.2K}$ (a) during temperature increase (1) and decrease (2); temperature gradient $\Delta\rho/\Delta T$ (b); microhardness (c); degree of ordering (d), internal distortions (e); and crystallite size (f) of nanocrystalline Ni₃Al.¹⁸

explained by assuming different growth mechanisms for low- and high-temperature ranges.

3. The low-temperature milling of Fe–Al alloys reduces the tendency of the resulting NM for recrystallisation, which is attributed to the formation of fine FeAl_2O_4 particles and boundary segregations (see Fig. 8). The temperatures of the onset of active grain growth are mainly correlated with the melting points. In the presence of interstitial impurities (oxygen, nitrogen, *etc.*) and with formation of oxides and nitrides in the system, the grain growth starts at higher temperatures. This was confirmed for the Ag–O,⁴⁹ Ti–N⁵⁰ and Mo–N⁵¹ systems. Their thermal stability was demonstrated in relation to two-phase nanosystems, Cu–Ag and TiN– Si_3N_4 .^{49, 52}

4. In film specimens, the size of crystallites is much smaller than the film thickness but is correlated with the latter (see Figs 9, 10). A decrease in the film thickness promotes the growth of grains (see Fig. 10); in multilayer films, thermal stability increases with a decrease in the thickness of layers (Fig. 11).⁵³

5. It was noted in several publications (see, for example, the studies^{21, 22, 53, 54}) that the thermal stability of grains increases as the grain size diminishes.

6. The growth of grains is accompanied by not only changes in structural parameters such as microdistortions, the degree of ordering, *etc.*, but also by changes in physicochemical properties of NM (Fig. 12).¹⁸

The features noted above were established using electron microscopy, diffraction and calorimetric techniques.

b. The models and theoretical concepts

The problem of maintenance of the nanostructure of NM has been discussed in several reviews and original studies (see, for example, the publications^{20–22, 28, 30, 31, 50–56}). The main factors considered to favour the production of thermally stable NM include the presence of nano- and micropores, boundary segregations and two- or multi-phase nanostructures, a decrease in the grain-boundary surface energy, the formation of supersaturated solid solutions, an appropriate grain morphology, and homogeneity of the grain size distribution. The stagnation of grain growth in nanocrystalline films and ultradisperse powders has been discussed in the literature.⁵⁷

The research into grain boundaries and, generally, interfaces has been the subject of numerous publications (including monographs, see for example, Refs 58–62). However, these works barely touch upon the specificity of nano-objects. In recent years, the structures of grain boundaries have been calculated and the NM properties and the probability of vacancy generation during boundary migration have been predicted using molecular dynamics techniques (see for example, the studies^{21, 22, 28, 63–69}). In particular, it was shown that one-component NM can be simulated by two-phase models (the grain body and grain boundaries). In estimating the properties that depend little on the structure, this approach provided satisfactory results.^{21, 22} The contribution of triple junctions to the excess energy of NM was found to be rather weighty.⁶⁷

The molecular dynamics simulation proved to be useful for confirming the generation of vacancies upon grain boundary migration.⁶⁶ This process is related to elimination of the free space existing as interface discontinuity; the 'injection' of vacancies inside the grain body should increase the free energy of the system and hamper the boundary migration. An increase in the vacancy concentration during recrystallisation of ultradisperse powders has been recorded experimentally by positron-annihilation analysis.⁶⁸

The following relation was obtained for the critical size of crystallites:^{69, 70}

$$\frac{L_c}{2} = \left[24NkTZ(\beta sd)^2 \frac{m}{D} \right]^{1/3}, \quad (2)$$

where N is the number of atoms in unit volume; k is the Boltzmann constant; Z is the coordination number; β is the excess relative free

volume of the grain boundaries; d is the distance between the vacancy sources and sinks; m is the boundary mobility; and D is the self-diffusion coefficient. When $L_0 < L_c$, excessive vacancies retard the migration of grain boundaries, and when $L_0 > L_c$, the grains grow in the usual way, for example, in conformity with the law ($L^2 \sim t$). If the number of dislocations as vacancy sinks is relatively low, the grain boundaries or film surfaces mainly act as the sinks. In this case,

$$\frac{L_c}{2} = 24NkTZ(\beta s)^2 \frac{m}{D}, \quad (3)$$

where $L_c/2 \approx d$. For example, for aluminium ($m = 2 \times 10^{-14} \text{ m}^4 \text{ J}^{-1} \text{ s}^{-1}$; $T = 273 \text{ K}$; $D = 1.3 \times 10^{-17} \text{ m}^2 \text{ s}^{-1}$), the L_c value amounts to $\sim 100 \text{ nm}$, *i.e.*, this is a typical value for an NM structure.⁷⁰

When using relation (2) [or (3)], one should take into account the estimates of the typical grain sizes in NM made in a publication.⁷¹ In crystallites with dimensions of less than L^* ,

$$L^* = \frac{\alpha E b}{2\tau_{PN}}, \quad (4)$$

where α is a coefficient dependent on the dislocation geometry and ranging from 0.1 to 10, E is the shear modulus, b is Burgers vector, and τ_{PN} is the Peierls–Nabarro stress, the existence of dislocations is unlikely. For example, for linear edge dislocations, the following L^* values (nm) were found for some metals⁷¹ and for titanium nitride:³²

Cu	Al	Ni	Fe	TiN
25	10	10	2	~ 1

When $L_c < L^*$, relation (2) should be used, while for $L_c > L^*$, the use of formula (3) is preferred. However in both cases, one should bear in mind that these relations are approximations.

Yet another interesting conclusion concerning triple junctions has been drawn in a study of grain boundary migration. Triple junctions can be considered as a sort of impurity at interfaces but they mainly play an important role at relatively low temperatures. It has been shown for zinc and aluminium^{72–74} that the migration velocity of grain boundaries with triple junctions is lower than that for grain boundaries without the junctions at low temperatures. This is due to different activation energies for migration of these boundaries. A temperature rise entails an inversion: the boundaries with junctions become more mobile and the grain growth is controlled by the grain boundary migration. In the case of 99.995% pure zinc, the upper limit of the predominant influence of triple junctions is $\sim 380^\circ \text{C}$ (tilt boundary grains in the $\langle 10\bar{1}0 \rangle$ system) and $\sim 430^\circ \text{C}$ (tilt boundary grains in the $\langle 10\bar{2}0 \rangle$ system). For 99.999% pure aluminium, these temperatures were found to be $\sim 400^\circ \text{C}$ (tilt boundary grains in the $\langle 111 \rangle$ system) and $\sim 510^\circ \text{C}$ (tilt boundary grains in the $\langle 110 \rangle$ system).

The retarding role of triple junctions should be enhanced by a decrease in the grain size (see Fig. 4). Analysis of the variation of the areas of two-dimensional grains showed that, with allowance made for triple junctions, the velocity of grain boundary migration is proportional to the grain perimeter, but the pattern of dependence on topological parameters would be more complex.^{8, 75} However, the general features of switching of the mechanism of the triple junction effect on grain growth and the temperature ranges in which each particular mechanism is effective have not yet been adequately studied.

In investigating the grain growth in metallic films, a thermodynamic approach taking into account tensile stresses has proved to be useful.⁷⁶ According to estimates, the boundary migration and injection of vacancies inside the grains create conditions

§ Number of triple junctions per grain (m); when $m = 6$, grains exist in an equilibrium form; when $m < 6$, smaller grains disappear and when $m > 6$, larger grains grow (anomalous growth situation).

where recrystallisation is thermodynamically unfavourable and the grain growth is retarded. The incubation period depends on the grain size (or the distance between the sinks) and on the temperature

$$t_{\text{inc}} = \frac{(\beta s d)^2 N k T}{\gamma D L_0 c_{\text{eq}}}, \quad (5)$$

where γ is the grain-boundary surface energy, L_0 is the initial grain size, c_{eq} is the equilibrium concentration of vacancies. For example, for $T/T_M \approx 0.3$ and $L_0 = d \approx 10$ nm, the t_{inc} value would be $\sim 10^7$ s, i.e., ~ 150 days. From general considerations, this appears reasonable, although somewhat overestimated. One should bear in mind that relations (2)–(5) are approximations and also the fact that the residual stresses in the crystalline films are not necessarily tensile but can also be compressive.

The thermodynamic aspects of the segregation effects have been considered in several studies (see, for example, the publications^{21, 22, 28, 56, 77, 78}). The patterns of adsorption at crystallite boundaries have been studied since long ago. It is noted in monograph⁵⁹ that a thermodynamic theory that regards the interfacial areas as a separate phase was proposed by Zhukhovitskii back in 1944. The same study presents the thermodynamic relations determining the activity of a component in the interfacial layer as a function of its bulk concentration. Well-known are also Arkharov's studies in which the attention is focused on the role of boundary segregations in the formation of the properties of metal alloys.

The general thermodynamic aspects of boundary segregations in metallic and ceramic alloys have been considered by Ishida;⁷⁹ as applied to NM, this topic was discussed in a number of publications.^{55, 56, 77, 78, 80} An important result obtained in these works is as follows: calculations performed in different approximations (Langmuir–McLean and Fowler–Guggenheim) showed that the free Gibbs energy (G) varies non-monotonically[¶] as a function of the crystallite size, the minimum G being located in the nano-size region (Fig. 13). Hence, the temperature rise in doped nanocrystals may produce situations where further increase in the grain size becomes thermodynamically unfavourable.

Nanocrystalline nickel alloys with a minor content of phosphorus (2 at.%–5 at.%) were used to demonstrate the possibility

Figure 13. Gibbs free energy for a binary nanostructured alloy with an average concentration of 5 at.% at $T = 600$ K vs. crystallite size (for a standard polycrystal, $G = 4$ kJ mol^{−1}).⁷⁷

[¶] We would like to note incidentally that this non-monotonic variation is correlated with the views⁸¹ of singular points reflecting the topological transitions in the nanocrystalline state.

Figure 14. Concentration profile of phosphorus in a triple junction for a nickel–phosphorus alloy (3.6 at.% P) after heating to 400 °C at a rate of 5 K min^{−1} (see Ref. 82).

The alloy containing 25 at.% P corresponds to nickel phosphide (Ni₃P).

of Ni₃P crystallisation *via* boundary segregations (Fig. 14).^{56, 82} It was found^{55, 83} that during the annealing of palladium–zirconium alloys (grain size 10–25 nm), the grain boundaries became enriched in zirconium.^{55, 83} In the Pd₉₀Zr₁₀ alloy, the grain size increased after annealing at 350 °C, whereas in the Pd₈₀Zr₂₀ alloy, no increase in the grain size was noted even after annealing at 500 °C, which was attributed to greater enrichment of grain boundaries in zirconium in this alloy. This fact was determined based on the change in the lattice spacing.

Experimental investigations of the boundary segregations in NM make use of unique analytical equipment (such as atomic tomograph, atomic force microscope) as well as advanced investigation methods (for example, electron energy loss spectroscopy and so on).⁸² Interesting features of iron segregation in nanocrystalline iron–yttrium alloys have been followed.^{14, 28}

The possibility of crystallisation at compound boundaries due to the inflow of surface active elements has been considered theoretically by Rabkin,⁸⁴ who noted the retarding effect of particles (so-called pinning effect) and pointed to low probability of complete stoppage of boundary migration. Nevertheless, stabilisation of the nanograin growth has been observed by many researchers [for example, during annealing of RuAl (see Fig. 7), iron or aluminium powders after milling in an attritor^{29, 43, 85}]. Evidently, to take into account numerous factors that govern the evolution of grain ensembles [such as boundary migration, diffusional segregation, phase crystallisation,⁸⁴ vacancy injection by moving grains, the possible relaxation of the residual stresses, size effects as applied to the intergrain surface energy and integral free energy (see Fig. 13), and so on], it is necessary to perform a versatile computer simulation of the main processes occurring during heat treatment of NM. An attempt at Monte Carlo simulation of some of these factors has been reported.⁸⁶

2. Phase transformations

The presence in NM of a nanocrystalline structure, supersaturated solid solutions or unusual crystalline phases is due to non-equilibrium conditions of NM preparation.

Experimental and theoretical studies of the thermal stability of these objects are few, although thermodynamic characteristics and the features of phase diagrams as applied to nanoparticles have been the subject of investigation of many researchers (see, for example, Refs 87–89). However, phase transitions in compact NM (diffusiveness, shifts, *etc.*) have not been studied systematically.

Several attempts have been undertaken to carry out rough calculations of state diagrams with allowance for the component

dispersity (see, for example, Refs 87, 90–93). Using the relations for the partial free energies of the system in the liquid and solid states (for the latter, the excess component of the boundary surface energy was taken into account), in the simple approximation of regular solutions, relations were derived that reflect the influence of the component dispersity on, for example, the decrease in the eutectic temperature ΔT_E :

$$\Delta T_E = \frac{\Delta G_2}{R \ln x}, \quad (6)$$

$$\Delta T_E = \frac{\Delta G_2}{R \ln x_E - \Delta S_{M2}}, \quad (7)$$

$$\Delta T_E = \frac{\Delta G_1}{R \ln[(1 - x_E)/(1 - x)] - \Delta S_{M1}}, \quad (8)$$

where G_i is the contribution of the excess boundary surface energy per mole, $\Delta G_i = 6V_i\sigma_i/L_i$ (V_i is the molar volume), σ_i is the grain-boundary surface tension, x and x_E are the limiting solubility and eutectic concentrations; ΔS_{M_i} is the melting entropy.⁹²

These relations are equivalent, their practical value being dependent on the presence of particular data for components 1 and 2.

Expressions (6)–(8) lead to a size dependence of the type $\Delta T_E \sim 1/L$. The calculated ΔT_E and T_E values for the TiC–TiB₂, TiN–TiB₂ and TiN–AlN systems are summarised in Tables 3 and 4. It can be seen that a tangible decrease in T_E can start when the dimensions of the dispersed component are several tens of nanometers, although one should remember that the calculations are rough. With more complicated approximations, the estimates cannot be brought to a numerical solution. The available thermodynamic information is inadequate for determining the solubility regions in the phase diagrams.

The phase stability in multilayer films has been considered in terms of various statistical thermodynamic approaches.^{94,95}

The presence of metastable structures is especially typical of NM prepared by mechanosynthesis or by film techniques. The

Table 3. ΔT_E values in TiC(TiN)–TiB₂ and TiB₂–TiC(TiN) pseudo-binary systems with different degrees of dispersity of one of the components.⁹²

L /nm	ΔT_E /K	
	TiC(TiN)–TiB ₂	TiB ₂ –TiC(TiN)

	20	2110

formation of supersaturated solid solutions and compounds was detected in the Fe–Cu, Fe–Ni, Fe–Ti, Fe–Al, W–Cu, Ni–Al, TiN–TiB₂, and TiN–AlN systems, *etc.*^{14,44,50,95–104} Detailed study of the Fe–Cu and Fe–Ni systems (crystallite size 3–50 nm)^{96,98,99,104} showed a pronounced increase in the solubility of the components in each other. Whereas iron dissolution in copper increases the thermal stability, the reverse process has virtually no influence on the grain growth parameters; two-phase Fe + Cu compositions were found to be less stable than single-phase ones.

In multilayer films (superlattices), cubic structures are often formed instead of hexagonal ones due to epitaxy (examples are aluminium and niobium nitrides with the NaCl structure in combination with cubic titanium and zirconium nitrides;^{30,50} and titanium with FCC structure in multilayer titanium–aluminium films¹⁰⁵).

Magnetron sputtering with both single-phase and two-phase TiB₂ + (0%, 25%, 50%, 75% or 100%) TiN targets at moderate deposition temperatures ($\sim 150^\circ\text{C}$) resulted in the synthesis of single-phase nanostructured boride–nitride films of the following composition: Ti(B_{0.73}N_{0.2}O_{0.05}C_{0.02})_{1.56} and Ti(B_{0.56}N_{0.29}O_{0.05}.C_{0.1})_{1.32} with a hexagonal structure and Ti(B_{0.34}N_{0.49}.O_{0.12}C_{0.05})_{1.49} and Ti(N_{0.6}O_{0.2}C_{0.2})_{1.58} with a cubic structure. The composition formulae were determined using Auger analysis. Judging by these formulae, these films were essentially non-stoichiometric because the homogeneity regions of titanium diboride and nitride in the equilibrium state differ from these values (TiB_{1.89–2.0} and TiN_{0.7–1.2}). However, the solubility of interstitial elements in films is rather high; therefore, fairly broad homogeneity regions appear in the state diagram of the TiB₂–TiN system.^{102,103} The equilibrium state diagram of the pseudo-binary TiB₂–TiN system (see Table 3) is an eutectic type diagram, the mutual solubility of the components in this system being very low. A similar situation is found in the TiN–AlN and NbN–AlN systems. While the equilibrium solubility of Al in TiN at 1000 °C equals ~ 2 at.%, the cubic equiatomic phase (Ti,Al)N occurs in nanostructured films even at room temperature.³⁰ Thus, the pattern of state diagrams of nanocrystalline systems[†] and the homogeneity regions of individual compounds substantially change.

Study of the effect of annealing at 700 and 1000 °C ($t = 15$ min) on the structure of Ti(B,N) films did not reveal decomposition: the films remained phase-homogeneous and the grain size changed insignificantly (Table 5).¹⁰⁶ Some changes in the microhardness will be discussed below.

An extensive study of the effect of annealing in the temperature range from 850 to 1000 °C on the structure and composition of and the chemical bonding in plasmachemical SiCN films has been reported.¹⁰⁸ Using electron microscopy and X-ray diffraction analysis and resorting to the data of infrared, Raman and photoelectron spectra of the films, it was shown that high-temperature annealing leads to a decrease in the amorphous matrix and yields oblong oriented α -Si₃N₄ nanocrystals (in the amorphous matrix of the initial films, 2–3 nm crystallites were detected).

Interesting examples of spinodal decomposition of nanostructured solid solutions, TiN–ZrN and TiN–AlN, have been reported.^{30,50,109,110} The dependences presented in Fig. 15 allow one to follow the influence of the annealing temperature on the change in the microhardness of films of individual titanium and zirconium nitrides and multilayer (TiN–ZrN) and doped [(Ti,Zr)N] films.¹¹⁰ It can be seen that starting from $T > 1000^\circ\text{C}$, the microhardness of doped films tends to increase with an increase in the annealing temperature; this is due to evolution of the ultradisperse products of spinodal decomposi-

[†] Unlike the equilibrium state diagrams of usual polycrystalline objects, in the case of nanocrystalline systems, it is appropriate to speak of quasi-equilibrium diagrams to mean their lability and possible variation with time.

Table 5. Effect of annealing on the average size (L /nm) and the microhardness (H_M /GPa)^a of crystallites in boride–nitride films.¹⁰⁶

Target	Initial film		$T_0 = 700\text{ }^\circ\text{C}$		$T_0 = 1000\text{ }^\circ\text{C}$	
	L	H_M	L	H_M	L	H_M
TiB ₂	3–5	41–46	—	40–46	—	35–39
TiB ₂ + 25% TiN	2.3 ± 1.1	40–46	4.4 ± 1.4	40–45	—	32–38
TiB ₂ + 50% TiN	2.9 ± 1.1	46–52	3.7 ± 1.2	47–54	3.4 ± 1.9	38–45
TiB ₂ + 75% TiN	5.4 ± 4.0	53–59	8.1 ± 4.4	52–58	7.9 ± 3.8	32–42
TiN	9.9 ± 8.8	36–40	13.0 ± 6.6	38–42	10.2 ± 7.0	33–40

^a The H_M values refer to a procedure¹⁰⁷ largely eliminating the effects of the substrate and film thickness; *i.e.*, here, H_M is the microhardness of the proper films.

**Figure 15.** Effect of the annealing temperature on the microhardness of monolayer ZrN (1) and TiN (2), 10-layer ZrN/TiN (3), doped (Zr,Ti)N (4) and 20-layer ZrN/TiN (5) films.¹¹⁰

tion. These films provide an example of so-called ‘smart’ materials whose properties not only deteriorate during operation but can also be upgraded to a certain extent.

Annealing of the (Ti,Al)N–Si₃N₄ nanocomposition at different temperatures showed a microhardness maximum and a grain size minimum at 800 °C, which should also be attributed to spinodal decomposition of the (Ti,Al)N phase; a substantial decrease in the microhardness and an increase in the crystallite size is observed after annealing at 1200 °C ($t = 30$ min in an atmosphere of 90 vol.% N₂ + 10 vol.% H₂).¹¹¹

The nanocrystalline cubic phase (Ti,Al)N is highly stable against oxidation.^{103, 112} Therefore, it is not accidental that one of the (Ti,Al)N-based layers is highly resistant to change in industrial and pilot multilayer superhard nitride films.¹¹³

3. Relaxation and diffusion

Relaxation processes in nanocrystalline compounds were analysed in the review;¹¹⁴ the diffusion processes in nitride films have been characterised.³⁰ If an NM has been prepared by, for example, severe plastic deformation or vapour quenching and represents a disordered solid solution, a temperature rise restores the short-range order, establishes a long-range order and induces the growth of grains. These regularities were followed for the Ni₃Al intermetallic compound in calorimetric experiments.^{114, 115} However, the use of differential calorimeters does not always permit detection of processes related to the relaxation of internal microstresses during low-temperature annealing. The relaxation of residual stresses can be detected in X-ray diffraction studies based on line narrowing and splitting into doublets. Relaxation is believed to precede the grain growth.¹¹⁴ Turning back to the data of Table 5, we would like to note that some decrease in the microhardness during annealing of boride–nitride films can, apparently, be attributed

to relaxation of the residual compressive stresses, where the grain size changed insignificantly.

The residual stresses in nanostructured nitride and other films caused by differences in the linear thermal expansion coefficients and elastic properties in the film–substrate system or in multilayer films can be rather pronounced. For example, in nitride films, the residual compressive stresses can reach 10 GPa and they can contribute noticeably to the hindering of dislocation and fracture migration (and, correspondingly, to the increase in hardness).³⁰ Stress relaxation processes consisting in migration, redistribution and annihilation of various defects as well as grain boundary migration are known to be diffusional processes. The activation energy of stress relaxation (E /kJ atom^{−1}) and the temperature ranges of this process for the films of some refractory compounds are given below³⁰

Compound	TiN	TiN	Ti(C,N)	CrN
$T/^\circ\text{C}$	400–900	250–430	450–900	240–670
$E/\text{kJ atom}^{-1}$	~200	~120	200–400	200–300

The given E values are similar in magnitude to the activation energies of nitrogen self-diffusion in nitrides (which is, more likely, a boundary rather than a bulk process).¹¹⁶ Comparison of the residual stress relaxation in titanium nitride and carbide–nitride showed that an equal level of compressive stresses in carbide–nitride films is attained at temperatures ~200 °C higher than in TiN; therefore, the high-temperature hardness of Ti(C,N) is higher.³⁰

The relaxation processes and the evolution of nanostructures in metals, alloys and intermetallic compounds (Fe, Cu, Ni; Al, Fe, Cu alloys; Ni₃Al, see Fig. 12) subjected to severe plastic deformation have been discussed in detail in a monograph.¹⁸ However, the mechanism of stress relaxation in NM as a whole is not entirely clear.

The information concerning heterodiffusion processes is important for the analysis of the thermal stability of multilayer films. A study of the mutual diffusion in single-crystalline multilayer TiN/NbN films (the thicknesses of separate layers are 4.4 and 12.3 nm for a total thickness of ~1 μm; isothermal maintenance at 750–875 °C, non-isothermal heating to 1200 °C) revealed the predominant diffusion of titanium.¹¹⁷ The activation energies (Q /kJ per atom) for different temperature ranges have been determined.^{30, 117}

$T/^\circ\text{C}$	< 830	830–875	885–930
Q	115	250	430

The last Q value is similar to the activation energy for the self-diffusion of metal atoms in transition metal carbides and nitrides.¹¹⁶ According to estimates,¹¹⁷ the duration of homogenisation in multilayer TiN/NbN films and, correspondingly, the working life of this nanocomposite with ~2 nm thick layers is ~10 h at 750 °C or ~2 h at 850 °C. To study heterodiffusion in multilayer films, one should employ high-precision X-ray diffraction and electron-microscopy procedures and also use powerful sources such as synchrotron radiation. The versatile capabilities of

X-ray diffraction for the assessment of $\text{In}_x\text{Ga}_{1-x}$ films with one ~ 10 nm thick quantum well have been demonstrated.¹¹⁸

A study of the thermal stability of multilayer Mo/NbN films (the metal has a body-centred cubic lattice and the nitride has a face-centred cubic lattice) showed that the formation of the tetragonal (Mo,Nb)N phase starts after maintenance for 3 h at 1000 °C.¹¹⁹

The diffusion of oxygen in films determines the stability of films against oxidation. The abundance of interfaces in NM creates conditions for substantial oxygen streams. Characteristic features of oxidation of nanostructured films have been analysed.^{30, 103, 112, 113, 120} The resistance of nitride films against oxidation is markedly increased by chromium or yttrium additives which 'lock up' the crystallite boundaries.¹¹³ Amorphous films have demonstrated both a poorer oxidation resistance (800 nm TiN films)¹²⁰ and a higher scale resistance (2–3 μm AlN–TiB₂ and AlN–TiB₂–SiC films)¹¹² compared to the same characteristics of crystalline films or bulk specimens of the same composition.

IV. Other stability aspects of nanostructures

For some types of NM (for example, for nanoporous, nano-semiconducting and nanocarbon materials), studies of thermal stability have started only recently (see, for example, Refs 121–126). It should also be noted that nanoparticle-related problems have been barely considered above, because, in view of the multispect character of agglomeration and sintering processes, these topics require separate consideration. We would only like to note that the sintering of nanoparticles and the grain growth in NM have much in common. Figure 16 shows the temperature dependence of the compaction during sintering of ultradisperse powders of metals and metal-like substances and also ionic and covalent compounds.¹²⁷ Whereas active sintering (compaction) of metals and metal-like or ionic compounds starts at homologous temperatures $(0.3–0.5)T_m$, the powders of covalent compounds (B, Si, Si₃N₄) are actively sintered only at $T \geq (0.8–0.85)T_m$, i.e., at much higher temperatures. Aluminium nitride, as an ionic-and-covalent compound, occupies an intermediate position. This difference is due to specific features of the diffusion mobility in objects with different types of chemical bonds. In all probability, the temperatures of the onset of the

active grain growth in these materials should lie within the same ranges.

The aspects of NM thermal stability considered above are far from exhausting the general problem of nanostructure stability. For example, the NM stability is appreciably affected by various fields (force, radiation, etc.). In particular, the grain growth upon superplastic deformation of fine-grained ceramic materials has been considered theoretically taking into account the additional driving forces for migration.¹²⁸

The microstructure changes induced by NM implantation or irradiation have been the subject of only a few studies (see, for example, Refs 129–131). The appearance of nanoclusters in metal alloys (Fe–Ni, Cu–Ni, Fe–Cr, etc.) at high levels of radiation damage has been noted.¹³² The formation of nanocrystalline diamonds ($L = 2–70$ nm) was detected on graphite irradiation with Ar⁺ ions (the fluence was $\sim 10^{22}$ cm^{–2}).¹³³ Amorphisation of nanocrystalline zirconium oxide on exposure to radiation by high-energy Xe²⁺ and Ne⁺ ions has been reported;¹³¹ meanwhile, gold nanoparticles with dimensions of 3 nm remained crystalline after irradiation. It is noteworthy that NM based on ZrO₂ are under vigorous research now (see, for example, studies^{134, 135}). The behaviour of irradiated NM is an extensive field for further research.

It should be emphasised that the stability of NM largely depends on the process used for their manufacture. A number of techniques such as high-pressure processes, sintering with controlled heating rates, pulse sintering, pulse modes of electro-deposition, moderate substrate temperatures during film deposition, the formation of multiphase structures and boundary segregations and some other are widely used in the preparation of NM (see, for example, the studies^{24, 31, 52, 136–142}). However, problems of deliberate selection of conditions for the production of the initial NM with a narrow nanocrystallite size distribution, the optimal content of doping or impurity elements for decreasing the grain-boundary surface energy or for the formation of barrier layers, and many other problems are far from being solved. It is not accidental, therefore, that the Japanese national program 'Material Nanotechnology' pays considerable attention to the development of NM with optimal structures and to the prevention of anomalous grain growth phenomena.¹⁴³

V. Conclusion

When generally evaluating of the state-of-the-art research into the thermal stability of NM, we would like to stress the following points. On the one hand, there exist quite a few experimental and theoretical facts demonstrating the possibility of production of thermally stable NM; on the other hand, examples of anomalous grain growth in NM are documented.

Unfortunately, our knowledge is still inadequate to unambiguously explain many facts and to compare the efficiency of various methods for nanostructure maintenance, say nothing of the possibility of making predictions. Note that the latter depends not only on the theoretical works and availability of reliable experimental information but also on the general level of the nanostructure theory. For example, it is not entirely clear what are the grain dimensions (of phase components) down to which the classical thermodynamics remain valid. The point is that objects with crystallite dimensions of $\sim 1–2$ nm or even less are already involved in NM investigation and application (see Table 5 and the studies^{32, 103, 106, 144–146}). A ~ 1 nm grain of titanium nitride with a lattice spacing of ~ 0.424 nm contains ~ 8 ($\sim 2^3$) unit cells, i.e., in essence, it is a cluster-consolidated object (unlike cluster-aggregated materials^{16, 147}). In this connection, the points such as the effect of the grain boundary curvature on its energy parameters, the applicability of the concepts of statistical thermodynamics or thermodynamics of irreversible processes, the type of excessive thermodynamic functions, the energy characteristics of triple junctions, and so on have been scarcely studied so far. These aspects have to be thoroughly analysed to be used in estimations.

Figure 16. Temperature dependence of compaction during sintering of various ultradisperse powders.¹²⁵
(1) Si, (2) Si₃N₄, (3) B, (4) AlN, (5) WC, (6) ZrC, (7) MgO, (8) Mo, (9) CaF₂, (10) Ni.

Note that research into the determination of the energy characteristics of the surfaces of isolated clusters, cluster aggregates and colloids is also in progress.^{148–150}

In the long-term American forecasts (for 10–15 years) concerning the arrival of nanotechnological products on the world market, nanomaterials occupy a leading position — of the putative total volume of 1 trillion US dollars, a sum of 340 billion US dollars is predicted for NM.^{151, 152} It is clear that substantiation of the operation capacity of NM, including thermal stability characterisation, is among the most important problems facing the science of nanostructured materials.

Institute of Physical and Organic Chemistry at the Rostov State University

This issue of the journal is composed of reviews prepared by scientists working at the Research Institute of Physical and Organic Chemistry at the Rostov State University (IPOC). The Institute was founded in 1971 as a subdivision of the North-Caucasian Scientific Centre of Higher School established a year before. The Institute includes six departments and four laboratories. Currently, the staff of the Institute comprises 200 associates, among them there are 14 Doctors of Science and 79 Ph.Ds. The Nuclear Magnetic Resonance Laboratory equipped with Varian spectrometers has the status of a Shared Access Centre of the Russian Foundation for Basic Research (RFBR). For RFBR grant holders from the south of Russia, similar functions are performed by the Laboratory for Quantum Chemistry, which implements the RFBR and Ministry for Industry, Science and Technology projects on computer network development and molecular simulation for higher education institutes in the south of Russia.

Since 1998, the Institute has been under the guidance of the Division of General and Technical Chemistry of the Russian Academy of Sciences (since 2001, the Division of Chemistry and Materials Sciences). This fact, together with the creation of joint laboratories with the Institute of the Problems of Chemical Physics and the Institute of Physical Chemistry of the RAS reflects the tendency towards the closer integration of Russian science and education, which has taken shape in the last decade, as a vital necessity dictated by the development of society. Related to this, an obvious advantage of research institutes affiliated to a university is the absence of departmental or other problems hampering the selection and recruitment of the most gifted students to work on scientific projects. The IPOC actively uses this opportunity in cooperation with the Department of Chemistry of the Rostov State University. The post-graduate course and the facilities for working towards doctorate degree, and the Academic Council for defending Ph.D. and Doctoral theses functioning at the Institute, provide the conditions necessary for raising the scientific level of young scientists.

The main fields of research developed at the Institute are related to fine organic synthesis, photochemistry, the synthesis

and study of the properties of metal coordination compounds, structural theory, and the mechanisms of organic reactions.

Of the interesting results of investigations performed at the Institute in recent years, noteworthy is the theoretical development of the principle of structural design of compounds with dynamic molecular behaviour able to undergo reversible low-barrier intramolecular rearrangements. This principle has underlain the targeted synthesis of bi-stable compounds existing as two or several stable forms whose interconversions can be induced by electromagnetic or electric fields. Studies into photocontrolled bi-stable structures have resulted in the development of new types of photochromic and fluorescent systems functioning as abiotic converters of light energy, highly sensitive photochemical chemosensors, effective molecular switches and 3D data recording media (molecular memory).

A traditional field of investigation at the Institute is the synthesis of polycyclic nitrogen- and oxygen-containing heterocycles and monosaccharides. The scientists working at the Institute have received more than 100 patents, including foreign ones, for physiologically active compounds exhibiting more than 50 types of biological activity including antidiabetic, antiaggregant, antiarrhythmic, antiulcer, local anaesthetic, antioxidant and others. Some of these products have already been authorised for clinical trials and the antiarrhythmic drug Ritmidazol has passed these trials and is allowed to be used in clinical practice by the Russian Federation Pharmacological Committee.

The organic ligands synthesised at the Institute serve for the preparation of coordination compounds of transition and non-transition elements with variable polyhedral types of chelate units. Efficient polymerisation catalysts, compounds with valuable magnetic characteristics, UV light converting luminophores, laser dyes, additives to lubricating oils, and so on, have been found among the new metal complexes.

The applied studies carried out at the Institute concentrate on electrochemistry (study of metal corrosion mechanisms, development of effective corrosion inhibitors for drilling tools operating in highly acidic and hydrogen sulfide environments), geochemistry (regional analytic surveys, landscape pollution mapping, analysis of man-caused pollution), development of new compo-

sites, coatings, lubricants and antifriction materials for aerospace and the automotive industry (some materials elaborated at the Institute were used in the spaceshuttle Buran). The process of manufacture of the Drotaverin drug (No-spa analogue) from Russian raw materials developed at the IPOC is currently under industrial development at the Volgograd chemical plant.

During the last 5 years, the scientists working at the Institute have published sixteen scientific monographs (six of them were published by companies in the USA, Germany and the Netherlands) with more than 500 scientific papers published in Russian and other international journals. More than 80 patents were granted, two inventions being patented abroad (in 23 countries). There are three State Prize laureates and a number of A M Butlerov and Alexander von Humboldt Prize winners, and winners of other prizes.

As in other scientific institutions of Russia, the Institute has faced severe financial problems and a shortage of personnel during the last decade. Suffice it to say that today's budgetary financing of the Institute does not exceed 5% of the pre-reform finances (on a comparable price schedule). The scientific potential and the 'critical mass' of the Institute and the intake of young specialists needed for future prospects are maintained almost exclusively by RFBR grants (the Institute has annually 10 to 12 initiative grants, and also leading scientific school grants and grants of the shared access laboratory 'Molecular spectroscopy' and of the library and database electronic access network), grants and programmes of the Ministry of Education and the Ministry for Industry, Science and Technology of the Russian Federation. Of special significance are international programmes and grants from the European Union (INTAS), Civilian Research and Development Foundation (CRDF, USA), Alexander von Humboldt and Volkswagen Stiftung Foundations (Germany), International Science and Technical Centre (ISTC), Council of National Research and Science (CNRS, France), SPECS and BioSPECS companies (Netherlands), the Servier pharmaceutical company (France), *etc.* Other forms of international collaboration and exchange are also used. Research dealing with photochromic and fluorescent chemosensors carried out at the Institute is a part of a Project executed by the Basic Research and Higher Education Centre at the Rostov, Kuban' and Taganrog Radio Engineering Universities financed by the CRDF, the Ministry of Education of the Russian Federation and the administrations of the Rostov Region and Krasnodar Territory. Within the framework of this project, more than 30 students and post-graduates were recruited on a competitive basis to work at the Institute where they received an additional scholarship.

The reviews presented in this issue illustrate the main fields of investigations carried out at the Institute and also some results of the collaboration with Universities in the USA and France. The paper by A D Dubonosov, V A Bren and V A Chernoi vanov entitled 'Norbornadiene – quadricyclane as an abiotic system for the storage of solar energy' and the paper by V Lokshin, A Samat (Marseilles University) and A V Metelitsa dealing with the synthesis and photochromic properties of spirooxazines represent the rapidly progressing research into photochemically active systems — molecular switches and optical memory elements, abiotic converters of light energy and fluorescent chemosensors.

The review by Yu A Zhdanov and Yu E Alekseev entitled 'Basic achievements in the coordination chemistry of modified monosaccharides' characterises the new trends in the development of carbohydrate chemistry, in particular, the possibility of preparing effective enantioselective catalysts by chirality transfer from the carbohydrate ligand to the metal centre.

The review by A D Garnovskii and I S Vasil'chenko 'Rational design of metal coordination compounds with azomethine ligands' gives a concentrated survey of the many-year research into targeted synthesis of mono- and polynuclear chelates and molecular complexes with coordination units of the type MN_xZ_y (where $Z = NR, O, S, Se, Te$), typical of the most important metal enzymes and metal proteins.

An original field of investigation carried out at the Institute is the chemistry of organotellurium compounds. Organotellurium compounds are not only precursors of some efficient semiconductor materials but, owing to specific features of the valence and hypervalent bonds formed by tellurium, they are also useful synthons for the synthesis of new heterocycles; this allows development of a peculiar synthetic strategy. I D Sadekov's review ' β -Telluroacroleins and β -tellurovinyl ketones: synthesis, reactions and structure' is devoted to one of the classes of organotellurium compounds studied at the IPOC.

Finally, the paper by V I Minkin, R M Minyaev, R Hoffmann 'Non-classical structures of organic compounds: unusual stereochemistry and hypercoordination' summarises the main results of investigations in this intriguing field of theoretical chemistry, including the results obtained in cooperation with the group of theorists headed by Nobel Prize winner, a foreign member of the RAS, Roald Hoffmann (Cornell University, USA).

Of course, the size of the issue does not permit all the fields of research carried out at the Institute of Physical and Organic Chemistry to be covered. Additional information concerning the Institute and its personnel can be found at the Institute websites (<http://www.ipoc.rsu.ru> and <http://rec.ipoc.rsu.ru>).

The increase in students' interest in scientific research and in the intake of post-graduates and young scientists, which has become evident in recent years, allows one to hope that the studies published in this issue will be continued in future years.

Abstract. Non-classical structures of organic compounds are defined as molecules containing non-tetrahedral tetracoordinate and/or hypercoordinate carbon atoms. The evolution of the views on this subject is considered and the accumulated theoretical and experimental data on the structures and dynamic transformations of non-classical organic compounds are systematised. It is shown that computational analysis using the methods and the software potential of modern quantum chemistry has now acquired high predictive capacity and is the most important source of data on the structures of non-classical compounds. The bibliography includes 227 references.

I. Introduction

Molecular structure is a key concept of theoretical organic chemistry. The description of molecular structures of organic compounds is underlain by the fundamental concept of two-centre two-electron covalent bonds, the tetravalence of carbon, and the tetrahedral geometry of the four single bonds it forms. Using only these concepts, which can be easily extended to other Main Group elements of the Periodic Table, it is possible to describe and predict all the key types of organic structures and kinds of isomerism. By means of a molecular meccano, these views can assume a material form as simple stereochemical models; these models appear to be an invention of Jacobus Henricus van't Hoff.[†] The fundamental nature of the principles that underlie these models can be compared only with the simplicity of their practical implementation, which can be understood by looking at the cardboard models

Figure 1. Three-dimensional stereochemical models hand-made personally by van't Hoff (courtesy Leyden Museum of Natural History).

made personally by van't Hoff (Fig. 1). By the same procedure, one can easily assemble molecular models of millions of organic and organoelement compounds. Actually, the prediction of the double-helix DNA structure (which is, perhaps, the most important discovery of the last century) required only one further structural concept — the notion of the hydrogen bond.

The development and extensive use of new methods for the investigation of molecular structure and dynamics as well as the development of organometallic chemistry, which linked organic chemistry to images and theoretical views of coordination chemistry, have extended the scope of the classical structural theory. Thus, it has become impossible to describe the whole diversity of the new types of structures and their dynamic transformations using only the ideas and the language of the classical structural theory. This triggered the development of two interrelated concepts, namely, the concepts of stereochemically non-rigid (fluxional) compounds and multicentre bonds. The development of the

[†] The Russian version of van't Hoff's article 'Sur les formules de structure dans l'espace'¹ and his original drawings illustrating the construction of spatial structures of molecules can be found in the monograph by Bykov.²

multicentre bond concept, in turn, has entailed the notions of hypervalence and hypercoordination. Thus, the description of molecular structures in terms of the notion of multicentre bonds can be likened to a complication in the standard molecular meccano by adding a set of new units, *i.e.*, multicentre bonds ($mc-ne$, where $n = 1, 2$ and $m > n$), for example, three-centre two-electron bonds ($3c-2e$). Examples of consistent application of this approach to the analysis of chemical structures of compounds containing hypercoordinate carbon atoms and derivatives of polyhedral boranes can be found in monograph.³

The orbital approach to the analysis of molecular structures and their transformations, developed in the second half of the XX century and based on semiquantitative orbital interaction theory, is more general and has a much more extensive predictive capacity.^{4–6} This theory focuses on the closure of the electron shells of valence molecular orbitals and on the presence of a rather large energy gap between the frontier MO as the key factors that influence the thermodynamic stability of a molecular structure. Kinetic stability of a molecular structure with respect to rearrangements or fragmentation may be due to the possibility that these processes are thermally forbidden by the orbital symmetry rules. An important advantage of the orbital approach as a qualitative theory of modern theoretical chemistry is that its views and notions can be directly transferred to and used in organometallic chemistry, in the coordination chemistry of transition metals and even in solid-state chemistry.^{7,8} Detailed analysis of the data accumulated by the early 1990s on the structures and properties of non-classical organic compounds carried out using the orbital interaction theory has been reported in our monographs^{9,10} and reviews.^{11,12}

The reliability of any qualitative views needs to be validated by strict theoretical calculations. By the early 1990s, the capacity for performing such calculations for compounds with more than 6–7 non-hydrogen atoms was quite limited; therefore, calculations for molecular systems were mainly carried out in the valence approximation by semiempirical quantum chemistry methods. The semiempirical methods have played and still play an important role in the theoretical simulation of structural chemistry problems. However, these methods are hardly applicable to non-classical structures, as they are parametric techniques in which parameters are selected by adjusting the calculated data to well-known experimental results obtained for classical molecular structures (references).

The situation has markedly improved during the last decade. Enormous progress in the manufacture of a new generation of high-performance computers and in the development of concomitant software made possible (and almost routine now) calculations of rather complicated molecules by means of high-level *ab initio* quantum chemistry techniques.¹³ The accuracy of calculations of this type is quite comparable with that attained in the experiment. This opens up new routes both for additional analysis of the previously developed qualitative structural theory of non-classical organic compounds made at a higher quantitative level and for the computational design of new molecular systems and new structural patterns with unusual geometry and unusual coordination types.

The purpose of this review is to consider the main results of the above-mentioned evolution of the views on non-classical organic structures. Whereas in the early stages of development, considerations of non-classical structures were focused on discussion of the structures of carbonium cations with a hypercoordinate carbon atom,^{3,14} in recent years, they have been markedly extended due to the appearance of new data on unusual stereochemistry of organic compounds. Currently, non-classical organic structures constitute a rather diverse field of theoretical and structural chemistry, which cannot be covered within the framework of a single review. Therefore, we restricted ourselves mainly to the analysis of recent data concerning non-classical types of carbon coordination.

Defining of the problem is as important for each investigation as the results obtained during its solution. Therefore, to preserve the general outlook, we have composed the first sections of this review in such a way as to allow the evolution of each problem to be followed starting from its background up to the most recent results. This strategy is employed to consider the structures of compounds containing a non-tetrahedral tetracoordinate carbon atom[‡] (so-called anti-van't Hoff–LeBel chemistry) and structures of compounds with penta- and hexacoordinate carbon atoms.

The final sections of the review are devoted to the theoretical design of compounds in which hypercoordinate (with coordination numbers from five to eight) carbon atoms, and atoms and ions isoelectronic with them, are encapsulated into planar organic and organoelement cages.

II. Tetracoordinate carbon atom with a planar configuration of bonds in the molecules and ions of organic and organoelement compounds: stereoelectronic strategies of stabilisation

The idea of the existence of a tetracoordinate carbon atom with a planar bond configuration[§] in organic molecules was rejected long ago by van't Hoff and LeBel² because it fails to explain the numbers of isomers of methane derivatives. Subsequently, this idea did not attract the attention of researchers for almost a century until Hoffmann, Alder, and Wilcox,^{15,16} relying on the orbital interaction method, defined the problem of stabilisation of such a centre and proposed ways in which its structure could exist. Seemingly paradoxical at first glance, this problem immediately became (and still remains) one of the most intriguing challenges to the imagination and the capabilities of theoreticians and experimentalists. The initial and later stages of development of this problem have been the subject of detailed reviews.^{9,17–23} Our goal is to consider the most recent results and to distinguish the key strategies directed at solving the problem of stabilising a planar tetracoordinate carbon atom. In this context, the data of earlier studies are resorted to for discussion.

The reasons for the instability of the planar bond configuration at a tetracoordinate carbon atom become clear on examining the Walsh diagram for the methane molecule (Fig. 2). It can be seen that one of the triply degenerate bonding t_{1u} MO of the tetrahedral (T_d) structure is transformed in the planar D_{4h} form (**1**) into a nonbonding a_{2u} MO, which is the p_z AO of the carbon atom and is occupied by two electrons.

Thus, only six electrons are used in the formation of four C–H bonds in the planar structure. According to the most precise calculations, the planar D_{4h} form of the methane molecule is unstable with respect to dissociation giving a hydrogen atom and a methyl radical. This structure is 138.4 [QCISD(T)(fc)/6-311+G(3df,2p)//CISD(fc)/6-311G**]²⁴ or 136.2 kcal mol^{–1} [CCD(full)/6-311++G**]²⁵ energetically less favourable than the tetrahedral T_d form.[¶] Moreover, the D_{4h} configuration does

[‡] Here and below, we mean the topological tetrahedral type rather than the exact tetrahedral geometry with angles of 109°28'.

[§] Below, carbon atoms with this bond configuration are referred to as planar tetracoordinate carbon atoms.

[¶] Expansion of the abbreviations and description of calculation techniques and the orbital basis sets can be found in the book by J B Foresman, A Frish *Exploring Chemistry with Electronic Structure Methods* (Pittsburg: Gaussian Inc., 1996).

Figure 2. Correlation diagram of the molecular orbitals for tetrahedral and square-planar configurations of the methane molecule.

not even correspond to any local minimum in the potential energy surface (PES) of methane. As predicted by both earlier (MINDO/3) and later (RHF/4-31G) calculations,^{9,26} the vibrational spectrum of the planar structure contains four imaginary frequencies, which imply the occurrence of four types of deformations resulting in barrier-free rearrangements of the molecule.

A different planar form of methane with C_{2v} symmetry, structure **2**, is preferred from the energy standpoint.

This form is not matched by any local minimum in the PES either, but it presents interest as illustrating the adaptation of a planar structure to the electron deficiency experienced by its C–H bonds. This structure and the energetically more favourable structure **3g** (C_s symmetry), which is shown in Fig. 3, can be considered as complexes formed by singlet methylene ($^1A_1$) and a hydrogen molecule. Both structures (**2** and **3g**) are stable with respect to dissociation into CH_2 and H_2 . Figure 3 shows the geometric structures of methane corresponding to all the stationary points in the PES found in calculations.²⁵

The electronic and steric structures of the model methane molecule with D_{4h} symmetry provide a key to the quest for stabilisation routes for compounds with a planar tetracoordinate carbon atom. Now we consider these routes.

1. π -Acceptor and σ -donor substituents

The replacement of hydrogen atoms in planar methane by π -acceptor groups results in delocalisation of the lone electron pair in the $1a_{2u}$ orbital (see Fig. 2), while σ -donor substituents partially make up for the electron deficiency of the σ -bonds in the D_{4h} and C_s structures of methane. The concept of electronic stabilisation first put forward by Hoffmann *et al.*^{15,16} and soon supported by extensive *ab initio* calculations²⁷ is the key and the most successful strategy used in computational and experimental quests for compounds with a planar tetracoordinate carbon atom. A recent review²¹ contains a rather comprehensive collection of data on the structures of a broad range of so-called polar organometallic compounds — derivatives of methane, ethene, and cyclopropane in which the hydrogen atoms have been replaced by lithium or sodium atoms or BeH , MgH , BH_2 or AlH_2 groups. This review considers both the results of early theoretical studies and the recent results obtained by Schleyer's group²⁸ using the density functional theory with an extended orbital basis set (B3LYP/6-

Figure 3. Geometric parameters of the structures corresponding to stationary points in the PES of the methane molecule found²⁵ by CCD(full)/6-311++G** calculations.

Here and below, λ is the number of negative eigenvalues of the Hessian matrix in the given stationary points: for a minimum, $\lambda = 0$; for a transition state (first-order saddle point), $\lambda = 1$; for a second-order saddle point (the top of a two-dimensional hill), $\lambda = 2$. The relative energies (ΔE /kcal mol⁻¹) of configurations are corrected for the zero-point energy (ZPE) of harmonic vibrations. Here and below, the bond lengths are given in Ångströms and the bond angles are in degrees.

311++G**). The results fully confirm the expected effect, namely, a substantial decrease in the energy gap between the planar and tetrahedral structures (here and below, the tetrahedral topology is meant). For compounds such as 1,1-dilithiocyclopropane or 1,2- and 1,1-dilithioethenes, structures with planar tetracoordinate carbon centres (structures **4**–**6**, respectively) are energetically the most favourable.

Divanadium complex **7** was, apparently, the first compound with a planar tetracoordinate carbon atom to be studied experimentally. Its structure was established by X-ray diffraction analysis.²⁹ In this compound and in the structurally related dizirconocene complex **8**, the planar configuration exists due to the multicentre bond formed by the carbon sp^2 orbital of the phenyl anion, similar to binding in the C_{2v} form of methane (structure **2**). Complex **9** belongs to the extensive class of bimetallic complexes in which planar tetracoordinate carbon atoms are linked to transition (or nontransition) metal atoms.³⁰ A virtually planar geometry of the carbon centre was found in compound **10**, which is related to substituted 2-lithiocyclopropene,³¹ and in a number of carbides, for example, in $Ca_4Ni_3C_5$, which was studied in detail both experimentally³² and theoretically.³³ Numerous examples of bimetallic complexes with structures similar to **7**–**10** and a description of the methods for their synthesis can be found in reviews.^{22,23} All these data can serve as a good illustration for

the effectiveness of R Hoffmann's concept of electronic stabilisation of a planar tetracoordinate carbon centre.

Cp is cyclopentadienyl, tmeda is tetramethylethylenediamine.

2. Carbon atom in the centre of the annulene ring

Yet another idea of stabilising a planar configuration of carbon, also proposed by R Hoffmann and coworkers,¹⁶ implies incorporation of this carbon atom into an annulene ring having an aromatic ($4n + 2$) electron shell. This gives rise to structures such as, for example, compounds **11** and **12**. Indeed, extended Hückel calculations showed that these structures actually have a closed electron shell characterised by a rather wide energy gap between the highest occupied and lowest unoccupied molecular orbitals. Meanwhile, structures **13**–**15** with antiaromatic annulene rings proved to be unstable.

The MINDO/3³⁴ and MNDO³⁵ semiempirical calculations with geometry optimisation confirmed the instability of planar structures **13**–**15**. However, according to these calculation techniques, the planar configuration is not realised for compounds **11** or **12** either. Figure 4 shows the stable conformations of fenestranes **11**, **12** and **15** which we determined by B3LYP/6-311 + G** calculations. It can be seen that the central carbon atom in these structures retains the tetrahedral configuration of bonds, although the angular distortions may reach 30°. It is of interest that in compounds **11** and **12**, the charges on the central carbon atom are +3.6 and +3.7, respectively,[†] i.e., all the valence electrons of carbon are displaced to the periphery of the molecule. The aromaticity of the 14-membered rings ($\sim 18 \pi$ electrons) is retained and the effective radius of the central atom decreases, which results in a lower steric strain. However, in compound **15**, the charge on the central carbon atom is 2e lower (+1.9) and, as a consequence, the conjugated 12-membered ring contains 14 π electrons, which complies with the aromaticity condition.

[†] From here on, Mulliken charges are considered.

Figure 4. Stable structures and geometric characteristics of fenestranes **11**, **12** and **15** determined by B3LYP/6-311 + G** calculations.

3. Carbon atom in a small ring

One conclusion drawn by Schleyer and coworkers²⁷ on the basis of extensive calculations states that stabilisation of a planar tetracoordinate carbon atom could be attained by incorporating it into a small ring. This was explained by the fact that the angular strain in three- and four-membered rings (the HCH angle in planar structure **1** is 90°) would be lower than in the case of the tetrahedral configuration (the HCH angle is 109.5°). This conclusion is also supported by the fact²⁶ that the HCH angle in molecule **2** (C_{2v} symmetry) is close to the bond angles in small rings. The role of this factor shows itself, for example, in comparison of the relative stabilities of the acyclic dilithiomethane and 1,1-dilithiocyclopropane. In the latter case, structure **4** with a planar carbon atom is more stable, whereas for the former case, the tetrahedral configuration is 2.5 kcal mol⁻¹ energy preferred (B3LYP/6-311 + G** calculation).²¹

4. Planar tetracoordinate carbon atoms in organoboron cages. The stabilising role of ligand–ligand interactions

This approach to stabilisation of structures with a planar tetracoordinate carbon atom is focused on the combined realisation of the electronic and steric effects considered above. Even early *ab initio* calculations by the Hartree–Fock procedure³⁵ showed that incorporation of a tetracoordinate carbon atom into a three-membered 1,2-diboracyclopropane ring creates favourable conditions for ring flattening: the boron atoms have vacant p_z orbitals involved in the delocalisation of the lone electron pair of carbon and, hence, they exhibit σ -donor properties. However, allowance for electron correlation in terms of the MP2/6-31G* (see Refs 36, 37) or B3LYP/6-311 + G* (see Ref. 21) approximations showed that neither structure **16**

nor planar 2,3-diborapentane **17c**, incorporating a diboracyclopropane ring, is a true minimum on the PES. According to the most precise MP2(full)/6-311 + G** calculations,³⁸ compound **17c** is a transition state of an almost barrier-free (the activation energy $\Delta E = 0.23$ kcal mol⁻¹) enantiotopomerisation of the tetrahedral conformation.

Figure 5. Geometric characteristics, relative energies (ΔE , kcal mol⁻¹), and λ values for boron-containing heterocyclic compounds **18a-c**, **19a,b** and **20** determined by MP2(full)/6-31G** and MP2(full)/6-311++G** calculations (the values in parentheses).³⁸

On passing to 2,3-diboraspicyclopentene, the energy levels of the tetrahedral (**18b**) and planar (**18a**) structures (Fig. 5) are reversed. In the planar structure **18a**, each three-membered ring contains two π electrons, *i.e.*, possesses a certain degree of aromaticity; this provides additional stabilisation to this structure. It can be seen from Fig. 6 that two bonding π MOs of structure **18a** fully correspond to the bonding π MO of the cyclopropenium ion. As a consequence, structure **18a** is indeed a true minimum on the PES. According to MP2(full)/6-311++G**+ZPE calculations, the structure with the planar carbon atom is 58.2 kcal mol⁻¹ energetically more favourable than structure **18b** with the tetrahedral spiro carbon atom. The latter corresponds to the top of a hill in the PES ($\lambda = 3$).

Figure 5 presents the data on the geometry of structures **18a** and **18b** and the type of PES stationary points corresponding to these structures. The same Figure also shows data for the isomeric stable species **19a** and **19b**, containing a planar tetracoordinate carbon atom. The structure **19a** is only 3.9 kcal mol⁻¹ energetically less favourable than the singlet carbene structure **20**, corresponding to the global minimum in the PES of $C_3B_2H_4$.

The stabilisation of the planar carbon centre in compounds **18a** and **19a,b** is due to a combination of all factors including the σ -donor and π -acceptor effects of the neighbouring boron atoms, the incorporation of this carbon in the small ring, and the presence

Figure 6. Shapes of the π -molecular orbitals of planar structures **18a** and **19a**.³⁸

of the stable π -conjugated system. The last-mentioned factor is nothing but creation of the conditions for stabilising ligand–ligand interactions, which are weaker or totally missing in the structures with tetrahedral carbon atoms. The enhancement of

this interaction following an extension of the π -system of the ligand environment provides additional stabilisation to structures with a planar carbon atom, for example, in compounds **21**–**23**.³⁸

5. The Jahn–Teller instability of tetrahedral structures

The ligand–ligand bonding interactions play an especially important role in the pentaatomic structures CX_2Y_2 , CX_3Y^{n-} and CX_4^{n-} ($X = Al, Ga; Y = Si, Ge; n = 0, 1$) which incorporate a planar tetracoordinate carbon atom.^{39–42} For example, the planar Al_4 cage in CAI_4^- behaves as an aromatic 2π -electron system.⁴³ According to calculations,⁴³ the stability of the planar structures for these compounds is directly related to the formation of bonding four-centre σ - and π -type orbitals in the ligand. In addition, the higher stability of the planar structures with respect to the tetrahedral isomers can be attributed to the fact that the 17- or 18-electron valence shells in the tetrahedral compounds CX_4 ($1a_1^2 1t_2^6 2a_1^2 2t_2^6 1e^1$ and $1a_1^2 1t_2^6 2a_1^2 2t_2^6 1e^2$) correspond to degenerate electronic states and, hence, they are subject to Jahn–Teller deformations.⁴⁰ Meanwhile, 16-electron compounds with the closed $1a_1^2 1t_2^6 2a_1^2 2t_2^6$ electron shell, for example, CAI_4 , retain the tetrahedral structure. It can be seen from the data shown in Fig. 7 that the structures of the CSi_2Ga_2 (**24c**) and CGe_2Al_2 (**25c**) 18-electron compounds with tetrahedral carbon atoms are energetically less favourable than the planar *cis*- (**24a** and **25a**) and *trans*-isomers (**24b** and **25b**). They do not correspond to local minima on the PES, being transition states. It is of interest that in the case of CSi_2Al_2 (**26a**), the four-membered ring formed by the

ligands is not sufficiently large for the carbon atom to occupy its centre. As a consequence, the carbon atom is expelled from the ring plane to form a somewhat more stable pyramidal form **26c**. However, the energy gap and the vibration frequency with a negative force constant are so small that the fluctuating structure CSi_2Al_2 should be considered as having C_{2v} effective symmetry.

The photoelectron spectra of the CAI_4^- , CAI_3Si^- and CAI_3Ge^- anions generated by laser vaporisation of the corresponding carbide clusters and detected using time-of-flight photoelectron spectroscopy^{40–42} are consistent with a planar structure of these anions. Theoretical and experimental facts supporting the planar structure for the 17-electron $SiAl_4^-$ and $GeAl_4^-$ anions were obtained in a similar way. Planar and nearly planar C_s forms were found for the 16-electron species, $SiAl_4$ and $GeAl_4$.⁴⁴ The simple planar clusters such as **24**–**26** represent, in principle, new types of structural patterns that can exist in solid-state compounds with properties useful for high-technology materials.^{43–45}

6. Flattening of the tetrahedral configuration of the carbon atom in sterically strained saturated systems

The strategy for steric stabilisation of the planar angular deformation of bonds at a tetrahedral carbon atom by placing the atom at the centre of a saturated polycyclic system is similar to that considered above in Section 1.2. Numerous theoretical and experimental studies have been devoted to the development of this approach (see the reviews^{17–20, 46} and references therein). Particular attention was drawn to $[m.n.p.q]$ fenestranes **27** and, subsequently, to bowlanes **28**. The most important result of these studies, as in the case of compounds of the type **11** and **12**, was the conclusion that complete flattening of the tetrahedral structure cannot be attained.

Both semiempirical (MINDO/3^{12, 47} and MNDO⁴⁸) and *ab initio*^{49, 50} calculations showed that the [4.4.4.4]fenestrane molecule (**29**), which is the best candidate to form a planar structure, exists preferentially as a flattened tetrahedral D_{2d} form (**29a** and **29b**). Contrary to suggestions,⁵¹ the isomeric pyramidal C_{4v} conformation proved to be energetically less favourable [by 28.5

Figure 7. Geometric parameters, relative energies ($\Delta E/\text{kcal mol}^{-1}$) and λ values for the CGa_2Si_2 (**24a**–**c**), CAI_2Ge_2 (**25a**–**c**) and CSi_2Al_2 (**26a**–**c**) clusters calculated by the MP2(fc)/6-31G** (for CGa_2Si_2 and CAI_2Ge_2) and MP2(full)/6-311 + G** (for CSi_2Al_2) techniques.⁴⁰

or 48.3 kcal mol⁻¹ according to MINDO/3⁴⁷ and MP2(fc)/4-31G⁵⁰ calculations, respectively]. Interconversion of the *D*_{2d} and *C*_{4v} forms proceeds *via* a transition state with *C*_{2v} symmetry, which is 17 kcal mol⁻¹ higher in energy than the *C*_{4v} form. The planar *D*_{4h} form **29** is unstable; it corresponds to the top of a hill on the PES. The pattern of conformational transitions given below reflects the general topology of the PES of [4.4.4]fenestrane.⁴⁷

Analogous structural transformations take place in the case of bowlane **28**. According to RHF/6-31G* calculations,⁵² the energy minimum corresponds to the flattened tetrahedral structure **28a**, while the structure **28b** with a pyramidalised quaternary carbon atom is a transition state in the interconversion of the mirror topomers **28a**.

7. Planar tetracoordinate carbon atom inside a rigid three-dimensional cage of bonds

A successful (in theory) route of development of the steric (mechanic) strategy for planarisation of bonds around a tetracoordinate carbon atom has been provided by computational design of alkaplans and spiroalkaplans. These polycyclic structures can be constructed from planar neopentane and spiro-pentane units by incorporating peripheral carbon atoms into rigidly connected cycloalkane fragments.^{53–56} Complete flattening of bonds around the central carbon atom is not attained in alkaplans; according to RHF/6-31G* calculations, the C–C–C angles in the hexaplane **30** and octaplane **31** molecules are 168.6° and 168.8°,^{53,54} In the case of spirooctaplane **32**, the deviation from the ideally planar configuration is only 3.1°. The complete planarisation of bonds around the central carbon is found in dimethanospiro[2.2]octaplane **33**; note that this result has been obtained by a rather high-level calculation (MP2/6-311+G**).⁵⁵ The higher occupied MO of each of the compounds **30–33** is a *p*_z orbital localised on the planar carbon atom. This accounts for the exceptionally low ionisation potentials of these hydrocarbons (4.5–5.0 eV), which are comparable with the ionisation potentials of alkali metals.

An interesting route of development of the alkaplans design can be found in a study by Wang and Schleyer.⁵⁷ In this case, flattening of a tetracoordinate carbon atom was attained using not only steric (mechanical) factors but also electronic factors which are favourable for this type of deformation. The calculations (B3LYP/6-311+G**) carried out by the researchers cited showed that boraplane **34**, formed from octaplane **31** *via* replacement of four carbon atoms adjacent to the central atom by boron atoms, has *D*_{4h} symmetry and, hence, contains a planar carbon atom. A peculiar feature of structure **34** is the perpendicular orientation of two B–C bonds with respect to the bonds of the central carbon atom. Unlike octaplane **31**, in the case of boraplane **34**, the highest occupied MO is not localised at the central atom but is distributed over the perimeter of the borocarbon skeleton. This involvement

of the lone electron pair in multicentre bonding is responsible for the additional stabilisation of the planar form, realised in neither octaplane **31** nor the C(BH₂)₄ fragment simulating the structure of the boraplane mirror plane.

III. The mechanism of intramolecular inversion of the tetrahedral configuration of bonds at the carbon atom

The results of theoretical and experimental studies of molecules and ions in the ground electronic state considered in the previous Section attest to the possibility of stabilisation of a planar tetracoordinate carbon atom. This brings up the question — whether it is possible to stabilise the structures of transition states of these compounds in such a way as to decrease substantially the energy barrier to the inversion of tetrahedral forms and to identify the classes of organic and organoelement compounds stereochemically non-rigid with respect to this inversion.[‡]

Even early semiempirical and *ab initio* (RHF/DZ) calculations^{58,59} of the PES for enantiotomerisation of the methane molecule carried out assuming that the four C–H bonds remain equivalent along the whole reaction path showed that the square-planar structure **1** does not correspond to a first-order saddle point and does not represent a transition state of stereoisomerisation. When this constraint was eliminated,^{9,60} MINDO/3 calculations showed that inversion of the tetrahedral configuration of the methane molecule proceeds as an asymmetrical digonal twist deformation, the transition state being a *C*_s structure the geometry of which is quite similar to the geometry of the transition *C*_s structure **3g** and to other structures of this type determined using rigorous *ab initio* calculation techniques.^{24,61,62} The data presented in Table 1 show that the relative energy of the *C*_s transition state is approximately 25–30 kcal mol⁻¹ lower than the energy of the planar methane structure with *D*_{4h} symmetry. However, this structure is still unstable with respect to the CH₄ → CH₃⁺ + H⁺ decomposition, which requires 104 kcal mol⁻¹. This means that the non-dissociation route of methane inversion is impracticable under usual conditions.

Table 1. Inversion barriers of the methane molecule obtained in the most precise *ab initio* calculations.

The inversion of the tetrahedral structure is one of the most important structural types of polytopal rearrangements. The reaction trajectories corresponding to digonal twist

‡ Stereochemically non-rigid molecules have low barriers to an intramolecular rearrangement (too low to be detected on the NMR time scale); therefore, they undergo fast (on the NMR time scale) reversible rearrangements.

($T_d - D_2 - \bar{T}_d$) or tetrahedral compression ($T_d - D_{2d} - \bar{T}_d$) deformations are symmetry allowed.^{15, 63, 64} The latter mechanism is also referred to as edge inversion^{65, 66} (as opposed to vertex inversion, characteristic of the stereoisomerisation of tricoordinated pyramidal structures). Detailed investigations^{61, 62} of the reaction pathway of methane stereoisomerisation using the method of intrinsic reaction coordinate (*i.e.*, the trajectory obtained by moving down from the point on the PES corresponding to the transition state along the transition vector⁶⁷) showed that these trajectories are actually more intricate (Fig. 8). As follows from Fig. 8, the change in the geometry can be described by the digonal twist pattern only at early stages of inversion, while after the initial rotation of the plane of one CH_2 fragment relative to the other, the central atom undergoes pyramidalisation, which is not taken into account in the above schemes.

Figure 8. Geometry evolution of the methane molecule along the energy profile of the tetrahedral configuration $T_d - C_s - \bar{T}_d$ according to *ab initio* calculations.^{25, 62}

It would be of interest to find out how the decrease in symmetry caused by partial replacement of the hydrogen atoms in the methane molecule by other atoms or groups would influence the type of reaction trajectory in the inversion process. Such calculations based on the intrinsic reaction coordinate technique have so far been performed only for the difluoromethane molecule (the Hartree–Fock method in a small STO-3G basis set).⁶⁸ Two transition states (planar *cis*- and *trans*-structures) were identified; they correspond to the reaction pathways typical of the digonal twist and tetrahedral compression mechanisms, respectively.

The question of what structural factors could stabilise the C_s form of the transition state of the inversion of type **3g** tetrahedral configuration has not been discussed in the literature. In principle, it is clear that a solution of this problem is the same as the solution of the problem of stabilisation of a planar tetracoordinate carbon atom. Thus in complex **35**, due to the presence of two electro-positive metal atoms at the carbon center, the barrier to inversion decreases to a level that can be determined by dynamic ^1H NMR from coalescence of the signals for the methylene group protons. According to EHMO calculations, stereoisomerisation of complex **35** proceeds *via* a non-dissociative mechanism and the transition state contains a planar tetracoordinate carbon atom.⁶⁹

The energy gap between the tetrahedral and planar structures formed by Main Group elements is known to narrow with a decrease in the electronegativity of the central atom.^{9, 70} On passing from carbon atom to isoelectronic Be^{2-} , B^- , Al^- , Si ,

$\text{M} = \text{Be, Zn, Cd, Hg; X} = \text{O, S, Se;}$ $\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk, Ar, Hal, NO}_2$.
 $\text{R}^1, \text{R}^2 = \text{Alk, Ar, Hal, NO}_2$.

and Ge atoms and to d^{10} atoms (Zn, Cd, Hg), the ordering in energy of the frontier orbitals is reversed; as a consequence, stabilisation of the planar configuration can be attained by introducing electronegative substituents containing lone electron pairs. There are quite a few examples of stereochemically non-rigid compounds of this type, in particular, one can mention bis(ethanolamino)germanium derivative **36** (see Ref. 71) and the extensive group of bis-chelate complexes **37** (see Refs 72, 73). It should be noted, however, that in the general case, the non-dissociative intramolecular inversion of configuration is not the only mechanism responsible for the exchange processes observed by NMR.^{72–74} Among compounds **35–37**, quite reliable proof for the non-dissociative mechanism of inversion has been obtained only for complexes **37** with d^{10} metals,^{72, 75} whereas for complexes **35** and **36**, a mechanism involving cleavage–recombination of one bond at the central atom also cannot be ruled out. This mechanism is realised for beryllium complexes **37** and 1,3,2-oxazaboroles **38**.^{72, 76, 77}

IV. Structures with a pyramidal configuration of bonds at a tetracoordinate carbon atom

Analysis of the stereochemical configurations and chirality of compounds containing tetracoordinate atoms, in particular, tetracoordinate carbon atoms, is based on consideration of topological characteristics of three possible simplexes (configurations whose symmetry ensures equivalence of all four bonds).⁷⁸ Apart from the tetrahedral T_d and planar D_{4h} structures, this condition is satisfied only by the square-pyramidal C_{4v} form. Early EHMO and *ab initio* (RHF/DZ)^{58, 59} calculations predicted that the C_{4v} structure **3e** of methane (see Fig 3) is energetically more favourable than the D_{4h} form; it is this structure that is formed as the transition state in the inversion of the tetrahedral configuration. This sets the task of stabilising a pyramidal tetracoordinate carbon atom in the molecules of organic compounds. High-level *ab initio* calculations carried out in recent years^{24, 25} fully confirmed the first conclusion: the total energy of the C_{4v} configuration of the methane molecule (calculated with allowance for the zero-point energy) is lower than the total energy of the C_s structure **3g**. However, it was found that the stationary point corresponding to the methane molecule with C_{4v} symmetry on the PES of methane is a third-order saddle-point, and, hence, this structure is not a transition state.

The search for routes for stabilisation of compounds containing tetracoordinate carbon atoms with a pyramidal configuration of bonds (below, pyramidal carbon) is mainly carried out in two ways: (1) electronic stabilisation and (2) steric stabilisation. The most important results obtained along the former route include the theoretical prediction of stability of the parent compound of

this class, namely, tetracyclo[2.1.0.0.1³0^{2,5}]pentane (**39**), which was called pyramidane, interpretation of the nature of the stability of structure **39** and a description of the possible methods for pyramidane synthesis.^{59, 79, 80}

The fact that structure **39** is a rather deep minimum on the PES of C_5H_4 was first established in a theoretical (EHMO, MINDO/3, HF/4-31G) study^{12, 59} of isomerisation routes of spiropentadiene **40**, the simplest spiroalkene, which was successfully synthesised only relatively recently.^{81, 82}

It can be seen from Fig. 9 that deformation of structure **40** with variation of the angle coordinates α and β gives rise to four topomers (degenerate isomers) of pyramidane **39**, having lower energies. However, structures **39** and **40** are separated from each other by a high energy barrier, which prevents the exothermic rearrangement **40** $\rightarrow$ **39**. This is the reason for the kinetic stability of spiropentadiene and the possibility of its synthesis. The pyramidane structure does not correspond to the global energy minimum in the PES of C_5H_4 ; however, as in the case of spiropentadiene, it is characterised by high kinetic stability with respect to the possible decomposition and rearrangement reactions.

Pyramidane **39** is computed to be the simplest organic system with a pyramidal carbon atom. As [3.3.3]fenestrane, this compound is the first member of the $[m.n.p.q]$ fenestrane **27** family. Therefore, it comes as no surprise that study of the structure and

Figure 9. Topography of the PES of C_5H_4 for structures **39** and **40** during deformation of the latter along the angular coordinates α and β .⁵⁹

properties of this compound was the object of a large number of studies,^{83–88} in which *ab initio* calculations were carried out at different approximation levels. The results of calculations of the total and relative energies of the pyramidane **39** molecule and its most stable isomers **40–43** and some other parameters of these molecules are summarised in Table 2.

Table 2. Total ($-E_{\text{tot}}$ /a.u.) and relative (ΔE /kcal mol⁻¹) energies of the pyramidane molecule **39** and its isomers **40–43** in the ground singlet electronic state, charges on the quaternary carbon atoms and dipole moments calculated by *ab initio* quantum-chemistry methods.

^a The C_{2v} structure **41a** is a transition state for the conformational isomerisation of **41** proceeding according to the pattern of wagging vibrations of the carbene centre with respect to the plane of the other four carbon atoms.^{85, 87, 88} ^b At this level of approximation, the C_s structure **42** has one imaginary frequency in the vibrational spectrum. ^c At this approximation level, the C_s structure **43** is a flattened region in the C_5H_4 PES (a first-order saddle point). The adjacent minimum corresponds to a C_2 cumulene form whose total energy is 0.6 kcal mol⁻¹ lower than the energy of the C_s structure.

It follows from the above data that the structure of pyramidine **39** is only 9 kcal mol⁻¹ energetically less favourable than the structure of its carbene isomer **43** which is most stable in the singlet electronic state. The singlet–triplet splitting calculated for structure **39** is rather large (46.8 kcal mol⁻¹) and the strain energy per C–C bond (19 kcal mol⁻¹) is lower than the strain energy in the tetrahedrane molecule (~25 kcal mol⁻¹).^{9, 84} However, it can be expected that pyramidine **39** has a relatively high kinetic stability. The lowest vibration frequencies calculated for the C_{4v} structure of pyramidine^{85, 88} are rather high: 453.6 and 478.9 cm⁻¹ (CCD/6-311 + G**). The PES of C_5H_4 contains no reaction valley to connect the two minima corresponding to isomers **39** and **43**.^{12, 85} The pyramidine structure is energetically more favourable than the structures of other classical carbenes, **41** and **42**. As shown by semiempirical^{79, 83} and *ab initio*^{85, 87, 88} calculations, both carbenes can serve as precursors of pyramidine and appropriate precursors can be found for each of these carbenes.^{89, 90} It has been reported⁸⁷ that the potential barrier to thermal isomerisation of bicyclo[2.1.0]pent-2-en-5-ylidene (**42**) into pyramidine **39** is equal to 16.3 kcal mol⁻¹, while a similar transformation of tricyclo[2.1.0.0^{2,5}]pent-3-ylidene (**41**) requires overcoming a potential barrier of only 3.5 kcal mol⁻¹. This implies that the generation of these precursors would be accompanied by immediate isomerisation in pyramidine. Simultaneously, structure **39** is separated from more stable isomers, for example 3-ethynylcyclopropene, by relatively high barriers corresponding to a half-life of more than 4–5 h at room temperature. Thus, synthesis of pyramidine should be possible.

The nature of the stability of the pyramidine molecule and features of its geometric structure (Fig. 10) are adequately interpreted using the scheme of orbital interactions (Fig. 11) between the fragments forming this molecule — the basal cyclobutadiene fragment and the apical carbon atom (structure **39a**). Stabilisation is mainly due to the formation of the bonding $1e$ MO of the pyramidine molecule upon overlap of the $p_{x,y}$ AO of the apical carbon atom with the degenerate e_g MO of the cyclobutadiene fragment. The sp_z AO pair of the carbon atom and the cyclobutadiene a_{2u} MO form a bonding ($1a_1$), a nonbonding ($2a_1$), and a high-lying antibonding MO of molecule **39**; only the first two of these orbitals are occupied with electrons.

This type of electronic structure is typical of all the pyramidal molecules formed by a π -conjugated cyclic fragment and an apical atom or group. Pyramidal structures of this type have only four bonding (or three bonding and one nonbonding) MOs, which can be populated by π -electrons of the basal fragment and by all valence electrons of the apical atom (or group). The eight-electron

Figure 10. Geometric characteristics of the pyramidine molecule (**39**) calculated by the B3LYP/6-311 + G** (DFT), MP2(full)/6-311 + G** (MP2) and CCD(full)/6-311 + G** (CCD) techniques.⁸⁸

rule determining the stability of pyramidal structures follows from the foregoing.^{9, 11, 12} This rule, attributed to three-dimensional aromaticity conditions,^{92, 93} holds for both heteroatomic systems and transition metal π -complexes (provided that isolobality relations are taken into account).⁷ Numerous examples of pyramidal structures can be found in reviews^{9, 12, 94–97} and recent works.^{25, 98}

The stability of non-classical pyramidal structure **39** is completely dictated by electronic factors. The efficiency of steric (mechanical) stabilisation of organic compounds with a tetra-coordinate pyramidal carbon atom was demonstrated by Rasmussen and Radom.⁸⁶ As in alkaplans and spiroalkaplans (see Section II.7), in compounds with a pyramidal carbon atom, the rigid cage of bonds is based on neopentane and spironeopentane structures with an additional cycloalkane fragment attached. The B3LYP/6-31G* and MP2(fc)/6-31G* calculations showed that the stable hemialkplane (**44**, **45**) and hemispiroalkplane (**46–48**) hydrocarbon structures obtained in this way contain a pyramidal quaternary carbon atom. The degree of pyramidalisation of bonds at the carbon atom in hemialkplanes is low but in spirohemialkplanes, this value approaches that in pyramidine **39** and the calculated lengths of the C–C bonds involving the apical carbon atom (1.632–1.650 Å) are similar to the corresponding bond lengths in pyramidine.

The strain energies of structures **44**–**48** are comparable with the strain energies of well-studied strained structures such as cubane and prismane. Thus, there are reasons for assuming that these compounds could be synthesised. Relying on an efficient method for the preparation of bridged spirooctaplanes,^{99–101} Rasmussen and Radom⁸⁶ proposed the following method for the synthesis of hemispirooctaplane **46** from the available hydrocarbon **49**.

It follows from the data of Table 2 that the apical carbon atom in structure **39** bears a considerable negative charge, while the highest occupied MO is localised almost entirely on this atom and can actually be regarded to be a lone electron pair orbital (see Fig. 10). Similar results have also been obtained for hydrocarbons **44**–**48**. This fact is responsible for fairly low (4.5–5.0 eV) ionisation energies calculated for pyramidal, hemialkyl, and hemispiroalkyl, commensurate in magnitude with the ionisation potentials of light alkali metals, as well as the exceptionally high basicity of these compounds. The proton affinities of compounds with a pyramidal tetracoordinate carbon atom calculated using various methods (they are given in Table 3) are record-breaking values for organic compounds including superbases such as proton sponges.

Formerly, it has been considered that $[m.n.p.q]$ paddlanes **50**, like $[m.n.p.q]$ fenestranes **27**, can also contain pyramidal carbon atoms in the molecule.^{51, 104}

However, all paddlanes known to date contain at least one large ring ($m > 8$), which leads to flattening of the tetrahedral configuration of the quaternary carbon atoms. The structures of lower [1.1.1.1]- and [2.2.2.2]paddlanes (structure **51**) do not

correspond to minima in the PES;^{48, 52, 105} according to the results of MINDO/3 and MNDO semiempirical calculations,⁴⁸ structure **51** relaxes towards unusual structure **51a** in which the distance between two planar carbon atoms is only 1.56 Å.

Essentially pyramidalised tetracoordinate carbon atoms are found in yet another group of sterically strained compounds, tricyclo[$n.1.0.0^{1,3}$]alkanes.^{99–101, 106–109} The first member of this series of bridged spirooctaplanes, compound **52**, has a sufficient lifetime along the pyramidal-to-spiropentane rearrangement pathway to be detected at -55°C .^{107, 110} Tricyclo[2.1.0.0^{1,3}]alkane (**53**) is still unknown but the next members of this series — compounds **54**, **55** and some of their derivatives — have been prepared and isolated.^{99–101}

Table 4 summarises the data characterising the spatial structures and strain energies of molecules **52**–**55**. As the ring size increases, *i.e.*, on passing from compound **52** to compound **55**, the $\text{CH}_2\text{—C—CH}_2$ angle rapidly decreases, together with the strain energy of the molecule. For compound **55**, the strain energy almost does not differ from that of spiropentane (63 kcal mol^{−1}).

^a The folding angle is $180^\circ - \angle ACE$; ^b the twisting angle is $90^\circ - \gamma$ (γ is the dihedral angle between the ABC and CDE planes).

V. Tetracoordinate carbon atom with a bisphenoidal configuration of bonds and inverted tetracoordinate carbon atom

The size of the $\text{CH}_2\text{—C—CH}_2$ angle in tricyclo[2.1.0.0^{1,3}]alkane **53** approaches 180° , and the bond configuration at a quaternary carbon atom is fairly close to that found in bisphenoid **56** ('butterfly' conformation). It has been proposed to call tetracoordinate carbon centres of this type 'half planar'.⁶⁴ In terms of the topological definition,⁹ according to which structures with tetracoordinate carbon atoms are divided into classical and non-classical (anti-van't Hoff–LeBel) ones, depending on the arrangement of the four bonds around carbon — either in both or in only one hemisphere, respectively, — structures of type **56** should be considered non-classical. For compounds containing tetracoordi-

nate carbon atoms, the only other non-classical topological form is represented by structure **57** with an inverted configuration of bonds at the carbon atom.

The half planar tetracoordinate carbon atom occurs in the structures of carbide clusters **58**^{111–113} and in zirconium complex **59**.¹¹⁴

X = H⁺, CO.

The electronic factors promoting stabilisation of the half planar carbon atom in these structures are similar to those effective in structures with planar or pyramidal centres (Fig. 12). In this case, as in the case of planar (D_{4h}) or pyramidal (C_{4v}) structures, the highest occupied MO of the methane molecule having C_{2v} symmetry is formed by the $2a_1$ AO of the lone electron pair of carbon (this AO is delocalised to a very low extent over equatorial C–H bonds). The electrons of this orbital are not involved in bonding, which results in weakening of the σ bonds formed by a half planar carbon atom. Therefore, σ -donor (for example, BHAr[–] groups in compound **59**) and π -acceptor groups are expected to stabilise the tetracoordinate half planar carbon atom. These views have been confirmed by calculations⁶⁴ for model compounds **60**. The results of these calculations are given in Table 5.

Figure 12. Walsh diagram illustrating the transformation of the t_{2u} orbitals of tetrahedral methane (see Fig. 2) during its deformation into the structure with a half planar carbon atom.⁶⁴

Table 5. Deformation energies (eV) of tetrahedral structures (the α and β angles correspond to structures with the minimum energy) and charges on the carbon atom in compounds **60** determined by EHMO calculations.⁶⁴

X	α^a /deg	β^a /deg	ΔE^b /eV	$\Delta E'^c$ /eV	q_C
H	109.5	109.5	3.06	0.98	–0.44
Me	117	105	3.76	1.15	–0.39
OH	112	117	6.46	2.65	+0.82
CN	114	107	2.70	0.93	–0.01
BH ₃ [–]	120	102	2.06	0.54	–0.96

^a The α and β values are given for the tetrahedral configuration corresponding to the global minimum in the PES of disubstituted methane **60**.

^b The deformation energy of the tetrahedral structure into a structure with a half planar carbon atom ($\alpha = 180^\circ$, $\beta = 140^\circ$). ^c The deformation energy of the tetrahedral structure into a structure with a carbon atom geometry identical to that in complex **59** ($\alpha = 180^\circ$, $\beta = 140^\circ$).

In derivative **60** with σ -donor substituents (X = BH₃[–]) in the axial positions, the energy gap between the tetrahedral and bisphenoidal conformations decreases by 1.0 eV, mainly, due to substantial charge transfer to the central carbon atom (*cf.* the charges q_C on half planar carbon atoms).

It should be noted that the conformation **56** is destabilised by the strong effect of the π -donor and σ -acceptor hydroxy group, pulling the electron density off the half planar carbon. As a result, the carbon atom acquires a positive charge. Stabilisation of configuration **56** in complex **59** and the rare earth metal complexes (Me₃SiCH₂)Y[(μ -CH₂)₂SiMe₂][(μ -OBu^t)Li(THF)₂]₂ (see Ref. 115) and (Me₃SiCH₂)Sm[(μ -OPh)(μ -CH₂SiMe₃)Li(THF)][(μ -OPh)₂.Li(THF)] (see Ref. 116) is also promoted by the additional coordination of a half planar carbon atom to a metallic centre formed due to electron donation from the carbon $2a_1$ AO to the metal AO.

An inverted (umbrella) configuration of bonds at the carbon atom (structure **57**) can be found in the molecules of some bicyclobutane derivatives, for example, in structures **61**¹¹⁷ and **62**,¹¹⁸ and undoubtedly, in the molecule of highly strained [1.1.1]propellane (**63**), which was synthesised by Wiberg and Walker¹¹⁹ in 1982.

The structures, methods of synthesis and the chemistry of [1.1.1]propellane and its derivatives and higher homologues have been considered in numerous reviews^{120–122} and theoretical studies.^{85, 123–126} As noted by Wiberg,¹²² [1.1.1]propellane appears to be the first multiatomic molecule whose stability, structure, vibrational and photoelectron spectra, and the enthalpy of formation were predicted before its synthesis and all the theoretical predictions were successfully confirmed by subsequent experimental research. Theoretical investigations of compound **63** were mainly focused on elucidating the nature of the central C–C bond and the possibility of its dissociation to give the isomeric biradical **63a**. The results of *ab initio* calculations^{122, 125, 126} convincingly confirm the conclusion, drawn on the basis of orbital interaction analysis,¹²³ stating that the non-dissociated form **63** is preferred. According to HF/6-31G* calculations, the energy benefit is equal to 65 kcal mol^{–1}. The energy gap between structures **63** and **63a**, interrelated by ‘bond-stretch isomer-

ism',^{127, 128} is rather narrow (the difference between the heats of formation of these compounds is only ~ 5 kcal mol⁻¹). The situation is reversed on passing to [2.2.2]propellatriene (**64**). Although the structure **64** with an inverted carbon atom is an energy minimum, the singlet biradical **64a** is energetically more favourable (by 5.1 kcal mol⁻¹), as shown by CASSCF/6-31G* calculations.¹²⁹

The inverted configuration of carbon atoms has been predicted by MP2/6-31G** and B3LYP/6-31G** calculations (see Ref. 130) for a series of polycyclic structures with a bicyclooctane skeleton.

