Abstract. The main ways of improving the compatibility of polymer – polymer compositions containing polyolefins as one component are considered. Considerable attention is given to the preparation of polyolefins in the presence of an ingredient bound to the catalyst in the catalytic (including consecutive) polymerisation of olefins. The so-called reactor blends and the synthesis and structure of diblock and conducting composites are described. The important role of compatibilisation of polymers of different nature with the use of a third component is pointed out. The formation mechanism of molecular compositions, the structure and properties of the intermediate layer and the main fields of application of synthetic polyolefin – polymer compositions are discussed. The bibliography includes 335 references.

I. Introduction

In recent decades, the assortment of composite materials produced from industrially important polymer blends or alloys has much expanded. Blending of two or more thermoplastics, an intricate physicochemical process which proceeds under the action of mechanical forces and high temperatures, is an efficient method for the preparation of novel materials with desired properties. Most pairs of polymers are incompatible; however, targeted modification of their morphology allows preparation of polymer blends with reasonable operating characteristics.

Molecular design of multicomponent polymeric systems is a rather complicated problem. That is why communications concerning various physicochemical, structural and other aspects of this problem have been reported only recently.^{1–13} One of the reasons preventing direct blending of polyolefins (PO) with engineering plastics is the non-polar character of the PO. In this

connection design of multicomponent thermoplastic composite materials requires that considerable attention be given to the structural and chemical modification of ingredients (compounds). To achieve compatibility means to minimise the interfacial stress and to improve the interfacial adhesion. This allows the preparation of materials with good deformation – strength characteristics, high impact viscosity, thermal stability, are readily reprocessed, *etc.*, without essential modification of their structure. In particular, improvement of the operating characteristics (*e.g.*, mechanical strength, crack resistance, light stability, colorability and printing sensitivity, reduction of electrifiability and sweating, *etc.*) of PO and, first of all, low-density polyethylene (LDPE) and polypropylene (PP) requires that they be modified with various additives including those of high-molecular-mass. Modification of the PO components of polymer – polymer compositions (PPC) is performed in both the formation (copolymerisation) stage by post-modification (graft polymerisation, modification of the surface, *etc.*) and immediately during the preparation of PPC (the so-called reactor blends or *in situ* preparation of PPC). Such modified PO act as compatibilisers (interfacial agents) and improve the compatibility of ingredients.

Yet another reason for increased interest in PPC is the fact that these types of polymer blends are often formed as processing waste and cheap, degraded polymeric products can be re-used.^{14–16} For both economic and environmental safety reasons, the volume of utilised polymer blends and thermoplastic alloys has been substantially increased since the early 1980s. Currently, requirements imposed on the environmental safety of processing and consumption of polymeric products are continuously increasing. This gives an impetus to researchers to place the problems of recycling of such materials as PO (60% of the total volume of polymeric waste), polystyrene (PS), poly(vinyl chloride) (PVC), poly(methyl methacrylate) (PMMA), poly(ethylene terephthalate) (PETP), poly(tetrafluoroethylene) (PTFE), polyurethane (PU), polyamide (PA), rubber, cross-linked polyethers, cellulose-containing and multilayered materials as a focus of their efforts. After development of efficient methods for separation, reprocessing and/or modification, these materials would be a cheap and important source of polymeric raw materials, since the countries with well-developed economies produce 20 vol.%, or 8 mass %, of

of nearly 200 million tons of solid household waste per year. However, different compositions of such complex raw materials are responsible for the formation of some incompatible ingredients in the recycling. This causes a deterioration in the physical properties of the end products and the materials become brittle. Moreover, some environmentally hazardous components of polymer blends favour the destruction of other blend components (in particular, PVC causes destruction of PETP and other polymers). Recycling and, especially, sorting expenditures aimed at separating raw materials into individual, compatible types of polymers lead to a substantial increase in the cost : property ratio compared to that for the processes based on the use of primary polymer blends. Different types of plastics, *e.g.*, thermoplastics, thermosetting plastics, multilayered blend-based composite materials, *etc.*, require a different approach.

A pair of polymers is considered compatible if its components have similar polarities, have similar functional groups or can interact under blending conditions to form donor–acceptor, hydrogen and other types of bonds, as well as if they are structurally similar and have similar solubilities. However, meeting these conditions is sometimes insufficient, so the number of compatible polymers is small. This especially concerns such non-polar polymers as PO. For instance, LDPE and high-density polyethylene (HDPE) are poorly compatible; co-crystallisation of linear low-density polyethylene (LLDPE) and LDPE results in the formation of separate crystal aggregates on the micrometre level;¹⁷ and PE and PP are immiscible on the molecular level. Moreover, even such a pair as isotactic and syndiotactic PP is also incompatible on the molecular level.

Therefore, when analysing polymer compatibility, one should take into account not only thermodynamic, but also chemical aspects, namely, the interaction between macromolecules. There are two approaches to the design of compatible polymer–polymer systems.⁴ These are (i) linking of macromolecules by chemical bonds (the synthesis of block copolymers, interpenetrating polymer networks, cross-linking of blend components) and (ii) modification of the chemical structure of polymers to obtain negative free energy of mixing (if polymer macromolecules contain functional groups that can strongly interact, some of the components are either modified, thus changing the chemical structure of the monomer units, or copolymerised). Thermodynamic incompatibility of polymer blend components prevents the formation of a common crystal lattice (*i.e.*, no mixed crystals are formed). Nevertheless, an intermediate, interfacial layer between the ingredients of a PPC can exist in this case due to the formation of common supramolecular structures, specific packing of the polymer chains and the absence of well-defined interfaces between the elements of supramolecular order even for crystalline polymers. This to a great extent determines the strength and nature of adhesive forces in the system, which strongly affects the surface area of true interface (phase contact), microrheological processes and contact reactions at the interface. Specific features of the adhesive interactions also depend on the preparation conditions of PPC: *e.g.*, mechanical mixing of components leads to the formation of intermediate layers only as a result of physical interparticle interaction.

A way to design novel materials with improved properties involves the preparation of microheterogeneous compositions with controllable structural inhomogeneity. This class of materials comprises compositions containing PO as one of the ingredients. The results of economic and environmental analysis¹⁶ of the ‘life cycle’ of polymers, which includes their synthesis, processing and modification, usage, waste separation, recycling, re-use and final utilisation of waste allowed one to rank (i) PO first among the widely used plastics and (ii) PP first among all PO. This choice is also determined by the variety of PO-based polymer blends, alloys and composites (including the *in situ* prepared compositions).

This review concerns main approaches to the PO-containing PPC. Particular emphasis is placed on the synthetic aspects of the

problem. Often, though not always, the use of such systems allows compatibility of components on the molecular level. The definition of such compositions as ‘molecular compositions’ (see the title of this review) should be considered to some extent conventionally since the preparation of PPC involves blending of components not only on the molecular level, but also on the level of microphase aggregates consisting of a large number of like macromolecules. In addition, sometimes it is impossible to clearly distinguish between different procedures for the preparation of PPC because many of them can be formed following different mechanisms. This also makes formal classification of PPC difficult.

II. Modern approaches to the description of the properties of polymer–polymer compositions

To gain an insight into specific features of PPC-containing systems, we have to briefly outline the methods for analysis of their thermodynamic and physicomechanical properties.

It does not always happen that the use of simple physical polymer mixtures consisting of components with complementary properties leads to desired results. The reason is thermodynamic incompatibility of most polymer pairs, which is largely because of a small entropy of mixing. Therefore, all polymer compositions to some extent undergo separation into different phases that are characterised by weak adhesion, which deteriorates the properties of the compositions. Usually, ‘compatibility’ of polymers refers to their mutual solubility. In the case of polymer blends, the term ‘miscibility’ is most often used. A necessary, but not sufficient, condition for thermodynamic compatibility of polymers is negative free energy of mixing, G_m :

$$\Delta G_m = \Delta H_m - T\Delta S_m.$$

Due to the high molecular mass of polymers, the entropy of mixing of two macromolecules, ΔS_m , changes only slightly. Hence, compatibility of a pair of polymers requires that the enthalpy of mixing, ΔH_m , be negative, zero or very slightly positive. In addition, specific interactions between miscible polymers must occur (see above).

Methods for studying and improving the thermodynamic compatibility of polymers have been reviewed by Tager and Blinov.¹⁸ According to their concept, the best miscibility is characteristic of those polymers whose molecules contain functional groups with opposite functionalities, capable of forming hydrogen, donor–acceptor, ionic, π -bonds and other types of bonds, rather than of structurally (or compositionally) similar polymers. The following simple equation for calculating the free energy of mixing of polymers was proposed by Tager:¹⁹

$$-\Delta g_x = \Delta G_{III} - (\omega_I \Delta G_I + \omega_{II} \Delta G_{II}),$$

where Δg_x is the mean free energy of mixing of polymers with each other per gramme of the blend; ΔG_I , ΔG_{II} and ΔG_{III} are the Gibbs energies of mixing of polymers I, II and their blend dissolved in the same solvent, respectively; and ω_I and ω_{II} are the mass fractions of polymers I and II in the PPC. Compatibility of polymers is strongly affected by not only the molecular nature and molecular masses of the components, but also their molecular mass distribution.²⁰ However, often, ‘compatibility’ of polymers means the achievement of good mechanical properties rather than compatibility on the thermodynamic level. Keeping this in mind, it should be noted that practically even compatible polymers can appear to be immiscible due to problems arising during the preparation of PPC.

There are three main methods for polymer blending. They include mechanical mixing, film casting from common (the same) solvent and *in situ* blending, *i.e.*, polymerisation of a monomer in the presence of the other (most often, preliminarily swollen) polymer. Each of these methods has specific advantages and drawbacks. For instance, the simplest method, mechanical mixing, cannot always be realised due to limited thermal stability of a

particular ingredient in specified temperature and homogenisation time ranges. Other polymers, being compatible at room temperature, can be incompatible at higher temperatures. Sometimes, casting from common (the same) solvent is precluded by solubility problems and by immiscibility of particular polymers in the presence of specific solvents. Often, the only way of overcoming these obstacles is to use *in situ* polymerisation. However, this is also not a universal procedure since during the polymerisation one monomer can become a solvent for the other polymer and this can induce phase separation of the components. For instance, polymerisation of vinyl chloride in the presence of chlorinated PE can result in monophase or two-phase products depending on the initial reagent ratio.²¹ Nevertheless, *in situ* polymerisation is considered as a potentially promising industrial method for the preparation of polymer blends. Numerous PPC prepared in this manner have been patented. This method allows the preparation of thermodynamically stable PPC; however, they can become unstable on heating, which means that such PPC have lower critical solution temperatures (LCST) and, hence, should be prepared at temperatures below LCST.

Considerable attention has been given to the problems of design of PPC from ingredients with complementary properties. Unfortunately, no general equations for the description of the dependence of a particular property of a PPC on its chemical composition have been proposed so far. For instance, the problem of calculations of the modulus of elasticity, E_{PPC} , for a polymer blend from the known moduli of elasticity of particular components or phases is still to be solved.^{22,23} The moduli of two-phase blends are often estimated using the Coran–Patel approach²⁴ based on the assumption that the magnitudes of the moduli of elasticity of a two-phase polymer blend (Young's modulus or shear modulus) must lie between the effective upper (E_u) and low (E_l) moduli calculated from the models of parallel and series linking of the components. The moduli E_u and E_l are calculated as follows:

$$E_u = \varphi_1 E_1 + \varphi_2 E_2,$$

$$E_l = \left(\frac{\varphi_1}{E_1} + \frac{\varphi_2}{E_2} \right)^{-1},$$

where E_1 and E_2 are the moduli of elasticity of the starting components 1 and 2 and φ_1 and φ_2 are their volume fractions ($\varphi_1 + \varphi_2 = 1$). The modulus of the two-phase blend, E , can be written in the form

$$E = f E_u + (1-f) E_l,$$

where $0 < f < 1$. The maximum and minimum value of the modulus of elasticity corresponds to $f = 1$ and $f = 0$, respectively.

Considering PPC as specific filled systems, one can use an approach known as the mean field approximation for spherulites in the matrix:²⁵

$$\frac{E_c}{E_m} = \frac{(1-\varphi)E'_m + (v^* + \varphi)E_r}{(1+v^*\varphi)E'_m + v^*(1-\varphi)E_r},$$

where E_c , E_m , E_r are the moduli of the composite, matrix and an elastic inclusion with the volume fraction φ , E'_m is the real part of the elastic modulus of the matrix, $v^* = 2(4 - \nu_m)/(7 - 5\nu_m)$ and ν_m is the Poisson coefficient of the matrix. This expression imposes no limitations on both the volume fractions of ingredients and the ratio of the modulus of elasticity of the matrix to that of the inclusion. If the moduli of elasticity of the matrix (E_m) and inclusion are substantially different, it is appropriate to use the simplified Guth relationship which takes into account the pair interaction between rigid particles:²⁶

$$E_{PPC} = E_m(1 + 2.5\varphi + 14.1\varphi^2).$$

At $\varphi < 0.4$, the results of calculations using this formula coincide with experimental data.

There are many equations derived based on different models of matrix compositions (*e.g.*, the Smallwood and Takayanagi equations, *etc.*); however, they are rarely used. All of them use the volume fraction of a component, φ , as the only structural parameter, though the experimental data show that the physico-mechanical properties of PPC are also affected by salient features of their morphology. For instance, the properties of ultrahigh-molecular-mass PE (UMMPE) depend not only on the volume fraction of crystallites, but also the ratio of the fractions of crystallites with compacted and aligned chains and on the type of mutual arrangement of these crystallites.²⁷

Therefore, PPC should be described using such molecular models that take into account additional morphological parameters. For instance, if a model implies an interaction between components 1 and 2,²⁸ we get

$$E_{PPC} = E_1 + E_2(1 - \varphi_1) + \Delta E.$$

The sign preceding ΔE points to the presence (a 'plus' sign) or the absence (a 'minus' sign) of an interaction. For instance, the modulus of elasticity of a PP–HDPE composition can be larger than those of the individual components at a particular component ratio and at rapid cooling of melt. In other words, the addition of the first ingredient improves the properties of the second (this is also called positive synergism of the polymeric constituents).

Recently, the elastic properties of partially crystalline material were studied theoretically based on the scaling concept and very good agreement with experimental data was achieved (see, *e.g.*, Ref. 29).

If the glass transition temperature, T_g , of the first component of a PPC approaches that of the second ingredient of the PPC, these polymers are partially compatible.³⁰ The degree of compatibility, D , is defined as the ratio of the difference between the T_g values of the blend components to the difference between the T_g values of pure polymers:³¹

$$D = \frac{T_{g1}^b - T_{g2}^b}{T_{g1}^p - T_{g2}^p}, \quad 0 < D < 1,$$

where T_g^b and T_g^p is the glass transition temperature of the blend component and of the pure polymer, respectively. The glass transition temperature of the PPC of compatible polymers is intermediate between the T_g values of the blend components and is determined using the Fox equation (the so-called blend rule)³²

$$\frac{1}{T_g} = \frac{\varphi_1}{T_{g1}} + \frac{\varphi_2}{T_{g2}}.$$

Large deviations from the Fox equation are often considered as an indication of strong interpolymer interaction.³³

According to the Hoffmann equation,³⁴ the melting temperature of a non-isothermally crystallised PPC (T_m) increases linearly as the crystallisation temperature of the ingredients (T_c) increases

$$T_m = \frac{1}{\delta} T_c + \left(1 - \frac{1}{\delta}\right) T_m^\circ,$$

where δ is the crystallite morphological factor and T_m° is the equilibrium melting temperature. For instance, a PPC consisting of poly(but-1-ene) (PB) and hydrogenated oligo(cyclopentadiene) (HOCP) has a $1/\delta$ value of ~ 0.34 , while the ternary PP–PB–HOCP blend (50:30:20)[†] is characterised by $T_m^\circ = 456$ K.³⁵

Szabo *et al.*³⁶ showed that the interpolymer interaction between such blend components as poly(isobutylene) (PIB) and linear LDPE obtained by copolymerisation of ethylene with

[†] Hereafter, the concentrations of blend components are given in per cent by mass.

α -olefins (LLDPE) can be estimated using the modified Flory–Huggins equation³⁷

$$\frac{1}{\phi_1} \left(\frac{1}{T_m} - \frac{1}{T_m^0} \right) = - \frac{RV_2}{\Delta H_2 V_1} \chi_{12} (1 - \phi_2)^2,$$

where ϕ_1 and ϕ_2 are the volume fractions of the polymers 1 and 2, V_1 and V_2 are the molar volumes of repeating units of the polymers 1 and 2, respectively, ΔH_2 is the enthalpy of melting of PE, and χ_{12} is the Flory–Huggins interaction parameter. The ΔH_2 is 4.1 kJ mol^{−1} and the parameter χ_{12} is −0.022 at 393 K. This proves that even relatively weak dispersion forces can make two polymers compatible.

Interesting information for estimation of the interaction between the PPC components can be obtained from the results of measurements of the surface (γ) and interfacial tension.

$$\gamma = \gamma_d + \gamma_p,$$

where γ_d and γ_p are the components of the surface tension of the polymer, which are due to the dispersion and dipole interaction, respectively. These characteristics of intermolecular interaction are immediately related to the cohesive energy of the system under study. The surface tension and its components depend on the nature of PPC ingredients and decrease upon their modification (Table 1).³⁸ In addition, the higher the temperature the smaller the γ values (Table 2). The surface tension at the interface between two immiscible polymers in a PPC (γ_{12}) can be calculated using the following equation:⁴⁰

$$\gamma_{12} = \gamma_1 + \gamma_2 - \frac{4\gamma_{d1}\gamma_{d2}}{\gamma_{d1} + \gamma_{d2}} - \frac{4\gamma_{p1}\gamma_{p2}}{\gamma_{p1} + \gamma_{p2}},$$

where subscripts 1 and 2 correspond to the first and second components, respectively.

Table 1. Surface tension and its components (dyn cm^{−1}) for PP and PA-6.³⁸

Polymer	γ_d	γ_p	γ
PP	28.3	12.5	40.8
PA-6	32.1	20.9	53.0
PP ^a	26.3	9.5	35.8
PA-6 ^a	30.1	10.7	40.8

^a Modified by grafting maleic anhydride (MA, 1%).

Table 2. Surface tension γ (dyn cm^{−1}) for some polymers at different temperatures.³⁹

T/K	LDPE	HDPE	PVA ^a	PMMA
293	35.3	35.3	36.5	41.1
413	27.3	28.8	28.6	32.0
453	24.6	26.5	25.9	28.9

^a PVA stands for poly(vinyl acetate).

Next, we present the surface tension (γ_{12}) values at the interface between the first polymer and the second polymer in the PPC at 423 K.⁴¹

First polymer	LDPE	HDPE	PE	LDPE
Second polymer	PVA	PVA	PVA (25%)	PP
$\gamma_{12}/\text{dyn cm}^{-1}$	9.8	11.0	1.3	1.3

The surface tension at the interface can also be approximated using the Wendt–Owens equation⁴²

$$\gamma = (\gamma_1^{1/2} - \gamma_2^{1/2})^2.$$

Thus, there are some modern methods that often allow a quite reasonable description of the properties of real PPC. However, many aspects of this problem remain unclear as yet.

III. *In situ* preparation of polymer–polymer compositions in the catalytic polymerisation of olefins

The method for the preparation of molecular PPC (hereafter, we will denote them ‘the *in situ* prepared PPC’) in the catalytic polymerisation or copolymerisation of α -olefins (ethylene, propylene, butene), diene monomers (butadiene, isoprene) and monomers of the acetylene type (acetylene, phenylacetylene, 3-bromopropyne, *etc.*) on metal complex catalysts involves the following stages.⁴³ First, this is a chemical or physical immobilisation of the catalyst components on the ‘polar’ ingredient of the PPC to be prepared. Usually, the catalyst components represent macromolecular metal complexes based on PMMA, PVC, PTFE, poly(vinylidene chloride) (PVDC), polyformaldehyde (PFA), PVA, poly(vinyl alcohol) (PVAle), poly(4-vinylpyridine) (P4VP), cellulose and other polymers. The second stage consists of a liquid-phase or gas-phase polymerisation or copolymerisation of corresponding monomer resulting in the desired PPC.

In the text below we consider the main approaches to the synthesis of catalyst components (of the Ziegler–Natta type), some features of the polymerisations catalysed by these, in essence, polymer-immobilised⁴⁴ catalysts and, finally, selected experimental data on the structure of particular systems.

1. Synthesis of catalyst components

Polymers containing functional groups (L) are macroligands that can bind the components of catalytic systems, *viz.*, a transition metal compound MX_n [TiCl_4 , VCl_4 , VOCl_3 , VCl_3 , TiCl_3 , $\text{Ti}(\text{O}i\text{Bu})_4$, CoCl_2 , MoCl_5 , *etc.*], an organometallic (organoaluminium, organolithium, organomagnesium, organozinc) compound, *etc.*

A general scheme of metal complex immobilisation taking into account the formation of chemical bonds can be represented as follows:

The penetration depth of the active catalyst into the near-surface layer of the component of a PPC can vary depending on the reaction conditions. This can be accompanied by both monodentate and polydentate coordination of MX_n by the intramolecular or intermolecular mechanism.⁴⁴ The optimum immobilisation procedures can involve either the use of a suspension of the PPC component or gas-phase coordination of the complexes. Many transition metal halides are relatively strong Lewis acids capable of forming ionic complexes. It is this type of

bonding that is used for the coordination of MX_n to PVC, PVDC, PTFE and poly- α -bromostyrene.

Yet another approach, applicable to crystalline compounds MX_n (e.g., TiCl_3 , VCl_3), is based on the formation of carboxylic acid salts. For instance, TiCl_3 is coordinated by chlorinated polymers (PVC, chlorinated PP, natural rubber) by the following mechanism:⁴⁵

Joint grinding of TiCl_3 and PVC leads to complete disappearance of the crystalline phase. Nearly complete oxidation of Ti^{3+} into Ti^{4+} is evidence for essential transformations in the TiCl_3 –PVC system.

Special methods for immobilisation of compounds MCl_3 (with retention of their submicrostructure) on polymers have been developed. The most efficient procedure involves solid-phase mechanochemical synthesis in the presence of polymeric constituents of PPC (most often, PO). Experimentally, this is achieved by activation of the reacting components in the vibrating, ball or differential agate mills (usually, in an inert atmosphere).^{46, 47}

The surface of polymers is also modified using cationic polymerisation,⁴⁸ which results in macromolecular analogues of stable carbonium salts.

To immobilise metal complexes on the surface of PO (the grafted layer is 10 to 30 Å thick), the surface of the polymer is functionalised by performing graft polymerisation of polar monomers.⁴⁶ In particular, the surface of PE, PP or ethylene/propylene copolymer can be modified by grafting, e.g., acrylic acid, 4-vinylpyridine, acrylonitrile, allyl alcohol, vinylpyrrolidone, etc.

$\text{R}^1 = \text{H, Me; R}^2 = \text{H, Me, C}_6\text{H}_5; \text{Y} = \text{OH, NHR, CH}_2\text{NH}_2, \text{SR, CH}_2\text{OH, CH}_2\text{SR}^2, \text{CO}_2\text{H, OCOMe; R}^3 = \text{H, Me, C}_2\text{H}_5, \text{CH}_2\text{CH}=\text{CH}_2, \text{C}_6\text{H}_5.$

In the text below we will show that graft polymerisation products can also be used individually as the third components (compatibilisers) to improve the compatibility of components of binary PPC.

Table 3 lists some characteristics of catalyst components MX_n that are used for the *in situ* preparation of PPC.

Polymer–polymer compositions can also be prepared *in situ* by anionic-coordination or ionic polymerisation using an alternative approach which involves immobilisation of organometallic compound on the polar component. In this connection, it is of interest to consider the modification of the surface of PETP or PA-66 via 1,2-polyaddition of compounds LiR to carbonyl groups.⁴⁹ Organomagnesium compounds are immobilised on graft-functionalised polymers.⁵⁰ Addition reactions of AlR_3 or AlR_2H to the multiple bonds of polymers, resulting in the formation of reactive organometallic centres have been reported. In particular, addition products of dialkylaluminium hydrides to random styrene (25%)/butadiene copolymers have been studied in detail.^{51, 52}

Table 3. Characteristics of catalyst components used for *in situ* preparation of PPC.⁴⁶

Polymer	Component MX_n	Immobilisation conditions of MX_n on the polymer surface			Immobilised metal content /mg g ⁻¹
		solvent	$T/^\circ\text{C}$	time /h	
PVC	VCl_4	CCl_4	20–40	2.0	0.8
	TiCl_4	heptane	50–70	2.0	1.1
PVDC	VCl_4	CCl_4	30–35	2.0	1.5
PMMA	VCl_4	CCl_4	20–25	1.5	0.5
	TiCl_4	heptane	60	2.0	0.8
PFA	VCl_4	CCl_4	20–25	1.5	1.0

PE–g-PVP ^d	VCl_4	CCl_4	25	1.0	6.0

^a Immobilisation is performed by grinding a mixture of components in a ball mill in the absence of solvent. ^b PAA stands for poly(allyl alcohol).

^c PAAc stands for poly(acrylic acid). ^d PVP stands for polyvinylpyrrolidone.

Organoaluminium compounds can undergo insertion into the multiple bonds of functional groups of the polymeric constituents of PPC.⁴⁴ Most likely, immobilisation of alumoxanes proceeds by the same mechanism. Both components of the metal complex system can be immobilised on the same polymer.

The coordination mechanism of polymers to transition metal compounds (one-component catalysts of olefin polymerisation) is much simpler. In particular, immobilisation of ZrR_4 (R — benzyl, π -allyl) and $\text{Cr}(\pi\text{-allyl})_3$ on the surface of polymer fibres proceeds via 1,2-polyaddition to the carbonyl groups of PETP or the reaction with amido groups of PA-66.⁴⁹

Probably, organometallic zirconocene derivatives known as the most efficient catalysts of olefin polymerisation, are immobilised on polymers following the same mechanism.

Currently, a new method for immobilisation of two different reactive centres on the same polymeric constituent of PPC has been developed. It allows bifunctional catalysis, i.e., simultaneous polymerisation of monomers of different chemical nature or conversion of one monomer into products of different structure. This method will be considered below.

2. *In situ* preparation of polymer–polymer compositions: general kinetic rules

The composition of PPC prepared *in situ* in the presence of catalyst components can be controlled by varying the polymerisation conditions and, first of all, duration of polymerisation and the amount of monomer consumed.

The rate of ethylene polymerisation (a PE-based, *in situ* prepared PPC) is to a great extent dependent on the nature of the polar component and the type of its bonding to the catalyst

Figure 1. Catalytic activity of $\text{VCl}_4 \cdot \text{L} - \text{AlBu}_2\text{Cl}$ systems in the polymerisation of ethylene for different types of immobilisation. Ligand (L): (1) vinyl acetate; (2) PVA; (3) PVAlc.

components. Generally, immobilisation of MX_n or $\text{AlR}_x\text{Cl}_{3-x}$ by covalent bonds is considered optimum. The component playing the role of macroligand stabilises the process,⁵³ which manifests itself as a steady-state polymerisation (except for the initial stage). It should be noted that polymerisation at 313 K in the presence of the traditionally used system $\text{VCl}_4 - \text{AlR}_2\text{Cl}$ is essentially a non-steady-state process. Here, the maximum activity is achieved immediately after blending the components; however, the rate of ethylene polymerisation reduces by a factor of 45 after 30 min.⁵⁴ In contrast to this, catalytic activity of the systems based on macrocomplexes reduces by 3 to 8 times after the same time interval. Systems in which VCl_4 is covalently bound to, e.g., PVAlc, exhibit higher catalytic activity compared to macrocomplexes with PVA (Fig. 1). Catalyst components formed in the reactions of TiCl_4 or VCl_4 with PVC or PVDC also demonstrate a stabilising effect.

Kinetic studies revealed⁵⁵ that the rate constants for the chain propagation and chain termination (by monomer or organo-aluminium compound) stages and the activation energies for the PE chain propagation in the presence of both the macrocomplex-based systems under consideration and traditionally used Ziegler–Natta catalysts have similar values. However, the formation of the reactive centres proceeds by different mechanisms, which is responsible for the stabilising effect of the polymeric catalysts.

The molecular mass of PE formed depends on the nature of the catalyst component and on the polymerisation conditions. Standard procedures for controlling the molecular mass of PE include addition of hydrogen. The *in situ* prepared PPC are isolated and treated using the same procedures as those used in the low-pressure polymerisation of olefins. This type of PPC can also be prepared under conditions of the gas-phase polymerisation of ethylene (in this case, the catalyst component is dispersed in the suspension layer).⁵⁶ Using components with specific molecular shape also allows preparation of granulated PPC.

Binary polyolefin compositions (e.g., PE–PP) can be synthesised using the catalyst components obtained by co-grinding of PO and MCl_3 (e.g., the size of TiCl_3 submicrocrystals co-ground with PE is ~ 1 nm).⁵⁷ The stereosequence of PP formed on such catalysts is determined by conventional factors. This method also allows the *in situ* preparation of such PPC as PE–PB, PE–polycyclohexene, PE–PS, etc. The PE–polybutadiene (PBd) and PE–polyisoprene (PI) compositions are prepared by polymerisation of the diene monomer on the PE–g-P4VP– $\text{CoCl}_2 - \text{AlEt}_2\text{Cl}$ system.⁵⁷ In these catalysts each Co atom produces the polydiene chain, the molecular mass of PI lies between 370 000 and 1 300 000 and the content of 1,4-*cis*-PI exceeds 80%.