VI. Carbonium ions with penta-, hexa- and heptacoordinate carbon atoms

The preceding Sections of the review were devoted to unusual (*i.e.*, other than tetrahedral) types of carbon coordination. In this and subsequent Sections, we consider compounds of hypercoordinate carbon in which a carbon atom is linked by covalent bonds to five and more atoms. Since a carbon atom has only four valence electrons, it can form only four two-electron (classical) bonds; hence hypercoordination of carbon implies delocalisation of σ -electrons.¹³¹ This effect does not fit into the scope of classical octet theory.^{3, 132} It is noteworthy that the notion of non-classical structure was first introduced to describe the structures of hyper-coordinate carbon.^{131, 133}

1. Methonium ion

The methonium ion is the parent compound for pentacoordinate carbon derivatives. Protonated methane (**65**) was first detected in the gas phase by mass spectroscopy by Talrose and Lubimova^{134, 135} and in superacid liquid media by Olah and co-workers.^{136–138} The methonium ion is important for astrophysics, as its microwave spectrum serves as an indicator of methane content in molecular galactic clouds. The methonium ion is the prototype of intermediate structures formed upon ion–molecular interactions¹³⁹ and, what is more important, in the reactions of saturated hydrocarbons with electrophiles;^{3, 140–143} therefore, it comes as no surprise that the study of its structure and properties has received particular attention from theoreticians. The results of calculations (up to the MP4SDQ/6-311G**//MP2/6-31G* level) carried out before 1984 are summarised in a monograph.¹⁴⁴

The possible structures of the CH₅⁺ cation are described by conformations **65a–e**. The global minimum in the PES of CH₅⁺ corresponds to structure **65a** with C_s symmetry, which can be regarded as a complex of the CH₃⁺ (C_{3v}) cation with an H₂ molecule. The stability of this complex is ensured by the formation of the 3c–2e bond (according to theoretical and experimental data, the energy of dissociation into fragments is 42–44 kcal mol⁻¹). This conclusion was confirmed by recent calculations at the most advanced (of those attainable to date) theoretical level.^{145–149}

Structure **65b** (C_s) corresponds to a first-order saddle point in the PES and serves as the transition state for rotation of the H₂ fragment; the potential barrier to this process found using various calculation methods is exceptionally low (less than 0.1 kcal mol⁻¹). Structure **65c** (C_{2v}) is also a transition state but of another process, namely, the exchange by hydrogen atoms between the CH₃ and H₂ fragments. A number of experimental studies have been devoted to isotope exchange reactions of this type proceeding at high rates.^{3, 137, 140} The energy of structure **65c** is only 0.9 kcal mol⁻¹ higher than the energy level of structure **65a**; with allowance for the zero-point vibrations, structures **65a–c** are nearly equivalent in energy. This means that proton 'exchange' in the methonium ion is almost barrier-free even at 0 K. Thus it has been hypothesised that the CH₅⁺ cation does not have any definite structure at all. It was proposed that the methonium cation should be considered as an intramolecular liquid and its structure described by statistical functions rather than atomic coordinates (see the publication¹⁵⁰ concerning the structure of the methonium cation entitled 'Cheshire cat smiles'). Powerful experimental proof pointing to an extremely high degree of stereochemical non-rigidity (fluxionality) of methonium cation was obtained when a high-resolution IR spectrum of this cation was finally recorded (after many years of unfruitful efforts) in a matrix of a small number ($n = 1–6$) of hydrogen molecules whose presence is needed for retarding the exchange processes. This spectrum proved to be much more complicated than would be expected for a structure having any definite type of symmetry. Indeed, in the 2770–3150 cm⁻¹ range alone, ~ 900 spectral lines were found.

The question of whether the methonium cation with its unusual fluxional behaviour can be described by a particular molecular structure is still debatable.^{148, 150–152} However, such a question does not arise for its derivatives. There exist a fairly broad spectrum of compounds in which structures like **65a,c**,^{3, 138, 139, 149} or **65b** are realised. The latter is found, in particular, in the structures of σ -complexes formed by metal ions (from Sc⁺ to Cu⁺) with the methane molecule. The structure and stereodynamics of these complexes have been studied theoretically (using density functional theory techniques) in relation to simulation of the problem of decreasing the barrier to the stereomutation of the methane molecule.⁶² It was shown that, when this transformation is catalysed by metal ions, the potential barrier to enantiotopomerisation decreases to 43–50 kcal mol⁻¹. In addition to the stationary points corresponding to structures **65a–c**, the PES of CH₅⁺ was found to contain higher-order stationary points corresponding to highly symmetrical forms **65d,e**.

Stabilisation of such bond configurations at a pentacoordinate carbon atom can be achieved only in more complicated structures.

2. The pyramidal cation (CH)₅⁺

The (CH)₅⁺ cation (**66**) is a classical example of a structure with a square-pyramidal configuration of bonds about a pentacoordinate carbon atom.^{153–155}

Almost simultaneously, Masamune *et al.*¹⁵⁷ synthesised the first derivative of the pyramidal $(\text{CH}_5)^+$ cation, compound **67**, its bishomo-derivatives and other analogues (**68–73**).^{158–160}

The pyramidal cation **66** has an unusual electronic structure: its electron density is concentrated on the apical carbon atom. Thus according to CCD/6-311+G** calculations, the negative charge on this carbon equals -0.18 and the whole positive charge

Figure 13. Geometric characteristics of the pyramidane molecule **39** and the $(\text{CH})_5^+$ (**66**) cation determined by the B3LYP/6-311 + G** (DFT), MP2(full)/6-311 + G** (MP2) and CCD(full)/6-311 + G** (CCD) calculations.⁸⁸

The synthesis of the 1,3,5-trimethyl derivative **76** from 1,5-dimethyl-3-methylenetricyclo[2.1.0.0^{2,5}]pentane (**77**) serves as a good illustration for the mechanism of transformation of the tricyclo[2.1.0.0^{2,5}]pentane skeleton in the pyramidal structure precursors **78**.¹⁶¹ It was found that the CD₂H group formed upon protonation of the deuterated compound **77** occupies only the basal position in cation **76**, *i.e.*, during the transformation of compound **77** into cation **76**, the deuterium label is not transferred from the basal carbon to the apical one. Thus, the formation of cation **76** does not proceed along the C_{2v}-symmetry pathway but follows the C_s pathway, allowed by the principle of orbital symmetry conservation.⁴ The chemical shifts ($\delta^{13}\text{C}$) of the apical quaternary carbon atom and the methyl-group carbon atom attached to it in compound **76** are about -20.89 and -3.20 ppm, respectively.

The eight-electron rule, like more general electron count rules for polyhedral structures,^{92, 162, 163} explains adequately the kinetic stability of the $(\text{CH})_5^+$ cation and its derivatives. The only difference in the orbital interaction diagram of cation **66** from the orbital interaction diagram of the pyramidane molecule presented in Fig. 11 is the fact that the nonbonding $2a_1$ MO localised on the

apical carbon atom in pyramidane **39** is transformed into the orbital of the C–H σ -bond in cation **66**.⁹

The square-pyramidal structure **66** is not the most stable form of $(\text{CH})_5^+$. According to the data of *ab initio* calculations^{164–166} (Table 6), the global minimum in the PES of $(\text{CH})_5^+$ is the vinylcyclopropenyl cation (**79**), which is only 2–3 kcal mol^{–1} more favourable than the D_{5h} structure of the cyclopentadienyl cation (**80**) in the triplet electronic state.

However, the rearrangements **66** → **79** and **66** → **80** do not take place, the former — due to the absence of a reaction valley connecting the cations **66** and **79** in the PES of the singlet electronic state of $(\text{CH})_5^+$ and the latter rearrangement is spin forbidden. Therefore, it is important to know to what extent the pyramidal structure **66** is energetically less favorable than the other possible structures of the $(\text{CH})_5^+$ cation which are stationary points in the PES of the singlet electronic state.

Early MINDO/3 semiempirical calculations^{167–169} provided the conclusion that the nonplanar C_s structure of the cyclopentadienyl cation **81** is preferred from the energy standpoint. However, more recent *ab initio* calculations^{88, 164, 165} showed that the C_s structure (**81**) does not correspond to a minimum on the PES and relaxes to the planar C_{2v} form (**82**), which is only 3–4 kcal mol^{–1} energetically more favourable than the pyramidal structure **66** and is separated from it by a rather high potential barrier. In the case of the cyclopentadienyl cation, one more C_{2v}

form (**83**) is possible; it is almost equivalent in energy to the C_{2v} structure **82**. According to the most advanced calculations,^{88, 165} structure **82** is a local minimum on the PES, while structure **83** is a first-order saddle point. Structure **83** corresponds to the transition state between the degenerate isomers (topomers) of structure **82**. The potential barrier to interconversion of the topomers of the singlet cyclopentadienyl cation **82** is only 0.1–0.2 kcal mol^{–1}, i.e., the reaction proceeds almost without a barrier (*cf.* the topomerisation of CH_5^+).^{88, 165} The most important results of calculations^{88, 92, 164–166} are summarised in Table 6.

The C_{4v} configuration of bonds at the pentacoordinate carbon atom can be realised in electrically neutral structures formed upon replacement of the CH^+ group by the isolobal BH group. This can give rise to a series of stable square-pyramidal *nido*-carboranes whose electronic structure would satisfy the eight-electron rule. Carboranes **84b,c**, which are isomers of borole **84a**, shown in Fig. 14 are examples of such structures. As shown by calculations,⁹⁸ structure **84c** containing a pentacoordinate pyramidal

^a The values in parentheses are the energies of the relatively most stable cyclic D_{5h} structure **80** of the cyclopentadienyl cation in the triplet state.

^b Calculation by the G2 method [approximately equivalent to QCISD(T)/6-311+G(3df,2dp) in the approximation level with allowance for the zero-point vibration energies] gives the values $-E_{\text{tot}} = 192.68503$ a.u. and $\Delta E = 13.1$ kcal mol^{–1} for structure **66** (relative to the energy of **80**) (see Ref. 166). ^c First-order saddle point (transition state).

Figure 14. Geometric characteristics and relative energies of the structures of borole (**84a**), its non-classical pyramidal isomers **84b** and **84c**, and 1,6- (**85a**) and 1,2-*closo*-carboranes $\text{C}_2\text{B}_4\text{H}_6$ (**85b**) calculated using the MP2(full)/6-311+G** and B3LYP/6-311+G** methods.^{98, 172} (Experimental data for *closo*-carboranes $\text{C}_2\text{B}_4\text{H}_6$ were taken from Ref. 172.)

carbon atom, being thermodynamically less stable than structures **84a,b**, is likely, nevertheless, to have rather high kinetic stability. A similar configuration is found for the carbon atoms in square-bipyramidal *closo*-carboranes whose structures have been studied in detail both experimentally³ and theoretically.^{170–172}

The stability of the bipyramidal systems produced by adding apical groups to a π -conjugated ring is controlled by the ten-electron rule.⁹ Irrespective of the size of the central ring, these structures have only five bonding MO, and the total number of electrons (the number of ring π -electrons + the number of valence electrons in the apical group) in a stable bipyramidal molecule or ion should not exceed 10. The simplest hydrocarbon system which meets this condition is the octahedral $C_6H_6^{4+}$ ion. However, this compound is unstable for electrostatic reasons. The replacement of four CH^+ groups by BH groups results in two stable electrically neutral bipyramidal 1,6- (**85a**) and 1,2-carboranes (**85b**), which contain pyramidal pentacoordinate carbon centres (see Fig. 14).

3. Trigonal-bipyramidal configuration of bonds at a pentacoordinate carbon atom

A trigonal-bipyramidal configuration of bonds is not realised in the methonium ion CH_3^+ , but can be stabilised by replacing the hydrogen atoms by electropositive atoms or groups. According to HF/4-31G calculations,¹⁷³ the D_{3h} conformation is preferred for disubstituted cations **86**. As shown by X-ray diffraction analysis, this configuration occurs in penta-aurated methonium ion **87**^{174,175} (the ligand AuL is isolobal to single-electron H and CH_3 groups).

M = Li, BeH.

The electronic structure of compounds with the D_{3h} configuration of bonds at the central atom, which is a Main Group element, can be represented by a combination of three equatorial $2c-2e$ bonds formed by the sp^2 orbitals of the central atom and one hypervalent $3c-2e$ bond of the central atom with two apical ligands. The greater the difference between the electronegativities of the atoms forming this bond, the lower its electron deficiency and the greater the contribution of the electrostatic component which stabilises the structure (for discussion of factors determining the structure of hypervalent compounds, see Refs 5, 176–182). Higher stability of such polarised structures is attained when ligands with like charges are separated in space, *i.e.*, placed in the apical positions of the D_{3h} structure.

By following this scheme, one can also propose another way of stabilising the trigonal-bipyramidal configuration of bonds at pentacoordinate carbon atoms in carbonium ions. In this case, a considerable difference between the electronegativities of the central atom and the apical ligands is attained by using atoms or groups with high electronegativity as the ligands. This type of stabilisation of trigonal-bipyramidal structures of transition states is peculiar to S_N2 reactions at tetrahedral carbon atoms involving compounds with highly nucleofugal (including positively charged) groups. Examples are¹⁸³ two model reactions, namely, degenerate gas-phase hydrolysis of protonated methanol [reaction (1)] and intramolecular rearrangement of hypothetical cation **88** [reaction (2)].

The results of MP2(full)/6-31G** and MP2(full)/6-311++G** calculations showed that putative intermediates **89** and **90** containing pentacoordinate carbon atoms with the trigonal-bipyramidal configuration of bonds, which are formed presumably in these reactions, are considerably stabilised: the differences between the energies of the intermediates and the initial structures amount to 12.8 and 3.8 kcal mol⁻¹. However, neither these nor other similar structures correspond to minima in the PES and, hence, they are not intermediates but are transition states. A similar result has been obtained in an attempt to 'freeze' (this term was proposed by Martin¹⁸⁴) the pentacoordinate structure of transition state **91** formed during the rearrangement of 1,8-bis(arylthio)anthracene-9-carbonium ion.¹⁸⁵ In this cation, the heteropentallene fragment is incorporated in a rigid cage, which fixes both the attacking and leaving groups in the orientation required by the S_N2 reaction conditions.^{10,186–188} The structure **91** corresponds to a transition state (rather than an intermediate) of a reaction with a low potential barrier whose height is 10–20 kcal mol⁻¹ (depending on the solvent and the substituents).

Stabilisation of a structure with a trigonal-bipyramidal configuration of bonds at the pentacoordinate carbon atom was achieved by Akiba *et al.*¹⁸⁹ They modified the dynamic system **91** by replacing the sulfur atoms by more electronegative oxygen atoms and thus ensured better conditions for collinearity of the axial bonds. They isolated and characterised the salt **92**, the cation of which contains a pentacoordinate carbon atom with a trigonal-bipyramidal configuration of bonds. The complete structural analogy between compound **92** and compounds with a pentacoordinate boron atom was confirmed by X-ray diffraction analysis of neutral pentacoordinate compounds of boron **93** (10-B-5) prepared recently by the same researchers.¹⁹⁰

X = O, S; R = H, OMe.

Thus, by varying the structure, one can embody all the theoretically possible types of coordination of a pentacoordinate carbon atom. Incidentally we would like to mention interesting results of theoretical^{155,191,192} and experimental^{175,192,193} studies of the structures of dications containing pentacoordinate nitrogen atoms, which are isoelectronic to carbonium cations. In these studies, relying on high-level (QCISD/6-311G** and CCSD(T)/

aug-cc-pVTZ) calculations, a structure with C_{4v} symmetry was attributed to the NH_5^{2+} dication (according to X-ray diffraction analysis,¹⁹³ its penta-aurated analogue **94** has a perfect D_{3h} configuration).

4. Hexa- and heptacoordinate carbonium ions

In the most symmetrical octahedral O_h configuration, structures of type AH_6 , where A is a Group IV element, have four bonding molecular orbitals, which can be occupied by eight electrons ($1a_{1g}^2 1t_{1u}^6 e_g 2a_{1g}$).^{5,6,9} One might expect that this type of octahedral structure would exist for the diprotonated methane CH_6^{2+} . Nonempirical calculations^{194–197} confirm the expected stability of the CH_6^{2+} dication. Besides, they indicate that the C_{2v} form in which the eight valence electrons are distributed over two $2c-2e$ and two $3c-2e$ C–H bonds, rather than the O_h form, is preferred for dication **95** for energy reasons.

As for the methonium ion **65**, dication **95** is a stereochemically non-rigid structure. According to MP3/6-31G**//6-31G** calculations,¹⁹⁵ redistribution of hydrogen atoms between the C–H bonds in the structure **95** in the gas phase requires overcoming a small potential barrier (only 4.3 kcal mol^{−1}). The octahedral bond configuration, which is unfavourable for the diprotonated methane, can be stabilised for its derivatives. Examples of this type are the CLi_6^{2+} (**96**)^{198,199} and $\text{C}(\text{AuPPh}_3)_6^{2+}$ (**97**) dications.¹⁷⁴ The latter has been isolated preparatively as the tetrafluoroborate salt.¹⁷⁴

The pyramidal dication **98** is the prototype of polyhedral organic structures containing a hexacoordinate carbon atom.

The hexamethyl derivative **99** of this dication has been prepared by Hogeveen and Kwant^{200,201} in superacid media using various precursors (Scheme 1).

The ^1H and ^{13}C NMR signals of the apical centres in **99** occur at a high field ($\delta^{13}\text{C} = 2.0$ ppm).^{200,201} As in the case of the $(\text{CH})_5^+$ (**66**) cation, the pyramidal structure of $(\text{CH})_6^{2+}$ (**98**) does not correspond to the deepest minimum in the PES. The transition of this structure to the energetically favourable isomer (according to HF/3-21G calculations), the fulvene dication, is associated with overcoming a high potential barrier.²⁰² The kinetic stability of the dication **98** is interpreted by the eight-electron rule.⁹ This rule also predicts the existence of another pentagonal-pyramidal non-classical structure **100**, which is the conjugate base of the dication **98** (in the same way as pyramidane **39** is the conjugate base for the pyramidal cation **66**). Nonempirical calculations⁸⁸ carried out at different approximation levels indicate that structure **100** actually corresponds to a minimum on the C_6H_5^+ PES. As can be seen from the data presented in Fig. 15, the bonds connecting the apical and the basal carbon atoms in the dication **98** are substantially

elongated with respect to similar bonds in the square-pyramidal ion **66**. In the cationic carbene **100**, the lengths of these bonds approach the greatest values known for C–C bonds.^{203,204} The longest single C–C bond known to date (1.80 Å) has been found in a [1.1.1]propellane derivative.⁴⁶

A hexacoordinate carbon atom can exist not only in ions but also in electrically neutral species. The octahedral CLi_6 (**96**) molecule can serve as an example.^{144,198,205} This molecule contains two valence electrons more than could be accommodated in the four bonding MO of the octahedral structure. These electrons

Figure 15. Geometric characteristics of the C_6H_5^+ cation (**100**) and $\text{C}_6\text{H}_6^{2+}$ (**98**) dication calculated by the B3LYP/6-311+G** and MP2(full)/6-311+G** methods.⁸⁸

are localised in the C–Li bonds. An additional bonding a_{1g} MO having a spherical symmetry is formed by delocalisation of orbitals of the lithium atoms surrounding the central carbon atom. In relation to the C–Li bonds, this MO is antibonding; nevertheless, it makes a substantial contribution to the molecular stabilisation due to ligand–ligand interactions [cf. stabilisation of the tetracoordinate planar carbon atom in structures **24**–**26** (see Fig. 7)]. Multicentre bonds also determine the stability of a series of carbide clusters **101** and carboranes **102** in which the formal coordination number of carbon is six. In nickel and cobalt clusters **103** with an antiprism structure, the coordination number is as high as eight.^{94, 206}

The simplest stable structure containing a heptacoordinate carbon atom is triprotonated methane **104**. In this compound, eight valence electrons are distributed over three $3c-2e$ C–H₂ bonds and one $2c-2e$ C–H bond.¹⁹⁷ The results of MP2/6-31G** and QCISD(T)/6-311G** calculations indicate that the whole positive charge in structure **104** is concentrated on the hydrogen atoms (each carries a charge of $\sim +0.6$), whereas the carbon atom is negatively charged ($q_C = -1.27$). Thus, the stability of this three-charged ion is mainly due to electrostatic forces.

Electrostatic interactions are also important for stabilisation of pyramidal cations with a six-membered basal ring. According to MP2/6-311 + G** and B3LYP/6-311 + G** calculations,⁸⁸ the di- and trication structures **105** and **106** in which the apical carbon atoms are coordinated to six and seven centres, respectively, exist, as predicted by the octet rule, as fairly deep minima in the PES.

The geometry calculated for structures **105** and **106** is shown in Fig. 16. In both cases, the C_{ap}–C_{bas} distances exceed the critical values for the single C–C bond lengths and the electron populations of the C_{ap}–C_{bas} bonds are rather low.

The presence of one $2c-2e$ C–H bond in the structure of triprotonated methane **104** provides an opportunity to replace this bond by a three-centre $3c-2e$ C–H₂ bond and thus to approach the CH₈⁴⁺ tetracation. However with a charge of +4, the Coulomb repulsion of the hydrogen atoms, which carry the entire positive charge, becomes the predominant destabilising factor. The results of MP2/6-31G** calculations showed that the CH₈⁴⁺ ion is unstable. The corresponding PES contains no minima for any of the possible CH₈⁴⁺ structures.^{143, 197} Meanwhile, the isolobal trinuclear boronium ion BH₈³⁺ is kinetically stable, although the calculation indicates that various pathways of its dissociation are highly exothermic. The structure of BH₈³⁺ (**107**) found by MP2/6-31G** and QCISD(T)/6-311G** calculations has four tetrahedrally oriented $3c-2e$ B–H₂ bonds.²⁰⁷

Figure 16. Geometric characteristics of the C₇H₆²⁺ dication (**105**) and C₇H₇³⁺ trication (**106**) calculated by the B3LYP/6-311 + G** and MP2(full)/6-311 + G** methods.⁸⁸

VII. Planar hexacoordinate carbon atom inside a cyclic borocarbon cage

A new line in the study of compounds with hypercoordinate carbon atoms is the quest for structures with a planar hexacoordinate carbon atom. The problem of stabilisation of these structures has been attacked simultaneously by two research groups, which have arrived at similar solutions.

One approach^{25, 208, 209} is based on expansion of the rigid cage of bonds formed by a planar tetracoordinate carbon atom in cyclic structures like **21**–**23**. This expansion results in a higher coordination number of the carbon atom. For example, 'doubling' of molecule **23** (by reflecting it in a mirror accommodating the central carbon atom and two boron atoms in the plane of the mirror) furnishes structure **108** containing a planar hexacoordinate carbon atom.

X = O (a), NH (b).

According to MP2(full)/6-311 + G** calculations, the resulting structure **108** has D_{2h} symmetry and corresponds to a minimum on the PES.

The calculated geometry of molecule **108a,b** is shown in Fig. 17. The C–B bond lengths are only ~ 0.1 Å longer than the length of the typical single C–B bond.²¹⁰ The replacement of the central carbon atom in structure **108** by the B[–] isolobal centre, as expected, does not weaken the stability of the structure.

The anion **109** and molecules **110a,b** (Fig. 18) are minima on the corresponding PES.²⁰⁹

Figure 17. Geometric characteristics of molecules **108a,b** (X = NH, O) containing hexacoordinate carbon atoms calculated by the MP2(full)/6-31G** and MP2(full)/6-311++G** methods (values in parentheses).²⁵

The lengths of the B–B bonds formed by the central boron atom (~ 1.7 Å) are within the limits of values typical of these bonds.²¹¹ Analysis of the electronic structure of compounds **108–110** shows that they are 6π -electron aromatic systems. The two electrons lent by the central carbon atom or by the B^- anion are delocalised in the π -system of the ligands. As a consequence, the carbon atom in the structure **108** bears a positive charge (+0.8 to +0.9), which decreases its effective radius and reduces the steric strain in the planar system. The aromatic nature of molecule **110** is emphasised by the presence of shortened peripheral B–B bonds, which are 0.06–0.08 Å shorter than the double B=B bond (~ 1.63 Å).²¹²

The second approach to solving the problem of stabilisation of a hexacoordinate carbon centre²¹³ is also underlain by the idea of surrounding this centre by a rigid cage composed of boron atoms. At the first stage of the investigation,²¹³ carried out by B3LYP/6-311++G** calculations using the density functional theory, a model planar structure **111** was considered with various atoms or ions X being placed at the midpoint of the benzene ring.

For none of the structures designed in this way (even for the structure with X = He or C^{4+}), were the researchers able to locate an energy minimum on the PES. Since the geometry of structure **111** (X = C^{4+}) was quite realistic (the $C_{\text{centre}}-C$ bond lengths were normal, 1.516 Å) and the instability of the structure was mainly due to excess charge, subsequent modification of the structure **111** with X = C^{4+} was carried out in the usual way.

The total charge of the molecule was neutralised by successive replacement of the carbon centres in the ring by boron atoms. Along this route, a number of stable structures **112–116**, containing a planar hexacoordinate carbon atom, have been identified. Two factors contribute to the stability of these structures: first, expansion of the inner cavity containing the carbon centre caused by the fact that C–B bonds are longer than C–C bonds; and second, aromaticity of these structures. It was noted²¹³ that, although structures **112–116** are not the most stable isomers,

Figure 18. Geometric characteristics of anion **109** and molecules **110a,b** containing hexacoordinate boron atoms calculated by the RHF/6-31G** (RHF), MP2(full)/6-31G** (MP2) and B3LYP/6-311++G** (DFT) methods.^{208,209}

The molecular configuration of **110b** is the transition state structure for rotation of the lithium atom above the ring (topomerisation) with a potential barrier of 0.20 (RHF), 0.63 (MP2) or 0.03 kcal mol^{−1} (DFT).

they are separated from the latter by rather high potential barriers and, therefore, the synthesis of these species may be practical.

VIII. Molecules and ions containing planar penta-, hepta- and octacoordinate carbon atoms or atoms of other non-transition elements

The possibility of the existence of stable compounds incorporating a planar heptacoordinate carbon atom is pointed out by the results of B3LYP/6-311+G** calculations for the cyclic CB₇ anion.²¹⁴ In this approximation, the *D*_{7h}-symmetric structure **117a** is a local minimum in the PES, which is separated from another local minimum corresponding to a more stable (by 9 kcal mol⁻¹) isomer **117b** by a fairly high potential barrier. The ion pairs formed by anions **117a** and **117b** with the Li⁺ counterions have the same energy. Like the cyclic structures with a hexacoordinate carbon atom considered above, the seven-membered analogue **117a** is also aromatic. Figure 19 shows the shapes of the four π MO of anion **117a**, three occupied orbitals and the lowest unoccupied one. The B–B (1.523 Å) and C–B (1.389 Å) bond lengths in the seven- and eight-membered rings in anions **117a** and **117b** are close to the C–B bond length in the H₂C=BH molecule (1.376 Å) and B–B bond length in the HB=BH molecule (1.523 Å), calculated by the same technique;²¹³ this indicates that these are conjugated double bonds.

The ring in compound **117a** is larger than the B₆ and C₂B₄ rings in compounds **108**–**116**; this entails an increase in the C_{centre}–B bond lengths in anion **117a** by approximately 0.2 Å. Due to this elongation, the bond becomes markedly weaker than the usual bonds in carboranes.²¹⁵ Therefore, even minor symmetry distortions can lead to substantial changes in the type of structure. The symmetry of the structure of ion pair **118** is reduced

Figure 19. Shapes and energy levels of the π -orbitals of anion **117a** calculated by the B3LYP/6-311G** method (see Ref. 214).

to *C*_s. These structures should be fluxional, following a bond switching isomerisation pattern (see Refs 216, 217), the calculated potential barrier being not higher than 0.1 kcal mol⁻¹.

A similar structure and the same type of structural rigidity are typical of neutral C₂B₆ (**120**) and NB₇ (**121a,b**) rings. The cyclic structure **120** is formed from cyclic structure **117a** through replacement of the B⁻ anion by an isoelectronic carbon atom, while **121** is produced when the central carbon is replaced by nitrogen. Calculations of the geometry of these molecules (Fig. 20) demonstrate that the central carbon atom in structure **120** forms only five (of the seven possible) rather short (within the range of usual lengths of C–B bonds) C–B bonds, and the nitrogen atoms in structures **121a** and **121b** form four and five short N–B bonds. However, the calculated potential barriers to migration of the central atoms inside the seven-membered rings do not exceed 0.8 kcal mol⁻¹, which permits these atoms to be regarded as effectively heptacoordinate planar atoms.²¹⁴

Figure 20. Geometric characteristics of anion **117a** and molecules **120** and **121a,b** calculated by the B3LYP/6-311+G(2df) methods.²¹⁴

The symmetrical *D*_{8h} structure **122** resulting from insertion of a carbon atom inside an eight-membered ring composed of boron atoms is unstable, according to the results of B3LYP/6-311G** calculations.²¹⁸ On the PES of the CB₈ molecule, this structure is matched by a flattened top of a hill (two imaginary vibration frequencies). Although the B–B bonds in the rings are double, the size of the eight-membered ring is so large that the B–C distances in structure **122** exceed the longest known value for B–C bond length. If the carbon atom in structure **122** is replaced by an isoelectronic atom or cation (Si or P⁺) with a greater atomic radius, structures **123** and **124** obtained in this way will be stable (matched by potential energy minima). The calculated B–Si (2.038 Å) and B–P (2.041 Å) bond lengths exceed only slightly the corresponding sums of the covalent radii (1.98 and 1.91 Å). Structures **123** and **124**, like structures **112**–**117**, contain aromatic sextets of π -electrons.

For the cyclic CB₈ molecule, the stable form is structure **125** (*C*_{2v} symmetry) in which the C–B bond lengths are 1.627 and

1.753 Å, and the other C...B distances (non-bonding contacts) occur within the limits of 2.5–2.9 Å. This structure, like analogous seven-membered structures **118**, **120** and **121**, tend to undergo low-barrier rearrangements [the potential barrier calculated in the CCD(fc)/6-311G**//B3LYP/6-311G** approximation is 2.05 kcal mol⁻¹] resulting in fast exchange of ligand positions in the environment of the central atom. Thus, the carbon atom in structure **125** is effectively octacoordinated.

As this review was being prepared for publication, new important studies devoted to derivatives of planar tetracoordinate and hypercoordinate carbon were published.

Wang and Schleyer²¹⁹ further developed the strategy described in their preliminary communication⁵⁷ involving delocalisation of the non-bonding higher occupied MO of alkylanes over the molecular cage by replacing the carbon centers in various positions of the cage by boron atoms and carried out B3LYP/6-31G* calculations for a series of new boroalkanes with a planar tetracoordinate carbon atom. The same researchers also proposed a general approach to the design of stable organoboron structures incorporating planar pentacoordinate carbon centres.²²⁰ It was found that the replacement of two-electron π -donor groups (O, NH, HC=CH) in structures **21**–**23** containing a planar tetracoordinate carbon atom by single-electron π -donor B or C atoms provides the possibility of increasing the coordination number of the planar carbon center. The insertion of non-classical substituents **127a**–**c** thus obtained into the skeletons of various aromatic hydrocarbons in place of the three-carbon (CH)₃ chains gives rise to structures with pentacoordinate planar carbon atoms (for example, structures **128**–**130**), whose stability was confirmed by B3LYP/6-311 + G** calculations.

This result is also confirmed by our MP2/6-311 + G** *ab initio* calculations for a number of other structures (for example, isomers **131**) with a pentacoordinate carbon atom.²²¹ We showed that by observing the above conditions of aromatic stabilisation of non-classical structures (see Sections II.3 and VII), stable structures with a pentacoordinate carbon atom can also be produced by other permutations of atoms in units **127** and in structures of type **128**–**130**.

Compound	$\Delta E/\text{kcal mol}^{-1}$	
	B3LYP/6-311 + G**	MP2/6-311 + G**
131a	0	0
131b	11.6	7.1
131c	32.4	21.9

The requirement of aromatic stabilisation and the selection of appropriate fragments of type **21**–**23**, **127a**–**c** and others allow one to predict rather reliably the existence of stable molecules and ions with hypercoordinate planar centres of any other element. The B3LYP/6-311 + G** calculations for stable structure **132** with a planar pentacoordinate nitrogen atom serves as an example.²²¹

In relation to the discussion of the pyramidal (CH)₅⁺ cation and its isomers (see Section VI.2), of interest is the debate initiated by the recent publication²²² reporting the synthesis of the unexpectedly stable pentamethyl derivative of the singlet cyclopentadienyl cation (CMe)₅⁺ (**133**). According to X-ray diffraction analysis data, the cation structure corresponds to structural type **83**. However, the subsequent high-level quantum-chemical calculations²²³ suggested that in reality, the researchers were dealing with the dihydro derivative **134** rather than with the cation **133**; this was recognised as proven after additional analysis.^{224, 225}

The outcome of this debate is an illustrative example of the increasing role of precise quantum-mechanical calculations in the study of structures with non-standard geometric and electronic characteristics.

IX. Conclusion

The results of the theoretical and experimental studies considered demonstrate the diversity of structural types of molecules containing atoms with a non-standard spatial orientation of bonds and coordination numbers other than those dictated by the valence rules. Not that these compounds are necessarily thermodynamically or kinetically stable — they often are metastable local minima. But one can think of generating them, and studying them. The advances in theoretical simulation methods and the stupendous progress in the development of the computing power of modern quantum chemistry enabled quite substantiated state-

ment of the problem of looking for new structures which might have been rejected only a few years ago by researchers with a classical way of thinking on the basis that 'that can't be so because it can never be so' (see, for example, the caustic remark²²⁶ concerning the studies searching for compounds with a planar tetracoordinate carbon atom). Meanwhile, these studies initiated by theoretical analysis have received some experimental validation. Many compounds of this type have already been synthesised.

Currently, theoretical investigations of new non-classical organic compounds are directed at elucidating the factors influencing stability and investigating the unusual dynamics and properties of such molecules and ions. Elucidation of unusual structural patterns presents substantial interest in the design of new high-tech materials with specific properties, while technological developments, especially ultralow-temperature laser vaporisation,²²⁷ allow one to expect that more theoretical predictions will be confirmed by experimental proof. The situation in this field seems to resemble the history of the development of fullerene chemistry.

As has already been noted, high-level *ab initio* calculations with obligatory allowance for the electron correlation energy are the most accurate and reliable methods for theoretical identification and evaluation of the possible existence of non-classical structures. The question thus arises of how one might choose particular structures on which calculations are to be performed. It is clear that exhaustive screening of atomic compositions cannot be a suitable strategy. There is good reason to believe that analysis of orbital interactions of molecular fragments based on the perturbation theory still remains conceptually the most comprehensive and the most fruitful way of designing stable non-classical structures. This conclusion is based on the fact that orbital interactions make, as a rule, the major contribution to stabilisation or, conversely, destabilisation of molecular structures.

Yet another, more utilitarian line is to simulate a non-classical organic structure that would resemble one or another inorganic or organometallic complex or cluster. The stability of molecules and ions of such compounds is ensured by the formation of multi-centre bonds, of a type which is dictated by the structure of the complex or cluster and can be reproduced in the organic analogue on the basis of the isolobal analogy.

It is evident that the principles of stabilisation of non-classical organic structures, *i.e.*, carbon compounds, can be directly extrapolated to the compounds of other non-transition elements. Some examples of unusual geometric configurations and types of coordination of boron, nitrogen, silicon, and phosphorus atoms have been included in this review.

The notion of 'non-classical compounds' appeared 50 years ago when the first examples of these structures became known, the term itself being introduced mainly to designate exceptions to customary rules. Nowadays, the exceptions appear to become indistinguishable from the rules. George Olah, who has been awarded the Nobel Prize for his contribution to the development of this field of chemistry, believes¹⁴³ that classification of structures into classical and non-classical ones will gradually vanish from chemists' language and chemists' practice, as the understanding of the general principles of the chemical bond becomes more profound.

The review was written with financial support from the Russian Foundation for Basic Research (Project Nos 00-15-97320, 01-03-32546, 02-03-33227) and the Civilian Research and Development Foundation (Grant RCI-2323-RO-02).

Spirooxazines: synthesis, structure, spectral and photochromic properties

V Lokshin, A Samat, A V Metelitsa

Contents

I. Introduction	893
II. Synthesis of spirooxazines from aromatic <i>o</i> -hydroxynitroso compounds	894
III. Synthesis of spirooxazines from 1-amino-2-naphthols and related compounds	899
IV. Chemical reactions of spirooxazines	900
V. Spirooxazine-containing molecular systems	902
VI. Structures of isomeric forms of spirooxazines and their interconversions in the ground state (solvatochromism and thermochromism)	904
VII. Spectral properties of spirooxazines	906
VIII. Dark decolouration of spirooxazines	910
IX. Photochemical properties of spirooxazines	911
X. Conclusion	913

Abstract. The review surveys synthetic approaches to spiro[1,4]oxazines belonging to one of the most promising classes of organic photochromes. The relationships between the structures of spirooxazines and their spectral properties as well as characteristics of thermal and photoinduced processes are considered. The bibliography includes 201 references.

I. Introduction

Reversible molecular rearrangements are of great interest because they play an important role in studies of many chemical and biological processes, which find use in modern technologies. Of special interest are light-induced rearrangements, the so-called photochromic rearrangements. These are reversible transformations of a chemical species between two states with different absorption spectra induced (at least in one direction) by electromagnetic radiation.¹ In recent years, photochromic organic compounds have been extensively studied because of their application in optical systems for recording and retrieval of information, molecular switches, dynamical chemosensors and biosensors, systems for accumulation of solar energy, transport systems, catalysis, optoelectronics and optobioelectronics.^{1–7} Since organic photochromic compounds find application in diverse fields, requirements on their characteristics are rather wide. In this connection, the directed synthesis of these compounds assumes great importance. Directed syntheses are planned taking into account the results of investigations on general relationships

between the molecular structure and spectral-kinetic properties of photochromic compounds.

Photochromism was first described at the end of the 19th century. However, extensive studies of organic photochromes were started only in the second half of the 20th century. Spirocyclic compounds composed of two heterocyclic fragments, which are linked through the sp^3 -carbon atom, immediately have come to the forefront.^{2–7}

X = CH (spiropyran, SPP), N (spirooxazine, SPO).

The spirocyclic form **A** of these compounds has absorption in the UV region. Excitation of this form with light of the corresponding wavelength causes the cleavage of the C_{sp^3} –O bond followed by isomerisation to give the flattened conjugated form **B**, which has absorption in the visible region.

Of the two above-mentioned classes of spiro compounds, spiropyrans were the first to be synthesised. In the 1960–70s, spiropyrans were the best studied organic photochromes.² On the background of these extensive studies, the synthesis of the first spirooxazines in 1961⁸ as well as two subsequent publications dealing with these compounds^{9,10} went unnoticed.

The starting point for the studies of the chemistry of SPO were investigations by Chu.^{11–13} In the beginning of the 1980s, he was the first to discover the extraordinary high photostability[†] of spiro{indoline-2,3'-naphtho[2,1-*b*][1,4]oxazine} (**1**) and its derivatives under continuous irradiation.

[†] Hereinafter, the photostability is taken to mean the resistance to photo-degradation.

Received 9 September 2002

Uspekhi Khimii 71 (11) 1015–1039 (2002); translated by T N Safonova

Due to this discovery, SPO have attracted the attention of researchers as photochromes showing promise for the practical use in materials with varying optical density. Since the mid-1980s, the number of publications (especially patents) devoted to SPO sharply increased, which gave impetus to their systematisation and analysis.

Spirooxazines were the subject of three reviews,^{4,6,14} two of which were chapters of monographs. Unfortunately, problems of the synthesis and structural modifications of SPO remained virtually beyond the scope of the reviews^{4,6} and received proper attention only from Japan researchers.¹⁴ However, the latter review was published more than a decade ago. In recent years, abundant new data on the synthesis of SPO have become available. Taking into account an importance of synthetic aspects, which, to a great extent, determine new areas of practical application of SPO, we believe that there is a need to consider these problems in more detail, with emphasis on the results obtained in the last 10–12 years. In citing patent data, we take into account only studies (with rare exception), which gave clear characteristics of the compounds (melting points and/or informative NMR spectra). The effects of the structural factors on the spectral properties and characteristics of thermal and photo-induced processes of spirooxazines in solutions are considered. For a correct comparison, prominence is given to the results obtained in approximately identical conditions.

II. Synthesis of spirooxazines from aromatic *o*-hydroxynitroso compounds

1. Conditions and reaction mechanism

One of the most commonly used procedures for the synthesis of SPO from aromatic *o*-hydroxynitroso compounds and alkylidene derivatives of nitrogen-containing heterocycles **2** (hereinafter, the 'nitroso' method) was borrowed directly from the chemistry of SPP with the only difference that the reactions with alkylidene derivatives **2** were carried out with aromatic *o*-hydroxynitroso compounds instead of aldehydes, such as salicylaldehyde.

X = CH (SPP), N (SPO).

Alkylidene derivatives **2** are generally prepared *in situ* by the reactions of bases (most often, triethylamine) with the corresponding quaternary salts **3**. Ethanol^{9,10} or methanol¹³ are traditionally used as solvents, although trichloroethylene,^{15–17} toluene,^{18,19} dioxane,²⁰ acetone,²¹ chloroform,²² amyl alcohol²³ and a heptane–ethanol mixture^{24,25} have also found use in recent years.

Unfortunately, as have been mentioned in the review by Chu,⁴ this method affords SPO in low yields (on the average, 30%–50%). The main reasons for low yields are as follows:

- low reactivity of the nitroso group due to the low electrophilicity of the nitrogen atom;
- instability of some SPO and nitroso compounds in the reaction conditions;
- difficulties associated with the chromatographic isolation of SPO (close values of R_f of SPO, starting compounds and by-products).

A number of recent studies were aimed at optimising the yields of SPO in these reactions. Thus, it has been found²⁶ that the presence of a drying agent and elevated pressure have a positive

effect on the yield of SPO **1** (determined by liquid chromatography). An excess of nitrosonaphthol and the use of toluene as the solvent have the same effect (however, this hinders the isolation of the final product).

Recently, it has been demonstrated[‡] that the reactions performed in the absence of a solvent under microwave activation led not only to a noticeable increase in the yield of SPO but also to an essential decrease in the reaction time (up to ~15 min) and reduction in the amount of impurities. This procedure for the synthesis of spirooxazines deserves further investigation.

The mechanism of the reactions of aromatic *o*-hydroxynitroso compounds **4** with alkylidene derivatives of nitrogen-containing heterocycles **2** remains virtually unknown. It was assumed that this mechanism is analogous to that of the synthesis of SPP²⁷ and involves the attack of the negatively charged carbon atom of enamine on the nitrogen atom of the nitroso group as the first step (Scheme 1, path *a*).

However, another point of view was expressed in the study.²⁸ The authors of the cited study believed that the key step involves the electrocyclic reaction of enamine **2** with the quinone oxime tautomer of *o*-hydroxynitroso compound **4'** giving rise to intermediate **5** (Scheme 1, path *b*). This mechanism is indirectly supported by the fact that the quinone oxime forms are much more stable in solutions than the nitrosophenol forms. For example, the NMR spectroscopic study of 1-nitroso-2-naphthol in such solvents as CDCl₃, C₆D₆, DMSO-*d*₆ and dioxane-*d*₈ revealed the presence of two isomers of the quinone oxime type (**C**

[‡] A Samat, V Lokshin, R Guglielmetti, J Hamelin, F Texier-Boullet, A V Koshkin, O A Fedorova, S P Gromov *Synth. Commun.* (in preparation).

and **D**), the ratio between these isomers being dependent on the nature of the solvent.²⁹

2. Modification of the heterocyclic fragment of spirooxazines
Hereinafter, two fragments involved in the SPO molecule will be referred to as the heterocyclic and oxazine fragments.

Although these names are not strict (oxazine fragment is also heterocyclic), they are, in our opinion, better than such terms as 'left' and 'right' heterocycles, which are sometimes used.

a. Substitution in the indoline ring

The majority of the known spirooxazines involve the indoline ring as the heterocyclic fragment. This preference of researchers is attributable to both the historical tradition associated with the chemistry of SPP and the fact that the replacement of this fragment in SPO by other fragments presents a very difficult problem (see below).

In the synthesis of indoline-containing SPP and SPO, 2-alkylidene derivatives of indoline **6** are used as the starting compounds, of which 2-methylidene-1,3,3-trimethylindoline (**7**) (Fischer's base) is the most well-known representative.

Procedures for the synthesis of these compounds have been developed in considerable detail and have been comprehensively surveyed in reviews.^{2,5,30} Hence, we will not discuss these procedures in the present review. Let us only note that most of 2-alkylideneindolines were prepared according to the Fischer synthesis (Scheme 2).

Scheme 2

If the starting phenylhydrazine **8** contains hydrogen as the substituent R^1 , the reaction affords indolenine **9**. Subsequent alkylation of compound **9** yields quaternary salt **10**, which is converted into 2-alkylideneindoline **6**. In the case that the substituent R^1 cannot be introduced by alkylation, it is inserted into the starting phenylhydrazine **8**.

The Fischer synthesis of indoline-containing synthons is a rather simple process, which accounts for the fact that the

substitution in the indoline fragment is most commonly used for the modification of SPO. A substituent is most often inserted at position 1 (at the nitrogen atom) as well as at position 5. Examples of selected 1- and 5-substituted spironaphthooxazines **11–32** are given in Tables 1 and 2.

Table 1. 1-Substituted spironaphthooxazines of the indoline series.

SPO	R	Ref.	SPO	R	Ref.
11	$-(CH_2)_{17}Me$	31 ^a	18	$-(CH_2)_2CO_2H$	9, 36
12	$-CH_2Bu^t$	32	19	$-(CH_2)_5CH(CO_2Et)_2$	31
13		33	20		37
14	$-CH_2CH(Me)Ph$	32	21		38
15	$-(CH_2)_2OMe$	34	22	$-(CH_2)_5CONH_2$	39
16	$-CH_2Ar$	35	23		21
17	$-CH_2CH=CH_2$	26, 31	24		40

^a A series of other *N*-alkyl-substituted SPO were described in the study.³¹

Table 2. 5-Substituted spironaphthooxazines of the indoline series.

SPO	R	Ref.	SPO	R	Ref.
25	$-F$	41	29	$-NO_2$	26
26	$-I$	41	30	$-NH_2$	43
27		15	31	$-NHCOMe$	15
28	$-OH$	42	32		44

3-Substituted derivatives **33–35** (see Ref. 44) and unique bridging structures **36–38** (see Ref. 45) were synthesised.

It should be noted that substituents in the indoline fragment (particularly, at position 1) not only have an effect on the photochromic properties of SPO but also improve such important useful characteristics of SPO as solubility, affinity for polymeric matrices and photostability.

b. Spirooxazines with non-indoline heterocyclic fragments

From a synthetic standpoint, the variation in the nature of the heterocyclic fragments in SPO is among the most stubborn problems. Unlike aldehydes of the salicylaldehyde type, aromatic *o*-hydroxynitroso compounds are not involved in condensation with heterocyclic salts of type **39**, except for salts **3**, which give stable bases **2**.

This fact practically precludes the use of a broad spectrum of oxygen- and sulfur-containing heterocycles, which are successfully employed in the synthesis of SPP.² As a result, the range of heterocyclic systems suitable for the synthesis of SPO is limited to nitrogen-containing heterocycles.

New SPO in which the indoline fragment is substituted by sterically hindered (**40–42**)^{46–49} or saturated (**43**,^{50, 51} **44**^{17, 52, 53}) azaheterocycles have been synthesised in recent years.

Besides, compounds containing azaindoline (**45–47**)^{20, 54} or dibenzooxazepine (**48**)^{18, 55–57} fragments were synthesised. It should be noted that compound **48** exhibits photochromic properties only at low temperatures (from -40 to -20 °C).

3. Modification of the oxazine fragment of spirooxazines

a. Substitution in the naphtho[2,1-*b*]oxazine fragment

Most of procedures for the structural modifications of the oxazine fragment in SPO are based on the insertion of the substituent R into the naphthalene fragment. The substituent is most commonly introduced into this fragment already in the step of the preparation of the starting 1-nitroso-2-naphthol. The general scheme of

the synthesis of SPO containing substituents in the oxazine fragment is given below.

The localisation of the nitroso and hydroxy groups at positions 1 and 2 of the starting nitrosonaphthols **49** unambiguously determines the type of the resulting oxazine fragment as naphtho[2,1-*b*][1,4]oxazine (**50**). 1-Nitroso-2-naphthols occupy a prominent place among other aromatic *o*-hydroxynitroso compounds due both to their high stability (compared, for example, to *o*-nitrosophenols) and the fact that they can be readily prepared by nitrosation of the corresponding naphthols.

In recent years, the range of SPO of type **50** has been steadily extended due to the involvement of ever more complex nitrosonaphthols in this reaction (Table 3). This structural modification of SPO is one of the most commonly used processes, although the progress in this field is limited by the inaccessibility of some naphthols and the necessity of adapting the conditions of their nitrosation to the nature of the substituent.

Table 3. Substituted 1,3,3-trimethylspiro{indolino-2,3'-naphtho[2,1-*b*][1,4]oxazines}.

51–67

55	7'-NO ₂	64	64	8', 9'-	68
56	8'-OH	65	65	9'-OH	58, 65, 71, 72
57	8'-COPh	19	66	10'-Me	68, 73
58	8'-CN	29, 66	67	10'-C ₆ H ₄ Me- <i>p</i>	68, 73
59	8'-SO ₃ Na	65, 67			

It is the difficulty to access 4-substituted 2-naphthols that accounts for the lack of 6'-substituted SPO in Table 3.

To close this gap, an original approach to 6'-substituted SPO has been developed. In this procedure, 1,2-naphthoquinones **68** rather than 2-naphthols were used as the source of 1-nitroso-2-naphthols. The reactions of compounds **68** with hydroxylamine afforded monooximes **69**, which are tautomers of nitrosonaphthols **49**.

In the general case, 1,2-naphthoquinones are not more readily available compounds than naphthols. However, a number of their 4-substituted derivatives can be easily prepared by the nucleophilic substitution reaction of potassium 1,2-naphthoquinone-4-sulfonate (**70**). Thus, Rickwood and co-workers^{20, 74} used various secondary amines as nucleophiles for the preparation of 4-amino-substituted 1,2-naphthoquinones **71**, which were then employed in the synthesis of 6'-amino-substituted SPO (Scheme 3, method *a*). These authors also developed a simplified (but much less universal) approach to the synthesis of the same compounds^{20, 74, 75} on the basis of the reaction of 1-nitroso-2-naphthol, secondary amine and Fischer's base **7** without isolation of substituted nitronaphthol **72** (Scheme 3, method *b*). However, the mechanism of the insertion of the amino group is not entirely known. It was assumed²⁰ that the reaction involves the nucleophilic addition of secondary amine at position 4 of the quinone oxime tautomer of 1-nitroso-2-naphthol. Subsequent oxidation of intermediate **73** can occur under the action of the second 1-nitroso-2-naphthol molecule, which partially accounts for low yields.

Scheme 3

By combining both approaches, Rickwood and co-workers^{20, 76} prepared a large series of 6'-amino-substituted SPO (**74–83**). Using the synthesis of SPO **84** (see Ref. 20) and **85** (see Ref. 76) according to the method *a* as examples, the authors demonstrated that O- and C-nucleophiles can be employed as nucleophilic reagents.

This scheme has been substantially refined in subsequent studies. In particular, NMR spectroscopic studies demonstrated that the reaction of 4-substituted naphthoquinones **86** with hydroxylamine is non-regioselective and affords, in the general case, a mixture of oximes **87** and **88**, which are difficult to separate.^{16, 29, 77} The use of this mixture in the reaction with Fischer's base provides a possibility for the generation of two types of SPO, viz., naphtho[2,1-*b*][1,4]oxazines **89** and naphtho[1,2-*b*][1,4]oxazines **90**.

The predominance of a particular type of SPO depends on the ratio of the oximes in the mixture and their relative reactivities to Fischer's base. Thus, due to the low reactivities, 4-amino-substituted oximes **88** give the corresponding SPO **90** only in trace amounts.²⁹ However, if sulfur-containing substituents are inserted at position 4, compounds of type **90** (for example, **91–94**) rather than compounds of type **89** (for example, **95**) are generated as the major products in mixtures of SPO.¹⁶

R = Prⁱ (**91**, 25.5%), C₆H₁₁ (**92**),
Ph (**93**), C₆H₄OMe-*p* (**94**).

Apparently, these results have stimulated the researchers to revise the structure of compound **85**. In the recent patent,⁷⁸ structure **96** was assigned to this compound based on the results of X-ray diffraction study of the starting oxime.

It should be noted that the synthetic efforts to prepare 6'-substituted SPO were compensated by good photochromic characteristics of most of these compounds, primarily, by high colourability and unusual spectral features.

A special type of the modification of the naphtho[2,1-*b*]oxazine fragment involves the insertion of substituents at position 2'. For example, 2'-substituted SPO **97–100** were synthesised.^{44, 79–81}

R = Me (**97**), Pr (**98**), Ph (**99**).

Unlike structurally similar SPP, SPO of this type do not exhibit photochromic properties at room temperature although short-lived coloured forms of some of these compounds were detected upon laser flash photolysis with nanosecond time resolution.⁸⁰

b. Aromatic annelation and heteroannelation

The need for the extension of the gamma of the photochromic characteristics of SPO provides a steady impetus to the synthesis of new types of SPO whose structures differ from the classical naphtho[2,1-*b*]oxazine structure **50**. This aim can be achieved by synthesising SPO with the use of aromatic and heterocyclic *o*-hydroxynitroso derivatives, for example, nitrosophenols, nitrosophenanthrols, *o*-hydroxynitrosoquinolines, *etc.*, instead of 1-nitroso-2-naphthols. This type of structural modifications, which has received considerable attention already in early studies,^{4, 6} was further developed in recent years.

In particular, new derivatives belonging to the class of SPO characterised by aromatic annelation, such as naphtho[1,2-*b*]oxazines (**101**),^{16, 82–84} phenanthro[9,10-*b*]oxazines (**102**),^{81, 85} anthra[2,1-*b*]oxazines (**103**)²³ and benzooxazines (**104**),^{44, 86} were synthesised. A procedure for the synthesis of a new representative of this type of SPO, *viz.*, spirofluoroanthene[3,2-*b*]oxazine (**105**), was covered by a patent.⁸⁷

Heteroannelation of the benzooxazine fragment was particularly widely reflected in recent patents and publications. New compounds of this type are listed in Table 4.

Interesting results were obtained by Lareginie *et al.*⁷⁷ In attempting to synthesise SPO **117** and **118** containing the anne-

lated imidazo[1,2-*a*]pyridine and imidazo[1,2-*a*]pyrimidine rings, respectively, compounds **119** and **120** having open merocyanine structures were prepared instead of the expected compounds with spirocyclic structures.

X = CH (**117**, **119**, **121**), N (**118**, **120**, **122**).

Compounds **119** and **120** are the only known examples of stable merocyanines of the spirooxazine series. Physicochemical and X-ray diffraction studies of these compounds provided valuable information on the probable three-dimensional and electronic structures of the short-lived coloured forms of SPO, which can usually be obtained only by indirect methods.^{97–99}

In conclusion of this section, let us mention an interesting attempt to synthesise SPO **123**, which contains no nuclei annelated to the oxazine ring.²⁸ Unfortunately, the synthesis afforded 1,2-oxazines **124**, which do not exhibit photochromic properties.

III. Synthesis of spirooxazines from 1-amino-2-naphthols and related compounds

As early as 1971, when analysing various hypothetical approaches to spirocyclic photochromic compounds, Bertelson² noted that the oxazine ring of SPO could be, in principle, constructed by the reactions of carbonyl compounds with amines. The first step forward in this direction was made by Japanese scientists¹⁰⁰ who demonstrated that SPO **1** can be prepared by the reaction of 2-hydroxyiminomethyl-1,3,3-trimethylindoleninium perchlorate (**125**) with 1-amino-2-naphthol hydrochloride (**126**) in the presence of triethylamine.

Although the mechanism of this reaction remains to be studied, it seems rather probable that the reaction produces a carbonyl-containing intermediate of type **127**, which then interacts with the amino group.

Minkin and co-workers^{85, 101} have made an essential contribution to the development of this field of investigation. The Russian researchers found that the carbonyl-containing intermediate (to which the structure of ketene **128** was assigned), which can react with 1-amino-2-naphthol (**129**) to give SPO **1**, can be prepared by mild oxidation of Fischer's base **7**.¹⁰¹

Selenium dioxide and pyridinium chlorochromate were successfully tested as oxidising agents. However, the best results were obtained with the use of dimethyl sulfoxide promoted by the addition of sodium bicarbonate. The advantages of this approach over the classical 'nitroso' method are that it affords the reaction

products in higher yields and gives rise to smaller amounts of impurities, which substantially facilitates the chromatographic purification of the products.

The use of annelated analogues of 1-amino-2-naphthols, such as 9-amino-10-phenanthrols and 1-amino-2-anthrol, instead of 1-amino-2-naphthols themselves, made it possible to prepare SPO of types **102** and **103**.^{85, 101}

Additional advantages of the procedure under consideration were revealed in the study.¹⁵ In particular, this procedure was employed for preparing SPO **132–134** starting from readily accessible aminonaphthols **130** and **131**.^{102–104} These products contain strong electron-withdrawing substituents at position 6' and possess good photochromic characteristics.

$\text{R}^1 = \text{H}$ (**132**, **133**), 5-OMe (**134**);
 $\text{R}^2 = \text{CN}$ (**130**, **132**, **134**), $\text{SO}_2\text{C}_6\text{H}_4\text{Me-}p$ (**131**, **133**).

Yet another important advantage of this procedure is that the reactions can be carried out under much milder conditions. This made it possible to increase the yields of SPO **43** and **44**, which were prepared from bases of type **2** unstable under the reaction conditions (prolonged heating).¹⁵

These mild reaction conditions allowed the Russian researchers⁸ to isolate stable intermediate **135** whose structure was established by NMR spectroscopy.

Compound **135** is rapidly converted into SPO **1** upon heating in different solvents. It is not inconceivable that this compound is also the direct precursor of SPO **1** in the 'nitroso' method (see structure **5**, Scheme 1), but this hypothesis calls for an additional verification.

Within the framework of this method, yet another unexpected result was obtained.¹⁰⁵ It appeared that oxidation of Fischer's base in the presence of secondary amines afforded (in much higher yields) 6'-amino-substituted SPO analogous to those prepared according to Scheme 3.

Since 1-amino-2-naphthol (**129**), unlike 1-nitroso-2-naphthol, cannot react with secondary amine by the Michael addition mechanism (Scheme 3, method *b*), the step in which the amino group is inserted into the molecule remains an open question.

IV. Chemical reactions of spirooxazines

The syntheses of the first spirooxazines have presented difficulties due to which SPO had an unjust reputation of chemically unstable compounds.⁴ However, these compounds can be subjected to various chemical transformation in spite of a certain instability, particularly, in the presence of water and acids. These transformations are considered below.

1. Electrophilic substitution of the hydrogen atom

Russian scientists made an essential contribution to investigation of this type of reactions of SPO.^{64, 106, 107} In particular, they demonstrated that nitration of SPO **1** with nitric acid ($d = 1.35 \text{ kg m}^{-3}$) in concentrated sulfuric acid afforded 8'-nitro-substituted derivative **136**.

However, nitration of benzoannulated compound **137** under the same conditions gave rise to dinitro compound **139** along with the expected 8'-nitro derivative **138**.¹⁰⁶

Attempts to use a softer nitrating agent, *viz.*, 2,3,5,6-tetra-bromo-4-methyl-4-nitrocyclohexa-2,5-dien-1-one (**140**), failed.²⁹ However, the reaction of this reagent with SPO **141** containing the activated indoline fragment gave rise to 4-nitro derivative **142**.

Bromination of SPO **1** with *N*-bromosuccinimide (NBS) proceeded initially at position 5 of the indoline ring. Further bromination of the resulting SPO **143** yielded 5,6'-dibromo derivative **144** in a mixture with by-products.¹⁰⁷

2. Synthesis of esters, amides and ethers

a. Acylation and alkylation of hydroxy-substituted SPO

Acylation of 9'-hydroxy-containing SPO **65** and its derivatives is the most widespread reaction of SPO. Acid chlorides^{60, 71, 72, 108} or acid anhydrides¹⁰⁹ can be employed as acylating agents, which are most often prepared *in situ* from the corresponding acids and dicyclohexylcarbodiimide (DCC).^{40, 110–112} A series of acyl derivatives of SPO **65** are given in Table 5.

Analogous approaches are used for acylation of the hydroxy groups at positions 5 (see Refs 42 and 112) and 8' (see Ref. 69).

Alkylation of the HO groups of hydroxy-containing SPO is less well studied. Dürr *et al.*⁷² synthesised SPO **154** and **155** by the treatment of the corresponding hydroxy derivatives with alkyl halides in anhydrous acetonitrile in the presence of potassium carbonate.

Table 5. Acyl derivatives of 9'-hydroxy-substituted SPO **65**.

Dimethyl sulfate was successfully used for methylation of the hydroxy groups at positions 5' and 8'.^{59,69}

b. Reactions of carboxy-substituted SPO

N-Carboxyethyl-substituted SPO **18**, which was synthesised for the first time by Ono,⁹ is a convenient reagent for the preparation of esters and amides. Various compounds of this type (**156–161**) containing luminescent, complex-forming or antioxidant fragments were synthesised by Chinese researchers.^{36,113}

3. Synthesis of coordination compounds

Recently, Chinese researchers¹⁰⁸ reported the preparation of stable crystalline complexes of SPO **150** with Re(I) salts with compositions [Re(CO)₃(phen)(SPO)]ClO₄ (**162**), [Re(CO)₃(4,4'-Me₂bipy)(SPO)]ClO₄ (**163**) and [Re(CO)₃(4,4'-Bu₂bipy)(SPO)]·PF₆ (**164**) (phen is 1,10-phenanthroline, bipy is 2,2'-bipyridyl).

The structures of compounds **162–164** were confirmed by spectroscopic methods. In addition, the structure of compound **164** was established by X-ray diffraction analysis. Photocolouration

of SPO was observed upon irradiation of compounds **162–164** in the absorption band of the organometallic fragment (~420 nm), which was attributed to the intramolecular energy transfer.

The synthesis of stable complexes of SPO of type **115** with Ru(bipy)₂Cl₂ was described in the earlier study.⁸⁵ However, attempts to isolate these compounds in the solid state failed.

In the studies,^{114,115} the formation of stable luminescent adducts of the coloured form of SPO with metal salts in solution has been reported. In some cases, these reactions proceeded even without irradiation.⁶² Nevertheless, the conclusions about the coordination nature of these compounds should be made with caution.

Indeed, Malatesta and co-workers^{116,117} showed that SPO (for example, SPO **165**) can react with metal salts, for example, with CuCl₂, on heating through the redox mechanism to give compounds of type **166**.

Apparently, the naphthooxazole fragment, which is present both in molecule **166** and products of its transformations,¹¹⁷ is responsible for the fluorescence observed.

Recently, analogous transformations have been found in the reactions of SPO **1** with silver salts¹¹⁸ and lead salts.¹¹⁹

4. Reactions of hydroxymethyl- and formyl-substituted SPO

Hydroxymethyl derivative **52** proved to be very useful in studies of chemical transformations of SPO. French researchers^{61,120} used this compound for the preparation of numerous SPO derivatives (Scheme 4), which are of interest not only as photochromes but also as precursors for the preparation of biphotochromic compounds (see below).

The key reaction in Scheme 4 involves mild oxidation of SPO **52** with periodinane **169** (Dess–Martin reagent) to give formyl derivative **170**. Compound **170** can be involved in different reactions at the aldehyde group, for example, in the Wittig and Knoevenagel reactions, which made it possible to prepare a series of vinyl derivatives **171–175**, which have an extended conjugation system and, as a consequence, possess unique photochromic characteristics.¹²⁰ The same formyl-substituted SPO **170** was used as the starting compound in the synthesis of compounds **176** and **177**, which contain substituents possessing properties of spin traps.^{121,122}

5. Other reactions

Of other SPO transformations, reduction of nitro derivative **136** with hydrazine hydrate in the presence of Raney nickel giving rise to amino derivative **178**¹²³ and the preparation of salt-like SPO **179**, which unexpectedly exhibits photochromic properties in the crystalline state,¹²⁴ deserve notice.

Scheme 4

R = CO₂Et (**171**), CN (**172**, **175**), CO₂Me (**173**), CHO (**174**), Me (**176**), PO(OEt)₂ (**177**).

V. Spirooxazine-containing molecular systems

The synthesis of complex molecular systems involving covalently bound photochromic fragments is a promising field of the chemistry of SPO. These systems are increasingly employed as photomodulators, which can change their physicochemical characteristics under irradiation, thus influencing the structure and properties of their chemical environment.

1. Spirooxazine-containing crown ethers

The first compound of this type, *viz.*, SPO **180**, was prepared by Japanese scientists.^{125, 126} They introduced a macrocyclic fragment into the starting 3-hydroxymethyl-2-naphthol. Other approaches were used by the Russian–French research team,^{58, 127–129} who have actively developed this area of investigation in recent years. In particular, compounds **181** and **182** were prepared by acylation of hydroxy-containing SPO **51** and **65**, respectively. The synthesis of SPO **183** and **184** was carried out according to a procedure shown in Scheme 3 (method *b*).

Substantial changes in the parameters of the photochromic transformations of crown-containing SPO in the presence of some metal cations were observed in virtually all studies. The recent comprehensive study¹³⁰ showed that the complex formation is a very complicated process.

2. Spirooxazine-containing biphotochromic systems

The term ‘biphotochrome’ was introduced by Dürr¹³¹ to describe molecules containing two covalently bound photochromic units of the same or different types.

Depending on the mode of binding of two fragments, such compounds can be arbitrarily divided into three types, all having representatives of the spirooxazine series.

Φ1 and Φ2 are identical or different photochromic molecules.

The properties of compounds of the type **A** in which the photochromic units are linked *via* a non-conjugated chain are determined, to a large extent, by the type of the bridge. Thus, the polyether chain in compound **185** ensures the photomodulated affinity for Na⁺ ions,¹³² whereas the phosphorus-containing

groups in SPO of types **186** and **187** enhance, in the authors' opinion,¹³³ their photostability.

The major impetus for the synthesis of annelated biphotochromes of the type **B** containing common aromatic nuclei was the desired preparation of coloured forms possessing unusual spectral characteristics. However, since the photochromic fragments in these compounds are not independent, their simultaneous photoexcitation presents problems. Of three biphotochromic compounds of the type **B** considered below, *viz.*, SPO–SPO **188**,^{134,135} SPO–chromene **189** (see Ref. 29) and SPO–dihydroindolizines of type **190**,¹³⁶ simultaneous excitation of both photochromic fragments was observed only for compounds **190**. As a result, the absorption spectra of the coloured forms of these compounds are shifted to the IR region.

A series of biphotochromes of the type **C** in which the photochromic fragments are conjugated through the vinyl bridges have been described in the recent study.⁶¹

Compounds **191–194** containing the spirooxazine and chromene fragments were prepared from functionally substituted photochromes **168** and **170** by the Wittig reaction.

The photochromic behaviour of the above-mentioned compounds, which has been thoroughly studied later,^{137–140} proved to be very complex. For example, not only successive opening of both oxazine rings but also the *Z* → *E* isomerisation and electrocyclic cyclisation to form compound **195** were observed for SPO **191** obtained in the *Z* configuration.¹⁴⁰

3. Spirooxazine-containing polymers

Most polymeric photochromic SPO-based materials are solutions of photochromes in the corresponding polymers. This procedure for the preparation of polymeric photochromic materials is much simpler than that proceeding *via* the covalent binding of SPO with polymers. However, the latter method has considerable advantages, in particular it:

- provides a higher concentration of the photochrome;
- hinders diffusion of the photochrome thus reducing the toxic risk in the course of the *in vivo* functioning of the material (for example, in contact lenses);
- improves the 'photomodulating' influence of the photochrome on the structure and characteristics of the polymer.

Most of the above-described spirooxazine-containing polymers belong to the class of polyacrylates. The corresponding monomers, for example, SPO **145**, are generally prepared by acylation of hydroxy-containing SPO.^{60, 72, 112, 141} However, it is also possible to introduce functional groups capable of being polymerised into the indoline precursors.^{142–144} A more complicated approach was used for the preparation of phosphorus-containing methacrylate monomer **196**. The polymer, which was prepared on the basis of this monomer, mimics the structure of phospholipid membranes.¹⁴⁵

In addition to polymerisation (generally, radical) of spirooxazine-containing monomers, spirooxazine-containing polymers are also synthesised by the introduction of SPO into an available polymer containing functional groups. An example of this approach is the preparation of polymer **198** through the oxirane-

ring opening of poly(glycidyl methacrylate) **197** under the action of the hydroxy group of SPO **65**.¹⁴⁶

Polysiloxanes belong to another large class of spirooxazine-containing polymers. Studies of these polymers were initiated in the beginning of the 1990s by Krongauz and co-workers¹⁴² and are being carried out actively by this research team^{147–149} as well as by Japanese scientists.^{84, 150, 151} The main approaches to the synthesis of the polymers of type **200** are given in Scheme 5.

The synthesis of spirooxazine-containing polysulfones⁴³ starting from amino-substituted SPO **30** was also described.

VI. Structures of isomeric forms of spirooxazines and their interconversions in the ground state (solvatochromism and thermochromism)

The structures of spirooxazines were comprehensively studied by ¹H NMR spectroscopy, Raman spectroscopy,¹⁵² quantum-chemical methods^{98, 153, 154} and X-ray diffraction analysis.^{16, 70, 77, 155–160}

The NMR spectra of spirooxazines are informative and allow one, with rare exception (for example, in the case of SPO **85** and **96**), to establish reliably the structures of the resulting compounds. Numerous publications^{15, 35, 40, 58, 61, 106, 107, 161} and a special-purpose study¹⁶² included the detailed assignments of the signals for protons and carbon atoms in the ¹H and ¹³C NMR spectra of a broad spectrum of SPO. It should be noted that an unexpected correlation between the chemical shift of the 2'-carbon atom of SPO in the ¹³C NMR spectra and the positions of the absorption maxima of their coloured forms was found in the study.¹⁶³

According to the results of Hartree–Fock quantum-chemical calculations (HF 6-31G**/3-21G),^{153, 154} four possible acyclic isomers of SPO, which are responsible for thermal and photo-induced colouration, adopt transoid configurations, viz., *cis-trans-trans* (CTT), *trans-trans-trans* (TTT), *cis-trans-cis* (CTC) and *trans-trans-cis* (TTC), the TTC isomer being most stable.

R = Si(OEt)₂Me.

The X-ray diffraction data on the thermally unstable merocyanine form of SPO are scarce. The results of ¹H NMR spectroscopic study and X-ray diffraction analysis of open form **120**,

which was obtained in the synthesis of SPO **118**,⁷⁷ provided evidence for its *TTC* configuration.

In the ¹H NMR spectroscopic study of SPO **1**,⁹⁹ which was carried out directly on irradiation giving rise to the 90% conversion of the cyclic form, it was demonstrated that the *CTC* isomer can be formed in a small amount along with the most stable *TTC* isomer.

The tautomeric equilibrium between the cyclic **A** and merocyanine **B** forms in the ground state is typical of SPO in solutions. The **A** ⇌ **B** equilibrium was studied by ¹H NMR spectroscopy,^{85, 95, 96} circular dichroism spectroscopy^{164, 165} and spectrophotometry.^{13, 96, 166–169}

If the concentrations of the equilibrium forms **A** and **B** are sufficiently high that they can be reliably identified by NMR

1, 77, 201–203

spectroscopy, the equilibrium constants can be determined (K_e). Due to the presence of the prochiral sp^3 -hybridised carbon atom in the indoline ring, the kinetics of the reaction $A \rightleftharpoons B$ can be studied by dynamic ^1H or ^{13}C NMR spectroscopy (from the shapes of the signals of the diastereotopic methyl groups bound to this carbon atom). The potential barrier is determined by the energy of the $C_{\text{spiro}}-O$ bond cleavage.

For most of SPO, the equilibrium $A \rightleftharpoons B$ is substantially shifted to the cyclic isomers **A**. In these cases, it is most convenient to monitor the equilibrium by spectrophotometry, which enables one to detect the coloured form at very low concentrations (lower than 1%). If the molar extinction coefficients (MEC) of acyclic isomers are known, the equilibrium constant and thermodynamic parameters of the equilibrium can also be determined.

The available published data allow one to follow the influence of the molecular structure of various indolinospirooxazines on the quantitative characteristics of the equilibrium $A \rightleftharpoons B$ (Table 6). In the series of SPO containing aromatic or heterocyclic fragments annelated to the oxazine nucleus, the equilibrium constant increases on going from naphthalene to phenanthrene and phenanthroline. The insertion of electron-donating groups (Oalk) at position 5 of the indoline fragment leads to an increase in the equilibrium concentration of the merocyanine form in solutions of SPO.

The equilibrium position is sensitive to the changes in the polar properties of the solvents and temperature of the solutions. In polar solvents, the equilibrium is shifted to acyclic isomers. The equilibrium constant increases as the temperature is raised. The temperature dependence of the equilibrium constant enables one to determine the thermodynamic characteristics of the equilibrium, *viz.*, the standard enthalpy (ΔH°), free energy (ΔG°) and entropy (ΔS°) (see Table 6).

The phenomenon related to the changes in the positions and sometimes in the intensities of the bands in the electronic absorption or fluorescence spectra of solutions due to changes in the properties of the solvent (polarity, tendency to be involved in specific interactions) is called solvatochromism.¹⁷⁰ The solvatochromism of spirooxazines is associated with the influence of the nature of the solvent on the position of the equilibrium $A \rightleftharpoons B$. The solvatochromic effect of SPO can be estimated from the change in the equilibrium constant in passing from one solvent to another (at the same temperature). As can be seen from Table 6, the largest changes in the equilibrium constant on going from weakly polar to polar solvents are observed for SPO of the phenanthroline series. The strong solvatochromic effect is observed also for 5-alkyloxy-substituted compounds **207** and **208**.

Thermochromism is a reversible change in colour of a compound due to a change in temperature in the range limited by the boiling point of the solvent (for solutions) or melting point (for solids).¹⁷¹ Apparently, the temperature dependence of the equilibrium constant between the cyclic and merocyanine forms of SPO in solutions is an indication that the corresponding SPO are thermochromes, *viz.*, compounds exhibiting thermochromism, and the thermochromic effect can be estimated from the standard enthalpy of the equilibrium. How fast the colour changes following the change in temperature, in particular, how fast solutions of SPO become coloured with increasing temperature, depends on the rate of attainment of the equilibrium. For SPO, $k_{BA} > k_{AB}$, *i.e.*, thermal colouration is the rate-limiting process for the attainment of the equilibrium. Hence, the activation energy (E_a^{AB}) of the process $A \rightarrow B$ can be rather accurately determined from the temperature dependence of the rate constant of colouration k_{AB} . If the preexponential factors in the Arrhenius equation have close values, the larger is E_a^{AB} , the more pronounced is the temperature dependence of k_{AB} for SPO. Hence, the thermochromic effect in SPO of the phenanthroline series is more pronounced in non-polar solvents, whereas the rate of the colour change with temperature is higher in alcohols (see Table 6).

VII. Spectral properties of spirooxazines

1. Electronic absorption spectra of cyclic forms of spirooxazines

Electronic absorption spectra of spirooxazines are characterised by long-wavelength absorption with maxima predominantly in the region of 330–380 nm and molar extinction coefficients (MEC) of 4000–20 000 litre mol⁻¹ cm⁻¹ (Fig. 1, Table 7). The effect of the substituents on the spectral characteristics of spirooxazines is associated with the structural features of SPO molecules, *viz.*, with the presence of two acoplanar fragments, heterocyclic and oxazine responsible for photochromism.

The structural simulation showed that the electronic absorption spectra of SPP, which are structural analogues of SPO, can be considered with a certain degree of approximation as linear combinations of the absorption spectra of the constituent fragments. This approximation is possible because the fragments weakly interact with each other due to acoplanarity. The long-wavelength absorption bands are assigned to the photochemically ‘active’ pyran moiety, whereas the short-wavelength bands are assigned to the heterocyclic moiety.¹⁷³ An analogous approach was used^{13, 166} for the interpretation of the absorption spectra of SPO. In particular, the absorption spectrum of SPO **1** in ethanol has a group of long-wavelength bands with maxima at 345 and 317 nm, which were assigned to electron transfers in the naphthooxazine moiety, and bands with maxima at 297 and 235 nm, which were assigned to transitions in the heterocyclic fragment.¹³

The validity of this assignment was confirmed by a comparison of the absorption spectra of solutions of SPO containing substituents in the heterocyclic and oxazine fragments, respectively. As can be seen from Table 7, the substituents in the oxazine fragment of spiroindolinonaphthooxazines exert a more substantial effect on the positions of the long-wavelength absorption bands than the substituents in the indoline moiety. The spectral range of changes in the positions of the long-wavelength absorption maxima of SPO containing substituents in the naphthooxazine moiety with respect to unsubstituted SPO **1** is ~40 nm, whereas this range for SPO containing substituents in the indoline fragment is only 3 nm (cyclohexane).

The effect of substituents in the oxazine moiety of SPO on the positions of the absorption maxima is determined by their electron-donating and electron-withdrawing properties. Compounds containing electron-donating groups at positions 5' and 9' are characterised by short-wavelength (with respect to unsubstituted SPO **1**) shifts of the maxima of the long-wavelength absorption bands, whereas compounds containing electron-donating groups at positions 6' and 8' are characterised by the corresponding long-wavelength shifts. Electron-withdrawing sub-

Figure 1. Electronic absorption spectra of SPO **217** in ethanol ($c = 1.1 \times 10^{-4}$ mol litre⁻¹, $T = 293$ K) (1, 2) and SPO **29** in toluene ($c = 3.4 \times 10^{-5}$ mol litre⁻¹, $T = 293$ K) (3, 4). Curves 1, 3 were measured before irradiation; curves 2, 4 were recorded after irradiation with light at $\lambda = 365$ nm.

Table 7. Positions of the absorption maxima ($\lambda_{\max}$) and molar extinction coefficients ($\epsilon_{\max}$) of the cyclic isomers **A** of spirooxazines.

stituents at positions 5', 6', 7', 8' and 9' cause long-wavelength shifts of the absorption maxima in the spectra of solutions of SPO.

The electronic absorption spectrum of SPO **172** is characterised by an unusually broad long-wavelength absorption region due to a band with a weakly pronounced maximum at 430 nm. Conceivably, this absorption can be assigned to the intramolecular charge transfer from the naphthooxazine ring to the CN groups *via* the vinyl chain.

An extension of the π system of the oxazine fragment upon benzoannellation leads to a shift of the absorption boundary to the long-wavelength region. The electronic absorption spectrum of SPO **204** of the phenanthrene series has an additional maximum at 375 nm (toluene) compared to the absorption spectrum of naphtho derivative **1**, which is the manifestation of the vibrational nature of the long-wavelength absorption band belonging to the modified phenanthrene system.¹⁷⁴ This effect is even more pronounced in the case of anthracene derivative **103**. The spectrum of the latter compound has an additional long-wavelength vibrational maximum at 427 nm (heptane).¹⁷⁵

The modifications of the heterocyclic moiety of SPO by the replacement of the indoline fragment with the spatially hindered (SPO **40**¹⁷) or saturated (SPO **43**,⁵¹ **44**¹⁷) azaheterocycles lead to substantial changes in the position of the long-wavelength absorption band.

Nevertheless, substituents in the indoline fragment of SPO can exert an effect on the position of the long-wavelength absorption maximum assigned to the transfer in the oxazine fragment. This effect depends on the nature of the substituents in both moieties of SPO. For example, the insertion of the methoxy group at position 5 of the indoline fragment has virtually no effect on the position of the long-wavelength absorption band in the case of SPO devoid of substituents in the naphthooxazine fragment (*cf.* **1** and **141**, Table 7), whereas such an insertion leads to a small (1–4 nm) long-wavelength shift in the case of 6'-cyano-substituted SPO (*cf.* **132** and **134**) and a noticeable short-wavelength shift by 13 nm in the spectra of 9'-methoxy-substituted SPO (*cf.* **216** and **217**).

In most cases, the electronic absorption spectra of SPO are independent of the polarity of the solvents and their ability to be involved in specific interactions (see Table 7). In this connection, noteworthy is the spectrum of 5-nitro-substituted SPO **29**. The maximum of long-wavelength absorption in the spectra of solutions of this compound is shifted bathochromically as the polarity of the solvent is increased. Apparently, this fact is attributed to the enhancement of resonance stabilisation of bipolar structure **29'** with increasing polarity of the solvent. This shift was not observed in the spectrum of 8'-nitro-substituted SPO **136**.

2. Electronic absorption spectra of the coloured forms of spirooxazines

The spectra of the coloured forms of SPO show absorption in a substantially longer-wavelength region than the spectra of their cyclic isomers. The maxima of the bands are observed in the region of 480–670 nm and the bands are much more intense (40 000–80 000 litre mol⁻¹ cm⁻¹; see Fig. 1, Table 8). Under normal conditions, the long-wavelength bands in the stationary absorption spectra have an asymmetrical shape, which is man-

ifested as a shoulder on the short-wavelength side (SPO **132**) or, more rarely, on the long-wavelength side (SPO **51**) relative to the maximum of the band. The position of the shoulder depends on the nature of the solvent (*cf.* SPO **29** and **216**). This effect is a consequence of the fact that the long-wavelength transition of the most stable *trans* isomer of the merocyanine form is vibrational in nature rather than results from the overlapping of bands of several stereoisomers.

The spectral characteristics of the coloured forms of SPO are sensitive to structural modifications and, unlike those of the cyclic forms, depend substantially on the substituents not only in the oxazine moiety of SPO but also in the heterocyclic fragment due to conjugation of both fragments occurring after the ring opening. The positions of the absorption maxima and the molar extinction coefficients (MEC) of the coloured forms **B** of a number of the above-considered spirooxazines and new SPO **219–221** are given in Table 8.

R = 9'-NO₂ (**219**), 10'-NO₂ (**220**), 11'-NO₂ (**221**).

The electron-donating substituents at positions 5', 6' and 9' of the naphthooxazine moiety of spiroindolinonaphthooxazines cause short-wavelength shifts of the maxima of the absorption bands of the open form, whereas the presence of such substituents at position 8' leads to long-wavelength shifts. Electron-withdrawing groups at positions 5'–9' cause a long-wavelength shift of this maximum. By contrast, the insertion of electron-donating substituents into the indoline fragment of SPO leads to a long-wavelength shift of the absorption maximum, whereas the introduction of electron-withdrawing substituents causes a short-wavelength shift. The most essential spectral changes occur upon the insertion of a substituent at position 5 of the indoline fragment and at position 6' of the naphthooxazine fragment.

Benzoannellation of the naphthooxazine fragment causes a slight shift of the absorption maximum of the coloured form. Thus, benzoannellation at positions 5', 6' (SPO **204**) leads to a short-wavelength shift, benzoannellation at positions 8', 9' (SPO **103**) causes a long-wavelength shift, whereas benzoannellation at positions 7', 8' (according to the results of the study¹⁷⁶) has virtually no effect on the absorption spectrum (it remains similar to the spectrum of the form **B** of SPO **1**).

On going from naphthalene SPO **1** and phenanthrene SPO **204** to quinoline SPO **218** and phenanthroline SPO **115**, respectively, no noticeable spectral changes occur in absorption of the merocyanine forms.

In general, the spectral changes that are observed for a series of SPO and are associated with the insertion of substituents into the acyclic isomers **B** of spiroindolinonaphthooxazines, are typical also of other SPO of the indoline series. Thus, the introduction of the NO₂ group at positions 9', 10' or 11' of phenanthrene derivatives of SPO leads to a long-wavelength shift of the absorption maximum of the coloured form.¹⁷⁷ Analogous changes occur also upon the introduction of the alkyloxy substituent at position 5 of the indoline fragment of phenanthroline-containing SPO **207** and **208** (see Table 8).

The replacements of the indoline fragment by the azabicycloalkane (SPO **40–42**),^{46–49} piperidine (SPO **43**),⁵¹ homoazaadamantane (SPO **44**)¹⁷ or dibenzooxazepine (SPO **48**)¹⁸ fragments cause short-wavelength shifts of absorption bands of acyclic isomers of SPO. In the case of SPO **40–42**, these shifts are associated with disruption of coplanarity resulting in the absence of conjugation between the lone pair of the nitrogen atom and the

Table 8. Positions of the absorption maxima ($\lambda_{\max}$) and molar extinction coefficients ($\epsilon_{\max}$) of the coloured forms **B** of spirooxazines.

^a Acetone as the solvent. ^b Heptane as the solvent.

aromatic nucleus. The shortest-wavelength absorption is observed for the merocyanine forms of azaindoline-containing **SPO 45–47**. In particular, the spectrum of the form **B** of **SPO 222** (6'-substituted derivative **SPO 47**) in toluene has an absorption maximum at 478 nm.²⁰

The positions of the absorption maxima of the open forms of **SPO** depend on the polar properties of the solvents. The observed

solvatochromic effect can be both positive and negative. In the case of spiroindolinonaphthooxazines, the sign of this effect is determined by the degree of quinoidation (or bipolarity) of the merocyanine form, which depends on the electron-donating and electron-withdrawing properties of the substituents and their positions in a particular moiety of **SPO**.^{64, 66}

Analysis of the dependence of the spectral characteristics of photomerocyanines **B** on empirical Brooker's parameters (χ_R and χ_B) of the solvents enables one to estimate their polar properties.^{178–181} For 6'- and 8'-cyano-, 8',9'-dicyano- and 8'-nitro-substituted spiroindolinonaphthooxazines, there is a correlation between the frequencies of the absorption maxima of the acyclic isomers **B** and the parameters χ_B , whereas a correlation with the parameters χ_R is lacking, which is indicative of the negative

solvatochromism.⁶⁶ The above-mentioned correlation is most pronounced in the presence of an additional substituent, *viz.*, the methoxy group, at position 5. The observed effect provides evidence for a substantial charge delocalisation in the ground state of photomerocyanines resulting in stabilisation of the bipolar structure. By contrast, there is a correlation between the frequencies of the absorption maxima of the coloured forms **B** and the parameters χ_R for unsubstituted SPO **1** as well as for 6'-NC₅H₁₀-, 8'-OMe-, 9'-OMe- and 5-NO₂-substituted SPO, whereas there is no correlation with the parameters χ_B , *i.e.*, these compounds exhibit the positive solvatochromism. This effect results from a weak polarity of the ground state of the acyclic isomer, *i.e.*, from the predominantly quinoid structure of photomerocyanine **B**.