In situ preparation of conducting compositions PE–polyacetylene (PAC) involves immobilisation of the catalytic system $\text{Ti}(\text{O}i\text{Bu})_4 - \text{AlR}_3$ on the surface of modified PE films followed by gas-phase or liquid-phase polymerisation of acetylene⁵⁸ and

results in the formation of *trans*-PAC similarly to the process in homogeneous systems.

Thus, the use of catalyst components allows the preparation of PPC based on polyolefins and various polymers in the anionic-coordination polymerisation. Let us consider the structure of particular PPC in more detail.

3. HDPE–PMMA Compositions

Main characteristics of the properties of the *in situ* prepared polymer–polymer compositions HDPE–PMMA and polymer blends of HDPE and PMMA (with similar molecular mass characteristics) are listed in Table 4.

Table 4. Density (ρ), yield stress (σ), elongation at break (ε) and glass transition temperature of polymer–polymer compositions HDPE–PMMA.⁶⁰

Parameter	Starting components ^a	PMMA content in composition ^b /volume fraction			
		0.04	0.07	0.14	0.29
ρ /kg m ⁻³	1.190	0.959	0.968	0.983	1.019
	0.948	0.962	0.965	0.965	1.017
σ /MPa	5000	3200	3155	3500	—
	2500	2700	1200	1150	—
ε (%)	2–3	250	210	180	—
	370	80	70	45	—
T_g /K	225	217	221	221	221
	221	203	—	221	221

^a The data for PMMA are listed in the numerator and the data for HDPE are given in the denominator. ^b The data for molecular (*in situ* prepared) compositions are presented in the numerator and the data for polymer blends are listed in the denominator.

An increase in the volume fraction of PMMA (φ) in the synthetic PPC is accompanied by a decrease in the relative elongation at break (ε) and an increase in the yield stress (σ). Compared to the *in situ* prepared PPC of similar chemical composition, polymer blends are characterised by smaller ε and σ values (by 3 to 4 times for ε and 1.5 to 2 times for σ). The glass transition temperatures of the components are virtually independent of the procedure for the preparation of PPC, which suggests low thermodynamic compatibility. Both components of such PPC are linear polymers whose chemical composition and structure can be studied by selective extraction. This method is often used for analysing polymer blends and, in particular, interpenetrating polymer networks (IPN).⁵⁹ Polymer blends prepared without the formation of a complex with VCl_4 in the ethylene polymerisation using the $\text{VCl}_4 - \text{AlEt}_2\text{Cl}$ system exhibit a ready and complete separation into the starting components. In the case of *in situ* prepared PPC the content of non-extractable PMMA ($\varphi = 0.007 - 0.14$) varies between 4.4 mass % and 6.7 mass %.⁶⁰ Most likely, this is evidence that a fraction of PMMA molecules is chemically grafted onto PE. This assumption is confirmed by the results of various physicochemical studies. For instance, new bands with maxima at 1740 and 1300 cm⁻¹, corresponding to stretching vibrations of carbonyl and ester groups, appear in the IR spectra of non-extractable products along with the main absorption bands typical of the PE backbone.

The assumption that the integrated intensity of X-ray diffraction reflections is proportional to the content of the crystalline component in a polymer blend consisting of amorphous and crystalline phases holds for any blend including polymer blends based on crystalline PE and amorphous PMMA. Hence it follows that if the structure of the PE constituent of a PPC is independent of the chemical composition of the PPC, the height of the most intense peak of PE, corresponding to the (110) reflection, can serve

Figure 2. Empirical correlation between the height of the (110) peak of HDPE and the chemical composition of polymer blends of HDPE and PMMA (1) and molecular polymer–polymer compositions HDPE–PMMA (2).⁶⁰

as a quantitative characteristic of the chemical composition of the PPC. For mechanically mixed polymer blends, this correlation corresponds to curve 1 in Fig. 2, whereas for *in situ* prepared PPC the plot is shifted to the left. This looks like an apparent reduction of the volume fraction of PE and does not correspond to the true chemical composition of the *in situ* prepared PPC determined independently (from the density, material balance of polymerisation, *etc.*). This contradiction can be readily eliminated assuming that some structural domains of PE formed do not contribute to the (110) peak intensity.

Indeed, in contrast to polymer blends, the X-ray diffraction patterns of the *in situ* prepared PPC display a clearly seen peak labelled by an arrow in Fig. 3. This peak corresponds to a new

Figure 3. X-Ray diffraction patterns of PMMA (a), HDPE (b), *in situ* prepared composition HDPE–PMMA (c) and a blend of HDPE and PMMA (d) ($\phi = 0.19$).⁶⁵

interplanar distance ($\sim 3 \text{ \AA}$) in the structure of PPC and is indicative of the interaction between PE and PMMA on the molecular level and of a local distortion of the phase boundaries. The latter is due to the fact that chain propagation (the growth) of the PE macromolecules is accompanied not only by crystallisation, but also by interpenetration of the first component into the bulk of the second component (due to diffusion of macromolecules or their segments). As the distance from the surface of PMMA increases, this interaction, which determines the thickness of the intermediate layer, weakens. If the intermediate layer is sufficiently thick, it can form an individual phase. In addition, a salient feature of this system is the propagation of the PE chains accompanied by mixing of the components, which also improves their compatibility and the physicochemical properties of *in situ* prepared PPC (the so-called operating compatibility) compared to the properties of conventional polymer blends (see Table 4). This type of PPC, prepared by copolymerisation of propylene and CO on phosphinepalladium complexes resulting in a propylene–CO alternating copolymer and followed by blending with PMMA, is thought to be miscible.⁶¹ Experiments⁶² on multicomponent PPC containing LDPE and small amounts of hydrophilic polymers [PVA or poly(vinyl acetal), 2% to 6%] showed that, as a rule, in the presence of surfactants the macromolecular coils of the additives undergo insertion into the LDPE domains in both the amorphous phase and intermediate layer.

4. HDPE–PVC Compositions

PVC-Based materials exhibit some valuable properties. At the same time, they are characterised by low thermal stability and thermal plasticity in processing and by low impact toughness at negative temperatures. Sometimes, these drawbacks can be eliminated by modifying PVC with thermoplastic polymers or copolymers, and the resulting PPC combine the advantages of the starting components. This is also favoured by miscibility of PVC and a broad spectrum of polymers containing appropriate functional groups. Such composite materials can be used for the preparation of, *e.g.*, polymer films for enclosing greenhouses.⁶³

As applied to the HDPE–PVC systems, this method for *in situ* preparation of PPC involves immobilisation of VCl_4 , VOCl_3 or TiCl_4 on the surface of PVC latex or suspension PVC ($M_n = 5.5 \times 10^4$, the specific surface area is $6 \text{ m}^2 \text{ g}^{-1}$ and the particle diameter lies between 50 and 100 μm) via the formation of a macromolecular carbonium salt following the above-mentioned mechanism.^{49, 64–66} Similarly to the case of the HDPE–PMMA systems, the chemical composition of PPC is controlled by varying the consumption of ethylene for polymerisation. Using selective extraction with boiling THF in a Soxhlet apparatus for 24 h, the fraction of graft PVC was estimated (Table 5). The larger the volume fraction of PE in synthetic PPC, the larger the amount of non-extractable PVC due to an increase in the number of polymer

Table 5. Percentage of PVC grafted onto PE in the suspension polymerisation of ethylene using the $\text{PVC} \cdot \text{VCl}_4 - \text{AlEt}_2\text{Cl}$ system.

PVC content in composition		Percentage of grafted PVC ^a (mass %)
mass %	volume fraction	
17	0.12	3.3

chains or their segments that enter the reaction. The IR spectra of such graft polymers exhibit new bands at 615, 640, 833, 968 and 1260 cm^{-1} corresponding to PVC in addition to the absorption bands of PE. We will consider possible mechanisms of grafting in the next sections of the review.

Similarly to the HDPE–PMMA compositions, it was found that some of the structural domains of PE in the HDPE–PVC systems are X-ray silent. The plot of the empirical dependence of the height of the (110) peak on the chemical composition of the HDPE–PVC system is shifted to the left relative to the plot of analogous dependence for mechanically mixed polymer blends. The proportion of structural domains that do not contribute to the intensity of the (110) peak of PE is $\sim 20\%$ (estimated from the decrease in φ value taking into account the non-extractable fraction of PVC and also from the results of optical measurements). This value is in reasonable agreement with the decrease in the proportion of the ‘X-ray responsive’ PE. Unlike polymer blends, a salient feature of the structure of *in situ* prepared PPC is the appearance of a new interplanar distance ($\sim 4 \text{ \AA}$). Therefore, grafting of the PE chains or their segments onto PVC macromolecules occurs in the loose, intermediate near-surface layer.

The mechanics of two-component systems treats this type of PPC as compositions with a framework or interpenetrating structure and adhesive interaction between the components over a wide range of component ratios. According to the cubic model which ignores any polymer–polymer interactions,⁶⁷ the yield stress of PE (σ_0) and PPC (σ) must be related by a simple formula:

$$\frac{\sigma}{\sigma_0} = 1 - \varphi^{2/3}.$$

Indeed, the experimental and theoretical data for polymer blends are in reasonable agreement (Fig. 4a), which points to the absence of interactions between the HDPE matrix and PVC particles. No agreement between experiment and theory is observed for the *in situ* prepared PPC. This serves as additional evidence of the polymer–polymer interactions which favour a 60% (on the average) increase in the yield stress, σ , of such compositions. Polymer compositions containing a heat-treated component (*e.g.*, crystalline HDPE) become sensitive to the sample preparation conditions. In particular, the points corresponding to the samples prepared at low and high melt cooling rates are grouped near different theoretical curves (see Fig. 4b).

Table 6 lists the numerical values of the main physicochemical characteristics of different polymer–polymer compositions HDPE–PVC. As can be seen, the *in situ* prepared PPC are characterised by greater ultimate strength at elongation, relative

Figure 4. Theoretical (solid curves) and experimental dependences of the yield stress (a) and Young's modulus (b) for polymer blends of HDPE and PVC (open circles) and corresponding *in situ* prepared PPC HDPE–PVC (solid circles) on the volume fraction of PVC.⁶⁵ Stress rate 0.03 s^{-1} ; the cooling rate is 1 (1) and $20\text{--}30 \text{ K min}^{-1}$ (2).

elongation and tear resistance. The impact toughness of the film samples obtained was estimated from the impact cold resistance to a standard load (a 0.5 kg ball) fallen from a height of 0.5 m.⁶⁸ Polymer blends of analogous chemical composition exhibit poorer physicochemical characteristics in the whole range of HDPE/PVC ratios.

Yet another important feature of the *in situ* prepared polymer–polymer compositions HDPE–PVC, *viz.*, their ability to undergo high-frequency welding, should be pointed out. This is apparently due to the improved compatibility of the components and higher homogeneity of the PPC. As the PVC content increases from 23 mass % to 55 mass %, the duration of the welding process is reduced from 70 down to 18 s; however, the impact toughness of the PPC reduces at high PVC content. If the content of PVC is lower than 20%, high-frequency welding of molecular composites becomes impossible. Polymer blends do not undergo high-frequency welding in the whole range of component ratios, which is evidence of high inhomogeneity of their structure.

Comparison of strain–stress diagrams of conventional polymer blends and synthetic PPC showed that the latter behave as ductile materials and are not subject to brittle fracture both at room temperature and at 203 K. This allows the use of the *in situ* prepared PPC at low temperatures. The optimum content of PVC in such compositions is nearly 45 mass %.

It should be noted that the formation of a grafted layer from the polymer formed was also observed during the cationic polymerisation of styrene or isobutylene in a suspension of PVC with immobilised Et_2AlCl (in a heptane–1,2-dichloroethane

Table 6. Numerical values of physicochemical characteristics of polymer–polymer compositions HDPE–PVC.⁶⁶

Property	Starting components		PVC content in the <i>in situ</i> prepared PPC (mass %)					PVC content in mechanical mixtures (mass %)

mixture at 253 K).⁴⁸ Depending on the polymerisation conditions, the degree of heterophase grafting varied from 2 vol.% to 13 vol.% for PS and from 7 vol.% to 15 vol.% for PIB (with *n*-pentane as selective extracting agent). In the latter case, the 250 μm PVC particles were coated with a separable PIB layer 50 μm thick. Probably, flaking of the grafted layer from PVC is due to large differences in the surface energy (immiscibility) and mechanical properties of PIB and PVC. The concentration of chlorine in the exterior of the grafted layer is much lower than in the interior and sharply decreases as the thickness of the grafted layer increases.

Thus, synthetic methods make it possible to prepare PPC with improved physicomechanical and operating characteristics. Simple blending of the corresponding components does not allow improvement of these characteristics.

IV. Synthesis of polar ingredients in the presence of polyolefins

An alternative approach to the *in situ* preparation of PPC implies the synthesis of the second (hereafter, 'polar') component in the presence of a PO. In the reaction bulk, the PO has little effect on either the radical and ionic polymerisation or on the polycondensation of the component precursors.

Polyolefins can be modified by mechanochemical treatment with the monomer in the presence of Lewis acids.⁶⁹ For instance, the preparation of a layered material based on PE fibre (glass fibre) involves stacking of aligned fibres that were preliminarily soaked with methyl methacrylate (MMA) in a sheet die followed by bulk polymerisation of MMA at room temperature^{70,71} with the amine–peroxide system as initiator.⁷² The polymerisation is conducted until thickening of the material; shrinkage control is achieved by adding excess monomer. The final preparation stage of the composition involves heating to 328 K (this temperature corresponds to complete conversion of MMA).

Compatibility of particular pairs of polymers (*e.g.*, PO and PS) can be improved by performing *in situ* cationic polymerisation of styrene in the presence of corresponding polyolefins with Lewis acids (*e.g.*, AlCl_3) as catalysts.⁷³ The reaction mechanism is similar to the benzene ring alkylation according to Friedel–Crafts.

The degree of grafting depends on the nature of the Lewis acid and reaches a maximum value (15.7%) for AlCl_3 .

The procedure for preparation of polymer–polymer blends based on crystalline polymers (HDPE, PP, PA-12) after their deformation *via* delocalised crazing by drawing in liquid monomers (styrene, MMA, *etc.*) involves drawing a polymer film (*e.g.*, PP) in MMA containing the necessary amount of both initiator and cross-linking agent.^{74–76} As the desired degree of drawing is achieved, *in situ* polymerisation of the monomer in the PP matrix is carried out. Deformation is accompanied by continuous filling of the newly formed, porous polymer structure with the polymerised blend. Generally, delocalised crazing allows substantial enhancement of the swelling of the polymer (swelling of PP or PE in conventional monomers is at most 10 vol.%–15 vol.%, since the low-molecular-mass component can penetrate only the amorphous domains of the polymer structure while crystallites remain intact). From the standpoint of the preparation procedure such PPC can be classified as IPN. Experiments with the HDPE–PMMA system showed that complete separation of the blend components by successive selective extraction with chloroform at 333 K for 6 h (to dissolve PMMA) and with *n*-decane at

393 K for 2 h (to remove HDPE) is also impossible, while the homopolymers are completely dissolved under these conditions. The content of the insoluble (non-extractable) product is 25 mass %–30 mass %. This is due to either or both chemical grafting of the polymer chains and their interpenetration on the molecular level.

Thus, despite thermodynamic incompatibility of their components, the *in situ* prepared polymer–polymer compositions are to some extent compatible and the degree of compatibility is higher than in the case of simple mixing of polymer melts. Nevertheless, such PPC represent two-phase systems, which is confirmed by the data of calorimetric studies, according to which the glass transition temperatures of the components remain unchanged.

It is of considerable interest to consider the formation of the PU phase in PE in more detail. Thermoplastic PU is widely used in blends with other polymers including PO.⁷⁷ For instance, the formation of *in situ* compositions containing 85% PE and 15% PU from diisocyanates (diphenylmethane-4,4'-diisocyanate or dicyclohexylmethane-4,4'-diisocyanate) and diols (polyetherdiol or 1,4-butanediol) in PE melts (413 K) in the presence of catalyst was reported.⁷⁸ During the process the molecular mass of the dispersed phase changes in nearly the same manner as in the case of bulk polymerisation of virgin PU under analogous conditions (Fig. 5). Since the solubility of the isocyanate monomer in PE melts is rather high, while the solubility of the diol is low, the stoichiometry ratio between them violates, which imposes some limitations on the degree of polymerisation by *in situ* blending.[‡] A number of procedures which facilitate the formation and favour strengthening of the interfacial layers was developed. As a rule this is achieved by introducing various additives (compatibilisers) which improve adhesive interactions between the starting components and the *in situ* formed phases.

Figure 5. Formation kinetics of PU (curing at 413 K) in the dispersed phase (1) and in the bulk (2) under comparable conditions.⁷⁸

For instance, consecutive anionic polymerisation of styrene and 4-vinylpyridine in the presence of BuLi at 195 K resulted in block copolymers which induce phase separation.⁸⁰ Block copolymers of styrene and 2-vinylpyridine were synthesised using consecutive polymerisation of the monomers with potassium cumene as initiator.⁸¹ Atactic ethylene/propylene diblock copolymers were prepared by hydrogenation of poly(butadiene-*b*-2-methyl-1,3-pentadiene), polybutadiene and poly(2-methyl-1,3-pentadiene).^{82,83} The preparation of a partially deuterated ethylene/propylene diblock copolymer based on perdeuterated butadiene used as co-monomer was also reported.

[‡] Semi-interpenetrating polymer networks based on cross-linked PU and linear poly(butyl methacrylate) are prepared by introducing the latter component in the monomeric form followed by performing radical polymerisation simultaneously with cross-linking.⁷⁹

V. On some synthetic methods for preparation of polyolefin – polyolefin compositions

Multicomponent, PO-based polymer blends represent the most abundant group of PPC; most often, they serve as materials for recycling. This group of polymer compositions comprises blends of normal PE and high-molecular-mass or ultrahigh-molecular-mass HDPE, blends of different types of PE (LDPE, medium density PE and HDPE), *etc.*^{84,85} These materials exhibit some valuable properties, such as improved impact toughness, resistance to external factors including cold resistance, have good optical and rheological characteristics, high crystallisation rate, *etc.*^{86,87} These parameters of the PPC are nonlinear functions of their chemical composition, which is due to the influence of the interfacial layer and to the changes in the structure and properties of the constituent phases in the blends caused by the interaction with other components. One of the main goals of research into such PPC is the development of methods for improvement of processability of PO.

1. Systems based on different types of polyethylene

Design of novel materials with improved properties involves the preparation of microheterogeneous composites as an integral part. Microheterogeneous composites represent (i) PPC based on different types of PE (high density and low density PE) and (ii) highly oriented systems containing LDPE and HDPE.⁸⁸ Low density PE, with its long-chain branchings, and linear HDPE (LHDPE) are of similar chemical nature. Therefore, one could expect that they will form homogeneous blends which, nevertheless, represent microheterogeneous systems. An increase in the concentration of HDPE in the blend leads to a decrease in the crystallite size and to an improvement of the structural homogeneity of PPC. If the content of HDPE exceeds 30%, phase separation occurs, HDPE forms a dispersed phase and interfacial interaction between the polymeric constituents is observed. Further increase in the concentration of HDPE causes the formation of ordered HDPE domains that are structurally similar to the HDPE crystallites. Polymer – polymer compositions containing 80% HDPE have superiority in mechanical properties compared to the starting components. This is thought to be a result of the highest possible structural homogeneity of the polymer compositions due to the maximum compatibility of the components. Neutron scattering studies showed that the melts of HDPE and LDPE are compatible in the whole range of their concentrations.⁸⁹ A key factor that governs the extent of co-crystallisation of HDPE and LDPE is the similarity of crystallisation rates of each component. The amount of co-crystallite formed increases as the isothermal crystallisation temperature reduces under quenching conditions.⁹⁰ The co-crystallisation is also influenced by the branching composition of the constituent macromolecules, as was shown taking a blend of linear PE (1% to 20%) and branched PE as an example.⁹¹ These systems can also exhibit partial compatibility like, *e.g.*, a blend of LLDPE (1-octene comonomer), HDPE and LDPE.⁹²

As the content of LDPE in its blends with the ethylene – propylene – 1,4-hexadiene terpolymer increases, the T_g value is shifted towards higher temperatures (*i.e.*, towards the region of β -relaxation of PE, which is due to an increase in the mobility of small independent structural fragments of the macromolecules).⁹³ This confirms that the blend components are miscible on the molecular level. In addition, LDPE and ethylene/propylene copolymers are characterised by close values of the density of cohesive energy in the amorphous phase; these polymers also seem to be compatible on the molecular level. The addition of small amounts of LDPE (merely 2.5%) to LLDPE (1-hexene co-monomer with a density of 0.900 g cm⁻³) leads to the formation of well-defined spherulites and to a substantial decrease in their size.⁹⁴ Hence, LDPE is a nucleating agent for the crystallisation of LLDPE and the addition of LDPE shifts the α -relaxational processes towards higher temperatures or longer times. The table presented below

lists the melting temperatures (T_m), densities (ρ), crystallite volume fractions (x) and spherulite radii (r) for individual LLDPE and for the LLDPE component of the LLDPE – LDPE composition containing 2.5% LDPE.⁹⁴

Sample	T_m /K	ρ /g cm ⁻³	x (%)	r /μm
LLDPE	370.3	0.9031	33.2	6.5
LLDPE – LDPE	372.5	0.9048	34.3	0.7

Linear LDPE has superiority in mechanical properties (*e.g.*, elongation at break) compared to LDPE. LLDPE-based blends exhibit intermediate properties (*e.g.*, torque⁹⁵) between those of the starting polymers. Studies on both film and melt behavior of such blends revealed no severe problems originating from polymer incompatibility. On the other hand, non-polar and low-polar crystalline polymers are poorly miscible with one another and with non-crystalline polymers. In this respect, a classical example is provided by blends of PE and PIB.⁹⁶

Polymer – polymer compositions prepared from solutions of polyolefins are also used, though much more rarely. For instance, linear PE ($M_w = 53\,000$, $M_n = 16\,000$) and branched PE ($M_w = 76\,800$, $M_n = 11\,300$) are mixed in predetermined ratios from 1% solution in xylene and then precipitated with methanol.⁹¹ Studies on the properties of such PPC allows the development of methods for compatibilisation of these polymers for their blending, processing and further use of the material.

Crystallisation of blends of HDPE and LLDPE has been the subject of intensive research (see, *e.g.*, Refs 97 and 98). The morphology and mechanical properties of films prepared from blends of UMMPE with a viscosity-average molecular mass of 6×10^6 and low-molecular-mass PE (4×10^4) by gelation⁸ or crystallisation from solutions are determined by the degree of entanglement of the macromolecules of both polymers. Here, LDPE has no time to form crystals since it crystallises at a much lower rate than HDPE. The modulus of elongation of such PPC is as high as 50 GPa, which is a quite appropriate value for conventional usage. These PPC exhibit lower viscosity, which favours substantial improvement of the performance of the equipment used for fabrication of blend-based films.

Structural peculiarities of the blend-based PPC under consideration determine^{99–101} the tensile strength of the PE blends,¹⁰² their operating characteristics¹⁰³ and dielectric and other properties. For instance, isothermal crystallisation of blends of the linear and branched PE at 397 K results in compact branched structures. Carrying out the process at 288 K leads to the formation of open, lamellar spherulite structures; quenching favours the appearance of a continuous spherulite texture.⁹¹ The dielectric properties of PPC depend, first of all, on their morphology, heat treatment conditions and the content of linear PE. This also concerns the PPC based on industrially used LDPE and LLDPE.¹⁰⁴ At the same time, HDPE and LLDPE are compatible in the whole range of their concentrations provided that quenching occurs at low melt cooling rate.¹⁰⁵ In the presence of HDPE the blend morphology is governed by the distribution of lamellae (crystallites), which is due to higher mobility of the HDPE molecules. The macromolecules of LLDPE form mixed crystals (co-crystallise) with the HDPE molecules. The lattice parameters of the crystalline phase increase as the number of side chain branchings increases. Vol'fon¹⁶ constructed a 'map' of the morphology behaviour of the LDPE – LLDPE blends with the predominant 'shish-kebab'-like morphology, containing 0.5% to 5.0% LDPE and quenched at different temperatures in the range from 393 to 463 K. Polymer – polymer compositions with low content of LDPE are characterised by a higher degree of crystallinity of LLDPE, higher melting temperature and rigidity.⁹⁴ The ultimate strength decreases while the yield stress increases as the content of LDPE increases (Fig. 6).

§ For gelation, polymer solutions in decalin, prepared at 408 K, are poured in an aluminium pan and the solvent is evaporated.

Figure 6. Yield stress (σ) and ultimate strength (σ_u) of compositions LLDPE–LDPE as functions of the component ratio at 296 K.⁹⁴

Information on ‘ternary’ PE-based PPC is scarce. Donatelli⁹⁹ studied ternary films prepared from low, medium and high density PE and showed that two polymers can be compatible within rather narrow limits of the content of branched units while they separate into individual crystalline phases at higher concentration of branchings.

2. Polyethylene–polypropylene systems and other compositions

Low-temperature impact brittleness of PP originates from the relatively high glass transition temperature of this compound (~ 263 K). An increase in the cold resistance of PP-based materials is a topical problem. Blends of PP and HDPE have been studied in most detail. At particular chemical compositions, these PPC are characterised by high breaking strength, modulus of elasticity and impact toughness and low brittleness temperature. The structural-dynamical parameters of the amorphous domains, the supramolecular structure and physicomachanical properties of such systems consisting of polymeric constituents with different molecular-mass characteristics have been studied. The properties of PPC prepared from isotactic PP and PE also depend on which catalyst was used for the polymerisation of ethylene, namely, a heterogeneous (Ziegler–Natta type) or a one-centre homogeneous metallocene catalyst.¹⁰⁶ Isotactic PP and HDPE are thermodynamically incompatible and form different types of crystal lattices. Since the melting temperatures of these polymers are different, they form individual structures.¹⁰⁷

In situ preparation of PPC from HDPE and PP by polymerisation at low pressure involves immobilisation of the catalyst components on either PP or PE. (This procedure was used in the polymerisation of, *e.g.*, propylene with the product of co-grinding of HDPE and TiCl_3 as the catalyst component.⁴⁶) The newly formed PPC can have virtually any chemical composition and exhibits improved strain–stress properties and cold resistance as compared to conventional polymer blends. It should be noted that the polymerisation method allows one to control the properties of the PP polymerisate, its stereosequence and molecular-mass parameters. Not only PE, but also other polymers and copolymers can be used for the preparation of the catalyst component. In particular, blends of PE and synthetic ethylene–propylene rubber (SKEP), PP and polybutene, PP and poly(4-methylpentene), *etc.*, were prepared. The structure of this type of PPC is shown in Fig. 7. Co-grinding of the catalyst (MCl_3) and HDPE leads to coating each catalyst submicroparticle with the polymer layer (‘skin’). Probably, sub-microcrystals (*e.g.*, TiCl_3) are inserted into the amorphous phase of PE. Nucleation of the PP phase with the globular structure gradually transforming into a lamellar one occurs in the bulk of the catalyst component particle. Microheterogeneous mixing of the growing PP phase with the PE phase is thought to result in the formation of IPN.

Figure 7. Structure of a submicroparticle of composition HDPE–PP. (1) Catalyst microparticle; (2) HDPE ‘skin’; (3) PP phase.

Binary compositions containing PP (70%) and HDPE (30%) are prepared by *in situ* polymerisation on binuclear metal complex catalysts immobilised on the SiO_2 surface.¹⁰⁸ The mechanical characteristics of this material (Young’s modulus, tensile strength) are 1.5 to 2 times higher than the corresponding characteristics of ‘pure’ PP. This is due to the very complex and unusual morphology of the material.

Considerable attention has been given to the studies of polymer blends based on PP and some other polymers such as elastomers, different crystalline and amorphous thermoplastics [PETP, polycarbonates, PS and acrylonitrile–butadiene–styrene (ABS) terpolymers]. Gupta *et al.*¹⁰⁹ analysed the rheological properties of binary and ternary blends of PP with ABS and LDPE. Ethylene/propylene block copolymers exhibit improved impact toughness and low brittleness temperature (down to 256 K).