Hence, electron-withdrawing substituents in the naphthooxazine moiety of SPO would be expected to facilitate delocalisation of the negative charge on the oxygen atom giving rise to properties typical of bipolar structures. Electron-donating groups in the indoline fragment, which facilitate delocalisation of the positive charge on the nitrogen atom, exert an analogous effect. By contrast, a bipolar structure is thermodynamically unfavourable in the presence of electron-donating substituents in the naphthooxazine fragment, which facilitate an increase in the negative charge on the oxygen atom, and electron-withdrawing substituents in the indoline fragment, which lead to an increase in the positive charge on the nitrogen atom. As a consequence, the merocyanine form undergoes quinoidation. If substituents are present in both moieties of SPO, their effect would depend on which properties prevail.

There is a certain dependence of the changes in the intensities of long-wavelength absorption bands of the coloured forms of SPO on their molecular structures and properties of the solvents (see Table 8). The molar extinction coefficients of the absorption maxima of the merocyanine forms ($\epsilon_{\max}^B$) are larger for the structures exhibiting bipolar properties than for the corresponding quinoid isomers. Thus, the $\epsilon_{\max}^B$ coefficients for SPO **61**, **132**, **134**, **136**, **141**, **211** and **215** whose acyclic isomers have bipolar structures are in the range of 57 000–67 000 litre mol⁻¹ cm⁻¹, whereas these coefficients for the quinoid forms **B** of SPO **1**, **33**, **56**, **214** and **216** are in the range of 40 000–45 000 litre mol⁻¹ cm⁻¹.⁶⁶ An analogous effect is observed for indoline-containing SPO **115** and **206–208** of the phenanthroline series. The larger $\epsilon_{\max}^B$ coefficients are observed for SPO **207** and **208** containing electron-donating (OAlk) substituents in the indoline moiety of SPO, which facilitate polarisation of the merocyanine form.⁹⁶ In polar solvents, the $\epsilon_{\max}^B$ values for the absorption maxima of the coloured forms of SPO are generally larger than those in weakly polar solvents. The largest $\epsilon_{\max}^B$ coefficients are observed for SPO **207** and **208** in alcohols. This is associated with the formation of intermolecular hydrogen bonds, which can stabilise bipolar forms of acyclic isomers.

VIII. Dark decolouration of spirooxazines

As mentioned above, the thermochromism of SPO is the temperature-induced change in the equilibrium between isomers in the ground electronic state. By analogy, the photochromism can be considered as the photoinduced change in the equilibrium giving rise to a new equilibrium between the isomers in which at least one isomer, for example, the cyclic isomer (in the general case, both **A** and **B** isomers), occurs in the excited state. The equilibrium position attained under continuous irradiation is known as the photostationary state. For a quantitative analysis of the system, it is important to establish the identity (or difference) of the products of thermal and photochemical transformations of the starting SPO. Generally, products of thermal and photochemical reactions of SPO observed in stationary conditions at temperatures higher than 10 °C are spectrally identical. After termination of irradiation, the system relaxes from the photostationary state to the thermal equilibrium state occurring at this temperature. This state

Figure 2. Evolution of the absorption spectra of SPO **58** in toluene ($c = 1.2 \times 10^{-4}$ mol litre⁻¹, $T = 293$ K) under irradiation with light at 365 nm (**1**) and after termination of irradiation (**2**).

is characterised by the rate constant, which is equal to the sum of the rate constants of the forward (k_{AB}) and reverse thermal reactions (k_{BA}) (Fig. 2). Since $k_{BA} \gg k_{AB}$ in most cases (*cf.* Tables 6 and 9), the observed relaxation process, which is referred to as a dark reaction and follows an exponential law in solutions, is described by the rate constant k_{BA} . The value, which is inversely proportional to the apparent rate constant of dark decolouration, is often used in the discussion of the practical use of photochromes and referred to as the lifetime of the coloured form (τ_B). For solutions of SPO, τ_B ranges from 10⁻¹ to 10⁴ s.

The characteristics of the dark decolouration reaction of SPO, *viz.*, the rate constant (k_{BA}) and the activation energy (E_a^{BA}), vary over wide ranges depending on the molecular structure of SPO and the nature of the solvent (Table 9).

The solvents have an ambiguous effect on the rate constant of the reverse reaction of SPO, which is determined by the electron-donating and electron-withdrawing properties of substituents in the heterocyclic and oxazine fragments. In the case of spiroindolinonaphthooxazines, certain tendencies in the change of k_{BA} can be revealed. For monosubstituted compounds containing electron-donating substituent in the naphthooxazine fragment (for example, SPO **1**, **51**, **77**, **213**, **216**) or an electron-withdrawing substituent in the indoline fragment (SPO **29**), the rate constant increases in parallel with the polarity of the solvent. By contrast, the rate constant decreases with increasing polarity of the solvent for SPO containing electron-withdrawing groups in the indoline moiety (for example, SPO **58**, **132**, **133**, **136**, **213**) or electron-donating substituents in the naphthooxazine moiety (SPO **141**, **207**, **208**). If several substituents are present in both fragments of SPO, the direction in which the rate constant of the reverse reaction changes depending on the polar properties of the solvents is determined by the relation between the electron-donating and electron-withdrawing properties of the substituents in the indoline and naphthooxazine fragments. Therefore, the revealed correlations reflect to a certain extent the polarity of merocyanines. It should be noted that the rate constant of the reverse thermal reaction in solvents, which have specific interactions (such as alcohols) and can form intermolecular hydrogen bonds with photoinduced forms of SPO, can change stepwise rather than in parallel with the polar properties of the solvents, which are determined, for example, by the dielectric permeability (see Table 9).

In considering the effect of the molecular structure of SPO on the rate constant of the dark reaction, it is necessary to take into account the above-mentioned opposite relationships between the rate constant and the polar properties of the solvents. Nevertheless, there are general regularities, which persist regardless of the nature of the solvent. The introduction of electron-withdrawing substituents into the naphthooxazine moiety of spiroindoli-

^a For these SPO, k_{BA} and E_{a}^{BA} were determined at 298 K. ^b For SPO of the phenanthroline series, k_{BA} and E_{a}^{BA} were determined at 296 K. ^c Heptane as the solvent.

nonaphthooxazines leads to a decrease in the rate constant of the reverse thermal reaction, the simultaneous insertion of electron-donating groups at position 5 of the indoline fragment substantially enhancing this effect. The presence of electron-donating substituents at position 5 of the indoline fragment exerts an analogous effect in other spiroindolinooxazines, for example, in SPO of the phenanthroline series. The steric effect of bulky substituents on thermal decolouration of SPO is manifested in a decrease in the rate constant (*cf.*, for example, SPO **170** and **210**, **115** and **206**, Table 9).

The temperature dependence of the rate constant of the dark reaction characterised by the activation energy has a tendency to be enhanced in polar solvents, particularly, in alcohols (see Table 9). Conceivably, a strengthening of intermolecular interactions between the alcohol molecules and merocyanine forms of SPO through hydrogen bonding leads to an increase in the activation barrier to the recyclisation reaction. There is no rather strict relationship between the activation barrier to the dark reaction and the molecular structure of SPO. However, it should be noted that spiroindolinonaphthooxazines containing electron-withdrawing substituents in the oxazine fragment are characterised by higher E_{a}^{BA} compared to the compounds with electron-donating substituents.

IX. Photochemical properties of spirooxazines

The efficiency of photoreactions is estimated from the quantum yields. However, the determination of the quantum yields for photochromic systems presents difficulties associated primarily with the determination of the molar extinction coefficients of the coloured forms. This is the reason why many researchers use more readily available parameters, such as the colourability⁹⁵ or photochromic response.⁶

In the general case, by the colourability is meant a certain value, which is either proportional or equal to the product of the quantum yield of the photoreaction (Φ_{col}) by the molar extinction coefficient at the absorption maximum of the photoproduct (ϵ_{B}). For instance, the optical density at the induced absorption maximum measured directly after the flash of a photolytic lamp was taken as the colourability (A_0) in the study.¹⁷⁹ Since the energy of photolysing radiation remained stable in the course of the experiment, the authors of the cited study believed that it is reasonable to compare the efficiency of photoprocesses involving structurally similar photochromes in solutions with the same concentration.

In another study,⁶⁸ the colourability (A_{∞}) was assigned the equilibrium value of the optical density at the absorption maximum of the photoproducts formed in solutions of SPO with the same concentration in the photostationary state. Sometimes, ϵ_{app} {the apparent molar extinction coefficient numerically equal to the ratio $A_0/([A]I)$, where $[A]$ is the initial concentration of the

photochrome and l is the optical path length} is used instead of A_0 .¹⁸⁰

The photochromic responses for several groups of SPO were given in the review.⁶ The authors noted that an estimating comparison of the efficiency of photocolouration of photochromes belonging to the same group of SPO can be performed, whereas a comparison of photochromes belonging to different groups is impermissible. A more strict approach to the estimation of the efficiency of photoreactions was proposed in the study.¹⁸¹ In the cited study, the product $\Phi_{\text{col}}\varepsilon_{\text{B}}$ was determined taking into account the fraction of light absorbed by the initial form. In this case, the colourability is independent of the conditions of irradiation. However, the uncertainty in the estimation of the photochemical activity of molecular systems associated with the determination of ε_{B} persists.

The universal character of the quantum yields (unlike the colourability) enables one to compare the photochemical properties of compounds with different structures in various media and in a wide temperature range. The correctness of the determination of the quantum yields of phototransformations depends on how much the molar extinction coefficients of the coloured forms determined by a particular method differ from the true values.

One method for the determination of the molar extinction coefficients, which is based on stabilisation and accumulation of photoproducts, involves the photocolouration reaction at low temperatures excluding the reverse[†] thermal reaction.^{13, 166, 175, 182} It is assumed that low-temperature photolysis affords only one stable isomer of the coloured form.

In alternative methods for the determination of the molar extinction coefficients, the coloured form is stabilised by the reactions with acids (protonation) or metal ions (complex formation). Actually, the starting form is completely consumed in these reactions, *i.e.*, the complete conversion $\text{A} \rightarrow \text{B}$ takes place. However, the resulting compounds have spectral characteristics, which differ from those of the photoproducts, and the assumption that their molar extinction coefficients have similar values seems to be unjustified.

A method for the determination of the molar extinction coefficients of the coloured forms with the use of the quantitative analysis of the equilibrium $\text{A} \rightleftharpoons \text{B}$ by NMR spectroscopy and spectrophotometry is quite rigorous, but the application of this method is limited to a narrow range of compounds for which the content of the coloured form in the equilibrium mixture is sufficient for NMR spectroscopic study.^{95, 96}

Good results were obtained with the use of a photokinetic method by analysing the kinetic curves, which are measured under continuous irradiation.¹⁸³ However, this method places stringent requirements on the planning and execution of the experiment as well as on the accuracy of the determination of the initial parameters (initial concentration of the photochromic compound, intensity of incident light, temperature, *etc.*). Thermal and photochemical processes, which occur in the systems within the framework of the assumed model, are described by a differential equation system including the molar extinction coefficients of the initial forms and final products, quantum yields of forward and reverse photoreactions and rate constants of thermal processes. A solution of this differential equation system enables one to obtain model characteristics of photochromic systems. However, even in the simplest case, the model includes four processes (forward and reverse thermal and photochemical reactions) involving two forms of SPO (initial cyclic and merocyanine) and, hence, the differential equation system cannot be solved analytically. To solve such systems, researchers have to use various approximations, in which particular processes are ignored.

[†] The occurrence of the reverse photoreaction leads to the attainment of a photostationary state rather than to the complete conversion $\text{A} \rightarrow \text{B}$ and, as a consequence, to the error in the determination of the molar extinction coefficients.

For example, in one of the first studies¹⁸⁴ devoted to the detailed investigation of the kinetics of photoinduced processes in SPO molecules, the authors considered spiroindolinonaphthooxazines containing electron-donating substituents at position 6' and concluded that the reverse photoreaction could be ignored because the ratio of the quantum yields of the reverse and forward photoreactions is in the range of 0.03–0.07. In more recent studies^{166, 168, 185} of the kinetics of photoinduced reactions of SPO, whose molecular structures differ from those studied earlier, the authors also ignored the reverse photoreaction with the unjustified reference to the results of the study.¹⁸⁴

An approach which involves the numerical integration of differential equations using the Runge–Kutta method and an iteration procedure using the Powell minimisation algorithm shows more promise. In this approach, the calculated and experimental photokinetic curves are compared and the modification of the parameters of the photochromic system is terminated once the discrepancy between the curves reaches the specified minimum value. The results obtained with the use of this method (in particular, for SPO)^{66, 96} are characterised by high stability and are independent of a particular experimental apparatus.

The quantum yields of photocolouration (Φ_{AB}) of SPO are higher than those of photodecolouration (Φ_{BA}), but the differences do not always reach the value given in the study.¹⁸⁴ As can be seen from Table 10, the quantum yield ratio $\Phi_{\text{BA}}/\Phi_{\text{AB}}$ varies from 0.001 to 0.5 depending on the structure of SPO and the nature of the solvents.

The efficiency of the forward photoreaction decreases in the presence of electron-withdrawing substituents in the naphthooxazine fragment and, by contrast, the presence of electron-donating groups in this moiety of SPO does not lead to changes (or increases) in the yields of the coloured isomers compared to unsubstituted SPO **1**. The introduction of electron-donating groups at position 5 of the indoline fragment leads to a noticeable decrease in the quantum yield of the forward photoreaction.

The quantum yields of photodecolouration upon the above-mentioned structural modifications are changed in the opposite order. For SPO containing electron-withdrawing substituents in the naphthooxazine fragment, Φ_{BA} are higher than those for SPO containing electron-donating substituents. In most cases, the introduction of the alkoxy groups at position 5 of the indoline fragment facilitates photorecyclisation.

The dependences of the quantum yields of the forward and reverse photoreactions of SPO on the nature of the solvent are opposite in character, *i.e.*, the quantum yields of photocolouration are lower in polar solvents and alcohols, whereas the efficiency of photodecolouration is lower in non-polar solvents (see Table 10).

The influence of the molecular structure and properties of the solvents on the efficiency of photoprocesses in SPO molecules correlates with their effect on the activation energy of thermal recyclisation because of the characteristic features of the structural and energy mechanisms of photoinduced reactions in SPO molecules.

The formation of the coloured product proceeds in two steps involving the $\text{C}_{\text{spiro}}-\text{O}$ bond cleavage followed by *cis*–*trans* isomerisation to the stable merocyanine form. Picosecond^{188–190} and femtosecond^{191, 192} photolysis revealed the existence of a short-lived cisoid¹⁹⁰ intermediate generated in the course of the $\text{A} \rightarrow \text{B}$ transformation. In these studies, an important conclusion concerning the energy mechanism of SPO photocolouration was made. It was established that only singlet excited states are involved in the photoinduced transformations of SPO.

The excitation of SPO molecules to the S_1 state is accompanied by the adiabatic $\text{C}_{\text{spiro}}-\text{O}$ bond cleavage and the formation of the cisoid isomer of the merocyanine form, which is then transformed into the ground state. Isomerisation gives rise to the metastable *TTC* isomer. This accounts for the fact that an increase in the potential barrier E_{a}^{AB} can lead to a decrease in the observed yield of the coloured product **B**. For the reverse photoreaction

Table 10. Quantum yields of photocoloration (Φ_{AB}) and photodecoloration (Φ_{BA}) of spirooxazines.

(assuming that it proceeds through the same cisoid intermediate), an increase in the barrier E_a^{BA} leads to an increase in probability of recyclisation.

Apparently, high quantum yields of photocoloration of nitro-substituted spiroindolinonaphthooxazines are associated with the triplet reaction mechanism.¹⁸⁷ This assumption is indirectly supported by low photostability of 5-nitro-substituted spiroindolinonaphthooxazine **29**.¹⁹³

The resistance of photochromes to photodegradation depends also on the involvement of the triplet states of the starting, intermediate and final forms in phototransformations of the photochromes because the molecules in the triplet state possess higher reactivity and can interact with dissolved oxygen and solvent molecules as well as can undergo irreversible intramolecular rearrangements. The degrees of photodegradation of SPO are lower than those of their structural analogues, *viz.*, spiropyran,¹⁹³ which is in good agreement with the singlet mechanism of phototransformations found for a series of SPO.

Destruction of spirooxazines was considered in the review.¹¹⁶

X. Conclusion

On the basis of the above-considered published data, it can be stated that a qualitative and quantitative leap forward has been made in the chemistry of SPO. Particularly considerable progress

has been achieved in the synthesis and functionalisation of spirooxazines. Numerous investigations revealed the structural factors, which exert an effect on the spectral characteristics, thermodynamic parameters of equilibria, kinetics of relaxation processes and efficiency of SPO phototransformations.

Due to the preparation of a large number of new SPO, the field of their practical application has been substantially extended. In particular, the possibilities of the use of spirooxazines in materials for recording information, optical switches¹⁹⁴ and photochromic chemosensors^{195, 196} were considered.

However, a series of practically important properties of spirooxazines are as yet insufficiently known, which leaves a wide sphere of research activity. In particular, photochromic processes in the solid phase were poorly studied.^{124, 197} Data on the fluorescence properties of spirooxazines are scarce.¹⁹⁸ Data on cross-sections of two-photon light absorption of cyclic and merocyanine forms of SPO are lacking. The latter parameter is of importance in using SPO for the construction of media for the three-dimensional recording systems (molecular memory) and photomodulated biomaterials. For spiropyran, this parameter reaches $10^{-48} \text{ cm}^4 \text{ s}$ (which is a large value for organic molecules; see Ref. 199). For structurally similar spirooxazines, this parameter would be expected to assume values of the same order of magnitude. Finally, there are only scarce data on the supra-molecular effects exhibited by spirooxazines. The first evidence²⁰⁰

for the formation of stable aggregates of merocyanine forms in solutions of spirooxazines, which are characterised by narrow absorption bands and are of interest for multifrequency systems,²⁰¹ have been published only recently.

We are grateful to Academician V I Minkin for helpful discussion and valuable advice in the discussion of the paper.

V. Polymer-bound norbornadienes and sensitisers	923
VI. Conclusion	925

Abstract. Data on the valence isomerisation of norbornadiene and its derivatives into the corresponding quadricyclanes published between 1990 and 2001 are considered and described systematically. The applicability of this reaction for the storage of solar energy is discussed. The bibliography includes 112 references.

I. Introduction

About ten years have passed since the publication of our review¹ in which the norbornadiene–quadricyclane system was considered as a promising accumulator and converter for solar energy. However, the interest in the problem of solar energy accumulation has not slackened. This results from the fact that irreplaceable natural energy sources, *i.e.*, coal, oil and natural gas, are still being consumed almost without control;^{2–4} furthermore, the problems related to climate changes on the Earth due to the emission of enormous amounts of carbon dioxide, as well as products of incomplete combustion of natural fuel, into the atmosphere are becoming ever more critical.⁵

The possible ways to utilise solar energy are extremely diverse.^{6,7} They include the use of solar energy to perform various photocatalytic processes,^{8–10} photodecomposition of water and photolytic production of hydrogen,^{11,12} as well as various photo-biological processes, including artificial photosynthesis.^{13–15} An alternative abiotic approach to the transformation of solar energy is to accumulate it as the strain energy in metastable photoinduced isomers of organic compounds. The norbornadiene–quadricyclane system is most promising for this purpose.^{16,17} Its advantage is that the valence isomerisation of bicyclo[2.2.1]hepta-2,5-diene (norbornadiene, NBD) (**1**) into tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclane, Q) (**2**) better fits the requirements for organic photochromes intended as solar energy accumulators.¹

Received 24 June 2002

Uspekhi Khimii 71 (11) 1040–1050 (2002); translated by S S Veselyi

The photoisomerisation of NBD results in a metastable quadricyclane structure containing highly strained cyclobutane and two cyclopropane fragments. As a result, the reverse thermal or catalytic reaction **2** → **1** is characterised by a considerable thermal effect ($\Delta H = -89 \text{ kJ mol}^{-1}$) (see Ref. 18), which is greater than the ΔH value for other photochromic systems. There is a wide range of homo- and heterogeneous catalysts that enable this reaction to be performed and hence thermal energy to be evolved,^{1,16} but the high activation barrier to the thermal transformation **2** → **1** (even at 140 °C, the half-life period of quadricyclane **2** is 14 h)¹⁹ makes it possible to store the accumulated solar energy for a long time.

However, the system **1** → **2** has a number of considerable drawbacks. First, the longwave absorption edge of non-substituted NBD **1** (λ_{ae} , $\epsilon = 1 \text{ litre mol}^{-1} \text{ cm}^{-1}$) is no higher than 300 nm.²⁰ Second, the quantum yield (Φ) of the valence isomerisation **1** → **2** in the absence of sensitising agents is ~ 0.05 (see Refs 20, 21). In order that this system could be used on industrial scale as a solar energy accumulator, one has to chemically modify NBD for shifting the values of λ_{ae} towards the maximum of the light energy of the Sun (400–600 nm) and at the same time for increasing the photoisomerisation quantum yield. This review presents a generalisation of the studies that dealt with this problem and were carried out between 1990 and 2001. The following general directions can be distinguished: (1) the use of sensitisers for the valence isomerisation **1** → **2**, including those chemically bound to the NBD molecule; (2) modification of the structure of the starting NBD to increase λ_{ae} and Φ ; (3) the use of various polymeric systems containing NBD (or its derivatives) in the lateral or main chain of the macromolecule, as well as polymer-bound sensitisers.

II. Photosensitisation of the valence isomerisation of norbornadiene into quadricyclane

As a rule, the isomerisation **1** → **2** involves the triplet state of NBD.^{22–25} Therefore, at the initial stage of the studies under discussion, the photosensitisation was performed mostly by various carbonyl compounds (acetophenone, propiophenone, benzophenone, acridinone, Michler's ketone and some others) known as triplet sensitisers (S).^{24–27} Since the energy of the triplet state (E_T) of NBD is very high ($\sim 257 \text{ kJ mol}^{-1}$),^{22,28} only a small number of sensitisers with high E_T fit the classical triplet–triplet transfer scheme:

The intramolecular energy transfer from the second triplet (via the T_2 state) of the anthracene fragment to the norbornadiene moiety of compound **7** causes its isomerisation to quadricyclane **8**.⁴⁴ This mechanism was proven using two-photon flash-photolysis ($\lambda_{\text{exc}}^1 = 260\text{--}290\text{ nm}$, $\lambda_{\text{exc}}^2 > 410\text{ nm}$); the quantum yield of the photoreaction in benzene is 0.022.

In the past decade, intense studies were carried out on the photophysical and photochemical features of intramolecular processes of energy or electron transfer through a rigid steroid bridge (SB), which links benzophenone (BP) or benzidine (BZ) with a norbornadiene molecule.^{45–48} For example, the dichromophoric 3 β -{[2-(methoxycarbonyl)bicyclo-[2.2.1]hepta-2,5-dien-3-yl]carbonyloxy}androst-5-en-17 β -ylbenzophenone-4-carboxylate (**9a**, NBD–SB–BP) undergoes isomerisation upon steady-state irradiation ($\lambda_{\text{irr}} > 350\text{ nm}$) to give a photo-product **10a** (Q–SB–BP) with a quantum yield $\Phi = 0.038$.

It should be noted that only the benzophenone chromophore can absorb irradiation under these conditions. Singlet-excited benzophenone forms the triplet state ^3BP by fast and efficient intersystem crossing. The main pathway of ^3BP deactivation involves triplet–triplet energy transfer to the norbornadiene fragment through the system of σ -bonds of the steroid bridge.

The quantum yield of isomerisation of 3 β -{[2-methoxycarbonyl]bicyclo[2.2.1]hepta-2,5-dien-3-yl]carbonyloxy}androst-5-en-17 β -yl-2,2',6,6',N,N',N'-heptamethylbenzidine (**9b**, NBD–SB–BZ) in cyclohexane is 0.07 ($\lambda_{\text{irr}} > 300\text{ nm}$), with quantitative formation of the photo-product **10b** and with no side reactions. In this case, the isomerisation scheme suggested by Tung *et al.*⁴⁵ involves not only the triplet–triplet energy transfer but also the formation of a triplet radical-ion state, which then undergoes recombination to the triplet-excited state of NBD.

The rate constants for the corresponding steps are as follows: $k_1 = 1.1 \times 10^7\text{ s}^{-1}$, $k_2 = 5.2 \times 10^7\text{ s}^{-1}$, $k_3 = 5.2 \times 10^5\text{ s}^{-1}$ (the values in parentheses correspond to the energies of the states with respect to the ground state of compound **9b**).

The latter examples of valence isomerisation open a new approach to sensitisation, in which a coloured chromophore sensitizer that is remote from the norbornadiene fragment can undergo photoexcitation.

III. 'Donor–acceptor' norbornadienes

Non-substituted NBD is a formally non-conjugated, non-planar, strained diene. The steric strain in its molecule allows through-space interaction of the C=C bond π -orbitals.^{49–51} As a result, non-substituted NBD absorbs light in a longer-wave spectrum region than two isolated C=C bonds. The systems **11** in which the interaction of electron-donating substituents at one of the carbon–carbon double bonds in the molecule with electron-withdrawing substituents at another bond results in a low-intensity charge transfer band ($\epsilon < 10^2\text{ litre mol}^{-1}\text{ cm}^{-1}$) were called 'donor–acceptor' NBD.⁵² The long-wave absorption edge of these compounds (λ_{ae}) can be as high as 500–560 nm.

X = CH₂, CMe₂; R¹, R² = H, Me, Ph, 4-MeOC₆H₄;

R⁴, R⁵ = CN, CO₂Me, CO₂Et, CONHPh; R³, R⁶ = H, Me.

The geometrical structure and electronic absorption spectrum of norbornadiene were studied^{53–55} with consideration of indirect conjugation of double bonds and π , σ -interaction. This interaction was observed experimentally when studying the electronic absorption spectra of bicyclo[2.2.*n*]alka-2,5-dienes **13**.⁵²

When *n* changes from 3 to 1, the angle θ decreases gradually. This is accompanied by a bathochromic shift of the long-wave absorption band (λ_{max}) from 305 to 338 nm with simultaneous increase in the molar extinction coefficient (ϵ_{max}) from 178 to 200 litre mol^{−1} cm^{−1}. The value of λ_{ae} in the spectra of norbornadienes **11** can be as high as 560 nm, while the quantum yields of the photoreaction **11** → **12** are high ($\Phi = 0.26\text{--}0.75$). However, despite high Φ values, the applicability of compounds **11** for the storage of solar energy is limited due to the following factors: (1) the low extinction coefficient ($\epsilon_{\text{max}} \approx 1000\text{ litre mol}^{-1}\text{ s}^{-1}$) makes the efficiency of the **11** → **12** process low and requires prolonged exposure to light; (2) many quadricyclanes **12** are unstable at room temperature and undergo spontaneous rear-

rangement to the original NBD **11**. Although some attempts to increase the thermal stabilities of quadricyclanes by introduction of perfluoroalkyl substituents have been undertaken a long time ago,⁵⁶ it is only in recent years that reliable methods for the synthesis of the 'donor–acceptor' NBD **14** have been developed; the latter are not only thermally stable at room temperature but also absorb solar energy quite efficiently (Table 1).^{57, 58}

R¹, R² = 4-MeOC₆H₄, 4-Me₂NC₆H₄, 2-benzofuryl, 2-thienyl.

Table 1. Spectral characteristics of norbornadienes **14** and thermal stabilities of quadricyclanes **15**.^{57, 58}

^a Half-life of quadricyclane. ^b Quadricyclane is stable at 20 °C.

Unlike compounds **11**, norbornadienes **14** have high values of $\epsilon_{\max}$ ranging from 5000 to 20 000 litre mol⁻¹ cm⁻¹. Their absorption edge increases as the electron-donating properties of the substituents R¹ and R² increase; in fact, λ_{ae} = 580 nm for norbornadiene **14a**. The thermal stabilities of quadricyclanes **15** are sufficiently high for the practical storage of solar energy; the number of cycles **14** ⇌ **15** reaches 10³ without considerable destruction of the starting compound.

IV. 2,3-Disubstituted norbornadienes

The synthesis of 'donor–acceptor' norbornadienes faces considerable difficulties: polysubstituted cyclopentadiene derivatives and disubstituted acetylene derivatives are first synthesised and then brought into the Diels–Alder reaction. 2,3-Disubstituted norbornadienes can also be synthesised from non-substituted cyclopentadiene and 1,2-disubstituted acetylene. The studies carried out over the past ten years have shown that in many cases, the presence of an electron-donating substituent and an electron-withdrawing substituent at one of the two double bonds of the norbornadiene molecule is sufficient for their spectral and photochemical characteristics not to be inferior, and sometimes even to be superior, to the corresponding parameters of the 'donor–acceptor' NBD. Two substituents of the same nature shift the λ_{ae} value only slightly towards the solar radiation maximum.^{59, 60} For example, the absorption of 2,3-di(*tert*-butylsulfonyl)norbornadiene (**16**) is characterised by a slight bathochromic shift with respect to the maximum absorption of non-substituted NBD **1**, although the **16** → **17** isomerisation occurs quantitatively in ether under irradiation with light with $\lambda_{\text{irr}} > 280$ nm.

The valence isomerisation of the 2,3-dicyanonorbornadiene–pentaamminoruthenium(II) complex **18** is an exception.⁶¹ The long-wave absorption maximum of norbornadiene **18** in methanol is observed around 490 nm ($\epsilon \approx 14\,000$ litre mol⁻¹ s⁻¹); the λ_{ae} is 700 nm, but the quantum yield of the formation of the quadricyclane **19** upon irradiation with light with $\lambda_{\text{irr}} = 500$ nm is as low as 8.3×10^{-4} .

Combination of an electron-withdrawing and an electron-donating substituents at one of the carbon–carbon double bonds in NBD favours an increase in the isomerisation quantum yield. The electronic absorption spectra and the quantum yields of the phototransformation of 3-phenylnorbornadiene-2-carboxylic acid (**20a**) and its esters **20b–d** are listed in Table 2.^{62, 63} Although these systems absorb in the spectral region $\lambda < 360$ nm, the fast and quantitative photoisomerisation **20** → **21**, which takes a few seconds in DMSO, acetonitrile, ethanol and THF ($c = 5 \times 10^{-5}$ mol litre⁻¹), allows us to consider the norbornadienes **20** to be an efficient system for the accumulation of solar energy.

R = H (**a**), CH₂Ph (**b**), CH₂C₆H₄OMe-4 (**c**), (CH₂)₆OC₆H₄OMe-4 (**d**).

Table 2. Spectral characteristics of norbornadienes **20** and quantum yields of the photoreactions **20** → **21** in acetonitrile.^{62, 63}

Com- pound 20	R	$\lambda_{\max}$ /nm ($10^{-4} \epsilon_{\max}$ /litre mol ⁻¹ cm ⁻¹)	λ_{ae} /nm	Φ ($\lambda_{\text{irr}} = 284$ nm)

2-Trifluoroacetyl-3-phenylnorbornadiene (**22**) absorbs light at $\lambda_{\text{ae}} \leq 460$ nm; its photoisomerisation into the quadricyclane **23** in benzene occurs quantitatively with a quantum yield $\Phi = 0.62–0.86$ (depending on the starting concentration of norbornadiene).^{64, 65}

R = CF₃ (**22**, **23**), NHAr (**24**, **25**).

Involvement of the carbon–carbon double bond of norbornadiene in the conjugation chain Ph–C=C–CONHR affects the λ_{ae} and Φ values even more significantly.

We have studied the spectral and photochemical features of 3-phenylnorbornadiene-2-carboxamides **24**.^{66, 67} Compounds **24** are characterised by absorption in the region 280–305 nm (Table 3) and $\lambda_{\text{ae}} = 375–435$ nm.^{66, 67} Irradiation with light with a wavelength corresponding to the long-wave absorption maximum ($\lambda_{\text{irr}} = 313$ nm) results in their isomerisation to give quadricyclanes **25** with high quantum yields. Electron-withdrawing substituents in the *N*-phenyl ring increase the Φ value in comparison with non-substituted 3-phenyl-2-(*N*-phenylcarbamoyl)norbornadiene **24a**, whereas electron-donor substituents decrease this

Table 3. Spectral characteristics of 3-phenylnorbornadiene-2-carboxamides **24** and quadricyclanes **25** and quantum yields of the photoreaction **24** → **25** in propan-2-ol.^{66, 67}

value. However, it should be noted that as electron-withdrawing groups are introduced, the λ_{ae} values of norbornadienes **24** become closer to those of quadricyclanes **25**, hence the efficiency of solar energy accumulation decreases. The quadricyclanes obtained upon valence isomerisation **24** → **25** are stable at room temperature and in the presence of acid catalysts. In the presence of MoO₃ as a heterogeneous catalyst, they undergo rearrangement to the original NBD with a rate constant of $k = 5 \times 10^{-2} - 10^{-3} \text{ s}^{-1}$ at 293 K.

Since the triplet mechanism of isomerisation of norbornadiene into quadricyclane can occur with high quantum yields in the presence of aromatic ketones, we studied norbornadienes **26** with one of the C=C bonds involved in the conjugation chain of the Ph–C=C–C=X fragment (Table 4).^{67–71}

R¹ = H, Me, OMe, CH=CHPh; R² = Br, Ar; X = O, CHCOAr.

Irradiation of NBD **26** in propan-2-ol at a wavelength corresponding to the maximum absorption in the long-wave region ($\lambda_{\text{irr}} = 313$ or 365 nm) results in quadricyclane structures **27**. Absorption at the highest wavelengths is observed in the case of 2-[2-(3-nitrobenzoyl)vinyl]-3-phenylnorbornadiene (**26i**): its absorption edge approaches 500 nm while the quantum yield of isomerisation is rather high ($\Phi = 0.25$). The highest value $\Phi = 0.60$ is observed for norbornadiene **26f**. Quadricyclanes **27** are stable at 293 K; however, they readily undergo isomerisation into the original compounds under conditions of homogeneous catalysis if a small amount of trifluoroacetic acid

($10^{-2} - 10^{-3} \text{ mol litre}^{-1}$) is added to their solutions in heptane ($5 \times 10^{-5} \text{ mol litre}^{-1}$). Since heterogeneous catalysis is more suitable for practical solar energy accumulation,¹ it seemed reasonable to study the effect of oxides, viz., V₂O₅, WO₃ and MoO₃, on quadricyclanes **27**. The best catalytic activity was observed for molybdenum(VI) oxide, which is characterised by the highest metal electronegativity in this series.⁷² Stirring of solutions of quadricyclanes **27** in heptane ($5 \times 10^{-5} \text{ mol litre}^{-1}$) with MoO₃ (0.2–0.5 mg per 2 ml of a solution) results in the original norbornadienes **26** with a rate constant $k = 10^{-2} - 5 \times 10^{-3} \text{ s}^{-1}$ at 291 K. Conditions for the repeated phototransformation **26** ⇌ **27** have been determined. The calculated turnover number with the loss of the working substance not exceeding 3% is $8 \times 10^2 - 10^3$.

Elongation of a conjugation chain involving one of the double bonds in norbornadiene may be a way to increase the λ_{ae} and Φ values. In view of this, we studied the spectral and photochemical properties of 3-arylnorbornadiene-2-carbaldehyde derivatives **28**, namely, oximes, imines, hydrazones, etc. (Table 5).^{67, 69, 71, 72} By varying the electron-donating and electron-withdrawing substituents at the C=C double bond in norbornadienes **28**, it became possible to shift the values of λ_{max} to 500 nm and λ_{ae} to 620 nm. Heterogeneous catalysis with Mo(VI) oxide described above proved to be efficient for the reverse reaction of the majority of quadricyclanes **29**.

R = H, NO₂, NH₂; X = NOH, NOME, NAr, NNPh, C(CN)₂, C(CN)CO₂Et, C(CO₂Et)₂.

^a For compounds **28a–c, k**, $\lambda_{\text{irr}} = 365$ nm.

More complete data on the effect of substituents on the state of C=C double bonds in norbornadiene were obtained from an X-ray diffraction study of compounds **28c** and **28g** (see Ref. 73) and comparison with literature data on the structure of non-substituted NBD^{53, 74} and 2-(2,2-diphenylvinyl)norbornadiene-3-carboxylic acid **30**.⁷⁵

Compounds	R ¹	R ²
1, 2	H	H
28c, 29c	Ph	CH=NPh
28g, 29g	Ph	CH=C(CN) ₂
30, 31	CO ₂ H	CH=CPh ₂

The lengths of single bonds in the molecule **28c** have ordinary values (1.57 Å on average), but the lengths of the C(2)=C(3) (1.342 Å) and C(5)=C(6) double bonds (1.310 Å) differ markedly from the lengths of similar bonds in non-substituted NBD **1** (1.333 Å). X-Ray diffraction data suggest that the C(2)=C(3) bond is conjugated with the azomethine C=N bond and with the π -bonds in the phenyl substituents; this results in its elongation with simultaneous shortening of the C(5)=C(6) bond. In the molecule **28g**, which contains a stronger electron-withdrawing substituent, the C(2)=C(3) bond is elongated considerably [to 1.38(1) Å], whereas the C(5)=C(6) bond is shortened [to 1.29(2) Å]. The quantum yield of this photoreaction increases in the order: 0.05 (**1**) < 0.15 (**28c**) < 0.74 (**28g**). A similar pattern of changes in the lengths of double bonds was found for norbornadiene **30**;⁷⁵ the C(2)=C(3) bond in this molecule is elongated to 1.359 Å due to the conjugation with the π -systems of the substituents, while the C(5)=C(6) bond is shortened to 1.271(4) Å. The presence of two electron-withdrawing substituents at the C=C double bond in norbornadienes **32a, b** affects the distribution of the bond lengths less significantly.^{76, 77} For example, the elongation of the C(2)=C(3) bond in the molecule of 2,3-dicyanonorbornadiene (**32a**) is insignificant [to 1.339(2) Å], whereas the C(5)=C(6) bond is shortened to 1.315 Å [in the molecule **32b**,

R = CN (**a**), CONH₂ (**b**).

the lengths of these bonds are 1.341(3) and 1.285(4) Å, respectively].

X-Ray diffraction data suggest convincingly that if one of the double bonds in norbornadiene is involved in a conjugation chain with an electron-donating and an electron-withdrawing substituents, its length increases in parallel with the λ_{ae} and Φ values.

In view of this, it seemed attractive to use organic cations as the electron-withdrawing component, although it has been shown previously^{78, 79} that the presence of pyridinium or pyrylium cations gives high values of λ_{ae} and Φ but results in irreversible opening of the cyclopropane fragment in the quadricyclanes formed. We have studied the photochemical properties of 2-benzooxazolyl and 2-benzimidazolyl derivatives of 3-phenylnorbornadiene **33a, b**.^{67, 69, 80} The benzooxazole derivative **33a** is characterised by $\lambda_{\text{ae}} = 550$ nm, but the **33a** → **34a** rearrangement occurs irreversibly. The λ_{ae} value for the benzimidazolyl derivative **33b** is 340–365 nm, depending on the type of the counter ion (I[−], ClO₄[−], BF₄[−], SbCl₆[−]), while the quantum yield of the photoreaction is 0.41–0.45. None of the known catalysts of the reverse reaction¹ affects quadricyclanes **34b**, whereas thermal initiation (343 K, solution in acetonitrile) results in the original NBD with a rate constant $k = 6 \times 10^{-4} \text{ s}^{-1}$, with complete restoration of the original spectrum. The cycle **33b** ⇌ **34b** can be repeated many times.

In order to increase the amount of accumulated solar energy per mol of the original compound, we have studied the dinorbornadiene systems **35a–e**.⁸¹ Dinorbornadienes **35a–e** absorb light in the region of 345–450 nm; the λ_{ae} values for compounds **35c–e** are as high as 530–560 nm. Irradiation of these compounds with light with a wavelength of 365 nm (**a, b**) or 436 nm (**c–e**) results in valence isomerisation into the corresponding monoquadricyclanes **36** and then into diquadricyclanes **37**. The two-step pattern of the photoreaction postulated previously for dinorbornadienyl derivatives of diamides⁸² was confirmed for 3-phenylnorbornadiene-2-carbaldazine (**35b**). The primary photoproduct **36b** is characterised by a new absorption band at 380 nm ($\lambda_{\text{irr}} = 436$ nm, $\Phi = 0.023$); its subsequent irradiation with a wavelength within this band ($\lambda_{\text{irr}} = 365$ nm, $\Phi = 0.028$) gives the diquadricyclane **37b**. The reverse transformation into the original dinorbornadienes can be carried out under conditions of homogeneous or

heterogeneous catalysis (addition of $\text{CF}_3\text{CO}_2\text{H}$ or MoO_3 , respectively).

V. Polymer-bound norbornadienes and sensitizers

One of the leading approaches to the accumulation of solar energy developed in recent years involves the use of polymeric systems containing non-substituted NBD or its derivatives in a lateral or main chain of the macromolecule as well as polymer-bound sensitizers of the valence isomerisation $\text{NBD} \rightarrow \text{Q}$. This is primarily due to the fact that norbornadiene fragments incorporated in a polymer are more stable than free NBD molecules with the same substituents. In many cases, this makes it possible to avoid side reactions and to increase the quantum yield of $\text{NBD} \rightarrow \text{Q}$ photoisomerisation and the turnover number.

The first studies along this direction were aimed at the synthesis of polymer-bound benzophenone or acetophenone, but the photo-stability of such sensitizers proved to be rather low.^{83, 84} Polymeric photosensitizers of a new type (38) containing ammonium or phosphonium groups (for binding the substrate) together with sensitizing nitroaryloxy groups were used to carry out the 39 → 40 photoisomerisation.⁸⁵

The quantum yield of this reaction was 0.19 at $\lambda_{\text{irr}} = 366 \text{ nm}$ in the absence of a sensitizer and 0.42 in the presence of the polymer 38, suggesting that intermolecular energy transfer occurred from the sensitizer (38) to the norbornadiene (39).

Irradiation of the polymers 41 in the visible spectral region ($\lambda_{\text{irr}} > 350 \text{ nm}$) results in their valence isomerisation into the quadricyclane derivatives 42.⁸⁶ A mechanism of this process was suggested, which involved the intramolecular electron transfer from the carbazole (CA) sensitizer to the norbornadiene fragment:

The reverse reaction occurs in the presence of catalytic amounts of (5,10,15,20-tetraphenyl-21*H*,23*H*-porphyrinato)-cobalt(II) (Co-TPP).

The valence isomerisation of polyesters 43 containing benzophenone and norbornadiene fragments occurs both in polymeric films and in solutions in dichloromethane ($\Phi = 0.62\text{--}0.84$) and involves a stage of efficient energy transfer from the sensitizer to NBD.⁸⁷ Compounds 44 are rather stable; the reverse reaction 44 → 43 releases $\sim 90 \text{ kJ mol}^{-1}$ of the accumulated thermal energy.

Polyamides 45 containing non-substituted norbornadiene fragments in the main chain are characterised by values $\lambda_{\text{ae}} \leq 440 \text{ nm}$.^{88–90} Irradiation of these compounds in this spectral region results in the selective isomerisation of NBD into quadricyclanes without side reactions. Incorporation of a sensitizer, e.g., Michler's ketone or 4-(*N,N*-dimethylamino)benzophenone, in the polymer increases the efficiency of the 45 → 46 process. The reverse transformation occurs upon addition of Co-TPP to a solution of the polyamide 46 in dichloromethane or upon irradiation of polymeric films of 46 with light with $\lambda_{\text{irr}} = 235\text{--}260 \text{ nm}$.

Polyesters **47** with similar composition also readily undergo photoisomerisation on exposure to sunlight in polymeric films or as solutions in THF to give quadricyclane derivatives **48**.⁹¹

The reverse transformation of solid polymers **48** occurs efficiently under irradiation with light with $\lambda_{\text{irr}} = 272$ nm and is accompanied by liberation of heat (~ 84 kJ mol⁻¹).

'Donor-acceptor' NBD can also be incorporated in the main chain of a polymeric molecule.^{92,93} Owing to the existence of a charge transfer band, polyesters **49** have $\lambda_{\text{ae}} \leq 500$ nm. Irradiation of polymeric films of compound **49** with visible light yields isomeric compounds **50**; the reverse reaction occurs slowly at room temperature.

The majority of studies in this field deal with polymers in which the NBD residues are 'attached' to the main chain of the macromolecule.^{5,94-103} For example, polyisoprene **51** is isomerised in a benzene solution in the presence of $(\text{PPh}_3)_2\text{CuBr}$ as the sensitiser.⁹⁴ The reaction **52** $\rightarrow$ **51** is thermally reversible on heating of the polymer to 180 °C.

Irradiation of polymers **53**, which contain the residue of 3-phenylnorbornadiene-2-carboxylic acid, with light with $\lambda_{\text{irr}} = 313$ nm results in their isomerisation into quadricyclanes **54**.^{95,96} The reverse transformation is performed upon irradiation at $\lambda_{\text{irr}} = 248$ nm, heating to 100 °C, or adding Co-TPP to a solution of the polymer **54** in dichloromethane.

Polymer-bound amides **55a-e** were obtained in order to shift λ_{ae} to higher wavelengths; they are characterised by absorption at $\lambda_{\text{max}} = 323-351$ nm and an absorption edge at $\lambda_{\text{ae}} = 425-440$ nm.⁹⁷ Under irradiation of compounds **55a-e** with light of a mercury lamp or with sunlight, the valence isomerisation occurs readily, both in solid phase and in solutions of the polymers in THF. Its efficiency increases in the series: **55e** < **55d** < **55a** < **55b** < **55c**. Addition of Co-TPP to solutions of the quadricyclanes **56a-e** at 298 K results in their isomerisation into norbornadienes **55a-e** with a rate constant $k = (0.5-0.7) \times 10^3$ s⁻¹. The amount of the accumulated solar energy is evaluated to be 60 kJ mol⁻¹, although the presence of an *N,N*-disubstituted amide group in the norbornadiene fragment increases it to 80-86 kJ mol⁻¹ (see Ref. 98).

$\text{R} = \text{H (a)}, \text{Me (b)}, \text{OMe (c)}, \text{Cl (d)}, \text{COMe (e)}.$

Binding of NBD moieties with a polyester macromolecule gave photoactive systems **57**.⁵ Valence isomerisation of the latter into quadricyclanes **58** occurs readily under irradiation of the polymer at $\lambda_{\text{irr}} \leq 400$ nm, both in solid phase and in solutions in THF ($\Phi = 0.33-0.41$). The reverse transformation **58** $\rightarrow$ **57** is carried out using low-temperature initiation (62-75 °C). The amount of solar energy accumulated in this photoreaction is very high, viz., about 90 kJ mol⁻¹.

Polymers **59** with the residues of 'donor-acceptor' NBD were obtained in order to shift the λ_{ae} values farther towards the solar radiation maximum.⁹⁹ However, they were found to have $\lambda_{\text{ae}} \leq 350$ nm. Nevertheless, these compounds are characterised

by high turnover rate of the $59 \rightleftharpoons 60$ transformation and can store 55–74 kJ mol⁻¹ of thermal energy.

Polymers **61** containing trifluoromethyl-substituted NBD present an improved version of systems of this type. Their efficient phototransformation into the isomers **62** can be carried out under irradiation in the visible spectral region (up to $\lambda_{\text{ae}} \leq 505$ nm).¹⁰⁰

The main drawback of the majority of the polymeric systems described above is their insufficient photo- and thermal stability, which limits the NBD $\rightleftharpoons$ Q turnover number. When norbornadienes **63** bound to a rigid polymeric system undergo photoisomerisation, they maintain the most important spectral and photochemical features of the NBD $\rightarrow$ Q transformation, but they have an enhanced stability in the cyclic reactions $63 \rightleftharpoons 64$.^{101, 102}

Norbornadiene-containing polystyrenes insoluble in organic solvents are even more stable.¹⁰³ Irradiation of their suspensions in dichloromethane results in isomeric quadricyclanes; in the presence of Co-TPP, the reverse reaction occurs with liberation of accumulated energy (44–77 kJ mol⁻¹).

VI. Conclusion

Analysis of recently published studies on the valence isomerisation of norbornadiene and its derivatives into the corresponding quadricyclanes revealed two major trends in relation to the accumulation of solar energy: (1) the total number of publications on this subject has decreased somewhat; (2) at the same time, we observe a significant increase in the number of studies that not only pose a certain problem but also suggest specific ways to solve it practically. In our opinion, this indicates that this problem is nearly solved rather than that the interest in the accumulation of solar energy with the use of NBD is being lost. As mentioned previously,¹ the thermal energy obtained by the method in question is more expensive than that generated by conventional methods, but cost issues will inevitably become less important as natural fuel resources are exhausted. We distinguished four main competing approaches that are used for enhancing the efficiency of isomerisation of norbornadienes into quadricyclanes. It can be concluded that considerable success has been reached along each of these directions. Efficient ways for the photosensitisation of this reaction have been developed using metal complexes or sensitizers chemically bound with the NBD molecule; in certain cases, the number of working cycles can be as high as 5000. Owing to the enhanced thermal stabilities of 'donor–acceptor' systems in which NBD molecules contain perfluoroalkyl substituents, such derivatives are promising for practical application. 2,3-Disubstituted NBD are serious competitors to these systems. This is primarily due to the facts that they are easier to synthesise and that they can absorb sunlight in the spectral region $\lambda > 400$ nm. Polymer-bound NBD can provide acceptable cyclicity and allow up to 94 kJ mol⁻¹ of solar energy to be accumulated. It is also obvious that, beside the accumulation of solar energy, the norbornadiene–quadricyclane system finds diverse new fields of application: creating molecular switches^{61, 104, 105} and optical waveguides on their basis,^{106, 107} developing new types of photochromic chemosensors for metal cations^{108, 109} and photo-switchable organic magnetic materials.^{110–112} Furthermore, NBD-containing polymers can be used as energy-boosting additives for rocket fuel.⁹⁴

Abstract. The published data on the synthesis, reactions and structures of novel organotellurium synthones, *viz.*, β -tellurovinylcarbonyl compounds, are systematised and generalised. Special attention is given to the use of these compounds in the synthesis of tellurium-containing heterocycles. The bibliography includes 57 references.

I. Introduction

β -Tellurovinylcarbonyl compounds (aldehydes and ketones) are of particular interest as starting compounds for the synthesis of various tellurium-containing heterocycles and metal chelates with the coordination sites MO_2Te_2 and MN_2Te_2 (M is metal). However, the chemistry of these compounds has not been adequately investigated. The first β -telluroacroleins and β -aryltellurovinyl ketones were prepared by nucleophilic addition of arenetelluroate anions ArTe^- to α -acetylenic aldehydes and ketones (yields 65%–75%).¹ Bis(β -acylvinyl) tellurides were synthesised in 3%–11% yields² using a similar approach, *i.e.*, by nucleophilic addition of the telluride anion Te^{2-} to α -acetylenic ketones (the reasons for the low yields of ketone will be discussed below). Two other types of β -tellurovinylcarbonyl compounds, *viz.*, aryl β -chlorotellurovinyl ketones and aryl β -trihalogenotellurovinyl ketones were prepared in the 1980's.³ The former were synthesised in four steps; the final step included the rearrangement of 3-(aryltelluro)propenoyl chlorides (yields 50%–95%).³ Aryl (β -trihalogenotellurovinyl) ketones were obtained in good yields by oxidation of tellurenyl halides with halogens.⁴

Earlier, β -tellurovinylcarbonyl compounds were used exclusively for the preparation of tellurophenes containing strong electron-withdrawing groups in position 2 (NO_2 , CHO, COMe, CO_2Et)⁵ and 1,6-dioxo-6 α -tellurapentalenes.⁶

Significant progress in the chemistry of β -telluroacroleins and β -tellurovinyl ketones has been achieved over the last 8–10 years owing to the development of methods for their synthesis. (β -Formylvinyl)(methyl)tellurium dihalides, a novel class of β -tellurovinylcarbonyl compounds, have proved to be convenient starting compounds in the synthesis of (β -halogenotellurovinyl)carbonyl

derivatives and the previously unknown β -halogenotellurovinyl aldimines. Preparative procedures for the synthesis of various tellurium-containing heterocycles based on β -tellurovinylcarbonyl compounds have been developed.

The distinguishing feature of organotellurium compounds is the formation of intramolecular hypervalent coordinative bonds between the oxygen (or nitrogen) atom and the tellurium atom [$\text{O}(\text{N}) \rightarrow \text{Te}$]; their lengths vary over a wide range, sometimes being close to the lengths of ordinary covalent bonds. Similar bond types were studied mostly for aromatic derivatives in which tellurium-centred groups [TeHal , TeOR , TeOCOR , TeSCN , TeR , $\text{Te}(\text{R})\text{Hal}_2$, TeHal_3 , *etc.*] were in the *ortho*-position relative to the substituents containing sp^2 - or sp^3 -hybridised oxygen or nitrogen atoms (CHO, COR, CO_2R , NO_2 , $\text{CH}=\text{N}$, $\text{N}=\text{N}$, CH_2NR_2).^{7–9} The intramolecular coordination $\text{O}(\text{N}) \rightarrow \text{Te}$ ensures stabilisation of various organotellurium compounds, primarily of dicoordinated tellurium derivatives, which are thermodynamically and kinetically unstable in the absence of these bonds, and significantly affects their reactivities. The preparation of pure arenetellurenyl halides,^{7–10} azides,^{8,10} acylates,^{7,8,10} and alkoxides^{8,10} is possible provided they contain the coordinative bond $\text{O}(\text{N}) \rightarrow \text{Te}$. Tellurium-centred cyclopentadienes are stable if they contain tellurium-containing substituents with *o*-formyltelluranylbenzene or their respective azomethine fragments.¹¹ However, data on X-ray diffraction analysis of β -tellurovinylcarbonyl compounds and (β -halogenotellurovinyl) aldimines containing intramolecular coordinative bonds $\text{O}(\text{N}) \rightarrow \text{Te}$ are very scarce.

II. Synthesis and reactions of β -tellurovinylcarbonyl compounds

In this review, the synthesis and reactions of β -telluroacroleins and β -tellurovinyl ketones will be considered separately for each individual group of β -tellurovinylcarbonyl compounds. Reactions typical of carbonyl groups and tellurium-containing substituents (reactions involving double bonds are still unknown) and conversions resulting in the formation of tellurium-containing heterocycles from β -tellurovinylcarbonyl compounds and their derivatives will be discussed.

1. Synthesis of β -alkyl(aryl)telluroacroleins and β -tellurovinyl ketones

Two main approaches to the synthesis of β -alkyl(aryl)telluroacroleins and β -substituted tellurovinyl ketones of the general formula $\text{RTeC}(\text{R}^1)=\text{C}(\text{R}^2)\text{COR}^3$ are known, *viz.*, nucleophilic substitution of the telluroate anions RTe^- for chlorine atoms in β -chlorovinylcarbonyl compounds and nucleophilic addition of RTe^- to the triple bonds of α -acetylenic aldehydes and ketones.

The former approach is more general and allows the preparation of compounds containing a broad range of substituents in the carbon triad C=C–C(O). As far as the nucleophilic addition is concerned, this yields only β -tellurovinylcarbonyl derivatives devoid of α -substituents.

β -Aryltelluroacroleins (**1**) and β -aryltellurovinyl ketones (**2**) were prepared by reaction of β -chlorovinylcarbonyl compounds **3** and **4** with arenetelluroate anions^{12–15} generated in the reaction of aryllithium with tellurium powder in THF or by reduction of diaryl ditellurides with lithium in THF in the presence of catalytic amounts of naphthalene (Tables 1 and 2).

The stereochemistry of reactions of nucleophilic substitution of arenetelluroate anions for the chlorine atom in β -chlorovinylcarbonyl compounds was studied in the example of β -chlorovinyl ketones **4** (R = Ph, 4-MeC₆H₄, 4-BrC₆H₄, 4-MeOC₆H₄),^{12, 14, 15} since the configurations of substituents at the double bond of the starting compounds and the derived tellurovinyl ketones **2** could easily be established from the values of coupling constants of olefinic protons. Ketones **4** synthesised by treatment of sodium salts of β -oxoaldehydes **5** with SOCl₂ represent a mixture of *Z*- and *E*-isomers where the latter predominate.

As described earlier,^{14, 15} the ratios of *Z*- and *E*-isomers in chlorovinyl ketones **4** depend on the nature of the substituent in position 4 of the phenyl ring and are equal to 0 : 1 (R = 4-BrC₆H₄), 1 : 12 (R = Ph), 1 : 5 (R = 4-MeC₆H₄), 1 : 1.5 (R = 4-MeOC₆H₄). However, aryl β -aryltellurovinyl ketones **2a–i** prepared from them represent exclusively *Z*-isomers.^{12, 14, 15} Thus, substitution of ArTe[–] for the chlorine atom results in complete reversal of the configuration of the *E*-isomers of aryl β -chlorovinyl ketones **4** and complete retention in the case of *Z*-isomers. This was rationalised in terms of a two-step vinylic nucleophilic substitution mechanism, *viz.*, vinylic substitution through addition–elimination.¹⁷ The first step of this reaction includes addition of highly nucleophilic arenetelluroate anions¹⁸ to the double bond of chlorovinyl ketones, the electrophilicity of the double bonds being enhanced owing to the presence of the oxo group. The conformers **A** stabilised by the coordinative bond O → Te certainly possess the highest stabilities compared with the other conformers existing due to the rotation of the carbanions formed around the simple bond. Subsequent elimination of the chloride ion from conformers **A** yields the *Z*-isomers of aryl β -aryltellurovinyl ketones **2a–i**, which are additionally stabilised by the coordinative bond O → Te.^{14, 15}

β -Chloro- β -phenylpropenal obtained as a mixture of *Z*- and *E*-isomers in a 9 : 1 ratio¹⁹ reacts with arenetelluroate anions to yield exclusively the *Z*-isomers of compounds **1a,b**.^{14, 15} The reaction of arenetelluroate anions with 2-chlorocyclohex-1-enecarbaldehyde has the same stoichiometric result, *i.e.*, exclusive formation of *Z*-isomers of compounds **1g–i** (see Table 1).^{14, 15}

In contrast to chloroacroleins and chlorovinyl ketones non-substituted in the α -position, compounds **3** (R¹ = Ph, R² = Me, Et) react with arenetelluroate anions to afford mixtures of *E*- and *Z*-isomers of compounds **1c–f**; their isomeric ratios vary widely (see Table 1). In this case, the O → Te interaction, which stabilises conformers **A**, competes with the steric repulsion of bulky phenyl and alkyl groups, as a result of which the stereospecificity of the reaction is lost.^{14, 15}

Among β -alkyltellurovinylcarbonyl compounds, β -methyltelluroacroleins were the first to be synthesised by nucleophilic substitution of the chlorine atom in β -chlorovinylcarbonyl derivatives.^{14, 15, 20} Thus 2-methyltellurocyclohex-1-enecarbaldehyde **6** was prepared by reaction of β -chlorocyclohex-1-enecarbaldehyde with lithium methanetelluroate obtained from methylithium and tellurium in tetrahydrofuran. This reaction proceeds smoothly only at -70°C .

The approach to the synthesis of β-methyltelluroacrolein **7** is based on the reaction of equimolar amounts of the corresponding β-chloroacrolein with lithium telluride with subsequent alkylation of intermediate lithium telluroate **8** with methyl iodide.²¹

β-Butyltellurovinyl ketones **9a–e** were synthesised by nucleophilic substitution of the chlorine atom in the corresponding β-chlorovinyl ketones **10** using the reaction with the butanetelluroate anion generated by reduction of dibutyl ditelluride with diisobutylaluminium hydride.²² Compounds **9a–e** were obtained as mixtures of *E*- and *Z*-isomers,²² however, their ratios were not indicated.

$\text{R}^1 = \text{R}^3 = \text{Me}$, $\text{R}^2 = \text{H}$ (**a**); $\text{R}^1\text{–R}^3 = (\text{CH}_2)_2$, $\text{R}^2 = \text{H}$ (**b**);
 $\text{R}^1\text{–R}^3 = (\text{CH}_2)_3$, $\text{R}^2 = \text{H}$ (**c**); $\text{R}^1 = \text{Me}$, $\text{R}^2\text{–R}^3 = (\text{CH}_2)_3$ (**d**);
 $\text{R}^1 = \text{Me}$, $\text{R}^2\text{–R}^3 = (\text{CH}_2)_4$ (**e**).

(β-Acylvinyl)triethylammonium chlorides **11** obtainable in high yields upon treatment of chlorovinylcarbonyl derivatives with triethylamine²³ can be used in the synthesis of β-aryltellurovinyl aldehydes **1** and ketones **2** instead of β-chlorovinylcarbonyl compounds.^{14–16} The reactions of compounds **11** with sodium tellurophenolates prepared by reduction of diaryl ditellurides with sodium borohydride are carried out in methanol with subsequent short-term boiling of the reaction mixture (Table 3).

This approach to the synthesis of β-aryltellurovinylcarbonyl compounds is more convenient than that from chlorovinylcarbonyl compounds, since ammonium salts are more storage-stable

Table 3. Synthesis of β-aryltelluroacroleins and β-aryltellurovinyl ketones from β-acylvinyltriethylammonium chlorides **11**.

than their chlorine-containing analogues. Moreover, the preparation of arenetelluroate anions is preparatively more simple, and the yields of the reaction products are usually higher.

Enol phosphates **12** were also used as starting compounds in the synthesis of β-substituted tellurovinylcarbonyl compounds.²⁴ Their reactions with lithium butanetelluroate prepared from butyllithium and tellurium powder in THF result in β-butyltellurovinyl methyl ketones **9a,f,g**.

$\text{R}^1 = \text{R}^3 = \text{Me}$, $\text{R}^2 = \text{H}$ (**a**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Me}$ (**f**);

A large variety of telluroacroleins and tellurovinyl ketones non-substituted in the α-position were prepared by nucleophilic addition of alkane(arene)telluroate anions generated by reduction of dialkyl(aryl) ditellurides with sodium borohydride in methanol or ethanol to the triple bonds of acetylenic aldehydes or ketones **13** (Table 4).^{1, 14, 15, 25, 26} The reaction proceeds under

mild conditions and results in β -alkyl(aryl)telluroacroleins and β -alkyl(aryl)tellurovinyl ketones (yields 60%–90%).

The stereochemistry of the nucleophilic addition of arenetelluroate anions to the triple bond was studied for the acetylenic derivatives **13**, where $R^1 = H$, $R^2 = H$, Ph.^{14, 15, 26} It was found that all these reactions yield *Z*-isomers in high yields. In the case of β -aryltellurovinyl phenyl ketones **2b,c**, the coupling constants for the alkene protons $^3J_{HH}$ are equal to 8.79 Hz, which corresponds to the *cis*-configuration. The *Z*-configuration of the substituents in β -phenyltelluroacrolein (**1k**) was also determined from the ^1H NMR spectra.

However, reaction of the butanetelluroate anion with propionaldehyde yields a mixture of *Z*- and *E*-isomers of the aldehyde **9h** in an 89 : 11 ratio.²⁶ This seems to be due to the lower electronegativity of the butyl substituent as compared with the phenyl one. Indeed, according to quantum-chemical calculations,^{27–30} the lengths and, hence, the stabilities of the intramolecular coordinative bond $O(N) \rightarrow Te(II)$ depend on the electronegativities of substituents at the tellurium atom: the higher this value the shorter the coordinative bond. Weakening of the coordinative bond on going from $R = Ph$ to $R = Bu$ results in partial cleavage of this bond in the butyl derivative and the appearance of the *E*-isomer of compound **9h** in the solution.

Arenetelluroate anions, which are the strongest nucleophiles in the series of structurally related anions ArM^- ($M = O, S, Se, Te$),¹⁸ react with symmetrical diacetylenic ketones to give only the bisadducts **14** (yields 84%–88%),²⁵ whereas alcohols and phenols add to one or both triple bonds depending on the reaction conditions.

$Ar = Ph, 4-MeC_6H_4$.

Due to the relatively low electrophilicity of the triple bond in β -aminovinyl ethynyl ketones **15**, they do not react with nucleophiles, such as amines, alcohols and phenols. However, arenetelluroate anions readily add to compounds **15**. Thus ketone **16** was prepared in 68% yield.²⁵ Acid hydrolysis of this ketone results in the elimination of diethylamine and the formation of diketone **17**.²⁵

$Ar = 4-MeC_6H_4$.

A specific synthetic procedure was used to prepare β -trifluoroacetylvinyl tellurides **18a–g**.³¹ Like other heterosubstituted alkenes (vinyl sulfides, vinyl ethers, *N*-vinylamides, carbazoles, *etc.*) (see Ref. 31 and references cited therein), vinyl tellurides $RTeCH=CH_2$ react with trifluoroacetic anhydride in THF to give ketones **18a–g** (yields 50%–84%). However, in contrast to the previously mentioned heterosubstituted alkenes, the use of catalysts is necessary, among them *N,N,N',N'*-tetramethylethylenediamine (TMEDA) is the most efficient. The yields of alkylvinyl tellurides **18a–d** are higher than in the case of compounds **18e–g**.

$R = Bu^n$ (**a**), Bu^i (**b**), $EtO_2C(CH_2)_2$ (**c**), $NC(CH_2)_2$ (**d**), Ph (**e**),
 $\text{O} \begin{array}{c} \diagup \diagdown \\ \text{N}CH_2CH=CH_2 \end{array}$ (**f**), $PhCH=CH$ (**g**).

It is of note that the 1,1-disubstituted vinyltelluride, *viz.*, 1-butyltelluro-1-phenylethylene, does not enter into this reaction.³¹

2. Reactions of β -alkyl(aryl)telluroacroleins and β -alkyl(aryl)tellurovinyl ketones

Reactions of β -alkyl(aryl)tellurovinylcarbonyl compounds have been studied relatively little. Like other aldehydes and ketones, they are reduced with sodium borohydride to 3-aryltelluroprop-2-en-1-ols **19**,¹³ which can be used as the starting compounds in the synthesis of 5*H*-1,2-oxatelluroles. Compounds **19** ($R^1 = R^2 = H$) were prepared by nucleophilic addition of arenetelluroate anions to the triple bond of propargyl alcohol.^{13, 32, 33}

$R^1 = R^2 = H$, $R^3 = Ar = Ph$; $R^1 = Ph$, $R^2 = R^3 = H$; $Ar = Ph$,
 4- $EtOC_6H_4$; $R^1 - R^2 = (CH_2)_4$, $R^3 = H$; $Ar = Ph$, 4- $EtOC_6H_4$;
 $R^1 = R^2 = R^3 = H$; $Ar = Ph$, 4- $MeOC_6H_4$, 4- $EtOC_6H_4$.

Azomethine **20** was prepared by condensation of β -aryltelluroacrolein **1b** with *p*-toluidine.¹⁵

β -Alkyl(aryl)telluroacroleins, particularly compounds **1k** and **9h**, enter into the Wittig reaction with *in situ* generated methylenetriphenylphosphorane to give dienyl tellurides **21** and **22**.²⁶ The configurations of the starting alkenes are retained.

Z- β -Alkyl(aryl)tellurovinyl trifluoromethyl ketones **18a,b,e** react with zinc cuprates **23** at low temperatures (from $-78^\circ C$ to $-30^\circ C$) to give *E*-isomers of α,β -unsaturated trifluoromethyl

ketones **24**.³⁴ However, compounds **24** are obtained in high yields only with cuprates **23** where $R^2 = \text{Ar}$ and $\text{CH} = \text{CHPh}$. In the case of alkylzinc cuprates, the yields of ketones **24** do not exceed 70%; dialkylated ketones **25** are formed as side products (yields 11%–19%).³⁴

$R^1 = \text{Bu}^n$ (**a**), Bu^i (**b**), Ph (**e**); $R^2 = \text{Ph}$, 4-MeC₆H₄, 4-MeOC₆H₄, 4-EtOC₆H₄, PhCH=CH, C₈H₁₇, C₁₀H₂₁, C₁₂H₂₅;
X = (CN)(ZnCl)₂, ZnCl.

It is noteworthy that the reaction of organocopper derivatives Ph₂CuLi, Ph₂CuMgBr, Ph₂Cu(CN)Li₂ and Ph₂Cu(CN)(MgBr)₂ with ketones **18a,b,e** is accompanied by the predominant formation of the diphenyl derivatives **25**, whereas ketones **24** are the side products.³⁴

Only one reaction of β -alkyl(aryl)telluroacroleins involving the two-coordinate tellurium atom is presently known. Like other vinyl tellurides,³⁵ β -methyltelluroacroleins **6** and **7** are oxidised to the four-coordinate tellurium derivatives **26a–d** by halogens or thionyl chloride under mild conditions (PhH, 0–5 °C).^{15,20,21}

$R^1 - R^2 = (\text{CH}_2)_4$, X = Cl (**a**), Br (**b**), I (**c**); $R^1 = 4\text{-BrC}_6\text{H}_4$, $R^2 = \text{H}$, X = Br (**d**).

3. Synthesis of tellurium-containing heterocycles

a. Tellurophenes

A series of substituted tellurophenes **27** containing strong electron-withdrawing groups in position 2 were synthesised by reaction of β -chloroacroleins with sodium telluride and the α -halogenomethyl derivatives **28**.^{5,36,37}

This reaction proceeds under mild conditions and results in the heterocycles **27** in 25%–30% yields. Presumably, β -substituted telluroacroleins **29** are the intermediate products in this reaction.

$R^1 = \text{Bu}^t$, $R^2 = \text{H}$; $R^3 = \text{CHO}$, COMe, CO₂Et, NO₂;
 $R^1 = 3\text{-MeOC}_6\text{H}_4$, 4-MeOC₆H₄; $R^2 = \text{H}$, $R^3 = \text{CO}_2\text{Et}$;
 $R^1 - R^2 = (\text{CH}_2)_4$; $R^3 = \text{COMe}$, CO₂Et, NO₂;
 $R^1 - R^2 = (\text{CH}_2)_5$, $R^3 = \text{CO}_2\text{Et}$; X = Cl, Br.

2,4-Disubstituted tellurophenes **30** were prepared from α -aryl- β -chloroacroleins.³⁸

The above-described methods for the synthesis of tellurophenes are similar to the reactions used in the synthesis of substituted thiophenes and selenophenes.

b. 2-Aryl-2-chloro-5H-1,2-oxatelluroles

3-Aryltelluroprop-2-en-1-ols **19**^{13,32,33} were used as starting compounds in the synthesis of four-coordinate derivatives of 5H-1,2-oxatellurole.^{13,33} Thus 2-aryl-2-chloro-5H-1,2-oxatelluroles **31a,b** were synthesised in 44%–82% yields by oxidation of alcohols **19** with Bu^tOCl. This reaction seems to proceed through the intermediate formation of σ -telluranes **32** which are further converted into the heterocycles **31a,b** with elimination of Bu^tOH.¹³

$R^1 = R^2 = R^3 = \text{H}$; Ar = Ph, 4-MeOC₆H₄, 4-EtOC₆H₄; $R^1 = R^2 = \text{H}$, $R^3 = \text{Ar} = \text{Ph}$; $R^1 = \text{Ph}$, $R^2 = R^3 = \text{H}$; Ar = Ph, 4-EtOC₆H₄.

Oxatelluroles **31** containing substituents in position 5 of the heterocycle are formed as a mixture of two isomers as can be evidenced from the ¹H NMR spectra of these compounds. Thus the signals of the methine protons of 2-chloro-2,5-diphenyl-5H-1,2-oxatelluroles are observed as two singlets at $\delta = 6.02$ and 6.27.

4. Bis(β -acylvinyl) tellurides

Of the methods for the synthesis of bis(β -acylvinyl) tellurides that have been studied, the data about the reactions, structures and applications of these compounds in the synthesis of tellurium-containing heterocycles are virtually absent in the literature.

The syntheses of bis(β -acylvinyl) tellurides **33a–e**, like those of β -alkyl(aryl)telluroacroleins and β -alkyl(aryl)tellurovinyl ketones, were carried out using the nucleophilic addition of potassium telluride to the triple bond of α -acetylenic ketones.² To this end, acetylenic ketones were made to react with potassium telluride and hydroxylamine-*O*-sulfonic acid in an aqueous solution of sodium acetate.

$R^1 = \text{H}$; $R^2 = \text{Me}$ (**a**, 11%), Et (**b**, 6%), Pr (**c**, 3%);
 $R^1 = R^2 = \text{Me}$ (**d**, traces); $R^1 = \text{Ph}$, $R^2 = \text{Me}$ (**e**, 3%).

The low yields of ketones **33a–e** are due to the competing heterocyclisation of the intermediate oximes **34** into isotellurazoles **35**.^{2,39} Under these conditions, 3-mono- (**35a–c**) and 3,5-disubstituted isotellurazoles (**35d–f**) are obtained in nearly the same yields (3%–10%) as ketones **33**.

- 35: R¹ = H; R² = Me (a, 6%), Et (b, 5%), Ph (c, 4%);
 R¹ = R² = Me (d, 10%); R¹ = Ph, R² = Me (e, 7%);
 R¹ = CH₂=CH, R² = Me (f, 5%).

This method is inapplicable to the synthesis of isotellurazoles non-substituted in position 3, since bis(β-cyanovinyl) tellurides (NCCH=CR)₂Te (R = H and Ph), are the only reaction products (yields 20% and 14%) when α-acetylenic aldehydes are used instead of ketones.

Nucleophilic substitution of the telluride anion for the chlorine atom in β-chlorovinylcarbonyl compounds is used in the preparative synthesis of ketones and aldehydes **33**.^{14,15} Lithium telluride, prepared from lithium and elementary tellurium in THF in the presence of catalytic amounts of naphthalene, reacts with β-chloroacroleins and β-chlorovinyl ketones to give compounds **33f–h** in 39%–60% yields.^{14,15}

- R¹ = R² = H; R³ = Ph (f), 4-MeC₆H₄ (g);
 R¹–R² = (CH₂)₄, R³ = H (h).

The synthesis of bis(β-benzoylvinyl) tellurides **33f,i** was carried out using β-chlorotellurovinyl phenyl ketones **36** and β-trichlorotellurovinyl phenyl ketones **37**.⁴ Reduction of the former with lithium triethylborohydride in THF affords ketones **33f,i** in 53%–92% yields; the yields in the latter case were not indicated.

- R = H (**33f**), Ph (**33i**); n = 1 (**36**), 3 (**37**).

This method obviously holds little promise for the synthesis of ketones **33f,i**, since chlorotellurium derivatives **36** are prepared in four steps from α-acetylenecarboxylates,³ and trichlorotellurovinyl ketones are produced upon their oxidation.

Special mention should be made of the unusual course of the reduction of compounds **36** and **37**. Tellurenyl halides⁴⁰ and tellurium trihalides⁴¹ devoid of the coordinative bond O(N) → Te are reduced to the corresponding ditellurides. In the case of the chlorotellurium derivatives **36**, ditellurides **38** are formed in trace amounts, apparently due to the presence of strong intramolecular coordinative bonds O → Te in the starting tellurenyl chlorides.

An analysis of the ¹H NMR spectrum of ketone **33f**^{14,15} [a ten-proton multiplet of aromatic protons at δ = 7.24–8.10

and an AX system (two two-proton doublets at δ = 8.36 and 9.14, ³J_{HH} = 9.67 Hz)] prompts a conclusion that the benzoylvinyl fragments of this compound exist in conformations with the *cis*-arrangement of the hydrogen atoms.

5. β-Halogenotellurocarbonyl compounds and their analogues; β-halogenotellurovinyl aldimines

a. Synthesis

Aryl β-chlorotellurovinyl ketones **36** are among the most well-studied β-tellurovinylcarbonyl compounds XTeC(R¹)=C(R²).COR³ where X is an electronegative substituent. They were prepared in four steps starting from α-acetylenecarboxylates **39**.^{3,4,42–44} The first step includes nucleophilic addition of arene telluroate anions generated by reduction of the corresponding diaryl ditellurides with sodium borohydride in EtOH–THF to esters **39**. This leads to methyl(ethyl) 3-aryltelluropropenoates **40** (predominantly, *Z*-isomers) (yields 58%–95%).³ However, ester **40** (R = H, Ar = Ph) is formed as a mixture of *Z*- and *E*-isomers (13 : 1).³ Hydrolysis of esters **40** with KOH and subsequent acidification of the reaction mixture result in β-(aryltelluro)acrylic (**41**, R = H) or β-(aryltelluro)cinnamic acids (**41**, R = Ph) (yields 68%–95%). Treatment of acids **41** with oxalyl chloride gives 3-(aryltelluro)propenoyl chlorides **42**. The latter are rearranged into ketones **36** (yields 31%–96%) on boiling in deuteriochloroform or by treatment with AlCl₃.^{3,4,42–44} Telluraflavones are formed in some cases in addition to ketones **36** (see below).⁴²

R² = Me, Et.

R ¹	Ar	Yield (%)	Ref.
H	Ph	82	3
Me	Ph	76	3, 43
Me	4-FC ₆ H ₄	—	43
Me	4-MeOC ₆ H ₄	—	43
Me	4-Me ₂ NC ₆ H ₄	31	4, 43
Ph	Ph	81	3, 4
Ph	2-MeC ₆ H ₄	75	3
Ph	3-MeC ₆ H ₄	92	42
Ph	4-MeC ₆ H ₄	92	3
Ph	4-MeOC ₆ H ₄	96	3, 4
Ph	3-FC ₆ H ₄	78	42
Ph	3-MeOC ₆ H ₄	4	42
Ph	4-MeCOC ₆ H ₄	50	3
Ph	1-C ₁₀ H ₇	82	3
4-MeOC ₆ H ₄	Ph	—	4
2,5-(MeO) ₂ C ₆ H ₃	Ph	70	44
4-Bu ^t C ₆ H ₄	Ph	—	4

The rates of both thermal and catalytic rearrangements of compounds **42** are governed by the electronic nature of *p*-substituents in the aryl nuclei.³ Thus in the case of β-(phenyltelluro)cinnamoyl chlorides, compound **42** (R = Ph, Ar = 4-MeOC₆H₄) could not be isolated at all, since it undergoes rearrangement into ketone **36** (R = Ph, Ar = 4-MeOC₆H₄) in nearly quantitative yield even at 20 °C. The half-transformation time of the acid chloride **42** (R = Ph, Ar = 4-MeC₆H₄) in boiling CDCl₃ is 1 h, whereas that for compound **42** (R = Ar = Ph) is 30 h under

identical conditions. The presence of strong electron-withdrawing substituents (*e.g.*, Ar = 4-MeCOC₆H₄) inhibits almost completely the thermal rearrangement, the yield of ketone **36** (R = Ph, Ar = 4-MeCOC₆H₄) being < 1% on boiling in CDCl₃ for 72 h.

The putative mechanism of the catalytic rearrangements of acid chlorides **42** into compounds **36** involves an attack of the acylium cation on the aromatic carbon atom bound to tellurium (*ipso*-acylation) to yield the spirocyclic σ-complex **43**. Subsequent nucleophilic attack of the chloride ion on the tellurium atom yields ketones **36**.

It should be noted that such rearrangements were first observed for *o*-(aryltelluro)benzoyl chlorides *o*-ClCOC₆H₄TeAr (Ar = Ph, 4-MeC₆H₄, 2-C₄H₃S). Heating of these compounds with ZnCl₂ gave *o*-chlorotelluro)benzophenones *o*-ClTeC₆H₄.COAr in high yields.^{45–47}

The structures of the rearrangement products of aroyl chlorides **42** depend on the position and the nature of substituents in the ArTe fragments. In the case of *p*-substituted β-(aryltelluro)prope-noyl chlorides **42**, the only reaction products are ketones **36**.³ However, the introduction of donor substituents into the *m*-position of aryl substituents results in the activation of the *o*-positions towards electrophilic attack and prevents *ipso*-acylation, which results in either a mixture of ketones **36** and telluraflavones **44** or only the latter compounds.^{42, 44}

R ¹	R ²	R ³	Yield of 36 (%)	Yield of 44 (%)	Ref.
Ph	Me	H	92	0	3
Ph	F	H	78	5	3, 42
Ph	F	F	—	18	42
Ph	OMe	H	4	78	3
Ph	OMe	OMe	0	90	3
4-MeOC ₆ H ₄	OMe	H	5	44	44
3,4-(MeO) ₂ C ₆ H ₃	OMe	H	5	68	44
2,5-(MeO) ₂ C ₆ H ₃	OMe	H	5	—	44
4-MeOC ₆ H ₄	OMe	OMe	0	52	44
3,4-(MeO) ₂ C ₆ H ₃	OMe	OMe	0	57	44
2,5-(MeO) ₂ C ₆ H ₃	OMe	OMe	0	72	44

The above-described method for the synthesis of ketones **36** has certain limitations: it is a multistep procedure and affords only those aroyl derivatives that are not substituted in the α-position.

A method for the preparation of β-halogenotellurenylvinyl-carbonyl compounds based on the use of β-methyldihalogenotellurovinylcarbonyl compounds **26** is devoid of these drawbacks. Until now, such compounds were mostly employed for the preparation of 2-halogenotellurocyclohex-1-enecarbaldehydes **45**,^{15, 20} they can undoubtedly be used in the synthesis of vinyl-tellurenyl halides containing a broad range of substituents in the carbon triad.

Like 2-formylphenyl(alkyl)tellurium dibromides,⁴⁸ compounds **26** (their syntheses were discussed in Section II.2) undergo reductive elimination of methyl halide upon boiling in acetic acid in the presence of catalytic amounts of the corresponding hydrohalic acids.^{15, 20}

X = Br, I.

It is noteworthy that reductive elimination of methyl halides is extremely sensitive to the admixtures present in the reagents used and is therefore poorly reproducible.

The mesylate derivative **46** is an example of tellurenyl derivatives containing electronegative substituents other than halogen atoms, which has been prepared by direct synthesis.⁴⁴ This compound is an unstable oil; it was synthesised by heating a mixture of β-(phenyltelluro)-2,5-dimethoxycinnamic acid (**47c**), phosphoric anhydride and methanesulfonic acid. It is of note that sulfur (**47a**) and selenium analogues (**47b**) undergo cyclisation into benzocyclopentenones **48a, b** under identical conditions.⁴⁴

M = S (a), Se (b), Te (c).

b. Reactions

Reactions of (β-halogenotellurovinyl)carbonyl compounds characteristic of the constituent two-coordinate tellurium atom have been studied largely for aryl β-halogenotellurovinyl ketones **36**.

Ketones **36** enter into reduction, oxidation and exchange reactions of chlorine atoms by other anionoid substituents. Aryl β-chlorotellurovinyl ketones **36** and their bromo analogues **49** undergo oxidative addition of chlorine and bromine under mild conditions (CH₂Cl₂, 0 °C) to give aryl β-trichlorotellurovinyl ketones **37a–k** and aryl β-tribromotellurovinyl ketones **50a–c**, respectively.⁴

37: X = Cl; R = H, Ar = Ph (**a**, 70%); R = Me: Ar = Ph (**b**, 74%), 4-FC₆H₄ (**c**, 92%), 4-Me₂NC₆H₄ (**d**, 39%); R = Ph: Ar = Ph (**e**, 66%), 3-FC₆H₄ (**f**, 88%), 4-FC₆H₄ (**g**, 88%), 2-MeC₆H₄ (**h**, 82%), 4-MeOC₆H₄ (**i**, 55%); R = 4-MeOC₆H₄, Ar = Ph (**j**, 85%); R = 4-Bu^tC₆H₄, Ar = Ph (**k**, 79%).
50: X = Br; Ar = Ph: R = H (**a**, 52%), Me (**b**, 70%), Ph (**c**, 89%).

Iodine, possessing the weakest (in comparison with other halogens) oxidizing properties, does not oxidise tellurenyl iodides. Thus phenyl β -iodotelluro- β -phenylvinyl ketone ITeC(Ph)=CH.COPh is not converted into the corresponding tellurium triiodide in a reaction with iodine.

The attempts to prepare mixed tellurium trihalides were unsuccessful. Thus the reaction of tellurenyl bromide **49** ($\text{R} = \text{Me}$, $\text{Ar} = \text{Ph}$) with chlorine gave a mixture of tellurium trichloride **37b** and tellurium tribromide **50b** in a 2:1 ratio, whereas treatment of tellurenyl chloride **36** ($\text{R} = \text{Me}$, $\text{Ar} = \text{Ph}$) with bromine yields a mixture of analogous tellurium trihalides, but in a 1:2 ratio.⁴

At the same time, the reaction of tellurenyl iodide **51** with bromine results in tellurium tribromide **50c**.⁴

The chlorine atoms in tellurenyl chlorides **36** are highly mobile and readily exchangeable for other anions (Br^- , I^- , CF_3COO^-), which affords the tellurenyl derivatives **49**, **51**, **52** in high yields.³

Quite unexpected results were obtained in the reaction of aryl β -chlorotellurovinyl ketone **36** ($\text{R} = \text{Ar} = \text{Ph}$) with AgBF_4 (see Ref. 3). β -Fluorotellurovinyl phenyl ketone **53** was isolated instead of the expected tetrafluoroborate. Obviously, this reaction results in the decomposition of the complex ion BF_4^- , but the reasons for this decomposition have not been established.

The condensation of aldehydes **45** with aromatic amines (boiling of equimolar amounts of reactants), which affords azomethines **54a,b**, is the only well-studied reaction of (β -halogenotellurovinyl)carbonyl compounds **45** involving the carbonyl group.^{15,20}

$\text{X} = \text{Br}$ (**a**), I (**b**).

Earlier,¹⁰ it was shown that the reaction of *o*-butyldibromotellurobenzaldehyde (**55**) with aromatic amines is accompanied by reductive elimination of butyl bromide to give azomethines **56**.

$\text{Ar} = \text{Ph}$, $4\text{-MeC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$.

2-Methyldihalogenotellurocyclohex-1-enecarbaldehydes **26a–c** and aldehyde **56d** react with aromatic amines in a similar manner. The yields of azomethines **24a–d**, **57** amount to 86%–91%.^{15,20,21}

$\text{Ar} = 4\text{-MeC}_6\text{H}_4$; $\text{X} = \text{Cl}$ (**54a**), Br (**54b**), I (**54c**);

$\text{Ar} = 4\text{-MeOC}_6\text{H}_4$; $\text{X} = \text{Br}$ (**54d**).

$\text{Ar} = 4\text{-MeC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$.

This procedure for azomethine synthesis has certain advantages over those mentioned above, since it excludes the conversion of aldehydes **26** into the tellurenyl derivatives **45**.

o-Aminophenols **58** react with aldehyde **26b** in a similar way: the yields of azomethines **59** vary from 78% to 85%.⁴⁹

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$; $\text{R}^1 = \text{NO}_2$, $\text{R}^2 = \text{H}$.

Reactions of 2-methyldibromotellurocyclohex-1-enecarbaldehyde **26b** and *o*-butyldibromotellurobenzaldehyde (**55**) with aromatic acid hydrazides proceeds in the same way as with aromatic amines. Short-term (10 min) boiling of equimolar amounts of the reactants results in *N*-aroylhydrazones of 2-bromotellurocyclohex-1-enecarbaldehyde or *o*-bromotellurobenzaldehyde **60**.⁵⁰

$\text{R}^1-\text{R}^2 = (\text{CH}_2)_4$, $\text{R}^3 = \text{Me}$; $\text{Ar} = 4\text{-BrC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$;

$\text{R}^1-\text{R}^2 = (\text{CH}=\text{CH})_2$, $\text{R}^3 = \text{Bu}$, $\text{Ar} = 4\text{-MeOC}_6\text{H}_4$.

6. Synthesis of tellurium-containing heterocycles

β -Halogenotellurovinylcarbonyl compounds and their aza analogues were used as starting compounds in the synthesis of tellurium-containing heterocycles comprising one or two heteroatoms in addition to the tellurium atom.

a. Isotellurazoles

The synthesis of isotellurazoles **35a–f** by the reaction of α -acetylenic ketones with hydroxylamine-*O*-sulfonic acid and potassium telluride (Section II.4) has significant disadvantages in comparison with other methods due to very low yields of isotellurazoles and the impossibility of obtaining compounds non-substituted in position 3. The procedure for the synthesis of isotellurazole from compounds of the type **45** is devoid of these drawbacks.²⁰ Thus 4,5-tetramethyleneisotellurazole **35g** was prepared in 70% yield by passage of ammonia through a solution of 2-bromotellurocyclohex-1-enecarbaldehyde **45** in benzene. The putative mechanism of this reaction involves the intermediate formation of imine **61**; dehydrobromination of the latter under the action of ammonia yields isotellurazole **35g**.²¹

The synthesis of isotellurazoles from aldehydes **26** as starting compounds is preparatively more convenient, since it excludes the conversion of aldehydes into the tellurenyl derivatives of the type **45**. Passage of ammonia through benzene solutions of tellurium dibromides **26b,d** gave isotellurazoles **35g,h** in ~70% yields.²¹ Allowing for the fact that the reaction of tellurium dibromides **26b,d** with aromatic amines proceeds through elimination of methyl bromide, a mechanism for the formation of isotellurazoles has been proposed.²¹ Its initial step includes the formation of imines **62**, which are further converted into imines **61** by elimination of methyl bromide; their cyclisation into isotellurazoles is described above.

$\text{R}^1-\text{R}^2 = (\text{CH}_2)_4$ (**26b**, **35g**); $\text{R}^1 = 4\text{-BrC}_6\text{H}_4$, $\text{R}^2 = \text{H}$ (**26d**, **35h**).

This method for the synthesis of isotellurazoles is similar to that proposed by Renson for the synthesis of isoselenazoles.⁵¹ However, due to the high thermal stability of tellurodibromides **26** (σ -telluranes of the type $\text{R}^1\text{R}^2\text{TeX}_2$), the respective reactions are carried out at room temperature, while those of less stable selenium analogues should be carried out only at -78°C .

b. *N*-Arylisotellurazolium salts

N-Arylisotellurazolium perchlorates **63** were prepared in 78%–86% yields by treatment of solutions of aldimines **54** in acetone or DMF with the silver perchlorate–acetonitrile complex in acetone.²¹

$\text{R}^1-\text{R}^2 = (\text{CH}_2)_4$; $\text{Ar} = 4\text{-MeC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$;

$\text{R}^1 = 4\text{-BrC}_6\text{H}_4$, $\text{R}^2 = \text{H}$; $\text{Ar} = 4\text{-MeC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$.

c. 1,6-Dioxa-6a-tellurapentalenes and 1-oxa-6-aza-6a-tellurapentalenes

Aryl β -chlorotelluro- β -methylvinyl ketones of the type **36** were used as starting compounds in the synthesis of 1,6-dioxa-6a-tellurapentalenes **64**.^{6,43} Condensation of these compounds with carboxylic acid chlorides in CH_2Cl_2 or MeCN in the presence of excess of a base (triethylamine, pyridine, 2,6-lutidine) gives heterocycles **64** (yields 11%–85%). This reaction occurs with various (saturated, unsaturated, aromatic, heterocyclic, *etc.*) acid chlorides.

$\text{Ar} = \text{Ph}$; $\text{R} = \text{Me}$, Ph , $4\text{-O}_2\text{NC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$;

$\text{Ar} = 4\text{-FC}_6\text{H}_4$; $\text{R} = \text{Me}$, Ph , $4\text{-FC}_6\text{H}_4$, $4\text{-O}_2\text{NC}_6\text{H}_4$, $4\text{-NCC}_6\text{H}_4$,

$4\text{-MeOC}_6\text{H}_4$, $2,4\text{-(NO}_2)_2\text{C}_6\text{H}_3$, $3,5\text{-(NO}_2)_2\text{C}_6\text{H}_3$, furyl-CH=CH ,

thiophenyl-CH=CH , $4\text{-MeOC}_6\text{H}_4\text{CH=CH}$;

$\text{Ar} = 4\text{-MeOC}_6\text{H}_4$; $\text{R} = \text{Me}$, $4\text{-O}_2\text{NC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$;

$\text{Ar} = 4\text{-Me}_2\text{NC}_6\text{H}_4$; $\text{R} = 4\text{-O}_2\text{NC}_6\text{H}_4$, $4\text{-NCC}_6\text{H}_4$.

The use of imidoyl chloride **65** instead of acid chlorides has led to 1-oxa-6-aza-6a-tellurapentalene **66**.⁴³

d. 2-Aroyl-1,2,3-telluradiazines

Dehydrobromination of aldimines is the key step in the synthesis of isotellurazoles. A similar approach was used in the synthesis of 2-aryol-1,2,3-telluradiazines **67**.⁵⁰ These heterocycles were synthesised in 76%–82% yields by treatment of benzene solutions of *N*-aryolhydrazones **60** with triethylamine.

$R^1 - R^2 = (CH_2)_4$; Ar = 4-BrC₆H₄, 4-MeOC₆H₄;

$R^1 - R^2 = (CH=CH)_2$; Ar = 4-MeOC₆H₄.

e. 1,2,6-Oxatellurazocine benzo-derivatives

Benzo-1,2,6-oxatellurazocine derivatives **68** were prepared by dehydrobromination of the corresponding β-bromotellurovinylaldehydes **59** in the presence of an equimolar amount of triethylamine with subsequent short-term boiling of the reaction mixture.⁴⁹

$R^1 = R^2 = H$; $R^1 = H$, $R^2 = Me$; $R^1 = NO_2$, $R^2 = H$.

7. β-Trihalogenotellurovinylcarbonyl compounds

The only available data in the literature concerns aryl β-trihalogenotellurovinyl ketones X₃TeC(R)=CHCOAr (X = Cl, Br).

a. Synthesis

The only known method for the synthesis of aryl β-trichlorotellurovinyl ketones **37** and aryl β-tribromotellurovinyl ketones **50**, viz., the oxidative addition of chlorine and bromine to aryl β-chloro- (**36**) and aryl β-bromotellurovinyl ketones (**49**), respectively, is described in Section II.5.b.

b. Reactions

Reactions of aryl β-trihalogenotellurovinyl ketones were studied primarily for the chloro derivatives **37**. The latter are reduced to bis(β-aryolvinyl) tellurides with lithium triethylborohydride and react with various nucleophiles. It should be noted that under the action of hypophosphorous acid as reducing agent tellurotrichlorides **37b,e** are reduced to tellurenyl chlorides **36b,f**.⁴ Of special interest is the striking difference between the structures of the reaction products of aryl β-trichlorotellurovinyl ketones **37** and tellurotrichloride derivatives containing no intramolecular coordinative bonds O → Te with nucleophiles.⁴¹ Reactions of the latter with nucleophiles result in the exchange of anionoid substituents for chlorine atoms or reduction of tellurium trichlorides to ditellurides, no detelluration occurs. The Michaelis addition of nucleophiles to the enone fragment of the ketones **37** proceeds with the elimination of the tellurium atom; sometimes, the trichlorides are reduced to tellurenyl chlorides.

Reaction of tellurium trichlorides **37b,e** with aqueous ammonia yields diketones **69**, tellurenyl chlorides **36** and metallic Te.⁴

Compound 37	R	Yield of 69 (%)	Yield of 36 (%)
b	Me	56	13
e	Ph	63	36

Ketones **69** and methyl ethers of enols **70** (a mixture of *Z*- and *E*-isomers) are formed in the reaction of tellurium trichlorides **37b,e** with triethylamine.⁴

Compound 37	R	Yield of 69 (%)	Yield of 70 (%)
b	Me	38	56
e	Ph	15	80

The reaction of tellurium trichloride **37e** with sodium benzenethiolate which proceeds with elimination of the tellurium atoms yields the *Z*-isomer of β-phenyl-β-phenylthiovinyl phenyl ketone **71**. The reaction of tellurium trichloride **37e** with hydrazine gives a mixture of pyrazole **72** and tellurenyl chloride **36** (R = Ph).⁴

8. β-Methyldihalogenotelluroacroleins

The synthesis of β-methyldihalogenotelluroacroleins was considered in Section II.2. Reductive elimination of methyl halides from these compounds results in β-halogenotelluroacroleins. Reaction with aromatic amines and acid hydrazides yields β-halogenotellurovinylaldehydes (Section II.5.b). The use of β-methyldihalogenotelluroacroleins in the synthesis of isotellurazoles was considered in Section II.6.a.

III. Structures and spectral characteristics of β-tellurovinylcarbonyl compounds

β-Tellurovinylcarbonyl compounds are convenient objects for the study of intramolecular coordinative bonds between O or N atoms and tellurium-containing substituents and the effects of these bonds on the structural and chemical properties of compounds under study.

The molecular and crystal structures of five β-tellurovinylcarbonyl compounds of the general formula **A** have been studied^{3,4,15,31} using X-ray diffraction analysis (Tables 5 and 6).

Compounds containing two-coordinate tellurium atoms (*e.g.*, carbonyl derivatives **1b**, **18c**, **36** and azomethine **20**) possess *Z*-configuration of the C=C bond, which ensures the formation of the intramolecular coordinative bonds O → Te and N → Te. The configuration of the substituents at the Te atom in the above-mentioned compounds can be described as a slightly distorted T-shaped structure, since the value of the angle X—Te—Y is close to 180° (164.4°–170.9°). According to the N-X-L nomenclature,⁵² these compounds represent 10-Te-3-telluranes. The lengths of the C—Te bonds in the two-coordinate tellurium derivatives **1b**, **18c**, **36** and **20** (2.06–2.119 Å) and the values of the bond angles X—Te—C (93.6°–98.5°) are similar to those of other two-coordinate tellurium derivatives.^{8,9,53}

The five-membered tellurium-containing rings in compounds **1b** and **20** are virtually planar; the phenyl rings in these compounds deviate from the planes of the heterocycles by 57.3° and 60.0°, respectively.

In addition to the presence of the intramolecular coordinative bond C=O → Te, the distinguishing feature of the trifluoromethyl derivative **18c**³¹ is the interaction of the carbonyl atom of the ethoxycarbonyl group with the Te atom. However, the length of this bond (3.92 Å) exceeds the sum of the van der Waals radii of O and Te (3.70 Å⁵⁴) and can therefore be neglected in the analysis of the polyhedron of the tellurium atom in this compound.

The coordination polyhedron of the Te atom in tellurium tribromide **50c**, a four-coordinate tellurium derivative, represents a trigonal bipyramid; the intramolecular coordinative bond O → Te is not taken into account.⁴ Here, the tellurium atom, the vinyl fragment and one bromine atom lie in the equatorial plane, while the other two bromine atoms are in the axial positions. The Te—Br_{equiv.} bond (2.513 Å) is shorter than the Te—Br_{ax.} bond (the average length is 2.660 Å). Taking account of the intramolecular coordinative bond O → Te (2.362 Å), the geometry of the bonds at the tellurium atom can be regarded as an octahedron.

In addition to intramolecular interactions, the crystals of compound **50c**, like those of aryltellurium tribromides,⁵⁵ contain the intermolecular bond Te...Br (3.757 Å), which enables binding of individual molecules into polymeric chains.

Apart from bond lengths, the intramolecular coordinative bond O(N) → Te is characterised by the covalence factor (χ), which is calculated by the formula⁵⁶

$$\chi = \frac{(R_A + R_B) - d_{AB}}{(R_A + R_B) - (r_A + r_B)},$$

where *R* and *r* are the van der Waals and covalent radii of the non-bonded elements A and B and *d*_{AB} is the distance between the atoms A and B.

Obviously, the higher the value of χ the shorter the bond.

The Te—Y bond lengths in β-tellurovinylcarbonyl compounds (see Table 5, compound **18c** will be mentioned separately) depend on the nature of the substituent X and increase in the following order: Cl < Br₃ < C₆H₄OEt-4 (for Y = O) ≅ C₆H₄OEt-4 (for Y = NC₆H₄Me-4). Depending on the nature of X, similar changes in the bond lengths corroborated by the results of quantum-chemical calculations^{27–30} were observed in the case of *o*-tellurinated phenylcarbonyl derivatives and (β-halogenotellurovinyl)aldimines.^{7–9}

2-Trifluoroacetylvinyl 2-ethoxycarbonyl ethyl telluride (**18c**) presents special interest.³¹ The intramolecular coordinative bond in this compound (3.22 Å, $\chi = 0.24$) is the longest in the series of organotellurium compounds (*e.g.*, the length of the O → Te bond in aldehyde **1b** is 2.725 Å). The reason for the significant elongation of the O → Te bond in the ethoxycarbonyl derivative **18c** seems to be due to the decrease in the electron density of the oxygen atom of the trifluoroacetyl group which, in turn, is determined by specific electron-withdrawing properties of the trifluoromethyl substituent.

β-Halogenotellurenylvinyl ketones of the general formula RC(TeX)=CHCOAr were studied by ¹²⁵Te NMR spectroscopy (Table 7).^{3,57}

Two main conclusions can be drawn from the data presented in Table 7. First, the chemical shifts of the Te atoms in these halogenotellurium derivatives are primarily affected by the electronegativity of the halogen atom: the higher the electronegativity the more low-field the ¹²⁵Te signal. The nature of substituents at

^a Bis(diethylcarbamato)tellurium served as the standard; the $\delta^{125}\text{Te}$ values are given relative to Me_2Te , these are calculated according to the formula $\delta(\text{Me}_2\text{Te}) = \delta[\text{Te}(\text{S}_2\text{CNET}_2)_2] + 833$.

the carbon atoms only weakly affects the $\delta^{125}\text{Te}$ value (the maximum δ value does not exceed ~ 50 ppm).

IV. Conclusion

The data presented in this review suggest that the chemistry of β -tellurovinylcarbonyl compounds has progressed considerably in recent years. This can be exemplified by the development of procedures for the preparative synthesis of these compounds and azomethines prepared from them as well as by studies of the reactivity of β -tellurovinylcarbonyl compounds and the effect of the intramolecular coordinative bond $\text{O}(\text{N}) \rightarrow \text{Te}$ on the reaction features. The use of β -tellurovinylcarbonyl compounds and related aldimines has made it possible to develop preparative procedures for the synthesis of isotellurazoles, *N*-arylisotellurazolium salts and novel tellurium-containing heterocycles, such as 5*H*-1,2-oxatelluroles, 1,6-dioxa-6*a*-tellurapentalenes, 1,2,3-telluradiazines and 1,2,6-oxatellurazocines.

Further investigations in this field will presumably be carried out along the following lines:

1. Synthesis of novel β -tellurovinylcarbonyl compounds (ditellurides, telluronium ylides, tellurimides, telluronium salts).

2. In-depth studies of reactions of β -tellurovinylcarbonyl compounds which have been studied insufficiently even for known compounds.

3. Further studies of possible applications of compounds considered and newly prepared in the synthesis of miscellaneous tellurium-containing heterocycles.

4. Synthesis of complex compounds including metal chelates containing the coordinative site MN_2Te_2 from β -tellurovinyl aldimines.

5. Systemic studies of the effect of the nature of tellurium-containing substituents and donor sites (COR , $\text{CH}=\text{NR}$) on the lengths and stabilities of the intramolecular coordinative bonds $\text{O} \rightarrow \text{Te}$ and $\text{N} \rightarrow \text{Te}$.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 00-15-97320) and INTAS (Grant 884-01).

Rational design of metal coordination compounds with azomethine ligands

A D Garnovskii, I S Vasil'chenko

Contents

I. Introduction	943
II. Azomethine metal chelates	944
III. Molecular complexes with azomethine ligands	956
IV. Bi- and polynuclear azomethine complexes	958
V. Conclusion	961

Abstract. This review surveys the state of art in the coordination chemistry of chelating azomethine systems, viz., amino(hydroxy)-azomethines, β -aminovinyl ketones, β -aminovinylimines and their sulfur- and selenium-containing analogues. Variations in the fine structure of azomethine ligands allow one to perform the targeted synthesis of chelate and molecular, mono-, bi- and polynuclear, homo- and heterometallic structures. The bibliography includes 425 references.

I. Introduction

Advances in coordination chemistry are to a large extent associated with the construction of new types of ligand systems. However, there are some well-known rather simple ligands, which can also allow progress in the chemistry of complex compounds relying on the principles of rational design (variation in the fine structure of ligand systems). Among these ligands are, for example, Schiff bases (azomethines) and their structural analogues, which are the 'oldest' ^{1,2} and most studied ^{3–24} ligands in coordination chemistry. The complexes with these ligands have attracted interest for more than 150 years primarily because the nature of substituents in azomethine ligand systems **1** can be varied over a wide range and it is possible to prepare mononuclear metal chelates **2** exhibiting various physicochemical properties and containing coordination units with different geometry.

$R^1, R^2, R^3, R^4 = \text{H, Alk, Ar, HetAr}; R^2 - R^3 = \text{CH}=\text{CH}-\text{CH}=\text{CH},$

Received 30 September 2002

Uspekhi Khimii 71 (11) 1064–1089 (2002); translated by T N Safonova

In earlier reviews ^{2–23} and numerous more recent papers, most attention has been concentrated on azomethine-based chelate compounds. However, not only chelates **2** but also other structural types of metal complexes of chelate-forming azomethines have been much studied. ^{20, 22, 24–33}

Taking into account the classification proposed by one of the authors of the present review, ^{24–26} complex compounds of Schiff bases and their analogues can be divided into the following three types: chelates **2**; molecular complexes **3**; bi- and polynuclear compounds (**4** and **5**) and polymeric structures (**6**).

$R^1 - R^4 = \text{Alk, Ar}; X, Y = \text{NTs, O, S}; M = \text{Ni, Cu, Zn},$
 $A = \text{Hal, NO}_3; M = \text{B, Al, Sn, Ti, Zr, Hf, Th, Zn, Cd, Hg};$
 $n = 2 - 4.$

$M = \text{Co, Ni, Cu}.$

All attempts to synthesise the fourth type of complexes, viz., π -complexes, ^{24–26} with azomethine ligands failed because, apparently, of a shortage of complex-forming agents and the lack of procedures for the synthesis, which could be used for the preparation of these (predominantly organometallic ^{24, 34–36}) compounds. However, it should be noted that the reactions of N, N' -bis(salicylidene)ethylenediamine with typical π -complex-forming

agents, viz., metal hexacarbonyls, afforded chelate compounds **7**.³⁴

M = Cr, W.

7

Metal chelates involve deprotonated (anionic) di- or polydentately coordinated azomethine ligand systems. Neutral chelate-forming azomethine compounds **3**, most of which are monodentately coordinated to the metal atom, serve as ligands in molecular complexes. Chelates **4** as well as compounds **5**, which are adducts of chelate compounds **2** and Lewis acids (M^2A_n),^{24,30} and metal-containing azomethine polymers **6**^{31–33} can be assigned to bi- and polynuclear structures.

The present review surveys the data (published predominantly in the last decade) on the synthesis and structures of different types of azomethine metal complexes. Particular attention is given to the choice and modifications of ligand systems (rational design) and procedures for the synthesis of complexes of Schiff bases and their analogues, which are of importance in the preparation of compounds with the desired mode of arrangement of the coordination bond and geometry of the metallocycles as well as in the construction of complexes of different nuclearity and with different degrees of oligomerisation.

II. Azomethine metal chelates

This section is devoted primarily to the employment of azomethine compounds, which have an intramolecular hydrogen bond giving rise to a five- or six-membered coordination unit and contain varying aldehyde and amine fragments, as chelating ligands. Chelate compounds based on these ligands can be prepared by reactions of ligand systems with metal salts as well as with the use of template and electrochemical synthesis methods.²⁴

1. Chelate compounds with five-membered metallocycles

a. Complexes with N,N-donor atoms

Aromatic azomethine chelates containing the five-membered MN_4 coordination unit became available in 1977.³⁷ These compounds are prepared by the reactions of Schiff bases of monotosylated *o*-phenylenediamine with metal acetates (method *a*)^{17,37–39} or metals under the conditions of electrosynthesis. The latter method involves the reactions of zero-valent metals (anode) with ligands in an electrolytic cell equipped with a platinum cathode (method *b*).^{39–43}

Compounds **8** contain aromatic^{37,38} and heterocyclic^{38–43} fragments as the substituent R.

R = Ar, HetAr; M are 3d metals.

(a) $M(OAc)_2$, MeOH, Me_2CO ; (b) M^0 , $-2e^-$, MeCN.

In compounds **9**, ligands containing the pyrrole substituents, which are capable of forming additional coordination bonds, can serve as both bidentate ligand systems **10**^{40,41} and tridentate ligand systems **11**.⁴¹

10: M = Zn, Cd.

11: M = Co, Ni; L = H_2O .

The quinone-imine groups can be involved in chelates **12** containing a five-membered coordination unit.^{44–48}

12

13

14

Complexes with Schiff bases of 2-formylpyrrole **13**^{5,12,20,21,49–55} and 2-formylbenzimidazole **14**^{43,56–60} studied earlier belong to azomethine complexes containing the five-membered MN_4 coordination unit. It should be emphasised that chelates of type **13** were generated under the conditions of chemical^{5,12,20,21} and electrochemical^{49–55} syntheses, whereas chelates **14** were prepared only by the electrochemical method^{56–60} because of the rather low acidity of the N–H bond in benzimidazole. This approach was also employed in the synthesis of chelate compounds **15** and **16** with the use of pyrrole-based aldimine ligands possessing nitrogen-⁵⁵ or sulfur-containing⁶¹ fragments. Tropone imine complexes also contain the MN_4 coordination unit with the azomethine bond.²⁰

15

16

b. Chelates with N,O-donor atoms

Azomethines **17**, which were derived from *o*-aminophenol and contain an intramolecular hydrogen bond, serve as bidentate ligands and form bicyclic chelate compounds **18** with the five-membered MN_2O_2 coordination unit.^{20,22,25,62,63}

R = Ar, HetAr; M = Cu, Mn, Co, Ni, Zn, Cd etc.

These reactions, particularly those used for the preparation of copper(II) chelates⁶² (**18**, M = Cu), are accompanied by partial hydrolysis of the exocyclic azomethine bond resulting in contamination of chelate compounds **18** with *o*-aminophenol complex **19**. Because of this, copper chelate **18** (R = Ph, M = Cu) was prepared in the presence of an excess of benzaldehyde.⁶²

The template synthesis of manganese complexes **20**⁶⁴ is of interest.

R = H, 4-NO₂; X = H, 2-NO₂, 3-NO₂, 2-MeO, 4-MeO, 4-Me₂N.

The reactions of compounds **17** with acetates of other metals (Co, Ni, Zn, Cd) in methanol afforded virtually pure complexes with composition ML₂.^{20, 22, 24, 65, 66} The exceptions are the palladium chelates PdL₂, which were prepared⁶⁶ from azomethines **17** [R = C₆H₄R¹; R¹ = H, 4-Cl, 4-NMe₂, 2,4-(OMe)₂] in an Me₂CO–MeOH mixture.

Of complexes **18** with varying substituents R, noteworthy are chelate compounds containing heterocyclic fragments, for example **21**^{67, 68} and **22**⁶⁹ prepared by chemical and electrochemical methods.

It was proposed (although this assumption was not supported by X-ray diffraction data) that complexes analogous to compounds **23**, which are generated from *o*-aminophenol and heteroaromatic aldehydes, can contain tridentate ligands.⁷⁰

R = H, C₄H₄-cyclo; n = 1, 2; A is absent or is NO₃, OCOMe;
M = Ni, Pb, Th, UO₂.

Compounds **17** whose aldehyde fragments possess substituents capable of being involved in additional coordination can serve as tridentate ligands as well.⁷¹ Thus, the P,N,O-tridentate mode of coordination of the ligand was found in chelate **25**, which was prepared from compound **24** and the [RuCl₂·4DMSO] complex by the ligand-exchange reaction²⁴ in THF and structurally characterised.

In most cases, bidentate ligands **17** are involved in tetracoordinated complexes with composition ML₂. However, monocyclic chelates **26** of the L¹L²MCl type, which are composed of one monoanion of Schiff bases of *o*-aminophenol, were also synthesised⁷² by the reactions of the corresponding ligands with the

[(R₃P)(Cl)M(μ-Cl)]₂ (M = Pd, Pt), [(η⁵-Cp)(Cl)Ir(μ-Cl)]₂ and [(4-PrⁱC₆H₄Me-I)(Cl)Ru(μ-Cl)]₂ complexes in methanol.

Recently,⁷³ complexes **27** and **28** containing three metallocycles each were prepared by the template synthesis.

c. Chelate compounds with N,S(Se)-donor atoms

The synthesis of chelates containing the five-membered MN₂S₂ coordination unit involves the well-studied reactions of Schiff bases of *o*-mercaptoaniline with metal salts.^{20, 22, 24, 39, 74, 75}

R = Ar, HetAr, Fc; M = Co, Ni, Pt, Pd, Zn; A is an anion.

The reactions of Schiff bases of *o*-mercaptoaniline, which occur predominantly in the closed form of 2,3-dihydrobenzothiazole **29**,^{76, 77} with metal salts in alcohols (methanol, ethanol) afforded chelate compounds **30** containing the open deprotonated form of *o*-mercaptophenylazomethine **31** as the ligand system. In these chelates, aromatic^{78–87} or heterocyclic^{39, 69, 75, 88–90} as well as organometallic systems (for example, ferrocene⁷⁴) are most often involved as the substituent R.

Chelate compounds **30** exhibit a specific type of valence tautomerism.^{83, 84} For example, heating of complexes **32** in toluene over a short period of time gave rise to cobalt and nickel 2,2'-bis(1,2-diphenylethylenediimine)benzothiolates **33** through the formation of the C–C bond.

It should be noted that this transformation was not observed for chelates **30** containing the 3,5-di-*tert*-butyl-4-hydroxyphenyl fragments as the substituents R.⁸⁶

In some cases, the reactions afforded tri- (**34**)⁸⁵ and tetrameric (**35**)^{81, 82} structures along with complexes **30**.

Most of chelates of tridentate azomethine ligands characterised by the N,S-ligand environment are azomethine complexes prepared from heterocyclic aldehydes.^{39, 69, 75, 89–90} Compounds **36** (X = NMe,³⁹ S⁶⁹) serve as examples of this type of chelate compounds.

M = Pd, Zn, Cd; X = NMe, S.

2-(2-Pyridyl)-2,3-dihydrobenzothiazole⁸⁹ and 2-methyl-2-(2-pyridyl)-2,3-dihydrobenzothiazole⁷⁵ act as donor ligands of the N₂S type to give complexes **37** and **38**, respectively. 2-(2-Pyridyl)-2,3-dihydrobenzothiazole also serves as the tridentate ligand in tetracyclic chelates **39**.⁹⁰

The complex formation involving bis-2,3-dihydrobenzothiazoles **40** gives rise to tricyclic chelates **41** with composition ML, in which mercaptoazomethines act as tetradentate ligands.⁹¹

R = H, Me, Ph; M = Cd, Zn, Hg.

The use of 2,6-dicarbonyl derivatives of pyridine **42a,b** (LH₂ ligands) as the aldehyde (ketone) fragment made it possible to prepare chelates with pentadentate ligands.^{88, 92, 93} The structure of complex **43** was established by X-ray diffraction analysis.⁹²

If the nature of the ligand system in compounds **42** (R = H) and the reaction conditions are changed,⁹⁴ the complex formation is accompanied by a redox process with the resulting changes in the type and denticity of ligand system **42** giving rise to chelate compound **44**.

Apparently, chelate compounds prepared on the basis of 2,5-bis(2,3-dihydrobenzothiazol-2-yl)thiophene derivatives **45**⁹⁵ can also be assigned to five-membered azomethine chelates containing N,S-donor centres.

M = Zn, Cd; R = Ph,

There are only a few complexes **46**, which belong to azomethine chelates containing five-membered metalocycles and the MN₂Se₂ coordination unit. These complexes were prepared by template synthesis from metal *o*-aminobenzeneselenolates and the corresponding aldehydes.⁹⁶

Similar reactions involving the *o*-aminobenzenetellurol chelate compound⁹⁷ afforded metal-free ditelluride rather than a tellurium-containing chelate analogous to complex **46**.⁹⁸

2. Chelate compounds with six-membered coordination units

a. Complexes with N,N-donor atoms

Not only numerous classical bis-β-aminovinylimines **47**^{4, 12, 17, 20, 22, 24, 99–104} but also monoanionic complexes **48**^{101, 105–116} and binuclear structures **49**^{108, 109, 112, 114, 117} are examples of six-membered metal chelates prepared on the basis of bidentate azomethine N,N-donors **1** (X = NR⁵).

A = Hal, OAc.

Most of chelate compounds **47** ($n = 2$) typical of β -aminovinylimines were obtained by the reactions of ligands **1** ($X = \text{NR}^5$) with metal salts in alcohols. In this connection, of particular interest is the synthesis of the first structurally characterised tris-diiminate complex **47** ($R^1 = R^3 = \text{Me}$, $R^2 = \text{H}$, $M = \text{Al}$, $n = 3$), which was prepared by the ligand-exchange reaction of 2-methylamino-4-methyliminopent-2-ene with $\text{Me}_3\text{N} \cdot \text{AlH}_3$ in toluene.¹⁰³

First publications on complexes **48** appeared in the mid-1990's. These studies were devoted primarily to the directed synthesis of chelates, in which the metal centre is shielded by bulky substituents, and were aimed at constructing new catalysts of polymerisation and other processes.

β -Aminovinylimines **1** bearing bulky substituents (predominantly, $\text{C}_6\text{H}_3\text{-2,6-Pr}_2^i$) at the nitrogen atom were used for the preparation of this type of chelate compounds with lithium,¹¹³ barium,¹¹⁸ magnesium,^{119–121} boron,¹⁰⁷ aluminium,^{110, 122–124} gallium and indium,¹¹⁰ scandium,^{125, 126} samarium and gadolinium,^{127, 128} ytterbium,¹²⁹ tin,¹³⁰ titanium,^{101, 105, 131} zirconium,^{101, 132, 133} vanadium,¹⁰⁵ chromium,^{105, 134} copper,^{106, 109, 111, 114, 115–117, 135} zinc,^{108, 112, 114} platinum¹¹⁶ and rhodium.¹³⁶

Chelates **48** were synthesised either from lithium complexes **50** (predominantly) or by the reactions of β -aminovinylimines with different complex-forming agents.

Thus, a series of boron-containing complexes of β -diketimines **51–54** were prepared.¹⁰⁷

Tol = 4-MeC₆H₄.

Chelate **51**, which was used as the starting compound in the synthesis of complexes **52–54**, was prepared by the reaction of $\text{BF}_3 \cdot \text{OEt}_2$ with lithium derivative **50** and isolated from a solution in toluene. β -Aminovinylimines were used for the synthesis of complexes of aluminium, gallium and indium **48a**,¹¹⁰ titanium and zirconium **48b**¹⁰¹ and chromium **48c**.¹³⁴

The metal-exchange method was also used for the preparation of copper complexes with β -aminovinylimines.^{109, 111, 115} Noteworthy are the syntheses using lithium salts **55a,b** and the $\text{CuCl}_2 \cdot 0.8 \text{ THF}$ complex,¹¹¹ *i.e.*, procedures combining the metal- and ligand-exchange reactions.²⁴ These reactions afforded mononuclear chelate compounds **56a,b** containing the labile chlorine atom, which can be replaced by the OAr or CNAr groups.¹¹¹

R = H (**a**), Me (**b**).

Monovalent copper chelates **57** and **58** were synthesised analogously.^{109, 115}

R = H, Ph.

R¹ = H, Me, Bu^t; R² = H, Ph.

Copper chelate **59**¹¹⁴ and zinc chelate **60**¹¹² were synthesised from the corresponding ligands and $\text{Cu}(\text{OAc})_2$ or ZnMe_2 , respectively. The structures of virtually all chelate compounds described above were established by X-ray diffraction analysis.

Binuclear complexes **49** were prepared primarily according to analogous methods, *viz.*, by the metal- or ligand-exchange reactions or with the use of a combined procedure. Thus, the reaction of aminovinylimine **61** with copper(II) chloride in alcohol gave rise to copper complex **62**, which was isolated and structurally characterised.¹¹⁷

Lithium complex **55a** was used for the preparation of bridged binuclear zinc chelates **49** ($M = \text{Zn}$; $A = \mu\text{-Cl}$, $\mu\text{-Br}$, $\mu\text{-OAc}$).¹⁰⁸

Binuclear complex **63**, which served as the starting compound for the preparation of chromium-containing chelates **64–67**, was prepared by the ligand-exchange reaction of lithium salt **55a** with the $\text{CrCl}_3 \cdot (\text{THF})_3$ complex in THF.¹³⁴

Ar = $\text{C}_6\text{H}_3\text{Pr}_2^{i-2,6}$.

In some cases, binuclear complexes **49** were synthesised with the employment of specific techniques. For example, structures **49** ($\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ar}$, $\text{M} = \text{Zn}$; $\text{A} = \text{H}$, F , OAc , OH , OMe) were prepared from mononuclear zinc complexes **48** [$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ar}$, $\text{M} = \text{Zn}$; $\text{R}^4 = \text{Me}$, Et , $\text{N}(\text{SiMe}_3)_2$] and reagents, which were used for the formation of bridging fragments.^{108, 112, 137, 138}

Recently,¹³⁹ it has been demonstrated that the reactions of β -aminovinylimines with CuCl_2 in alcohols can give rise to dimeric complexes **68** in which the aminoimine ligand is monodentately coordinated to the metal centre.

Chelates **69**,^{17, 20, 22, 24, 39, 99, 140–145} **70**,¹⁴⁶ **71**^{45, 147} and **72**¹⁴⁸ take an important place among chelate compounds containing the

six-membered MN_4 coordination unit, which were prepared on the basis of N,N-donor bidentate azomethine ligand systems.

These complexes were synthesised predominantly by the direct reactions of the corresponding ligands with salts (predominantly, acetates) of 3d metals. In some cases, chelates **69** were prepared by template^{140–142} or electrochemical^{39, 143, 144} synthesis methods. It should be noted that azomethines based on N-unsubstituted 2-aminobenzaldehyde and aliphatic (aromatic) monoamines are unstable. Because of this, most of the syntheses were carried out with the use of 2-monotosylaminobenzaldehyde imines as precursors.^{140–145} Complexes **72** ($\text{R} = \text{Ph}$, $\text{C}_6\text{H}_3\text{F}_2$ -2,6, $\text{C}_6\text{H}_3\text{F}_3$ -2,4,6) were prepared by the reactions of the lithium salt of 7-(N-aryliminomethyl)indole with titanium tetrachloride.¹⁴⁸ The Schiff base derived from 2-aminobenzaldehyde and ethylenediamine is quite stable. Hence, this Schiff base and sources of complex-forming metal were used for the preparation of chelate compounds **73a**¹⁴⁹ with tetradentate ligands.

$\text{R} = \text{H}$, Me ; $\text{M} = \text{Ni}$ (a), Cu (b), $\text{FeCl}(\text{Br})$ (c).

Tricyclic chelates **73a**¹⁴⁹ were prepared by the reactions of the corresponding ligands with nickel acetate in methanol. Complexes **73b** were synthesised by the reaction of a suspension of $\text{Cu}(\text{OMe})_2$ in methanol with the ligand. Chelates **73c** were prepared by the reactions of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ or FeBr_3 with the corresponding ligands in acetone.¹⁵⁰ The synthesis of nickel complex **74** was described in the study.¹⁵¹

b. Chelate compounds with N,O-donor atoms

Metal chelates of bidentate hydroxyazomethines **1** ($\text{X} = \text{O}$) belong to the best-studied class of chelate compounds containing the six-membered MN_2O_2 coordination unit.^{2, 4, 7, 9–16, 18–25} These compounds still attract interest today. Considerable attention is given to the synthesis and properties of chelate compounds with poorly studied metals, viz., aluminium,¹⁵² scandium and yttrium,¹⁵³ titanium,^{154–156} rhenium¹⁵⁷ and molybdenum.¹⁵⁸ Aluminium(III) chelate compounds were synthesised from azomethine **75** and Me_3Al . These reactions can afford not only neutral chelates **76** but also cationic complexes **77**. The structure of coordination compound **77** was established by X-ray diffraction analysis.¹⁵²

$\text{R} = \text{C}_6\text{H}_3\text{Me}_2\text{-2,6}, \text{C}_6\text{H}_3\text{Pr}_2\text{-2,6}, \text{C}_6\text{H}_3(\text{CF}_3)_2\text{-3,5 etc.}$

The reactions of Schiff bases **78** with organometallic derivatives **79a,b** gave rise to scandium and yttrium chelate compounds **80a,b**.¹⁵³

$\text{M} = \text{Sc (a)}, \text{Y (b)}$.

Titanium chelate complexes **81** were synthesised by the metal-exchange method from lithium salts of the ligands and titanium tetrachloride.^{154–156}

$\text{R}^1\text{--}\text{R}^5 = \text{H, F}$.

Chelates of Re(V) **82**¹⁵⁷ and Mo(VI) **83a,b**¹⁵⁸ were prepared with the employment of unusual sources of complex-forming metals.

$\text{R}^1 = \text{Ph, cyclo-C}_6\text{H}_{11}; \text{R}^2 = \text{H, Cl}$.

$\text{R} = \text{Me (a)}, (\text{CH}_2)_n\text{NH}_2; n = 2, 3 \text{ (b)}$.

An important line of investigation in the chemistry of complexes with hydroxyazomethine ligands deals with the synthesis and studies of chelate compounds **2** ($\text{X} = \text{O}$) containing various substituents $\text{R}^1\text{--}\text{R}^3$, including fragments annelated to the metalocycle. As an example we refer to the synthesis of zinc complexes **84–86** (Scheme 1).¹⁵⁹

The reactions of azomethines, which were prepared from salicylaldehyde and chiral α -phenylethylamines, with zinc acetate afforded optically active zinc complexes **87**.¹⁶⁰

Metal chelates in which heterocyclic fragments are annelated to metalocycles were examined in the studies.^{20,22} For example, benzofuran derivatives of chelate compounds **88** were prepared.^{161,162} Chelates **89** and **90** were synthesised on the basis of β -aminovinyl ketones^{163–168} or *o*-hydroxybenzaldimines^{169,170} and the nitroxyl imidazoline radicals and their magnetic properties were studied. Complexes **89** and **90** were prepared

Scheme 1

predominantly from the corresponding ligands and metal acetates in aqueous ethanol.

In some cases, *o*-hydroxyazomethine chelates were synthesised by the electrochemical method.^{24, 43, 60, 171, 172}

An increase in denticity of the hydroxyazomethine ligands can be achieved by the introduction of the substituents R containing centres which can be involved in additional coordination, in particular, the alkylamino, hydroxy, alkoxy or alkylthioalkyl fragments as well as their aryl analogues. Such ligand systems are involved in complexes **91–94**.^{12, 24}

X = O; Y = NR₂, OR, SR; R = H, Alk, Ar; n = 2–4.

Salicylaldehyde-based azomethine complexes have been studied for many years.^{12, 173} In these complexes, additional coordination can occur through the dimethylaminoalkyl substituents. For example, a ligand of this type is present in the structurally characterised manganese chelate **95**.¹⁷⁴

This type of metal binding was observed in complex **96**.¹⁷⁵

By contrast, X-ray diffraction analysis demonstrated that the nitrogen atom of the aminoalkyl substituent is not involved in additional coordination in molybdenum complexes **83b** synthesised by the template method.¹⁵⁸

Among chelate compounds **91–94**, complexes of salicylide-amino alcohols have received the most study. Early investigations devoted to their synthesis, structures and properties have been surveyed in reviews.^{176–178} Recently, chelate compounds of titanium(IV),¹⁷⁹ vanadium(V),^{180, 181} dioxomolybdenum(VI),^{180, 182, 183} cobalt(III),¹⁸⁴ nickel(II)^{185–187} and copper(II)¹⁸⁶ were prepared and characterised. Titanium complexes of type **93** containing the deprotonated OH groups were synthesised from the ligands and Ti(OPrⁱ)₄.¹⁷⁹ Complexes **93** with vanadium^{180, 181} and molybdenyl^{182, 183} were prepared by the ligand-exchange reactions with the use of acetylacetonates of these metals. As an example we refer to compound **97**.

The structures in which the OH groups are retained are typical of nickel (**98**)¹⁸⁶ and copper (**99**)¹⁸⁷ complexes synthesised by the template method.

In the fluorine-containing barium β-ketoiminate complexes Ba[CF₃COCH=C(NR)CF₃]₂ [R = CH₂(CH₂CH₂O)₂, (CH₂)₂, (CH₂CH₂O)₂ or CH₂CH(CH₂CH₂O)₃], which were prepared from the corresponding ligands and BaH₂ in a mixture of heptane and THF,¹⁸⁸ the metal atom is coordinated by the oxygen atoms of the alkoxy groups.

Most of the complexes prepared on the basis of mercapto-alkylimines are bi-^{189, 190} or trinuclear.¹⁹⁰ However, Zelentsov and Suvorova¹⁹¹ expected that the mononuclear nickel complex could be isolated.

Iminothiol complexes **100** were prepared by the electrochemical cleavage of the disulfide bond.¹⁹²

Salicylideneanilines **101** containing various proton- and electron-donating groups YR in the *ortho* position of the *N*-aryl fragment are very widespread azomethine tridentate ligands.

Although most of the complexes prepared on the basis of ligands **101** have binuclear structures (see Section IV), mononuclear chelates (predominantly of type **102**) were prepared with the employment of some complex-forming agents. Thus, mononuclear complexes of boron,¹⁹³ aluminium,¹⁷⁵ tin,^{194,195} rhenium,^{196–198} molybdenum,¹⁹⁹ tungsten,¹⁹⁹ cobalt,^{200–204} nickel,^{201–208} copper^{201,203,207,208} and cadmium^{202,209} are known. A series of chelate compounds under consideration were synthesised by the direct reactions of compounds **101** with different sources of metals, *viz.*, AlMe₃ (in PhMe), tin, nickel, zinc, copper and cadmium salts (in alcohols). Analogously, boron complexes **103** were synthesised by the reactions with B(OR)₃, where R² = Me, Et, Pr or Buⁿ, in a mixture of toluene and THF.¹⁹³

102: Y = NTs, P, O, S; L = Py, bipy, , etc.; n = 1, 2;

103: R¹ = H, Cl, Br; R² = Me, Et, Prⁿ, Buⁿ.

Oxorhenium chelates **102** (M = ReO) were prepared by the ligand-exchange reactions of [ReOCl₃(PPh₃)₂], compounds **101** and ligands L. In particular, 2-(2-hydroxyphenyl)benzoxazole,^{197,198} 2,3-dihydro-2-(2-hydroxyphenyl)benzothiazole¹⁹⁷ and triphenylphosphines containing the proton-donating group (OH or CO₂H) in the *ortho* position of one of the benzene rings¹⁹⁸ were used as the ligands L. Dioxomolybdenum and dioxotungsten complexes were prepared¹⁹⁹ from Schiff bases **104** and **105** and acetylacetonates of MoO₂ and WO₂, respectively (in MeOH).

R = H, 5,6-C₄H₄-cyclo.

The electrochemical method is widely employed for the preparation of chelate compounds **102**.^{200–204,207} This method proved to be particularly useful in the case of chalcogen-containing tridentate azomethines. Thus, chelates **106** were synthesised from the corresponding disulfides and diselenides.^{194,210}

An important advantage of this method is that it allows one to use various N-donor ligands,^{200–208} including ambidentate 1-alkyl-2-aminobenzimidazoles.^{201–204}

Chelates **102**, like other complexes, can be prepared by the template electrochemical method.²⁰²

M = Ni, Zn; L = H₂O, MeCN.

It should be noted that the donor centres Y in azomethines **101**, like those in other compounds containing N-donor fragments at the nitrogen atom,²⁴ are not necessarily involved in coordination to the metal atom. Thus, X-ray diffraction analysis demonstrated that the nitrogen atom of the pyridyl fragment in chelates **107**, which were obtained from the potentially tridentate pyridine-substituted azomethine by the reactions with metal salts or under the conditions of the electrochemical synthesis, is not bound to the metal atom.^{211,212}

By contrast, X-ray diffraction analysis revealed the Zn–N_{py} interaction (the distance is ~ 2.8 Å) in the analogous zinc chelate **108**.²¹³ It was suggested that additional coordination also occurs in complex **109**.²¹⁴

The difference in the behaviour of the coordinatively active pyridyl substituent in complexes **107** and **108** was attributed to the instability of four-membered metallocycles.²¹⁵ Actually, stable bicyclic chelate compounds with tridentate ligands were obtained under conditions favourable for the formation of five-membered coordination units due to the insertion of the methylene group (complex **110**)¹⁷⁵ or the quinoline substituent (complexes **111**²¹⁶ and **112**²¹⁷).

Bissalicylidene derivatives of aliphatic, aromatic and heterocyclic diamines **113**^{2,9,12,20–22,24,218} serve as tetradentate N,O-donor azomethine ligands, which gave rise predominantly to tricyclic chelates **114**.

$R^1 = \text{H, Alk}; R^2 = \text{H, Alk, Ar, Hal, NO}_2, \text{OAlk}; A = \text{Alk, Hal};$

$Z = (\text{CR}^3\text{R}^4)_m, \text{Ar, HetAr}; R^3, R^4 = \text{H, Alk, Ar}; n = 0, 1, 2.$

In recent years, chelate compounds **114** with aluminium,^{218–221} gallium,^{218, 222} indium,^{218, 222–225} tin,²²⁶ titanium,²²⁷ manganese,^{228–237} vanadium,^{238, 239} chromium,^{230, 240} molybdenum,²⁴¹ cobalt,^{236, 241} iron,^{231, 236, 241} nickel,^{231, 236, 241, 242} ruthenium,^{243–245} palladium,²⁴⁶ osmium,²⁴⁷ copper^{231, 236, 246, 248–250} and zinc^{251, 252} have been prepared. Aluminium, gallium and indium complexes were synthesised by the reactions of ligands **113** with alkyl and other derivatives of these metals.²¹⁸

Chelate compounds of Group III metals were prepared with the use of a mixture of acetonitrile and THF²²¹ or cyclohexane²²² as the solvent. Tin complexes of the general formula R_2SnL ($\text{R} = \text{Me, Bu}^n, \text{Ph}$) were synthesised in benzene with the addition of triethylamine under an atmosphere of nitrogen starting from the corresponding tin(IV) dichloride and tetradentate Schiff bases derived from salicylaldehyde, 3-methoxysalicylaldehyde, 4-benzoyl-3-methyl-1-phenylpyrazol-5-one, *o*-phenylenediamine and 1,3-propylenediamine.²²⁶

Complexes **114** ($\text{M} = \text{Mn}$: A is either absent²³⁶ or is ClO_4 ,^{228, 233} Cl ,^{229, 231, 237} H_2O ,²²⁹ $\text{M} = \text{Cr}$: A = Cl ²⁴⁰) were prepared from ligands **113** and the corresponding manganese or chromium salts in alcohol. Adducts of bis(salicylidene)ethylenediamine chelates of manganese and chromium with atomic nitrogen (**115**) were synthesised from azido complexes.^{230, 253}

$\text{M} = \text{Mn, Cr}.$

Osmium nitride complexes **114** [$\text{M} = \text{Os}$: $R^1 = \text{H}, R^2 = \text{H, Cl, Me, OMe}; A = \text{N, MeOH}; Z = (\text{CH}_2)_2$] were prepared by the reactions of the corresponding ligand **113** with $[\text{NBu}_4][\text{Os}(\text{N})\text{Cl}_4]$ in MeCN or MeOH.²⁴⁷

The direct reactions of the reagents were used in the synthesis of chelates **114** containing nickel ($\text{M} = \text{Ni}$; A is absent),²⁴² ruthenium ($\text{M} = \text{Ru}$; A = Cl),²⁴⁴ copper [$\text{M} = \text{Cu}$; A is absent; $R^2 = 5-(\text{N}=\text{NPh})$,²⁴⁹ OMe ²⁵⁰] or zinc [$\text{M} = \text{Zn}$; A = THF, Py; $R^2 = 3,5\text{-Bu}^t$, $3\text{-Bu}^t\text{-5-(4-Py)}$; L = Py or absent].^{251, 252} Ruthenium chelate compounds were also prepared by ligand exchange in the $\text{RuCl}_2(\text{PPh}_3)_3$ complex.²⁴⁵ The same synthetic approach

$R^1 = \text{Me, CF}_3; R^2 = \text{H, Me, CMe}_3; Z = (\text{CH}_2)_2, (\text{CH}_2)_3,$

$\text{MeCHCH}_2, \text{CH}(\text{CH}_2)_4\text{CH}.$

was applied in the preparation of chelates of Ru(II) ²⁵⁴ and Ru(III) ²⁵⁵ from bis- β -aminovinyl ketones **116**.

Ruthenium chelate compounds **117** were synthesised by combining the ligand- and metal-exchange reactions²⁵⁴ with the use of the triphenylphosphine complex $\text{RuCl}_2(\text{PPh}_3)_3$ and its arsine analogues $\text{RuY}_2(\text{AsPh}_3)_3$ ($\text{Y} = \text{Cl, Br}$) as the source of metal.²⁵⁵

$\text{X} = \text{H, F}.$

Copper and nickel chelate compounds with ligand **116** [$R^1 = \text{H}; R^2 = \text{C}_6\text{H}_4\text{OMe-4}; Z = (\text{CH}_2)_3, 1,2\text{-C}_6\text{H}_{10}\text{-cyclo}$] were synthesised in methanol with the use of acetates of the corresponding metals.²⁵⁶

A series of studies were devoted to modifications of ligand systems of type **113** by varying the Z bridge (for example, complexes **118**,²⁵⁷ **119**,²⁵⁸ **120**,²⁵⁹ **121**²⁶⁰ and **122**²⁶⁰) and aldehyde fragment (complexes **123**²²⁶ and **124**²⁶¹).

118: $\text{M} = \text{Ni, Cu}.$

119: $\text{M} = \text{Ni, Cu, Co, Zn, Cd}.$

120: $\text{M} = \text{Ni, Cu, Co, Zn, Cd}.$

123: $R^1 = \text{Bu}^n, \text{Ph}; R^2 = (\text{CH}_2)_3, \text{C}_6\text{H}_4\text{-}o.$

It was demonstrated^{262–264} that potentially penta- or hexadentate N,O-donor azomethine systems containing the bis(salicylidene)ethylenediamine fragment, like the above-considered compounds **118–123**, form chelates with tetracoordinated ligands, such as complexes **125**²⁶² and **126**.²⁶⁴ Chelates **117** and **120–125** were synthesised from the corresponding ligands and various metal sources. Complex **118** was prepared by the template method.

According to the X-ray diffraction data,²⁶¹ the ligand in complex **124** is coordinated through the crown fragment rather than through the azomethine group. It should be emphasised that ligands in complexes **124**–**126** can be considered as ambidentate ligand systems.²⁷ Taking into account that the lanthanum cation is the hardest acid of all the cations involved in these complexes,²⁴ the structure assigned to complex **124** seems to be justified.

c. Chelate compounds with N,S(Se)-donor atoms

In 1968, the template synthesis (method *a*) of metal chelates **127** of sulfur-containing bidentate Schiff bases generated from the sodium derivative of *o*-mercaptobenzaldehyde was carried out by two independent research groups.^{265,266} These compounds were the first representatives of azomethine chelates containing the MN_2S_2 coordination unit.

Method *a*

X = S, Se; R¹ = Alk, Ar, AlkO *etc.*; R² = Me, Buⁿ;
M = Co, Ni, Cu, Zn *etc.*

Complexes **127** are also often prepared by the reactions of stable mercaptosalicylaldehyde chelates with amines and their derivatives (method *b*).^{20,24}

Method *b*

M = Co, Ni, Cu, Zn.

The use of chelates **128** enables one to construct coordination compounds **127** containing various substituents at the nitrogen atom, *viz.*, aryl,^{267,268} pyridyl,²⁶⁹ methoxy²⁷⁰ and phenylamino groups,²⁷¹ as well as alkylthiovinyl-bridged complexes **129**.²⁷²

The method *a* is more universal than the method *b* because it allows one to prepare not only chelate compounds **127** containing the MN_2S_2 coordination unit but also complexes of Schiff bases with the MN_2Se_2 chelate unit.²⁷³

Chelates **127** can also be prepared starting from bisazomethine disulfide **130** and iron pentacarbonyl.²⁷⁴

R = C₆H₄OMe-4.

Complex compounds **131** synthesised from benzotellurazole **132** can be considered as tellurium-containing analogues of chelates **127**.²⁷⁵

Tridentate sulfur-containing azomethine complexes **133** were first prepared according to an original procedure employing the reactions of nickel iodide with Schiff base **134**.²⁰

Tetracoordinated nickel complexes **135** were synthesised analogously.²⁷⁶

Complexes **136**,²⁷⁷ **137**²⁷⁴ and **138**²⁷⁸ were constructed by the template method.

X = NTs, O, S.

The template synthesis²⁷⁹ was used for the preparation of chelates of tetradentate N,S-donor azomethine ligands **139**,²⁷⁴ **140**²⁸⁰ and **141**.^{281, 282}

The synthesis and structures of the structural analogues of these chelate compounds, *viz.*, chelates **142** and **143**, were described in the studies cited in review²⁰ and monograph.²⁴

M = Co, Ni, Zn;
R¹ = Alk, Ar; R² = H, Alk.

Let us emphasise that the rational design of chelate compounds of azomethine N,S(Se)-donors is of fundamental importance in the synthesis of complexes with selenium-containing ligands (for example, **144**²⁸³) or complexes **145**²⁰ containing alterdentate ligands, which are difficult to prepare.^{284–286} The latter complexes play an important role in studies of the stereo-dynamics of tetracoordinated azomethine structures.²⁸⁶

Investigations of the synthesis, structures and properties of chelate compounds of heteroaromatic Schiff bases containing N,S(Se)-donor centres **146–150** were started in the late 1960s–early 1970s.^{8, 161, 287–290}

A = O, S; X = S, Se; M = Co, Ni, Cu, Zn.

These complexes have still attracted attention in subsequent years.^{20, 22, 24, 267, 269, 291–307}

Azomethines derived from thio-substituted heterocyclic aldehydes (for example, compound **149a**), which exist in the thione-amine form **149b**,⁷⁷ are more stable than their aromatic analogues. Because of this, chelate compounds **150** are synthesised primarily by direct reactions of the corresponding ligands with metal salts.²⁴

In some cases, chelates of type **88** (X = S, Y = O) were prepared by template synthesis.¹⁶¹

Of the chelate compounds under consideration, complexes **150** containing the pyrazole fragment annelated to the metallo-cycle deserve most attention.^{20, 288–307} In these complexes, *d* metals (Co, Ni, Pd, Cu, Zn, Cd, Hg) act as complex-forming agents.²⁰ The synthesis of copper complexes of this type has presented substantial difficulties for many years. The first representative of these complexes (**150**, M = Cu; R¹ = Prⁱ; R² = Me, R³ = 2-Py) was prepared as late as 1992.²⁶⁹ Later on, these chelates became readily available.^{299–301, 303–307}

Some chelate compounds with tridentate ligands **149** [R³ = (CH₂)₂OH,^{185, 308} 2-pyridyl,^{269, 294, 309} 8-quinolyl^{298–300}] were synthesised. The structure of compound **151** was unambiguously established by X-ray diffraction analysis.²⁹⁸

The coordination of the oxygen atom of the hydroxy group to the metal atom is observed in complex **152**.¹⁸⁵ By contrast, the potentially tridentate pyridine-containing ligand in compound **153** is in fact (according to the X-ray diffraction data) bidentate.^{269, 292, 294}

Nickel complexes of **154**²⁹⁶ and **155**²⁹¹ and iron complex **156**²⁹⁸ can be cited as examples of chelates with tetradentate N,S-donor ligands. These chelates were synthesised by the reactions of the corresponding ligands with metal salts [Ni(OAc)₂, MeOH; FeCl₃, EtOH].

Examples of heteroaromatic azomethine chelates containing the six-membered MN₂Se₂ coordination unit are known, among which are complexes of nickel **157**³⁰⁹ and copper **158**.³⁰⁴

In conclusion, it should be noted that in searching for azomethine ligands on the basis of heterocyclic aldehydes, researchers were oriented primarily to five-membered heterocycles, *viz.*, furan, thiophene, their benzo analogues and azole systems. However, chelate compounds, such as complexes **159**³¹⁰ and **160**,³¹¹ can also be synthesised.

These complexes contain Schiff bases as chelating ligands, which were prepared from six-membered azine heteroaromatic aldehydes.

Chelates **160** are of importance in the investigation of the problem of the stereochemical non-rigidity of azomethine metal complexes.^{285, 286}

3. Structures of azomethine metal chelates

The structures of most of the above-considered chelates were unambiguously established by X-ray diffraction analysis. The detailed discussion of X-ray diffraction data is beyond the scope of the present review. Let us only briefly consider the structural aspects of the directed construction of azomethine metal chelates of a desired stereochemistry by varying the fine structure of ligand systems and electronic configuration of complex-forming metals.

Although data from X-ray diffraction analysis are available only for a limited number of five-membered metal chelates formed by bidentate Schiff bases, they provide evidence that chelate compounds containing the MN₄ or MN₂O₂ coordination units are tetrahedral.^{20, 22, 24, 65} Metal chelates containing the MN₂S₂ coordination units (M = Ni, Pd) have planar structures with a *cis* arrangement of the ligands.^{79–86, 312}

The structures of azomethine chelate complexes containing six-membered metallocycles and the same set of donor centres were studied in more detail.^{2, 4, 12, 14, 20–22, 313–319} It was demonstrated that tetrahedral or distorted tetrahedral polyhedra are typical of chelate compounds containing the MN₄ coordination unit (M = Co, Ni, Cu).^{17, 20, 24}

Most of complexes with the MN₂O₂ coordination unit (M = Ni, Cu) have planar structures with a *trans* arrangement of the ligands.^{12, 20, 21, 24, 313–315} Palladium complexes are characterised exclusively by the square-planar coordination.²¹ The tetrahedral coordination is observed in all beryllium complexes³¹⁷ and in most cobalt,³¹⁶ zinc, cadmium and mercury complexes.^{285, 286} Chelate compounds of *d*⁸ elements containing the MN₂S₂ coordination unit have *cis*-planar structures.^{20, 22, 24, 25} These structural features of chelate azomethine complexes have been discussed in the literature many times, including from the viewpoints of the mutual effect of metals and ligands²¹ and stereochemistry of metal chelates of the ML₂ type.³²⁰

Most alkylene- or arylene-bridged chelate compounds with tetradentate bisazomethine ligands have planar tricyclic structures. In addition to the above-discussed bis(salicylidene)ethylenediamine chelates characterised by X-ray diffraction analysis, complexes **161**,¹⁵⁰ **162**³¹⁸ and **163**³¹⁹ also have analogous structures.

The coordination units in chelates of the MN₄, MN₂O₂ and MN₂S₂ types adopt a tetrahedral configuration as a result of annelation of heteroaromatic fragments to metallocycles.^{20–22, 24} For example, these structures are typical of benzofuran- and pyrazole-based azomethine chelates (**164a** and **150**, respectively).²⁰

164a,b: X = O (**a**), S (**b**); R = Buⁿ, Ph.

A substantial flattening of the structure is observed on going from azomethines of the benzofuran series **164a** to azomethines of the benzothiophene series **164b**.²⁰

When examining the dependence of the stereochemistry of azomethine chelate compounds of type **2** on the nature of the substituent R⁴, the effects associated with the volume of this substituent or with the presence of additional donor centres are generally considered. The former effect causes primarily steric distortions of the polyhedra.^{12, 21} The latter effect leads to an increase in the coordination number of complex-forming metal from 4 to 5 or 6.^{22, 24, 25} Relying on these notions, the directed synthesis of complexes with the desired geometry of the coordination unit can be carried out.

Since the steric effects of the substituents at the nitrogen atom (R⁴) have been discussed in sufficient detail,^{12, 20, 21, 24} we will consider only some examples of these effects on the structures of azomethine chelates **2**.

In the crystalline state, nickel chelates **2** (M = Ni; R⁴ = H, Alk, Ar) have square-planar or distorted tetrahedral configurations depending on the volume of the R⁴ substituent,^{21, 313} whereas the complex configurational equilibria including planar, tetrahedral and octahedral (intermolecularly associated) structures, were observed in solutions of these chelate compounds.²¹ Distortions of the tetrahedral structures in copper chelates of type **2**, which are caused by substituents at the nitrogen atom exhibiting different steric effects, were unambiguously established by X-ray diffraction analysis. However, there is no consensus of opinion on the

structures of these complexes in solution (*cf.* Ref. 21). It is believed that square-pyramidal or distorted tetrahedral configurations as well as square–tetrahedron equilibria can occur in solution.

The influence of the nature of the substituents at the nitrogen atom, which are able to form additional coordination bonds, on the structures of complexes **2** has been the subject of investigation over the past 40 years. The presence of these substituents leads primarily to an increase in the coordination number of the central atom in chelates **2**, *i.e.*, the coordination is changed from square-planar or tetrahedral to penta- or hexacoordinated. This fact allows one to perform the directed synthesis of chelate compounds of the azomethine series with pyramidal or octahedral structures.

In recent years,^{101, 105–115} considerable attention has been given to the investigation of the structures of β -aminovinylimine chelates **48** containing the bulky diisopropylphenyl substituents R^3 at the nitrogen atom. In chelates with composition MLR^3 , the access to complex-forming metals is sterically hindered.

Ligands containing the same substituents can form chelates of different stereochemical types.^{22, 24, 215} In complexes of pyridine-containing azomethines, the nitrogen atom of the heterocycle can either form a bond with the metal atom (compound **108**²¹³) or not (compound **107**²¹²). The quinoline nitrogen atom is generally coordinated to the metal atom (compounds **111**^{215, 216} and **112**²¹⁷).

The dependence of the stereochemistry of chelate compounds on the nature of the metal atoms was partially considered at the beginning of this section. Noteworthy also is structure **165** characterised by the *trans* arrangement of the donor atoms and the 'umbrella' conformation of the coordination unit untypical of azomethine chelates of d^8 metals with the N,S-ligand environment.^{292, 293} The formation of this structure is associated with several factors. In palladium complexes, the ligands generally exhibit the square-planar coordination mode. However, the pyrazole fragment and bulky cyclohexyl substituents at the nitrogen atoms induce structural distortions.

The structural analysis of nickel chelates with Schiff bases of aromatic and heterocyclic *o*-hydroxy(thio)aldehydes clearly showed the influence of the fine structure of ligand systems on the structures of azomethine metal chelates. Three coordination modes, *viz.*, planar with a *cis* or *trans* arrangement of the ligands and tetrahedral, were found in the known complexes. The coordination mode is changed if the nature of the heteroatom in the chelate ring is changed, bulky substituents are inserted at the azomethine nitrogen atom, or on going from derivatives of aliphatic or aromatic aldehydes to heterocyclic analogues (Fig. 1).

III. Molecular complexes with azomethine ligands

o-Hydroxyazomethines serve as classical chelating ligands (Section II.2.b). However, as was first demonstrated in 1964,³²¹ these compounds can also be used for the preparation of molecular complexes **166**.^{20, 22, 24, 28, 29, 322–325}

$R = \text{Alk, Ar}; M = \text{Cu, Zn, B, Al, Sn, Ti, Th}; A = \text{Hal, NO}_3, \text{NCS}; m = 1, 2; n = 2–4.$

The reaction path depends on the nature of the solvent.³²³ Thus, metal chelates (Section II.2.b) are formed predominantly in media with high dielectric permeability (alcohols; path *a*), whereas molecular complexes **166** are generated primarily in aprotic non-polar media with low basicity (hydrocarbons, their halogen derivatives, ethers or mixtures of these solvents; path *b*).

Some reactions proceed in mixtures of benzene and alcohols. Thus, the direct reaction of the ligands with $ZnCl_2$ afforded complex **167**.³²⁶

Figure 1. Coordination modes in nickel complexes.

Bis(salicylidene)alkylenediamine molecular complexes **168a**³²⁷ and **168b**³²⁸ were synthesised analogously.

168a: R = H, M = Ca, A = NO₃, *m* = 3, *n* = 2;

168b: R = H, Me, OMe; M = Ti, Zr; A = F, Cl; *m* = 2, *n* = 4.

The template synthesis methods are employed more rarely. However, this approach was used for the preparation of adducts **169**.³²⁹

Molecular complex **170** was synthesised by ligand exchange in tungsten complex **171**.³³⁰

It was demonstrated that molecular complexes **172** could be prepared from chelates **173** under the action of hydrogen halides.³³¹

X = Cl, Br, I.

Recently,³³² metal chelates **174** were synthesised starting from a molecular complex analogous to complex **167**.

Taking into account the data on the synthesis of molecular complex **172**,³³¹ the possibility of the interconversion of chelates **2** and molecular complexes **3** may be considered as proved.

Among recent studies, let us mention the investigations of adducts of metal halides with β -aminovinyl ketones **175**^{101, 333} and their analogues **176**³³⁴ and **177**.³³⁵

R¹ = H, Br; R² = C₇H₁₅, Bz, C₆H₄Me-4, C₆H₄OMe-4, C₆H₄Br-4.

Molecular complexes **178** and **179** of metal halides with hydroxyazomethines containing five- or six-membered chelating fragments^{336–338} were prepared by the reactions of the corresponding ligands with metal chlorides in anhydrous benzene (M = Sn, Ti) or methanol (M = Cu, Zn, Cd). Palladium complexes **178** and **179** were synthesised by the ligand-exchange reactions of Schiff bases with PdCl₂(PhCN)₂.

X = NR, O, S; M = Sn, Ti, Pd, Cu, Zn, Cd; *m* = 1, 2; *n* = 2, 4.

Several structural types were proposed for the molecular complexes under consideration.^{20, 27, 29, 322–324} X-Ray diffraction studies demonstrated that hydroxyazomethines and β -aminovinyl ketones in molecular complexes **180** and **181a,b** act as monodentate ligands containing the O-donor centre. For the first time, this coordination mode was unambiguously established by X-ray diffraction analysis of complexes with bis(salicylidene)ethylenediamine **180**³³⁹ and tris(acetylacetonato)(4-aminopent-3-en-2-one)ytterbium **181a**.^{15, 340}

181: R = Me (a), Ph (b).

It is believed³³⁹ that complexes **180**, like compound **168a**,³²⁷ contain the ligand in the hydroxyimine form. However, X-ray diffraction analysis of complex **167**, which made it possible to locate the positions of protons in the structure, showed that the ligand occurs as the quinone-imine tautomer.³²⁶ According to the results of X-ray diffraction analysis, the ligands in complexes **182**^{341, 342} and **183**³⁴³ also occur in the form of β -aminovinyl ketones.

It should be emphasised that IR spectroscopy cannot be employed for revealing the mode of location of the coordination bond and establishing the tautomeric form of the hydroxyazomethine or β -aminovinyl ketone ligands because the absorption bands corresponding to both types of coordination (at the nitrogen atom of the C=N bond or at the oxygen atom of the carbonyl group) have similar frequencies. The ¹H NMR spectra also do not provide conclusive information for the solution of these problems.³⁴⁴

The data surveyed in this section provide the basis for the directed stereochemical²⁴ and regioselective^{24,345} syntheses of azomethine metal chelates.

IV. Bi- and polynuclear azomethine complexes

Bi- and polynuclear complexes containing azomethine ligand systems are formed by the reactions of bi- and polydentate Schiff bases or their complexes as well as of polymeric azomethines with metal sources or upon polymerisation of monomeric metal complexes.

1. Bi- and polynuclear complexes of polydentate Schiff bases and their analogues

A series of chelating azomethines form not only mononuclear complexes but also bi- and polynuclear structures. Such structures were constructed and characterised for chelates prepared on the basis of bidentate Schiff bases of *o*-aminophenol **17**^{64,346} and its thio analogue **31**,³⁴⁷ tridentate imino alcohols **83** (Y = OR) and iminothio alcohols **83** (Y = SR).^{24,177}

Reactions of substituted benzaldehydes **184** with aminoethanol and nickel acetate afforded binuclear chelates **185**.³⁴⁸

The lead complex with composition [Pb₂L]Cl was prepared by the reaction of the tripodal N(CH₂CH₂N=CH-C₆H₃OMe-3-OH-2)₃(H₃L) ligand with PbCl₂ in methanol in the presence of a base.³⁴⁹

Binuclear complexes **186** with tridentate azomethine ligands **2**, **24**, **280**, **350**–**353** were synthesised primarily from the ligands and the corresponding metal acetates.^{350–353}

M = Co, Ni; X, Y = NTs, O, S; m = 0, 1, 2.

Binuclear nickel complex **186** (X = Y = S, M = Ni, m = 0) was prepared by the template method from disulfide **187** and complex **188**.²⁸⁰

Tetradentate azomethine ligand systems of the bis(salicylidene)ethylenediamine series^{34,218} form not only mono- but also binuclear chelates.^{225,251,354–363} Such chelates were prepared for boron,^{218,357} aluminium,^{218,354,359} gallium,²¹⁸ indium,²¹⁸ titanium,³⁵⁸ europium and yttrium,^{225,357} cobalt,^{355,363} chromium and molybdenum,³⁴ iron,³⁵⁶ nickel and copper,³⁶¹ and zinc.^{251,360} Complexes containing the bridging bis(salicylidene)alkylidene-amino ligands **189a,b**, such as **190**³⁵⁷ and **191**,³⁵⁴ are the most widespread binuclear chelate compounds.

R¹ = H (**a**), Bu^t (**b**); R² = Me, Et; n = 2–6.

Conceivably, these binuclear structures are generated through the formation of intermolecular dimers due to coordination of the metal atoms by the oxygen atoms of the adjacent complex molecules.³⁴

Bisbidentate Schiff bases **192**,³⁶⁴ **193**,³⁶⁵ **194**³⁶⁵ and **195**³⁶⁶ show promise for the construction of bi- and polynuclear azomethine complexes.

Binuclear structures were prepared on the basis of compounds **192**–**194**. Tetranuclear complexes were derived from ligand **195**. Tripodal hexadentate ligands **196** gave rise to bi- and trinuclear nickel complexes.³⁶⁷

R = H, OMe.

Various bridging atoms, such as oxygen (for example, compound **197**¹⁷⁵) or chlorine (compound **198**³⁶⁸), play an important role in the formation of binuclear structures.

In some cases, atomic oxygen serves as an intermolecular bridge to form, for example, oxotitanium dimeric,^{369–372} trimeric

and tetrameric^{370,373} complexes of tetradentate Schiff bases. Structure **199** provides an example of dimeric complexes.³⁷²

There are data on oxygen-bridged complexes derived from bidentate Schiff bases. For example, complexes of di- μ -oxodimanganese(IV) with *N*-alkyl-substituted salicylideneamines were synthesised.³⁷⁴ Binuclear chelates **200**³⁷⁵ formed by the complex polydentate ligand containing two β -ketoiminate fragments also belong to this type of complexes.

R¹ = H, Me; R² = H, COMe;

R³ = Me, Ph, C₆H₄NO₂-4; M = Ni, Cu.

Trinuclear oxygen-bridged complexes **201**^{376,377} were prepared based on dendrimers with salicylideneamine groups.

2. Bi- and polynuclear complexes with metal-containing azomethine ligands

In the 1960s, it was demonstrated^{378–381} that the reactions of chelate compounds containing the azomethine ligands M¹L_m with metal salts M²A_n can give rise to bi- (**202**^{380,381}) and trinuclear (**203**³⁷⁸ and **204**³⁷⁹) structures.

$R^1 = \text{Alk, Ar}; M^1 = \text{Ni, Cu}; M^2 = \text{Co, Ni, Cu, B, Al, Ti, Sn};$
 $A = \text{Hal, NO}_3.$

The direct reactions of ligands with sources of complex-forming metals were used for the preparation of complexes **205**,³⁵⁸ **206**³⁸² and **207**.³⁸³

205: $X = \text{Cl, Br}; Y = \text{Me, Cl}.$

206: $M^1 = \text{Co, Ni, Cu, Zn};$
 $M^2 = \text{Na, K, Cs}.$

207

It should be noted that alkali salts in the heteronuclear structures under consideration can act as Lewis acids (M^2A_n). In particular, this is evidenced³⁸² by the formation of adducts **206** in the reactions of salicylaldehyde complexes of divalent metals (Co, Ni, Cu, Zn) with sodium, potassium and cesium salts. β -Amino-vinyliminate-based complexes **206** were described in the study.³⁸⁴

Unlike the above-considered binuclear halide complexes **202**, which were prepared by the reactions of the corresponding ligands with metal halides, coordination compounds of metal carbonyls were synthesised by ligand-exchange reactions.³⁸⁵ These reactions afforded two types of complex compounds with the M^1-M^2 and $M^1-M^2-M^1$ bonds, *viz.*, $M^1LM^2(\text{CO})_5$ (**208**) and $(M^1L)_2M^2(\text{CO})_4$ (**209**), respectively.

208

209

$M^1 = \text{Ge, Sn, Pb}; M^2 = \text{Cr, W}.$

Binuclear complexes can be prepared by the reactions of metal chelates, for example, of bis(salicylidene)ethylenediamines or bis(tris)- β -diketonates, in chloroform.³⁸⁶⁻³⁹¹ In azomethine chelate compounds, Ni(II)³⁸⁷⁻³⁹¹ and Cu(II)^{386, 389, 391} serve as the

M^1 metal and hexafluoroacetylacetonates of Ba and Mg,³⁹⁰ Y(III),^{386-389, 391} La(III)^{389, 391} and Gd(III)^{386, 389, 391} act as metal salts (M^2A_n). The structures of these complexes were established by X-ray diffraction analysis. Like in complexes **202**, the coordinatively unsaturated oxygen atoms of the bis(salicylidene)ethylenediamine anion are involved in coordination to lanthanides.

Bi- and trinuclear complexes were synthesised starting from coordination compounds of crown ethers containing the chelating hydroxyazomethine fragments.³⁹²⁻³⁹⁴ As an example of these compounds, we refer to heterotrinuclear complex **210** generated from heterobinuclear complex **211**.³⁹²

$M^1 = \text{Ba}(\text{CF}_3\text{SO}_3)_2; M^2 = \text{Cu, Ni}.$

It should also be noted that Schiff bases containing organo-metallic fragments can be used as azomethine ligands. Ferrocene derivatives **212**^{395, 396} and **213**³⁹⁷ as well as derivatives of benzene chromium tricarbonyls **214**³⁹⁸ and **215**³⁹⁹ are examples of these Schiff bases.

212

213

214

215

Ligands **212**, **213** and **214** give rise only to metal chelates, whereas azomethine **215** produces molecular complexes.

Ruthenium complex **216** shows promise as a ligand for the preparation of tri- and oligonuclear coordination compounds.⁴⁰⁰ The former complexes can be synthesised by the reactions of ligand **216** with divalent metal acetates and the latter complexes can be prepared on the basis of metal salts in oxidation states 3 and higher.

3. Azomethine metal polymers

Main methods for the preparation of polymers containing chelates of Schiff bases and their analogues involve the reactions with chelating macroligands and polymerisation of metal monomers.^{31–33, 401–405}

Chelating polymeric azomethine ligands are used in synthetic reactions similar to those involving monomeric Schiff bases and their analogues (see Sections II and III). Thus, the reactions of the ligands with metal salts afforded polymers containing chelates (for example, **217**,⁴⁰⁶ **218**⁴⁰⁷) and molecular complexes (**219**⁴⁰⁵). The metal exchange gave rise to metal polymers **220**.³²

$R^1 = (CH_2)_{12}O$; $R^2 = (CH_2CH_2O)_3$; $x = 0-100$; $y = 100-x$.

Polymer **222** was prepared from ligand **221** with the use of the template method.³² This approach is particularly efficient when metal polymers cannot be prepared by the reactions of ligands with metal salts or through metal exchange.

The oxidative polymerisation of monomeric chelates was used for the preparation of polymers with bis-salicylidene derivatives of aromatic^{408, 409} or heterocyclic^{410, 411} amines.

In some cases, polymeric azomethine complexes can be prepared in the course of usual syntheses. In particular, the reaction of ligand **223** with La(III) nitrate afforded polymeric structure **224** containing fragments of molecular complexes with the bis(salicylidene)ethylenediamine ligand coordinated through the oxygen atom.⁴¹²

Polymeric complexes of Schiff bases can also involve bridging fragments, for example, oxygen⁴¹³ or metal chelates.⁴¹⁴

V. Conclusion

The available data on metal complex compounds with azomethine ligands make it clear that the employment of the techniques of rational design in the search for ligand systems and synthesis procedures can be a help in performing the directed synthesis of complexes in which the mode of coordination and geometry of metalocycles are prespecified.

In addition to synthetic and structural problems arising in research on metal coordination compounds with azomethine ligands, theoretical and applied aspects are also of great importance, including competitive coordination,^{24, 27} standard and non-standard binding of metals to chelating ligands,^{28, 29} stabilisation through the complex formation of tautomeric forms untypical of free ligand systems⁷⁷ and isomerism of coordination units within chelates.^{24, 27}

Complexes of Schiff bases and their structural analogues are of practical importance because they allow one to perform the directed design of new types of azomethine coordination com-

pounds exhibiting catalytic, magnetically anomalous and liquid-crystalline properties. In this connection, it should be emphasised that metal chelates of Schiff bases in which the complex-forming metal atom is shielded by bulky substituents (compounds of type **48**: $R^1 = C_6H_3Pr_2^1$), belong to new-generation catalysts for polymerisation, copolymerisation, enantioselective synthesis and oxidation of alkenes (predominantly, epoxidation). In addition to the studies cited in the present review^{101, 105–136} these problems have also been considered in the studies devoted to the same subject.^{415–417}

Bi- and trinuclear complexes of type **204** ($A = Hal$; see also Ref. 418) serve as efficient catalysts for oligo- and polymerisation as well as for hydrogenation. These complexes, like binuclear chelates **202** (MA_n are lanthanide tris-hexafluoroacetylacetonates),^{386, 419} and azomethine coordination compounds with azole free radicals **89** and **90** (molecular ferromagnetics)⁴²⁰ exhibit magnetically anomalous properties.

Data on azomethine metal complexes possessing liquid-crystalline properties have been surveyed in the review⁴²¹ and more recent publications.^{422, 423}

Taking into account considerable advances that have been made in the construction of biomimetic models of active sites of non-haeme metalloproteins on the basis of azomethine metal chelates,^{267, 295, 299, 307, 424, 425} this line of studies shows considerable promise.

We acknowledge Ph.D. (Chem.) D A Garnovskii, A I Uraev and A S Burlov for help and invaluable advice in the preparation of the present review.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 00-15-97320).

Basic achievements in the coordination chemistry of modified monosaccharides

Yu A Zhdanov, Yu E Alekseev

Contents

I. Introduction	969
II. Metal complexes of monosaccharide <i>O</i> -derivatives	969
III. Metal complexes of nitrogen-containing monosaccharide derivatives	972
IV. Metal complexes of phosphorus-, sulfur- and selenium-containing monosaccharide derivatives	976
V. Conclusion	978

Abstract. The published data on the complexation of chemically modified carbohydrates (acetalated and acetylated monosaccharides, carbohydrate podands and coronands as well as nitrogen-, phosphorus-, sulfur- and selenium-containing monosaccharide derivatives) are generalised and systematised. The structural diversity of the metal complexes formed is demonstrated and the effect of the ligand chirality on the chiralities of the corresponding coordination points is discussed. The bibliography includes 155 references.

I. Introduction

Various aspects of the coordination chemistry of natural carbohydrates have been detailed in a number of reviews.^{1–8} The coordination chemistry of chemically modified carbohydrates has been studied in far less detail; the data available^{8–11} discuss only some aspects of this field of research. The interest in this topic is connected with further improvement of methods of synthetic chemistry of carbohydrates.

Chemical modification of monosaccharides aimed at the preparation of ligands consists predominantly in the coupling of natural monosaccharides, which are continuously reproduced upon photosynthesis, to *a priori* complex-forming (in the extreme case, chelatogenic) fragments. This approach allows a considerable increase in the structural diversity of carbohydrate complexes, which are chiral by nature. Such complexes and their metal complexes are necessary for the preparation of chirally pure pharmaceuticals.

This review is an attempt to get a better insight into this branch of chemistry. The material presented herein is arranged according to the principle used in our previous review.⁶ The ligands are classified into oxygen, nitrogen-, phosphorus-, sulfur- and selenium-containing monosaccharide derivatives according to the type of donor heteroatoms. Metal cations for each ligand class are cited in the order of complexity of their electronic configurations and in conformity with their positions in the Periodic Table, *i.e.*, *s*-, *p*-, *d*- and *f*-metals.

II. Metal complexes of monosaccharide *O*-derivatives

1. Complexes with *s*-metal cations

Free water-soluble monosaccharides represent^{2,3,6} weak complexones of *s*-metal cations owing to strong competition of water molecules for the coordination of these cations. *O*-Alkylation (acylation) or acetalation of monosaccharides increases their hydrophobicities as a result of which the corresponding derivatives become soluble in organic solvents where they play the role of moderate *s*-metal complexones due to the lack of water. This can be exemplified by the acetalated monosaccharide **1** (see Ref. 12) and the di-*O*-methyl derivative **2**.¹³ Thus substitution of the O(CH₂)₂OH and O(CH₂)₂O(CH₂)₂OEt fragments for the methoxy groups in compounds **1** and **2** yields^{12,13} carbohydrate podands (acyclic analogues of crown esters);² their affinities for *s*-metal cations markedly exceed those of the starting monosaccharides. This is especially typical of podands **3** (R is a per-*O*-acetylated monosaccharide residue)¹⁴ and **4**.¹⁵

As can be judged from qualitative reactions, regioisomeric mixtures of podands and coronands (*e.g.*, compounds **5** and **6**)^{15–19} readily bind alkali metal cations.

The coordination of coronands **7**,²⁰ **8**²¹ and **9** (see Ref. 22) involves carbohydrate fragments. Ethers **10** (see Ref. 23) and a coronand **11** coordinate *s*-metals in a similar way, *i.e.*, with the involvement of carboxy groups.²⁴ This imparts additional stability to complexes of the above-mentioned ligands.

X = CH₂COCH₂, CH₂;
Glyc is an acetalated or acetylated
monosaccharide residue.

R = H, Ac.

R = H, CO₂H.

2. Complexes with *p*-metal cations

This type of complex, like complexes with *s*-metal cations, are relatively scarce. They include a series of borates of acetalated sugars (*e.g.*, compound **12** and its derivatives).²⁵ The *O*-carboxymethyl derivative **13** binds Al(III) and some *d*-metal cations.²⁶ In a homoleptic complex **14**, the aluminium atom and three carbohydrate ligands form a trigonal pyramid.²⁷

Glyc³ – OBEt₂

12

Py is pyridine.

The Sn(IV) complexes of the general formula **15** are the most extensively documented in the literature.^{28–30} Organotin compounds with organometal fragments directly bound to the carbohydrate core^{31,32} are characterised by intramolecular coordination of the type **16a**.³¹

GlycO – (CH₂)_nSnR₃

15

R = Me, Bu, Ph;
Glyc is an acetalated monosaccharide
residue;
n = 0–2.

M = Sn (a), Si (b), Pd (c).

The stannylene carbohydrate acetals **17** form dimers **18**.^{33,34} Some analogous derivatives form trimers and even pentamers.³⁴

For other *p*-metals, only complexes of the type **16b,c** and **19a,b** have been described.³⁰

M = Si (a), Pb (b).