At the same time, the strain–stress properties of such blends prepared from, *e.g.*, isotactic PP and LDPE^{110,111} are to a great extent dependent on the blending temperature and duration of blending of the components. The diffraction patterns of the HDPE–PP blends with different chemical compositions represent superpositions of the diffraction patterns of the starting components, which indicates that no co-crystallisation occurs. The average crystallite size in the blends is nearly the same as those in the non-blended components (150 and 170 Å, respectively).¹¹² However, the specific volume of the blend exceeds the value obtained using the additivity scheme. This points to the formation of a loose structure resulting from an increase in the content of the amorphous phase. This conclusion was also confirmed by the results of radiothermoluminescence studies, according to which the glass transition temperatures of the components in blends of LDPE and PP decrease (Fig. 8). Such a negative synergistic effect of the blend components can be rationalised by different rates and

Figure 8. Glass transition temperature of the LDPE (1) and PP (2) phase as a function of the component ratio of LDPE–PP blend.¹¹²

temperatures of their crystallisation, by their thermodynamic incompatibility and by the absence of co-crystallisation in the blend. The rate of crystallisation of isotactic PP blended with LLDPE insignificantly decreases as the content of LLDPE increases.¹¹³ Dissolution of chain segments leads to the formation of an extended amorphous interfacial layer which precludes crystallisation of PP. The LDPE phase can be considered as a poor solvent for the PP phase (and *vice versa*).³

High density PE is incompatible with isotactic PP under steady-state conditions. However, compositions prepared from these polymers (PP:HDPE = 60:40) by injection moulding form a phase with regularly separated structure and an identity period of 0.15 μm . The regular structure cannot be formed by simple melt mixing but only by the spinodal decomposition (at zero shear rate).¹¹⁴ In the compositions consisting of isotactic PP and HDPE (0.1%–3%), phase separation occurs on gradual cooling from 473 down to 443 K.¹¹⁵ The average spherulite diameter is less than 10 μm for HDPE and greater than 100 μm for PP.²⁴ The proportion of ordered polymer chains in the amorphous phase of PP increases upon the addition of HDPE (10 mass % to 20 mass %) even for isotropic blends of these polymers prepared by melt mixing.¹¹⁶ The modulus of elasticity of the blends exhibits a synergistic effect due to the strengthening of the intercrystalline links in both the PP phase and in the interfacial layer.

It is interesting that, unlike the PPC based on syndiotactic PP and random ethylene/propylene copolymer[†] (a 80:20 blend, 4.9 mass % ethylene units), isotactic and syndiotactic PP synthesised on zirconocene catalysts are incompatible even upon heating up to 513 K (a 50:50 blend).¹¹⁸

The mechanical properties of PP–PE compositions can be substantially improved by using UMMPE instead of conventional PE.¹¹⁹ Such blends were prepared by coprecipitation of polymers from 1% xylene solutions at 398 K with excess methanol. Improved compatibility of PP and UMMPE can be most likely rationalised by the interpenetration of polymer chains in the amorphous phase due to the low degree of crystallinity of UMMPE.

A study on the morphology of blends of amorphous-crystalline block copolymers with amorphous homopolymers carried out taking the system consisting of ethylene/propylene diblock copolymer and atactic PP as an example showed that blending of the block copolymer responsible for the formation of the lamellar structure of microdomains and atactic PP leads to changes in the morphology of the microdomain structures and to microphase separation.^{120, 121} If the atactic PP chains are shorter than the block length, morphological transformations from lamellar structure into a bicontinuous cylindrical one, then into a discrete cylindrical and, finally, into a spherical structure occur. If the PP chain is longer than the block length, microphase separation occurs and a morphological change from lamellar to bicontinuous cylindrical structure is observed. In melts, these morphological transformations are accompanied by changes in the blend crystallisation kinetics.

In the blend of isotactic PP and SKEP the morphology of the ethylene domains depends only slightly on the viscosity ratio of the blend components and exhibits a strong dependence on the content of ethylene.¹²² The microstructure and chemical composition of SKEP (the dispersed phase) affect the rheology, morphology and properties of such compositions prepared by injection moulding.¹²³ The microstructure of a composition of isotactic PP and SKEP (60:40) essentially depends on which (a titanium- or vanadium-containing) catalyst it was prepared. Blends of isotactic PP and random SKEP, synthesised on vana-

dium-containing catalysts exhibit substantially improved impact toughness at low temperatures. The structure of the SKEP component affects both the crystallisation kinetics and the internal structure of spherulites of isotactic PP (the thickness of the crystalline lamellae and amorphous layer).

Among other PO–PO compositions, we will dwell on blends of isotactic PP and PIB. Problems of co-crystallisation and compatibility of blend components were considered by Cham *et al.*¹²⁴ Blends of PP and PIB are compatible in the amorphous phase and can even undergo co-crystallisation. Figure 9 presents the glass transition temperature and the Flory–Huggins interfacial interaction parameter of the PE–PIB compositions as functions of their chemical composition.¹²⁵ The maximum shift of T_g is 8.6 K for PE and 5.9 K for PIB (at 90% PE). This means that the solubility of PIB in PE is higher than that of PE in PIB. According to calculations, the solubility of PIB in the PE phase of the PE–PIB (10:90) composition is $\sim 17\%$ by mass, whereas the content of the PE phase in the PIB phase of the PE–PIB (90:10) composition is only 6 mass %. Low values of the Flory–Huggins interaction parameters χ_{12} and χ_{21} (see Fig. 9b) point to some degree of compatibility of the blend components despite the absence of specific interactions between their macromolecules. For unknown reasons, the χ_{12} value differs from χ_{21} .[†]

Figure 9. Glass transition temperatures (a) and Flory–Huggins parameters (b) of compositions PE–PIB as a function of the component ratio: (1) PE phase; (2) PIB phase.

Interesting results were obtained in studies of PIB–PS polymer networks containing from 10% to 70% PS.¹²⁷ Such blends were prepared by radical polymerisation of styrene preliminarily swollen in the PIB matrix. Electron microscopy studies did not reveal the formation of PS particles; however, cloudiness and rougher surfaces of the samples observed with increasing the content of PS are evidence of phase separation. Mechanical properties of PS are strongly dependent on its molecular mass. A decrease in the molecular mass probably favours compatibility of PS and PIB and an increase in the degree of grafting of the PS chains onto PIB, which manifests itself as increased ultimate strength, elongation at break and the fracture energy of the samples (at close PS content).

Information on polymer blends based on higher PO is scarce and fragmentary.

3. Preparation of polyolefin–polyolefin compositions by consecutive polymerisation

In the preceding section of this review we considered the formation of PPC in the course of the synthesis of one of the components. However, the *in situ* approach is also efficient if two or more polyolefin components are formed during the synthesis. This type of PPC is prepared by consecutive polymerisation of monomers on metal complex catalysts, which can be done

[†] For comparison, mention may be made that a study on the texture of a blend of syndiotactic and atactic PS revealed that the density of cross-link points strongly depends on temperature and exhibits relatively weak dependence on the initial chemical composition of noncrystallisable materials and on the degree of crystallinity of lamellar stacks.¹¹⁷

[†] This was also observed for polymer–polymer compositions PS–PMMA (the Flory–Huggins parameter for this system is 0.035 ± 0.010).¹²⁶

Figure 10. Formation of nascent morphology in the preparation of polyolefin compositions under conditions of polymerisation compatibility.

(1) Catalyst subparticle; (2) polymer prepared in the first stage of polymerisation (phase 1); (3) polymer prepared in the second stage of polymerisation (phase 2).¹²⁸

immediately in the polymerisation reactor using the Ziegler–Natta catalysts. The dispersity of the polyolefin compositions obtained is determined by both the size of the catalytic species (most often, TiCl_3) and peculiarities of the polymer morphology. Salient features of such PPC, differing from polymer blends of identical chemical compositions, are high molecular masses of the components and the presence of corresponding random and block copolymers localised within the interfacial layers.¹²⁸

A scheme illustrating the preparation of this type of PPC is presented in Fig. 10. The growing PP chains linked into crystalline fibrillae form a specific ‘skin’ around the TiCl_3 microcrystal. For instance, after completion of the polymerisation of propylene and removal of excess PP down to the specified post-polymerisation content, the reactor is filled with ethylene and then copolymerisation of ethylene with propylene on ‘living’ PP chains is carried out, followed by the homopolymerisation of ethylene. In this case, nucleation of the polymeric phase of PE occurs in the bulk of the globular PP particles formed in the first stage. The growing PE phase causes deformation of the ‘skin’ of the first submicroparticle and penetrates the PP layer. High-molecular-mass PE dispersed in the PP matrix represents particles of submicron size and is strongly amorphised. Hence, compatibilisation *via* polymerisation involves fine mixing of the components, which is accompanied by the formation of interpenetrating phases. The properties of the resultant product are determined by balance between its rigidity and strength (impact toughness). Semicrystallinity of the phase of isotactic PP has a crucial effect on the mechanical properties of these materials. The chemical composition of the elastomeric component and its content in particular PPC is also of great importance. Polymer–polymer compositions prepared using this approach consist of crystallisable polymers and are called polyallomers.¹²⁹ Studies on the morphology of polyolefins synthesised by consecutive polymerisation of propylene and ethylene in the presence of the $\text{TiCl}_3\text{–AlEt}_2\text{Cl}$ catalytic system showed^{130, 131} that the PE phase formed in the second stage causes deformation of the preliminarily formed PP layer followed by its disturbance and penetrates to the particle surface. A similar phenomenon was also observed for the polymerisation of propylene in the second stage of the process. Here, the PP phase penetrates the PE or SKEP layer formed in the first stage.¹³² The same is true for polymerisation of the butene–ethylene pair. Consecutive polymerisation also allows preparation of homogeneous ternary polyallomers containing, *e.g.*, the PP, PE and PB phases.¹³³

VI. Improvement of compatibility of polymeric components by introduction of compatibilisers

The most widely used strategies of improvement of the compatibility of immiscible polymeric components involve such approaches that initiate strong specific interactions (ion–ion and ion–dipole interactions, hydrogen bonds, *etc.*), formation of IPN, cross-linking, *etc.* Compatibility of the blend components is improved due to strengthening of the interfacial layers. Compatibilisation of different classes of polymers is achieved by introducing polymeric additives (specific ‘concentrates’ of the interface

phases) that favour manifestation of the above-mentioned compatibilising factors. These additives favour the formation of different types of bonds between the blend components and improvement of microheterogeneity of the systems in the stage of dispersion blending. Compatibilisers represent reactive copolymers containing chain segments that are compatible or miscible with both components of the PPC. These additives are of considerable interest as an alternative to conventional or graft copolymers. They can both be synthesised in the polymerisation stage and provide a means for *in situ* modification of the systems under study. This approach allows controlling the surface tension at the interface and the interfacial adhesion, thus providing more homogeneous distribution of the dispersed phase. The third component also acts as plasticiser.

It has been known for long¹³⁴ that block copolymers (in regard to polymer blends, they are often considered as ‘oil-in-oil’-type emulsifying agents¹³⁵) can emulsify polymer dispersions. This prevents phase separation. For instance, the addition of an AB diblock copolymer to a binary blend of polymers A and B causes a marked compatibilisation effect.¹³⁶ Moreover, a diblock copolymer AC can be used as a link between immiscible polymers A and B provided that polymer C is miscible with polymer B.¹³⁷ Yet another version of this approach involves blending of two incompatible polymers A and B using a diblock copolymer CD provided that both A and B are miscible with both C and D.^{138, 139} Blending of the diblock copolymer with the homopolymers having identical monomer units is a thermal process. However, if blending of a diblock copolymer consisting of blocks with different chemical nature with two immiscible polymers is accompanied by exothermic interaction between the blending pairs of polymers, this interaction can become an additional factor of compatibility of the immiscible components.

The most widely used compatibilisers represent additives containing anhydride (most often, maleic anhydride, or MA),^{140–145} carboxylic,^{146, 147} epoxy^{148, 149} and oxazoline¹⁵⁰ functional groups which react with the amino or carboxy groups of various thermoplastic polymers. Binary or ternary blends are also compatibilised using commercial products. Most often, these are PE-g-poly(maleic anhydride), ethylene–butyl acrylate–MA terpolymers (91 : 8 : 1) or poly(ethylene-co-vinyl acetate) (91 : 9) modified by grafting of MA (1%). Here, we restricted ourselves to the typical examples.

1. Compatibilisation of polyolefin blends

Weak interfacial interaction deteriorates the properties of composite materials based on PO blends. Compatibilisation of PO–PO block copolymers allows improvement of the miscibility of blend components and affects the properties of the interfacial layer in heterogeneous PO blends. If the molecular mass of a block copolymer is sufficiently large, it can act as an anchor at both sides of the interface. In particular, compatibility of a blend of isotactic PP and PE is often improved by using SKEP as the interfacial modifier.^{151–153} The cohesive energies of LDPE and ethylene/propylene copolymers in the amorphous phase are similar;⁹³ therefore, they are miscible on the molecular level. The addition (even in small amounts) of a random ethylene/propylene copolymer to the blend of HDPE and PP improves the impact toughness of the PPC;¹⁵⁴ that is, a portion of SKEP is dissolved in the amorphous domains of PE and PP, thus forming the interface layer. Multicomponent blends of LDPE, HDPE, isotactic PP, PB and poly(methylpentene) and recycled PO–PO blends can also be compatibilised by melt blending with ethylene/propylene block copolymers used as additives. An even more pronounced compatibilising effect is achieved by using synthetic ethylene–propylene–diene terpolymers (SKEPT) as additives to these polymeric compositions.¹⁵⁵ Grafting of compatibilisers onto a particular blend component (PE or PP) is also widely used. This approach allows improvement of blend processing conditions and an increase in the performance of the equipment used.

The mechanical properties of the PPC based on different types of PE (LDPE, HDPE, LLDPE and hydrogenated polybutadiene) and melt-mixed PS exhibit a strong dependence on the content (usually 2% to 10%) and molecular mass (60 000 to 270 000) of copolymer G [G stands for poly(hydrogenated butadiene-*b*-styrene)] used as an additive (see Fig. 11).^{156, 157} The hydrogenated triblock styrene-ethylene-butadiene-styrene terpolymer characterised by the total molecular mass of 35 000, the molecular mass of the central block of 7500 and the PS content of 29% is an efficient interfacial modifier for the HDPE-PS systems.^{158–160} Stability of polyolefin blends is often improved using ternary blends. For instance, the ternary blend of PP, polybutene and hydrogenated oligocyclopentadiene (50:30:20)³⁵ has one glass transition temperature, 289 K (*cf.* a value of 286 K obtained from calculations using the Fox equation), which confirms compatibility of the blend components.

Figure 11. Yield stress (a), tensile strength (b) and relative elongation at break (c) plotted as functions of the component ratio of composition HDPE-PS without (1) and with addition of 10% copolymer G (2).

Graft, triblock and star copolymers have high emulsifying ability and are even more efficient compatibilisers. These types of blends based on PP, HDPE and SKEPT (as a rule, with ethylidene-2-norbornene as the third monomer) are of commercial value and have therefore been the subject of intensive research.^{161–163}

If some fraction of the elastomeric constituent (SKEPT) of the blend of PP, SKEPT and PE is replaced by PE, this system can exhibit a higher or lower impact toughness depending on the blending conditions of the components, their rheological properties and viscosities.¹⁶⁴ Sometimes, the interfacial adhesion is improved by carrying out the reactions of dynamic selective cross-linking (see below).¹⁶⁵

2. Compatibility of polyolefin-polyamide systems

Polyamides (PA-6, PA-66, PA-12, *etc.*) exhibit high mechanical strength, rigidity and good processability and are therefore widely used in the automotive industry and for production of textile fibres. They have high melting temperatures and oil resistance. However, PA are characterised by ready deformation at low temperatures, cracking and high moisture absorption, which imposes limitations on possible applications of these materials.