3. Complexes with *d*-metal cations

d-Metal complexes are especially fully and diversely represented in the coordination chemistry as a whole and in the coordination chemistry of modified monosaccharides, in particular, which to some extent is characteristic of complexes of monosaccharide *O*-derivatives. Thus the above-mentioned *O*-carboxymethyl derivative **13** is coordinated²⁶ not only with the *p*-cation of Al³⁺, but also with *d*-cations Cu²⁺, Fe³⁺, Co²⁺, Ni²⁺ and Mn²⁺. The formation of copper bischelates **20** in the selective *O*-alkylation (acylation) of the acetalated glycoside **21** in organic solvents in the presence of copper(II) has been described.³⁵

We failed to retrieve any literature data on complexes of monosaccharide *O*-derivatives with *d*-metal cations of subgroups IB and IIIB. *d*-Metal complexes of subgroup IVB were studied in some papers devoted to the use of monosaccharide Ti(IV) complexes in modern organic synthesis.^{36–41} Ti(IV) complexes containing D- and L-tartaric acid derivatives, which are employed in the highly efficient enantioselective Sharpless epoxidation of allyl alcohols (optical yields 80%–100%) have been studied in most detail.^{36–38} (Sharpless was awarded a Nobel prize in 2001.⁴²) The Sharpless catalysts form very diverse structures in solution^{43,44} with cyclic (**22**)^{36–38,45} and bridge-type (**23**) dimers predominating.^{38,45,46}

Titanium complexes **24** serve as nucleophilic reagents in some enantioselective transformations.^{39–41} The chlorine atom in complex **25**,⁴⁷ which is a structural analogue of the complex **14**, is readily exchanged for alkyl and other groups, *e.g.*, the allyl group.⁴⁸ Like organometallic compounds, the substitution product adds enantioselectively to the carbonyl group.⁴⁸

$R^1 = \text{H, Me}; R^2 = \text{H, Ph, Bu}^t$.

The chiral ligands in the homoleptic complexes **26** based on diacetone glucose²⁷ and the oxygen-rich periphery form cavities which favour further coordination. X-Ray diffraction analysis data suggest that two pyridine and two carbohydrate ligands in the complex **27** are localised in the equatorial plane of the pseudo-octahedral structure.²⁷

$M = \text{Ti, Zr, Hf}$.

In the case of *d*-metals of subgroup VB, the vanadium-di-*O*-isopropylidene-D-glucose complex **28** is the only complex described so far.⁴⁹ According to X-ray diffraction analysis data, the ligands in this complex form a propeller-shaped structure having a Λ -configuration. Reaction of the complex **28** with lithium and sodium alcoholates of di-*O*-isopropylidene-D-glucose yields complexes $[\text{V}(\text{OGlyc}^3)_6\text{M}_3]$ ($M = \text{Li, Na}$) where the carbohydrate ligands form an environment for M^+ which resembles that of the solvate complex (structure **29**).⁵⁰ Thus, metal complexes of modified sugars can in principle be used as ligands for group IA metal ions:

$M = \text{Li, Na}$.

Carbohydrate-containing *d*-metal complexes of subgroup VIB are represented in the literature by carbene complexes of two types. The first of them includes complexes **30**⁵¹ where the acetalated carbohydrate moiety is in the β -position relative to the carbene carbon atom. In the second type of complex (**31**),⁵² the acetylated carbohydrate fragment is linked directly to the carbene carbon atom.

$M = \text{Cr, W}$.

$R = \text{Me, Et}; M = \text{Cr, Mo, W}$.

Carbene complexes of the second type (e.g., **32**) have been known for *d*-metals of subgroup VIIB.⁵³

$R = \text{Ph, tolyl}; M = \text{Mn, Re};$
Glyc is a protected monosaccharide residue.

Complexes **33** were prepared⁵⁴ from acetylated glycosyl bromides by exchange reaction with $\text{NaMn}(\text{CO})_5$. Interactions of 1,6-anhydrohexopyranoses **34** with Mn^{2+} , Mn^{3+} and Mn^{4+} follow the Angyal rule;^{3,6} the ligand complexes with the axial-equatorial-axial orientation of the three vicinal hydroxy groups are the most stable.⁵⁵

33: $R = \text{Ac}; X = \text{Mn}(\text{CO})_5$;
35: $R = \text{Me}; X = \text{Fe}(\text{CO})_2\text{Cp}$
(Cp is cyclopentadienyl).

The structurally unique iron carbonyl complexes **35**,⁵⁶ **36**⁵² and **37**⁵⁷ and the π -complex **38**⁵⁸ are of interest among carbohydrate compounds of group VIII metals. μ^3 -Carbide clusters, e.g., compound **39**, have been prepared.⁵⁹

$R = \text{Me, Et}$.

$R = \text{H, Ts}$.

In strongly alkaline aqueous media, vicinal diol groups of partially protected monosaccharides undergo deprotonation; the deprotonated forms of these compounds coordinate the metal complex *trans*- $[(\text{en})_2\text{CoCl}_2]\text{Cl}$ (en is ethylenediamine) to yield complexes **40** with a predominant Λ - or Δ -configuration depending on the stereochemistry of the monosaccharide.⁶⁰

Complex $[\text{Pd}(\text{OH})_2(\text{en})]$ reacts with 1,6-anhydro- β -D-glucose (levoglucosan) in strongly alkaline aqueous solutions⁷ to afford complex **41** (by analogy with the complex **40**). The complex $[\text{PtMe}_3(\text{Me}_2\text{CO})_3]^+\text{BF}_4^-$ is coordinated with acetalated aldoses (e.g., di-*O*-isopropylidene-D-glucose Glyc^3OH) to give the complex **42** with elimination of the terminal isopropylidene protective group. Per-*O*-acetylated aldoses form complexes similar to **43**.^{7, 61}

III. Metal complexes of nitrogen-containing monosaccharide derivatives

The predominance of nitrogen-containing ligands in coordination chemistry on the whole⁶² is also characteristic of the coordination chemistry of carbohydrates. Nitrogen-containing monosaccharide derivatives coordinate virtually all known metals.

1. Complexes with *s*-metal cations

The majority of *s*-metal complexones in the series of nitrogen-containing monosaccharides, *e.g.*, the amino derivatives **44**, **45**,⁶³ **46–48**,⁶⁴ **49** and ^{65, 66} **50**,^{67, 68} and the amido derivatives **51–59**, have simple structures.⁶⁹ Typical *s*-metal complexones, such as the azapodands **60** (see Ref. 70) and **61** have also been prepared.⁶⁹ The ability of these compounds to form complexes with *s*-metals was estimated by qualitative reactions.⁶⁴

44

45

46–50

51–54

55, 56

57–59

Compound	X
46	NH ₂
47, 51, 55, 57	NH(CH ₂) ₂ OH
48, 52, 56, 58	N(CH ₂ CH ₂ OH) ₂
49	NHC(CH ₂ OH) ₃
50	NHCHRCO ₂ [−] Na ⁺ (R = H, Me, CH ₂ Me, CH ₂ OH, CH ₂ C ₆ H ₄ OH-4)
53, 59	NHCH ₂ CO ₂ [−] Na ⁺
54	NHCHMeCO ₂ [−] Na ⁺

60

61

The podand activity of *N*-glycosylaminocarboxylates is probably due to their ability^{70, 71} to form the dimers **62** in non-polar media. The formation of the tetramer **64** from the acetalated *N*-glycoside, *viz.*, guanosine **63**, which also occurs in non-polar media, is yet another example of aggregation of cavity-free compounds into those with cavities.^{72–74} The tetramer **64** forms stable L₂M complexes (L = **64**) with K⁺ and Cs⁺ where the coordination apparently involves the carbonyl oxygen atoms. An

62

R = H, Et.

63

64

important role is played by the structure of the carbohydrate fragment; thus substitution of *O*-acetyl groups for the isopropylidene protective group in compound **63** prevents aggregation.⁷⁴

A series of carbohydrate azacrown ethers **65** form stable complexes with Na⁺ and K⁺ ions [logK_{st} = 4–6 (in CDCl₃)].⁷⁵ The azacoronands **66** and **67** (see Ref. 64) catalyse the enantioselective reduction of a prochiral ketone acetophenone under phase-transfer conditions with optical yields of 48% and 20%, respectively.⁷⁶

65

n = 3, 4.

66

67

2. Complexes with *d*-metal cations

In contrast to the poorly investigated coordination of nitrogen-containing monosaccharide derivatives with *p*-metal cations, there is a considerable body of data on analogous complexes with *d*-metal cations.

a. Complexes of *N*-glycosides and related compounds

N-Glycosides containing chelate-forming fragments as aglycons are unstable; therefore, their complexes with metals are prepared using different approaches, *e.g.*, reactions of aldoses with ethylenediamine with subsequent addition of copper(II) halides to the reaction mixtures.⁷⁷ At first, aldose **68a** as the aldehyde (form **68b**) reacts with ethylenediamine to produce the Schiff base **69**, which is immediately cyclised into *N*-glycoside **70**. In turn, the free amino group in compound **70** reacts with the aldose resulting in bis-*N*-glycoside, which yields complex **71** upon addition of copper(II) salts.⁷⁷ In the case of *N,N'*- and *N,N*-dimethylethylenediamine, only one amino group is involved in the formation of *N*-glycosides; the resulting complexes have the structures **72a** and **72b**, respectively.

68a

68b

The reactions of aldoses with $[\text{Ni}(\text{en})_3]^{2+}$ (**73**) afford the biscarbohydrate complexes **74**.^{9, 78} Apparently, the aldehyde form **68b** first reacts with the amino groups N(1) and N(2) of the complex **73** as is shown in the previous scheme, **68b** $\rightarrow$ **69** $\rightarrow$ **70**, the reacting ligands being localised in the coordination sphere of the complex. Further, the hydroxy groups at C(2) of the carbohydrate residues incorporated into the metal complex displace the ligand with the amino groups at N(3) and N(4) from the coordination sphere (as in the case of formation of the complex **40**) and are coordinated with the central metal atom (the formation of metal complexes by ligand exchange⁶²). The reactions with ketoses yield monocarbohydrate complexes **75**;^{9, 78, 79} noteworthy, the coordination involves the primary hydroxy group at C(1) in addition to the secondary hydroxy group at C(1).

Reaction of D-mannose with the Ni(II)–*N,N'*-dimethylethylenediamine complex yields compound **76** having unusual bridging structure;^{9, 80} one of the carbohydrate ligands in this complex assumes a furanose form seldom occurring in carbohydrate metal complexes. The $[\text{Ni}(\text{tn})_3]^{2+}$ complex (tn is trimethylenediamine) reacts with aldoses like $[\text{Ni}(\text{en})_3]^{2+}$ to yield products analogous to the complex **74**.^{9, 81} A similar result was obtained in the case of the Ni(II) β -alanine complex.^{9, 82}

Substitution of Co^{3+} for Ni^{2+} significantly changes the mode of coordination of the carbohydrate ligand: the conformation of the six-membered ring of the single carbohydrate ligand in

complex **77** is considerably distorted, which facilitates involvement of the hydroxy group at C(3) in the coordination.^{9, 83, 84}

The main principles of the geometry of the metal complexes under discussion are retained in the case of a structurally more complex amino component, viz., *N,N*-bis(2-aminoethyl)ethylenediamine (tren) **78**. Thus the reaction with nickel(II) yielded mono- (**79**) (in the case of D-glucose) and biscarbohydrate (**80**) complexes (in the case of D-mannose).⁸⁵

Triscarbohydrate complexes **81** with Ni^{2+} (see Refs 9, 85 and 86) and Co^{3+} (see Refs 9, 85 and 87) using *N*-glycosides **82** as ligands could also be synthesised.

$M = \text{Ni}^{2+}, \text{Co}^{3+}.$

All the metal complexes synthesised are characterised by a specific anomeric configuration (α or β) of the glycosidic imino group, λ - or δ -conformation of the five-membered metallocycles and helical Λ - or Δ -configuration⁸⁸ of the chelate point owing to the transfer of chirality from the carbohydrate ligands to the metal centre. Reversible chiral inversion of the Λ -diastereomer into the Δ -diastereomer in complex **81** ($M = \text{Co}^{3+}$) after substitution of the sulfate ion as the counterion for the halide ion has been described for the first time.⁸⁷ The synthesis of a bridging double-charged complex **83** based on D-glucose is another step forward.⁸⁹

R is D-glucose residue.

In a similar scheme (viz., by the reaction of a carbohydrate ligand with a metal-containing derivative), starting from *N*-glycoside **84** and alkynylcarbene complexes **85**, a mixture of complexes **86** and **87** (3 : 2) was obtained.⁹⁰ Ferrocenyl derivatives **88** and **89** were synthesised analogously.⁹¹

85–87: M = Cr, W; **88, 89:** Glyc is a protected or free monosaccharide; Fc is ferrocenyl; R = H (**88**), CH₂Fc (**89**).

The N,O-coordination of amino acid *N*-glycosides **90** (as salts) is a characteristic of complexes **91** with salts M₂[M²Cl₄] (M¹ = Na, K; M² = Pt, Pd). *N,N*-Coordination (structure **92**) is observed only in the case of histidine.^{7,92}

R = H, Me, CH₂OH, CH(OH)Me, CH₂CONH₂, (CH₂)₂CO₂Na.

b. Complexes of *O*- and *C*-substituted monosaccharides with nitrogen-containing fragments

The central metal atom in the copper complex **93** of *O*-(β-D-xylopyranosyl)-L-serine is surrounded⁹³ by four carbohydrate ligands with a distorted octahedral configuration.

The D-glucopyranosyl ester of glycine **94a** and its partially (**94b**) and fully substituted (**94c**) derivatives coordinate Fe(III) exclusively through the oxygen atoms of the carboxy groups to yield complexes **95a–c**,⁹⁴ their structures are simpler the larger the number of protective groups.

a: R = H, X = NH₃·CF₃CO₂H;
b: R = Ac, X = NH₃·CF₃CO₂H;
c: R = Ac, X = NHCO₂Bu^t.

O-Glycoside analogues **96** of the ferrocenyl derivatives **88** and **89** have been prepared.⁹⁵

R¹ = H, CH₂Ph; R² = Me, CH₂Fc; n = 2, 3, 5.

The type of coordination in 2-[poly(hydroxyalkyl)]thiazolidine-4-carboxylic acids **97** depends on the nature of the metal ion.^{96–98} The Cr²⁺ cation in complexes ML₂ (L = **97**), as in α-amino acid metal complexes, is coordinated through the imino group and the carboxy group of the heterocyclic fragment.⁹⁶ Similar structures are formed with Zn²⁺, the latter being coordinated at the hydroxy group through the C(2) atom of the carbohydrate residue.⁹⁷ The Pd²⁺ cation is coordinated through the nitrogen and sulfur atoms of the heterocyclic fragment⁹⁸ (the so-called competitive coordination⁶²). It is interesting to note that the stability constants of zinc complexes depend on the chirality of the C(1) atom of the carbohydrate fragment.⁹⁷

n = 2, 3

Metal complexes **98–102** were prepared in high yields using the electrochemical method.^{99,100} The copper chelates **98, 99a** and **101** possess a distorted planar configuration of the chelate point, and other complexes have octahedral structures.^{99,100}

M = Cu (**a**), Ni (**b**), Co (**c**).

c. Complexes of amino sugars and their derivatives

D-Glucosamine (**103a**), D-mannosamine (**103b**) and D-galactosamine (**103c**) react with [Ni(en)₃]²⁺ to yield complexes **104**^{9,101} similar to complexes **74** containing an amino group at C(2) instead of a hydroxy group. Reactions of D-glucosamine **103a** with [Co(NH₃)₃]³⁺, [Co(en)₃]³⁺ and [Co(phen)₂]³⁺ (phen is phenanthroline) yield complexes **105** by a ligand exchange mechanism.^{9,102} The use of an alternative workup of the D-glucosamine (**103a**)–[Co(en)₃]³⁺ mixture (see Ref. 103) gave eight monosaccharide metal complexes.

- a: $R^1 = R^3 = \text{H}$, $R^2 = \text{NH}_2$, $R^4 = \text{OH}$;
 b: $R^1 = \text{NH}_2$, $R^2 = R^3 = \text{H}$, $R^4 = \text{OH}$;
 c: $R^1 = R^4 = \text{H}$, $R^2 = \text{NH}_2$, $R^3 = \text{OH}$.

Among the complexes isolated,¹⁰³ only compound **106** with a pyranose form of the carbohydrate ligand is a normal product. In the other complexes, D-glucosamine **103a** is transformed into both D-mannosamine **103b** by the Lobry de Bruyn–van Ekenstein rearrangement,^{104,105} and D-fructosylamine by the Amadori rearrangement¹⁰⁵ (complex **107**). Complex **108** where D-glucosamine exists in an unusual open aminal form is of most interest. The complexes formed are diastereomerically pure and have a Δ - or Λ -configuration at the chelate point. The study¹⁰³ is undoubtedly one of the key studies in the coordination chemistry of carbohydrates, since it demonstrates extreme flexibility of unprotected monosaccharides in complexation with metals.

The oxidation products of the glycosidic hydroxy group of 2-amino sugars, *i.e.*, the carbohydrate α -amino acids **109**, coordinate *d*-metal ions only through the carboxy and amino groups.^{106–108} Complexes **110** provide yet another illustrative example of the non-involvement of the carbohydrate fragment in the coordination.¹⁰⁹

$n = 3, 4$.

$R = \text{H, OH}$; $M = \text{Re, Tc}$.

Monoamino sugars of the type **103a–c** form complexes **111** with platinum metals.^{9,110} The protected amino sugar **112** yields complexes of analogous structures.^{9,110} In the case of synthetic vicinal diamino sugars, coordination (*e.g.*, with the formation of the complex **113**) follows the same scheme.⁹

$M = \text{Pd, Pt}$; Glyc is a protected or free monosaccharide.

The reaction of protected *N*-glycosylaminocarboxylates **114** with platinum metal complexes gives complexes **115–117**.^{9,111}

$R = \text{H, CH}_2\text{CHMe}_2, \text{CH}_2\text{Ph, (CH}_2)_2\text{SMe}$.

$M = \text{Rh, Ir}$.

Complexes of *N*-glycosylaminocarboxylate **50** with Cu^{2+} (**118**) have a square-planar structure, whereas with Co^{2+} and Ni^{2+} ions, octahedron **119** is formed involving the hydroxy groups at the C(5) atom of the carbohydrate fragment.^{19,112–115}

$M = \text{Ni(II), Co(II)}$.

The structures of complexes of a carbohydrate amino derivative **49** with *d*-metal cations depend on the basicity of the medium. In alkaline media, reactions with the corresponding metal acetates yield monosaccharide complexes **120** and **121**, while in neutral media, bisaccharide complexes **122** are formed.⁶⁶

$M = \text{Cu(II), Ni(II)}$.

Some papers describe metal complexes of the Schiff bases prepared from natural and synthetic amino sugars. Thus the

Schiff bases **123a,b** of both unprotected and protected D-glucosamine form ordinary bischelates **124**,^{116–118} while the carboxylic derivative **123c** reacts with Cu(II) to give the binuclear bridging complex **125**.¹¹⁷ In the case of Pt(II), the coordination involves the nitrogen atoms to yield complex **126**⁷ due to the absence of a donor substituent in the *ortho*-position of the aromatic ring (all the hydroxy groups in the carbohydrate fragment are acetylated).

- a: R¹ = Ac, R² = Me, X = H;
 b: R¹ = R² = X = H;
 c: R¹ = Ac, R² = Me, X = CO₂H.

Mixed zero-valent palladium complexes **127** in which the double Schiff base is used as a carbohydrate ligand and dimethyl fumarate, fumarodinitrile and maleic anhydride are used as alkene components, have been synthesised.¹¹⁹

The coordination capabilities of amino sugars can be significantly enlarged owing to the introduction of coordinating fragments into the amino group as can be exemplified by the β-oxoamino derivatives **128**, which form binuclear complexes **129** with copper.¹²⁰

The ability of isocyanides, *e.g.*, compound **130** obtained from D-glucosamine, to enter into ligand exchange reactions was successfully employed¹²¹ in the preparation of complexes **131–136** with different structures. Complexes **132** and **134** can add other isocyanides as well as amines and alcohols, *e.g.*, with the formation of complexes **137**.¹²²

M = Pd, Pt.

M = Cr, W.

M = Rh, Ir.

R² = Bu^t, Ph.

Special mention should be made of a yet another interesting peculiarity of the complexation of the compounds under discussion. The feasibility of a transfer of chirality from a carbohydrate ligand to a metal centre in metal complexes of chemically modified carbohydrates was demonstrated above. A most illustrative example of this phenomenon is the reaction of the diol derivatives **138** (obtained from tartaric acid) with silver triflate,¹²² which yields either the polymeric complex **139** in the form of a right- or left-handed helix (supramolecular polymeric complexes, helicates¹²³), or, in the case of the *meso*-diol, the cyclic dimer **140**, depending on the chirality of the starting diol.

IV. Metal complexes of phosphorus-, sulfur- and selenium-containing monosaccharide derivatives

The discovery by Wilkinson of the ability of chlorotris(triphenylphosphine)rhodium(I) to efficiently catalyse homogeneous hydrogenation of alkenes at room temperature¹²⁴ gave a strong impetus to the appearance of a vast number of publications devoted to the molecular design and applications of this type of catalyst including enantioselective ones. This, in turn, generated the need for the synthesis of some organophosphorus carbohydrate derivatives, such as phosphines, phosphinites, phosphites and hydrogen phosphonates and phosphates.

Chiral phosphines **DIOP** (**141**) are the most popular phosphine ligands used in catalysis; the ruthenium complex **DIOP–Ru₂Cl₄[(-)-DIOP]₃** has a hypothetical structure **142**.^{125, 126}

The monophosphine ligand **143** reacts with Pd(II) to give complex **144**.¹²⁷

A series of [Rh(cod)(PPh₂Glyc)₂]ClO₄⁻ complexes (cod is cyclooctadiene) have been synthesised from acetalated monosaccharide monophosphine derivatives, *e.g.*, compound **145**.⁷

Synthetically more accessible phosphinites react with Rh(III) to yield complexes **146**^{3, 128–132} similar to monophosphine complexes of the acetalated ligands **145**.

Many studies by Russian investigators have been devoted to the complexation of carbohydrate phosphites (see, *e.g.*, a review¹³³). Thus hydrogen phosphonates derived from acetalated monosaccharides **147** yield palladium complexes **148**.^{134–137}

R = Et, Pr, Prⁱ;
Glyc is an acetalated monosaccharide residue.

Treatment of the readily available phosphite (Glyc³O)₃P with Cu(CO)Cl gives the tetramer {CuCl[P(OGlyc³)₃]}₄ having a cubic structure.¹³⁸

The bicyclopophosphite complexes LCuX (L = **149**; X = Br, I),^{139–142} with a cubic structure (**150**) in the solid state, have been prepared.¹⁴³

Phosphorodiamidites **151** form complexes (η³-C₃H₅)Pd(L)Cl and L₂Rh(CO)Cl¹⁴⁴ as well as *trans*-[PtCl₂L₂] (L = **151**).¹⁴⁵ Their structures and the coordination sites of metal ions have not been established.^{144, 145}

Glyc is an acetalated monosaccharide residue.

Carbohydrate phosphates have been investigated in less detail. The preparation of a cobalt complex with the phosphonate **152**¹⁴⁶ having a hypothetical dimeric structure **153** has been reported.

Some papers are devoted to sulfur- and selenium-containing monosaccharides, particularly thiolates and selenolates. These compounds are, in principle, soft bases, therefore the complexes of the corresponding carbohydrate derivatives with soft cations, such as Au⁺, and platinum metal cations (the principle of hard and soft acids and bases¹⁴⁷), have been studied first. Thus dithiol **154a** forms a mixed complex **154b** with gold(I).¹⁴⁸ The HS–SH group in the dithiol–rhodium complex **155a** forms a part of the chelate centre (structure **156**).⁷ The iridium cation in complex **157** prepared from the thioethers **155b** (R = Me, Prⁱ, Ph) is coordinated in a similar way.⁷

a: X = H
b: X = AuPEt₃.

The readily available carbohydrate dithianes react smoothly with K₂[PtCl₄]; thus compound **158** yields the complex **159**.⁷

A fairly large number of papers are devoted to complexes of acetylated β-D-thioglucose **160**. Gold complexes **161** are used in medicine^{149, 150} along with analogous gold complexes containing a deacetylated carbohydrate fragment. Iron, ruthenium, tungsten and platinum complexes **162–165** with acetylated thioglucose have been described.⁷

R = Me, Et, Prⁱ, Bu.

Some complexes of sulfur- and nitrogen-containing carbohydrate ligands have been investigated. Thiocarbamates **166** react

with bridge binuclear platinum complexes to yield complexes **167–172**.⁷

The metal atom in complexes with the thiourea ligand **173** (L) [M(η⁵-Cp)Cl₂L] (M = Rh, Ir), [Pd(*o*-C₆H₄CH₂NMe₂)ClL] and [MCl₂L₂] (M = Pd, Pt) is coordinated through the nitrogen atoms.⁷ The ligand **174** containing an *N,N*-dithiocarbamoyl fragment forms the complex **175** with bidentate *S,S*-coordination.⁷

The dihydrooxazole thioglucose derivatives **176** form complexes **177** and **178** with palladium.⁷ By virtue of its allylic structure, the latter complex is represented by two diastereomers differing in the position of the central allylic proton relative to the dihydrooxazole substituent R.

π-Allylic complexes are also typical of ligands **179** and **180** containing both sulfur and phosphorus. Thus the aryl ligand **179** forms complexes **181**,^{7, 151} whereas the ferrocenyl ligand **180** yields the complex **182**.^{7, 152} Zero-valent palladium complexes **183** have also been prepared. An analogous derivative of the unsaturated thio sugar **184** coordinates the Rh(II) cation to yield the structure **185**.⁷

Selenium-containing monosaccharides described in the literature are represented only by the selenoglucose derivative **186**, which was used as a source of complexes **187–191** having different structures.^{7, 153} The latter complex represents a mixture of three diastereomers **191a–c**.¹⁵³

V. Conclusion

The progress in the coordination chemistry of carbohydrates is favoured by three main factors, *viz.*, inexhaustibility of this class of compound due to continuous photosynthetic reproduction, the diastereomeric purity of carbohydrates and the chirality of metal complexes formed from them, which is associated with chirality transfer from the ligands to the metal centres.

Chemical modification of monosaccharides enables one to enhance considerably their coordination capabilities, particularly owing to the diversity of their oxygen donor centres. Moreover, hydrophobisation of starting monosaccharides makes possible the preparation and further utilisation of their metal complexes in non-aqueous media.

Localisation of coordination points of monosaccharide metal complexes localised in close proximity to the ligands often changes their conformation, anomeric configuration and even the nature as a result of molecular rearrangements (see, *e.g.*, Ref. 6 and this review). Mention should be made in this connection of the conversion of oximes of the aldehydo-forms of monosaccharides into the corresponding amides in the presence of Cu²⁺ (Beckman rearrangement).¹⁵⁴ Although such rearrangements are still very rare, their number will inevitably increase and, as a consequence, novel methods for the modification of carbohydrates by complexation with metals will be developed. At present, the chemistry of carbohydrates is still imperfect due to the use of accessory reagents, formation of side products, *etc.*¹⁵⁵ In our opinion, progress in this area will be achieved through further development of the coordination chemistry of modified carbohydrates.

Metal-oxide based nanoobjects: reactivity, building blocks for polymeric structures and structural variety †

A Müller, S Roy

Contents

I. Introduction	981
II. Reactions at well-defined sites of well-defined nanoobjects: an example	981
III. Nanoobjects as building blocks for extended structures	982
IV. Extending the structural variety	986
V. Conclusion	990

Abstract. From the unique ‘library’ of molybdenum-oxide based building blocks/fragments under reducing conditions in aqueous solution a huge variety of nanoobjects, allowing specific reactions at well-defined positions, can be generated. This enables us to perform a new type of nanochemistry. Examples include the well-known molecular big-wheel of the type {Mo₁₇₆} and big-ball of the type {Mo₁₃₂} including their derivatives which are considered here. In addition, the by far largest structurally well-characterised cluster having 368 molybdenum atoms with the shape of a lemon is outlined and discussed. The bibliography includes 71 references.

I. Introduction

The deliberate synthesis of multifunctional compounds and materials from well-known building blocks which can be easily generated or are available from a ‘virtual’ library is one of the most challenging problems in contemporary chemistry. Pertinent targets include the synthesis of materials, *e.g.*, based on cross-linked building blocks with desirable electronic properties. In solutions of oxoanions of the early transition elements an enormous variety of compounds can be formed by linking together metal–oxygen building blocks.^{1–9} The corresponding reactions are based on libraries with (virtual) building blocks, *i.e.* polyoxometallate (POM) fragments which, under appropriate conditions, lead to the generation of clusters ranging from those of mere aesthetic beauty to unusual materials. Examples include the spherical cluster anion {Mo₇₂^{VI}Mo₆₀^VO₃₇₂(CH₃COO)₃₀(H₂O)₇₂}^{42–} (also known as an inorganic superfullerene or keplerate[‡]), and the ring-shaped cluster anion {Mo₁₂₆^{VI}Mo₂₈^VO₄₆₂H₁₄(H₂O)₇₀}^{14–} (see Fig. 1 and reviews cited above). Additionally, interesting molecular magnets, novel-type supramolecular compounds, compounds with extended structures including those with mesoporous networks,^{3–7} and surfactant-encapsulated giant clusters soluble in organic solvents (with the option of generating monolayers and Langmuir–Blodgett films) can be obtained.^{10–14} In this context, we intend here to demonstrate perspectives for a new type of nanochemistry by highlighting:

- the possibility of performing reactions at well-defined positions of well-defined nanoobjects;
- the possibility of linking the nanoobjects;
- the possibility of obtaining numerous novel giant members of this ‘nanosociety’.

The results described here are not included in previous reviews.^{1–9}

II. Reactions at well-defined sites of well-defined nanoobjects: an example

1. Synthetic and structural aspects

The possibility of performing chemical reactions at well-defined sites of well-defined nanoobjects opens up interesting perspectives for the chemist, especially if novel functionalities emerge.^{1–17} For example, the high-yield facile synthesis of giant spherical {Mo₁₃₂} (Fig. 1 *a*)¹⁸ and ring-shaped {Mo₁₅₄} (Fig. 1 *b*)^{19,20} (first reported in Ref. 19 but not with optimal synthesis) molybdenum-oxide based clusters provides us with easily accessible nanostructured landscapes with nano-sized cavities and a variety of different functional groups. In particular, it proved possible to incorporate paramagnetic metal centres, *e.g.*, Cu²⁺ ions, inside the tetrahedral cavities of the {Mo₁₅₄}-type rings formed by four O atoms with appropriate size. It is significant that our approach paves the way to the deliberate synthesis of a broad range of compounds, which can be obtained by altering the boundary conditions, such as the pH, temperature, and/or the presence of different substrates, while on the other hand, it also opens up new perspectives for studies in the sense of a novel type of self-assembly (see also Ref. 21).

The synthesis of a cluster containing Cu²⁺ ions involves reduction of an acidified aqueous polymolybdate with copper powder. The ammonium salt of this cluster is obtained as the black crystalline compound **1**.¹⁵

Single crystal X-ray diffraction studies show the presence of the [{Mo₈^{V/VI}O₂₆(μ₃-O)₂X_i(H₂O)₃Mo^{V/VI}}]₁₄{Mo₂^{VI}O₅(H₂O)₂}₈]^{26–} cluster anion (ΣX_i = 4H + 5Cu) (**1a**), which can be considered as

† Dedicated to Prof. Ilya Moiseev.

‡ By definition, keplerates are compounds having one central point, the barycentre (either occupied by an atom or vacant), around which one or more spherical shells of atoms contained in the cluster are located. These atoms are vertices of Platonic or Archimedean solids.

The English text provided by the authors

a derivative of the aforementioned prototypal tetradecameric ring-shaped cluster anion $\{\text{Mo}_{154}\}$, ($\{\text{Mo}_{154}\} \equiv \{\text{Mo}_8\}_{14}\{\text{Mo}_1\}_{14}\{\text{Mo}_2\}_{14}$) (**2a**).^{4–7} The cluster anion **1a** lacks six $\{\text{Mo}_2\}$ building blocks as compared to the parent $\{\text{Mo}_{154}\}$ anion. Moreover, it contains non-uniformly distributed Cu^{2+} centres — with a maximal occupation number of 0.73 — in the 14 tetrahedral cavities marked by four oxygen atoms. The Cu^{2+} cations replace five of the 14 protons of the parent cluster **2a**, which are bonded to one of the two $\mu_3\text{-O}$ atoms that are involved in the formation of the cavities (Fig. 2). In the case of high H^+ ion concentrations, the maximum degree of protonation is attained, *i.e.*, all fourteen cavities of the cluster **1a** are occupied by protons bonded to the $\mu_3\text{-O}$ bridging atom.⁵ In presence of the HCOONH_4 buffer, the degree of protonation of cluster **1a** is lower and consequently Cu^{2+} ions can be coordinated to the basic four O atoms of the corresponding tetrahedral cavity.

2. Electronic spectra and magnetic aspects

Although the resonance Raman ($\lambda_e = 1064$ nm) and IR spectra of **1a** are nearly identical to those of the parent cluster **2a**, the electronic spectrum of the former exhibits, as a result of the abundance of Cu^{2+} centres, an additional band at ~ 520 nm and a blue shift of the higher energy intervalence charge transfer (IVCT) transition localised in the $\{\text{Mo}_5^{\text{V/VI}}\text{O}_6\}$ -type compartments,⁵ each of them containing two delocalised $4d$ electrons. The change in the charge transfer is caused by the fact that the encapsulated Cu^{2+} ions are coordinated to the $\mu_3\text{-O}$ atoms which belong to the $\{\text{Mo}_5\text{O}_6\}$ compartments, thus resulting in an electron density redistribution in this compartment.

The room-temperature EPR powder spectrum of compound **1** is similar to the spectra of tetrahedral copper complexes containing $\{\text{CuX}_4\}$ groups, in particular, $\{\text{CuO}_4\}$ types, and therefore indicating the presence of Cu^{2+} (d^9) centres. The spectrum is characterised by $g_x = 2.07$, $g_y = 2.15$, and $g_z = 2.37$, as well as by the hyperfine splitting constant $A_z = 125$ G (related to the nuclear spin of $^{63/65}\text{Cu}$ with $I = 3/2$). The values indicate that the $\text{Cu}^{2+} \cdots \text{Cu}^{2+}$ magnetic interactions are practically negligible ($\text{Cu} \cdots \text{Cu} \approx 6.2$ Å). This observation is also supported by magnetic susceptibility measurements. At high temperatures, the $\chi_{\text{mol}}T$ curve was found to reach a plateau at ~ 2.86 emu K mol^{−1}, which corresponds to about six Cu^{2+} centres per formula unit for $g = 2.2$. As the calculated inter- and intra-molecular antiferromagnetic coupling constants are very small, $\chi_{\text{mol}}T$ decreases only at temperatures below ~ 20 K. The temperature variation of the magnetic susceptibility can be described using the Curie–Weiss equation

$$\chi = \frac{C}{T - \theta}$$

with a very low Weiss temperature ($\theta = -0.5$ K).¹⁵

3. General aspects

Modification of the parent $\{\text{Mo}_{154}\}$ ring-type cluster anion **2a** — by introduction of paramagnetic Cu^{2+} ions under certain self-assembly conditions — is possible because of the presence of O_4 -type cavities with dimensions in agreement with the characteristic $\text{Cu}—\text{O}$ distances (2.0 ± 0.1 Å). The assembly of this cluster starts from simple mononuclear $\{\text{Mo}_n\}$ -type units, followed by the construction of larger intermediate building blocks (abundant in a virtual ‘library’), which are finally transformed into a mesoscopic organised complex ring-shaped structure — with a variety of functional groups — *via* molecular recognition processes for Cu^{2+} centres which get integrated at the suitable sites of the cluster.

The highly symmetrical mesoscopic $\{\text{Mo}_{154}\}$ -type parent cluster (see Fig. 1), which is the primary target of the self-assembly process in this case based only on molybdate, can undergo a variety of modifications due to alteration of the boundary conditions, or in other words, due to environmental influences, as for example, the presence of Cu^{2+} ions.

In this context, it is important to remember that assembly processes based on simple building blocks lead preferably to highly symmetrical species,[§] such as rings.^{4,5} This is consistent with many observations in cluster chemistry (see, for example, Ref. 24). Important is in this context that mesoscopic systems can, in spite of a high overall symmetry, exhibit versatile reactivity owing to the presence of large numbers of substructures with different functional groups. This feature is especially noteworthy as the accepted view is that higher symmetry leads to a decrease in the number of structural details and therefore reactivities. This rule actually only holds for smaller discrete species and crystalline systems with macroscopic homogeneity and microscopic translational invariance but not for discrete mesoscopic molecular-type species. An example for relevant mesoscopic systems is the situation with spherical viruses, mentioned in most biochemistry books.

It follows from the foregoing discussion that the molybdenum-oxide based ring-shaped clusters can be considered as nanostructured landscapes having a variety of functional groups at well-defined positions.^{4–7,20} This permits various types of reactions, including catalytic ones, to be carried out at strictly defined positions. These reactions include coordination of activated ligands, but also amphiphilic and multiphilic ones (for example, diprotonated cysteine ligands[¶]), which may lead to the generation of unusual surfaces within the cavities,²⁵ and the incorporation of metal centres or small fragments into appropriate cavities.

Another conclusion related to this work is that the reactivity and the electron density distribution in nanoobjects can be varied both by defect generations and by incorporation of open-shell heterometal atoms. In this particular case, the influence of the Cu^{2+} metal centres on the distribution of delocalised electrons within the above-mentioned compartments is indicated by the shift of the IVCT band from ~ 750 nm for the parent $\{\text{Mo}_{154}\}$ anion⁵ to ~ 680 nm for anion **1a**.¹⁵ Thus, one can adjust (tune) the electron density distribution, and even the related catalytic activity of the present type of nanoobjects, which can act as selective oxidants.²⁶

III. Nanoobjects as building blocks for extended structures

1. Synthetic and structural aspects

The search for extended structures based on linked nano-sized stable (!) building blocks and possessing specified electronic and magnetic properties is an exceptionally worthy task because such compounds could provide new types of functionalised materials.²⁷ In this context we attempted the synthesis of the large well-defined metal-oxide based nanoparticles with unique host properties in order to use them as building blocks. Linking these blocks according to $\text{M}—\text{O}—\text{M}$ or $\text{M}—\text{O}—\text{M}'$ patterns can furnish, in principle, a broad range of compounds differing in architecture.

Our route to unique extended structures involved the use of spherical metal-oxide based keplerate-type clusters with icosahedral symmetry.^{4,5} (The internal cavity diameter in this type of structures is sufficiently large even for encapsulating Keggin-type clusters. The related composites could be prepared through a facile synthesis.²⁸) Linking such large spherical objects gives rise

§ The process can formally (!) be correlated with a general symmetry formalism or symmetry-evolution principle for a quasi-isolated system.²² One important aspect of the symmetry-evolution principle is that the highly symmetrical species are often also preferably formed as they are kinetically inert. However, this principle is inapplicable to macroscopic chemical reaction systems as structure-formation-based precipitation is equivalent to symmetry breaking.²³

¶ Multiphilic ligands like cysteine containing various functional groups ($-\text{NH}_3^+$, $-\text{CO}_2\text{H}$, $-\text{S}—\text{S}—$) can be coordinated to the inert wall of the cavity.

Figure 1. Spherical $\{\text{Mo}_{132}\}$ - (a) and ring-shaped $\{\text{Mo}_{154}\}$ -type (b) clusters (the $\{\text{Mo}_1\}$ unit cannot be seen in this view; see Fig. 2) shown in polyhedral representation. The spherical cluster shows the pentagonal units in blue and the linkers in red.

Figure 2. Molecular structure of the cluster anion **1a** [top (a) and side (b) views] in crystals of **1** in the atomic representation. The $\{\text{O}_4(\text{Cu})\}$ tetrahedra are given in polyhedral representation. Colour code: oxygen is red, molybdenum is blue, except those of the $\{\text{Mo}_1\}$ shown in yellow. This drawing was first published in Ref. 15.

for instance to chain-type structures. Analogous chain structures are also produced upon linking fullerenes.^{29–31}

As an example, we shall consider the synthesis and structure of an unusual mixed-valence compound **3**, containing the discrete $\{\text{Mo}^{\text{VI}}(\text{Mo}^{\text{VI}})_5\}_{12}\{\text{Mo}_6^{\text{V}}\text{Fe}_{24}^{\text{III}}\}$ -type keplerate cluster **3a**.¹⁶

The black compound **3** is formed upon the addition of iron(II) chloride to an aqueous solution of sodium molybdate acidified with acetic acid in presence of air. Upon drying, a novel type of room-temperature solid-state reaction takes place, yielding compound **4** with a chain structure.¹⁶

Figure 3. Structure of the discrete anion **3a** in crystals of **3** (*a*, polyhedral representation); structure of the chain **4a** in crystals of **4** (*c*, space-filling representation; the Mo positions can be identified), and the linking area of the chain **4a** [*b*, atomic representation; bond lengths (Å) and angles (deg) in the $\{\text{M}_4\text{O}_4\}$ rings ($\text{M} = \text{Mo}/\text{Fe}$): $\text{Mo}-\text{O}$: 1.72–1.78; $\text{Fe}-\text{O}$: 1.96–1.98; $\text{Mo}-\text{O}-\text{Fe}$: 147.0–149.9; $\text{O}-\text{Mo}-\text{O}$: 101.5; $\text{O}-\text{Fe}-\text{O}$: 93.2]. This drawing was first published in Ref. 16.

(In general, mixed-valence compounds of this type with extended structures possess remarkable electronic properties.³²)

During the formation of **3**, Fe^{II} ions are oxidised to Fe^{III} , only a minor portion of the Fe^{II} ions being used to reduce Mo^{VI} centres. Nevertheless, the presence of Fe^{II} ions is necessary, because beginning the synthesis with Fe^{III} as the starting material leads even in the presence of a reducing agent immediately to a non-crystalline precipitate.

Both the spherical cluster $[\{\text{Mo}^{\text{VI}}(\text{Mo}^{\text{VI}})_5\}_{12}\{\text{Mo}_6^{\text{V}}\text{Fe}_{24}^{\text{III}}\} \cdot (\text{CH}_3\text{COO})_{20}\text{O}_{258}(\text{H}_2\text{O})_{84}]^{2-}$ (**3a**) (note: there is an error limit in the charge) and the related chains comprise 12 pentagonal $\{\text{Mo}^{\text{VI}}(\text{Mo}_5^{\text{VI}}\text{O}_{21})\}$ -type building blocks, containing a central pentagonal $\{\text{MoO}_7\}$ bipyramid sharing edges with five $\{\text{MoO}_6\}$ octahedra. The pentagonal fragments are connected through 24 $\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})_2\}^{3+}$ and 6 $\{\text{Mo}^{\text{VO}}(\text{H}_2\text{O})\}^{3+}$ linkers which are statistically distributed over the 30 vertices of an icosidodecahedron.[†] The six *4d* electrons of the Mo linkers are partially delocalised over positions of the pentagonal $\{\text{Mo}(\text{Mo}_5)\}$ building groups. The bidentate acetate ligands are located inside the sphere and are coordinated simultaneously to the two metal atoms Fe and Mo. Thus, they function as bridges between the Fe and Mo centres. In the crystals of **4**, the icosahedral spherical building blocks, *i.e.*, of the type $\{\text{Mo}(\text{Mo}_5)_5\}_{12}\{\text{Mo}_6\text{Fe}_{24}\}$ (Fig. 3*a*), are linked to form chains (Figs 3 and 4 as well as Scheme 1) through $\text{Mo}_\text{A}-\text{O}-\text{Fe}_\text{B}$ and a $\text{Fe}_\text{A}-\text{O}-\text{Mo}_\text{B}$ group (A and B stand for two neighbouring spheres). This results in a nearly square $\{\text{Fe}_2\text{Mo}_2\}$ fragment (Fig. 3*b*) the centre of which coincides with a crystallographic inversion centre. Interestingly, the geometric details of the $\text{Fe}_\text{A}-\text{O}-\text{Mo}_\text{A}$ - (inside a sphere), $\text{Fe}_\text{A}-\text{O}-\text{Mo}_\text{B}$ - and $\text{Fe}_\text{B}-\text{O}-\text{Mo}_\text{A}$ -type units do not differ significantly ($\text{Mo}\cdots\text{Fe} \sim 3.6$ Å). As shown below, this has important implications for the magnetic properties of compound **4**. The $\{\text{Fe}_2\text{Mo}_2\}$ square fragment in **4** is topologically equivalent to the cyclobutane fragment found in dumbbell-shaped $\{\text{C}_{60}\}_2$ dimers. The latter unit is also built up by two intra- and two inter-sphere C–C bonds.²⁹

[†] The presence of octahedral $\text{Fe}^{\text{III}}\text{O}_6$ groups could also be proved by Mössbauer spectroscopy. The presence of one $\{\text{Mo}^{\text{VI}}\text{O}\}^{4+}$ linker group, instead of $\{\text{Mo}^{\text{VO}}\}^{3+}$, and the related change of the number of Na atoms cannot be completely ruled out within the error limits of the invoked analytical techniques.

Figure 4. Schematic demonstration of the room-temperature solid-state reaction leading to the formation of the chain of **4** caused by linking the spheres **3a**. This drawing was first published in Ref. 16.

When compound **3** loses crystal water, the discrete spherical clusters **3a** approach one another, which is followed by their condensation to give infinite chains. The linking is caused by the fact that H_2O ligands in the $\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})_2\}^{3+}$ fragments in sphere A are substituted by terminal $\text{Mo}=\text{O}$ groups of the $\{\text{Mo}(\text{Mo}_5)\}$ pentagons belonging to the neighbouring sphere B. Thus, the $\text{Mo}=\text{O}$ group formally acts as ligand in accordance with the following Scheme 1.

The reaction is driven by the gain in entropy caused by the release of water molecules. This solid-phase S_N -type reaction, which functions well for compound **3**, does not happen, however, for the yellow compound **5**

5

which contains the $\{\text{Mo}^{\text{VI}}(\text{Mo}_5^{\text{VI}})\}_{12}\{\text{Fe}_{30}^{\text{III}}\}$ -type discrete neutral clusters.^{33,34} The reason is that cluster **3** shows the S_N -type reaction initiated by the $\text{Mo}=\text{O}$ groups due to the increase in the electron density on the terminal oxygen atoms of these groups caused by the influence of six partially delocalised $4d$ electrons, which are not abundant in the non-reduced **5**.

Not only the crystallinity but also the space group ($P2_1/n$) is preserved throughout the solid-state reaction $\mathbf{3} \rightarrow \mathbf{4}$. Comparison of the packing of the spherical clusters **3a** in the crystal lattices of compounds **3** and **4** has shown that the distances between the spherical $\{\text{Mo}(\text{Mo})_5\}_{12}\{\text{Mo}_6\text{Fe}_{24}\}$ -type units in **4** are shortened drastically along the crystallographic c axis (see Fig. 4) compared to the corresponding distances in **3**; as a result, the crystal lattice parameter c in **4** is 5.7 Å shorter than that in **3**.

2. An interesting mesoscopic magnetism

A convenient way of explaining the magnetism of compound **4** is to compare it with the cluster of compound **5** (see Refs 33, 34), which is the largest molecular paramagnet known.³⁵ In both systems, the antiferromagnetic exchange interactions between the $\text{Fe}(\text{III})$ centres ($S = 5/2$) abundant in a nearly perfect octahedral environment are mediated by the $\text{O}-\text{Mo}-\text{O}$ groups.

In the case of **5**, the $\chi_{\text{mol}}T$ value increases with an increase in T from 20 to 300 K (Fig. 5), and at room temperature, it approaches the value expected for 30 uncorrelated centres with $S = 5/2$, namely, 131.25 emu K mol⁻¹ (the spin-only value for $g = 2.0$). The room-temperature value of $\chi_{\text{mol}}T$ found for compound **4** is equal to 104.0 emu K mol⁻¹, which is closely similar to the value (105.0 emu K mol⁻¹) expected for 24 uncorrelated $\text{Fe}(\text{III})$ centres with $S = 5/2$. Since the partially delocalised $\text{Mo } 4d$ electrons in **4**, as in the reduced $\{\text{Mo}_{102}\}$ -type keplerate,³⁶ are strongly coupled, they contribute only to a negligible extent to the overall magnetic moment. Thus, the high-temperature results indicate that six of the thirty positions of the icosidodecahedron occupied by $\text{Fe}(\text{III})$ magnetic centres in the cluster of **5** are occupied in **4** by effectively non-magnetic centres. The magnetic susceptibilities measured in the 20–300 K range are in very good agreement with the Curie–Weiss function down to very low temperatures; however, the Weiss temperatures calculated for **4** and **5** differ significantly: $\theta(\mathbf{4}) = -13 \text{ K}$, $\theta(\mathbf{5}) = -21.6 \text{ K}$.

Figure 5. Comparison of the temperature dependences of $\chi_{\text{mol}}T$ for compounds **4** (curve 1) and **5** (curve 2).

These $\theta(\mathbf{4})$ and $\theta(\mathbf{5})$ values can be explained in terms of the following simple model. Since the geometric parameters of the corresponding $\text{Fe}-\text{O}-\text{Mo}-\text{O}-\text{Fe}$ groups, including the bridges between the spheres, are virtually identical in compounds **4** and **5**, the same single Heisenberg exchange constant J is assumed for the nearest-neighbour $\text{Fe}\cdots\text{Fe}$ interactions (see Ref. 37). Important is that θ is proportional to the absolute number of nearest-neighbour $\text{Fe}\cdots\text{Fe}$ contacts per sphere.[‡] This number is lower for compound **4** than for **5**, due to the presence of six centres that do not effectively contribute to paramagnetism, *i.e.*, that are effectively non-magnetic. A uniform statistical distribution of the non-magnetic centres over the 30 icosidodecahedron vertices results in 38 $\text{Fe}\cdots\text{Fe}$ contacts compared to the 62 contacts of a hypothetical all-iron configuration including 60 icosidodecahedron edges and 2 distinct bridges to the adjoining spheres in the chain. Thus, proceeding from the value $\theta(\mathbf{5}) = -21.6 \text{ K}$, we obtain $\theta(\mathbf{4}) = 38/62 \times \theta(\mathbf{5}) = -13.2 \text{ K}$, which is in excellent agreement with the value experimentally determined.

It is of interest to compare the case of uniform distribution of effectively non-magnetic centres with other distribution patterns, for example, the arrangement of all the non-magnetic centres on neighbouring sites of the icosidodecahedron. In this case, the Weiss temperature should increase to -18 K . Thus, the calculated $\theta(\mathbf{4})$ value perfectly reflects the uniform distribution of the magnetic centres in each individual sphere (with a ratio of the numbers of magnetic to non-magnetic positions equal to 24 : 6). If the average ratio equal to 24 : 6 is retained, while the magnetic to non-magnetic centre ratio in different spheres can be different, this situation cannot strictly correspond to the determined Curie–Weiss parameter. It is noteworthy that, because the Weiss temperature reflects the ordering and the distribution of the non-magnetic centres over the thirty possible positions, this value can be used to draw structural conclusions that cannot be obtained from the single crystal X-ray structure analysis.[§]

3. General outlook

Now we consider an interesting result related to the chemistry of extended structures. Spherical molybdenum-oxide based keplerate-type clusters possess a number of interesting features,²⁸ in particular, they can be used as building blocks in the development of various extended structures and nanomaterials. The linking of nano-sized spherical capsule-type objects, for instance, can lead to one-dimensional chains *via* a room-temperature solid-state reaction which can be regarded as a type of crystal engineering process. In view of the fact that we are dealing with spherical capsules of the type $(\text{Pentagon})_{12}(\text{Linker})_{30}$ ($\text{Linker} = \{\text{Fe}(\text{H}_2\text{O})\}^{3+}$, see Refs 33, 34, $\{\text{MoO}(\text{H}_2\text{O})\}^{3+}$, see Ref. 36), the linkers L can be changed stepwise with the option to change the surface properties. For example, by changing appropriately the degree of electron density on the surface of cluster **3**, by increasing in the present case the number of $\{\text{MoO}(\text{H}_2\text{O})\}^{3+}$ groups, the nucleophilicity of this cluster can correspondingly be increased, which could lead to different types of inter-sphere condensation reactions. In summary, the type of linking of the spherical units depends on the $\text{MoO}^{3+}/\text{Fe}^{\text{III}}$ ratio.

In addition, the presence of two $\text{Fe}^{\text{II}}\cdots\text{Mo}^{\text{VI}}$ and $\text{Fe}^{\text{III}}\cdots\text{Mo}^{\text{V}}$ couples with very close redox potentials makes compounds **3** and **4** especially interesting. In particular, this type of electronic structure can induce a temperature-dependent electron transfer in **4a**. In this context it is important to realize that the Fe and Mo atoms

[‡] This result follows from the standard expression for θ determined for systems with a single exchange constant.

[§] Single-crystal X-ray structure analysis does not allow one to distinguish between the situation of all spherical units having the same composition (as in the present case) and the situation where certain spheres have different compositions but also yield altogether for the whole compound the same $\text{Fe}^{\text{III}}/\text{Mo}^{\text{V}}$ average ratio of 24 : 6.

in solid metal oxides which occupy octahedral positions obey the following equilibrium:³⁸

The mentioned type of electron transfer is similar to electron delocalisation or hopping in ‘heteropoly blues’.¹ This was confirmed by quantum-chemical calculations for electron transfer transitions in substituted (at the metal) polyoxometallates and by Mössbauer spectroscopy data for the iron-substituted cerium salt of 12-molybdenophosphoric acid, containing 0.6 Fe^{II} atoms as the counter-cations and 0.9 Fe^{II} atoms in the Keggin part.³⁹ The Mössbauer spectrum of this compound measured at room temperature differed from the spectrum recorded at very low (4.2 K) temperature.³⁹ Other examples of electron hopping and delocalisation in mixed-valence oxometallate clusters have also been reported.⁴⁰

Finally, the 3 → 4 transformation and the resulting products are just one of a myriad of options that can be achieved in the future investigations of ‘our’ POM system.

IV. Extending the structural variety

1. General aspects

Nature’s evolution from the primordial earth to the present overwhelming variety of macroscopic forms and functionalities, the formation of which is directed by their molecular ‘counterparts’, *i.e.*, nano-sized biomolecules, should stimulate thoughts about the potential of material systems in general and the related first principles, *i.e.* natural laws.

We refer to processes based on reservoir systems containing appropriate building blocks, the linking of which can lead to an overwhelming or even, in a kind of combinatorial explosion, to practically an infinite number of molecular forms. This process is particularly valid on passing to the nanocosmos size category. The nanocosmos as such does not show the variety-limiting translational symmetry restriction of macroscopic crystalline materials but offers — unlike the microcosmos with its small molecules — the possibility of existence of larger arrays with local symmetries which are not in agreement with the overall symmetry. This is a well-known situation for spherical viruses with their hexagonal arrays. Figure 6 shows a model of the protein subunits of the Tomato Bushy Stunt Virus (TBSV) as an icosadeltahedron.^{41, 42}

In order to get a huge variety of structures the appropriate fragments chosen as building blocks should display a certain type of flexibility, which is a prerequisite for an extreme linking versatility of course not reaching by far that of amino acids.[†] This condition is well fulfilled by molybdenum-oxide based fragments which are collected as (virtual) building units in a ‘dynamic library’ with a potential to participate in a sort of ‘split and link’ processes depending on slight alterations of the relevant boundary conditions.

Remarkable in this context is the synthesis of a rather unusual giant molybdenum-oxide based nanocluster with the size of hemoglobin containing 368 metal and 1880 non-hydrogen atoms. The cluster has been formed by linking 64 {Mo₁}-, 32 {Mo₂}- and 40 {Mo(Mo₅)}-type units. The formation process was accompanied by a remarkable symmetry breaking process, which is nicely recognisable at the cluster surface. The preparation of the {Mo₃₆₈} nanocluster can be considered as the starting point for the synthesis of quite a number of other clusters with a comparable or even larger size. Referring to the present discovery we would like to attract attention to the momentous and far-

reaching step into the nanocosmos with perspectives for nano-chemistry (*via* symmetry breaking), molecular topology and surface sciences with catalytical relevance. The above-mentioned symmetry breaking can be considered in relation to a transition from positive to negative surface areas, *i.e.*, the monotony breakdown.

2. Synthesis and structure

The reduction of a molybdate solution acidified by sulfuric acid gives the dark blue compound¹⁷

6

which contains the giant mixed-valence cluster anion **6a** (Fig. 7).

6a

with {Mo(Mo₅)}' ≡ {Mo₆O₂₁(H₂O)₆}; {Mo(Mo₅)}'' ≡ {Mo₆O₂₁·(H₂O)₃(SO₄)}; {Mo₂}' ≡ {Mo₂O₃(H₂O)₂}; {Mo₂}'' ≡ {Mo₂(O_t)₂·(O_{br})₃(SO₄)}; {Mo₂}''' ≡ {Mo₂(O_t)₄(O_{br})(SO₄)}; {Mo₁} ≡ {MoO(H₂O)}; *x* ≈ 16.

Compound **6** crystallises in the space group *I4mm*, its unit cell comprises two giant blue lemon-like cluster anions **6a** with approximate *D*₄ symmetry; the anion has a nearly spherical {Mo₂₈₈O₇₈₄(H₂O)₁₉₂(SO₄)₃₂} central fragment (**B**) and two {Mo₄₀O₁₂₄(H₂O)₂₄(SO₄)₈} capping areas (**C**). As the average degree of reduction of the caps **C** is lower than the central fragment **B**, it is reasonable to suggest that the pathway to anion **6a** includes the initial formation of a fragment that resembles in shape the central fragment (**B**) of **6a** while owing to its more nucleophilic nature, it in turn gets capped by two more electrophilic caps **C** in course of the growth process (this refers to a relative consideration). The fragments **B** and **C** have local symmetries (see Fig. 7a), *D*_{8d} and *C*_{4v}, respectively. Figure 7a shows a clearly well-defined cross-section where the symmetry breaking^{43–45} occurs and a negative curvature is generated. It should be noted that the linking of fragments **B** and **C**, characterised by different local symmetry, occurs through vertices rather than edges of the corresponding polyhedra. This was to be expected, as this pattern ensures a higher flexibility.

More precisely, the anion **6a** is built up by the six well-defined building units mentioned above, namely, {Mo(Mo₅)}', {Mo(Mo₅)}'', {Mo₂'}, {Mo₂}'', {Mo₂}''' and {Mo₁} (see Fig. 7a), which are linked to produce the giant molecular container (vase) of **6a** with a giant cavity (diameter *d* ≈ 2.5 × 4.0 nm at the most extended points). This cavity can accommodate an enormous number (~400) of water molecules. Of the 1000 (crystal) water molecules indicated in the formula of **6**, 400 molecules are encapsulated inside the cavity.

The presence of the bidentate SO₄²⁻ ligands is indicated in the vibrational spectrum by a typical splitting of the ν₃(F₂)-type vibrational bands (1191, 1122 and 1060 cm⁻¹), while the presence of Mo^V centres along with the Mo^{VI} centres causes the IVCT (intervalence charge transfer) band at ~740 nm. As can be seen from the above formula, the anion **6a** incorporates two types of {Mo(Mo₅)} building units differing in the type of ligands. Thirty two {Mo(Mo₅)}' blocks containing SO₄²⁻ ions are present in fragments **B** and eight {Mo(Mo₅)}'' blocks which do not contain these ligands are located in the caps **C**. The binuclear {Mo₂} building units differ not only by the type of ligands but also by the type of coordination. Thus both Mo atoms of the {Mo₂}''' fragments located at the ends of both caps **C** contain two terminal oxygen atoms. This situation seems to be characteristic of growth termination. The {Mo₁} units are of the classical type, {OMo^V(H₂O)}³⁺; they contribute significantly to the highly reduced state of anion **6a** (64 of the 112 Mo^V atoms belong to these fragments). The remaining 48 Mo^V-type centres are formally

[†]This special situation of versatility could lead us, using a term from J-M Lehn’s lectures, to the category ‘Multiple Expression of Molecular Information’, a statement which can be related to the formation of the variety of giant clusters obtained from relevant substance ‘libraries’.

Figure 6. Drawing of an icosadeltahedron ($T = 3$) as a model for the topologically identical protein coat subunits of the Tomato Bushy Stunt Virus (TBSV). The drawing was taken from Ref. 41. The orange lobes are packed about the icosadeltahedron fivefold axes, whereas the blue and green lobes alternate about its local sixfold axes, not allowed for an icosahedral symmetry group.

distributed over several parts of the cluster areas which causes a widespread delocalisation of Mo(4d) electrons.

The structure of **6a** can be considered as a hybrid between the giant ring-shaped cluster of the $\{\text{Mo}_{176}\}$ type^{5–7} and the spherical $\{\text{Mo}_{102}\}$ -type cluster.³⁶ In the cluster **6a**, one can find both: the $\{\text{Mo}(\text{Mo}_5)\}$ and $\{\text{Mo}_1\}$ fragments, typical for the spherical $\{\text{Mo}_{102}\}$ cluster, as well as the $\{\text{Mo}(\text{Mo}_5)\}$ and $\{\text{Mo}_2\}$ fragments, typical for ring-shaped systems. The hybrid character of cluster **6a** also becomes obvious due to the presence of 24 $\{\text{Mo}_{11}\}$ groups with C_5 symmetry and 16 $\{\text{Mo}_{10}\}$ groups with C_s symmetry, containing one MoO_6 octahedron less (Fig. 8).⁷ (Note that the two groups have 56 MoO_6 octahedra in common; see Fig. 7a.) The $\{\text{Mo}_{11}\}$ groups with C_5 symmetry are identical to those of the spherical clusters,⁷ and the $\{\text{Mo}_{10}\}$ groups are identical to the $\{\text{Mo}_{10}\}$ fragment encountered in ring-shaped clusters, *i.e.* the $\{\text{Mo}_{11}\}$ group without the displaced MoO_6 octahedron.[†]

[†] The spherical- ($n = 12$) and ring-type ($n = 14, 16$) cluster species can be expressed by the same basic type of stoichiometry $\{\text{Mo}_{11}\}_n$, *i.e.*, they differ only in numbers n ; this was categorised by us as a Pythagorean harmony.⁷

Figure 7. Structure of **6a** in crystals of **6** in polyhedral (*a, c*) and atomic (*b, d*) representations perpendicular to the C_4 axis (*a, b*) and along the C_4 axis (*c, d*). Building units: $\{\text{Mo}_1\}$, yellow; $\{\text{Mo}_2\}$, red; $\{\text{Mo}(\text{Mo}_5)\}$, blue with blue-turquoise pentagonal bipyramids; the O atoms are small red spheres, the S atoms are grey spheres. Note that one capping part is turned against the other by $360/16^\circ$. Different building blocks and the arrays of different local symmetry are marked. This drawing was first published in Ref. 17.

Figure 8. $\{\text{Mo}_{368}\}$ metal atom framework of **6a** in wire-frame (a) and atomic (b) representations. For colour designations, see Fig. 7a. The $\{\text{Mo}_{11}\}$ and $\{\text{Mo}_{10}\}$ building blocks in (b) are emphasised through thick lines.

The high degree of reduction (about 112 Mo^{V} and 256 Mo^{VI}) of **6a**, which is much higher than that in the ring systems (for example, 28 Mo^{V} and 126 Mo^{VI})⁵ indicates that the cluster growth is promoted by reducing conditions. The largest cluster obtainable in an acidified molybdate solution in the absence of a reducing agent is the rather small $\{\text{Mo}_{36}\}$ anion,[‡] which, however, ‘starts growing’ upon the addition of a reducing agent.⁵ It is also significant that the higher the negative charge of the anion, the less probable is its uncontrolled linking but it initiates further protonation, which is a prerequisite for further linking. The high negative charge of anion **6a** is also influenced by the presence of SO_4^{2-} ligands coordinated to the intermediates and to the final cluster species. When the reaction is performed in the presence of the weakly coordinating ligands such as Cl^- or ClO_4^- (which do not appear in the cluster when HClO_4 or HCl are used as acidification agents, instead of H_2SO_4), the reaction affords only ring-like molybdenum-oxide based species⁵ rather than the hybrid cluster **6a**. It is also worth mentioning that, although the coordination capacity of SO_4^{2-} is higher than those of Cl^- or ClO_4^- , it is still not too strong; thus, it provides a coordination flexibility and, as a consequence, generation of a variety of different appropriate building blocks. The average degree of reduction of the two $\{\text{Mo}_{40}\}$ -type caps (**C**) in cluster **6a** is lower than that of the central fragment **B**. This observation agrees with our hypothesis that growth processes in polyoxometallate-type systems are mostly based on nucleophiles which form the initial fragment of the cluster and direct the formation of electrophiles by which they get capped (electrophiles and nucleophiles in a relative consideration).

As examples of such growth, one can consider the transition from a hypothetical extremely negatively charged V^{IV} -type Keggin ion to the stable cluster formed upon capping the Keggin ion with six additional VO^{2+} groups;^{1,2,47} the transition from the $\{\text{Mo}_{57}\}$ -type cluster to the extended $\{\text{Mo}_{63}\}$ cluster (via linking of $\{\text{Mo}_{57}\}$ to six MoO^{4+} groups⁴⁸); and the transition from the $\{\text{Mo}_{176}\}$ -type cluster anion to the $\{\text{Mo}_{248}\}$ anion via linking of $\{\text{Mo}_{176}\}$ to two neutral $\{\text{Mo}_{36}\}$ fragments.⁴⁹ A further example refers to remarkable processes occurring during the formation of the unusual unsymmetrical molybdenum-oxide based $\{\text{Mo}_{37}\}$ cluster. After a highly reduced ϵ -Keggin-type $\{\text{Mo}_{12}^{\text{V}}\}$ unit is capped by four electrophilic $\{\text{MoO}_3\}$ groups, these groups get reduced while the resulting $\{\text{Mo}_{16}\}$ species is capped by the positively charged $\{\text{Mo}_{11}\}$ and $\{\text{Mo}_{10}\}$ fragments. Often, processes of this type result in a lowering of the unusually high negative charge of the intermediates. In each of the examples described

above, the central nucleophilic core appears to have directed the formation of electrophilic fragments.

3. Perspectives

The knowledge of structural details of cluster **6a** will probably be the starting point for the synthesis of many other systems of comparable sizes as well as for the development of a new type of nanochemistry characterised by performing well-defined reactions at specified sites of well-defined nanoobjects and also includes their handling as intact units for instance for the preparation of composites, e.g., with silica and additionally surfactants to give micelles, films, and even liquid crystals.^{10–14, 50, 51} (The possibility of these studies is indicated by the syntheses and use of the giant spherical and ring clusters mentioned above.) The present results with the cluster having a giant surface also seem to be of relevance for some aspects of catalysis, as it is still a challenge to understand the details of the interaction mechanisms of substrates with the surfaces of heterogeneous catalysts.^{52–55} In the case of transition metal oxides, like MoO_3 , which play an important role in selective oxidation processes,^{54, 55} it would be a tremendous step forward to consider the surfaces of discrete and well-defined giant molybdenum-oxide based clusters for modelling catalytic reactions [note that the large surface of **6a** contains only $\text{Mo}=\text{O}$ and $\text{Mo}(\text{H}_2\text{O})$ groups].⁸ This would help to understand the surface properties for related catalytically active bulk materials which are difficult to investigate.⁵⁶

Another interesting aspect is the possibility of performing reactions within the cavity of the giant molecular container **6a**, the largest structurally well-defined one known, while for instance encapsulation-type reactions resulting in a novel type of supramolecular compounds are known for even smaller spherical clusters.^{28, 57} This type of nanochemistry/nanotechnology and supramolecular engineering^{58, 59} is based on the use of thoroughly characterised objects obtained by the ‘bottom-up’ method.

Symmetry breaking,^{43–45} observed in many natural processes, can be modelled by the present reaction. The symmetry breaking occurs here due to the presence of different local symmetry areas on the surface of **6a** as in the case of Fowler’s Phantasmagorical Fullerenes, due to the presence of negative and positive curvatures. Symmetry breaking is also relevant for the understanding of patternings in the macrocosmos including those cases where the antagonistic effects are important.^{60–65} This phenomenon was described long ago by D’Arcy Thompson in his famous book ‘*On Growth and Form*’.⁶² A remarkable example of symmetry breaking

‡ When the paper⁴⁶ dealing with the structure of $\{\text{Mo}_{36}\}$ was published, it was considered to be the largest inorganic anion(!).

§ The presence of the large number of $\{\text{O}=\text{MoO}_6\}$ -type pentagonal bipyramids in **6a** is interesting as this group is considered to be responsible for important types of selective oxidations based on molybdenum oxide catalysts.⁵³

was discussed by L. Addadi and S. Weiner.⁶⁶ They considered the formation of asymmetrical shapes during the growth of crystalline structures. The authors refer in this context to the famous Curie symmetry principle⁶⁷ (see also Refs 68, 69), which, as the authors state, cannot be generalised. It is also not fulfilled in our particular case, *i.e.*, when fragment **B** is regarded as inducing the ‘growth’ of the other fragment **C**. Addadi and Weiner⁶⁶ consider the above-mentioned process to be the first step towards understanding asymmetry in biology.

It would be a breakthrough if rather large nanoareas, such as **B** and **C** with different symmetries, could be further extended. In particular, this should be of course more easily possible under dissipative conditions.

The formation of **6a** under conservative conditions shows a type of patterning, emergence, and complexity at a nanolevel, not as is mostly considered at a macrolevel case, as, for instance, in the situations of dissipative self-organisation model processes leading to Bénard convection cells and to Belousov–Zhabotinsky-type reactions.⁶¹ The novelty of the present nanoobject is that symmetry breaking is observed during growth, *i.e.* self-assembly. This is caused by different distributions of a rather large number of different negative and positive vertices with polygons ranging from triangles to heptagons (Fig. 9). The complexity of the structure of cluster **6a** can be demonstrated by comparison with the Archimedean solids having only one type of vertex.

Figure 9. The four regular polyhedron depicting the surface of **6a**, consisting of $328 = 368 - 40$ Mo atoms (*i.e.*, without the Mo atoms of the pentagonal bipyramids). The polyhedron has 240 vertices in the central fragment **B**. 64 vertices are in the belt region, 32 vertices with the vertex configuration [3,4,4,5], 32 of the type [3,4,4,7]; 16 + 8 of the type [3,5,3,7], 8 of the type [3,5,3,6], and 16 of the type [3,6,3,7] are in each of the two **B** regions next to the belt and another two times 16, 8, and 16 with a vertex configuration of the type [3,5,3,6], [3,6,3,7], and [3,5,3,7], respectively, are next to the two collars, altogether 16 of type [3,7,3,7] along the two collars, 8 of types [3,6,3,7], [3,5,3,7], and [3,5,3,6] each in the interior of the two capping regions, and 4 of type [3,5,3] and 8 of type [3,6] along each of the two boundary lines. This drawing was first published in Ref. 17.

4. Combinatorial topology of the polyhedral structure of nanoclusters: relevance for the present symmetry breaking processes

This Section explains first of all the topological nature of the surface of **6a** but it could also be useful for a chemist in constructing rather large patterns showing positive and negative curvatures. Combinatorial analysis of the four regular polyhedral net formed by the Mo atoms in **6a**, as shown in Fig. 9 (for simplicity, the Mo atoms within the interior of the pentagonal

Figure 10. Shapes of positively (*a, b*) and negatively (*c*) curved surfaces. The sphere and the outer part of a torus are paradigms of surfaces exhibiting positive curvature (*a, b*); the saddle and the inner part of a torus are paradigms of surfaces exhibiting negative curvature (*c*).

bipyramids are omitted), reveals a clear correspondence between the overall distribution of positively and negatively curved surface segments (for illustration, examples of positively and negatively curved surfaces are given, Fig. 10) and the distribution of vertices with positive and negative combinatorial curvature. This is in line with the well-known Euler's theorem,⁷⁰ interpreted as a discrete version of the Gauss–Bonnet theorem.

Indeed, the surfaces of the central fragment **B** with D_{8d} symmetry and two capping regions **C** with C_{4v} symmetry are positively curved. The fragments **B** and **C** are connected by the two narrow collars exhibiting a strong indentation, thus creating two ring-shaped surface components of large negative curvature of relevance for the symmetry breaking. Additional negative curvature is ‘hidden’ in the jaggedness of the two circular boundary lines (see Fig. 9). Indeed, straightening them out into circles would create shapes that would each mimic the shape of a neck, *i.e.*, one half of the negatively curved inner part of a torus (see Fig. 10). The important role of pentagons and heptagons in the case of Fowler's Phantasmagorical Fulleroids is clearly illustrated by Fig. 11. Any fulleroid with icosahedral symmetry consisting of only pentagons and heptagons contains exactly $12 + 60N$ pentagons and $60N$ heptagons for some positive integer N . There are two such fulleroids with $N = 1$. In one of them, 72 pentagons are grouped in 12 sets each containing 6 pentagons. Each set generates the outcrops of a high positive curvature counterbalanced by a network of negatively curved channels built from its 60 heptagons, which results in a net positive curvature of four as required. The other one consists of 12 separate pentagons and 20 sets of three pentagons each, which are also connected by a network of negatively curved channels built from the heptagons exhibiting, however, a much smoother geometry because of the much better local balance of positive and negative curvature. Figure 11 shows the structures of two Fowler's Phantasmagorical Fulleroids, illustrating how areas

Figure 11. Fowler's Phantasmagorical Fulleroid structures (see Ref. 17 with related references).

exhibiting strongly positive curvature can be intertwined with areas exhibiting negative curvature to produce a surface of only moderately positive curvature.

V. Conclusion

The use of the cluster building blocks present in solutions of polyoxometallates and linking of special fragments such as the pentagonal-type $\{\text{Mo}(\text{Mo}_5)\}$ units by different types of linkers, e.g. paramagnetic (open shell) centres opens up new fascinating perspectives for nano-, supramolecular, solid-state and magnetochemistry. 'Playing' with pentagons not only can result in several giant spherical, quasi-spherical and circular species, but it is also of interest because of their role in the history of culture, virology, the geodesic domes of Fuller, and certain aspects of solid-state physics (see the fascinating quasicrystals). A special challenge will be, for instance, to fill the cavities and pores of nanoobjects such as of the spherical $\{\text{Mo}_{132}\}$ cluster with a variety of different guests and also to place molecules inside the cavities of ring-shaped clusters, resulting in different reactivities compared to those of the discrete (isolated nano-sized) ones.

We believe that the title of this review is justified, as our topic allows an unusual type of nanochemistry by performing controlled reactions at well-defined sites of structurally well-defined nanoobjects. Since such nanoobjects can be used as building blocks for the construction of extended structures based on crystal engineering, this field opens up new perspectives for solid-state chemistry, which becomes defined and accurate even up to the atomic level. It has been a long and thorny but successful way in polyoxometallate chemistry since 1956, when Jonassen and Kirschner published a review referring to the knowledge of that time and to the major earlier contributions of important chemists like Rosenheim, Werner, Pfeiffer, Pauling and Keggin.⁷¹

We thank Prof. M Luban, Dr. P Kögerler (Ames Laboratories, Iowa State University, USA) and Dr. H Bögge (Bielefeld University, Germany) for their collaboration. The financial support of the German Research Society (Deutsche Forschungsgemeinschaft), the Foundation for Chemical Industry (Fonds der Chemischen Industrie), and the European Commission is gratefully acknowledged. S Roy thanks the Graduiertenkolleg 'Strukturbildungsprozesse', Bielefeld University, for a fellowship.

Abstract. Published data on the prototropic tautomerism of some carbonyl and nitrogen-containing acyclic and heterocyclic compounds are systematised. Mechanisms of intramolecular and intermolecular proton transfer in tautomerisation reactions are considered. On the basis of the results of semiempirical and *ab initio* quantum-chemical calculations, preference is given to an intermolecular collective (dimeric, trimeric, tetrameric or oligomeric) mechanism. A new approach to the description of the solvent effect on the prototropic tautomeric equilibrium is proposed. The bibliography includes 107 references.

I. Introduction

Since the discovery of prototropic tautomerism, its nature and essence have attracted much attention. Studies performed for more than a hundred years led to the general conclusion that many processes typical of chemical reactions involve the tautomeric interconversion. Hence, the latter serves as a convenient model for studying the reaction mechanisms. In this connection, it is pertinent to mention the appropriate statement by Bilobrov¹ that tautomeric interconversions of molecules are one of the reasons for a striking diversity of the world of chemical reactions.

It is known that the more polar keto form dominates in the keto–enol equilibrium and the mobile hydrogen atom is transferred as the ion. However, in the case of acetylacetone and benzoylacetone, the equilibrium is almost completely shifted to the enol form. It is still unclear whether this fact is an exception from the general situation with the keto–enol tautomeric equilibrium or there are no general regularities at all. When discussing this problem, one might reason that there is no need to reveal the general regularities of this phenomenon. It is only necessary to establish the character of a particular process reliably and

unambiguously by chromatographic and spectroscopic methods and quantum-chemical calculations. The tautomeric equilibria can be quantitatively described with the advantageous use, for example, of intensities of stretching vibrations of the carbonyl (ν_{CO}) and hydroxy (ν_{OH}) groups in the IR spectra² and chemical shifts of the protons and carbon nuclei of the corresponding functional groups in the ¹H and ¹³C NMR spectra.³ Of theoretical methods, semiempirical^{4,5} and *ab initio*⁶ quantum-chemical methods find wide application. These methods allow one to calculate the energy, electronic and structural characteristics of individual tautomeric forms and estimate the tautomeric equilibrium constants (K_{T}). It should be noted that a necessary condition for the quantitative description of the tautomeric equilibrium is the existence of two rather deep minima in the plot of the proton-transfer energy vs. the reaction coordinate.

Investigations on tautomeric processes were surveyed in the reviews^{7–10} and considered in more recent detailed studies cited below.

The present review considers new views in the theory of prototropic tautomerism, in particular, the intermolecular mechanism of proton transfer, and a new approach to the determination of tautomeric equilibrium constants and quantitative description of the influence of the solvent on the equilibrium. The results of quantum-chemical calculations of prototropic tautomeric equilibria and their examination by spectroscopic methods are discussed in particular sections.

II. Keto–enol tautomerism

The keto–enol tautomerism is the most well-studied type of prototropic rearrangements. Since individual tautomeric forms can be readily detected by different methods, measurements of the equilibrium constants of this process present no difficulties. Due to the high affinity of the carbonyl oxygen atom for the proton, keto–enol tautomerism is observed in many compounds. The tautomeric equilibrium constants for various β -dicarbonyl compounds were estimated by Meyer¹¹ back in the early 20th century with the use of bromometric titration. These results are still scientifically useful. The constants K_{T} determined by Meyer correlate with the polarities of the solvents, which were determined by spectroscopic methods many decades later.

Modern studies of the keto–enol equilibrium confirmed the earlier views that the keto form is thermodynamically more stable than the enol form. This is evidenced, for example, by calculations

of the relative stabilities of the keto and enol forms and energy barriers to enolisation of ketones MeCOR ($\text{R} = \text{Me}, \text{H}, \text{F}, \text{CN}$).¹²

With the aim of studying the effect of substituents on the keto–enol tautomerism, the reaction coordinates and activation energies for enolisation of aldehydes XCH_2CHO ($\text{X} = \text{H}, \text{BH}_2, \text{NH}_2, \text{OH}, \text{F}, \text{CN}, \text{NC}, \text{Cl}$) were calculated by *ab initio* methods. The results of calculations at different levels of theory showed that the keto forms of the compounds under study are thermodynamically more stable than the corresponding enol forms.¹³

The *ab initio* calculations of the ethenethiol–thioacetaldehyde tautomeric interconversion demonstrated that ethenethiol in the gas phase is $2.6 \text{ kcal mol}^{-1}$ less stable than thioacetaldehyde.¹⁴

The position of the keto–enol equilibrium depends, among other factors, on the polarity of the solvent. Thus, the molecular modelling of the photoinduced transformation of the excited enol tautomeric form of 7-hydroxy-8-morpholinomethylquinoline into the keto form demonstrated that an intramolecular hydrogen bond between the protonated morpholine nitrogen atom and the deprotonated hydroxy group in cyclohexane hinders the proton transfer. By contrast, an intermolecular hydrogen bond is formed in 1,4-dioxane, and the morpholine nitrogen atom serves as a proton carrier.¹⁵

The tautomeric equilibrium in methyl esters of para-substituted benzoylactic acids was studied by ^1H NMR spectroscopy¹⁶ and the dependences of the equilibrium constants K_T on the solvent and the nature of the substituent were found.

The third-order terms were measured for the concerted acid–base catalysis of enolisation of simple aldehydes and ketones to form substituted acetic acids. It was concluded that aldehydes undergo enolisation under the conditions of base catalysis. The isotopic effect of the solvent in enolisation of aldehydes under the conditions of concerted acid–base catalysis shows that the transition state with proton transfer to the carbonyl group is formed more readily than that in the case of ketones.¹⁷

Until recently, the dielectric permeability of the medium has been used as the main parameter describing the influence of the solvent on the tautomeric equilibrium.^{18–20} However, Prezhdo *et al.*²¹ reasonably noted that the dielectric permeability of the solvent cannot be considered as a universal characteristic of interactions between molecules and the medium. To obtain a more adequate estimate of the polarity of the solvent, the dipole moment, polarisability, molar volume and specific and non-specific interactions should also be taken into account.^{22, 23}

In 1963, Dimrot *et al.*²³ proposed the empirical polarity parameters (E_T) for organic solvents. These parameters are estimated on the basis of the energy of electron transfer corresponding to long-wavelength absorption bands in the UV-vis spectra of *N*-phenoxypyrimidine dyes exhibiting negative solvatochromism.

The experimental constants K_T for acetoacetic ester in different solvents, which were determined by spectroscopic, kinetic, refractometric and bromometric methods, were published in the study.²¹ The plot of the constants K_T vs. E_T for 12 solvents, including acetoacetic ester (**1**), exhibits a hyperbolic character (Fig. 1). Analogous qualitative and quantitative characteristics were found for acetoacetic ester (**1**) and acetylacetone (**2**) by titrimetry, liquid chromatography and NMR spectroscopy.^{3, 24}

The experimental curves also indicate that the constants K_T are inversely proportional to E_T .

The proton transfer in keto–enol tautomerism can occur along the intermolecular hydrogen bond between the oxygen atom of the carbonyl group and the proton at the α position in the cyclic dimer of carboxylic acid.²⁵ This is somewhat contradictory to the concept according to which the involvement of the hydrogen atom in hydrogen bonding requires high electronegativity of the atom to which this hydrogen atom is bound. The IR

spectroscopic study²⁶ performed by one of the authors of the present review showed that a proton of the methyl group can be involved in intermolecular hydrogen bonding in acetophenone. In the studies,^{27, 28} preference was given to the mechanism of proton transfer through intramolecular hydrogen bonding, although the activation barrier for this process is rather high. In some early studies^{25, 29} and in more recent investigations,^{30–37} evidence was reported for the formation of dimeric associates through two-proton transfer in the case of carbonyl and nitrogen-containing acyclic and heterocyclic compounds in which intramolecular hydrogen bonding is energetically and geometrically unfavourable.

We proposed that the mechanism of tautomerisation involving dimers be used to obtain quantitative estimates of the energy of proton transfer and constants K_T for acetoacetic ester (**1**) and acetylacetone (**2**) upon transformations into the corresponding enol forms **1a** and **2a**.

We carried out calculations to establish the dependence of the enthalpy on the reaction coordinate (R_{CH}), which allowed us to construct the energy diagram for the two-proton transfer in the dimer of acetoacetic ester (**1**), *i.e.*, the dependence of ΔH on R_{CH} for the $\text{C} \cdots \text{H} \cdots \text{O}$ triad corresponding to an intermolecular hydrogen bond (for R_{CHO} , the value of $2.60 \text{ \AA}$ was assumed). From this diagram, we determined the activation enthalpies of the two-proton transfer $\Delta\Delta H^\ddagger = 91.1 \text{ kJ mol}^{-1}$ and heats of reaction $\Delta\Delta H = 32.2 \text{ kJ mol}^{-1}$, which have reasonable values for this

Figure 2. Activation enthalpy $\Delta\Delta H^\ddagger$ and heat of reaction $\Delta\Delta H$ for the proton transfer vs. the length of the CHO triad corresponding to an intermolecular hydrogen bond (R_{CHO}) in acetoacetic ester (**1**) (our data).

process. The $\Delta\Delta H^\ddagger$ and $\Delta\Delta H$ values depend on R_{CHO} . As can be seen from Fig. 2, $\Delta\Delta H^\ddagger$ and $\Delta\Delta H$ can be considered as average values based on the reference points in the middle of the linear region, although the linearity of the plot is disrupted in the vicinity of the boundaries. Analogous results were obtained for acetylacetone (**2**) (Fig. 3). In particular, at $R_{\text{CHO}} = 2.60$ Å, the activation enthalpy $\Delta\Delta H^\ddagger = 103.7$ kJ mol⁻¹ and the heat of reaction $\Delta\Delta H = 23.7$ kJ mol⁻¹.

The choice of the calculation method for estimating the constant K_T is of great importance. Since the thermodynamic equation $\ln K_T = -\Delta\Delta H/RT$ is independent of the reaction mechanism (in the case under consideration, on the mechanism of proton transfer), it is of little use for the adequate estimation of K_T . Besides, this equation describes the overall process of two-proton transfer, although if tautomeric interconversions of different nature take place (for example, in nucleic bases), the constants

Figure 3. Activation enthalpy $\Delta\Delta H^\ddagger$ and heat of reaction $\Delta\Delta H$ for the proton transfer vs. the length of the CHO triad corresponding to an intermolecular hydrogen bond (R_{CHO}) in acetylacetone (**2**) (our data).

K_T for each proton depend differently on the structural changes. We propose a new approach to estimating the tautomeric equilibrium constants according to which the constant K_T can be represented as a function of the orders of the bonds that are cleaved and formed in the course of proton transfer.³⁸ In the case of the keto–enol tautomerism proceeding through a cyclic dimer, the proton transfer is accompanied by an increase in the O–H (P_{OH}) bond order to the maximum value (~ 0.900) and a decrease in the C–H (P_{CH}) bond order to zero, i.e., the latter bond is cleaved. Simultaneously, the order of the C=O double bond (P_{CO}) decreases to the single-bond order (~ 1.000), while the order of the C–C (P_{CC}) single bond increases to the order of the C=C double bond (~ 1.600). Hence, the double bond is shifted from the carbonyl group to the adjacent C–C bond giving rise to the enol tautomeric form. The bond orders under consideration (P_{CH} , P_{OH} , P_{CO} , and P_{CC}) would change in parallel with changes in the percentage of the keto and enol forms in the course of proton transfer. On going from the first to the second energy term, the percentages of the keto and enol forms can be described by Eqn (1):

$$\frac{P_{\text{OH}}^1}{P_{\text{CH}}^1} E_n + \frac{P_{\text{CO}}^1}{P_{\text{CC}}^1} Kt = \frac{P_{\text{OH}}^2}{P_{\text{CH}}^2} E_n + \frac{P_{\text{CO}}^2}{P_{\text{CC}}^2} Kt, \quad (1)$$

where E_n and Kt are the initial contributions (in %) of the enol and keto forms, and P_{ij}^1 and P_{ij}^2 are the orders of the corresponding bonds in the first and second terms.

After dividing both sides of Eqn (1) by Kt taking into account that $K_T = E_n/Kt$ followed by simple algebraic transformation, we get Eqn (2) for the constant of the keto–enol tautomeric equilibrium.

$$K_T = \frac{P_{\text{CH}}^1 P_{\text{CH}}^2 (P_{\text{CO}}^1 P_{\text{CC}}^2 - P_{\text{CO}}^2 P_{\text{CC}}^1)}{P_{\text{CC}}^1 P_{\text{CC}}^2 (P_{\text{CH}}^1 P_{\text{OH}}^2 - P_{\text{CH}}^2 P_{\text{OH}}^1)}. \quad (2)$$

The value of K_T calculated according to Eqn (2) is independent of the external factors and depends only on the electronic structures of the molecules involved in tautomeric interconversions.

An analogous approach was applied to the quantitative description of the tautomerisation of acetophenone (**3**) to the enol form **4**.

The dependences of $\Delta\Delta H^\ddagger$ and K_T on R_{CHO} thus obtained are consistent with those for acetoacetic ester (**1**) and acetylacetone (**2**). A decrease in the length of the triad to $R_{\text{CHO}} = 2.60$ Å in the dimer of acetophenone leads to a decrease in $\Delta\Delta H^\ddagger$ from 405.0 to 120.4 kJ mol⁻¹ and a decrease in $\Delta\Delta H$ from 110.8 to 41.0 kJ mol⁻¹, the constant K_T being increased from 0.024 to 0.107.

A model was constructed for the quantitative description of the effect of the solvent on K_T . The plots of K_T vs. R_{CHO} for acetoacetic ester (**1**) (Fig. 4) and acetylacetone (**2**) calculated by Eqn (2) (Fig. 5) are hyperbolic curves, i.e., the constants K_T are inversely proportional to R_{CHO} . For compounds **1** and **2**, the constant K_T is also inversely proportional to the polarity parameter of the solvent E_T (Figs 6 and 7, respectively). A comparison of these dependences shows that the dimers are extended in more polar solvents and compressed in less polar solvents. Actually, the plots of R_{CHO} vs. E_T for compounds **1** and **2** (Figs 8 and 9,

respectively) indicate that the length of the triad corresponding to an intermolecular hydrogen bond is inversely proportional to the polarity of the solvent. This model can be used to advantage for the quantitative description of the effects of external factors on some biologically important processes (see below).

III. Imine–enamine tautomerism

Tautomerisation involving the proton bound to the nitrogen atom is a key step in reactions of heterocyclic compounds. The possibility of the transformation of imines into the corresponding enamines was first studied by Lawer.³⁹ This classical reaction can be represented as the intermolecular proton transfer in the dimer of imine **5** to form enamine **6**.

The influence of the α - and β -substituents on the position of the imine–enamine tautomeric equilibrium was estimated quantitatively. In particular, the percentage of the enamine form in α -substituted derivatives of the $R^1CH=C(Me)NHR^2$ type changes from 50% to 70%,⁴⁰ whereas this percentage in β -substituted analogues is in the range of 30%–100%.⁴¹

The investigation of the tautomerism in analogous *N*-substituted imines showed that an increase of the charge on the nitrogen atom⁴² as well as an increase in the volume of the substituent at the same atom^{42,43} led to a decrease in the percentage of imine in the equilibrium mixture. An attempt was made to find the dependence of the percentage of enamine on its pK_a ⁴⁴ assuming that the mobility of the proton of the amino group should facilitate an increase in the percentage of enamine. However, no correlation was revealed.

The study of the effect of the solvent on the imine–enamine equilibrium⁴⁵ demonstrated that the percentage of enamine increases in the series of the solvents $CHCl_3 < PhH < MeNO_2 < MeCN < MeCOMe < C_5H_5N < MeSOMe$. This series does not correlate with a change in the polarity parameter E_T of the solvent,²³ which accounts for all types of interactions. Apparently, this inconsistency results from experimental errors.

In 1971, using *N*-methylphenylhydrazone of ethyl pyruvate as an example, Ahlbrecht⁴⁶ discovered the hydrazone–enehydrazine interconversion as a special case of the imine–enamine tautomerism. The examination of the characteristic features of the transformation of hydrazone into enehydrazine is of great importance for the target synthesis of indole derivatives.⁴⁷ It was assumed that the hydrazone–enehydrazine tautomerisation is the rate-determining step of Fischer indolisation,⁴⁸ although we do not share this opinion.³⁶

The results of qualitative and quantitative studies of the imine–enamine tautomerism and, in particular, the hydrazone–enehydrazine tautomerism, were comprehensively discussed in the review.⁴⁹ Shainyan and Mirskova⁴⁹ believed that the proton transfer in these processes occurs through an intermolecular mechanism. It was also noted that the hydrazone form is more stable in the absence of conjugation with an electron-withdrawing substituent.⁵⁰ In the presence of an electron-withdrawing substituent in any position, conjugation with this substituent stabilises enehydrazine (due to the predominance of the negative mesomeric effect), which was confirmed by quantum-chemical calculations of the tautomerisation of acetophenone hydrazone to the corresponding enehydrazine.⁵¹

In our opinion, the tautomerisation of phenylhydrazones of some carbonyl compounds **7a–j** into the corresponding enehydrazines **8a–j** proceeds through the formation of cyclic dimers.

To confirm this assumption, the activation enthalpies ($\Delta\Delta H^\ddagger$), heats of reaction ($\Delta\Delta H$) and tautomeric equilibrium constants (K_T) for the above-considered reaction were calculated (Table 1).³⁸

Table 1. Activation enthalpies ($\Delta\Delta H^\ddagger$ /kJ mol^{−1}) and heats of reaction ($\Delta\Delta H$ /kJ mol^{−1}) for the hydrazone–enehydrazine tautomerism in phenylhydrazones **7a–j**.

Compound	R ¹	R ²	R ³	K_T	$\Delta\Delta H^\ddagger$	$\Delta\Delta H$
a	H	H	Ph	0.05	185.2	171.3
b	Me	H	Ph	0.04	150.0	130.4
c	Et	H	Ph	0.04	124.1	92.0
d	CO ₂ Et	H	Ph	0.05	145.5	128.4
e	Ph	H	Ph	0.05	134.2	98.2
f	4-MeC ₆ H ₄	H	Ph	0.05	133.3	97.0
g	4-NO ₂ C ₆ H ₄	H	Ph	0.05	140.0	107.8
h	Ph	H	4-MeC ₆ H ₄	0.04	133.8	98.0
i	Ph	H	4-NO ₃ C ₆ H ₄	0.05	134.8	98.0
j	(CH ₂) ₄		Ph	0.09	83.2	46.0

The constants K_T were calculated by Eqn (3).

$$K_T = \frac{P_{CH}^1 P_{CH}^2 (P_{NC}^1 P_{CC}^2 - P_{NC}^2 P_{CC}^1)}{P_{CC}^1 P_{CC}^2 (P_{CH}^1 P_{NH}^2 - P_{CH}^2 P_{NH}^1)} \quad (3)$$

As can be seen from Table 1, the constants K_T for phenylhydrazones **7a–i** have virtually equal values, whereas the constant for cyclohexanone phenylhydrazone **7j** is twice as large as these values. The electron-withdrawing (NO₂) and electron-donating (Me) substituents in the para position of the benzene ring of both the hydrazone and carbonyl fragments (compounds **7f–i**) exert only a slight effect on K_T and $\Delta\Delta H^\ddagger$, although it is known⁵² that these substituents have a substantial effect on the kinetics of indolisation. In our opinion, this is evidence that the hydrazone–enehydrazine tautomerisation is not a rate-determining step of Fischer indolisation of arylhydrazones.

IV. Tautomerism in diazoles

Tautomerism in the series of azoles is associated with the mobility of the hydrogen atom of the amino group.⁵³ In the study,⁵⁴ it was demonstrated that the tunnelling proton transfer can occur through an intermolecular hydrogen bond between the NH group of one pyrazole molecule and the lone electron pair of the nitrogen atom of the second molecule. Collective mechanisms involving dimers (**9**) and trimers (**10**) of pyrazole and oligomers of imidazole **11** were proposed.⁵⁴

However, the existence of an oligomeric structure of imidazole **12** seems to be unlikely because the IR spectra have no absorption bands of the N^+H group, which must be present in the structure of **12**.⁵⁵ Based on the ^1H NMR spectroscopic data,⁵⁶ it was suggested that solutions of N-derivatives of imidazole contain associates as stacks, which are stabilised by interplanar interactions due to overlapping of the π -electron clouds of the adjacent molecules. Later on, the possibility of the intermolecular proton transfer in imidazole and pyrazole proceeding through the tunnelling mechanism was demonstrated by Nesmeyanov *et al.*⁵⁷ by ^1H and ^{13}C NMR spectroscopy. However, an intermolecular structure was not described. In investigations of the proton transfer in imidazole, preference is given to an intermolecular mechanism. An intramolecular mechanism is energetically unfavourable, which was demonstrated by quantum-chemical calculations⁵⁸ and ^{13}C NMR spectroscopy.⁵⁹ Recently, the proton conductivity in crystalline imidazole was studied by ^{14}N NMR spectroscopy and the so-called migration and reorientation mechanisms were proposed for processes occurring in oligomeric chains.⁶⁰ This conclusion about the formation of oligomeric chains is in contradiction with the results of another study.⁵⁵ It is difficult to give preference to a particular investigation. However, it can be assumed that oligomeric chains can exist in the excited states, due, among other factors, to the difference in the potentials in measurements of the proton conductivities of the imidazole systems. It should be noted that the equilibrium constants depend substantially on the basis set used in *ab initio* quantum-chemical calculations.⁶¹

The ability of imidazole derivatives to occur in a particular tautomeric form depends on many factors. Thus, both the NH and 3-OH tautomeric forms of 2,4,5-triphenylimidazole 3-oxide were observed in aqueous solutions, whereas only the latter form was found in non-polar solvents.⁶² Quantum-chemical calculations⁶³ demonstrated that 4- and 5-nitroimidazoles are equally stable in the gas phase, whereas the 4-nitro isomer prevails in solutions. The self-associations of imidazole and 1-, 2-, 4-, and 5-methylimidazoles in aqueous solutions were studied by UV spectroscopy and it was demonstrated that these compounds are prone to dimerisation and polymerisation.⁶⁴

As mentioned above, the intramolecular proton transfer in imidazole is energetically unfavourable. The intermolecular H^1-H^3 proton transfer in the dimer is sterically hindered.⁶⁵ Hence, it was proposed that the tautomerisations of imidazole might proceed through a two-step mechanism involving the H^1-H^3 proton transfer.⁶⁶

This complex process can occur in two steps through the proton transfer in dimer **13** from position 1 to position 2 to give

H^2 -tautomer **14** followed by the proton transfer in dimer **15** from positions 2 to position 3 to form 3H-tautomer **16**.

We calculated the activation enthalpies of these steps and the heat of reaction for 4-fluoroimidazole **13**. The activation enthalpies of the first and second steps are 170.5 and 116.6 kJ mol⁻¹, respectively. The heat of the overall reaction ($\Delta\Delta H$) is -50.6 kJ mol⁻¹, *i.e.*, the H^1-H^3 tautomeric transformation in 4-fluoroimidazole is an exothermic process. The equilibrium constants for the first and second steps calculated by Eqn (3) are 2.87×10^{-2} and 3.96×10^{-2} , respectively.

The one-step H^1-H^3 proton transfer in 4-fluoroimidazole can also occur in trimer **17**.

To obtain a quantitative description of the simultaneous transfer of three protons, we calculated the energy, electronic and structural characteristics of these processes in the reaction coordinate mode (R_{NH}).⁶⁵ The high activation enthalpy ($\Delta\Delta H^\ddagger = 454.4$ kJ mol⁻¹) and low heat of reaction ($\Delta\Delta H = 3.8$ kJ mol⁻¹) provide evidence that the tunnelling proton transfer in the trimer of imidazole can occur. The tautomeric equilibrium constant ($K_T = 10^{-2}$) was calculated.

The tautomeric equilibrium for pyrazoles was systematically studied by Elguero and co-workers.⁶⁶⁻⁶⁸ Spectroscopic studies demonstrated that 1-substituted 5-hydroxypyrazoles in non-polar solvents exist predominantly in 4H form **18** with a small admixture of NH form **19**. In aqueous solutions, these compounds exist predominantly in NH form **18** with an admixture of OH form **20**.

In early studies, it was assumed that the long-range proton transfer takes place in pyrazole.^{66,69} Later on, the dynamics of the intermolecular tautomerisation of pyrazole derivatives in the solid state was studied by NMR spectroscopy and X-ray diffraction analysis.⁶⁷⁻⁶⁹ It was concluded that these compounds can exist as cyclic trimers. In the recent review by Japan researchers,³⁴ the results of subsequent studies performed by Elguero and co-

workers were discussed. In these studies, the dimeric,⁷⁰ trimeric^{71–73} and tetrameric^{74,75} mechanisms of proton transfer in pyrazoles through intermolecular hydrogen bonds were examined. Based on the results of NMR spectroscopy and X-ray diffraction analysis, it was concluded that the proton transfer in the compounds under study can proceed through so-called collective mechanisms.

V. Tautomerism in pyridines

In the reviews,^{9,76} it was reported that 2- (**21a**) and 4-pyridones (**22a**) as well as 2- (**23a**) and 4-thiopyridones (**24a**) in aqueous and polar solvents occur predominantly in the oxo and thioxo forms.

However, the amino rather than imino form is typical of 4-aminopyridine (**25a**).

Katritzky attributed this difference in the behaviour of these compounds to stabilisation of ionic intermediates.⁷⁶

It was demonstrated⁷⁷ that stability of tautomeric forms is associated with low enthalpies. Studies of the effect of the solvent on the tautomeric equilibrium led to the conclusion that the ratio between the hydroxy and oxo forms increases linearly as the polarity of the solvent increases.

In the review,⁷⁸ the influence of the structural and external factors, including the possible formation of intra- and intermolecular hydrogen bonds, on the tautomeric equilibrium in pyridine derivatives was examined by spectroscopic and quantum-chemical methods and by investigating individual tautomers.

The position of the tautomeric equilibrium in pyridine derivatives often depends on the concentration of the solutions used. In particular, the constant K_T for 2-pyridone (**21a**) decreases by a factor of 7 upon a 100-fold dilution of a solution in cyclohexane.²⁹ This is attributable to self-association of the molecules. Hence, it was suggested that 2-pyridone (**21a**) might occur as a dimer and 4-pyridone (**22a**) might exist as a chain associate.

With the aim of studying the effect of the nature of substituents on the tautomeric equilibrium in α -substituted 4-pyridones, the constants K_T were determined by UV spectroscopy. It was demonstrated that K_T depends linearly on the Hammett σ -constant of the substituent.⁷⁹ It was also found that the electron-donating and electron-withdrawing substituents led to increases and decreases in $\log K_T$, respectively.

An intramolecular mechanism of proton transfer was proposed for the lactam–lactim tautomerism in 2-pyridone (**21a**).⁸⁰ The activation barrier calculated by the CNDO/2 quantum-chemical method is 145 kJ mol^{−1}. It should be noted that this method is of little use for the estimation of the energy indices. The value calculated by this method is substantially overestimated. Actually, the activation energy determined in the study on the tautomeric equilibrium in 6-methoxy-2-pyridone⁸¹

(46 kJ mol^{−1}) is three times lower, which casts some doubt on the energetically unfavourable intramolecular mechanism of proton transfer proposed in the study.⁸⁰

Quantum-chemical methods find wide use for studying the tautomeric equilibria in pyridine derivatives. Thus, the relative stabilities of tautomers of monosubstituted (OH, SH, NH₂) pyridines were studied by the MNDO method.⁸² It was noted that the lactam form is energetically more favourable in all cases, which is in good agreement with the experimental data. Schlegel *et al.*⁸³ calculated the energies of tautomerisation of 2- and 4-pyridones by semiempirical and *ab initio* quantum-chemical methods. The calculations by the semiempirical CNDO/2 and MINDO/3 methods gave unreasonable results, whereas the results of *ab initio* calculations depend substantially on the basis set used. However, in some cases, the calculated values are close to the experimental data. Noteworthy is the study⁸⁴ in which the proton transfer in the lactim–lactam tautomerism in 2-pyridone (**21a**) was examined by *ab initio* methods. Three types of proton transfer were considered, *viz.*, those proceeding by intramolecular and self-association mechanisms and the proton transfer due to the addition of a water molecule. The authors of the cited study believed that the mechanisms, in which the proton transfer occurs either in a dimer or through the addition of a water molecule, are the most reasonable. The enthalpies (ΔH) of tautomerism in 2-, 3- and 4-pyridones were calculated by the semiempirical AM1, MNDO and PM3 methods.⁸⁵ The results obtained by different methods differ substantially from each other and from the experimental data. A good agreement with experiment was achieved only with the use of the AM1 method ($\Delta H = 32.5$ and 30.1 kJ mol^{−1}). The influence of the solvents on the tautomeric equilibrium in 2- and 4-pyridones was studied by the AM1 method,⁸⁶ for which purpose the dielectric permeability of the solvent was introduced into the equation for the total energy. The constant K_T thus calculated is in good agreement with experiment. It should be noted that the calculated and experimental constants K_T depend linearly on the Onsager parameter $\varepsilon - 1/2\varepsilon + 1$, where ε is the dielectric permeability of the solvent.

To obtain a quantitative description of the tautomerism **21a** → **21b**, **22a** → **22b**, the enthalpies (ΔH) and orders of the bonds that are changed (P_{ij}) were calculated by the AM1 and MNDO quantum-chemical methods.

For 2-substituted pyridines **21a**, **23a** and **26a**, the proton transfer was calculated with the use of a dimeric mechanism in the reaction coordinate mode (R_{NH}).⁸⁷

For the tautomerisation of 4-substituted pyridines **22a** and pyridinethiones **24a**, the proton transfer through a dimeric mech-

anism is sterically hindered. In this connection, we proposed a trimeric mechanism for the proton transfer in compounds **22a** and **24a**. In the trimeric forms, the pyridine rings are located perpendicular to the plane of the figure, which excludes repulsions between the hydrogen atoms at positions 2, 3, 5 and 6.

We calculated the equilibrium constants for all types of proton transfer occurring in the course of this process by Eqn (4). (For pyridinethiones, the oxygen atom is replaced by the sulfur atom.)

$$K_T = \frac{P_{\text{NH}}^1 P_{\text{NH}}^2 (P_{\text{CO}}^1 P_{\text{CN}}^2 - P_{\text{CO}}^2 P_{\text{CN}}^1)}{P_{\text{CN}}^1 P_{\text{CN}}^2 (P_{\text{NH}}^1 P_{\text{OH}}^2 - P_{\text{NH}}^2 P_{\text{OH}}^1)} \quad (4)$$

The activation enthalpies ($\Delta\Delta H^\ddagger$), heats of reaction ($\Delta\Delta H$) and equilibrium constants (K_T) for the tautomerisation reactions under study are given in Table 2. It can be seen that the 4-pyridone–4-hydroxypyridine tautomerisation (**22a** → **22b**) with proton transfer through a trimeric mechanism is characterised by a rather high activation enthalpy (446.5 kJ mol^{−1}) and low heat of reaction (9.2 kJ mol^{−1}). This indicates that the proton transfer in this process can proceed through a tunnelling mechanism. The 4-pyridinethione–4-thiopyridine transformation (**24a** → **24b**) is an exothermic process characterised by a substantial heat evolution and a large equilibrium constant. The largest constant K_T was found for the 2-pyridinethione–2-thiopyridine equilibrium (**23a** → **23b**) characterised by small energy indices $\Delta\Delta H^\ddagger$ and $\Delta\Delta H$. It can also be seen from Table 2 that the tautomeric equilibrium constant is inversely proportional to the activation enthalpy. The fact that the known dependence persists in this case provides evidence that the approach used is suitable for the quantitative description of prototropic tautomerism.

Table 2. Activation enthalpies, heats of reactions and equilibrium constants for tautomerisation of substituted pyridines.

Tautomerisation	$\Delta\Delta H^\ddagger$ /kJ mol ^{−1}	$\Delta\Delta H$ /kJ mol ^{−1}	$10^{-2} K_T$
23a → 23b	44.3	23.4	13.0
24a → 24b	102.0	−99.1	5.2
21a → 21b	195.5	29.7	3.8
26a → 26b	196.6	106.6	4.4
22a → 22b	446.5	9.2	1.8

In conclusion, let us mention the study⁸⁸ in which the vibrational spectrum of 2-hydroxypyridine in an argon matrix was studied by Fourier IR spectroscopy and the constant for the 2-pyridone–2-hydroxypyridine tautomeric equilibrium **21a** → **21b** was estimated. This value (0.4) differs substantially

from all known constants K_T , which were determined both by theoretical and experimental methods.

VI. Tautomerism in nucleotide bases

From the very beginning of molecular genetics, it has been discussed that mutations in DNA replication arise from the ability of nucleic acid bases to occur in rare tautomeric forms involved in mutagenesis.⁸⁹ The keto–amine tautomers **A** are the dominant forms of base pairs (for example, of the adenine–thymine pair) in DNA duplexes. However, each base pair can be transformed into its minor, while still quite stable, enolimine tautomer **B**.⁹⁰ Löwdin⁹¹ attributed the formation of rare tautomeric forms of nucleic acid bases to the concerted transfer of two protons within the base pair linked by a hydrogen bond.

If the ratio between the tautomer **B** and canonical tautomer **A** is larger than 10^{−4}–10^{−5} and the rare tautomer remains stable over time necessary for DNA replication, the double proton transfer may play an important role in spontaneous mutations.^{92–94} Rapid proton transfer between bases can make a contribution to the physical properties of DNA, such as duplex flexibility, protein recognition or stability in DNA replication, etc.⁹⁰ The accuracy of the *in vitro* replication per base pair is 10⁸–10¹⁰ (Ref. 95). A possible reason for mismatches in DNA replication is the formation of hypothetical structures including thermodynamically unfavourable tautomers of natural bases in mismatched pairs, such as AC or GT.⁹⁶ The typical frequency of mismatches upon the insertion of mismatching bases was estimated at 10^{−4}–10^{−6} (see Ref. 96), which is in good agreement with the experimental values (10^{−6}–10^{−10}, see Ref. 85).

In spite of importance of tautomerisation in nucleic acid bases, this process is not characterised experimentally, because studies of the superfast and reversible proton transfer between specific base pairs present difficulties.⁹⁷

The parameters of the tautomeric equilibrium in nucleic acid bases and dynamics of proton transfer are estimated by numerous calculation methods.^{98–101}

For example, the internal energies of isolated tautomeric forms of guanine and cytosine were calculated by an *ab initio* quantum-chemical method¹⁰² ($\Delta E = 84.6$ kJ mol^{−1}). The authors of the cited study proposed also the equation for calculations of the corresponding equilibrium constants. This equation includes the ratio of the standard state functions of individual tautomeric forms as the preexponential factor.

$$K_{aa'} = \frac{f_a}{f_{a'}} \exp\left(-\frac{\Delta E_{aa'}}{RT}\right),$$

where $K_{aa'}$ is the equilibrium constant of the tautomeric conversion $a \rightarrow a'$; f_a , $f_{a'}$ are the standard state functions of the tautomeric forms a and a' , respectively, and $\Delta E_{aa'}$ is the activation energy of the tautomeric conversion.

Calculations of isolated tautomeric forms of nucleic acids as applied to the quantitative description of the proton transfer in complementary base pairs of DNA do not necessarily provide adequate results. For example, one can calculate the activation enthalpy ($\Delta\Delta H^\ddagger$) of the simultaneous transfer of two protons in the cytosine (**27a**)–guanine (**28a**) complementary pair to form tautomers **27b** and **28b** (equilibrium processes are better described

by the enthalpy difference than by the total energy difference, which is a standard practice in *ab initio* calculations).

However, in this case, two tautomeric conversions, *viz.*, amine–imine (27a → 27b) and lactam–lactim (28a → 28b), take place and their equilibrium constants can have different values and depend on structural changes in DNA. Consequently, these constants K_T cannot be determined with the use of one thermodynamic equation, which is, in addition, invariant with respect to the mechanism of proton transfer.

An intermolecular mechanism was proposed for proton transfer in isolated mono- and dihydrated guanine complexes on the basis of the results of *ab initio* quantum-chemical calculations.¹⁰³ By contrast, an intramolecular mechanism of proton transfer from the amido group with the activation energy of 150 kJ mol^{−1} was suggested in another study¹⁰⁴ also on the basis of *ab initio* quantum-chemical calculations. In our opinion, the formation of such an intramolecular hydrogen bond is impossible from the viewpoint of geometry, although the energy barrier is rather low.

We calculated the activation enthalpies, heats of reaction and constants of the amine–imine (K_T^{AI}) and lactam–lactim (K_T^{LL}) tautomeric equilibria in the cytosine–guanine pair for different lengths of the triad group corresponding to the intermolecular hydrogen bond (R_{NHN} or R_{NHO}) by the semiempirical AM1 method in the reaction coordinate mode R_{NH} . The equilibrium constants were calculated by Eqns (5) and (6).

$$K_T^{AI} = \frac{P_{NH}^1 P_{NH}^2 (P_{CN}^1 P_{CN}^2 - P_{CN}^2 P_{CN}^1)}{P_{CN}^1 P_{CN}^2 (P_{HN}^1 P_{NH}^2 - P_{HN}^2 P_{NH}^1)}, \quad (5)$$

$$K_T^{LL} = \frac{P_{NH}^1 P_{NH}^2 (P_{CO}^1 P_{CN}^2 - P_{CO}^2 P_{CN}^1)}{P_{CN}^1 P_{CN}^2 (P_{NH}^1 P_{OH}^2 - P_{NH}^2 P_{OH}^1)}. \quad (6)$$

Based on the calculated data, we construct the plot of ΔH vs. R_{NH} for $R_{NHN} = 2.8$ Å, which is an energy curve with two minima. The first minimum or term corresponds to the amine and lactam tautomeric forms, and the second term corresponds to the imine and lactim tautomeric forms. The results of complete calculations are given in Table 3. It can be seen that $\Delta\Delta H^\#$ decreases linearly with decreasing R_{NHN} (R_{NHO}). An excellent correlation ($r = 0.99$) achieved in this case indicates that this approach is adequate for the quantitative description of proton exchange between the nucleotides under study. The dependence of K_T^{AI} (K_T^{LL}) on R_{NHN} is a hyperbolic curve, which indicates that the equilibrium constant is inversely proportional to the length of the triad describing an intermolecular hydrogen bond.

According to the opinion that the mutation frequency N_m can be determined from the product of the concentrations of rare tautomeric forms of nucleotides,^{90,92} this parameter can be calculated by Eqn (7)

$$N_m = K_T^{AI} K_T^{LL}, \quad (7)$$

Table 3. Activation enthalpies ($\Delta\Delta H^\#$ /kJ mol^{−1}), heats of reaction ($\Delta\Delta H$ /kJ mol^{−1}), amine–imine (K_T^{AI}) and lactam–lactim (K_T^{LL}) equilibrium constants and mutation frequencies (N_m) depending on R_{NHN} (R_{NHO}) of the proton exchange in the cytosine–guanine pair.

R_{NHN} (R_{NHO})	$\Delta\Delta H^\#$	$\Delta\Delta H$	K_T^{AI}	K_T^{LL}	N_m
3.00	282.6	65.6	1.51	2.16	0.33
2.95	274.6	75.2	1.90	3.00	0.57
2.90	238.7	75.2	2.19	3.38	0.74
2.85	211.5	64.2	2.34	4.28	1.00
2.80	183.1	66.9	3.15	4.83	1.52
2.75	157.6	58.5	3.35	5.50	1.84
2.70	140.9	66.0	4.17	6.70	2.79

because the constants K_T^{AI} and K_T^{LL} give the ratios between the imine and amine or lactim and lactam forms, respectively.

For some R , the mutation frequencies calculated by this equation (see Table 3) are substantially higher than the experimental values reported in the study.⁹⁶ However, it is known that experimental data obtained in studies of rapid processes proceeding at low concentrations of the compounds are sometimes of low accuracy.

The influence of the solvent on the tautomeric equilibrium of nucleotide bases can be manifested in a deformation of the solvation cavity of the cytosine–guanine dimer, in particular, in a change in the length of the triad corresponding to an intermolecular hydrogen bond [R_{NHN} (R_{NHO})]. As can be seen from Table 3, a decrease in the length of the triad group in the dimer leads to a decrease in $\Delta\Delta H^\#$ resulting in an increase in K_T^{AI} and K_T^{LL} and, consequently, in an increase in N_m . However, the tautomeric equilibrium constant is inversely proportional to the polarity parameter E_T . Consequently, a nucleotide dimer is extended along the intermolecular hydrogen bond in a more polar solvent, whereas this dimer might be contracted in a less polar solvent. Hence, it can be concluded that more polar solvents decrease the spontaneous mutation frequency, whereas this frequency increases in less polar solvents. Since water serves as the solvent in mutation processes in DNA, this approach to modelling the influence of the solvent on the tautomeric equilibrium (see Section II) cannot be applied in the case under consideration. However, this approach may be useful for the qualitative description of scientifically created conditions.

In addition to prototropic tautomerism in DNA, prototropic rearrangements proceeding directly in nucleic acid bases deserve notice. Thus, the amine–imine equilibrium (27a → 27c) in cytosine was considered.^{105, 106}

It is not difficult to understand that the $H^1 \rightarrow H^3$ proton transfer can proceed only through an intermolecular mechanism. In our opinion, this process involves two steps.

The first step represents the keto–enol (lactam–lactim) tautomerisation in compound **27a** with the proton transfer from the amino group to the carbonyl group through a dimeric mechanism. The second step involves the enol–ketone (lactim–lactam) tautomerisation in tautomer **27d** with the proton transfer from the hydroxy group to the imine N(3) atom. The activation enthalpies ($\Delta\Delta H^\ddagger$) of the first and second steps are 157.8 and 107.8 kJ mol^{−1}, respectively. The total enthalpy of the overall process ($\Delta\Delta H^\ddagger$) is 168 kJ mol^{−1}. The heat of reaction ($\Delta\Delta H$) is −5.0 kJ mol^{−1}. Consequently, the 1H → 3H proton transfer is an exothermic process. The rotation of tautomer **27c** about the C(2)–C(5) axis by 180° gives rise to an isomer of cytosine, viz., 2-oxo-6-aminopyrimidine (**27e**). Hence, this transformation can be formally considered as the 1,3-shift of the amino group and a new type of a molecular rearrangement.

VII. Conclusion

It is often assumed that the proton transfer as well as other molecular rearrangements involved in prototropic tautomerisation proceed through an intramolecular mechanism. The results of modern studies show that this mechanism of proton transfer is sometimes both energetically and geometrically unfavourable. From this viewpoint, the so-called collective (dimeric, trimeric, tetrameric or oligomeric) mechanism seems to be more reasonable. The mechanism involving dimers works well in the case of the proton transfer to the *ortho* position. For the proton transfer to the *para* position, trimeric models are more adequate from the viewpoint of geometry. By contrast, a two-step proton transfer is more suitable for the description of tautomerism in compounds containing functional groups in the *meta* positions (as was accepted, for example, for imidazole).

The quantitative description of the prototropic equilibrium by purely chemical methods presents certain difficulties,¹⁰⁷ because the experimental parameters, which are necessary for calculating the equilibrium constants, are sometimes impossible to determine with a high degree of accuracy for compounds present at low concentrations. In this connection, the representation of K_T as a function of the orders of the bonds, which are cleaved and formed in the course of proton transfer, can be used for estimating the reliability of experimental data.

It should be noted that the approach proposed to modelling the influence of the solvent on the prototropic equilibrium is, to a certain extent, formal. However, the K_T – E_T correlation taking into account the polarity parameter of the solvent may be of practical use.

Abstract. The key achievements and the potential of NMR spectroscopy for weakly aligned biomolecules are considered. Due to weak alignment, it becomes possible to determine a number of NMR parameters dependent on the orientation of biomolecules, which are averaged to zero in usual isotropic media. The addition of new orientational constraints to standard procedures of 3D structure determination markedly increases the achievable accuracy. The possibility of structure determination for biomolecules using only orientation-dependent parameters without invoking other NMR data is discussed. The methods of orientation, experimental techniques, and calculation methods are systematised. The main results obtained and the prospects of using NMR spectroscopy of weakly aligned systems to study different classes of biomolecules and to solve various problems of molecular biology are analysed. Examples of biomolecules whose structures have been determined using orientation-dependent parameters are given. The bibliography includes 508 references.

I. Introduction

The advances achieved in implementation of the programme of the human genome decoding marked a new stage in investigations of the structure and functioning of living organisms. Study of the human genome entailed the research into the genomes and gene products of many other organisms. The primary structures of many biomolecules have already been determined; however, for understanding of the functioning mechanisms, one should know the spatial structure of these molecules.

The key experimental methods used to determine the three-dimensional structures of biomolecules include X-ray crystallography (X-ray) and nuclear magnetic resonance spectroscopy (NMR).

Currently, The Protein Data Bank (PDB)¹ stores the results of structural studies for ~19 000 proteins and their complexes; however, only ~6000 structures are different and of these, ~1000 structures have essentially different homologies. The 3D structures for an enormous number of proteins are still to be determined.

By the end of 2002, ~83% of the structures of known biomolecules have been determined by X-ray, ~16%, by NMR, and ~1%, by other methods (mainly, by neutron diffraction). The proportion of structures determined using NMR steadily grows. Indeed, by the end of 1997, 1008 structures of various biomolecules had been determined using NMR; during the following four years, this number doubled, and by the end of 2002, it trebled. Moreover, for ~75% of these biomolecules, no data on the crystal structure was included in the PDB.² Nuclear magnetic resonance proved especially efficient for investigation of nucleic acids. It was used to determine more than one-third of all DNA structures and 60% of RNA structures.

Comparison of numerous structural data obtained by NMR and X-ray diffraction methods showed a high degree of compliance, indicating that NMR is a worthy companion for X-ray, although the latter remains the predominant method used to determine the spatial structures of biomolecules. However, many proteins (for example, most of membrane proteins) cannot be crystallised; therefore, X-ray diffraction is inapplicable to them. In addition, to elucidate the role of proteins in various processes, one should know not only their structures but also the dynamic behaviour, furthermore, under conditions resembling, as close as possible, the environment [either liquid or liquid-crystalline (LC)] in which these proteins exist as well as the structures and dynamic behaviour of their partners and complexes. First of all, this refers to processes such as enzymic catalysis, immune response, signal transduction, regulation of protein synthesis, *etc.* These problems can be solved by using NMR spectroscopy, while X-ray diffraction is not always suitable for this purpose.^{3,4}

Despite the fact that NMR and X-ray techniques are based on different kinds of physical phenomena, they have much in common, first, investigation objects; second, computation software that allows processing of both X-ray and NMR data; and third, databases which accumulate, archive and annotate the obtained structural information of biomolecules. Therefore, it is not a surprise that most of the new NMR research centres are established at large functioning sources of synchrotron radiation,

which is used most often in structural studies. The resolution achieved in both methods is 1.0–1.5 Å and the amount of specimen required is 30–50 mg. Currently, NMR techniques are still much inferior to X-ray as regards the time and cost of determination of one structure. However, owing to the fast development of research using NMR, these parameters may soon become comparable for both methods.

The progress made due to the use of synchrotron radiation, automated systems for sample crystallisation and handling, effective array detectors for data collection and processing, and development of the multiwavelength anomalous diffraction method has transformed X-ray into a fast and convenient method for determining the structures of biomacromolecules. The NMR spectroscopy methods are used predominantly only at a few research centres. In particular, NMR spectroscopy is becoming the major component in investigations of the 3D structures of biomolecules in at least several large research centres.^{2,5} For example, twenty high-frequency NMR spectrometers were installed last year at the RIKEN Genomic Sciences Centre in Japan. It is evident that NMR spectroscopy will be the main tool of investigating the structure–biological functions relationships for proteins.

The modern structural NMR spectroscopy has formed in two phases. The first phase (1985–1995) was characterised by vigorous development and active use of multidimensional Fourier Transform spectroscopy methods[†] for the study of structures of biomolecules.^{6–21} Initially, the measurements were carried out in liquid isotropic solutions using two- or three-dimensional homonuclear NMR methods based on the nuclear Overhauser effect (NOE), and the weights of macromolecules did not exceed 10 kDa.

Further progress of the research was held up by two restrictions of principle. First, the widths of resonance lines in the NMR spectrum in solution are inversely proportional to the spin–spin relaxation time T_2 , which decreases as the size of the molecule increases, and to the rotational correlation time. This diminishes the sensitivity of the pulse sequences used, as long delays are required for coherence transfer.

Second, larger molecules give rise to more complicated spectra, because the numbers of NMR-active nuclei and interactions between them increase.

In the early 1990s, methods of selective $^{15}\text{N}/^{13}\text{C}$ -enrichment of biomolecules as well as multidimensional heteronuclear spectroscopy and triple resonance spectroscopy with pulse gradients were developed. Thus the mass of eligible proteins was increased to 25 kDa.²² With the progress in a NMR hardware (the appearance of high-frequency spectrometers operating at 700, 800 and 900 MHz, probes with magnetic field pulse gradients, *etc.*) and with the advent of procedures for partial and selective deuteration of biomolecules, it became possible to study molecules with higher masses, up to 35–40 kDa.^{23–25} Combination of triple resonance spectroscopy with $^{15}\text{N}/^{13}\text{C}$ -enrichment and perdeuteration allows investigation of proteins weighing up to 50–60 kDa. The up-to-date TROSY (Transverse Relaxation Optimized Spectroscopy) and CRINEPT (Cross-Correlated Relaxation-Enhanced Polarisation Transfer) methods^{26–33} have increased this value to more than 100 kDa.^{34–36} For instance, the structure of an octameric protein with a 110 kDa mass has been determined.³⁷ Certainly, this is not the limiting value. For example, the segment-by-segment isotope labelling procedure reported recently,^{38,39} the decrease in the rotational correlation time by using low-viscosity solvents,⁴⁰ and the use of cryogenic probes and high-frequency NMR spectrometers (with an operating frequency of 1 GHz or higher) provide the possibility of increasing substantially the size

of molecules that can be studied, especially resorting to new, in principle, ideas and approaches.^{3,41}

The second phase in the study of the structures of biomolecules by NMR spectroscopy, which started in 1995, was marked by the advent of a new approach. It was proposed to use the orientation of biomolecules on exposure to the spectrometer magnetic field.^{42,43} For aligned molecules, one can determine additional parameters of NMR signals that bear structural information, first of all, the residual dipolar coupling constants (RDC).⁴⁴ However, even in strong magnetic fields, the orientation of biomolecules was very weak; therefore, it was possible to measure only the RDC for directly linked nuclei in biomolecules with highly anisotropic magnetic susceptibility. The accuracy of structure determination in these experiments was not inferior to that in NOE-based experiments but still left much to be desired.

Tjandra and Bax⁴⁵ proposed using micellar solutions and dilute LC phases for the orientation of biomolecules. In these media, the degree of alignment of biomolecules can be easily controlled by changing experimental conditions, for example, component concentrations and temperature. In this case, one can select the optimal values of the order parameters and to simplify the spectra.

By using NMR methods, one can determine a number of physical characteristics bearing information on the interatomic distances and angles in the molecule. Most of these values are orientation dependent, *i.e.*, they depend on the orientation of biomolecules relative to the direction of the magnetic field; in usual isotropic solutions, they are averaged to zero due to the fast rotation of molecules. Nevertheless, there exist some parameters containing indirect information on the distances between the magnetic nuclei and on dihedral angles which can be elucidated in experiments with isotropic solutions. For example, these are nuclear spin relaxation times in NOE experiments depending on the dipole–dipole couplings between them; the spin–spin coupling constants through three covalent bonds (^3J) or cross-correlated relaxation rates depending on the dihedral angle between these bonds. In addition, the chemical shifts of some protons and carbon atoms depend crucially on the environment and can be useful for determining the tertiary structure of proteins.

Despite the low accuracy of the results, the complexity and high cost, NOE experiments are widely used to determine the spatial structures of biomolecules in solutions. Recently, several other parameters characterising specific properties of various types of relaxation were added to the known parameters, ^3J and chemical shifts. However, by using isotropic parameters, one can establish only the local structure, whereas the use of orientation-dependent values allows determination of both the local and long-range structures.

Direct quantitative measurement of orientation-dependent parameters, for example, RDC, from the splitting observed in the spectra of oriented molecules is certainly preferable to rough evaluation of these parameters in NOE experiments using qualitative analysis of cross-peak intensities for isotropic solutions. In the former case, we are dealing with an effect that can be interpreted using only the first-order perturbation theory; in the latter case, experimental results can be interpreted only by resorting to higher-order perturbation theory (*i.e.*, a much rougher approximation); moreover, they can be masked by other effects. In addition, RDC can be measured faster and more accurately (and between a much larger number of different nuclei) in the spectra of oriented specimens than only between protons in NOE experiments. This means that RDC are more suitable for structural studies, as was brilliantly demonstrated in a publication⁴⁶ in which the 3D structure of a protein backbone was determined using only residual dipolar couplings without invoking the data of NOE experiments. This publication marks a change in the priority in the structural studies of biomolecules by NMR spectroscopy: cumbersome NOE-based experiments in isotropic media with approximate estimation of the distances between some close

[†] In 1991, Ernst (Switzerland) was awarded the Nobel Prize in chemistry for these studies.

protons are replaced by fast and efficient experiments with measurement of more informative and diverse parameters for oriented molecules directly related to their geometry.

A number of methods for the measurement of orientation-dependent NMR parameters have now been developed and development of new methods is in progress. They are based on investigations of biomolecules, either completely aligned in the solid phase or partially aligned in a liquid or LC medium. These methods are equally good for investigating both the structures of biomolecules and conformational changes, for determining the relative orientation of the domains, the formation of intermolecular complexes and for investigation of dynamic processes.^{47, 48} Experiments with weak alignment of biomolecules have been most successful so far, although it is expected that solid-state NMR techniques for highly oriented biomolecules (in the solid state) would prove to be more efficient in the study of structures and functions of membrane proteins.⁴⁹

In modern approaches, the new methods mentioned above are combined with 'classical' methods based on the NOE, the use of vicinal ^3J constants, chemical shifts and relaxation times. This permits reliable determination of the structures of proteins with a mass of up to 100 kDa and even more. The research of biomolecules by NMR spectroscopy can be classified into three groups of studies carried out in parallel:^{18–21}

- in liquid isotropic media;
- in weakly aligned media;
- solid-state experiments with magic angle spinning.

This review describes the scope of NMR spectroscopy of weakly aligned biomolecules in solutions. The procedures used in NMR studies of non-aligned molecules are also outlined. The ways of orienting biomolecules, the types of orientation-dependent parameters, experimental procedures, and calculation methods are described in detail; the main results and prospects for the use of NMR spectroscopy of weakly aligned molecules in the research of proteins, nucleic acids and oligosaccharides are analysed.

II. Methods of investigation of the structure of non-oriented biomolecules in solution

The structure of a biomolecule can be represented by either a set of Cartesian coordinates (x, y, z) of each atom or by a set of intrinsic coordinates [for proteins, these are bond lengths and angles $\phi, \psi, \omega, \chi_1$, and χ_2 for each amino-acid residue (Fig. 1)].

1. Nuclear Overhauser effect and its use in structural studies

Nuclear magnetic resonance techniques based on NOE have been used successfully for more than 20 years to elucidate the three-dimensional structures of biomolecules in solutions. NOE parameters are determined in 2D and 3D experiments and are used subsequently to calculate the interatomic distances. The studies of

small proteins, transport RNA, oligonucleotides and interactions of proteins with ligands and nucleic acids are described in detail in many publications.^{7–25, 50}

The NOE is underlain by the fact that the rate constant for the dipole cross-relaxation is inversely proportional to the sixth power of the distance between the interacting nuclei. The intensities of NOE cross-peaks, which are proportional to the rate constants for cross-relaxation are determined in experiments. Thus, if one distance between protons (R_0) is known (for example, from the trivial covalent geometry of the molecule), the other, unknown R_x can be determined from the relation

$$R_x = \left(\frac{I_0}{I_x} \right)^{1/6},$$

where I_0 and I_x are the integral intensities of the corresponding cross-peaks.

A 2D (or 3D) NMR spectrum of a protein contains numerous NOE cross-peaks corresponding to different pairs of protons. Depending on the intensity, they are classified into strong, medium-intensity and weak. Strong cross-peaks correspond to protons neighbouring *via* covalent bonds (for example, geminal protons in the methylene groups or vicinal protons in aromatic rings) and to neighbouring protons in a regular secondary structure of the protein (for example, H^N-H^α along the chain, $H^\alpha-H^\alpha$ and H^N-H^α in β -sheets). The medium-intensity cross-peaks usually correspond to H^N-H^α pairs in helices. Even for proteins with a mass below 10 kDa, the number of these responses is about 100; this is sufficient for determining the spatial structure of the protein globule. The structures of many proteins with masses of up to 100 kDa have now been determined using several hundred (in some cases, above several thousand) cross-peaks.

The major advantage of these studies over X-ray studies is that the structure of a biomolecule is determined in a solution rather than in a single crystal. The structures of some biomolecules are known to change upon crystallisation; therefore, structure determination in solution is preferred, in particular, for physicians and biologists. In addition, the molecules in the crystal are exposed to anisotropic crystal fields; therefore, discrepancy between the structures determined in the crystal state and in solution does not mean by itself that either of these structures is erroneous.

However, the NOE arises only between closely spaced (not more than 5–6 Å) magnetic nuclei (mainly, protons), whereas X-ray diffraction analysis allows determination of the position of any atom. Yet another important difference between these methods is manifested in investigations of mobile molecules. The crystal structure determined by X-ray is a simple superposition of all molecules present in the crystal, whereas NOE experiments provide certain averaged $(\langle r_{ij}^{-6} \rangle)^{-1/6}$ values rather than the distances themselves. This implies that in the former case, the contributions of all fluctuations to the distances between the nuclei in the crystal structure are identical, while in the latter case, the contributions of states with closely located protons to the measured distances are much greater than the contributions of states with remote protons, resulting in apparent shortening of the averaged distance.

Nuclear Overhauser effect experiments successfully supplement X-ray studies, especially in those cases where crystal data are not readily available, in a comparative study of oligonucleotides with different sequences, and in a study of transitions between various DNA conformations.

Until recently, data on the geometry of biomolecules in solutions have been mainly gained in NOE experiments. However, the knowledge of distances between protons found in these experiments does not suffice for structure determination. Therefore, the use of any additional information is useful both for structure refinement and for facilitating the structure determination procedure.

As the mass of the biomolecule increases, the NOE signals are broadened, which may result in line coalescence in the spectra.

Figure 1. Fragment of the protein polypeptide chain. Dashed lines designate the peptide planes. The backbone conformation is determined by the angles ϕ and ψ for each amino acid residue R and the side chain conformations are determined by the angles χ_1 and χ_2 .

This phenomenon can be controlled by using partial deuteration; however, this markedly decreases the number of NOE signals and increases the cost of structure determination. This makes the additional information obtained in other experiments even more significant.

2. Spin–spin coupling constants

The use of spin–spin coupling constants through three bonds ^3J in structural studies is based on the fact that they obey an empirical dependence on the dihedral angle θ described by Karplus:^{10, 13}

$$^3J(\theta) = A\cos^2\theta + B\cos\theta + C.$$

The coefficients A , B and C depend on the types of particular nuclei forming the dihedral angle; they are determined during optimisation of experimental ^3J constants and the angles found from high-resolution X-ray diffraction data for a multitude of molecules. There are several of these constants for protein molecules. The constant $^3J(\text{H}^N - \text{H}^\alpha)$ directly related to the torsion angle ϕ of the peptide chain is the most convenient for structural studies, as it can be determined rather simply and accurately. Data on the other torsion angle of the peptide chain ψ are contained in the $^3J(\text{N} - \text{H}^\alpha)$ and $^3J(\text{N} - \text{N})$ constants, but, unfortunately, they are both small and, moreover, change the sign. In return, data on the conformations of side chains, in particular on the torsion angle χ_1 , can be derived from the spin–spin coupling constants for different pairs: $\text{H}^\alpha - \text{H}^\beta$, $\text{N} - \text{H}^\beta$, $\text{C}' - \text{H}^\beta$, $\text{H}^\alpha - \text{C}^\gamma$, $\text{N} - \text{C}^\gamma$, $\text{C}' - \text{C}^\gamma$.

The possibility of using the spin–spin coupling constants through one or two bonds in structural research has been barely studied until recently. However, the advent of NMR spectroscopy of weakly aligned molecules brought about the necessity of separating the contributions of the coupling constants and RDC through one bond to the observed splitting because a researcher measures a spin–spin coupling constant every time he determines a RDC. At first glance, these constants provide little information and are measured with a too low accuracy, but they can still be used. For example, the $\text{C}^\alpha - \text{H}^\alpha$ and $\text{C}^\alpha - \text{C}^\beta$ constants proved to be ‘sensitive’ to the torsion angle ψ of the peptide chain.⁵¹ The number of spin–spin coupling constants suitable for conformational studies of nucleic acids and carbohydrates is greater and their information content is higher; therefore, they have been better studied.⁵² In addition, the knowledge of spin–spin coupling constants is important due to the fact that they allow one to plan NMR experiments with coherence transfer *via* the corresponding bonds.

3. Chemical shifts

The chemical shifts of nuclei depend on their local environment and, actually, they bear all information needed to determine the 3D structure of the molecule. However, calculation of a 3D structure using chemical shifts alone has not been performed so far, although some progress along this line has been achieved.^{53, 54}

The chemical shifts of the ^1H , ^{15}N , ^{13}C and ^{31}P nuclei are widely used as constraints in determining the structure of a biomolecule. Empirical correlations between the ϕ and ψ angles, which determine the conformation of a section of the peptide chain, and the H^N , H^α , ^{15}N , $^{13}\text{C}'$, $^{13}\text{C}^\alpha$ and $^{13}\text{C}^\beta$ chemical shifts are known.⁵⁵ For example, the $^{13}\text{C}^\alpha$ and $^{13}\text{C}^\beta$ chemical shifts in the α -helices and β -sheets are markedly different, which allows reliable identification of these elements of the protein secondary structure. Similar correlations have been found for nucleic acids.⁵²

The structural information contained in these chemical shifts duplicates to some extent the information obtained using ^3J constants (for example, data on ϕ angles). However, not all the ^3J constants can be measured (because they are too small or because of broadening or overlap of spectral lines), whereas chemical shifts can be determined for any atom.

The signal assignment and chemical shift determination procedures are almost entirely automated; they are performed at an initial stage of structural studies. When these values are known,

one can establish and locate rather reliably the elements pertaining to the secondary structure of the biomolecule,⁵⁶ which is important for further analysis.

The chemical shifts of nuclei are determined not only to obtain tentative data concerning the structure; their changes during functioning of the biomolecule can serve as a fast-response tool suitable for investigating biochemical processes, screening low-molecular-mass ligands, and determining the sites of their binding to the biomolecule. The results of these studies are required, first of all, for the development of drugs.

4. Determination of constants through one hydrogen bond

Hydrogen bonds are the key stabilising factor which determines the secondary and tertiary structures of biomolecules. Until recently, the existence of hydrogen bonds could be inferred only indirectly from the NMR parameters, for example, from the rates of proton exchange, ^1H and ^{15}N chemical shifts, isotope shifts or the spatial proximity of partners.

However, it was found that the constants through one hydrogen bond can be determined rather easily for the molecules of nucleic acids or proteins. In particular, the $^2J_{\text{N} \cdots \text{HN}}$ constants between the ^{15}N atoms of the purine and pyrimidine bases in the Watson–Crick pairs have been measured for both RNA⁵⁷ and DNA.²⁷ The spin–spin coupling constants found are rather high ($^2J_{\text{NN}}$ is about 6–7 Hz); they depend on the length of the hydrogen bond.⁵⁸ Therefore, measurement of the through-hydrogen-bond constants is not only indicative of the presence of this bond (this can also be inferred indirectly from the chemical shifts) but also allows one to determine the bond length.^{59, 60} Smaller constants ($^1J_{\text{HN}}$ of about 2–4 Hz) have been found between the imine group proton and its ^{15}N acceptor in the Watson–Crick pairs.

For proteins, the $^3J_{\text{CO} \cdots \text{HN}}$ constants have also been found.^{61–63} They are equal to 0.2–1.0 Hz and also depend on the length of the hydrogen bond.⁶³

5. Relaxation parameters

One relaxation parameter, the intensity of NOE peaks, has been mentioned above.

The times of heteronuclear relaxation contain information on the intramolecular dynamics. For example, the spin–spin relaxation time T_2 for a ^{15}N nucleus is a function of both frequency-dependent and frequency-independent constituents of the spectral density, and the spin–lattice relaxation time T_1 is a function of only frequency-dependent components. Due to anisotropy of rotational diffusion in the absence of large-amplitude motions in the molecule (and, hence, without broadening of NMR lines), the T_1/T_2 ratio for the ^{15}N nuclei in a protein molecule with an axially symmetrical diffusion tensor depends only on three variables: the angle between the vector of the $\text{N} - \text{H}$ bond and the principal axis of the diffusion tensor and the parallel and perpendicular components of the diffusion tensor. This fact can be used to determine the orientation of the $\text{N} - \text{H}$ bond vector, and the T_1/T_2 ratio can be included as an independent variable into the group of varied parameters for determining the structure of a biomolecule.^{64, 65}

In recent years, methods based on cross-correlation (or interference) of the relaxation mechanisms related to the dipole–dipole interaction (DD) and chemical shift anisotropy (CSA) have been used for gaining structural and dynamic information on biomolecules.⁶⁶ These methods are based on elucidation and use of DD–DD,^{67–69} DDI–CSA^{70–73} or CSA–CSA⁷⁴ type cross-correlations. One more type of cross-correlation is found in paramagnetic proteins, namely, that between the DD and the Curie spin, which is the net magnetic moment of the system of interacting nuclei and the unpaired electron.⁷⁵ These tensor correlations are very convenient for studying the dynamics⁷⁶ and determining various torsion angles in biomolecules.^{77, 78}

For example, to find the ψ angle in proteins, one can measure the following relaxation rates: DD($\text{C}^\alpha - \text{H}^\alpha$)–DD($\text{N} - \text{H}^N$),^{68, 69} DD($\text{C}^\alpha - \text{H}^\alpha$)–CSA(^{15}N),⁶⁸ DD($\text{C}^\alpha - \text{H}^\alpha$)–CSA($^{13}\text{C}'$)^{70, 71} and

$\text{CSA}(^{13}\text{C}') - \text{CSA}(^{13}\text{C}')$.⁷² The use of cross-correlated $\text{DD}(\text{C}-\text{H}) - \text{CSA}(^{31}\text{P})$ relaxation has been proposed for determining the angles in the phosphodiester chain of RNA.⁷³

The cross-correlation of relaxation parameters has also been used to study the glycoside bond in polysaccharides,⁶⁹ to explore the intramolecular dynamics in proteins^{76,79} and to determine the conformations of the sugar rings in RNA⁸⁰ and the geometry of metal binding in zinc-containing protein molecules.⁸¹ The research making use of relaxation parameters is only at the beginning but encouraging results have already been obtained.^{82,83} For instance, TROSY spectroscopy has been embodied owing to these studies.

III. Study of membrane proteins by solid-state NMR spectroscopy

Studies into the structure of biomolecules by solid-state NMR spectroscopy carried out by several research groups are currently in progress.^{84–91}

Biomolecules are oriented to the greatest extent in the solid phase; however, due to the absence of rotational or translational degrees of freedom, the NMR spectra exhibit lines corresponding to interactions of magnetic nuclei not only within the molecule but also with the magnetic nuclei of neighbouring molecules. This makes the spectrum more complicated; it contains a large number of overlapping lines. In addition, the protein molecules forming a crystal unit cell are oriented in different ways relative to the crystal axes, and, hence, the RDC for the same pairs of nuclei are different in the magnetic field of the spectrometer.

In order to simplify the NMR spectra, one can use the LC phases of the studied substances. In an ideal case, the spectra should exhibit only intramolecular interactions, while intermolecular interactions should be averaged to zero. However, the mere use of LC phases would not ensure a full success due to the same problem: there are too many magnetic nuclei in a biomolecule. Nevertheless, the fact that intermolecular interactions are not manifested in the spectra is a step forward. By using methods for simplification of NMR spectra with allowance for the fact that the principal axes of molecules are unidirectional, it becomes possible to interpret the results obtained much more accurately than with crystals. This new line of research is currently vigorously developing, especially in investigations of insoluble membrane proteins.

Membrane proteins participate in important processes in cells (intercellular bonds, signal transduction, toxin secretion, transport of ions and nutrients); therefore, they are of interest as potential targets for drugs. It is difficult to determine the spatial structure of a membrane protein by X-ray or liquid-state NMR. These proteins virtually do not crystallise and are almost insoluble; even if a crystal or a solution is obtained, the protein structure may no longer correspond to the native structure. In addition, for understanding of the mechanism of functioning of a membrane protein, it is important to know the positions of elements of the secondary structure of the protein itself relative to the membrane.

Only several dozens of structures for membrane proteins have now been determined by X-ray with a resolution of 0.3 nm, while for soluble proteins, this number is more than 3000 for the same resolution. The structures of several more membrane proteins have been established using electron microscopy of two-dimensional crystals obtained by crystallisation of protein-containing lipid bilayers. However, this does not provide a satisfactory resolution. Thus, NMR spectroscopy appears to be the most promising technique for large-scale determinations of the structures of membrane proteins.

Solid-state NMR is convenient for investigations of membrane proteins in lipid bilayers, because both the tertiary structure of the membrane-embedded protein and the protein orientation relative to the membrane surface can be determined simultaneously.

Membrane proteins are oriented in the same way with respect to the membrane but are arranged chaotically on its surface. Actually, both the membrane and the protein are in the LC state, the degree of alignment of biomolecules being very high. This accounts for the multiple dipolar splittings of lines, which makes the resultant spectrum unresolved, like the spectra of usual organic crystals. However, in the case of membrane proteins, in view of the fact that the proteins are similarly oriented on the membrane, there is a unique opportunity to prepare specimens in which the membranes themselves are also aligned. Such a specimen would be suitable for investigation by solid-state NMR techniques.

In most of these techniques, magic-angle spinning of the oriented specimen is combined with other NMR tools (multi-dimensional spectroscopy, multi-quantum experiments, *etc.*). In this case, the orientation-dependent information is lost (due to averaging), but it can be restored by analysing, for example, the spinning sidebands.^{92–94}

In order to decrease the RDC value for highly aligned molecules and to simplify the NMR spectrum, magic-angle spinning in the spin space is used; this is attained by using special pulse sequences.

Magic-angle spinning (or spinning at a very similar angle) results in virtually complete averaging of relatively small RDC from remote nuclei, leaving only the contributions from non-averaged large RDC, which are usually due to directly linked or very close nuclei. Since the distances between such nuclei are often known with high accuracy (the distances between the nuclei at the sites of contact of different chain sections are an exception), the experimental RDC values can be used to find the orientation of each pair of nuclei relative to the magnetic field. The set of these parameters called orientational constraints determines the conformation of the biomolecule in space. This method developed in a number of studies^{95–99} can be successfully used to determine the structure and polymorphism of the membrane proteins.

Up till now, solid-state experiments have been carried out using the RDC of a covalently bonded $^{15}\text{N} - ^1\text{H}$ pair which lies in the plane of the peptide bond. Potentially suitable are the RDC for the directly linked $^{13}\text{C} - ^1\text{H}$, $^{17}\text{O} - ^{13}\text{C}$, and $^{15}\text{N} - ^2\text{H}$ heteronuclear pairs,^{96,100} the $^{13}\text{C} - ^{13}\text{C}$ and $^{15}\text{N} - ^{15}\text{N}$ homonuclear pairs, and the ^2H -quadrupole couplings.⁹⁷ The first attempts were undertaken using the $^1\text{H} - ^1\text{H}$ coupling constants for exchanging protons. They were determined by the homonuclear dipole–dipole decoupling technique in the MAS (Magic Angle Spinning) spectra of highly deuterated proteins and peptides.^{101,102}

The $^{15}\text{N} - ^1\text{H}$ dipolar coupling constants are mainly determined in SLF (Separated Local Field)¹⁰³ and PISEMA (Polarisation Inversion with Spin Exchange at the Magic Angle) experiments.¹⁰⁴ The procedures of these experiments make it possible to exclude the homonuclear proton–proton constants and to increase sharply the resolution of spectra. These procedures are vigorously developing now.^{85,105,106} The known REDOR (Rotational Echo Double Resonance) procedure has started to be used in the solid-state investigations of biomolecules.^{103,107,108}

The PISEMA spectra as well as the usual heterocorrelated $^1\text{H}/^{15}\text{N}$ NMR spectra exhibit readily diagnosable cross-peaks, which form resonance patterns called PISA-Wheel, because they correspond to α -helices or β -sheets that are somewhat tilted in the membrane body. These resonance patterns serve as excellent and clearly visible indicators for the presence of secondary structure elements (α -helix or β -sheet) and their orientation with respect to the membrane.^{109–112} For visualisation and reliable identification of this type of spectral images and for numerical simulation of the spectra of proteins, a very convenient SIMMOL program,¹¹³ integrated into the SIMPSON program,¹¹⁴ used for the analysis of the solid-state protein spectra, has been developed.

Note that usual methods of NMR spectroscopy in the liquid state are also applicable to membrane proteins provided they are placed in, for example, micelles.^{115,116} The NMR spectra of solutions of these encapsulated membrane proteins resemble the

spectra of soluble proteins. For increasing the relaxation times, one can use low-viscosity solvents or reversed micelles.⁴⁰ This procedure was used to establish the structure of the transmembrane domain of membrane protein A from *E. coli* embedded in dodecylphosphocholine micelles¹¹⁷ (the structure proved to be identical to the structure determined by X-ray diffraction analysis in n-octyltetraoxyethylene micelles) and the OmpX membrane protein from *E. coli* in dihexanoyl phosphatidylcholine micelles.³³

Gramicidin A is the first membrane protein whose structure has been determined by solid-state NMR using isotope labels.^{96, 118–120} Subsequently PISEMA experiments were used to sequence the structure of the transmembrane M2 segment of the nicotine acetylcholine receptor,^{121, 122} which is a single helix arranged at an angle of 12° to the membrane normal. A membrane pore designed in molecular modelling accommodated five of these helices. It was established in similar experiments that the M2 protein of the influenza virus A forms an ion channel out of four helices located at a 35° angle to the membrane normal,^{123, 124} while the Vpu protein forms a similar channel in the HIV-1 membrane at an angle of 15°.¹²⁵ Structural and topological studies of some other membrane proteins have been reported.^{126–128}

The results of numerical modelling of the high-resolution solid-state NMR spectra of uniformly isotope-enriched membrane proteins, rhodopsin and porin, in oriented lipid layers made it possible to increase the efficiency of the experimental procedures used.¹²⁹

The structures of only two membrane proteins have now been deposited with the PDB, namely, gramicidin A and M2 of the acetylcholine receptor. The intensive development of solid-state NMR spectroscopy provides every reason for hoping that the number of these structures will increase within the next few years.

Encouraging results were also obtained in the development of procedures for determination of the structures of single-crystalline specimens of ¹³C- and ¹⁵N-enriched peptides.^{88, 130}

The high degree of alignment of molecules in solid specimens brings about specific problems; the procedures used to solve these problems allow one to diminish artificially the effects of the high degree of alignment down to acceptable values which normally correspond to weakly aligned molecules. Weak alignment of molecules can also be attained in the liquid phase.

IV. Methods for alignment of biomolecules in solutions

The idea of the orientation of molecules for gaining structural information sprang up in the early 1960s. Later, this was implemented in practice with the advent of the method for the orientation of molecules by placing them in an LC medium; this method has been used to determine the structures of small organic molecules.¹³¹ Other ways of orientation appeared non-competitive at that time due to low degrees of alignment achieved and the limitation on the number of magnetic nuclei in the molecule, which had to be not more than 10–12; otherwise, interpretation of the NMR spectrum became impossible due to overlap of lines.

At that time, the possibility of studying biomolecules in this way seemed impracticable. However, the idea to use weakly aligned molecules for structural purposes, paradoxical at first glance, made it possible to simplify the NMR spectrum and to eliminate the limitation on the number of magnetic nuclei in the molecule. In addition, the lines in the NMR spectra of weakly aligned biomolecules, unlike the lines of highly aligned molecules, are not virtually broadened due to faster reorientation.

Weak alignment of biomolecules can be attained by a much greater number of methods than high alignment. The type of alignment depends on the specific interactions of the biomacromolecule with the orienting forces or particles; therefore, the orientation mechanisms in different media can differ in principle; this is important for selecting the optimal experimental condi-

tions, more facile data interpretation, and for automation of experiments and calculations.

The simplest methods used for orientation of biomolecules include exposure to magnetic or electric fields or pressure, stretching or straining of microporous matrices, flow and gradient of velocity in the flow. Lyotropic liquid crystals, polymer gels, zeolites and so on can be used as media for the orientation. Virtually all of these methods have been covered in a review.¹³² Orientation by particles is accomplished due to stereospecific interactions of the biomolecules with highly anisotropic particles shaped like discs (bicelles, membrane fragments) or rods (phages, viruses) which are readily aligned under the action of a magnetic field. The molecules of the orienting media can be either oriented (additionally oriented, reoriented) under the action of the magnetic field of a spectrometer or retain their initial orientation.

The media that can be oriented due to steric interactions are preferred because they have no influence on the rotational correlation time and, hence, the line widths in the NMR spectrum remain constant. The orientation on complex formation often affects appreciably the mechanisms of rotational correlation, and, hence, T_2 . The orienting properties of various media have been described in detail in reviews.^{133–135} Currently, intensive search for new methods for the orientation of biomolecules is in progress. Figure 2 sketches different types of LC media used for weak alignment of biomolecules in NMR spectroscopy.

1. Alignment induced by an external magnetic field

Molecules with a non-zero anisotropy of magnetic susceptibility can be aligned on exposure to an external magnetic field. The orientation of molecules in solution obeys the Boltzmann law, the degree of alignment being proportional to the magnetic field strength squared.¹³⁶ In practice, the degree of alignment of molecules is slight and cannot be observed under usual conditions.

The partial alignment of molecules induced by a magnetic field, resulting in new or additional line splittings in high-resolution NMR spectra, was first observed by Bothner-By and coworkers.^{137, 138} They studied the paramagnetic complex bis[(*p*-tolyl)-tris(pyrazolyl)borato]cobalt(II). The orientation under the action of a magnetic field was very weak and took place only for some of the molecules, mainly complexes with paramagnetic metals. With the progress in NMR hardware, the magnetic fields in the spectrometers have become stronger; therefore the orientation effects are observed more and more frequently¹³⁹ and they should be taken into account for precise determination of spin–spin coupling constants.

It was shown⁴² that biological molecules, for example, DNA duplexes and quadruplexes can also be aligned in the magnetic field of the spectrometer. In particular, the researchers observed rather substantial changes in the ¹J_{CH} constants in DNA dodecamers upon an increase in the magnetic field strength. It was proposed to use this effect in structural studies.

The research group headed by Prestegard⁴³ demonstrated the orientation of molecules of a paramagnetic protein, cyanomethmyoglobin, on exposure to a magnetic field. The measured ¹J_{NH} values differed from the known ones. The difference between the constants (–1 to 5 Hz) was attributed to the residual ¹⁵N–¹H dipolar coupling.

Tjandra *et al.*¹⁴⁰ observed magnetic field-induced orientation even for the diamagnetic ¹⁵N-enriched human ubiquitin protein. The anisotropy of magnetic susceptibility of this protein is an order of magnitude lower than those for cyanomethmyoglobin or DNA dodecamers; correspondingly, the residual constants are also lower (< 0.3 Hz). The studies were carried out using three NMR spectrometers with different magnetic fields. The constants ¹J_{NH} were measured using two procedures. A constant was found to comprise two components: an orientation-independent component caused by the dynamic frequency shift and orientation-dependent component caused by the ¹⁵N–¹H RDC. The residual ¹³C–¹H dipolar couplings for the same protein enriched in ¹³C have been measured.¹⁴¹ The measurements were carried out using

Figure 2. Schematic view of the media for weak alignment of biomolecules.

(a) Helfrich lamellar phases with bilayers remote from one another; (b) aqueous solution of disc-like particles with a negative anisotropy of diamagnetic susceptibility orienting with their normal $\mathbf{n}$ perpendicular to the magnetic field $\mathbf{B}_0$; (c) aqueous solution of the same particles with a positive anisotropy of diamagnetic susceptibility orienting parallel to the magnetic field $\mathbf{B}_0$; (d) aqueous solution of rod-like particles (suspensions of filamentous phages and viruses, cellulose crystallites), which align with their long axis parallel to the field; (e) stretched or compressed porous polymer gels.

two spectrometers operating at 360 and 750 MHz. However, the residual dipolar couplings were relatively weak (due to the weak degree of alignment of the biomolecule) and inapplicable for structural studies.

The complexes of proteins with DNA or with paramagnetic metals are aligned much better on exposure to a magnetic field.

2. Alignment induced by paramagnetic ions

To enhance the alignment of biomolecules in a magnetic field, it is necessary to increase the anisotropy of magnetic susceptibility of these molecules or the orienting system (membranes, media, and so on). This can be done, for example, by adding paramagnetic metal ions (mainly, lanthanide ions). These ions form a paramagnetic complex with a studied molecule, which is aligned more efficiently in the magnetic field of the spectrometer. This was shown for the first time using the paramagnetic complex of myoglobine.⁴³ The degree of alignment thus attained is not very large and is inferior to that attained in dilute LC media but it is quite sufficient for structural investigations.

A paramagnetic ion can be linked to the studied biomolecule in several ways. Some proteins initially contain paramagnetic ions, for example, the myoglobine mentioned above and heme-containing proteins. In other metal-containing biomolecules, diamagnetic metal ions can be replaced by paramagnetic ions. The proteins devoid of metal can be built up by attaching a protein fragment containing metal atoms to one of its ends. The orientation of the biomolecule would be different depending on whether the paramagnetic label is attached to the C- or N-end. This provides additional structural information and proves fairly useful for removing the degeneracy of orientation data in determining the three-dimensional structure of a biomolecule. By successive replacement of several different ions in a biomolecule, one can attain its multiple orientations.

The position of the Eu^{3+} in the Eu–DNA quadruplex system was determined by using magnetic orientation induced by the paramagnetic ion.¹⁴²

As a result of orientation induced by replacement of the Ca^{2+} ion in calcium-containing biomolecules by lanthanide ions^{143–147} [in particular, by Tb^{3+} (see Ref. 144) or by Ce^{3+} (see Ref. 146)], it became possible to observe the dipole splitting and to determine the structures of a number of proteins. The same replacement

made it possible to measure the RDC for pairs of nuclei in the NH_2 groups and to study the conformational mobility of the side chains in the asparagine and glutamine residues in the molecule of the Ca_2 -calbindin protein.¹⁴⁵

A situation where two aligning factors, for example, a paramagnetic ion and an LC medium, compete with each other is favourable for structure determination. In these cases, the resulting RDC is equal to the sum of the RDC for the initial diamagnetic protein molecule induced by the LC phase and that induced by the paramagnetic ion. When the diamagnetic ion in the protein is replaced by different paramagnetic ions, the alignment tensor can be determined unambiguously.¹⁴⁸

The method in which a standard paramagnetic label is attached to the N- or C-end of the protein molecule is promising. Various small proteins and protein tags have been proposed as labels, for example, the Zn-finger protein in which the diamagnetic Zn^{2+} ion can be replaced by paramagnetic Co^{2+} and Mn^{2+} ions,¹⁴⁹ or the terminal fragment of the EF-hand oncomodulin protein consisting of 12 amino acid residues in which Co^{2+} can be replaced by paramagnetic lanthanide ions.¹⁵⁰ The range of these labels is broad.¹⁵¹ Donaldson *et al.*¹⁵² proposed the shortest sequence, consisting of only three amino acid residues, binding the Cu^{2+} ion for adding a paramagnetic label to the N-end of a studied protein. The protein molecules containing a paramagnetic label exhibit a substantial anisotropy of paramagnetic susceptibility and are efficiently aligned in a magnetic field, whereas the orientation of a diamagnetic protein is very weak. By recording the NMR spectra before and after the substitution, one can determine the dipolar constants and the dipolar shifts. If in paramagnetic relaxation experiments, the Mn^{2+} ion is replaced by a paramagnetic ion, it is possible to determine the distance between the unpaired electron and the proton of the amide group. When these distances and the dipolar shifts of the amide protons are known, one can calculate the z coordinates for these protons.¹⁴⁹

In addition to the orientation (or reorientation) effect in the magnetic field and the possibility of measuring RDC, the presence of a paramagnetic ion in a biomolecule allows one to measure other parameters containing structural information also. In particular, these are the paramagnetic shifts of nuclei, the constants of cross-correlated relaxation between the electron and

nuclear spins^{153,154} and between nuclear spins and the Curie spin.^{75,155,156}

The pseudocontact shifts caused by the dipolar coupling between the magnetic moments of the electron and the nucleus also carry structural information and can be used as additional parameters for structure determination of a protein.¹⁵⁷ The paramagnetic heme-containing protein of the rat cytochrome *b*₅ in the paramagnetic (oxidised) and diamagnetic (reduced) states was studied in this way.¹⁵⁸ The structures determined from the data obtained in NOE-based experiments, by means of RDC, and using information on the pseudocontact shifts are in good agreement.

Using data on dipolar coupling, one can determine the anisotropy of the magnetic susceptibility of the whole protein. In particular, comparison of the dipolar couplings and the anisotropies of the magnetic susceptibility of cytochrome-*c*' from *Rhodobacter capsulatus* in the paramagnetic and diamagnetic states found by different methods with one another and with published results^{159,160} showed good agreement of these values. It was also shown that the protein exists in solution in the monomer form.

Taking into account the self-orientation of cytochrome *b*₅₉₂ molecules from *E. coli* containing heme in the oxidised state, Arnesano *et al.*¹⁶¹ were able to refine the structure of this protein and to separate the diamagnetic and paramagnetic contributions from the total magnetic anisotropy of the molecule.

3. Alignment induced by an electric field

An electric field can be used as an orientation factor; however, this restricts the possible electrochemical and electroconvective processes involving biomolecules in aqueous and salt-containing aqueous solutions.^{162,163}

An electric field was first used to align the *p*-nitrotoluene molecules.¹⁶⁴ This study was undertaken to determine the sign of the spin–spin coupling constant.

The orientation of molecules on exposure to an electric field has an obvious advantage over the magnetic field-induced orientation: there is no need to carry out measurements using at least three NMR spectrometers to distinguish between the orientation effects and those caused by dynamic frequency shifts; it is sufficient to employ only one spectrometer but three different electric field strengths.

It has been proposed^{165,166} to use an alternating pulse electric field synchronised with a sequence of radiofrequency pulses. In this case, multidimensional NMR experiments can be carried out with the electric field being switched on and off at particular time instants. The researchers cited developed two 2D experimental procedures for determination of the RDC. In one experiment, the electric field was applied only in the second dimension to observe the dipolar splitting, while the isotropic chemical shifts were observed in the direct dimension. In the other experiment, the electric field was switched on only during mixing; as a consequence, cross-peaks were observed only for the pairs connected by dipolar coupling. In these experiments, alternating electric fields with a frequency of 28.5 kHz and a strength of 40–70 kV cm^{−1} were used.

A similar 2D ²H NMR experiment for observing the correlation between the isotropic chemical shift and the residual anisotropic couplings (in this case, quadrupole coupling induced by a pulse-modulated constant electric field) has been proposed.¹⁶⁷ For decreasing the influence of the molecular motion on the measured signal, multiquantum filtration is used.^{168,169} This technique is equally suitable for dipole-coupled systems with a spin of 1/2.

In these experiments, nitrobenzene thoroughly purified from ionic impurities was used as an orienting compound. The molecules of some proteins have higher dipole moments than nitrobenzene; however, it is still unknown to what extent the method involving orientation in an electric field is applicable to biomolecules. These studies are only at the beginning.

4. Orientation in liquid-crystalline media

The self-orientation of biomolecules (except for the molecules containing paramagnetic centres) even on exposure to strong magnetic and electric fields is very low. A higher degree of alignment can be attained by placing a biomolecule in the LC medium, which is oriented in a magnetic field and thus aligns the biomolecules it contains. This medium should meet a number of requirements: it should be miscible with water, not interact chemically with the studied molecule, accommodate high concentrations of the biomolecules under study and the required buffer components and also to be stable for a long time over a broad temperature range. However, every LC possesses a high degree of alignment; therefore, the main difficulty in searching for these systems is the requirement of weak alignment of the biomolecules, *i.e.*, several orders of magnitude weaker than the degree of alignment of the LC molecules.

Systematic search resulted in a number of LC systems suitable for structural studies of biomolecules. For weak alignment of biomolecules, first, traditional lyotropic LC systems were tested, for example, solutions in quarternary ammonium, pyridinium,^{170,171} and other salts in aqueous alcohol. Mere dilution by water allows one to decrease somewhat the degree of alignment in these systems but only to certain critical concentrations below which the system is no longer liquid-crystalline and, hence, aligned. Liquid-crystalline media based on cetylpyridinium chloride–hexanol¹⁷⁰ and cetylpyridinium bromide–hexanol proved to be the systems of choice.¹⁷¹ These systems form lamellar phases of the Helfrich type consisting of double layers, which can be moved apart by adding a solvent, so that the distance between them will markedly exceed the thickness of the bilayer itself (see Fig. 2*a*). These lyotropic phases are very convenient and simple systems, relatively stable over a broad range of temperatures and concentrations. They withstand the concentrations of salts optimal for the existence of biomolecules and are stable for a long period of time. The magnetic anisotropy of the pyridinium rings determines the orientation of lamellae in a magnetic field: the symmetry axes of the lamellae are arranged along the field direction.

A new non-ionic lyotropic LC medium based on alkyl poly(ethylene glycols) and alkanols, which has certain advantages, has been proposed.¹⁷² In particular, the solution can be prepared outside the magnetic field of the spectrometer. The specimen has a low viscosity and can be transferred into the ampoule just by a pipette. In a magnetic field, the system is rapidly oriented. The components of this system are commercially available and inexpensive compared to the components of other systems used to study biomolecules by NMR spectroscopy techniques. They can be used with equal efficiency to study both proteins and nucleic acids. Advantages of these systems include low sensitivity to the pH and to high concentrations of salts and the protein.

5. Orientation by disc-like particles

a. Bicelles

Disc-like particles (bicelles, membrane fragments, *etc.*) can also be oriented in a magnetic field, form ordered LC media and align biomolecules that occur together with them in a solution.

Ram and Prestegard¹⁷³ were the first to propose disc-like mixed micelles as a model membrane system for NMR investigations. Bicelles, which are formed in aqueous solutions of lipids and surfactants and represent discrete bilayer disc-shaped structures, proved to be most convenient for this purpose.¹⁷⁴ They are equally applicable to studies of membrane proteins, which are incorporated and fixed in bicelles, by solid-state or liquid-state NMR and to NMR studies of water-soluble proteins in the presence of bicelles which are aligned in a magnetic field and align the protein molecules due to specific interactions with them.^{175–179}

The researchers' attention to bicelles as a medium for the study of biomolecules was enhanced when it was found that enzyme activity is retained in this medium.¹⁶⁷ Tjandra and Bax^{45,177} proposed using a dilute solution of bicelles as an orienting solvent

for biomolecules. Even the first results demonstrated that the distances and angles determined using ^1H – ^{15}N , ^1H – ^{13}C and ^{13}C – ^{13}C RDC in the molecules of human ubiquitin in dilute bicellar LC media were in agreement with the corresponding parameters determined in their crystal structure.¹⁷⁸

Bicelles (especially, those containing phospholipids) are much more similar to native membranes than small micelles. Therefore, the structure determined for membrane proteins encapsulated into bicelles is more plausible.¹⁸⁰ (However, data on micelle-induced bending of biomolecules have been reported.¹⁸¹) If the bicelle discs are small, they are freely and rapidly reoriented in solution and are not oriented under the action of a magnetic field. Such bicelles can form an ideal system for the investigation of encapsulated membrane proteins by conventional high-resolution NMR techniques used to study water-soluble proteins.¹⁸² In addition, a bicelle is oriented much more easily by a magnetic field than a spherical micelle with an embedded protein. This allows one to use procedures based on residual dipolar couplings in the studies of membrane proteins encapsulated in bicelles.

An anisotropic bicelle with a high ratio of the radius to the thickness can be oriented on exposure to an external magnetic field. By varying the composition and component ratio and their concentration in an aqueous solution, one can change gradually the degree of bicelle orientation and, hence, the degree of alignment of the studied biomolecules (which occur in the aqueous phase or inside the bicelles).

Studies of membrane proteins and peptides encapsulated in bicelles are usually carried out with high concentrations of phospholipids. This method was used to determine the orientation of the N-terminal fragment of the ARF1 protein relative to the surface of a bicelle oriented in a magnetic field¹⁸³ and to compare the orientation of the same fragment relative to micelle or bicelle surfaces.¹⁸⁴

Below we consider the use of bicelles for the studies of biomolecules only in solutions. By varying the component concentrations, one can change the degree of alignment of the dissolved biomolecules in these systems over broad ranges in order to attain the desired values of residual dipolar splitting. Various additives can be used to improve the properties of the system.

Bicelles consist of a mixture of at least two phospholipids with short and long hydrophobic tails; long-chain phospholipids form the flat surface of the disc, while the short-chain ones form the rounded edges. A typical thickness of a lipid bilayer is 40–50 Å. The dimensions of the bicelles increase with an increase in the molar ratio of the long-chain to short-chain lipids.¹⁸⁵ An important feature of such systems is the ability to pass from the nematic LC state into an isotropic state on changing the temperature; as this takes place, one can record the spectra of the dissolved molecules in both states of the system, which is necessary for determining the dipole contributions to the observed splitting. In particular, the transition of the basic DMPC–DHPC system (DMPC is dimyristoylphosphatidylcholine, DHPC is dihexanoylphosphatidylcholine) from the nematic to isotropic state takes place at 35 °C. This system is used most widely. It forms an alignable LC phase at very low bicelle concentrations ($\approx 3\%$ – 5%). The distances between separate bicelles in solution reach 300 Å; this is quite sufficient for biomolecules to fit between them. The disc radius is directly proportional to the [DMPC]/[DHPC] ratio and is inversely proportional to the total concentration of phospholipids in water with their ratio remaining constant.¹⁸⁶

The procedures for sample preparation for NMR studies and the properties of the basic DMPC–DHPC bicellar system have been described in detail in the literature. The dependences of the stability and the orienting properties of this medium on the temperature, pH, salt composition, the relative concentrations of components and additives have been studied.^{187–189}

The properties of bicelles (size, shape, surface charge, the anisotropy of diamagnetic susceptibility or the anisotropy of

dielectric constant) can be varied over broad ranges. Usual bicelles are stable only in narrow ranges of temperatures and pH. Charged lipids¹⁹⁰ or aromatic surfactants¹⁹¹ can be added to bicellar systems in order to extend the temperature range, increase the stability, enhance the orienting ability and change the type of orientation. The additives counterbalance the destructive influence of high salt concentrations on the system and minimise the interactions between the macromolecule under study and the bicelle. This effect shows itself with both positively and negatively charged additives. The addition of cationic lipids imparts to the system a low positive charge, which has an influence on the alignment of proteins caused by electrostatic and steric forces.¹⁹²

A large number of compositions able to form aqueous bicellar solutions under certain conditions have now been found.¹⁷⁹ The most promising among them are DLPC–CHAPSO¹⁹³ [DLPC is dilaurylphosphatidylcholine, CHAPSO is 3-(chloroamidopropyl)dimethylammonio-2-hydroxy-1-propane sulfonate] for studies over a broad temperature range and DIODPC–CHAPSO¹⁹⁴ (DIOIPC is 1,2-di-*O*-dodecyl-*sn*-glycero-3-phosphocholine) for studies of macromolecules in highly acidic media. Struppe *et al.*¹⁹⁵ have modified the DMPC–DHPC system by adding 25 mass % of dimyristoylphosphatidylserine (DMPS) or dimyristoylphosphatidylglycerol (DMPG). These ‘acidic’ bicelles are stable at pHs from 5.5 to 7 and are suitable for use in NMR studies of membrane proteins, because natural membranes are often charged, as they contain negatively charged lipids.

Many bicellar systems are susceptible for hydrolysis, which hampers long-term experiments (taking many days). Ottiger and Bax¹⁹⁶ proposed replacing diacyl phospholipids by dialkyl analogues in order to make the bicelles stable against hydrolysis. New bicelle systems are similar in orienting properties to DMPC–DHPC type systems but they are suitable for operation in both acidic and alkaline media. The DIODPC–CHAPSO system is also stable against hydrolysis.¹⁹⁴

The mechanism of orientation of biomolecules by bicelles is complicated and includes, apart from steric repulsion, electrostatic interactions and adsorption on the bicelle surface. The steric interactions are usually rather weak and can be easily modelled.¹⁹⁷

Bicelles can be oriented in different ways: by attaching an additional peptide tail to the C-end of the protein molecule, for example, so-called peptide Hi-tag; by changing pH; by adding cationic lipids, which would make the system slightly positively charged; by adding particles with highly anisotropic diamagnetic susceptibility or paramagnetic ions.¹⁹² The orientation of the director of the bicellar LC phase can also be varied by rotating the sample.¹⁹⁸

Usually, the degree of alignment of bicelles and transition of a bicellar LC system into the isotropic state are detected by measuring the quadrupole splittings in the spectra of heavy water, which is the major component of the system. Another method for measuring the degree of alignment of phospholipid bicelles in a magnetic field based on ^{31}P NMR spectroscopy has been proposed.¹⁹⁹

The morphology of three lyotropic LC phases — bicellar phase, a mixture of pentaethylene glycol monododecyl ether with hexanol and the cetylpyridinium bromide–hexanol system — was studied in detail in translational diffusion anisotropy experiments.²⁰⁰ Bicelles remain stable in the studies under elevated pressures. The interest in these studies is increasing at present.²⁰¹

Thus, lyotropic bicellar systems are very convenient media for investigating aligned proteins. However, there exist a number of proteins that destroy bicelles when interacting with them; therefore, study of the structures of these proteins using bicelles is problematic.^{178,202}

b. Orientation of biomolecules in bicelles doped with lanthanide ions

Bicelles are usually oriented in a magnetic field in such a way that their normal is perpendicular to the field direction,²⁰³ while the planes of the discs are located chaotically. This orientation can be changed by adding paramagnetic ions or by incorporating into the

bicelles an aromatic compound or macromolecules with a great anisotropy of diamagnetic susceptibility.