Polyamides are often used in the form of blends with low-module polymers, such as PO and, in particular, LDPE, which exhibits excellent elastic properties at low temperatures and low moisture absorption. Using such blends reduces the cost of materials. The high commercial value of the systems based on PA-6 and LDPE has attracted considerable attention.¹⁶⁶ Interest in the compatibility problem of PO and PA is also due to the fact that the polyolefins and polyamides represent two main groups of materials for recycling.^{167, 168}

The components of the two-phase system LDPE-PA-6 are incompatible; therefore, this blend is characterised by weak interfacial adhesion and high dispersity of the LDPE domains. The properties of such PPC are determined by the size and shape of the dispersed phase; it should be noted that these parameters depend on the elasticity of the components.^{10, 169} The addition of interfacial modifiers, *viz.*, block or graft copolymers (their content is 0.5% to 1%) leads to a decrease in both the degree of crystallinity of LDPE and the crystal lattice parameters and to improvement of the mechanical properties (especially, yield stress, Young's modulus, impact toughness, relative deformation). The components of this system were compatibilised by the introduction of the block copolymer of styrene, ethylene and butylene to the modified extrudate.¹⁷⁰ Based on the analysis of the shape of thermomechanical curves of the blends, it was suggested that PA-6 was nearly molecularly dispersed in the LDPE matrix in the presence of 5% of the ternary block copolymer.

In the case of melt mixing of blend components the introduction of a third component can facilitate the blending and improve the mutual solubility of the components, thus providing predominant interaction of functional groups with a particular component. The most detailed studies on the problems of graft functionalisation of PO with MA or acrylic acid were carried out taking compositions of PO and PA as examples.^{171–173} *In situ* grafting in the extruder at 473 K in the presence of dicumyl peroxide (DP) (PP:MA:DP = 94:6:0.3) was followed by granulation. Free-radical melt grafting of MA, glycidyl methacrylate and diethyl maleate (DEM) onto PO was also studied in detail.^{174, 175} *In situ* preparation of PPC based on PA-6 and LDPE that was graft functionalised with MA or DEM led to interesting results.¹⁷⁶ The addition of PP-MA compatibilisers improved the interfacial adhesion and the impact toughness of the compositions of PP and PA-6.^{177, 178} Probably, the interfacial adhesion becomes stronger due to the formation of hydrogen bonds between the end amino groups of PA and grafted MA; this leads to nearly complete homogeneity of polymer blends.¹⁴¹ It is appropriate to use functionalised PO, *e.g.*, carboxy derivatives for compatibilisation of polyamide matrices and the dispersed PO phase.^{179, 180} As a rule, grafting of carboxy or anhydride groups onto the PO chains is performed during melt mixing. Reactions of the amino or amido groups of the PA phase with functional groups of the PO phase result in the formation of *in situ* prepared copolymers characterised by weakened interfacial tension and improved interfacial adhesion of their components.¹⁸¹

Improvement of fracture toughness is often achieved by energy dissipation within the interfacial layer of immiscible components of PPC. The introduction of a block copolymer additive should result in a decrease in both the interfacial tension and phase dispersity; in many instances this depends on the number of 'stitches' between the two phases.¹⁸² Nearly perfect compatibility was observed, *e.g.*, upon addition of small amounts of the PP/MA copolymer to blends of PE and PA-6.¹⁸³ Park *et al.*¹⁸⁴ studied the morphology, thermal and rheological properties of the composition of PP, PA-6 and PP/MA (5%) including the dependence of its viscosity on the chemical composition at low shear rate (Fig. 12). The results obtained point to the negative deviations from the additivity rule for the simple system PP-PA-6 and to positive deviations for the blends of PP, PA-6 and PP/MA. These results were used for assessing the texture of the PPC and evaluating the chemical interaction between the starting polymers. Currently, the composition of SKEP, PA-6 and the melt-prepared

Figure 12. Shear viscosity (η) of compositions PP–PA-6 (a) and PP–PA-6–(PP/MA) (b) plotted vs. shear rate. (a) PP (1), PP–PA-6 = 75:25 (2), PP–PA-6 = 50:50 (3), PP–PA-6 = 25:75 (4) and PA-6 (5); (b) PP–PA-6–(PP/MA) = 75:25:5 (1), PP–PA-6–(PP/MA) = 50:50:5 (2) and PP–PA-6–(PP/MA) = 25:75:5 (3).

graft copolymer of carboxy- or anhydride-modified SKEP and PA-6 has been the subject of intensive research.

Sometimes, more complex interfacial modifiers are used. For instance, *in situ* modification of the blend of PP and MA (the degree of grafting was 0.3 mass % or 0.8 mass %) with poly(propylene glycol)-bis-(2-propylamine) with $M_w = 230, 400$ and 2000 was reported.^{185, 186} This was done based on the fact that polymers containing ether groups [e.g., poly(ethylene glycol) or poly(propylene glycol) (PEG or PPG)] are compatible with PA due to the formation of hydrogen bonds¹⁸⁷ and resulted in the PP–MA–co-PPG composition which exhibits good compatibility with PA-6 due to hydrophobic-hydrophilic interactions between the ether

groups of PPG and amido groups of PA-6. Some characteristics of mechanical properties of the PP–PA-6 compositions prepared in different manner are listed in Table 7. It should be noted that all the compatibilised compositions have lower melt flow indices than the simple polymer blend. Increasing the degree of grafting of MA and the chain length of PPG leads to improvement of the strength properties of the compositions. Schematically, the formation of such a PPC can be represented as follows:

The limiting factor in the design of compatible systems with optimum characteristics is the concentration of reactive groups.

Compatibilisation of immiscible polymers using isocyanate groups which react not only with the amino or carboxy groups, but also with hydroxy groups has been rarely reported. For instance, blending of LDPE and PA-6 involves the modification of LDPE by grafting the product of the interaction of 2-hydroxy-methyl methacrylate and isophoronediiisocyanate (the reaction is carried out in xylene at 393 K in the presence of 1% DP in N_2 atmosphere) followed by mixing the modified LDPE and PA-6 in N_2 atmosphere at 518 K for 4 h.¹⁸⁸ In the course of blending the NCO groups interact with the terminal amino groups. Chemical bonding between the butyl acrylate or MA groups and terminal amino groups is formed in the compositions based on PA-6 and PE–MA, in the ethylene–butyl acrylate–MA (91:8:1) terpolymer and in the ethylene/vinyl acetate (91:9) copolymer modified by grafting MA (1%).⁴¹

Table 7. Mechanical properties and melt flow indices of PPC modified in a different manner.⁹⁴

PPC	Component ratio (by mass)	Unnotched impact toughness /MPa	Strength properties /MPa		Melt flow index ^a

3. Third component in the compatibilisation reactions of polyolefins with other polymers

Compatibility of PVC and chlorinated PE with ethylene/vinyl acetate copolymers (EVAC) is often used to improve the mechanical properties of PPC.⁷⁸ Such a modification can also be performed in the polymerisation stage. For instance, blends of styrene and acrylonitrile or styrene and MMA are selectively grafted onto chlorinated PE using TiCl_3 .⁷⁹ The addition of PE-g-PS (merely 2.5 mass %) to the PE-PS films substantially improves their strain-stress properties.⁸⁰

The LDPE-EVAC-PETP system has considerable advantage over the LDPE-PETP composition, namely, the presence of polar functional groups in the copolymer provides the possibility of controlling the contact reactions, *i.e.*, the chemical interaction at the interface.¹⁸⁹ It is solely the polar interaction of the PP-MA additive (4 mass % MA) and the carbonyl groups of the blend of PP and the liquid-crystalline polymer that is responsible for improvement of the mechanical properties of this system.¹⁹⁰ A number of reaction compatible blends of PO [with PE-g-poly(glycidyl methacrylate) or PE-glycidyl acrylate (GA) as compatibiliser] and polycarbonate (PC), PETP and other polymers was reported.^{142, 191, 192} The composition of PP and PC can be compatibilised using the PP-GA graft copolymer (2.5%–20%), which favours weakening of the interfacial interaction, improves the mechanical properties of the composition, increases the crystallisation temperature of PP and changes the blend morphology. In the molten state (in both the internal blending chamber and twin screw extruder) the epoxy groups of the third component react with the terminal groups of PC by the mechanism shown below

Interestingly, the coupling reaction between the polymeric constituents makes extraction of the entire PC phase from the ternary blend impossible, as in the case of compositions of PE and PMMA, PE and PVC, LLDPE and PA-6, *etc.*

This method allows compatibilisation of LLDPE modified by grafting MA¹⁹³ and PValc (the component ratio is 70:30). Another example is provided by the analogously modified composition of PP and liquid-crystalline polymer, which exhibits improved strength, deformation characteristics and the modulus of elasticity.¹⁹⁴

Numerous methods for the introduction of reactive polymeric reagents capable of *in situ* compatibilising of PO and PS have been reported.^{149, 195} One of them involves generation of reactive radicals on the surface of PO or PS to form the grafted

layer^{196, 197} (detailed consideration of this approach is presented below).

The morphology and properties of PPC based on PP and ethylene/dimethylaminoethyl methacrylate copolymers containing up to 27 mass % dimethylaminoethyl methacrylate units by mass have been studied in detail.¹⁹⁸ The components of this PPC are incompatible and form two-phase structures. As the content of the copolymer increases, the compositions become brittle and the interfacial adhesion between the constituent phases weakens substantially.

The third component, *e.g.*, PS-b-poly(ethylene-co-butene)-b-PS (PSBECB) is often used as plasticiser, especially for improvement of the impact toughness of brittle polymers.¹⁹⁹ This compatibiliser represents a microheterogeneous thermoplastic elastomer in which the PS end blocks (as a rule, 10–35 mass %) are linked into rigid domains that form a lattice in the flexible matrix of the ethylene/butene copolymer (EBC). It is used if one component of a PPC is compatible with the EBC blocks while the other component is compatible with the PS blocks. This additive allows the preparation of polymer blends containing not only PP, HDPE, LHDPE, but also the ABS plastics and other components.^{200, 201}

In studies of ternary systems containing, *e.g.*, PA, a modified additive, PSBECB-MA, is used.²⁰² It is thought that the EBC blocks are compatible with PP and the interfacial adhesion between PA and PSBECB is provided by the formation of imides in the reaction of the terminal amino groups with anhydride. In this case, the formation of domains with rigid polyamide core and flexible elastomer 'skin', which favours improvement of the strength and viscosity without changing the polymer rigidity, cannot also be ruled out.²⁰³ Finally, the PSBECB constituent of ternary blends containing impact-resistant PS reduces the degree of crystallinity of PP.²⁰⁴ The modulus of elasticity and yield stress of PP-PSBECB blends decrease as the content of the block copolymer increases.²⁰⁵ Good compatibility of PSBECB and PP can be due to the random nature of the copolymer in the EBC block. The effect of repulsion²⁰⁶ between different polymer chain segments in EBC (though the repulsion between the ethylene and butene segments must be very weak) can improve the compatibility of the PE-PP pair. It was shown that PSBECB is a good compatibiliser for polymer blends based not only on isotactic PP, but also syndiotactic PP.²⁰⁷ In both cases, the additive, PSBECB, favours a decrease in the modulus of elasticity, yield plateau and an increase in the yield stress. The use of the compatibiliser consisting of PSBECB and MA allows reduction of the tear resistance for the block copolymer and isotactic PP.

Summing up, we considered the most widely used strategies of using polymeric compatibilisers for improvement of compatibility of polymer blend components. It should be mentioned that polymeric supports for metal complex catalysts, obtained by the grafting of corresponding, *in situ* polymerisable monomers onto PO (see the grafting scheme presented in Section III.1) contain the interfacial modifier which improves compatibility of the components of PPC.

VII. Polyolefin-based polymer blends prepared by reactive blending

Many polymeric compositions considered above are prepared by reactive blending in extruder reactors. Since this process is accompanied by numerous chemical reactions between the components or specially introduced compatibilisers, it would be reasonable to call the blends obtained 'reactor blends' or 'extrusion blends'. However, in this review we will use the term 'reactor blends' in a somewhat narrower sense.

As a rule, functionalisation of polymers by graft polymerisation represents an individual stage of the process and is followed by their blending. Currently, extruder reactors are widely used as continuous reactors combining the stages of dispersion of blend components and chemical reactions between

them.^{180, 208–210} In particular, chemical modification of thermoplastics in a twin screw extruder is thought to be a promising procedure for production of novel materials.

Extrusion combines the *in situ* functionalisation of blend components and the formation of block or graft copolymers at the interface. Inter-chain copolymers prepared by extrusion are often used *in statu nascendi* for compatibilisation of thermodynamically incompatible blend components; this particularly concerns the PE–PA-6 blends modified using the third component.²¹¹ In these cases, at low concentrations of the interfacial modifier and initiator the additives favouring improvement of the relative elongation at break and the impact toughness perform three functions. First, they act as reactive interfacial modifiers that improve compatibility of the components in the molten state. Second, they are grafted onto PO by the radical mechanism. Third, their functional groups react with the terminal groups of the components (*e.g.*, PA), thus forming covalent or hydrogen bonds. Most often, reactive blending is performed in the presence of peroxide (0.5% to 2.0%) with MA, bifunctional or multifunctional monomers as interfacial modifiers. The additives having long hydrocarbon chains (*e.g.*, alkylmaleic monoamide or alkylmaleic monoether) are more efficient compatibilisers than the short-chain additives. Non-monomeric additives are used more rarely. For instance, the addition of stearic acid (5%) to the blend of LDPE and PA-6 (75 : 25) allows control of the phase morphology.²¹²

The effect of *in situ* reactive blending in an extruder reactor was also observed in studies of blends of LLDPE modified by grafting of maleic acid or MA with PA-6 or PA-11.^{213–215}

In situ mechanochemical preparation of self-compatible polymer blends by solid-phase extrusion grinding of immiscible polyolefin constituents represents a variant of the approach in question.^{16, 216, 217} The process is accompanied by scission of polymer chains and, hence, generation of free radicals capable of entering the reactions with another polymer chain or undergoing recombination with other macroradicals (this was experimentally proved taking the PE–PP system as an example), thus forming a block copolymer or a graft copolymer. The latter acts as an *in situ* generated compatibiliser. This procedure is particularly convenient when performing recycling since the process proceeds at a low temperature, so both the mechanical and oxidative degradation are reduced to a minimum.