The orienting properties of bilayer membranes doped with lanthanide ions^{204–207} are rather attractive not only for investigating membrane proteins but also for investigating proteins encapsulated in them in solutions.^{150, 208, 209} This system combines two mechanisms for the ordering of biomolecules, namely, the influence of the membrane and the effect of paramagnetic ions. In the presence of Er^{3+} , Eu^{3+} , Tm^{3+} , or Yb^{3+} ions, the negative diamagnetic anisotropy of bicelles increases and their symmetry axis becomes parallel to the magnetic field. The biomolecules in the bicelles are also reoriented.^{204, 205} The transition accompanied by the change in the orientation of the bicellar system with respect to the magnetic field from the perpendicular to the parallel upon the addition of paramagnetic ions, as well as the formation of the LC phase upon increasing the bicelle concentration are cooperative phenomena depending on the interactions between the bicelles and on the temperature. In some cases, two types of alignment have been observed, the equilibrium between them being dependent on the concentrations of the paramagnetic ions and bicelles.²⁰⁸

The systematic research of mixtures of phospholipids with long and short chains over a broad range of concentrations and temperatures by small-angle neutron scattering showed the presence of phases with different morphologies such as lamellae, multilamellae, monolamellar vesicles and bicellar discs.²¹⁰

However, the large concentration of paramagnetic ions in the system results in undesirable line broadening and line shifts in the NMR spectra, which hampers their analysis. When chelating phospholipids are added in an equimolar amount with respect to paramagnetic ions,²⁰⁶ the ions form chelates incorporated in the membrane, and the paramagnetic effects are levelled. In addition, due to the alignment of the lanthanide chelates in the membranes, the total anisotropy of the diamagnetic susceptibility increases to such an extent that the lanthanide ion concentration needed for the reorientation of bicelles can be decreased. The possibility of inducing substantial changes in the type of bicelle orientation and, hence, the orientation of biomolecules by adding paramagnetic ions is also attractive due to the fact that a second set of RDC can be obtained rather easily. Owing to the new set, the number of RDC is actually doubled; on the one hand, this markedly increases the accuracy of the determined structure and, on the other hand, eliminates the ambiguity of the order parameters (see below).

If phospholipids containing, for example, a biphenyl group²⁰³ in one of the long chains, are added instead of nonlipid amphiphilic aromatic compounds or paramagnetic ions, it is possible to create bicellar systems with positive anisotropy of magnetic susceptibility ($\Delta\chi$).^{211, 212}

Study of a number of hydrophobic membrane proteins in solution became possible due to the effect of binding of lanthanide ions to protein-containing micelles.²¹³ The use of bicelles, membrane fragments and viruses for this purpose is problematic because membrane proteins change appreciably the structures of these particles when react with their lipids. This influences the quality of NMR spectra.

c. Purple membrane fragments

A method for aligning water-soluble biomolecules in the presence of purple membrane fragments (PM) was proposed almost simultaneously in two publications.^{214, 215} Purple membrane fragments are prepared from halobacteria, which form wide disc-like particles consisting of bacteriorhodopsin and some residual lipids when occurring in an aqueous solution with a concentration of $1–10 \text{ mg ml}^{-1}$. These particles are stable on sharp changes in the temperature, pH and ionic strength of the solution. They have great negative charges and, therefore, they can induce orientation of biomolecules (due to electrostatic interaction), which can be controlled by changing the concentrations of the PM fragments or by adding cations for reducing the electrostatic interaction between the macromolecule and the membrane.²¹⁵ These systems

are highly stable against temperature or pH variations and represent an excellent alternative to bicelles.

The orientation of biomolecules induced by PM fragments was demonstrated using two proteins, namely, human ubiquitin and p53. The maximum values of the $^1\text{H}–^{15}\text{N}$ RDC were $\sim 20 \text{ Hz}$. It is worth mentioning that in this case, too, the axial and rhombic components and the direction of the principal axis of the alignment tensor differ appreciably from the corresponding values in bicelles and other orienting media, which makes the membrane fragments a convenient medium for determining the additional set of RDC. The presence of several sets of RDC in which the principal axes of the corresponding diagonalised tensors are arranged at substantially different angles allows one to construct the complete 'triangulation' system of biological macromolecules in solution (see below).

A solution of PM fragments is not a liquid-crystalline system. Typical PM fragments are several micrometers in diameter and are $45 \text{ \AA}$ thick. Their alignment in a magnetic field is due to seven α -helices of bacteriorhodopsin. In a magnetic field, PM fragments are oriented in such a way that the normal to the membrane is parallel to the magnetic field direction and, due to high concentration of bacteriorhodopsin, the degree of alignment is extremely high.²¹⁴

The concentration of liquid crystals in solution cannot be lower than the value where the LC phase is formed; conversely, the concentration of the aligning particles in a suspension can be arbitrarily low. The alignment can be monitored based on quadrupole splitting of deuterium in the spectrum of heavy water.

The use of lanthanide ions, as in the case of bicelles, allows one to change the direction of the predominant orientation of biomolecules in the presence of PM fragments.²¹⁶ In a study dealing with the structure of a membrane protein,²¹⁷ an oxygen molecule has been used as a paramagnetic probe.

6. Orientation by rod-like particles

It should be borne in mind that bicelles are stable only in narrow temperature and pH ranges (beyond this range, hydrolysis of the ester bond can take place) and that many proteins interact with bicelle membranes to destroy them. Therefore, it is more preferable to use solutions of more stable particles that can be oriented and to orient the dissolved biomolecules without destroying their structure. This role can be played by any rigid, charged, rod-like macromolecular ensembles consisting, for example, of rod-shaped viruses and bacteriophages of the filamentous phage family, inorganic filamentary crystallites, polymeric crystallites and other relatively rigid filamentary polymeric structures (for example, polytetrafluoroethylene whiskers).

a. Liquid-crystalline colloid suspensions of rod-shaped viruses

Widely known suspensions of bacteriophage fd and the tobacco mosaic virus,²⁰² bacteriophage Pf1 or M13²¹⁸ were among the first systems to be proposed as alternatives to bicelles. These systems are very convenient for attaining medium degrees of alignment of the dissolved biomolecules; moreover, it is possible to control the orientation parameters by adding the bacteriophage Pf1 subject to magnetic alignment.^{218, 219} This procedure was used to determine the $^1\text{H}–^1\text{H}$, $^1\text{H}–^{13}\text{C}$ and $^1\text{H}–^{15}\text{N}$ RDC of various proteins and oligosaccharides. The orientation of the molecular alignment tensor in these systems differs substantially from the orientation in the medium of usual bicelles; this allows the measurements to be taken simultaneously in both media.

The procedure of preparation of the bacteriophage Pf1 specimen for the partial alignment of biomacromolecules has been described in detail elsewhere.^{220–222} The bacteriophage Pf1 is a DNA phage composed of 7349 nucleotides and packed in a protein shell with a nucleotide: protein ratio of 1:1. This is a rod-like system with a length of $20\,000 \text{ \AA}$ and $60 \text{ \AA}$ in diameter, which is spontaneously oriented in a magnetic field; Pf1 has a negative surface charge. The orienting properties of the phage under various experimental conditions were considered in detail

using DNA and RNA as examples. Based on quadrupole splitting of deuterium, one can judge the degree of system alignment, which can be changed by varying the phage concentration and the temperature.²²⁰ The researchers recommended a medium pH of 6.5–8.0 and $[\text{NaCl}] < 100 \text{ mmol litre}^{-1}$.

Most biomolecules and orienting particles are charged and this should be taken into account when selecting the appropriate medium. Bacteriophages represent ideal media for the orientation of RNA and DNA molecules: negatively charged molecules of nucleic acids are aligned due to steric interactions with negatively charged phages Pfl, which produce a stable orientation over a broad range of conditions in a solution.

The use of negatively charged particles to align positively charged biomolecules is problematic, although in some cases, such media prove very convenient for investigations of proteins.²²⁰ Even when the bacteriophage concentration is abnormally low, these systems are effective.²²³ Presumably, in this case, a different orientation mechanism is involved associated with weak binding of the protein under study to the phage. The observed orientation is due to fast exchange between the bound and free states of the protein.

In the cholesteric phase of the bacteriophage fd, the degree of alignment of the dissolved protein and, what is especially important, the rhombicity, depend on the pH.²²⁴ The pH value can be varied over a broad range, from 2 to 8 (an erroneous opinion that working with phages is possible only at high pH values has been established).

The alignment of a phage-based LC system can be fixed and made independent of an external magnetic field. For this purpose, the system is placed in a polyacrylamide matrix. The polymer-stabilised system fully retains its specific orientation characteristics.²²⁵

b. Cellulose crystallites

Suspensions of cellulose crystallites are, probably, the cheapest, the most stable and the simplest media for the orientation of biomolecules.²²⁶ They are produced from natural cellulose fibres (for example, from filter paper) by careful hydrolysis by sulfuric acid, concentration and extensive dialysis. After some period, the system separates into an upper isotropic phase and a lower anisotropic phase. The latter is isolated, concentrated by evaporation and then used.

The cellulose crystallites are rods with dimensions $\sim 200 \times 10 \text{ nm}$. A separate crystallite has a large negative diamagnetic anisotropy; therefore it is oriented in a magnetic field with its long axis normal to the direction of the applied field. The orientation process is slow; to attain complete orientation, a freshly prepared specimen should be kept for several hours in a magnetic field. The surface negative charge of the crystallite caused by sulfate groups is smaller than the surface charge of bacteriophages; therefore, they orient biomolecules by a steric mechanism rather than an electrostatic one.

7. Stressed polymer gels

Polymer gels form promising media for the orientation of biomolecules. The effect of orientation of small molecules incorporated in rubber-like polymers has been known for a long time.²²⁷ Two groups of researchers working independently of each other proposed using this phenomenon for the orientation of biomolecules in polyacrylamide gels. The orientation is attained either upon mechanical treatment (stretching or straining)^{228, 229} or by means of aligned PM fragments or other particles embedded in the gel.²²⁹

The gel is prepared by polymerisation of an aqueous solution of a mixture of acrylamide and methylenebisacrylamide in a special tube whose diameter differs slightly from the diameter of an NMR ampoule. The polymerisation is initiated by a mixture of ammonium persulfate with tetramethylethylenediamine. After polymerisation, the gel is thoroughly washed, dried and placed in an NMR ampoule, and an aqueous solution of the studied

protein is added. The protein and water slowly diffuse into the gel, which swells. Subsequently the gel is subjected to mechanical treatment and, as a result, the macromolecules having penetrated into the gel are aligned. If the diameter of the tube used initially to prepare the gel is smaller than the diameter of the ampoule used in NMR experiments, the gel is compressed, while in the opposite case, the gel is stretched, and the axis of the alignment tensor of the biomolecules incorporated in the gel is oriented across or along the ampoule, respectively.

The pore sizes and the diffusion properties of the polyacrylamide gels can be changed by controlling the concentration of acrylamide and methylenebisacrylamide. Instead of the simple protein–water system, one can use protein–surfactant–water micellar systems.

Yet another option is to incorporate other particles into the gel during polymerisation, for example, PM fragments, phages and viruses able to orient protein molecules. Polymerisation is carried out in a magnetic field and, hence, the above particles are incorporated in the gel in the oriented state. The orientation of molecules of the protein introduced into the gel is due to the interaction with the oriented (orienting) particles.

The orientation of particles immobilised in the gel during polymerisation can be attained using other types of external macroscopic treatment, for example, electric or mechanical treatment.

A distinctive feature of polymer gels is that the direction of their orientation is determined by the preparation procedure and does not depend on a magnetic field. This allows one to change smoothly the gel orientation with respect to the direction of the magnetic field. This feature can also be used to produce a new, biaxial orientation of the system after completion of NMR measurements. In this axially asymmetrical system, one can determine the set of orientation-dependent parameters, which cannot be found in usual uniaxial LC media.²²⁸ The orientation in these systems is not violated when the specimen is rotated. This allows one to measure the spin–spin coupling constants during magic angle spinning of the specimen (to set the RDC to zero).²²⁵

By varying the pressure, polyacrylamide concentration or cross-linking density in the gel, one can change over wide limits the degree of alignment of biomolecules, whereas the direction and asymmetry of the alignment tensor remain virtually constant.²³⁰ Relatively large protein molecules can also be studied in gels because their relaxation times in the gel are rather long.

A simple funnel-like apparatus has been proposed for uniform squeezing of the polyacrylamide hydrogel.²³¹ The degree of alignment depends on the ratio of the diameters of a cylindrical hydrogel specimen before and after squeezing.

8. Mineral liquid crystals

The media for the orientation of biomolecules considered above are organic materials; therefore, the solvent signals predominate in the NMR spectra, because the number of molecules of the medium is much greater than the number of the biomolecules under study. This creates certain difficulties, especially in the studies of oligosaccharides or oligonucleotides for which the synthesis of isotopically enriched analogues is very complex and expensive.

Mineral liquid crystals devoid of ^1H or ^{13}C nuclei are very convenient in this respect. Systematic research into these crystals started not long ago. They are colloid systems consisting of highly anisotropic ribbon-, plate- and disc-shaped or column nanoparticles, which tend to form various types of LC phases. Systems oriented by a magnetic field are of special interest for NMR spectroscopy.

One system of this type is an aqueous suspension of vanadium pentoxide V_2O_5 , in which a nematic phase is formed within a certain range of concentrations and pH.²³² The particles of this phase are long (several hundreds of nanometers) 1 nm thick ribbons with a width of 25 nm. Due to the high negative charge of the particles, the mechanism of orientation of biomolecules is

similar to that effective in suspensions of viruses and phages. Yet another class of mineral liquid crystals well oriented in a magnetic field has also been proposed, namely, a series of swelling gels of salts of the solid acids generally described as $H_nM_nZ_2O_{3n+5}$ ($M = Sb, Nb, Ta$; $Z = P, As$; $n = 1, 3$), whose particles are plate-like.²³³

The ^{13}C – ^1H dipolar coupling constants of pentasaccharide Lewis X measured in these systems with a natural abundance of the ^{13}C isotope proved to be comparable in the order of magnitude with the RDC measured in organic LC, in particular, in a bicellar medium.

Advantages of inorganic systems over organic systems include high stability and inertness over a broad temperature range, the possibility of recovery of the substance under study by flocculation and the fact that at lower concentrations, they are oriented in the magnetic field much better and faster.

Unfortunately, none of the systems considered above is universal for structural research.¹⁷² The DMPC–DHPC bicellar system is susceptible to irreversible degradation due to hydrolysis at low pH values.¹⁸⁸ The DIODPC–CHAPSO system is more stable at low pH values but does not form an LC phase in a neutral medium.¹⁹⁴ The cetylpyridinium chloride–hexanol system is destabilised at high protein concentrations and, to increase its stability, high salt concentrations are required.¹⁷⁰ Conversely, the cetylpyridinium bromide–hexanol system is stable at low ionic strength of the solution.¹⁷¹ Phages are effective in neutral media, but at pH < 6, they tend to aggregate.²¹⁸ Purple membrane fragments and bicelles often bind proteins too strongly, which is manifested as line broadening in the NMR spectra and in perturbation of the alignment tensor; as a consequence, it is impossible to determine the real structure of the molecule in solution.^{214, 215}

V. Measurement of orientation-dependent parameters

1. Orientation-dependent parameters

Today, a number of NMR parameters containing diverse structural information concerning the molecules under study can be measured in experiments. Table 1 presents some of these NMR parameters. The most valuable and diverse structural information can be derived from orientation-dependent parameters such as RDC, the quadrupole coupling constants (QCC), and the chemical shift anisotropy.

The dipolar coupling constants proved to be more useful at any stage of structure determination for a biomolecule than the traditional parameters obtained mainly in NOE-based experiments. Comparison of the distances found in these experiments with those found using RDC showed that the use of the latter is preferred. The distances longer than 5–6 Å are inaccessible for NOE procedures, whereas the use of RDC allows determination of even longer distances.

Table 1. NMR parameters carrying structural information.

NMR parameter	Structural information
Chemical shifts ^1H , ^{13}C , ^{15}N , ^{31}P	signal assignment, secondary structure, torsion angles
Constants ^3J	torsion angles
NOE signals	proton–proton distances (< 5 Å)
Relaxation parameters	torsion angles, bond orientation, dynamics
RDC	bond orientation, internuclear distances, dynamics
CSA	bond or functional group orientation
QCC	distances, angles, bond orientation, dynamics

The fundamental difference between these methods is as follows: NOE signals permit one to estimate the length of the vector connecting the interacting nuclei, while RDC, in addition, provides information on the orientation of this vector with respect to the direction of the magnetic field; this allows one to determine the relative spatial orientation of the remote fragments of the molecule.

Another important difference is that the measured parameters depend in different ways on the distance. Dipolar couplings depend on the distance as $1/r^3$ and the NOE signals, as $1/r^6$. With a smoother dependence, one can distinguish sections corresponding to interactions between more remote nuclei.

Even when the number of NOE restraints is great, the use of RDC markedly increases the accuracy of structure determination. In those cases where NOE signals provide little information, as in the studies of nucleic acids or large, partially deuterated (to simplify the spectrum) proteins, RDC can play a crucial role.²³⁴

In order to determine orientation-dependent parameters, one must measure NMR spectra in both isotropic and oriented states. Two different patterns of these measurements are possible, each of them having advantages and shortcomings:

- separate measurements (isotropic and anisotropic parameters are determined in different experiments corresponding to isotropic and oriented states);

- simultaneous measurements (isotropic and anisotropic parameters are determined in one correlation experiment).

Up to the present day, separate measurements for the isotropic and oriented states have been carried out most often. In these experiments, it is possible to select the optimal conditions for recording the spectra for each of the states, in particular, the solvent, the concentration, the temperature, *etc.* However, the structure of a biomolecule may change depending on the experimental conditions. In addition, this type of measurement often requires large amounts of substances because a non-destructive transfer of biomolecules from one medium to another is very complicated. Yet another problem is the difficulty of signal assignment due to the dependence of chemical shifts and their anisotropies on the experimental conditions.

The techniques based on synchronous measurements of isotropic and anisotropic parameters are devoid of the above drawbacks. The measurements are carried out in multidimensional correlation experiments of various types, in one stage of which (evolution/recording), the orientation-dependent parameters are not averaged to zero.

This can be implemented in, for example, a COSY experiment in two ways. If the initial sample has anisotropic interactions, they can be temporarily removed at one stage of the correlation experiment by magic angle spinning (in the real or spin space). If the initial sample is isotropic, anisotropic interactions can be induced by some orienting factor.

This idea was proposed rather long ago; however, only experiments using magic angle spinning have been developed. Currently, experiments of a different type are quite topical, namely, those associated with fast controlled orientation/disorientation of the molecule. One of these experiments which uses orientation in an electric field^{165–167} was mentioned above.

It is noteworthy that NMR studies of oriented biomolecules were often preceded by traditional experiments in isotropic media. In many cases, this is a necessary phase because well-developed NMR procedures making use of orienting media are often missing. This is especially true for identification of the resonance signals of a primary sequence. However, another existing tendency is to make NMR spectroscopy of oriented molecules all-sufficient, *i.e.*, to develop a method which would allow determination of the structure of a biomolecule relying only on the measurements in an aligned phase.⁴⁶ However, we rather believe that both types of experiments, those in oriented and isotropic states, should supplement each other.

Below we discuss the experiments in which NMR spectra of weakly aligned molecules have been recorded; attention is focused

on methods specific to these molecules. In terms of the value to be measured, the experiments can be classified into those determining RDC, CSA and QCC.

2. Determination of the residual dipolar coupling constants

The possibility of measuring the RDC for biomolecules accounts for the interest in the NMR spectroscopy of weakly aligned systems.^{47,235}

The weak orientational contributions to the measured spin–spin coupling constants can be distinguished most easily for directly linked nuclei, which are located at the shortest distances and, hence, have the largest dipolar contribution. The pairs of nuclei encountered in biomolecules are H–C, H–N, C–C and C–N. However, due to low natural abundance of the required magnetic isotopes, one must use isotope-enriched specimens.

Almost any type of procedure for precise determination of spin–spin coupling constants developed to date is suitable for RDC determination. First of all, these are experiments based on E COSY (Exclusive COSY) or *J*-correlations and their modifications.

As a rule, RDC are determined in 2D or pseudo-2D experiments from the difference between the splittings of the scalar constant *J* in isotropic and aligned phases. In the case of large protein molecules where analysis of the results of 2D experiments is difficult (especially, if the protein contains predominantly α -helices), 3D NMR experiments are carried out.

In principle, dipolar constants can be measured between any pair of magnetic nuclei with a significant interaction but in practice, only several pairs are taken.

The first RDC between directly linked nuclei to be used were the ^1H – ^{13}C and ^1H – ^{15}N constants.^{45,141} Currently, the RDC between these nuclei constitute the major array of values measured in the NMR spectroscopy of weakly aligned biomolecules. Their interpretation in structural studies is simple because the distances between directly linked nuclei in biomolecules are well known and are virtually constant. This allows unambiguous determination of the orientation of the bond vector relative to the direction of the magnetic field. In $^{15}\text{N}/^{13}\text{C}$ -enriched proteins, one can determine the bond vector for any pair of interacting nuclei (except for oxygen). This information, which can be supplemented by the data from conventional isotropic experiments, is often sufficient for a considerable increase in the accuracy of structure calculations.

Although each of these RDC determines the orientation of the bond vector for one pair of nuclei, the total structure of the biomolecule still remains uncertain, no matter how many constants are known, because they do not contain translational information.

The next step was to use the ^1H – ^1H RDC.^{218,219} Unlike the RDC for heteronuclear pairs, ^1H – ^{13}C and ^1H – ^{15}N , which determine the orientation of vectors connecting these nuclei, the constants for the ^1H – ^1H pair simultaneously bear information on the distances between the nuclei (up to 7.4 Å).²¹⁹

In the presence of scalar and residual dipolar couplings, the efficiency of transfer in different types of homonuclear mixing (isotropic or dipolar) depends appreciably on the relative magnitudes of the constants.^{236–238} In the general case, efficient transfer for all possible relative values of the indirect and dipolar constants requires two different mixing sequences (Hartmann–Hahn and COSY).²³⁹

Today, in a typical study of a biomolecule by NMR spectroscopy, numerous experiments of different types are carried out to determine the RDC for both directly linked and remote nuclei. The procedures for RDC measurement are being further developed by adding new nuclei, for example, ^{19}F (see Ref. 240). The TROSY technique developed recently for increasing the resolution and sensitivity was immediately used in experiments for the determination of RDC,²⁴¹ in particular, in HSQC (Heteronuclear Single Quantum Coherence),²⁴² HNCO (3D ^1H , N, C' Heteronuclear Correlation Experiment),^{243,244} HN(CO)CA (3D ^1H , C',

C $^\alpha$ Heteronuclear Correlation Experiment)²⁴⁵ and other experiments.

Procedures for determining small scalar couplings and dipolar constants in purine or pyrimidine bases in nucleic acids^{246,247} and for detection of internucleotide dipolar couplings²⁴⁸ have been proposed.

a. Dipolar coupling constants between the nuclei separated by one bond

Numerous effective procedures for the measurement of RDC between nuclei separated by one bond have now been developed and used successfully for model proteins, most often, ubiquitin. Specific features of the application of these procedures to particular pairs of nuclei in biomolecules have been considered in detail in a number of publications. In proteins, these are RDC for N–H $^{\text{N}}$ (see studies^{140,241–243,249–257}), C $^\alpha$ –H $^\alpha$ (see studies^{177,251,253,258–261}), C $^\alpha$ –C' (see studies^{241–245,253,259,261,262}), C $^\alpha$ –N (see studies^{241,244,252,253,255,263}) and C'–N (see studies^{241,243,244,257}) pairs in the backbone and the C $^\beta$ –H $^\beta$ (see studies^{259,260,264}), C $^\alpha$ –C $^\beta$ (see studies^{244,245,259}), C $^{\text{Me}}$ –C and C $^{\text{Me}}$ –H pairs in the side chains.^{265,266} Many procedures are applicable to the determination of various types of constants and some allow one to measure simultaneously a number of constants.^{252,253} Special procedures for measuring the constants characterising particular groups, for example the side-chain NH $_2$ groups in asparagine and glutamine are being developed.²⁶⁷

The direct RDC in proteins are interpreted as values determining the direction of the vector of the corresponding bond, the bond length being considered constant. In particular, the C–H length is 1.095 Å, N–H is 1.02 Å, C $^\alpha$ –C' is 1.525 Å, C–C is 1.517 Å, N–C $^\alpha$ is 1.329 Å and N–C' is 1.45 Å.

In the case of ^{15}N -enriched RNA and DNA, one can determine only a limited number of ^1H – ^{15}N RDC, because imine-group protons usually undergo fast exchange. Therefore, it is more convenient to use ^1H – ^{13}C RDC for usual or ^{13}C -enriched specimens.²⁶⁸ Some C–H resonance signals of nucleic acids overlap appreciably even in 2D spectra, and special 3D experiments have been developed to resolve the signals.²⁶⁹

An elegant E COSY procedure of the S ^{3} E (Spin State Selective Excitation) type, which was called IPAP (In-Phase/Anti-Phase) procedure, has been proposed.²⁵¹ This procedure was successfully used in ^1H -coupled [^{15}N , ^1H]-HSQC and HN(CO) experiments, which made it possible to record in-phase and anti-phase *J*-coupled NMR spectra that supplement each other. The sum of and the difference between these spectra contain either only the high-field or only the low-field component of the doublet; therefore when they overlap, *J*-splittings can still be measured and the resolution does not deteriorate compared to that in the decoupled spectrum.

In most studies, different constants are found in different experiments. However, many specimens are unstable; moreover, the orientation of molecules in them can change. Therefore, 3D procedures have been developed; they allow one to measure several RDC of different types within a single experiment.²⁷⁰

Ottiger and Bax²⁵³ measured simultaneously four RDC between directly bonded nuclei in the backbone of the $^{13}\text{C}/^{15}\text{N}$ -enriched ubiquitin molecule. The results were in good agreement, especially with the N–C' and C $^\alpha$ –C' RDC. The distances found using these constants coincided with the corresponding X-ray diffraction data, while the N–H $^{\text{N}}$ and C $^\alpha$ –H $^\alpha$ distances proved to be somewhat longer. The researchers attributed this to vibrations whose amplitudes are much greater than the N–C' and C $^\alpha$ –C' vibration amplitudes.

The ^1H – ^1H coupling, resulting in line broadening in the spectra of oriented specimens, can be eliminated by using either adiabatic ^1H -selective homonuclear decoupling²⁵⁴ or partial deuteration.

The measurement of the C'–N RDC is faced with some difficulties due to low gyromagnetic ratios of the nitrogen and carbon nuclei and to the longer C'–N distance (1.33 Å). The

$D_{C'N}$ value is 8.3 times lower than D_{NH} . Therefore, the accuracy of determination of $D_{C'N}$ by this method can be considered to be critically low.²⁵³

The $D_{C'N}$ constant is usually determined from the difference between the $^1J_{C'N}$ splitting in isotropic and oriented phases, or from the in-phase splittings in HSQC (or TROSY) $^{13}C'$ -coupled spectra,^{252,253} or from the anti-phase splittings in TROSY–HNCO $^{13}C'$ -coupled spectra.²⁵⁵ However, due to the insufficient resolution of many of the ^{15}N – $\{^{13}C'\}$ doublets, their splitting cannot be measured with the required accuracy. To solve this problem, Permi and Annala²⁴¹ proposed that the doublet components should be displayed in two different sub-spectra (this is done in a similar way in the IPAP and S³E procedures described above).²⁵¹

A different, more facile method for solving the problem of precise measurement of splittings in poorly resolved multiplets based on J -correlation spectroscopy principles has been proposed.²⁶³ According to this method, the value of interaction is determined from the ratio of the amplitudes of two resonances rather than from the difference between the resonance frequencies. To this end, relative intensities of the signals in two 3D TROSY–HNCO spectra with different $^1J_{C'N}$ dephasing gaps, equal to $1/2^1J_{C'N}$ and $1/1^1J_{C'N}$, are found. The researchers also proposed a different, perhaps, more facile, way of recording two CT TROSY (Constant Time TROSY) ^{15}N – ^1H spectra, namely, with $^{13}C'$ -decoupling or with a 180-degree pulse at the $^{13}C'$ frequency applied simultaneously with the ^{15}N -pulse shifted by 180°.

Yet another modification of the HNCA–TROSY experiment allows the assignment of the signals of atoms along the biomolecular chain, together with the possibility of measuring the scalar and dipolar constants.²⁷¹

A procedure of spinning the specimen at different angles has been developed for fast determination of the sign of the ^1H – ^{13}C RDC.²⁷²

b. Dipolar coupling constants between the nuclei separated by several bonds

The above described experiments are suitable for determination of only RDC for directly linked atoms. The measurement of homonuclear and heteronuclear RDC through several bonds is hampered not only due to their lower values but also due to the lower values of spin–spin coupling constants.²⁷³ Nevertheless, in some studies, this is done using the procedures designed for the measurement of RDC of directly bonded nuclei. In particular, procedures for determination of C' – H^N (see studies^{241,243,252,257,274}), C^α – H^N (see studies^{241,243,244,274}), N – C^α (see studies^{241,244,274}), N – C' ^{243,252,274} and C^α – C' ^{243,274} RDC, the H^β – H^β and H^N – H^N RDC for side chains^{264,274,275} and H – H RDC for methyl groups²⁶⁵ have been developed.

Two-dimensional two- and zero-quantum experiments for the measurement of geminal spin–spin coupling constants and RDC in the NH_2 and CH_2 groups of proteins and for the determination of the signs of these constants have been described.²⁷⁴

Vicinal RDC in proteins were measured most often for the H^α – H^N , C^α – H^N , C' – H^N and C^δ – H^N pairs.^{244,276} Special J -correlated 2D spectroscopy techniques²⁷⁷ and a new CT COSY (Constant Time COSY) type experiment²⁷⁸ have been elaborated to measure the vicinal $^1H3'$ – ^{31}P RDC for nucleic acids.

Below, we describe in more detail the works devoted to measurement of vicinal ^1H – ^1H RDC.

The procedures described above designed for measuring the RDC of directly bonded atoms are poorly applicable to the ^1H – ^1H coupling due to low values of the corresponding J -constants. Nevertheless, numerous methods for determining these RDC in overlapping multiplets have been developed, because these constants allow one to determine longer distances than the methods based on NOE.²¹⁹ A special 2D experiment has been proposed on the basis of the TOCSY (Total Correlation Spectroscopy) pulse sequence and called DCOSY (Dipolar Coupling

Spectroscopy). The technique is based on the dependence of the direct cross-peak intensity on the RDC value. In this procedure, usual cross-peaks displayed in the spectra can be distinguished from the peaks of the relayed coherence transfer because they have different signs. A problem arises in the case of superposition of cross-peaks of these two types because signal deconvolution is impossible; this restricts the scope of the experiment.

The multiple relay cross-peaks are eliminated in another simple method for estimation of the ^1H – ^1H RDC based on analysis of the diagonal and cross-peak intensities in CT COSY experiments.²⁷⁹ However, since the cross-peaks in this experiment are anti-phase or out-of-phase, their integration is often faced with difficulties. Therefore, a 3D variant with additional ^{15}N -editing has been developed;²⁸⁰ the sensitivity of this method is not inferior to that of the NOE-based method. Another method for determining the ^1H – ^1H RDC in CT COSY experiments is based on the time dependence of the zeroing conditions for proton–proton cross-peaks.²⁸¹

Apart from methods based on estimation of the cross-peak intensities, special methods for direct determination of the sign and the magnitudes of the ^1H – ^1H RDC from the splittings measured in the spectra have also been developed.^{274,282}

An HNCA type experiment with observation of E COSY between the H^N and H^α protons has been developed.²⁸² Unfortunately, this method is applicable to the precise determination of the values and signs of RDC only between H^N and H^α .

Peti and Griesinger²⁸³ have further developed this method into a three-dimensional one by adding a NOESY (Nuclear Overhauser Enhancement Spectroscopy) stage. Their method, called JHH NOESY (J_{HH} -based NOESY), requires a minimum isotope enrichment and can be combined with elements of the S³E experiment for further spectral resolution enhancement.

An advantage of another 3D experiment (HNHA) developed for the measurement of unresolved RDC between the protons of amide groups and other protons in ^{15}N -enriched protein molecules is the possibility of using homonuclear decoupling and the TROSY procedure, which allows one to study large oriented proteins.²⁸⁴ Yet another simple and reliable method for the measurement of proton–proton RDC in the spectra with unresolved but not very large multiplets is based on iterative analysis of the shapes of multiplets in phase-sensitive COSY spectra.²⁸⁵

The signs of ^1H – ^1H RDC depend on the orientation of the proton–proton vector with respect to the external magnetic field, and their determination is often difficult, especially in the absence of scalar coupling between the protons or if the protons do not have a common partner through the bonds. Therefore, a very convenient JHH TOCSY (J_{HH} -based TOCSY) type experiment has been developed and called 'signed COSY'.²⁸⁶ This method determines the sign of the ^1H – ^1H RDC with respect to the sign of the ^1H – X direct coupling constants in linear X – ^1H – ^1H three-spin systems ($X = ^{13}C$ or ^{15}N). The advantages of this method include high sensitivity and the possibility of diagonal peak suppression, cross-peaks being observed only between the directly interacting protons.

Recently, it was found unexpectedly that the signs and magnitudes of the H^N – H^α RDC can be determined even in a usual homonuclear COSY experiment.²⁸⁷ It was found that only RDC with positive signs are manifested in the spectrum, while cross-peaks corresponding to negative RDC are either missing or greatly broadened and can be easily identified.

3. Measurement of the chemical shift anisotropy

The chemical shift is a tensor value. It is anisotropic, only the average value being observed for an isotropic liquid. In a study of a single crystal, all the six components of the symmetrical tensor can be found experimentally by measuring the values along the principal axes of the crystal. Only diagonal elements can be determined for a powdered specimen. However, due to the pronounced line broadening in the NMR spectra of solids, the accuracy of these measurements is low. Liquid crystals have some

advantage in this respect, although only a linear combination of diagonal elements can be determined.

The chemical shift anisotropy $\Delta\delta$ for each nucleus on passing from isotropic into an oriented state is determined using the relation

$$\Delta\delta = \sum_i \sum_j A_{ij} \delta_{ii} \cos^2 \theta_{ij},$$

where θ_{ij} is the angle between the principal axis of the chemical shift tensor δ_{ii} and the principal axis of the diagonalised molecular alignment tensor A_{ij} ; summation involves all i and j .

The $\Delta\delta$ value is a key parameter in investigations of biomolecular structures by solid-state NMR and in relaxation measurements to study chain dynamics. The correlation between the CSA and dipolar coupling provides important information about the angles⁶⁷ and is a key value in TROSY experiments.²⁶

The $\Delta\delta$ value for aligned biomolecules can be directly measured. In this case, the change in the chemical shift induced by transition of a biomolecule from the isotropic phase to the aligned phase provides information on the orientation of the CSA tensor of this nucleus with respect to the molecular alignment tensor.¹⁷⁵ In order to use this information, one has initially to find the components of the order parameter tensor of a biomolecule (which can be determined, for example, from RDC) and the principal components of the CSA tensor for the given nucleus (which can be determined from solid-state experiments or calculated if the structure of the protein under study is known). The measured differences between the chemical shifts of the isotropic and oriented molecule are converted into values describing the orientation of the vectors of a pair of bonds relative to the order parameter tensor. For example, for $^{13}\text{C}'$ nuclei of the carbonyl groups in the proteins, the vectors of the $\text{C}'-\text{O}$ and $\text{C}'-\text{N}$ bonds can serve as this pair;²⁸⁸ for phosphate ^{31}P atoms in nucleic acids, these are $\text{P}-\text{O}(1)$ and $\text{P}-\text{O}(2)$ bond vectors.²⁸⁹

The possibility of using the CSA parameter, together with RDC, in the structural studies of biomolecules was first indicated by Tjandra and Bax;⁴⁵ the same researchers confirmed this experimentally.¹⁴¹

According to Ottiger *et al.*,²⁹⁰ the average $\Delta\delta$ value for the ^{15}N nucleus in the amide group in protein molecules is -168 ± 20 ppm and the angle α between the $\text{N}-\text{H}$ bond vector and the principal axis of the ^{15}N CSA is $13 \pm 5^\circ$. A more thorough determination of the ^{15}N $\Delta\delta$ for the lysozyme molecule confirmed the legitimacy of using the average $\Delta\delta$ and α values in proteins:²⁹¹ values of -171.5 ± 2.2 and $18.3 \pm 0.8^\circ$, respectively, were found.

A correlation between the $^{13}\text{C}^\alpha$ CSA and elements of the secondary structure of the biomolecule has been established.²⁹² The $\Delta\delta$ value for C^α atoms in α -helices was found to be 6.1 ± 4.9 , that for β -sheets is 27.1 ± 4.3 ppm.

The procedure for involvement of CSA values in structure determination has been substantiated and developed taking the CSA of carbonyl groups (which can be easily measured) as examples.^{288, 293} The increase in the structure accuracy attained thereupon was estimated.

In a series of studies, Tjandra and Bax and co-workers justified the possibility of inclusion of this type of information, namely, the CSA of the amide nitrogen atoms,²⁹⁰ carbonyl C' atoms²⁹³ as well as C^α (see Ref. 292) and $^1\text{H}^\text{N}$ (see Ref. 294) atoms into standard procedures for structure determination of biomolecules.

Particular examples of using CSA can be found in subsequent publications. The $\Delta\delta$ value for the carbonyl-group C' atom was used as a restraint in the well-known XPLOR programme.²⁹⁵

In metal-containing proteins, so-called pseudocontact paramagnetic shifts appear due to the presence of a paramagnetic centre;²⁹⁶ these can be used as additional structure constraints. These constraints were taken into account in determining the structures of a number of protein biomolecules. Owing to the pseudocontact shifts, one can exactly determine the position of the

metal ion in a protein and to determine the components of the magnetic susceptibility tensor of a protein.^{158, 297}

4. Measurement of the quadrupole coupling constants

Nuclei with a spin of $> 1/2$ possess a nuclear electrical quadrupole moment and interact with an electric field gradient. This interaction is described by the second-range quadrupole coupling tensor $\mathbf{q}$. Its z -component, defined as

$$q_{izz} = \frac{eQ_i V_{izz}}{h},$$

where eQ_i is the quadrupole moment of an i th nucleus, V_{izz} is the element of the electric field gradient tensor at the i th nucleus, can be manifested in the NMR spectra.

The quadrupole coupling constant can be found from line splitting in the NMR spectrum and order parameters of the molecule in the nematic phase. Since a QCC depends only on the electronic properties of the ground state and the nuclear electric quadrupole moment, it bears information on the electronic structure around the nucleus under study. The QCC values found from the quadrupole splitting observed in the nematic phase can be used to determine the orientational and geometric parameters of the molecule.

The tensor $\mathbf{q}$ has a zero trace and, therefore, it has almost no influence on the NMR spectra in isotropic solutions, except for line broadening in some cases. Line broadening is also observed in anisotropic solutions, but simultaneously, additional splittings appear due to the non-zero average q_{izz} .

In practice, this splitting is not observed for most of the quadrupole nuclei due to fast relaxation. The iodine, bromine and chlorine nuclei, having very high eQ_i values, cannot furnish resolved NMR spectra unless the symmetry or alignment are such that they give relatively small V_{izz} . In the case of ^2H and ^{14}N nuclei, the eQ_i value is much smaller; therefore, quadrupole splitting can be observed in anisotropic solvents (however, the relaxation rate for ^{14}N is most often too great for observing a high-resolution spectrum).

The most convenient nucleus is deuterium with a much smaller nuclear quadrupole moment and moderate line broadening. Therefore, well resolved dipole–dipole interactions between protons and deuterons can be observed in a proton spectra of partially deuterated compounds. It should be noted that ^2H NMR spectra often do not display resolved dipole splittings, mainly due to the fact that deutron–deutron interactions are 36 times weaker than the corresponding proton–proton interactions.

Quadrupole couplings are much stronger than dipolar couplings under the same experimental conditions; therefore, they could be an alternative to the latter in the structural studies of weakly aligned biomolecules. In this case, deuterium is also the nucleus of choice. However, low sensitivity (100 times lower than the sensitivity of a proton), together with low natural abundance in biomolecules (667 times less than that of hydrogen) restrict its practical use.

The dependence of quadrupole couplings on the degree of alignment of molecules shows itself in the quadrupole splittings of signals. In NMR experiments with oriented molecules, these splittings are used only to confirm and measure the ordering of the lyotropic LC phase.

The quadrupole coupling constants of deuterium in $^{13}\text{C}/^{15}\text{N}$ -enriched proteins dissolved in D_2O , in which all the protons of amide groups are subject to exchange with solvent deuterons, can be used to describe $\text{N}-^2\text{H}\cdots\text{O}=\text{C}$ hydrogen bonds, moreover, in non-oriented specimens.²⁹⁸ This is done relying on the dependence of the relaxation time T_1 for deuterium on QCC, which, in turn, depends on the length of the hydrogen bond and the angle between the amide and carbonyl bonds.

The use of QCC for investigations of weakly aligned biomolecules became possible owing to the recently developed procedures for partial deuteration. However, line broadening caused by

quadrupole relaxation and non-resolved dipole splittings in the NMR spectra make QCC less promising than RDC. Nevertheless, using the procedure for measurement and interpretation of ^2H quadrupole splittings in the spectra of partially deuterated and oriented proteins reported by Mittermaier and Kay,²⁹⁹ one can observe the ^2H quadrupole splittings of the side-chain methyl groups in a protein molecule.

The possibility of using QCC for determining the structure and dynamics of weakly aligned deuterated carbohydrates has been demonstrated.³⁰⁰ A special pulse scheme of ^1H – ^2H 2D experiment was developed, and good prospects for this procedure for investigation of small carbohydrate molecules were shown. This requires, however, partial deuteration and ^{13}C -enrichment of the molecules. The applicability of this scheme to large biomolecules is also restricted by the ^2H relaxation times.

VI. Strategy of structure determination for weakly aligned biomolecules by NMR spectroscopy

1. Algorithms of structure calculation

Different types of information are used to determine the structure of a biomolecule. An algorithm for structure solution³⁰¹ implies minimisation of the system total energy function E_t

$$E_t = E_c + E_{vW} + E_{\text{NMR}},$$

where E_c determines the covalent geometry (bond lengths, angles, planarity, chirality); E_{vW} takes into account contacts without covalent bonding (for example, repulsion or some empirical functions including the Lennard–Jones, electrostatic and hydrogen bond potentials); E_{NMR} describes the experimental NMR restraints which are established during different NMR experiments carried out in different media.

The last term E_{NMR} consists (arbitrarily) of three terms

$$E_{\text{NMR}} = E_i + E_a + E_{\text{DB}},$$

where E_i includes the NMR parameters which do not depend on the orientation; E_a includes the orientation-dependent NMR parameters; E_{DB} corresponds to empirical information found in structural databases.

The term E_i involves the NMR parameters determined from isotropic spectra. In particular,

$$E_i = E_O + E_J + E_{J_{\text{CH}}} + E_{J_{\text{CC}}} + E_{C(\text{shift})} + E_{H(\text{shift})} + \\ + E_{\text{relax}} + E_{N(\text{relax})} + E_{\text{CCR}} + \dots$$

Here, E_O takes into account the NOE cross-peaks; E_J is for the vicinal ^3J constants; $E_{J_{\text{CH}}}$ corresponds to $^1J_{\text{CH}}$, $^2J_{\text{CH}}$ and $^3J_{\text{CH}}$ constants; $E_{J_{\text{CC}}}$ includes the $^1J_{\text{CC}}$, $^2J_{\text{CC}}$ and $^3J_{\text{CC}}$ constants; $E_{C(\text{shift})}$ includes the C^α and C^β chemical shifts; $E_{H(\text{shift})}$ is the term for proton chemical shifts; E_{relax} is the ratio of the ^{13}C and ^2H relaxation times; $E_{N(\text{relax})}$ is the ratio of the T_1/T_2 relaxation times for the ^{15}N atom; E_{CCR} takes into account cross-correlated relaxation data, etc.

For each term in the function, a potential is introduced. Usually, it has the form

$$E = k(\delta_{\text{calc}} - \delta_{\text{obs}})^2,$$

where k is the force constant, and δ_{calc} and δ_{obs} are the calculated and measured values of the corresponding energy, respectively.^{141, 302}

Now we consider the E_a term in more detail

$$E_a = E_d + E_{\text{CSA}} + E_{\text{QCC}} + \dots,$$

where E_d represents the RDC for the ^{15}N – ^1H , ^{13}C – ^1H , ^1H – ^1H and ^{15}N – ^{13}C pairs; E_{CSA} is the chemical shift anisotropy; E_{QCC} are the quadrupole couplings.

A set of so-called distance and angle restraints for the molecule under study is formed from the different-type data obtained in NMR experiments; these restraints are used in the iteration procedure for minimisation of the total energy of the biomolecule

in order to find the global energy minimum. This procedure, called adjustment, may use various methods developed in molecular dynamics. The ‘simulated annealing’ technique is the most popular.

The result of adjustment is evaluated using numerical performance criterion.³⁰³ In crystallography, the R -factor — a quantitative estimate of the degree of agreement between the measured and calculated reflections — is a key criterion of the quality of structure determination. It is defined as

$$R = \sum \frac{|A_{\text{exp}} - A_{\text{calc}}|}{|A_{\text{exp}}|},$$

where A_{exp} and A_{calc} are the experimental and calculated values, respectively. A similar criterion can also be defined for the set of RDC. However, introduction of the R -factor in the same form is impossible for RDC, because the dipolar coupling tensor is unitary; hence, the average $|A_{\text{exp}}|$ value will be zero.

It has been proposed²⁹³ to define the Q -factor for CSA in the form

$$Q = \frac{\text{rms}(\Delta\delta_1 - \Delta\delta_2)}{\text{rms}(\Delta\delta_1)},$$

where the numerator is the root-mean-square difference between the measured ($\Delta\delta_1$) and predicted ($\Delta\delta_2$) values.

This criterion is also applicable for RDC and for other orientation-dependent values. However, for these, it is not quite convenient for interpretation. Although in the case of full fitting, its value is 0, the value for completely random structure is $\sqrt{2}$. Therefore, the following R -factor was proposed for RDC:³⁰³

$$R_{\text{dip}} = \left[\frac{\langle (D_1 - D_2)^2 \rangle}{2\langle D_1 \rangle^2} \right]^{1/2},$$

where D_1 and D_2 are the predicted and calculated RDC values.

This fitting criterion is smaller than the previous one by a factor of $\sqrt{2}$. Theoretically, this quality criterion corresponds to the case where the distribution of bond vectors is completely random, while their number is infinite. In reality, the vector distribution is not entirely random, the number of measured values is small and the $(2\langle D_1 \rangle^2)^{1/2}$ value determined experimentally is not equal to the expected root-mean-square difference between the measured and predicted values. Therefore, in the same publication,³⁰³ a different quality criterion was proposed to take into account the pattern of distribution of the vectors

$$R_{\text{dip}} = \left[\frac{5\langle (D_1 - D_2)^2 \rangle}{2A_a^2(4 + 3\eta^2)} \right]^{1/2},$$

where A_a is the axial component of the order parameter tensor and $\eta = A_r/A_a$ is its rhombicity.

The success of using NMR spectroscopy techniques for determination of the structures of biomolecules is largely determined by the possibility of automation. With the development of multidimensional methods and triple resonance experiments, signal assignment procedures and 3D structure determination were consecutively automated. This process is currently in progress and there are grounds to believe that in the near future, NMR would be competitive with X-ray in the determination of the 3D structure of biomolecules regarding not only the accuracy but also the duration and cost.³⁰⁴

Now we consider a typical procedure used to analyse the spectra taking protein structure determination as an example.

First, automated processing of the multidimensional spectrum is carried out in order to identify, describe and catalogue all the observed signals and also to verify them (distinguish real signals from possible artifacts).

The next stage is to assign the identified signals to particular members of the primary sequence; this is accompanied by identification of secondary structure elements in the biomolecule. This is

done using information for homologous molecules with a known structure. The secondary structure elements are recognised or confirmed using known chemical shifts, J -constants, specific NOE signals and hydrogen bonds. The use of $^1\text{H} - ^1\text{H}$ RDC in standard calculation programmes is faced with some problems, because the corresponding distances and angles with the magnetic field are unknown for most protons, unlike the constants through one or two bonds. Therefore, the procedure for the calculation of a biomolecular structure should envisage the possibility of varying both the length and orientation of the internuclear vector. In particular, it was shown for ubiquitin that inclusion of the $^1\text{H} - ^1\text{H}$ RDC in the calculation markedly increases the accuracy of the structure determination.³⁰⁵

Finally, the last stage is determination of the 3D structure of the protein. Of prime importance in this stage is the problem of folding. Homologous structures for folding are found by searching through databases (see below).

An algorithm for fast packing of the already known elements of the secondary structure of the protein molecule to form a protein fold using the residual RDC has been developed:³⁰⁶ first, the relative orientations of the secondary structure elements with respect to one another are determined, then, using data on the elements located at short distances, the packing of secondary structure elements is completed.

The inclusion of the option of RDC analysis into the Rosetta *ab initio* programme allows one to solve the protein folding problem relying only on these constants, without using additional information.³⁰⁷

Tian *et al.*³⁰⁸ developed a strategy of simultaneous resonance assignment and folding of the protein molecule based on RDC measurements. This strategy allows rather quick and reliable identification of most signals in the NMR spectrum and provides a good initial approximation for the structure of a biomolecule on the basis of brief information on the chemical shifts and vicinal constants. This sharply accelerates the NMR structure determination procedure for proteins. Another similar strategy³⁰⁹ is based on a single 3D triple-resonance experiment (HA)CANH.

In the general case, information of different types can be used as the initial data:

- distance restraints found in the analysis of multidimensional NOESY spectra;
- torsion angle restraints determined from experimental and/or statistical data including data from relaxation experiments, NOESY, chemical shifts, and spin – spin coupling constants;
- residual dipolar couplings, CSA and QCC;
- distance restraints from the data on disulfide bridges and hydrogen bonds.

There exist several algorithms for structure determination using this set of data embodied in different computer programmes.^{141, 301} Most of the conventional programmes were developed before the experiments with oriented biomolecules were carried out. As spectroscopic information on oriented molecules was accumulated, these programmes were upgraded. In particular, the XPLOR programme was modified,^{302, 305} the algorithms for inclusion of RDC information into the CNS programme were developed,³¹⁰ and the DYANA programme was supplemented by the PSEUDYANA module designed to take into account the pseudo-contact shifts.^{154, 158, 297} New versions of these programmes contain all the parameters determined from the NMR spectra of oriented biomolecules.

An important component of the structure determination for a biomolecule is graphical visualisation of molecular structures. This is done, most often, using the graphical viewers MOLMOL, GRASP, RASMOL, WHATIF and MIDAS. For the computation and visualisation of the structures of biomolecules from different-type NMR data, the combined VMD–XPLOR programme package was developed;³¹¹ The special IVM module, which allows use of the intrinsic coordinates instead of Cartesian ones, was designed to accelerate the adjustment procedure.³¹²

The interactive MODULE programme,³¹³ which permits one to determine order parameters for macromolecules and for multi-domain systems and complexes on the basis of RDC, is an excellent add-in to the existing programme packages used in the molecular simulation.

The achievements and prospects for the development of research into the theory and calculation of the structures of biomacromolecules using NMR data have been covered in detail in reviews.^{304, 314}

2. Dipolar coupling and the order parameter tensor

Dipolar coupling is a unique feature of matter which provides information on molecular structure and dynamics. The dipolar coupling between the spins of nuclei i and j situated in a magnetic field is characterised by the dependence on the distance r_{ij} between them and on the angle θ between the internuclear vector $\mathbf{r}_{ij}$ and the magnetic field (Fig. 3)

$$D_{ij} = \frac{K(3 \cos^2 \theta - 1)}{2r_{ij}^3},$$

where $K = (h\gamma_i \gamma_j / 4\pi^2)$ is the constant depending on the gyromagnetic ratios γ_i , γ_j of nuclei i and j , respectively.

Figure 3. Scheme representation of the parameters used for determination of the dipolar coupling and elements of the Saupe order matrix; i and j are nuclei located in magnetic field $\mathbf{B}_0$; θ is the angle between the internuclear vector $\mathbf{r}_{ij}$ and the magnetic field direction; (x, y, z) is a molecular-fixed system of coordinates; θ_x , θ_y , θ_z are the angles between the corresponding molecular axes and the magnetic field direction; α_x , α_y , α_z are the angles between the vector connecting the nuclei i and j and the molecular axes x , y , z .

Dipolar couplings occur both between the nuclei of one molecule and between the nuclei of neighbouring molecules. In an isotropic medium, rigid molecules are arranged chaotically and execute chaotic translational and reorientation motion; therefore, dipolar coupling is averaged over the whole molecular ensemble and over the observation time, *i.e.*,

$$D_{ij} = K \left\langle \frac{3 \cos^2 \theta - 1}{2r_{ij}^3} \right\rangle$$

(the angled brackets mean averaging over time and over all the possible orientations and distances).

Apart from participation in the molecular motion as a whole, the nuclei are involved in the intramolecular motion; the RDC are averaged over these motions, too. Since the characteristic frequencies of these types of motion are substantially different, they are supposed to be not correlated, and these two averaging operations are considered to be independent, *i.e.*,

$$D_{ij} = K \left\langle \frac{3 \cos^2 \theta - 1}{2} \right\rangle \langle r_{ij}^3 \rangle^{-1}.$$

If the magnetic field is uniform (as is normally the case for NMR spectrometers), the translational motions do not influence the averaged constant and it depends only on the reorientation motion and the instantaneous distribution of the molecular axes in the magnetic field.

In an isotropic medium in the absence of aligning factors, the spatial distribution of molecular axes is spherically symmetrical and the times of molecular reorientation are markedly shorter than the characteristic times of an NMR experiment; therefore, in this medium, the dipolar couplings are completely averaged and are not manifested in the spectra because the average $\langle (3 \cos^2 \theta - 1)/2 \rangle$ is zero.

Under the action of aligning factors or when the molecules are placed in an aligned medium, the molecular motion in the specimen becomes anisotropic, the direction along the orientation axis, which is called the director, being the predominant one. The molecules of the compound under study are compelled to move anisotropically even if they do not tend to be oriented along the director. This anisotropic motion, together with the partial alignment along the director is responsible for the fact that magnetic dipole–dipole interactions are observable, because in this case, the average $\langle (3 \cos^2 \theta - 1)/2 \rangle$ value is no longer equal to zero.

Saupe³¹⁵ proposed describing the degree of ordering of a molecule by the value $\langle (3 \cos^2 \theta - 1)/2 \rangle$, which he called the order parameter tensor. This value can range from -0.5 to 1 . Zero corresponds to the absence of orientation and the values 1 and -0.5 correspond to the maximum degrees of alignment along and normal to the direction of the orienting factor, respectively.

Since the magnetic field in a spectrometer has spatially fixed axes, it is convenient to express the components of coupling tensors in this laboratory system of coordinates, which can be converted into a molecular-fixed system of coordinates in different ways, namely, using the order matrix, the formalism of the motion constants or averaged Wigner rotation matrix. In the Saupe scheme, the alignment of molecules is described by a symmetrical order matrix S having a zero trace, whose elements are determined by the expression

$$S = \frac{1}{2} (3 \cos \theta_p \cos \theta_q - \delta_{pq}),$$

where p, q mean one of the Cartesian axes ($p, q = x, y, z$) of a molecular-fixed system of coordinates; θ_x, θ_y and θ_z are the angles between the corresponding molecular axes and the direction of the magnetic field (see Fig. 3); δ_{pq} is the Kronecker symbol ($\delta_{pq} = 1$ for $p = q$ and $\delta_{pq} = 0$ for other cases).

The degree of order along the axis containing two nuclei i and j and having the angles α_x, α_y and α_z with molecular axes x, y and z is determined by the relation

$$S_{ij} = \sum \cos \alpha_p \cos \alpha_q S_{pq}.$$

The 3×3 order matrix is characterised by only five independent elements (because it is symmetrical and has a zero trace, *i.e.*, $S_{xx} + S_{yy} + S_{zz} = 0$). With appropriately chosen molecular axes, the matrix can be reduced to a form in which its elements are independent and their number varies from 1 to 5, depending on the symmetry of the molecule or, more precisely, the symmetry of the system of interacting nuclei. For example, the degree of alignment of highly symmetrical molecules having a threefold (or higher-fold) axis of symmetry can be described by only one independent element of the matrix. The degrees of alignment of molecules having two perpendicular symmetry planes, can be described by two independent elements. When the molecule has only one plane of symmetry, knowledge of the three independent elements of the order parameter matrix is required. In the general case, where the molecule is asymmetric, three elements determine the direction of the principal axis of the tensor with respect to the magnetic field

and the other two describe the degree of orientation along this direction and the degree of orientation in the plane normal to the principal axis. In the system of x, y, z principal axes, the order parameter tensor is diagonal and only two independent values determine the above degrees of orientation: S_{zz} and the asymmetry parameter

$$\eta = \frac{S_{xx} - S_{yy}}{S_{zz}}.$$

Since the symmetry of biomacromolecules is low, as a rule, all five elements of the order parameter tensor need to be known to describe their orientation.³¹⁶ In these molecules, the distances between the directly bonded nuclei virtually do not change and only two independent values determine the orientation, namely, the order parameter and the angle between the bond vector and the magnetic field direction; therefore, these parameters are often called orientational constraints.

For clarity, the orientation of biomolecules is commonly described, instead of S_{ij} tensor components of the order matrix, as is usually done in NMR spectroscopy of small molecules,¹³¹ by the axial A_a and rhombic A_r components of the diagonalised molecular orientation tensor $\mathbf{A}$, *i.e.*, in the system of the principal axes of the tensor of the magnetic susceptibility anisotropy of the molecule and three Euler angles determining the position of the principal axis of this tensor relative to the direction of the magnetic field. In this system, the expression for the RDC between the nuclei P and Q has the form

$$D_{PQ}(\theta, \varphi) = S \frac{\mu_0}{4\pi} \gamma_P \gamma_Q h \frac{A_a (3 \cos^2 \theta - 1) + (3/2) A_r \sin^2 \theta \cos 2\varphi}{4\pi^2 r_{PQ}^3},$$

where θ and φ are the angles for the vectors of the nuclei P and Q in the coordinate system of tensor $\mathbf{A}$, h is the Planck constant, γ_P and γ_Q are the gyromagnetic ratios of these nuclei, r_{PQ} is the distance between them, S is the main order parameter, μ_0 is the magnetic susceptibility of a vacuum.

If the magnetic susceptibility tensor is axially symmetric, then η (or A_r) is equal to 0, and only one parameter S_{zz} (or A_a) determines the RDC, which, in turn, determine the direction of vectors connecting the pairs of nuclei relative to the principal orientation axis. This allows easy interpretation of the dipolar constants, for example, for the DNA molecule or some DNA–protein complexes.¹⁴¹ For the case where the aligned molecules have a nearly axial symmetry, a simple algorithm for including the information on dipolar couplings has been developed using the CNS computation programme as an example.³¹⁷

However, most often, the molecule is not axially symmetrical; therefore, for data interpretation, one should also determine the second component of the tensor, which measures the degree of its deviation from the axial symmetry, *i.e.*, its rhombicity and asymmetry. This is a difficult task for molecules with a small number of magnetic nuclei.

For biomolecules containing a large number of identical pairs of nuclei whose vectors are approximately uniformly distributed in space, this task is markedly easier.³¹⁸ In this case, by analysing the column diagram for the distribution of dipolar couplings (corresponding to the spectrum of a powdered specimen), one can determine unambiguously the axial and rhombic components of the diagonalised tensor (Fig. 4). No preliminary structural information on the biomolecule is required; in this stage, there is even no need to determine the main direction of the tensor.

The same principle underlies a method used to determine components of the diffusion tensor from the T_1/T_2 distribution for ¹⁵N nuclei of the amide groups in the protein molecules.³¹⁹ It should be noted that diffusion and orientation tensors for proteins in bicelles are unidirectional,³²⁰ which can also be used in determining the orientation of a biomolecule.

To evaluate the possibility of determining the tensor components from the set of measurable orientation-dependent param-

Figure 4. Column diagram for the distribution of dipolar couplings (a) and the component of the diagonalised molecular alignment tensor A (b).³¹⁸

ters, a method for analysing the pattern of filling of the orientational space by internuclear vectors has been proposed.³²¹

If only few RDC have been determined for a biomolecule, or they are non-uniformly distributed in space, or they contain several domains with different orientations, the column diagram analysis mentioned above is inapplicable. Therefore, a more advanced procedure for the analysis of the whole set of RDC and determination of the axial and rhombic components of the order parameter has been developed on the basis of the maximum likelihood method.³²²

Determining the orientation of the order parameter tensor relative to the molecule-fixed system of coordinates is a rather complicated problem, which can be solved unambiguously if the structure of the biomolecule is already known. This results in multiple possible orientations of the vectors of each pair of nuclei, corresponding to the mirror reflections relative to each axis of the order tensor (altogether 8). This appreciably complicates the energy hypersurface in searching for the minimum. Finally, the convergence of the iteration is very slow.

Attempts at estimating the order parameter tensor of the biomolecule on the basis of calculation results or specific experiments have been undertaken in a number of studies. The most trivial approach implies a network search among the possible pairs of the parameters A_a and A_r .³⁰²

If data on the biomolecule structure have been derived preliminarily from other experiments, they can be used for more precise determination of the axial and rhombic components of the tensor.^{323,324} Finally, one can do without the preliminary determination of the values of this tensor by including them as variable parameters into programmes for calculation of the biomolecule geometry.³²⁵ In particular, such a modification of the XPLOR algorithm has substantially facilitated the calculation and accelerated its convergence; the obtained results are very close to those found with the conventional algorithm.³²⁶

To simplify the analysis of RDC, a method for predicting the orientational order has been proposed, based on a model taking into account the steric repulsion between the protein molecule and the aligning particles of the LC medium.¹⁹⁷

A more advanced method for predicting the order parameter taking into account only steric effects has been reported;³²⁷ in this method, the protein molecule under study is modelled by an ellipsoid. The principal axes of the orientation tensor and the moment of inertia tensor of the molecule coincide. The other components of the orientation tensor are determined using the standard algorithm for minimisation of the difference between the predicted and experimental RDC. The order parameter tensor differs from the moment of inertia tensor because it has a zero trace. Therefore, when information about the other two axes of the moment of inertia tensor is used to predict the other elements of the order parameter tensor, the eigenvectors of these tensors are taken to be parallel if there are no electrostatic effects.³²⁸ An analytical solution to the problem of alignment of ellipsoidal

particles by planar obstacles has been obtained. If the 3D structure of the protein molecule is known, the order parameters of both the protein molecules incorporated in membranes and the molecules aligned under the action of a magnetic field or an LC medium can be predicted using simple expressions.

In a more convenient algorithm for predicting the order parameter tensor from the moment of inertia tensor, the eigenvalues of the order tensor are proportional to the molecular asymmetry in the planes determined by the corresponding pair of eigenvectors of the moment of inertia.³²⁹ This method, which the authors called TRAMITE (Tracking Alignment from Moment of Inertia Tensors), proved to be very convenient in investigating not only protein molecules but also non-rigid or small molecules.

The relative orientation of the order parameter tensors can be determined without knowing the protein structure on the basis of correlation analysis of two sets of RDC by conducting experiments in two media that orient in different directions.³³⁰ The graphical representation of the correlation map of such sets depends appreciably on the relative orientation of the tensors; therefore, it allows one to obtain a good initial approximation for further analysis of RDC.

A new strategy for the calculation of the 3D structure based on the transformation of a set of RDC into a set of angles between vectors has been developed.^{331,332} The values comprised in this set no longer depend on the direction of the orientation tensor with respect to the molecular axes; they can be used in calculations instead of RDC.

Skrynnikov and Kay³³³ also proposed that a set of pairwise angular restraints independent of the chosen system of coordinates be used instead of RDC. This set proved to be very convenient for evaluating the compliance of the set of RDC with the next structure generated in adjustment programmes. Using n vectors of dipole couplings, $n(n-1)/2$ new values determining the angles between each pair of vectors are composed. In addition, the maximum and minimum values are determined for each angle between the vectors proceeding from the current generated structure. If the vector angle does not fall in the range between these values, it is considered as a mismatch. The total number of these mismatches can serve as a quality criterion for a given structure and can be used in calculations. The compliance of RDC with the structure is visualised by the 'RDC compliance map'. Using this map, it is convenient to evaluate the quality of each generated structural element or domain and its compliance with experimental data.

The procedures considered are based on the strategy of a generalised, model-free order parameter, developed previously for analysing the diffusion tensor in the interpretation of relaxation data.^{334,335}

Yet another method which allows one to solve the problem of ambiguity and to obtain an exact solution for the set of equations with RDC is to convert these equations to elliptical equations in the principal alignment frame.³³⁶

The effects caused by molecular motions of different types that influence the resultant RDC values of a globular protein have been studied by molecular dynamics methods.³³⁷ The structures of biomolecules calculated by virtue of these constants for different models of globule reorientation proved to be model-dependent. It was found, however, that the application of the developed self-coordination procedure to the sets of RDC measured for several (in the ideal case, five) different oriented LC media allows one to determine the structure without making suggestions concerning the pattern of the reorientation motion of the globule. This procedure does not require the simulation of these motions.

Taking rubredoxin as an example, it was shown that two or more different alignment media can be used to remove the degeneracy of orientation parameters when determining the structure of protein molecules (in order to obtain a larger number of parameters).^{338,339}

Actually, the dependence of dipolar couplings on the degree of alignment of the protein molecules and the globule orientation in

the spectrometer magnetic field can be used for obtaining numerous sets of parameters for different directions and magnitudes of the order parameter tensor, for example, in experiments with various aligning factors and also with a change in the conditions affecting the orientation (temperature, relative concentrations of components and additives). However, the sets of parameters determined are often linearly related and do not provide new information.

The precision of NMR determination of the structure of a biomolecule is still inferior to that of X-ray determination. One of the reasons for this is the lack of perfection of the computation algorithms used, which mainly copy the X-ray algorithms. With the progress in NMR techniques, specific computation algorithms that reflect the specific character of NMR experimental data are developed.³⁴⁰

3. The effect of vibrational motions

When the set of RDC is interpreted, the bond lengths are usually assumed to be constant and known for each type of bond. Therefore, the measured RDC describe either the variation in the angle orientation of the mean position of the bond or fluctuations around this mean position. However, RDC-based studies of the structures of small molecules have shown that the effect of the molecular vibrations may be appreciable in some cases.³⁴¹

The influence of vibrational motions on the averaging of RDC has been studied by quantum chemistry methods for direct N–H^N, C^α–H^α, C'–N and C^α–C' RDC and also the RDC between C'–H nuclei separated by two bonds.³⁴² The vibrational averaging was shown to influence the constants and to entail a resultant elongation of the effective bond lengths by 0.5%–3%, the effect of bending or torsion vibrations being more pronounced than the effect of stretching vibrations. The hydrogen bond formed by an amide group also increases the effective N–H bond length. The changes in the effective bond length are fairly small but, nevertheless, they can be used, especially in those cases where RDC from different types of bonds (nuclear pairs) are used to determine the structure of a biomolecule.

4. Databases for energy minimisation and for the search for homology and motifs

The use of homologous sequences with a known structure to generate structural models for a biomolecule is helpful for structural studies.

The most labour-consuming and prolonged stage in NMR investigations of the protein structure is the assignment of signals in the spectra to particular amino acid residues of a known primary sequence. This is especially true for NOESY spectra.

In protein databases, information on the spatial structure of a large number of proteins has been accumulated and the results of processing of numerous NMR spectra are presented. This information can be used for recognising separate structural elements and motifs often repeated in proteins. This is especially useful at the preliminary stage.

Apparently, RDC are the most convenient values that can be measured and used to search for similar images in protein databases. A trivial method is based on comparing the whole set of the N–H RDC measured for a biomolecule with the sets of these constants calculated from known structures deposited with protein databases.³⁴³ Thus in the search for homologies in the PDB, Meiler *et al.*³⁴⁴ created the DipoCoup programme taking into account all types of RDC and even pseudocontact shifts.

Delaglio *et al.*³⁴⁵ have developed a method for the construction of a 3D structure of a protein molecule by means of the search for similar fragments in a specially composed sample from the PDB. The fragment should contain 7 amino acid residues. Comparison is carried out against not only RDC but also chemical shifts taken from a special database for each fragment.

Instead of comparing the whole set of N–H RDC, one can search through databases for structural motifs (fragments) con-

taining, for example, ~20 amino acid residues using image recognition techniques. Andrec *et al.*³⁴⁶ intend to compose a library of structural motifs on the basis of available protein databases for use in RDC-based studies. By applying special fitting criteria (for example, self-consistency of overlapping fragments) for each set of experimental data, one can restrict consecutively the fragment retrieval.³⁴⁷

It is possible to compose a large number of such protocols for the design of a protein structure based on homologies and RDC. However, the information contained in protein and nucleic acid databases can also be used in a different procedure for determining the structures of biomolecules.

The crystal structures of many proteins and nucleic acids have now been established with high accuracy. Analysis has shown that only a few dihedral angles determining the molecular conformation are possible in these structures for energy reasons. This conformational information accumulated as a database can be used for determining the structures of new biomolecules.

In order to select the conformations that are physically realised and described in databases from amongst the possible conformations proposed by the procedure of structure adjustment in experimental results, an additional pseudo-potential is introduced into the energy function in the following form:

$$E_{DB}(i) = -k_{DB}(\ln P_i),$$

where k_{DB} is a scale coefficient or a force constant and P_i is the partial probability that this parameter falls in the allowed range of values.

The introduction of this pseudo-potential into the energy function restricts the possible range of dihedral angles and accelerates the convergence during the iteration procedure.

Similar potentials with one-, two-, three- and four-dimensional potential surfaces describing the degree of likelihood of various combinations of torsion angles have been reported.^{348–355}

The use of such potentials for minimisation is especially efficient for the adjustment of parameters determined from the spectra of oriented specimens, for example, dipolar couplings. In particular, the introduction of this type of potential for describing the positional coupling between pairs of bases in nucleic acids has sharply increased the accuracy of DNA structures determined in NOE-based experiments and using RDC.³⁵⁶

5. De novo structure determination using only residual dipolar couplings

At present, the 3D structure of a biomolecule is commonly determined using NOE. The new NMR techniques developed in recent years are usually considered as auxiliary and are used in those cases where the number of NOE signals is too small. However, the new methods are gradually becoming self-sufficient (without using the NOE data) methods for structure determination.

The method for determining the structure of a biomolecule with the use of only RDC may have been all-sufficient if it was not for the ambiguity of RDC interpretation caused by the fourfold degeneracy and the ambiguity of determination of the order tensor orientation.

An attempt at using only orientation parameters in structural studies was undertaken by Tjandra.³⁵⁷ Subsequently, in a study of cytochrome *c'* (although using several methods), Hus *et al.*³⁵⁸ developed an algorithm that allows the structures of any paramagnetic proteins and complexes to be determined without resorting to NOE data. The algorithm employs the geometric information contained in paramagnetic pseudocontact shifts¹⁵⁸ and cross-correlated Cuire spin–dipole electron–nuclear relaxation^{153,359} as well as the information contained in RDC (only N–H RDC were used). This algorithm underlies the SCULPTOR programme (Structure Calculation using Long-Range, Paramagnetic, Tensorial and Orientational Restraints) meant for determining the structures of biomolecules using only orientation-

dependent data. This algorithm is also applicable to many metal-containing molecules.¹⁴³

An algorithm for determining protein backbone structure on the basis of only RDC has been proposed.⁴⁶ The authors have defined it as MECCANO (Molecular Engineering Calculations using Coherent Association of Nonaveraged Orientations). This is a key study which demonstrates the real possibility of determining the structure of a biomolecule using the set of RDC alone. To solve the ambiguity problem, two sets of RDC were determined for the molecule in the LC media with different orientations and the self-coordination procedure was carried out for all RDC and each peptide plane.

The ambiguity of interpretation of the RDC determined in one experiment has been eliminated by invoking additional information.³⁴⁵ In particular, a new algorithm for the protein folding was proposed, which can be used to attain self-consistency of all sorts of protein fragments during the search and screening of the structures of protein fragments in the database.³⁴⁷

Yet another algorithm using only RDC and the changes in the chemical shifts of carbonyl carbon atoms has been proposed.²⁸⁸

The all-sufficiency of RDC for the structural studies of biological macromolecules by NMR spectroscopy has been proven.³⁶⁰

VII. The use of NMR spectroscopy for the study of the structures of biomolecules

As has been noted in the Introduction, the X-ray and NMR techniques are based on different kinds of physical phenomena and the structural data obtained by these methods supplement each other. X-Ray diffraction analysis produces a three-dimensional map of the electron density of the molecule, which is used to identify the relative positions of atoms (each experimental point on the map bears information on all atoms). An NMR study gives the distances and the angles between some pairs of atoms, which are used to reproduce a set of non-contradictory three-dimensional structures, and each experimental point bears information on the distance between some pair of atoms, or the size of some angle, or on the orientation of some bond vector with respect to a specified direction. In X-ray diffraction studies, hydrogen atoms almost cannot be seen, whereas in the case of NMR, they provide the main bulk of information. In turn, NMR spectroscopy virtually does not determine oxygen and sulfur. Whereas solution of the phase problem by X-ray requires the presence of a heavy atom in the molecule, in the case of NMR, isotope enrichment is needed to replace the non-magnetic ¹²C and quadrupole ¹⁴N nuclei by magnetic isotopes, ¹³C and ¹⁵N, respectively. An X-ray study gives rise to a static (frozen) structure of a biomolecule containing no mobile groups, while NMR allows one to study biochemical processes and the behaviour of flexible groups.

The main achievements and the potential of NMR spectroscopy of weakly aligned molecules in the research into various classes of biomolecules are briefly considered below.

1. Proteins

An advantage of NMR procedures for aligned specimens is the fact that information on the long-range order can be derived from dipolar coupling parameters. This provides a substantial increase in the accuracy of determination of the molecular structures of proteins and protein complexes determined by other NMR techniques.

The number of measured RDC characterising the polypeptide chain is great. It can be markedly increased by replacing non-magnetic nuclei by magnetic isotopes. The efficiency and simplicity of including RDC into the standard set of parameters for determining the 3D structures of not only biomolecules but also their complexes have been convincingly demonstrated in many publications.^{361–367} For example, Gronwald *et al.*³⁶⁸ could determine the structure of the protein kinase Byr2 only after adding RDC to NOE data.

The structure of a very important anti-HIV protein, cyano-virin-N, which binds to the glucoproteins of the viral shell and inhibits their activity, has been studied.³⁶⁹ This protein can become a key point in the development of a new anti-AIDS strategy. The ¹H, ¹³C, ¹⁵N NMR signals were assigned and a twisted folding was confirmed using RDC analysis;³⁷⁰ this is significant for further research into the structure–activity relationship for this protein.

The structure of the signalling human G α interacting protein (GAIP) in solution was determined in two different LC media.³⁷¹ Comparison with the crystal structure of the homologous rat RGS4 protein complexed to the α -subunit of the G protein showed the presence of equally aligned fragments which do not change after binding to G α , indicating that these fragments are not involved in the G α interaction. Comparative analysis of the structures of the bound and free proteins allowed the researchers to represent the binding geometry and the GTPase activation mechanism.

The structure of the DinI protein inhibiting the activity of the RecA protein from *Escherichia coli*, which initiates the repair or mutagenesis of DNA, was also determined in two different LC media (bicelles and phages).³⁶⁶ This made it possible to identify the role of the C-terminal α -helix, which forms a negatively charged ridge on the globule; this mimics electrostatically the DNA phosphodiester backbone and thus it can compete with DNA for binding to RecA.

The structure of hen lysozyme was studied in particular detail in two bicellar LC phases with different orientations;³⁷² comparative analysis with and without RCD data was performed and the importance of RDC restraints has been demonstrated. The protein structure was determined more precisely in this study than this had been done by X-ray crystallography.

Using RDC, it was possible to study the thermal stability of the protein aporubredoxin in the native (metal-containing) and metal-free forms.³⁷³ The native form of the protein proved to be fairly stable over a broad temperature range, while the metal-free form is susceptible to reversible thermal denaturation.

Analysis of the RDC for molecules of denatured proteins in a strained polyacrylamide gel showed that the topology of the native state of some structure elements is retained^{374,375} and is insensitive to the replacement of hydrophobic residues in the amino acid sequence by polar residues of a similar size.³⁷⁶

2. Domain orientation in proteins

The molecules of many proteins consist of two or more packed independent domains. The type of biological process executed by multidomain proteins, for example, enzymic catalysis, often depends on the relative orientation of the domains. Therefore, one of the goals of structural studies is to determine the relative orientation of the domains. The crystal structures of these proteins may differ from the structures occurring in liquids, because the forces acting during crystal packing may change the relative orientation of the domains. By investigating multidomain proteins by liquid-state NMR, one can determine the domain orientation and its changes induced by different factors (*e.g.*, ligand binding or covalent interactions). However, usually, the number of observable domain–domain contacts is small. Therefore, only measurement of the orientation-dependent NMR parameters offers new opportunities for determining the orientation of domains or secondary structure elements for the molecules of non-rigid proteins.

The foregoing can be illustrated by the results of the investigation of a two-domain protein barley lectin.³⁷⁷ First, it was demonstrated that the ¹⁵N–¹H RDC are applicable for determination of the relative domain orientation in the fragment of this protein and the use of the SVD method (Singular Value Decomposition) was theoretically substantiated.³⁷⁸ The orientation of each domain can be determined with a few RDC (five is plenty). The domain orientation and dynamics were studied in different LC media.³⁷⁹ The domain orientation was found to differ from

that determined for a highly homologous protein in the crystal. Furthermore, differences in the order tensor values suggest that the two domains have different reorientational dynamics and can be considered as independently reoriented.

In a study³⁸⁰ dealing with determination of the relative orientation of Zn-finger domains of the TFIIIA protein in the protein–DNA complex, RDC were also shown to be highly sensitive and reliable parameters. After inclusion of RDC, the spread in interdomain angles (thoroughly studied by X-ray, NMR and computer simulation) is reduced from 24 to 9°. However, in this case, too, the local structure of the domains should be known before; moreover its accuracy influences also the accuracy of RDC-based determination of the orientation.

The relative orientation of the monomer subunits in the cyanovirin-N domain-swapped dimer³⁸¹ and the full structure of its monomeric mutant³⁸² were established. This was done using a combination of SVD techniques³⁷⁸ and calculations based on the molecular shape;¹⁹⁷ less than one-third of the total number of RDC was involved. A combination of 'simulated annealing', torsion angle dynamics and rigid-body minimisation proved to be even more successful for determining the full structure of this protein.³⁸³ The combinations of these methods open up good prospects for fast determination of the full structure of homologous or chimeric proteins and structural analysis of mutations if the structure of the main protein is known.

The different orientation of domains in the ribosomal protein S4 Δ41 in the crystalline and liquid states has been demonstrated³⁸⁴ using RDC measured in two different uniaxial LC phases formed by DMPC/DHPC bicelles and bacteriophage Pf1. It was shown that domain orientations determined in the isotropic medium using NOE and in two anisotropic media are identical and the helical subdomain is twisted by 45° around the long axis of the molecule with respect to the subdomain in the crystalline phase.

Orientation of paramagnetic protein metal complexes in the magnetic field has also been used to establish the relative orientation of domains.¹⁴⁴ For this purpose, it is possible, for example, to replace the diamagnetic Ca²⁺ ion in calcium-containing proteins by a paramagnetic Tb³⁺ ion. This replacement virtually does not influence the protein structure as a whole. It was shown that Tb³⁺ is bound in only one of the domains and induces a substantial protein orientation. It is possible to measure not only domain–domain long-range pseudocontact shifts but also RDC.

If the crystal structure of a multidomain protein is known, the relative orientation of its domains in a liquid can be easily determined by measuring the RDC for only some easily identifiable residues incorporated in different domains.³⁸⁵ In particular, this procedure was used to determine the conformation of the complex formed by the maltodextrin-binding MBP protein with β-cyclodextrin containing 370 residues; it was also demonstrated that the relative orientation of its domains in the crystal structure differs substantially (by ~ 11°) from that in the liquid, although the structure of each domain corresponds to that in the crystal. Full structure determination for this protein using RDC, NOE and vicinal constants³¹⁰ confirmed the domain orientation determined by a fast assay.³⁸⁵ Measurements of the diffusion tensor anisotropy³⁸⁶ also confirmed the relative orientation of the domains established using RDC and showed substantial deviations from X-ray data. Finally, the RDC procedure was used to carry out a systematic study of the relative orientation of the domains of free and β-cyclodextrin- and maltotriose-bound MBP proteins.³⁸⁷ The domain orientations for apo-MBP and the MBP complex with maltotriose were found to coincide with the orientation in the crystalline phase, whereas in the case of the MBP–β-cyclodextrin complex, they were found to be different. The authors attributed this to the crystal packing effect.

The discrepancy of the conformations of multidomain proteins determined in the crystal phase and in solution appears to be the rule rather than an exception. Therefore, NMR spectroscopy of oriented biomolecules can be considered to be a unique method

for investigating their conformations in solution. This is especially important in the studies of enzymes and in the search for new drugs.

The ¹³C^α–¹³C^β RDC in ¹⁵N-, ¹³C- and ²H-enriched proteins can also be used to determine domain orientation.²⁴⁵ It should be noted that both intra- and interdomain structures of one of the studied proteins, namely, the maltose-bound protein in the liquid and crystalline states were found to be similar.

The RDC method was used to demonstrate the unique possibility of fast identification of medium- and large-scale interdomain motions in modular proteins.³⁸⁸ Actually, RDC provide information on the relative motions of domains. By using these data, together with structural and relaxation data, one can calculate the amplitudes and time scales of these motions.

In a study of relative orientation of Bacteriophage lysozyme T4 domains using RDC, the averaged conformation of this protein in solution was determined.³⁸⁹ The lysozyme T4 hydrolyses the β(1-4)-glycoside bond in the peptidoglycan substrate, which is bound to the protein in a gap between two domains. The crystal structures of various mutants of this enzyme are characterised by different opening angles, which implies a substantial mobility of the domains. In the native enzyme structure in solution, the opening angle was found to be 17° greater than that in the crystal phase.

A significant deviation (25°) from the crystal structure was found for Ca²⁺-calmodulin.³⁹⁰

The applicability of RDC to investigations of the dependence of functional properties on minor structural differences in homologous series of proteins was demonstrated in relation to the variation of the calmodulin-binding geometry for five different calmodulin-regulated kinases.³⁹¹

Yet another example is determination of the relative orientation of the subdomains of the heparin-binding domain of the vascular endothelium growth factor VEGF₁₆₅; this became possible only after RDC had been included in the analysis.³⁹²

Using RDC, it is also possible to study the dynamics of flexible fragments in non-rigid proteins; the RDC values averaged over various modes of motion are collated with the experimental values. For example, the mutual arrangement and the mobility of three helices in the p8^{MTCP1} protein molecule were determined in this way.³⁹³

The MODULE graphical interactive programme³¹³ mentioned above is convenient for the simulation of multidomain macromolecules. This programme allows each domain to be described by its own set of RDC. By varying domain orientations, one finds the best agreement of the sets of RDC with experimental data.

The methods developed for investigating the relative orientation and the dynamics of separate protein domains can also be used to study the structure and dynamics of individual rigid fragments of various molecular systems, for example, in non-rigid proteins, oligosaccharides and molecular complexes. Evidently, they would also be useful in the study of non-rigid organic molecules and liquid crystals.³⁹⁴

3. Protein–ligand complexes

Determination of the geometry of protein binding to the ligand is important as regards elucidation of the structure–biological activity relationships for proteins.³⁹⁵ The spatial structure of the protein–ligand complex needs to be known for the development of new pharmaceuticals, because this allows the search for a new drug to be target-directed, *i.e.*, aimed at providing the structural and charge complementarity of the required ligand to the active cavity of the protein.

The NMR spectrum of the ligand is usually rather simple and the signals can be readily identified even without isotope enrichment. This is taken into account in the most widely used scheme of investigation of protein complexes which implies the use of ¹⁵N/¹³C-enriched proteins and ligands with natural isotope abundance. Hence, it is possible to use special heteronuclear filtration

and editing methods in experiments for resonance correlations of only the protein, only the ligand, or only through-space protein–ligand couplings.^{24, 396}

Study of the change in the ligand conformation upon binding in protein complexes is often difficult, especially in the complexes with low affinity. In this case, the ligand cannot be observed separately in the free and bound states in the spectrum due to fast exchange. Therefore, it was proposed to use the dipolar couplings of the ligand in the oriented complex. Using the protein complex of a trisaccharide as an example, the possibility of measuring the orientation parameters of a free and bound ligand and determining its conformation has been demonstrated.³⁹⁷

The isotope enrichment of proteins, unlike that of small organic molecules, is currently a relatively easy task. In the development of new drugs, the use of traditional NMR procedures is complicated by the fact that the ligand becomes a kind of invisible. The structure of a non-enriched ligand complexed with an enriched protein can be determined by measuring the RDC of the ligand in an oriented complex.³⁹⁸ The structure of the whole complex can be determined with the highest accuracy if RDC are also used in determining the protein structure.

Algorithms for determination of the geometry of complexes making use of orientation parameters of both the ligand and the protein and taking into account the molecular symmetry have been developed.³⁹⁹ The geometry of the α -methyl-D-mannoside and its complex with a 53 kDa protein has been found using this type of algorithm.⁴⁰⁰

The orientation of a ligand (a transducin peptide fragment) weakly bound to light-activated membrane rhodopsin has been studied.^{401, 402} The rhodopsin-containing discs are oriented similarly to membrane fragments. The possibility of investigating the binding dynamics and ligand orientation was shown.

The measurements of the RDC for a ^{13}C -enriched Gb₃-oligosaccharide⁴⁰³ made it possible to locate its binding site to the protein verotoxin 1. The exchange between the bound and free states of the trisaccharide was fast on the NMR time scale and the measured RDC values were weight-averaged over these states. One of the three possible binding sites was reliably identified on the basis of simulation results (X-ray). The structural changes induced by the ligand have been observed for MBP binding to β -cyclodextrin.³⁸⁷

4. Protein–protein complexes

In recent years, NMR studies of multiprotein complexes and protein–protein interactions, like the studies of multidomain proteins, have become nearly routine. These studies make use of intermolecular NOE, cross-saturation, paramagnetic methods, analysis of chemical shift perturbations, analysis of relaxation parameters and so on. It is obvious that combination of RDC-based procedures with TROSY is the most promising for relative positioning of the proteins in the complex.⁴⁰⁴

Most of the above methods for determining the relative orientation of domains are also applicable to studies of various types of complexes (protein–protein, protein–ligand, protein–nucleic acid).

If the structure of each protein forming the complex is known, one can determine rapidly and accurately the structure of the whole complex using RDC and intermolecular NOE signals. This was demonstrated⁴⁰⁵ in relation to a protein–protein 40 kDa complex. In the algorithm described, dockings of the proteins incorporated in the complex are considered rigid. The use of this method markedly accelerates determination of the structures of complexes by NMR. The same method was used to determine the structures of two protein–protein complexes from the phosphotransferase system of *E. coli* sugars.^{406, 407}

McCoy and Wyss⁴⁰⁸ were able to solve the problem of protein docking using only the information contained in the RDC and chemical shift perturbations.

To determine the relative orientation of domains or molecules in calcium-containing proteins and complexes, one can use a facile

procedure which does not require aligning solvents,¹⁴³ orientation being induced by replacement of the Ca^{2+} ions by lanthanide ions having a similar ionic radius.

The presence of a paramagnetic label in one monomer in symmetric complexes, for example, in homodimers, eliminates the symmetry-related degeneracy and the overlap in the spectra and allows one to determine the RDC and pseudocontact shifts specific for each of the monomers.⁴⁰⁹

5. Protein side chain conformations

For the present moment, the attention of researchers focuses on the 3D structure of the protein backbone. However, significant items are determined by the side chain conformation; in some cases, they play a crucial role in the functioning of a biomolecule.

The assignment of signals corresponding to the side chain nuclei to particular members of the protein sequence is the most difficult and lengthy phase in determination of the protein structures by traditional methods based on NOE.

The dipolar coupling constants proved to be very convenient for investigating the side chain conformations and dynamic behaviour. The RDC values for side chains can also be useful for determining the backbone structure as additional structure constraints. A lot of various RDC can be measured (homonuclear or heteronuclear, between either directly linked or remote nuclei). The $\text{C}^\beta\text{--H}^\beta$ (see studies^{259, 260, 264}) and $\text{C}^\alpha\text{--C}^\beta$ (see studies^{244, 245, 259}) RDC as well as C--C ,^{265, 410} C--H ^{266, 410} and H--H ^{264, 265} RDC for methyl groups are used most often.

Even the earliest measurements of RDC in side chains showed good agreement with the values predicted on the basis of the 3D structure of the protein backbone.⁴¹¹ The subsequent studies confirmed the high information content of these constants not only in protein structure determination but also in a study of side chain dynamics.

In particular, the torsion angles χ_1 and their dynamic behaviour in ^{13}C -enriched partially deuterated proteins were determined with high accuracy using the direct $^1\text{H}^\beta\text{--}^{13}\text{C}^\beta$ RDC in CH and CH_2 groups²⁶⁰ (which can be interpreted rather easily, especially using the force potential of torsion angle databases).³⁵⁵

The possibility of precise determination of the orientation of functional groups in asparagine and glutamine in the protein side chains was shown.²⁷⁶ Determination of the arrangement of these groups is especially important because they are involved in specific hydrogen bonds.

The information concerning the positions of the methylene and methyl groups is important in determining the positions of the hydrophobic side chains in the protein.

A simple and efficient method for the measurement of RDC in methyl and methylene groups has been developed based on the 3D version of the well-known [$^1\text{H}\text{--}^{13}\text{C}$] CT HSQC experiment.⁴¹¹ The only drawback of this method is the fact that the sum of only two C–H RDC in the methylene group is determined.

Another method specially developed on the basis of the S^3E type HSQC experiment is more convenient for investigating the methylene groups of ^{13}C -enriched proteins.²⁶⁴ A new pulse sequence, SPITZE–HSQC (Spin State Selective Zero Overlap HSQC), made it possible to measure simultaneously the C–H and H–H RDC. The glycine methylene groups in ubiquitin were used as an example to demonstrate the unique possibilities of this method for fast determination of the magnitudes and signs for all three RDC in the methylene group, $D(\text{H1}, \text{H2})$, $D(\text{C}, \text{H1})$ and $D(\text{C}, \text{H2})$, in the spectra with minimal spectral overlap and a better signal-to-noise ratio compared to that in the HSQC experiment.

The first RDC-based systematic study of the methyl groups in the proteins showed a similarity in their geometry; the average value for the C–C–H angle (110.9°) proved to be greater than 109.5° (see Ref. 410).

Study of the methyl groups is complicated by two circumstances. First, a fourfold increase in the number of resonance signals after switching-off the ^1H decoupling may result in peak superposition and deteriorate the resolution. The specially devel-

oped IPAP–CT HSQC type protocol permits one to separate the multiplet components and markedly facilitates the measurement of RDC in the methyl groups.²⁶⁶ Second, the rotation of the methyl groups around a threefold symmetry axis decreases RDC by a factor of $(3\cos^2\theta - 1)$ (θ is the angle between the symmetry axis of the group and the C–H bond), *i.e.*, by almost 70%. The geminal H–H constants for which both the magnitude and the sign can be measured in a single experiment are more advantageous in this respect.²⁶⁵ The measurements of these constants are especially reasonable if deuterium substitution is used, *i.e.*, the protein molecule is perdeuterated except for the methyl groups.

The measurement of the quadrupole splittings in the spectra of aligned proteins with partially deuterated and ^{13}C -enriched methyl groups ($^{13}\text{CH}_2\text{D}$) is yet another promising line of investigations of these groups. The high correlation observed between quadrupole splittings and the $^{13}\text{C}^{\text{Me}} - ^{13}\text{C}$ RDC has been interpreted²⁹⁹ as being indicative of the similarity of all the methyl groups in proteins. The researchers cited calculated the average QCC for the methyl groups in the free rotation approximation taking the angle between the rotation axis and the axis of the electric field gradient tensor to be 109.5° . They proposed that the resulting value (167 ± 1 kHz) should be used subsequently in interpreting the ^2H relaxation data in the protein methyl groups.

An isotope effect was observed on deuterium substitution at the methyl groups. The spin–spin coupling constants for directly linked C–H and C–C nuclei decreased with an increase in the number of deuterium atoms in the group.⁴¹² The very weak isotope effect also had an influence on the methyl group geometry: the C–C–H angle slightly changed (by fractions of a degree).

6. Carbohydrates

Oligosaccharides are important compounds participating in many processes that take place in a cell. They occur in biological systems either in the free state in solution or as parts of proteins (glycoproteins) or lipids (glycolipids) on the cell surface. They are used more and more often in the development of drugs.

The cell functions of oligosaccharides are directly related to their structures, conformations and dynamic behaviour. Knowing these structures both in the free state in solution and in the bound state is an important prerequisite for understanding of the major factors that control the recognition of oligosaccharides by specific cell receptors.

At present, multidimensional high-resolution NMR spectroscopy in combination with molecular simulation is the major method used to determine the structures of carbohydrates. The advent of the procedures based on the measurement of RDC gave a renewed impetus to these studies.

The use of RDC for structure determination and conformational analysis of oligosaccharides was started in 1998 simultaneously by three research groups, headed by Prestegard,⁴¹³ Widmalm⁴¹⁴ and Homans^{415,416} and, later, by a group headed by Bush.⁴¹⁷ Actually, by that time, the methods based on the measurements of RDC and CSA have already been used to determine the structures of oriented glycosides, glycolipids and other carbohydrates,^{418–427} but this line of research has been generally recognised only after successful use of these methods in the studies of biomolecules.

Bolon and Prestegard⁴¹³ proposed a simple COSY experiment for measurement of the $^1\text{H} - ^1\text{H}$ RDC in oriented oligosaccharides and demonstrated its efficiency in relation to a trisaccharide. The high information content of these new data for the conformational analysis of oligosaccharides was used by Kiddle and Homans⁴¹⁵ to refine the conformation of another trisaccharide, studied previously using NOE and $^{13}\text{C} - ^1\text{H}$ and $^1\text{H} - ^1\text{H}$ vicinal constants. The $^{13}\text{C} - ^1\text{H}$ RDC were measured for a ^{13}C -enriched trisaccharide dissolved in a bicellar LC medium.

Rundlof *et al.*⁴¹⁴ used C–H dipolar coupling to study the conformation of a tetrasaccharide, lacto-N-neotetrose (LNnT), from human milk with natural ^{13}C abundance. By using energy minimisation, experimental data were adjusted to the molecular

model generated by the molecular dynamics method. Good correspondence was observed for a conformation in which the linear tetrasaccharide was described as a uniaxial cylinder. To confirm this model, LNnT was also studied in two other lyotropic LC media with conformation averaging.⁴²⁸ Using the Monte Carlo and molecular dynamics methods, various molecular structures were generated, the orientation parameters and RDC were calculated for them and compared with experimental values. It was shown that, apart from the expected difference between the orientational characteristics of the tetrasaccharide LNnT in two different media, a slight difference between the conformations was found.

Martin-Pastor and Bush⁴¹⁷ studied the conformations of six other natural oligosaccharides isolated from human milk; they used molecular dynamics and NMR spectroscopy based on NOE and RDC measurements for molecules oriented in bicelles. The inclusion of information contained in RDC markedly increased the reliability and the accuracy of results. The conformational study of these oligosaccharides and the pentasaccharides LNF-2 and LNF-3 (LNF is lacto-N-fucopentose) was continued on the basis of analysis of C–H RDC.^{418,429} (It should be noted that the conformations of these complex oligosaccharides were studied without isotope enrichment.) To this end, a strategy was developed for fast comparison and calculation of the difference between the experimental and calculated RDC for a large number of structures generated during computer simulation.⁴²⁹ Two different consecutive algorithms were used to analyse thousands of generated structures in the space of dihedral angles corresponding to the high and low values of the energy to be minimised. This two-stage strategy proved to be very efficient for a conformational study of the carbohydrate antigens of blood groups Lewis X and Lewis A trisaccharide⁴²⁹ and two synthetic trisaccharides of blood groups A and B and tetrasaccharide alditol of blood group A.⁴³⁰

These studies demonstrated the possibility of measuring the heteronuclear C–H RDC in oligosaccharides with a natural ^{13}C abundance. The 2D *J*-modulation HSQC procedures developed recently allow one to measure them with a higher accuracy.⁴³¹

The paramount importance of the $^1\text{H} - ^1\text{H}$ RDC for determination of the 3D structures of oligosaccharides was noted in another study.⁴³² The authors developed a new procedure for the measurement of RDC and determined the structure of a partially deuterated decasaccharide also using traditional NMR methods. The decasaccharide structure could be determined only when direct ($^1D_{\text{CH}}$) and long-range (D_{HH}) dipolar couplings have been included in the analysis. A method for determination of the conformation distribution function for disaccharides in the LC medium has been proposed.⁴³³

A new strategy for conformational analysis of flexible oligosaccharides based on the use of RDC has been reported.⁴³⁴ This strategy implies analysis of order matrices for each of the sugar rings. The resultant RDC values averaged over internal motions are used to estimate the amplitude of these motions. These data are well combined with the results of conventional relaxation methods.

The $^{13}\text{C} - ^1\text{H}$ and $^1\text{H} - ^1\text{H}$ dipolar coupling constants were used successfully to determine the structure and dynamics of simple sugars in solution.⁴³⁵ The structures of saccharose (disaccharide) and raffinose (trisaccharide) in solution were found to differ substantially from their structures in the crystal phase. For example, the disaccharide can exist with four different orientations of monosaccharides with respect to each other (for example, like protein domains³⁹⁹). However, only one orientation was observed, possibly due to the short bridging unit. Meanwhile, in the case of the galactose fragment of raffinose, clear-cut dynamic behaviour was found, which markedly decreased the degree of orientation of this fragment compared to the other two fragments.

The quadrupole couplings in deuterated carbohydrates were used to determine the structure and dynamic behaviour of $^{13}\text{C}/^2\text{H}$ -

enriched methyl- β -D-glucopyranoside.³⁰⁰ The quadrupole constants of endocyclic deuterons proved to be very uniform; therefore, a single average value of this constant can be used in relaxation studies of glycan fragments in glycoproteins and glycopeptides.

Comparison of the results of structure calculations of the pentasaccharide constructed from D-mannose residues by molecular dynamics methods with the structures obtained using relaxation data and RDC has shown³²⁸ that, although the results obtained using RDC are in good agreement with both the model of averaging over the whole possible ensemble of conformations and with one structure of this ensemble, it is still more legitimate to take into account all the conformational motions of the molecule. The relaxation data can be interpreted only in the ensemble model. The researchers also carried out quantitative conformational analysis of the core region of N-glycans in water using RDC and molecular dynamics methods.⁴³⁶

In determining the structure of a flexible heptasaccharide,⁴³⁷ success was achieved owing to the combination of traditional NMR experiments with the measurement of direct ($^1D_{CH}$) and long-range (D_{HH}) dipolar couplings.

The 3D structure of the enterobacterial cyclic antigen containing four repeating trisaccharide units was also determined by combined use of RDC, data of NOE experiments and vicinal $^3J_{CH}$ constants.⁴³⁸

Using only RDC, Freedberg was able to study rather easily the deformation of the fructofuranosyl ring of sucrose.⁴³⁹

Thus, the NMR spectroscopy techniques for aligned molecules open up new, unique opportunities for research into the structures and for conformational analysis of both simple sugars and complex oligosaccharides and their protein complexes in solution.⁴⁴⁰

7. Nucleic acids

Study of the structure of nucleic acids by conventional NMR spectroscopy methods is much more difficult than the study of protein structures, due to a number of specific features of biomolecules of this class. First, there is a relatively low density of protons in nucleic acids, and, correspondingly, small number of NOE constraints. Second, due to the non-globular structure of the DNA molecule, the spectra contain no NOE signals between different sections of the chain but contain only signals due to nucleotides that adjoin each other in the sequence. Even in the RNA molecule, which is less linear and has a clear-cut tertiary structure, the number of internucleotide contacts is very little. Third, the dispersion of nuclear chemical shifts is insignificant; therefore, only a relatively small number of resonance signals can be resolved. Finally, it is necessary to determine five (rather than two as in proteins) backbone angles per structural unit.

The foregoing implies that global characteristics of nucleic acid structures such as helical twisting, helix step and torsion angles in the chain are difficult to determine, although a number of local conformation parameters (for example, the conformations of carbohydrate chains and the torsion angles of the glycoside bonds) can be established rather accurately. The RDC and CSA measurements in weakly aligned nucleic acids provide new, in principle, opportunities for structural studies.^{218, 441–444}

Almost any of the alignment methods mentioned above is applicable to nucleic acids; the use of filamentous phages is considered to be the method of choice.²²⁰

The attempts to measure the RDC for nucleic acids have been undertaken even in the first experiments with weakly aligned biomolecules in bicellar systems⁴⁵ and in LC suspensions of phages;²¹⁹ however, Bayer *et al.*,⁴⁴⁵ who used the ^1H – ^{13}C and ^1H – ^{15}N RDC in the protein–RNA complex, were able to considerably improve the resolution in the determination of the structure of a nucleic acid.

The structure of the DNA dodecamer d(CGCGAATTCGCG)₂ has been studied in a bicellar medium.⁴⁴⁶ In addition to the 162 NOE responses, 198 ^{13}C – ^1H ,

10 ^{15}N – ^1H and 200 ^1H – ^1H RDC were determined. It was shown that the dodecamer structure could in principle be determined using only RDC.

The same dodecamer was used to demonstrate a procedure of direct determination of the parameters of nucleic acid helices using only RDC⁴⁴⁷ based on the analysis of their order matrix. An advantage of this method is that it does not require the knowledge of the refined molecular structure.

A method for fast determination of a stoichiometry in homomultimeric nucleic acid complexes by analysis of RDC induced by a magnetic field has been proposed.⁴⁴⁸ Depending on the number of monomer units in the multimer, the components of its diamagnetic susceptibility vary. Having found or calculated the diamagnetic susceptibility of the monomer, one can determine the diamagnetic susceptibility of the multimer from the RDC values and, hence, the number of monomer units in the multimer. This does not require the knowledge of any structural information or even assignment of the resonance signals.

Using RDC, it is possible to determine the relative lengths of hydrogen bonds²⁴⁸ and their orientation in DNA.⁴⁴⁹ A systematic study of two DNA duplexes has shown⁴⁵⁰ that inclusion of RDC into the set of NMR parameters used in structural studies substantially increases the accuracy of determination of both the local and global structures of duplexes.

The use of RDC allows fast determination of the relative positions of known elements of RNA secondary structure.⁴⁴¹ For example, a few additional ^{15}N – ^1H RDC proved sufficient for determining the global structure of transport RNA⁴⁵¹ and a hammerhead ribozyme,⁴⁵² in which the local structures of helical regions had already been known.

The spatial packing of nucleic acid homodimers with C_2 symmetry has been established unambiguously using two sets of RDC measured independently.⁴⁵³ In this case, two independently oriented states of DNA quadruplexes were obtained using a bacteriophage solution as an orienting medium and on exposure to a strong magnetic field of the NMR spectrometer (800 MHz). The developed procedure was tested in relation to a $^{15}N/^{13}C$ -enriched deoxynucleotide sequence d(GGGTTCAGG), which dimerises in solution to give a quadruplex and forms a pair of G(CA) triads and GGGG tetrads.

The measurement of RDC is a rather fast and facile method for detecting the specific conformational changes taking place in RNA upon binding to drugs. This was demonstrated using the conformational changes induced by binding of an aminoglycoside antibiotic to the RNA chain.⁴⁵⁴

Measurement of the ^1H – ^{31}P RDC has been proposed for determining the geometry of binding of nucleic acids to the phosphodiester backbone.^{455, 456} The efficiency of measurement of the vicinal $H3'$ – P RDC (NOESY version of the CT COSY experiment) was demonstrated in the study of the d(CGCGAATTCGCG)₂ dodecamer mentioned above.⁴⁵⁶ The scalar and dipolar $H3'$ – P constants were measured in isotropic and LC states both without and with ^{31}P decoupling. Yet another variant of using through-space ^1H – ^{31}P RDC has been developed on the basis of the TOCSY experiment.⁴⁵⁵ In this case, one should measure the ^{31}P – ^1H RDC with base protons H6 and H8. The efficiency of this procedure was demonstrated by determining the structure of HIV-2 TAR 30-mer RNA in a solution of bacteriophage Pf1.

Wu *et al.*²⁸⁹ demonstrated that the great ^{31}P CSA values observed in aligned samples of nucleic acids can be efficiently used to determine the orientation of the phosphodiester groups relative to the molecular alignment tensor.

When in the NMR spectrum many proton resonances overlap, and, moreover, protons have many coupling partners (as, for example, the protons of the RNA ribose), it can be difficult to measure the ^1H – ^1H constants. In these cases, one can use selectively fluorinated compounds. In particular, an E COSY-based procedure with X-filtration has been developed for these measurements. The resulting ^1H – ^{19}F RDC were used successfully

to determine the structure of 2'-fluorolabelled 21-mer RNA hair-pin.⁴⁵⁷

The use of RDC simplifies the study of the structures of protein–DNA^{380, 458–460} and protein–RNA complexes.⁴⁴⁵ In particular, combined use of the measured J_{NN} constants through a hydrogen bond and the RDC induced due to alignment of the RNA molecule by the magnetic field made it possible to determine the geometry of binding of the 16-mer HTLV-I Rex peptide to the 30-mer RNA aptamer.⁴⁶¹

A new algorithm for fast assignment of NMR signals and simultaneous determination of the tertiary RNA structure has been developed;⁴⁶² in this case, the time-consuming NOE-based sequential assignment step is completely excluded.

Determination of components of the alignment tensor is much more complicated in the case of nucleic acids because the column diagram approach (see Ref. 318) based on the rather uniform distribution in space of the directions of internuclear vectors in proteins is inapplicable in this case. The mapping strategy developed by Warren and Moore³²² may be a good substitute for nucleic acids. The authors used this strategy to determine the structure of the sarcin-ricin RNA loop.⁴⁶³

Thus, the use of RDC markedly extends the scope of modern NMR techniques as applied to structure determination for any type of nucleic acids and their complexes.^{463–466}

8. Internal dynamics

The study of dynamic processes in macromolecules represents yet another promising application of NMR spectroscopy of aligned biomolecules. Unlike the spin relaxation or chemical exchange methods used conventionally, this method provides information on the dynamic behaviour on a time scale typical of biologically significant motions (picoseconds to seconds).^{467, 468}

We have already mentioned studies in which RDC have been used to examine the dynamics of protein side chains,²⁶⁰ domain orientation^{379, 385} and the conformational mobility in carbohydrates.^{328, 434, 436} It is usually assumed that internal motions in the biomolecules are either missing or negligible or that they are similar and have an axial symmetry.

However, in reality, internal motions of various types always occur in biomolecules and neglecting them should undoubtedly influence the accuracy of structure determination based on RDC. Indeed, when the biomolecule contains non-rigid fragments, RDC are determined by averaging not only over reorientations of a biomolecule as a rigid particle but also over internal motion. The additional averaging gives rise to deviation of the RDC values of flexible fragments from the values expected for the given degree of orientation of the biomolecule as a whole and deteriorates the accuracy of the determined structure. These deviations can serve as a measure of mobility of the given fragment and a criterion for choosing a particular model of motion.

For separating the structural information in RDC from dynamic information, a special strategy based on analysis of the order matrix was developed; this strategy allows one to distinguish the most flexible fragments of a biomolecule. The internal motions are especially pronounced in carbohydrates; naturally, RDC were first used to study their dynamics.^{434, 435} The potential of this method was also demonstrated for proteins in analysis of the internal dynamics of ubiquitin⁴⁶⁹ and the functional dynamics of the active state of ribonucleotide binase.⁴⁷⁰ The most extensive prospects are opened for investigations of the RNA internal dynamics and the dynamics of RNA binding to proteins.⁴⁷¹

Another strategy for extracting dynamic information from RDC^{337, 472} is based on a large number (at least five) of independent measurements in different orienting media.

VIII. Conclusion

The information considered in this review demonstrates the vigorous development of the application of NMR spectroscopy to biomolecules.[‡]

An advantage of NMR spectroscopy for weakly aligned biomolecules is the fact that, along with structure determination, it allows one to determine rather promptly the relative arrangement of individual groups during functioning of the biomolecule without the necessity of repeated labour-consuming determination of the structures of all current states of the dynamic system.[§] Therefore, this method can be regarded as most promising in the studies of the structure–biological function relationship for biomolecules.

The development of NMR spectroscopy of weakly aligned biomolecules is especially topical for biology and medicine. Apart from the possibility of determining the tertiary and quaternary structures and the dynamics of biomolecules and their complexes, this technique is suitable for: quick diagnostics of molecules in solutions and investigation of their functions; screening of drugs; fast elucidation of structure–property relationships for mutant or modified biomolecules; spectroscopic studies of the biomolecules of various tissues and organs *in vivo* either in the oriented state or in exchange between oriented and non-oriented states; visualisation of the structures of various biological objects using the degree of alignment of biomolecules or their fragments as the contrast factor.^{473–477}

The combination of this method with other methods (for example, with small-angle X-ray scattering in solution,⁴⁷⁸ diffraction methods and advanced structural analysis using synchrotron radiation⁴⁷⁹) opens up new opportunities for research into biomolecules.

The Tables presented in the Supplement summarise characteristics of the systems used for weak alignment of biomolecules and the results of studies using NMR of weakly aligned molecules for compounds deposited with the PDB and the BMRB (Biological Magnetic Resonance Bank).⁴⁸⁰

The authors are grateful to Ph.Ds S S Mamyán and G A Panosyan for stimulation and support of the work, and their discussion and valuable remarks. This review was written with financial support from the U.S. Civilian Research and Development Foundation (CRDF, Grant CGP 2002 AC1-2304-YE-02).

IX. Supplement

Table S.1 presents brief characteristics of the systems used for weak alignment of biomolecules. Table S.2 lists the structures of biomolecules deposited with the PDB and the BMRB which were determined using dipolar coupling parameters. Note that the term 'structure' is used to mean both a set (ensemble) of structures with close values of minimisation criteria in the adjustment programmes used and a single (the most probable) of these structures. Some identical biomolecules are recorded in the databases under different numbers. The structures of these biomolecules were determined by different groups of researchers or by the same group but based on different assumptions.

[‡] K Wütrich (Switzerland) was awarded a Nobel Prize in 2002 for a series of studies dealing with NMR spectroscopy of biomolecules.

[§] For the series of fundamental research dealing with the development of the procedures for the measurement of residual dipolar couplings of weakly aligned molecules, three outstanding scientists, A Bax, A Bothner-By and J H Prestegard, were awarded the Laukien Prize at the 43rd Experimental NMR Conference, Pacific Grove, CA, 2002.

Table S.1. Media used for weak alignment of biomolecules (the alignment direction is indicated relative to the magnetic field direction).

System				Biomolecule	Aligning factor	Alignment direction	Ref.
composition	description	advantages	drawbacks				
Without orienting medium	isotropic solution of biomolecules	no special orienting media are required	very weak alignment	nucleic acids, paramagnetic proteins	magnetic field of the spectrometer		42, 43, 140, 142–147, 149, 150, 152, 161
DMPC/DHPC, DMPC/CHAPSO	isotropic solution of discs with encapsulated protein	the same	—	membrane proteins	the same	⊥	183, 184
DMPC/DHPC	bicellar LC, flat discs, 4–5 nm thick	easily modifiable	hydrolysis at low pH	proteins, nucleic acids, carbohydrates	bicelles with negative $\Delta\chi$	⊥	174, 175, 179, 180, 182, 185–190, 196, 200
DMPC/DHPC/CTAB	the same	stable, positively charged	—	proteins	the same	⊥	192, 196, 200
DMPC/DHPC/SDS	"	stable, negatively charged	—	proteins, nucleic acids	"	⊥	192, 196
Dialkyl phospholipids	"	broad pH range, stable against hydrolysis	—	proteins, nucleic acids, carbohydrates	"	⊥	196

1IUUF		two DNA-binding domains in <i>Schizosaccharomices pombe</i> Abp1 protein	"	144	47	459
1J46		wild type HMG-Box domain of the human male sex determining factor SRY complexed to DNA	"	113	274/197, 101/96	492
1J47		M9I mutant of HMG-Box domain of the human male sex determining factor SRY complexed to DNA	"	113	274/197, 101/96	492
1J4V		domain-swapped dimer of the HIV-inactivating protein cyanovirin-N	"	202	136	383
1J4W		complex of the KH3 and KH4 domains of human FBP with single-stranded 29-mer DNA	"	203	140/154	460
1J5K		complex of the KH3 domain of hnRNP K with a single-stranded 10-mer DNA	"	99	147/140	493
1J6T		complex of the enzyme IIA ^{Mtl} and histidine-containing phosphocarrier protein HPr from <i>E. coli</i>	"	233	528	494
1J7O		calcium calmodulin N-terminal domain	3	71	323	390
1J7P		calcium calmodulin C-terminal domain	3	67	305	390
1JO7		influenza A virus promoter RNA	32	31	22	464
1JOX		LP5.1 hairpin from <i>Bacillus</i> RNase P RNA	24	21	56	495

Table S.2 (continued).

PDB code	BMRB number	Description	The number of calculated structures	The number of residues	The number of RDC	Ref.
1JWE	4297	N-terminal domain of <i>E. coli</i> DnaB helicase	20	114	84	496
1K31, 1KQV		Ca Ln calbindin D _{9k}	30	79	64	497
1KSM		the same	see ^a	79	64	497
1KAT	5185, 5198	phage-derived peptide antagonist complexed with vascular endothelial growth factor	24	118	146	498
1KHM	4405	C-terminal KH domain of hnRNP K (KH3)	20	89	209	361
1KMX	5238	heparin-binding domain of vascular endothelial growth factor	20	55	38	392
1KQQ		dead ringer ARID-DNA complex	20	169	94	499
1KR8		d(GCGAAGC) hairpin	14	7	38	466
1KVN	4935	protein SRP19 of <i>Archaeoglobus fulgidus</i>	10	104	66	500
1KVV	4935	the same	see ^a	104	66	500
1L4S	5315	ribosome associated factor Y	20	112	80	501
1L5E		the domain-swapped dimer of cyanovirin-N in a metastable folded state	see ^a	202	80	502
1LUD	5396	dihydrofolate reductase complexed with trimethoprim and NADPH	24	162	229	
1LVZ	5376	metarhodopsin II bound C-terminal peptide of transducin α -subunit	20	11	38	402
1M2Y		mutant <i>Pyrococcus furiosus</i> rubredoxin	see ^a	54	400	308
1MAG		gramicidin A	"	34	141	95
1MPE		tetrameric mutant of the B1 domain of streptococcal protein G	21	224	33	
1UD7	4493	ubiquitin core mutant 1D7	20	76	63	504
2EZM		HIV-inactivating protein cyanovirin-N	see ^a	101	380	369
2EZN		the same	40	101	380	369
1QCK		human barrier-to-autointegration factor Baf	20 + see ^a	178	259	503
2EZX		the same	20	178	496	505
2EZY, 2EZZ		"	20	178	496	505
2GAT		C-terminal domain of chicken transcription factor GATA-1 bound to DNA	see ^a	98	48	141
3GAT		the same	34	98	48	141
3EZA		complex of the N-terminal domain of enzyme I and the histidine-containing phosphocarrier protein HPr from <i>E. coli</i>	see ^a	334	238	406
3EZB		the same	40	334	238	406
3GB1		immunoglobulin binding protein B1 domain of streptococcal protein G	—	56	300	503
4GAT		wild type DNA-binding domain of area complexed to a 13-mer DNA containing a CGATA site	see ^a	92	48	141
6GAT		L22V mutant DNA-binding domain of area complexed to a 13-mer DNA containing a TGATA site	"	92	49	141
	4319	oxidised rubredoxin	—	54	53	506
	4320	reduced rubredoxin	—	54	53	506
	4335	calerythrin (EF-hand calcium-binding protein)	—	176	172	363
	4822	regulatory domain of human cardiac troponin C (apo form)	—	89	53	507
	4823	regulatory domain of human cardiac troponin C (holo-form)	—	89	53	507
	4824	regulatory domain of human cardiac troponin C (complex with peptide)	—	89	52	507
	4927	circular permuted variant of the potent HIV-inactivating protein cyanovirin-N	—	202	75	370
	4986	maltodextrin-binding protein (MBP) (ligand free)	—	370	903	387
	4987	maltodextrin-binding protein (MBP) (maltotriose bound state)	—	370	908	387
	5368	human ADP ribosylation factor 1 (ARF1)	—	360	—	508

^a Average structure.

Abstract. The published data on the methods of chemical synthesis of oligonucleotides containing 5'- and 3'-terminal or internal carboxy or aldehyde functional groups are considered. The known methods are systematised and their advantages and disadvantages are discussed. The bibliography includes 65 references.

I. Introduction

At present, modified oligonucleotides are widely employed in molecular biology for the study of regularities of nucleic–protein recognition, in antisense biotechnology as well as in the design of therapeutic drugs for the treatment of viral and hereditary diseases. Successful solution of these tasks requires the synthesis of oligonucleotide conjugates with various compounds, *e.g.*, reporter molecules, intercalators, biologically active peptides and enzymes possessing unique properties. In this context, the preparation of single- or double-stranded DNA molecules containing functional groups differing from those of natural DNA in reactivity is of special importance. The introduction of new reactive groups into the oligonucleotide chain allows successful synthesis of hybrid molecules.

Numerous methods for the synthesis of oligonucleotides containing nucleophilic groups (*e.g.*, amino or thio groups) are known;¹ their incorporation is usually achieved using commercially available reagents. In contrast, the preparation of oligonucleotides containing reactive electrophilic groups (*e.g.*, carboxy or aldehyde groups) is rather problematic. The body of literature on this subject is rather scarce.[†] We believe that the analysis and systematisation of the available data can give an impetus to the development of methods for the synthesis of oligonucleotides with electrophilic groups.

Carboxy or aldehyde functional groups can be introduced at any predetermined position of a synthetic DNA fragment, *viz.*, as the 5'- or 3'-end group or within the oligonucleotide chain. It is the

position that has been chosen as the basis for the classification of methods for the synthesis of modified oligonucleotides.

In all the studies reviewed herein, oligonucleotides were prepared by the automated solid-phase phosphoramidite method using a standard protocol.^{1,2} The synthesis of oligonucleotides containing a dialdehyde group is not considered here, being detailed in another review.³ Standard procedures for the isolation of modified oligonucleotides (reversed-phase, ion-exchange HPLC, polyacrylamide gel electrophoresis, *etc.*) and the methods used to confirm the structures of intermediate and target products also fall beyond the scope of this review, since in the vast majority of studies the correct analysis using NMR spectroscopy and mass spectrometry has been carried out.

II. Synthesis of oligonucleotides containing a 5'-terminal carboxy or aldehyde group

The carboxy group is commonly incorporated at the 5'-end of the oligonucleotide using a modified non-nucleoside unit attached to the oligonucleotide chain in the final step of the automated synthesis. It is desirable to protect the carboxy group in the course of solid-phase synthesis by esterification.

A method for the synthesis of carboxy-containing oligonucleotides using a phosphoramidite derivative of methyl 12-hydroxydodecanoate **1** synthesised as shown in the scheme below has been described.⁴

The attachment of phosphoramidite **1** to the oligonucleotide chain was carried out in accordance with a standard protocol of

[†] Several papers describing the preparation of 5'-carboxy- and 5'-aldehyde-containing oligonucleotides have recently been surveyed in brief in a review¹ devoted to the synthesis of various derivatives of nucleic acid fragments.

automated oligonucleotide synthesis. The 5'-ester group was hydrolysed with aqueous trimethylamine ($\text{Me}_3\text{N}:\text{H}_2\text{O} = 3:1$, 37°C , 48 h) with subsequent deprotection with ammonia to yield the target oligonucleotide. This reaction sequence was used because treatment of an ester with a concentrated aqueous solution of ammonia yields the corresponding amide.

The reactivity of the carboxy group incorporated was confirmed in the reaction with amines in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (DEC).⁴ At the concentration of the amine of 5×10^{-3} mol litre⁻¹ and pH 4.0, *N*-acylurea is formed. One possible reason is the protonation of the free amino group of the nucleophile in acidic media. Attempts to avoid the formation of a side product by increasing the concentration of the amine up to 0.1–0.5 mol litre⁻¹ or by increasing the pH to 5.5–6.7 failed. This problem was overcome by adding imidazole to the reaction mixture: this reacts with *O*-acylisourea to give an active intermediate, *viz.*, acid imidazolid, which reacts with the amine. The rapid formation of imidazolid prevents *O* → *N*-acyl migration. This approach allowed the preparation of conjugates of 5'-carboxy-containing oligonucleotides with amines in quantitative yields.⁴

A method for the synthesis of modified oligonucleotides **2a,b** containing ester groups at the 5'-termini has been described.⁵ Post-synthetic treatment of these compounds successively with 0.1 M NaOH (4 h, 20°C) and concentrated aqueous ammonia (7 h, 55°C) afforded the 5'-carboxy-containing oligomer **3**.

R = $\text{Cl}(\text{CH}_2)_2$ (**2a**), CF_3CH_2 (**2b**); CPG is controlled pore glass.

A similar procedure was proposed by Guzaev *et al.*⁶ for the synthesis of 5'-carboxy-containing oligonucleotides. In this case, automated oligonucleotide synthesis included incorporation of a non-nucleoside phosphoramidite **4** prepared by treatment of 6-aminohexanol (**5**) with *N*-chloroacetoxy succinimide with subsequent phosphitylation of compound **6**. It was found⁶ that an attempt to synthesise a bromoacetamide analogue of phosphoramidite **4** gave products of the Michaelis–Arbuzov reaction as deduced from ^{31}P NMR spectra. The presence of both nucleophilic and electrophilic reaction centres in the target phosphoramidite **4** makes the latter storage-unstable; therefore, compound **4** was introduced into an automated oligonucleotide synthesis immediately after its preparation.

Postsynthetic treatment of model oligonucleotides **7** with lysine in the presence of a base, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and then with concentrated aqueous ammonia gave oligomers **8** with 5'-terminal carboxy groups. It is noteworthy that the derivatives **7** can be used in the synthesis of oligonucleotides containing various functional groups.

A method for the synthesis of oligonucleotides with 5'-terminal carboxy groups involving introduction of the carboxy groups after completion of the automated oligonucleotide synthesis has been described.⁷

In this case, the 5'-terminal hydroxy group in the oligonucleotide **9** was activated with 1,1'-carbonyldiimidazole and the derivative **10** reacted with 6-aminohexanoic acid in pyridine to yield the carboxy-containing oligonucleotide **11**.

B is a heterocyclic base.

After detachment of compound **11** from the solid phase and deprotection of the functional groups, an intercalator (daunomycin) was attached.⁷

An original approach to the synthesis of modified oligonucleotides containing an iminodicarboxylic acid residue at the 5'-end has been developed.⁸ The phosphoramidite derivative **12** was synthesised starting from 5'-azido-5'-deoxythymidine (**13**). Reduction of the azide with propane-1,3-dithiol gave nucleoside **14** with a 5'-group; alkylation of the latter with ethyl bromoacetate and subsequent phosphitylation of the derivative **15** afforded 5'-modified phosphoramidite **12**. The resulting compound was introduced into a standard automated oligonucleotide synthesis; after its completion, the ester was hydrolysed with aqueous sodium hydroxide.

The method for the synthesis of oligonucleotides with 5'-terminal carboxy groups described in study⁹ is based on the use of the modified phosphoramidite derivative **16a** which was introduced into the automated oligonucleotide synthesis in the final step. The 2-chlorotrityl and trityl groups commonly employed in peptide synthesis, which can easily be eliminated by mild acid treatment,¹⁰ were used for the carboxy protection.

The starting phosphoramidites **16a,b** were obtained by phosphitylation of 2-chlorotrityl (**17a**) and trityl (**17b**) esters of 4-hydroxyvaleric acid (formed upon reduction of the corresponding oxo derivatives **18a,b** with sodium borohydride) with 2-cyanoethyl-*N,N,N',N'*-tetraisopropylphosphorodiamidite. Since the total yield of compound **16a** markedly exceeded that of compound **16b** and taking into account the higher stability of the 2-chlorotrityl group under the conditions used in the automated procedure, modified oligonucleotides **19** containing 5'-terminal carboxy groups were prepared from the phosphoramidite derivative **16a**.

The 5'-terminal 2-chlorotrityl protective group was removed under standard conditions. The carboxy group in the oligonucleotide **19** formed was activated using 1-hydroxybenzotriazole (HOBt) and *O*-(benzotriazol-1-yl)-*N,N,N',N'*-tetramethyluronium (HBTU) hexafluorophosphate (40 min, 35 °C). The activated oligonucleotide was used⁹ in solid-phase syntheses of a series of conjugates of modified oligonucleotides containing various nucleophilic components including fluorescent labels and short-chain peptides (Scheme 1).

X = Cl (**a**), H (**b**).

The introduction of an aldehyde group at the 5'-end of an oligonucleotide has been described.⁴ The 5'-terminal ester group of a synthetic oligomer **20** was deprotected with aqueous trimethylamine, and the resulting compound **21** was introduced into a reaction with 3-aminopropane-1,2-diol in the presence of DEC and imidazole to give the vicinal diol **22**. The latter is a precursor of the aldehyde which can be formed upon oxidation of the diol **22** with sodium periodate (Scheme 2).

It was recommended⁴ that the oxidation of the vicinal diol **22** should be performed immediately before further modification of the oligonucleotide **23**, since the aldehyde group reacts with the amino groups of the heterocyclic bases. The reactivity of the aldehyde function was demonstrated by the reaction of the oligonucleotide **23** with biotin hydrazide with subsequent reduction of the acylhydrazone formed with sodium cyanoborohydride.

The introduction of the aldehyde group into the 5'-end of the oligonucleotide can be effected using an alternative approach which does not require any preliminary synthesis of a carboxy-containing oligomer. For this purpose, a phosphoramidite derivative of an aldehyde-containing nucleoside (or a non-nucleoside unit) or its precursor is incorporated inside the oligonucleotide chain in the final step of the automated synthesis. Obviously, in the former case, the carbonyl group must be protected. Such protection is necessary in order to avoid side reactions during the synthesis and postsynthetic treatments. Only one protective group, *viz.*, the 1,3-bis(*m*-chlorophenyl)imidazolidine group, meets all the requirements for protective groups in automated oligonucleotide synthesis,¹¹ however, this group is not used very often.

The problems related to the side reactions of aldehyde groups can be overcome by introducing a precursor of an aldehyde-containing fragment, *e.g.*, vicinal diol, instead of an aldehyde-containing fragment, into the oligonucleotide chain. The phosphoramidite derivative **24** was synthesised¹² in order to obtain oligonucleotides with 5'-terminal aldehyde groups.

Phosphoramidite **24** was synthesised from the alcohol **25** as the starting compound. The latter was converted into *tert*-butyldimethylsilyl ether **26** which was further oxidised into the vicinal diol **27** using catalytic amounts of osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide. After benzylation of the diol **27**, *tert*-butyldimethylsilyl protection was removed with tetrabutylammonium fluoride followed by phosphitylation of compound **28**.

The resulting phosphoramidite derivative **24** was introduced into an automated oligonucleotide synthesis; after its completion, protective groups were removed with concentrated aqueous ammonia. The oxidation of the *vic*-diol groups in the resulting

Scheme 1

R is amine, amino acid, peptide residue

Scheme 2

ImH is imidazole.

oligomers with sodium periodate was carried out as described previously,⁴ *i.e.*, immediately before further transformation of the aldehyde function.¹²

p-toluenesulfonate (PPTS). This protective group is stable under conditions of the automated oligonucleotide synthesis and is deblocked with 80% aqueous acetic acid in 1 h. In addition, the

TBDMS = $\text{Bu}^t\text{Me}_2\text{Si}$, TBAF = $\text{Bu}_4\text{N}^+\text{F}^-$.

The method for the synthesis of oligonucleotides with 5'-terminal aldehyde groups proposed by Forget *et al.*¹³ also entails the introduction of modified phosphoramidite **29** in the final step of the automated synthesis. It is noted that the two-step synthesis of compound **29** is a simpler and more convenient procedure than that described elsewhere.¹²

The *vic*-diol fragment of commercially available hexane-1,2,6-triol (**30**) was selectively blocked with the 4-methoxybenzylidene protective group under the action of 4-methoxybenzaldehyde dimethylacetal in the presence of catalytic amounts of pyridinium

Pyr is pyrimidine heterocyclic base,
R is a fragment of the oligonucleotide chain.

hydrophobic nature of this protective group allows one to use it as an analogue of the dimethoxytrityl group in the isolation of target oligomers by reversed-phase HPLC. In the final step, treatment of deprotected oligonucleotides with a 50-fold excess of sodium periodate (30 min, 20 °C) gave the modified oligonucleotides **31** containing an aldehyde group at the 5'-end. A series of conjugates of oligonucleotides **31** with peptides¹³ and sugars¹⁴ containing aminoxy groups have been synthesised.

An original procedure for the synthesis of oligonucleotides **32** containing 5'-terminal glyoxylic amide has been developed.¹⁵ This functional group reacts with hydrazines, hydroxylamines and ω -aminothiols without any activation, but unlike the aldehyde group, it is storage-stable.

In the synthesis of modified oligonucleotides **32**, a commercially available phosphoramidite with a linker containing a protected amino group was incorporated into the oligomeric chain in the final step of the automated synthesis. Monomethoxytrityl protection was removed with trichloroacetic acid in dichloromethane; the free amino group was acylated with diacetyltartaric anhydride in the presence of lutidine. The acetyl groups in the modified oligonucleotide **33** formed were removed by treatment with concentrated aqueous ammonia; the amide bond was resistant to ammonolysis. The oxidative cleavage of the vicinal diol **34** with sodium periodate (1.7 equiv. of NaIO₄, pH 6.6) yielded modified oligomers **32** with 5'-terminal glyoxylamide groups which were further used in the synthesis of oligonucleotide-peptide conjugates.

MMTr = (4-MeOC₆H₄)Ph₂C.

III. Synthesis of oligonucleotides containing a 3'-terminal carboxy or aldehyde group

At present, the synthesis of oligonucleotides with a 3'-terminal carboxy or aldehyde group usually entails incorporation of an additional non-nucleoside unit. Two different approaches to the synthesis of oligonucleotides modified at the 3'-end are known. In one of them, a fragment containing a protected hydroxy group is immobilised on a polymeric support. After completion of oligonucleotide synthesis, a reactive electrophilic group is formed at the 3'-end of the oligonucleotide as a result of chemical or photolytic cleavage of the covalent bond between the polymer and the linker. An alternative approach consists in the introduction of a carboxy or a carbonyl group after detachment of the synthesised oligonucleotide from the polymeric support. On the whole, the methods for the synthesis of oligonucleotides with 3'-terminal reactive electrophilic groups have a significant disadvantage, *viz.*, in both cases, the principle of incorporation of the functional group

excludes further solid-phase reactions with the nucleophilic components.

The dinucleotide **35** containing a photolabile *o*-nitrophenyl group and a carboxy group at the 3'-end, which was further used for the attachment of amines, has been synthesised.¹⁶

After termination of the solid-phase synthesis, the dinucleotide immobilised on the polymer through an ester bond was treated with a 33% aqueous solution of triethylamine (60 °C, 12 h) to detach it from the support and then with concentrated aqueous ammonia to remove the protective groups. The terminal carboxy group can be used for the attachment of reporter molecules to the oligonucleotide; these can selectively be removed from the support owing to the presence of a photolabile fragment.

In many cases, selective cleavage of the oligonucleotide from the polymeric support without removal of all protective groups acquires special importance in the synthesis of nucleotide-peptide conjugates. To this end, Greenberg *et al.*¹⁷⁻¹⁹ used polymeric supports modified with photolabile groups.

Initially, in the synthesis of carboxy-containing oligonucleotides, a method was applied in which the first nucleoside fragment was attached to the polymer **36** through a photolabile *o*-nitrobenzyl linker. In the final step of the synthesis, the oligonucleotides were split from the polymer by irradiation with light with the wavelength ~ 400 nm. The yields of the modified oligomers did not exceed 62%, which can be attributed to the destruction of the target product upon irradiation.¹⁷

Polymers **37** with linkers of variable lengths between the first nucleoside fragment and the photolabile group were used for the synthesis of oligonucleotides, the time of photolysis was thereby reduced.¹⁸ Vaniline (**38**) was used as a starting compound in the synthesis of the polymeric support **37** (Scheme 3). In the first step, vaniline was alkylated with 3-bromopropanol after which the intermediate **39** was subjected to nitration in glacial acetic acid accompanied by simultaneous *O*-acetylation to form the derivative **40**. Removal of the acetyl and introduction of the *tert*-butyldimethylsilyl protective group and further reduction of the formyl group to the hydroxymethyl group gave substituted benzyl alcohol **41**. Condensation of compound **41** with the corresponding protected hydroxycarboxylic acid in the presence of dicyclohexylcarbodiimide yielded the derivative **42**, one of the protected hydroxy groups in which was converted into a carboxy group as a result of selective deprotection and subsequent oxidation with pyridinium dichromate.

Immobilisation of the resulting compound **43** on a polymeric support was carried out using activated trichlorophenyl esters in the final step of the synthesis. To minimise the formation of side products, the remaining amino groups of the polymer were acetylated.

The use of the polymeric support **37** made it possible to obtain the target oligonucleotides with 3'-terminal carboxy groups in quantitative yields. The yield of a modified oligonucleotide was

Scheme 3

defined as the ratio of the amount of the modified oligomer obtained upon photolysis and deprotection with concentrated aqueous ammonia to the amount of the oligomer prepared by treatment with ammonia without preliminary irradiation.

The oligonucleotides prepared were further employed in the synthesis of conjugates with peptides and fluorescent labels without removal of protective groups.¹⁹ The reactions were carried out in organic media; the carboxy groups were activated with a HOBT–HBTU mixture (HBTU:HOBT:peptide = 1:1:5) in the presence of diisopropylethylamine. The yields of the conjugates were 85%–100%.

It was proposed²⁰ that polymeric support **44** with a linker containing an allylic-type ester selectively cleavable under the action of a palladium catalyst²¹ would be used in the synthesis of oligonucleotides with 3'-terminal carboxy groups. This allows the removal of the modified oligonucleotide from the polymeric support without deprotection of the functional groups.

The synthesis of the modified polymer **44** was carried out as shown in the scheme below.

The use of the polymeric support **44** requires a change in the standard protocol of the automated synthesis. Thus *tert*-butyl peroxide was used instead of iodine in a pyridine–water mixture, since this results in iodination of the double bond in the oxidation of internucleotide phosphite groups.²⁰ Moreover, the methyl

group was used instead of the β-cyanoethyl group to protect the internucleotide phosphate groups. The reason is that during the cleavage of an ester bond between the oligonucleotide and the polymeric support under the action of tris(dibenzylideneacetone)-dipalladium(0) and triphenylphosphine in a *n*-butylamine–1.2 M formic acid mixture, the β-cyanoethyl protective group is cleaved completely at 55 °C in 1 h, whereas removal of the methyl group was less significant under identical conditions (10% in 7 h). The same method was used for the synthesis of a series of modified oligonucleotides.²⁰

dba is dibenzylideneacetone.

Since functional groups are introduced at the 3'-end of the oligonucleotide owing to the cleavage of the ester bond between the solid phase and the oligomer, the requirements of the polymeric supports are very strict as regards the stabilities and reactivities of the ester fragments. A series of homologous polymers **45a–d** and **46** have been designed in a search for a polymeric support which meets better these requirements.^{22,23}

The polymeric supports **45a–d** were prepared by the reaction of glycolic (**47**) and 4-hydroxybutyric acids (**48**) containing a dimethoxytrityl protective group with the amino groups of the polymer in the presence of *N,N'*-diisopropylcarbodiimide and *N*-hydroxysuccinimide. After detritylation, the polymers **49a–c** were introduced into a reaction with protected acids **47** and **48** in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride and catalytic amounts of *N*-methylimidazole. When polystyrene was used as a starting support, the activation of the carboxy group in compound **47** was carried out in the presence of carbodiimide and *N*-hydroxysuccinimide.

DIC = $\text{Pr}^i\text{N}=\text{C}=\text{NPr}^i$, HOSu = ;
P = CPG (**49a–c**), PS (**49d**);
 $n = 1$ (**47, 49b–d**), 3 (**48, 49a**).

The modified polymeric support **46** was prepared by esterification of the protected 4-hydroxybutyric acid **48** with propane-1,3-diol in the presence of DCC resulting in compound **50** which was further acylated with succinic anhydride and immobilised on a solid phase using the carbodiimide method.

The polymeric supports **45a–d** and **46** were used in the synthesis of oligonucleotides **51** containing a 3'-terminal carboxy group using the phosphoramidite approach. Cleavage of the oligomers from the solid phase and deprotection of internucleotide phosphates were performed by treatment with a 0.1 M aqueous solution of sodium hydroxide or 0.5 M DBU in H_2O ; deprotection of heterocyclic bases was achieved by subsequent treatment with concentrated aqueous ammonia.

$m = 1, 3$.

Conjugates of modified oligonucleotides **51** with α,ω -diaminoalkanes were prepared by treatment of oligomers immobilised on modified supports with the corresponding amino component. However, the action of these reagents on oligodeoxyribonucleotides is accompanied by transamination of *N*-protected cytidine residues. Therefore, prior to the synthesis²³ benzoyl protective groups of the heterocyclic bases (cytosine and adenine) were

selectively removed with hydrazine in acetic acid. Under these conditions, oligonucleotides remained bound to the polymeric supports.

The 3'-terminal carboxy group was introduced into the oligonucleotide following termination of the automated synthesis.⁷ The cleavage of the target product containing a 3'-terminal phosphate group from the modified polymer **52** occurred under the action of 0.1 M dithiothreitol (DTT) in concentrated aqueous ammonia as a result of cleavage of the disulfide bond and subsequent intramolecular attack of the sulfide ion formed at the carbon atom. The carboxy group was introduced by treatment of the activated deprotected 3'-phosphorylated oligonucleotide **53** with ω -aminocarboxylic acid.

(P)—NH—aminopropylfructosyl-500, $n = 5, 10$.

The synthesis of modified oligonucleotides containing a 3'-terminal iminodiacetic acid residue has been described.⁸ These compounds can bind metal ions which stabilise the function of certain proteins. 3'-Azido-3'-deoxythymidine (**54**) as a starting nucleoside component was further converted into 3'-amino-3'-deoxythymidine and alkylated with two equivalents of ethyl

Scheme 4

bromoacetate. The resulting product **55** was converted into a modified phosphoramidite derivative **56** which was introduced into the oligonucleotide synthesis in the final step. The elongation of the chain was performed from the 5'-end of the oligomer to its 3'-end. On termination of the synthesis, the carboxy groups of the target oligonucleotides were deblocked with an aqueous solution of sodium hydroxide.

The synthesis of oligonucleotides containing 3'-terminal aldehyde groups has been described.²⁴ The polymeric support **57** was treated with monosubstituted glycerol **58** and the modified polymeric support with a linker was introduced into the automated oligonucleotide synthesis. After deprotection and cleavage from the polymer, the oligonucleotide containing a fragment with a vicinal diol group was oxidised with sodium periodate to yield modified oligomers **59**. Treatment of oligonucleotides **59** with sodium chlorite gave oligonucleotides **60** with 3'-terminal carboxy groups (Scheme 4).

An original approach²⁵ to the introduction of aldehyde groups into the 3'-termini of oligonucleotides based on the use of a commercially available polymeric support **61** in an automated synthesis²⁶ has been proposed.

Ammonolysis of the ester bond between the polymer and the synthetic oligonucleotide yields the oligomer **62** containing a 3'-terminal α -aminoalcohol fragment. Subsequent removal of the dimethoxytrityl group and oxidative cleavage with sodium periodate results in oligonucleotides with 3'-terminal aldehyde groups.

Conjugates of synthetic oligonucleotides with aminoxy derivatives of some peptides have been prepared.²⁵ The reactions were carried out in aqueous solutions in the presence of a threefold excess of aminoxy components (pH 4.5, 2 h). The yields of the conjugates were $\sim 50\%$.

IV. Synthesis of oligonucleotides containing an internal carboxy or aldehyde group

Oligonucleotides with electrophilic groups within the chain are especially preferred in molecular biology studies. This type of modification seems to hold great promise, since it leaves the ends of the oligomeric chain free, which allows incorporation of a radioactive or fluorescent label at the 5'-end and further transformations of the functional group on the polymeric support provided this can selectively be deprotected. A reactive group can be introduced at any predetermined position of the oligonucleotide chain, *viz.*, at a heterocyclic base, at the 2'-position of the carbohydrate fragment or the internucleotide phosphate group. The presence of a reactive functional group in the oligomeric chain influences the stability of DNA duplexes formed by modified oligomers and complementary NA matrices as can be judged from the change in the melting temperatures of such duplexes in comparison with the melting temperatures of non-modified analogues.

1. Oligonucleotides containing a carboxy or aldehyde group in the heterocyclic base

The preparation of oligonucleotides containing a reactive electrophilic group in the heterocyclic base entails the introduction of a modified phosphoramidite derivative, with a carboxy or aldehyde group either blocked or formed upon postsynthetic treatment of the oligomer, into the automated oligonucleotide synthesis. The methyl group of thymidine is modified especially easily. Modified oligonucleotides containing 5-carboxy-2'-deoxyuridine **63** have been synthesised.²⁷

Substitution of the carboxy group for the methyl group of thymidine was carried out by oxidation with 2-methyl-1,4-naphthoquinone (menadione) in the air under irradiation (350 nm, 16 h). Esterification of the carboxy group in compound **63** was carried out in dry ethanol in the presence of carbodiimide and 1-hydroxybenzotriazole without preliminary protection of the hydroxy groups of the carbohydrate residue. The resulting compound **64** was converted into the phosphoramidite derivative **65**, which was further incorporated into the oligonucleotide chain in the automated synthesis. The hydrolysis of the ethyl ester of 5-carboxy-2'-deoxyuridine with simultaneous removal of the remaining protective groups and cleavage of the target product

from the solid phase were performed by treatment with 0.2 M sodium hydroxide in methanol.

To investigate the relationship between the structure and biological properties of the anticodon domain of *E. coli* tRNA^{Lys}, Davis *et al.*^{28,29} synthesised modified RNA fragments containing substituents with carboxy groups in position 5 of uridine or N⁶ of adenosine.

The synthesis of modified oligoribonucleotides containing 5-methoxycarbonylmethyluridine or 2-thio-5-methoxycarbonylmethyluridine has been described.²⁸ The starting nucleosides for the synthesis of phosphoramidites **66a,b** were prepared by the Vorbruggen glycosylation³⁰ of the corresponding disilylated 5-methoxycarbonyluracil and 5-methoxycarbonylmethyl-2-thio-

uracil derivatives with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose. Subsequent transformations were carried out by standard procedures used in the synthesis of ribonucleoside phosphoramidite derivatives.

Compounds **66a,b** were incorporated into the oligoribonucleotide chain. The oligomers synthesised were deprotected with 10% DBU in methanol (12 h, 25 °C) and Et₃N·3 HF; interestingly, treatment with DBU was accompanied by deprotection of the carboxy group. The structures of the modified oligoribonucleotides were confirmed by mass spectrometry and ¹H NMR spectroscopy. The authors²⁸ call special attention to the fact that incorporation of the 5-methoxycarbonylmethyluridine and 2-thio-5-methoxycarbonylmethyluridine residues into the RNA fragment did not virtually affect the thermal stability of the RNA hairpin.

The same group of American investigators reported the synthesis of oligoribonucleotides containing a modified nucleoside **67**.²⁹ The target phosphoramidite derivative **68** containing protected hydroxy and carboxy groups was synthesised starting from adenosine (**69**) (Scheme 5). Acetylated adenosine reacted with ethyl chlorocarbonate to give the nucleoside **70**. Simultaneous introduction of carboxy and secondary hydroxy groups into compound **70** was effected by treatment with L-threonine. Trimethylsilyl ethyl and *tert*-butyldimethylsilyl protective groups, which can be removed with Et₃N·3 HF after termination of the automated synthesis, were selected for the protection of the incorporated functional groups.

The phosphoramidite derivative **68** was used²⁹ for the synthesis of the modified oligoribonucleotide sequence of the *E. coli* tRNA^{Lys} fragment.

An interesting procedure for the synthesis of oligodeoxyribonucleotides containing 5-methoxycarbonylmethyluridine residues has been described.^{31,32} Condensation of dimethyl-2-bromomethyl fumarate (**72**) and arabinoaminooxazoline **73** synthesised from D-arabinose under the action of cyanamide and 6 M aqueous ammonia (Scheme 6) is the key step in the synthesis of the modified phosphoramidite derivative of 5-methoxycarbonylmethyl-2-deoxyuridine **71**. Treatment of *O*²,2'-anhydro-5-methoxycarbonylmethyluridine formed (**74**) with acetic anhydride in boiling acetic acid results in the opening of the anhydrocycle. Acetyl protective groups are removed by treatment with methanolic ammonia. The resulting modified nucleoside **75** can be used as a starting compound in the oligoribonucleotide synthesis.

The opening of the anhydrocycle in compound **74** under the action of hydrogen bromide in trifluoroacetic acid or of acetyl bromide in acetonitrile results in 2'-bromo-2'-deoxy-3',5'-di-*O*-acetyl-5-methoxycarbonylmethyluridine (**76**); reduction of the latter with hydrogen over palladium or with tributyltin hydride in the presence of azoisobutyronitrile affords compound **77**. Further transformations of nucleoside **77** into phosphoramidite **71** were carried out using standard methods.

The phosphoramidite derivative **71** was used³² in the synthesis of oligonucleotides containing substituents with protected carboxy groups in position 5 of the heterocyclic base. The presence of a modified fragment in the oligonucleotide chain was confirmed by HPLC of products of enzymatic hydrolysis by snake venom phosphodiesterase and alkaline phosphatase.

These oligonucleotides immobilised on a solid phase were treated with 50% solutions of diamines in ethanol at room temperature to give the corresponding amides. However, it was shown³² that the 5-methoxycarbonylmethyl group (methyl ester) in position 5 is not very reactive: the reaction time with diamines is 12 h.

In order to reduce the reaction time with diamines, the same group of Japanese investigators used modified oligonucleotides in which the carboxy group of the substituent at C(5) of the heterocyclic base was protected as a cyanomethyl ester.³³ The target phosphoramidite **78** was prepared from the diacetyl derivative **77**. The key stage in this synthesis is esterification of the free carboxy group of nucleoside **79** with bromoacetonitrile in the

Scheme 5

Thr = NH₂CH(CO₂H)CH(OH)Me, Tf = CF₃SO₂, TMSE = Me₃Si(CH₂)₂.

Scheme 6

presence of potassium carbonate in hexamethylphosphoric triamide (HMPA). The yield of the product **80** was 70%. The increase in the reaction time and the use of chloroacetonitrile and triethyl-

amine decreased the yield of the ester **80** to 30% due to the formation of the *N*³-cyanomethyl derivative.

The strategy of synthesis of oligomers with a cyanomethylated carboxy group within the chain is similar to that described in study.³² The presence of a modified unit was confirmed by enzymatic hydrolysis with nuclease P1 and alkaline phosphatase. Aminolysis of the resulting oligonucleotides showed that the cyanomethyl ester is more reactive than the methyl ester and the use of this particular type of oligonucleotides allows the reduction of the reaction time to 1 h, whereas the concentration of the amino component can be decreased to 0.6–1.0 mol litre⁻¹. However, the reaction with tyramine was over only in five days, which can be attributed to poor solubility of this compound in organic solvents and low pK_a of its amino group. It was found that the addition of catalytic amounts of triazole to the reaction mixture significantly increases the rate of aminolysis.

In the synthesis of oligonucleotide conjugates with two different amino components, advantage was taken of the difference in the reactivities of methyl and cyanomethyl esters.³⁴ To this end, the phosphoramidite derivatives **71** and **78** were employed in the synthesis of oligonucleotides **81** containing both 5-methoxycarbonyl and 5-cyanomethoxycarbonylmethyluridine residues.

The incorporation of two different functional groups was carried out in the following way. First, the oligonucleotide **81** immobilised on a solid phase was treated with tyramine in the presence of triazole (20 °C, 3 days); in this case, tyramine reacted selectively with the cyanomethyl ester. After washing of the polymer, tris(2-aminoethyl)amine (50% ethanolic solution) was added to the oligonucleotide **82** and complete aminolysis resulted in the derivative **83**. The presence of two different amide groups was confirmed by enzymatic hydrolysis of the isolated oligonucleotide under the action of snake venom phosphodiesterase, alkaline phosphatase and nuclease P1.

The methods for the synthesis of oligonucleotides containing an aldehyde group in the heterocyclic base usually entail mild oxidation of the methyl group of thymine. Thus the synthesis of modified oligomers containing 5-formyl-2'-deoxyuridine residues has been described.^{11,35} The key step in this synthesis was the

R is a fragment of a protected oligonucleotide chain.

oxidation of the methyl group of protected thymidine **84** to the formyl group under the action of potassium persulfate in the presence of copper sulfate and 2,6-lutidine (yield 52%). It was recommended to use the 1,3-diphenylimidazolidine protective group, which is stable under alkaline conditions and is removed by treatment with an acid, for protection of the aldehyde group.^{36,37} By introducing various electron-withdrawing substituents into the benzene rings of *N,N'*-bis(phenyl)ethylenediamine, one can vary the pK of the amino groups and thus control the ease of cleavage of the protective group under the action of acids.

X = H (**a**), 4-F (**b**), 4-Cl (**c**), 3-Cl (**d**).

The stabilities of modified nucleosides **85a–d** in acidic media have been investigated. It was shown that the diphenylimidazolidine protective groups do not withstand conditions of the cleavage of the 5'-dimethoxytrityl protective group (3% trichloroacetic acid in dichloromethane, 25 °C). A decrease in the concentration of trichloroacetic acid to 1% helps avoid the deprotection of the introduced carbonyl group in compound **85d**, which has been chosen for the synthesis of the phosphoramidite derivative and subsequent oligonucleotide synthesis. Bis(3-chlorophenyl)-imidazolidine protection was removed in the final step using

80% aqueous acetic acid. The presence of an aldehyde group in modified oligonucleotides was confirmed by enzymatic hydrolysis with a mixture of snake venom phosphodiesterase and alkaline phosphatase. An alternative approach to the synthesis of oligonucleotides containing 5-formyl-2'-deoxyuridine residues has been described.³⁸ In this case, the phosphoramidite derivative of the precursor compound **86** was introduced into the automated nucleotide synthesis. The carbonyl group was generated by post-synthetic treatment of the oligonucleotide fragment containing a *vic*-diol group, with sodium periodate.

5-Iodo-2'-deoxyuridine (**87**), which was further converted into the vinyl derivative **88** by reaction with vinyl acetate in the presence of catalytic amounts of palladium acetate and triphenylphosphine (Scheme 7), has been used as a starting compound for the synthesis of the phosphoramidite **86**.³⁸ The vinyl fragment was oxidised with osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide and the *vic*-diol group in position 5 of compound **89** was protected by acetyl groups. Phosphoramidite **86** was introduced into the automated oligonucleotide synthesis.

The resulting modified oligomers **90** were treated with concentrated aqueous ammonia to remove acetyl protective groups and to achieve detachment from the solid phase and then the *vic*-diol group was oxidised with sodium periodate (50 equiv. of NaIO₄, 1 min, 0 °C). Compound **91** was reduced with sodium borohydride, which served as an indirect evidence for the internal position of the carbonyl group in the oligonucleotide.

R¹ and R² are fragments of a protected oligonucleotide chain;
R³ and R⁴ are fragments of a deprotected oligonucleotide chain.

The effect of the aldehyde group incorporated into a heterocyclic base on the thermal stabilities of duplexes formed from the oligomer **91** and its complementary natural oligonucleotide, has been studied.³⁸ It was shown that the presence of a formyl group decreases the melting temperatures of the heterogeneous 12- and 6-membered duplexes by 4.1 °C and 5.8 °C, respectively, in comparison with the non-modified analogues.

The phosphoramidite derivative **86** was also used in the synthesis of an oligonucleotide sequence containing a recognition site for the transcription factor NFκB.³⁹ It is known⁴⁰ that 5-formyluridine binds covalently to the ε-amino group of lysine. Compound **86** was synthesised according to a scheme similar to that described in³⁸ except that the vinyl fragment was introduced into the derivative **87** using tributylvinyltin in the presence of catalytic amounts of the Pd(MeCN)₂Cl₂ complex instead of vinyl acetate, which made it possible to increase the yield of compound **88** from 68% to 80%.³⁹

Oligomers containing 5-formyl-2'-*O*-methyluridine residues were synthesised in order to investigate the covalent binding of modified oligonucleotides to the transcription factor NF κ b.³⁹ Commercially available *O*²,2'-anhydrouridine was used as a starting compound in this synthesis; the anhydro ring was opened with trimethylborate. Iodination of the resulting derivative **92** afforded modified nucleoside **93**, which was further converted into the phosphoramidite derivative **94**.

After termination of the automated oligonucleotide synthesis and complete deprotection of the functional groups, the *vic*-diol group was oxidised with sodium periodate. It was shown³⁹ that the introduction of a formyl group did not virtually affect the binding of the modified oligomer to the transcription factor.

The above-described approach was also used in the synthesis of oligonucleotides containing 5-formyl-2'-deoxycytidine.⁴¹ The vinyl residue was introduced into the C(5) position of the heterocyclic base **87** by treatment of the protected nucleoside with a mixture of tributylvinyltin and bis(triphenylphosphine)dichloropalladium, which made it possible to markedly reduce the reaction time (from 16 to 1.5 h) and to increase the yield of the target product **95** to 80%. The modified 2'-deoxycytidine **96** was prepared from the protected uridine **95** by activation of the

TPSCl = 2,4,6- $\text{Pr}_3\text{C}_6\text{H}_2\text{SO}_2\text{Cl}$.

4-oxo group with 2,4,6-triisopropylbenzenesulfonyl chloride and subsequent interaction of the intermediate compound with ammonia. In compound **96**, the vinyl group was oxidised, the exocyclic amino group and the hydroxy groups of the *vic*-diol formed were simultaneously protected and the 3'-hydroxy group was selectively deprotected. The nucleoside formed was used for the preparation of the corresponding phosphoramidite derivative incorporated into the oligonucleotide chain.

After deprotection of the oligonucleotides and oxidative cleavage of the *vic*-diol group with sodium periodate, some physicochemical properties of the synthetic oligomers, *e.g.*, pK_a of the 5-formyl-2'-deoxycytidine residue and the melting temperatures of the DNA duplexes formed by the modified oligonucleotides and the complementary NA matrices, were established. It was shown⁴¹ that the introduction of the carbonyl function had virtually no effect on the thermal stability of the modified duplex.

Oligomers containing 6-formyl-2'-*O*-methylcytidine fragments were synthesised in order to investigate the DNA-binding domain of the protooncogen *c-myc*.⁴² Since 6-(1,2-diacetoxyethyl)-2'-deoxyuridine is unstable even at room temperature,³⁸ its protected analogue, *viz.*, 1-6-(1,2-diacetoxyethyl)-[4-ethoxy-2-oxo-1,2-dihydropyrimidin-1-yl]-2'-*O*-methyl-5'-*O*-dimethoxytrityl- β -D-ribofuranoside (**97**), was used as a precursor of 6-formyl-2'-*O*-methylcytidine.⁴²

2'-*O*-Methyluridine (**92**), in which the acylation of the hydroxy groups of the carbohydrate fragment was followed by the activation of the 4-oxo group with thionyl chloride (Scheme 8), was used

Scheme 8

Scheme 9

R^1 and R^2 are fragments of a protected oligonucleotide chain; R^3 and R^4 are fragments of a deprotected oligonucleotide chain.

as a starting compound in the synthesis of nucleoside **97**. Subsequent treatment of the protected 2'-*O*-methyluridine product with sodium ethoxide in ethanol and *tert*-butyldimethylsilyl chloride yielded the derivative **98**. Treatment of nucleoside **98** with iodine in the presence of lithium diisopropylamide at -78°C afforded the corresponding protected 6-iodouridine **99**. The introduction of a vinyl fragment into the derivative **99** and its subsequent oxidation with osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide was carried out as described previously.³⁸

After acetylation of hydroxy groups, removal of *tert*-butyldimethylsilyl protection and introduction of dimethoxytrityl protective groups, compound **97** was used for the preparation of the corresponding phosphoramidite derivative which was incorporated into the oligonucleotide chain by the automated synthesis. Standard postsynthetic treatments and oxidation with sodium periodate afforded target oligomers containing 6-formyl-2'-*O*-methylcytidine.

It was shown⁴² that the introduction of one modified fragment decreased the melting temperature of a 23-membered DNA duplex in comparison with its natural analogue by 6°C .

An original approach to the synthesis of oligonucleotides containing an aldehyde group in position 8 of deoxyadenosine has been described.⁴³ This approach involves the introduction of the phosphoramidite derivative of compound **100** containing a pent-4-enylthio group and prepared starting from thiol **101**, into an automated synthesis (Scheme 9).⁴⁴ The oxidation of the double bond of the pent-4-enyl residue was carried out after termination of the synthesis of the oligonucleotide with osmium tetroxide in the presence of hydrogen peroxide and *N*-methylmorpholine *N*-oxide in the dark at 25°C . These conditions excluded the destruction of the modified oligomer and the unwanted oxidation of sulfur.

The *vic*-diol group was converted into the aldehyde group by oxidation with sodium periodate (100 equiv.); the presence of this group was confirmed by reactions of the modified oligonucleotide with aminoxy compounds and ^1H NMR spectroscopic data.

Conjugates of modified oligonucleotides with fluorescent labels have been prepared.⁴⁵ It was shown that the introduction of one heterocyclic base with an aldehyde group localised in a C(3) linker decreases the melting temperature of an 11-mer duplex by 14°C .

2. Oligonucleotides containing a carboxy or aldehyde group in a non-nucleotide fragment

Endo *et al.*⁴⁶ have prepared a non-nucleoside phosphoramidite **102** containing a protected carboxy group which can be incorporated into the chain or be attached to the 5'-end of the oligonucleotide. The key step in the synthesis of compound **102** is condensation of benzyl 4-aminobutyrate with 2,2-bis(hydroxymethyl)propionic acid in the presence of DCC and HOBT resulting in compound **103**. Phosphoramidite **102**, which was further used for the synthesis of model oligonucleotides **104** containing an

$\text{X} = \text{OH}$ or NHR .

internal protected carboxy group, was obtained by protection of one primary hydroxy group of the diol **103** with an equimolar amount of dimethoxytrityl chloride and subsequent phosphitylation of the tritylation product. Conjugates of modified oligomers **104** with various amines and diamines were synthesised using the solid-phase method. It was shown⁴⁶ that treatment of the oligonucleotide **104** immobilised on a polymeric support with a solution of alkyl amine in an organic solvent results in the quantitative formation of the conjugate **105** ($X = \text{NHR}$).

An alternative procedure for the introduction of a protected carboxy group into the oligonucleotide was proposed by Hebert *et al.*⁴⁷ who synthesised model dinucleoside phosphates from the phosphoramidite derivative **106**.

The amino and carboxy groups in 4-hydroxy-L-proline (**107**) were protected, which has been used as a starting compound in the synthesis of phosphoramidite **106**; deprotection of the amino group in the resulting compound **108** with piperidine and subsequent acylation with fluorenylmethyl hydrogen succinate in the presence of DCC and HOBT led to the amide **109**. The derivative **109** was then phosphitylated with the formation of the target phosphoramidite **106** which was employed in the oligonucleotide synthesis. The yield for the step of attachment of the modified fragment was 97%.

Fm is fluorenylmethyl; pip is piperidine.

The use of other acylating reagents for the treatment of compound **108** with a deprotected amino group has made it possible⁴⁷ to prepare dinucleoside phosphates containing various functional groups.

The introduction of an aldehyde group into the oligonucleotide chain was carried out by a group of Belgian investigators^{48,49} who used non-nucleoside phosphoramidites **110a,b** containing a *vic*-diol fragment for automated synthesis. The phosphoramidite derivative **110a** was prepared from commercially available deoxyribofuranosyl chloride **111**. The introduction of the dec-9-enyl fragment was carried out under the action of the corresponding organocadmium compound⁵⁰ with subsequent separation of the epimers **112a** ($R:S = 65:35$). Despite the fairly high yield of the *R*-epimer, further modification was performed on the *S*-epimer, since its configuration corresponded to the β -configuration of the anomeric centre of natural nucleosides. As a consequence, modified oligonucleotides synthesised with the use of the *S*-epimer can form stable duplexes with mRNA. The *S*-epimer **112a** was oxidised with osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide; the hydroxy groups in the resulting *vic*-diol derivative were protected as *tert*-butyldimethylsilyl ethers eventually resulting in the derivative **113a**.

$R^1 = (\text{CH}_2)_8\text{CH}=\text{CH}_2$ (**112a**), $\text{C}_6\text{H}_4\text{CH}=\text{CH}_2$ -4 (**112b**);
 $R^2 = (\text{CH}_2)_2\text{CN}$ (**110a**), Me (**110b**);
 $X = (\text{CH}_2)_8$ (**110a**, **113a**), 4-C₆H₄ (**110b**, **113b**).

Compound **113b** was prepared in a similar way. In this compound, the protected *vic*-diol group is located in the *para*-position of the benzene ring, which was used as an analogue of the heterocyclic base of the nucleoside. Removal of *p*-chlorobenzoyl protection and selective incorporation of dimethoxytrityl protective groups with subsequent phosphitylation of compounds **113a,b** gave the phosphoramidite derivatives **110a,b**, which were introduced into the automated oligonucleotide synthesis.

After deprotection of the modified oligonucleotides, the *vic*-diol groups were oxidised with sodium periodate. The carbonyl-containing oligonucleotides were used^{48,49} for the synthesis of conjugates with biotin and fluorescent labels.

3. Oligonucleotides containing an aldehyde group in the apurine site

The formation of the apurine (AP) site is a simpler and, therefore, more popular procedure for the introduction of the aldehyde group into the oligonucleotide chain. Elimination of the purine base from the oligonucleotide occurs under the action of strong acids (HCl, HCOOH). In the oligomeric chain, the apurine fragment exists as three tautomers, *viz.*, α - and β -anomeric forms of deoxyribofuranose **114** (1:1) and the aldehyde-containing structure **115** (~1%).^{51,52} Depending on the nature and concentration of the amine, its addition to the AP-containing oligonucleotide leads to either the scission of the chain due to β -elimination of 3'-phosphate and the formation of the derivative **116**,^{51,53-55} or the addition of the corresponding amine and the formation of the Schiff base which is reduced to the conjugate **117** upon treatment with sodium cyanoborohydride (pH 5.0).^{51,52,56,57}

B is purine heterocyclic base;

R¹ and R² are fragments of an oligonucleotide chain.

The rate of acid hydrolysis of the *N*-glycosidic bond, which depends on pH, plays a crucial role in the formation of the apurine site. It is known⁵⁸ that among other natural nucleosides, the highest apurinisation rate ($7.3 \times 10^{-2} \text{ min}^{-1}$) is manifested by 2'-deoxyadenosine. The half-transformation time upon treatment of 2'-deoxyadenosine with 30 mM HCl at 37 °C is 9.5 min. Most frequently, apurinisation of an oligonucleotide is effected by treatment with 80% formic acid (20 °C, 30 min) or 0.2 M hydrochloric acid (37 °C, 90 min).⁵⁶

To avoid drastic acid conditions for the formation of the apurine site, it was proposed⁵¹ to use the artificial adenosine analogue, dideoxynebularin (**118**).

The apurinisation rate constant of this unit within the oligonucleotide chain upon treatment with 30 mM HCl (37 °C, 13 min) is $23.7 \times 10^{-2} \text{ min}^{-1}$, the half-transformation time is 2.9 min. However, the absence of a 3'-hydroxy group in the structure of the monomeric fragment **118** makes impossible its use for the formation of the intrachain AP site.

Synthesis of oligonucleotides containing 8-propylsulfinyl-2'-deoxyadenosine residues **119** obtained by the oxidation of the corresponding sulfide⁴⁴ has been described.⁵⁷ Apurinisation of this unit was carried out at pH 3 (65 °C), which was followed by the preparation of modified oligonucleotide conjugates with fluorescent labels.

4. Oligonucleotides containing a carboxy or aldehyde group in the 2'-position of the carbohydrate fragment

In the majority of cases, modification of the 2'-position does not result in any significant destabilisation of the DNA duplex. It should be noted, however, that the synthesis of oligonucleotides containing a reactive group in the carbohydrate residue is the most tedious procedure, which requires the selection of an orthogonal system of protective groups.

Obviously, the 2'-carboxy group should be blocked in the course of the automated synthesis. The methyl ester commonly used for this purpose is removed with sodium hydroxide in H₂O or methanol.

Modified oligonucleotides containing 2'-*O*-carboxymethyl groups protected with methyl or allyl esters have been synthesised.⁵⁹ The latter can selectively be removed by treatment with a Pd(0) complex in the presence of morpholine which facilitates further transformations of the carboxymethyl group on solid supports in organic media. Modified phosphoramidite derivatives **120a,b** were synthesised starting from adenosine (**69**). The key step in this synthesis was the alkylation of the 2'-position of the carbohydrate residue of protected adenosine **121** with methyl bromoacetate or with allyl chloroacetate in the presence of a strong organic base, *e.g.*, *tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine (BDDDP).⁶⁰ The use of alkali metal hydrides as a base^{61, 62} has several disadvantages, *e.g.*, formation of side products, fairly low yields ($\leq 18\%$), *etc.*, and significantly restricts the selection of protective groups. Alkylation in the presence of BDDDP leads to the formation of the target compounds **122a,b** in 35%–40% yields. Deprotection of 3'- and 5'-hydroxy groups, selective introduction of dimethoxytrityl protection and further phosphitylation of nucleosides **122a,b** yielded the phosphoramidite derivatives **120a,b**, which were further incorporated into the oligonucleotide chain in the course of the automated synthesis.

R = Me (a), All (b).

On completion of the synthesis, methyl ester is saponified with 2 M sodium hydroxide (20 °C, 30 min), while allyl ester is selectively removed by treatment with tetrakis(triphenylphosphine)-palladium in the presence of morpholine. The reactivity of the incorporated 2'-*O*-carboxy group was confirmed by reaction with

ethylenediamine in aqueous solution in the presence of water-soluble carbodiimide.

An original approach to the preparation of oligonucleotides containing a 2'-carboxymethylthio group has been developed.⁶³ The phosphoramidite derivative of 2'-methoxycarbonylmethylthio-2'-deoxyuridine **123** obtained from 2'-mercapto-2'-deoxyuridine (**124**) was introduced into the automated oligonucleotide synthesis.

The synthesis of 2'-mercapto-2'-deoxyuridine (**124**) from uridine **125** was carried out *via* the cyclic nucleoside **126** using

the opening of the anhydro ring with 4-methoxytoluenethiol in the presence of tetramethylguanidine with subsequent treatment of the derivative **127** with trifluoroacetic acid. The alkylation of compound **124** was carried out using methyl bromoacetate without any preliminary protection of the heterocyclic base and the carbohydrate residue. The yield of 2'-methoxycarbonylmethylthio-2'-deoxyuridine (**128**) was 73%; the reaction was accompanied by the formation of trace amounts of the side product, *viz.*, the N^3 -alkylated nucleoside.⁶³

The yield of the model dinucleoside phosphate dU^*pT (dU^* is a modified deoxyuridine fragment) during the introduction of the modified fragment **123** was 60%–70%. This fact is attributed to the steric hindrances due to the presence of a bulky substituent in the 2'-position. The solid-phase method was used in the synthesis of conjugates of the model compound dU^*pT with aliphatic amines (yield 50%).

Syntheses of 15-mer 2'-modified oligonucleotides with heterogeneous composition have been carried out; the presence of the modified unit was confirmed by enzymatic hydrolysis with a mixture of snake venom phosphodiesterase and alkaline phosphatase.

The synthesis of oligonucleotides containing an aldehyde group in the 2'-position of the carbohydrate residue has been developed.^{59, 64} In this synthesis, the phosphoramidite derivative **129** containing a protected *vic*-diol fragment was used as a modified unit. The key steps in the synthesis of compound **129** include alkylation of the 2'-position of the protected uridine **130** with allyl methyl carbonate in the presence of $\text{Pd}(0)$ and triphenylphosphine and subsequent oxidation of compound **131** with osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide to give the derivative **132**. These authors have selected the conditions where the oxidation of 2'-*O*-allylic ether occurred selectively, without the involvement of the double bond of the heterocyclic base. The hydroxy groups of the *vic*-diol fragment of the modified uridine **132** were protected as benzoates (Scheme 10).

The phosphoramidite derivative **129** was used in the synthesis of modified oligonucleotides. The benzoyl protective groups of the 2'-*vic*-diol fragment were removed by standard postsynthetic treatments; the aldehyde function was generated by treatment with sodium periodate. Model conjugates of modified oligonucleotides with 2,4-dinitrophenylhydrazine, methyl ester of methionine⁶⁴ and some compounds containing aminoxy, hydrazino, hydrazido or 1,2-aminothio groups have been prepared.⁶⁵

V. Conclusion

At present, the preparation of oligonucleotide conjugates with various molecules holds great promise for directed changes in physicochemical and substrate properties of nucleic acid fragments, which is a prerequisite for their application in molecular biological and clinical studies. Synthesis of conjugates wherein the reactive group of the oligonucleotide reacts selectively with the ligand, whereas other functional groups of the reacting molecules remain unaffected, seems to be an optimum procedure for the synthesis of conjugates. Such reactions include interaction of carboxy or aldehyde groups of modified oligonucleotides with amino compounds.

The formation of conjugates with amide bonds requires the activation of the carboxy group. The choice of an activating reagent depends, in particular, on the composition of the reaction medium. In aqueous solutions, water-soluble carbodiimide is most commonly used, while the syntheses performed in organic media utilise preferably condensation reagents based on phosphonium or uronium salts. Each of these variants has disadvantages of its own. In the former case, heterocyclic fragments of nucleic acids react with carbodiimide involving the polarised double bond C=N. In the latter case, conjugation in organic media often poses the problem of solubility of the reacting molecules. For this reason, very often the ligand molecule is added to an oligonucleotide immobilised on an insoluble polymeric support. Further treatment of the conjugate with ammonia or alkali aimed at the cleavage of the bond between the oligonucleotide and the polymer and deprotection of functional groups may lead to the destruction of the non-nucleotide fragment of the hybrid molecule.

In the case of oligonucleotides containing an aldehyde group, additional activation of the electrophilic group is unnecessary and the reaction can be carried out in water-organic media, which helps overcome the problem of solubility of the interacting molecules. The possibility of using hydrazines, hydrazides, hydroxylamines and compounds containing 1,2-aminothiol groups along with amines for the synthesis of conjugates is an indisputable advantage of oligonucleotides containing aldehyde groups. Therefore, the use of modified oligonucleotides with aldehyde groups is synthetically more preferable as can be judged from the increasing number of publications on this subject.

The authors are thankful to E A Romanova, Ph.D. (Chem.), Senior Researcher of the A N Belozersky Research Institute of Physicochemical Biology (Moscow State University), for her valuable assistance in the preparation of this review.

This work has been carried out within the framework of the Program 'Leading Scientific Schools' (Project No. 00-15-97944) and with the financial support of the Wellcome Trust (Grant No. 057361).