Nearly three decades ago a new product, *viz.*, a thermoplastic blend based on SKEP finely dispersed in the PP matrix appeared in the world market. Such polyolefin blends are prepared by dynamic vulcanisation and called thermoplastic elastomers or thermoplastic vulcanisates.²¹⁸ They represent multicomponent polymer blends which possess the mechanical properties of elastomers at room temperature and the rheological properties of thermoplastic polymers at elevated temperatures. A salient feature of the procedure for their preparation is the combination of blending and vulcanisation (with SKEPT as the third component). This leads to the formation of PPC with specific morphology, namely, two-phase systems in which the particles of the cross-linked elastomer of size 1 to 10 μm are dispersed in a continuous thermoplastic polymer matrix and the content of the elastomeric component exceeds that of the thermoplastic polymer. Usually, such systems are cured with DP. Dynamic vulcanisation can be performed in two ways (Fig. 13). Thermoplastic elastomers offer improved processability, *e.g.*, their melts behave as thermoplastics despite the presence of the cross-linked elastomeric constituent.²¹⁹ The thermoplastic nature of the blend can be due to the curing dynamics features which prevent the formation of a three-dimensional rubber network in the dispersed phase. However, the melt viscosity of the PPC enriched with PP increases as the content of SKEPT increases up to 25%. The crystal structure of the starting PP can either change or remain unchanged depending on the procedure for preparation. The structure and properties of this type of dynamically cured polymer blends, peculiarities of their

Figure 13. A scheme of dynamic vulcanisation process.

rheology and structural characteristics have been the subject of detailed studies (see, *e.g.*, Refs 220 and 221). The deformation mechanism of thermoplastic elastomers based on isotactic PP and SKEPT involves the deformation of the structure of the composition in the first stage followed by simultaneous deformation of both the cross-linked SKEPT domains and PP macromolecules; the strength and elongation at break are determined by the tension of the cross-linked elastomer.²²²

Blends of PO and SKEPT can be prepared using numerous methods that are not only of scientific, but also practical value. One of these procedures involves the formation of blends of cross-linked SKEPT (ternary SKEP) and PO using roll mills or peroxide-initiated dynamic vulcanisation in an extruder. This method was first proposed for PPC;²²³ however, at present it has found wide industrial application for production of plastics and thermoplastic elastomers. It offers such advantages as short blending time, short-term processing cycle, small energy expenditure for recycling and the possibility of easy control over the properties of products by varying the component ratio.

Main conditions for the preparation of materials based on dynamically vulcanised polymer blends with optimum properties have been formulated and a number of factors determining the structure and properties of such blends were pointed out.²²⁴ For instance, polymeric compositions with high content of rubber can be used as thermoplastic elastomers, while polymer blends with high content of plastic can be used as rigid plastics 'enriched' with rubber. Peculiarities of their morphology improve processability despite the presence of the cross-linked elastomeric component.¹⁹⁹ Dynamic vulcanisation also allows the preparation of such PPC as, *e.g.*, SKEPT–PP, SKEPT–PP–HDPE, LDPE–SKEPT, *etc.*^{225, 226}

VIII. *In situ* preparation of diblock chemical hybrids

In this section we will consider diblock polymeric compositions in which one of the block materials does not belong to the polyolefins. From the standpoint of structure and properties this group of PPC comprises diblock copolymers, namely, graft copolymers in which one component (the polymeric support) represents a macromolecular organometallic compound. These copolymers can be prepared using the Ziegler–Natta catalysts and by consecutive polymerisation of olefins.

Lithium-containing block copolymers of ethylene and butadiene²²⁷ and of ethylene and isoprene²²⁸ seem to be the first representatives of this group of PPC. The molecular mass of the PE blocks varied from 13 000 to 36 000. Since ethylene polymerisation was accompanied by cross-linking of 1,2-butadiene units, this method was found to be more appropriate for the preparation of ethylene/styrene diblock copolymers²²⁹ or blends consisting of PS blocks and blocks of ethylene/propylene copolymer (EPC).^{230, 231} The synthetic procedure involves treatment of the organolithium compound with TiCl_4 to replace lithium by titanium, reduction of titanium and the formation of the catalyst component for polymerisation of ethylene (the molecular mass was 7000–33 000 for PE blocks, 10 000–11 000 for PS blocks and 33 000 for EPC blocks).

The PS–b-poly(ethylene-co-propylene) composition was also synthesised using the PS–Li macroanion and TiCl_4 .²³² The molecular mass of the EPC blocks was as high as 500 000, the $M_w:M_n$ ratio was 2.24 to 4.23, the degree of crystallinity varied from 7% to 20% and the content of ethylene units in the block was 70% to 80%.

The efficiency of the catalyst, expressed as the number of polymer chains per Ti–C bond was rather high (0.88). According to the results of differential scanning calorimetry (DSC) studies, the thermogram (Fig. 14) exhibits a small peak of PS at $T_g = 369$ K. Both the melting temperature (410 K) and relatively low molecular mass ($M_n = 63$ 000, $M_w:M_n = 1.4$) point to a linear structure of the PE blocks.[‡]

Figure 14. A DSC scan of block copolymer PS–PE.²³²

Among numerous methods for the *in situ* preparation of diblock PPC in the radical polymerisation of a particular compo-

‡ For comparison, mention may be made that consecutive anionic copolymerisation of equivalent amounts of styrene and 4-vinylpyridine on LiBu at 195 K resulted in a PS–b-P4VP (PS:P4VP = 59:41) composition ($M_n = 62$ 300),⁸⁰ which was used as compatibiliser for blends of polar and non-polar polymers belonging to different classes. Anionic polymerisation of styrene in the presence of polymers is accompanied by chain entanglement of newly formed linear macromolecules and the polymer network of cross-linked chains²³³ and results in macroscopically heterogeneous gels. The formation of cross-linked or grafted chains was also observed in the anionic polymerisation (using LiBu, AlEt_3) of diisocyanates in the presence of butadiene, isoprene and butadiene-styrene rubbers.²³⁴ In the last-named case the formation of graft polymers occurs due to the involvement of the side double bonds in positions 3 and 4.

nent, two procedures are most widely used. The first method (preparation of IPN) is in essence a radical polymerisation of vinyl monomers in the presence of soluble or swollen polymers (here, a typical example is provided by the polymerisation of styrene in the presence of polybutadiene). The second procedure involves the use of polymeric peroxide or azo initiators (see, *e.g.*, Refs 235 and 236) whose concentrations are comparable with those of the components.

In situ preparation of diblock PPC can proceed either by conventional polymerisation mechanisms or as a stepwise (consecutive) process involving ‘switching’ of the polymer formation mechanisms (in this case, each block is formed on the active centres of different chemical nature). The latter can be exemplified by the preparation of diblock copolymers based on olefins and vinyl monomers in the presence of the $\text{TiCl}_3\text{--AlEt}_3\text{--ZnEt}_2$ system.²³⁷ The stage of ethylene polymerisation involves the formation of polymer chains with terminal zinc–carbon bonds that provide the possibility for the next stage, TiCl_3 -catalysed polymerisation of vinyl monomers, to proceed. By choosing the most appropriate combinations of the olefin and vinyl monomers one can prepare block, graft or block/graft copolymers representing either the end products (PPC) or compatibilisers of PO and vinyl polymers.

Methods for the preparation of modified poly- α -olefins by switching of polymerisation mechanisms (anionic-coordination mechanism changes to cationic or anionic mechanism, anionic mechanism is replaced by the radical one, *etc.*) have long been developed. A typical example is as follows:²³⁸ first, polymerisation of propylene is performed on the $\text{TiCl}_3\text{--Et}_2\text{AlCl}$ catalytic system. After some time, the unreacted monomer is separated and 4-vinylpyridine and SnCl_4 or Bu^nLi are added. This procedure can also be used for preparation of polyolefin chains with the MMA, vinyl ketone, acrolein and other fragments. Isotactic PP synthesised on the ethylenebis(tetrahydroindenyl)zirconium dichloride ($\text{C}_2\text{H}_4[\text{H}_4\text{Ind}]_2\text{ZrCl}_2$)–methylalumoxane catalytic system by successive treatment with the borane–dimethyl sulfide complex and pentane-1,2-diylmagnesium dibromide was transformed into PP with the MgBr terminal groups.²³⁹ The modified PP was then used as anionic initiator of polymerisation of MMA at temperatures between 195 and 318 K. ^1H NMR and gel permeation chromatography studies confirmed the formation of the PP–b-PMMA system ($M_n = 5300\text{--}3000$) which can be used as polymeric additive to blends of PP and PMMA.

It was established experimentally that the polymerisation mechanism changes from anionic-coordination to radical during the preparation of diblock copolymers of PE and PMMA.²⁴⁰ The addition of MMA to the $\text{VCl}_4\text{--AlR}_2\text{Cl}$ catalytic system in the course of anionic-coordination polymerisation of ethylene leads to its inhibition and initiation of the polymerisation of MMA (probably, as a result of radical induced cleavage of the V–C bond). The process results in the PE–b-PMMA system.

It is known that both homopolymerisation and copolymerisation of polar monomers on metal complex catalysts proceed solely by the coordination mechanism in the absence of electron-donor additives and can follow both coordination and radical pathways in the presence of such additives. It cannot be ruled out that in many instances the polar monomer itself acts as electron donor.

Kinetic studies confirmed that graft copolymerisation of MMA is radical initiated. 'Living'⁸ coordination polymerisation of propylene on the $V(acac)_3 - AlEt_2Cl$ system was used for the synthesis of a diblock copolymer of PP and PMMA.²⁴¹ The polymerisation proceeds at 195 K; raising the temperature up to 298 K in the presence of MMA leads to the formation of a radical centre as a result of homolytic cleavage of the $V - C$ bond.

The macroradical is stabilised by the vanadium ion, which provides the possibility for 'living' polymerisation of syndiotactic PMMA blocks to proceed; chain termination in the radical polymerisation occurs on the organoaluminium compound.

Diblock copolymers of propylene and methyl vinyl ketone were synthesised using the stereospecific Ziegler–Natta catalysts.²³⁸ In first stage, a conventional anionic-coordination polymerisation of propylene proceeds, while the second stage of the process (in contrast to the radical polymerisation of MMA) represents an anionic polymerisation of methyl vinyl ketone catalysed by terminal alkylaluminium groups.

No additional treatment is required to 'switch' between the catalytically active centres in the schemes presented above since MMA itself acts as the 'switching' agent. Transformation of the anionic process into a radical one was also observed by Souel *et al.*²⁴² who studied polymerisation of isoprene in the presence of butyllithium. Treatment of the product, 'living' oligomeric isopropenyllithium, with Me_3PbCl results in an adduct whose decomposition in the presence of styrene leads to the formation of PI - b-PS.

Let us consider yet another procedure for *in situ* preparation of PPC based on polymers belonging to different classes, namely, polyolefins and polydienes. We will dwell on the copolymerisation of olefin and diene monomers under the action of bifunctional immobilised catalysts. For instance, copolymerisation of ethylene and butadiene can be performed using complexes of Co^{2+} and V^{4+} immobilised on the PE-g-poly(vinylpyrrolidone) (PE-g-PVP) system.⁴⁶ Alkylation of this heterometallic complex with AlR_2Cl leads to the formation of active centres initiating the polymerisation of ethylene (V-centres) and butadiene (Co-centres).

§ Polymerisation proceeds until complete consumption of monomer; however, the addition of a fresh portion of the monomer leads to a restart of the process at the same rate.

In the text below the combination of Co- and V-centres will be shown in a simplified form as $\begin{pmatrix} \text{Co-P}' \\ \text{V-P}'' \end{pmatrix}$. These active centres

coexist in the presence of ethylene and butadiene and retain their catalytic activity despite essential modification. Butadiene is known to be a strong inhibitor of ethylene polymerisation. The rate of copolymerisation of ethylene and butadiene on vanadium-containing active centres is low. Indeed, the rate of ethylene polymerisation decreases in the presence of butadiene (Fig. 15); however, inhibition of the reaction proceeding in the presence of heterometallic cobalt – vanadium catalysts is less pronounced. In turn, the rate of butadiene polymerisation on the Co-centres also somewhat decreases in the presence of ethylene²⁴³ whose molecules undergo insertion into the polymer chain (1 or 2 ethylene molecules per macromolecule), thus reducing the molecular mass of polybutadiene. The mechanism of this process is similar to that of chain transfer to polymer and consists in decomposition of the less stable σ -alkyl cobalt derivative that is formed from the π -allylic product upon addition of ethylene.

Figure 15. Kinetic curves for the synthesis of HDPE–PBd compositions under comparable conditions.

(1) Ethylene polymerisation on monometallic catalyst; (2) copolymerisation of ethylene and butadiene on bimetallic catalyst; (3) copolymerisation of ethylene and butadiene on monometallic catalyst.

Here, route *A* corresponds to chain transfer while route *B* corresponds to copolymerisation of ethylene and butadiene. However, spatial proximity of both active centres and co-operative chain propagation processes make migrations by, *e.g.*, the inter-chain exchange mechanism²⁴⁴ *via* transfer of the polybutadiene chain to PE (route *C*) or recombination of polymer chains (*D*) quite probable.

If these reactions are accompanied by chain disproportionation, the $P'-P''$ diblock copolymer is formed; persistence of

Table 8. Formation of PE–polybutadiene block copolymers in the PPC prepared by copolymerisation of ethylene and butadiene on bifunctional cobalt–vanadium catalyst.⁴⁶

Ethylene consumption for polymerisation /g	Content of polybutadiene units ^a in product (mass %)
0.5 ^b	2.7 (–)
0.5	38 (95)
1.0	24 (90)
2.0	14 (90)

^a The value in parentheses is the content of 1,4-*cis* units. ^b For copolymerisation of ethylene and butadiene on monofunctional catalyst (VCl₄ on PE–g-PVP).

ethylene polymerisation after chain transfer results in a polyblock copolymer. Such a reaction mechanism is few and far between. Obtaining convincing proof of this mechanism presents considerable difficulties, since analysis of the structure of such ‘chemical hybrids’ characterised by possible formation of interpenetrating polymer chains is a rather complicated problem. However, experiments with ¹⁴C-labelled butadiene allowed one to collect proof of the formation of block copolymers (Table 8). Quantitatively, the formation of the random copolymer was estimated by comparing its radioactivity with that of the ethylene/butadiene copolymer synthesised on the Co-containing monometallic catalyst. The stereosequence of polybutadiene units (mostly 1,4-*cis*-butadiene) in the block copolymers is such that mutual influence of the monomers is weak. Probably, this method for *in situ* preparation of diblock chemical hybrids will appear to be useful in the case of PPC based on polyolefins and polyallene and on other polymers.[¶]

Synthesis of binary polymer networks belongs to new avenues of current research. Binary networks consist of two chemically different polymer chains linked by one covalent bond, whereas IPN comprise two independent networks that cannot be separated without cleavage of covalent bonds.²⁴⁶ The distinctions between these systems are illustrated in Fig. 16.

Figure 16. The structure of two-component (a) and interpenetrating (b) polymer networks; polymer A (1) and polymer B (2).

As applied to polyolefins, binary polymer networks were prepared for, *e.g.*, the poly(isobutylene)–poly(dimethylsiloxane) system.²⁴⁷ Allyl-tritelechelic PIB was synthesised by ‘living’ polymerisation of isobutylene at 193 K using the tricumyl chloride–TiCl₄–*N,N*-dimethylacetamide catalytic system. Allylation at the end groups was performed using allyltrimethylsilane. Allyl-tritelechelic PIB undergoes cross-linking with SiH-ditelechelic poly-

(dimethylsiloxane) by hydrosilylation under the action of Pt-containing catalysts. This method was used for preparation of novel thermoplastic elastomers PS–b-PIB.²⁴⁸

Thus, *in situ* prepared PPC can be synthesised from various classes of incompatible monomers following any polymer formation mechanism. The diblock copolymers considered in this section are most often used as polymeric additives that improve compatibility of immiscible polymers rather than individually.

IX. Preparation of conducting composites using the principle ‘compatibilisation *via* polymerisation’

Mixing of conducting and dielectric particles is a well known procedure used for preparation of conducting polymers.²⁴⁹ The synthesis of a conducting polymer surrounded by a dielectric matrix is often used to improve the strength and electrical conductivity of polymeric materials.^{250, 251} According to percolation theory,²⁵² an increase in the content of the conducting polymer to a particular critical value causes a sharp decrease in its electrical resistance (the so-called percolation threshold is reached).

The method for *in situ* preparation of molecular compositions containing a polyolefin as one component can also be extended to the conjugated polymers (in particular, doped PAC). Conducting PAC films are very brittle, which is detrimental to their operating characteristics, and unstable (film destruction occurs with time). Therefore, the preparation of materials that can be processed in a conventional manner requires modification of such films.

An attempt at preparing a composite material with good electrical properties by simple dispersion of powdered PAC obtained by catalytic polymerisation of acetylene according to Shirakava using the Ti(OBu)₄–AlEt₃ system in the PE matrix failed,²⁵³ since only large PAC aggregates of size 10 to 100 μm were formed. Blending of components on a molecular level can be achieved by performing direct polymerisation of acetylene on any surfaces moistened with the catalyst solution. In particular, such a polymerisation can be carried out on 300 μm-thick LDPE films impregnated with Ti(OBu)₄ and alkylated with AlR₃.²⁵³ The reaction on the surface of the PE powder impregnated with the same catalytic system is carried out in the liquid phase (in dibutyl ether)²⁵⁴ or in the gas phase.²⁵⁵ Sometimes, polymerisation is performed from the gas phase in viscous media (*e.g.*, silicon oil) in the presence of PE-supported catalysts.^{256, 257} Polystyrene solutions (5%–20%) in toluene can be considered as examples of such high-viscosity (10–400 sP) media. Suspension polymerisation allows the preparation of materials with good electrical and mechanical properties. High density PE films containing PAC (6 mass %–10 mass %) remain flexible and elastic and exhibit high strength. The conductivity of the compositions prepared by doping such films with iodine or lithium lies between 10 and 100 Ω^{–1} cm^{–1} and increases upon film drawing due to alignment effects.²⁵⁵ Polyacetylene obtained by polymerisation of acetylene on a PE matrix at 383 K has a *trans*-structure stereosequence and undergoes cross-linking with time, thus forming a three-dimensional structure in the bulk of the PE matrix. Such composite materials are characterised by a conductivity of 1 to 5 Ω^{–1} cm^{–1}. High-molecular-mass PAC latex particles are formed on the Luttinger catalysts in the presence of surfactants, mainly copolymers of styrene or PE blends and poly(ethylene oxide) (PEO).²⁵⁸

To improve the adhesion between the conducting components and the polymeric support (*i.e.*, films based on PE, PP, SKEP, PS, *etc.*, and shaped as necessary), the latter is modified by grafting of functional groups [poly(acrylic acid) (PAAc) or poly(allyl alcohol) (PAA)] that serve as ‘immobilisers’ of the catalyst of acetylene polymerisation.⁵⁸ After polymerisation these supports become coated with a dark PAC film 10–50 μm thick, which acquires conducting properties (see Table 9) after treatment with iodine vapours or other electron acceptor dopants such as SbF₅, AsF₅, FeCl₃ and perchlorates.

¶ It should be noted that copolymerisation is also performed using other catalytic systems. For instance, the microblock copolymer of butadiene and styrene is formed when the system LiR–KOR is used.²⁴⁵ In this case, butadiene undergoes polymerisation of the Li centres, while styrene is polymerised on the K centres. The microblock size is determined by the frequency of C–Li ⇌ C–K transitions.

Table 9. Properties of conducting films prepared by polymerisation of acetylene in the presence of catalytic system $\text{Ti}(\text{OBu})_4\text{--AlEt}_3$ and immobilised on dielectric supports.⁵⁸

Support	Titanium content /mmol g ⁻¹	Polymerisation time /h	PAC film thickness /mm	Specific conductivity ^a

PVAIc	0.20	2	0.02	3.9

^a Dimensionality is $\Omega^{-1} \text{ cm}^{-1}$.

In this case, we deal with the surface conductivity of the *in situ* prepared PPC, while the polymeric supports remain dielectrics. This method can also be used for the preparation of multi-layered PPC containing a conducting layer with controllable conductivity parameters. Materials based on this type of PPC are relatively easy to produce and retain their properties on long storage (more than three years). Probably, improved stability of these materials is due to the presence of a barrier preventing the oxidation of PAC.

High-conductivity compositions, namely, block copolymers of PAC and PS are also prepared by ‘switching’ the polymerisation mechanisms,^{259,260} that is, the polymerisation of the styrene oligomer ($M_n = 1000$) obtained on LiBu in the presence of AlCl_3 and $\text{Ti}(\text{OBu})_4$ additives is followed by the polymerisation of acetylene or propyne. It is noteworthy that an increase in the content of acetylene units in the copolymer leads to changes in its morphology, *viz.*, fibrillar structures typical of PAC disappear and the polymer acquires a *trans*-structure. The syntheses of soluble block copolymers consisting of PAC blocks and polymeric support blocks (PS or polyisoprene) were reported.^{261,262} In this case, CuCl_2 in anhydrous THF at 193 K is used as catalyst. Polymeric support blocks exhibit dielectric properties; however, doping of the block copolymers allows the preparation of materials whose conductivity is comparable with the metal conductivity. This type of conducting composition can be synthesised using a terpolymer of, *e.g.*, diene, ethylene and propylene and blends of thermoplastic elastomers as well.^{253,255,263}

Bolognesi *et al.*²⁶⁴ reported an interesting method for preparation of a comb-like copolymer in which the *trans*-PAC chains are grafted onto a polybutadiene or polyisoprene matrix [this was done using the $\text{Ti}(\text{OBu})_4$ catalytic system and a mixture of tetramethylenediamine and *sec*-butyllithium].²⁶⁴ A large body of patent literature exists on this subject. For instance, the procedure for preparation of a readily processable composition of PE and PAC involved treatment of a thin PE film with the catalyst followed by polymerisation of acetylene.²⁶⁵ The conductivity of the material obtained was $5 \Omega^{-1} \text{ cm}^{-1}$. To obtain doped, high-conductivity compositions based on PO and oriented PAC, plastic fibres or ribbons were washed with a solution of the Ziegler–Natta catalyst and placed stretched in a vessel filled with acetylene gas.^{266,267} Polymer blends based on conducting material were also prepared in another manner using porous films or membranes.^{268,269} The newly formed macromolecules that fill porous matrices with uniaxially oriented pores were found to have a preferential orientation along the pore axis. The approach based on the use of porous HDPE films obtained by uniaxial drawing of the polymer in liquid media *via* delocalised crazing was used for the preparation of PE–PAC compositions.²⁷⁰ The content of PAC was at most 8 mass % and the results obtained after selective extraction of PE indicated the formation of a rigid three-dimensional PAC network reinforcing the PE matrix. However, the formation of PAC chains grafted onto PE in such systems also cannot be ruled out. This will cause the orientation of both phases,

viz., the finely dispersed porous PE matrix and rigid-chain PAC macromolecules. Doping the polymer blend with iodine led to an increase in the bulk conductivity by 14 to 16 orders of magnitude, which points to a low percolation threshold for the conductivity of the structures with marked anisotropy of the mechanical and electrophysical properties. The conductivity of compositions containing up to 3% doped PAC was described in the framework of the simple percolation model.

The structure and various (including electrical) properties of films based on PAC and polybutadiene have been studied in detail.^{271,272} It is appropriate to prepare these compositions from diene–ethylene–propylene terpolymers and PAC.²⁵⁵ Polymerisation of acetylene in the elastomeric matrix results in a product which exhibits not only high conductivity and resistance to aggressive media, but also reasonable operating characteristics. Cross-linking of these compositions leads to immobilisation of PAC. Graft polymers consisting of polydiene and PAC are relatively easy to prepare. In this case, the metal–carbon bonds formed with participation of vinyl groups of the 1,2-polybutadiene units in the first stage of the process are then involved in grafting of PAC in the second stage.²⁷³

Soluble graft block copolymers of PAC (up to 5%) and atactic PS, soluble block copolymers of PAC and polyisoprene (including doped block copolymers)²⁷⁴ and the PAC–b-poly(norbornene)–b-PAC triblock copolymers with different block lengths were synthesised. Graft copolymers are characterised by micro-phase separation.

Polymer–polymer compositions based on polyolefins and conjugated polymers can be prepared using not only PAC, but also such components as polyphenylacetylene, poly(propargyl alcohol) and poly(propargylamine), which are obtained by polymerisation of the corresponding monomers on the $\text{Mo}(\text{V})$ complexes immobilised on PE, PP or PS.²⁷⁵ Polymerisations of crystalline diacetylenes in a microporous polymeric matrix resulted in compositions of isotactic PP and substituted polydiacetylenes.²⁷⁶ Drawing the PP film in 20% solutions of substituted 2,4-hexadiynes followed by removal of the solvent allowed the preparation of a film containing up to 20% diacetylene units. Studies on the γ -radiation-induced, solid-phase polymerisation revealed an increase in the degree of conversion of the monomer in the PP matrix as compared to the reaction in solution. This was explained by a higher initiation rate rather than the mechanical effect of the matrix. A method for ‘internal’ doping of the polyconjugated system with iodine that is partially separated during the polymerisation of the iodine-containing monomer was reported.²⁷⁷

Preparation of blends of polyconjugated polymers and UMMPE by gelation^{278–280} is also of interest. For instance, a UMMPE–poly[2-butyl-5-(2-ethylhexyl)-1,4-phenylenevinylene] (70 : 30) composition was prepared from solution (more correctly, a gel) in *p*-xylene. No information on the conducting properties of such PPC was reported.

Products of the *in situ* polymerisation of pyrrole are also used as components of conducting PPC. The procedure for preparation of such PPC as PE–PAC involves immobilisation of the catalyst on the surface of functionalised PE films. This method was also used for the synthesis of PE–polypyrrole (PPr) compositions.²⁸¹ To this end, a film consisting of PE and sulfonated PS was immersed in a solution containing FeCl_2 and FeCl_3 and then polymerisation of pyrrole was performed at 275 K for 30 min in

Figure 17. 'Strain-displacement' curves for double film PE-sulfonated PS (without PPr) (1) and ternary films PE-sulfonated PS-PPr (2-4) with different conductivities prepared by electrochemical polymerisation.²⁸¹ Conductivities ($\Omega^{-1} \text{ cm}^{-1}$): (2) 3.8; (3) 7.5; (4) 14.9.

the dark followed by post-polymerisation doping. The surface conductivity of the polymerisation product was $\sim 250 \Omega^{-1} \text{ cm}^{-1}$. Films prepared from this material exhibit good mechanical properties; however, the films characterised by higher conductivity are less elastic and more rigid (Fig. 17).

Conventional methods for the synthesis of conducting compositions have some inherent drawbacks, such as high rigidity and dark colour of products, a complicated procedure for preparation of samples with specified conductivity and long duration of the formation of films thicker than $10 \mu\text{m}$. To eliminate these drawbacks, it was proposed to prepare this kind of PPC in the form of PPr-based polymer alloys by chemical²⁸² or electrochemical²⁸³ polymerisation of pyrrole on polymer supports. The method involves coating an electrode with a polymeric support film $\sim 20 \mu\text{m}$ thick. The PPr chains begin to grow from the film side adjacent to the electrode surface. Therefore, initially only the 'electrode' side of the film is conducting. The opposite, 'surface' side of the film acquires conducting properties only after being penetrated by the PPr chains. Polymer alloys prepared in this manner exhibit some attractive properties including high conductivity (more than $300 \Omega^{-1} \text{ cm}^{-1}$), stability in air, good film-forming ability and high homogeneity. Werner²⁸⁴ reported the synthesis of a number of PPr-based, conducting, thermoplastic and elastic *in situ* prepared PPC including those containing PB. Methods based on the use of monomers (e.g., pyrrole or aniline) as solvents for the polymerisation have also been developed.²⁸⁵⁻²⁸⁷

Conducting compositions containing tailor-made PO can be prepared by the blending of components. In particular, microporous PE films synthesised by rapid melt extrusion followed by annealing exhibit a well-developed surface and can be used as supports for composite materials prepared by coating these films with a thin layer ($4-7 \mu\text{m}$) of conducting polyaniline (PAn) from aqueous dispersion.²⁸⁸ This kind of material is characterised by strong adhesion between their components. Despite its very small thickness, the PAn layer has the same conductivity ($0.2 \Omega^{-1} \text{ cm}^{-1}$) as that of a much thicker film cast from the PAn dispersion.

PAn-Based conducting compositions are also prepared by polymerisation of monomers in porous polymeric matrices obtained by cold drawing of polymer films (including HDPE films) in reactive liquid media by a delocalised crazing mechanism.^{289, 290} Electrochemical polymerisation in thin pores of the PE matrix in the acid-aqueous electrolytes results in the formation of oxidised PAn (emeraldine salt). The specific surface conductivity of the undoped product is $9 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$ (the conductivity of undoped PAn is only $10^{-10} \Omega^{-1} \text{ cm}^{-1}$, see Ref. 291). Doped PAn exhibits a conductivity of $5 \Omega^{-1} \text{ cm}^{-1}$ (see

Ref. 292). In finely dispersed porous matrices, PAn forms spherulites $60-100 \text{ nm}$ in diameter (cf. 300 nm in diameter fibrillae formed outside the matrices). The films are characterised by uniform dispersion of the PAn phase in the bulk and by complete phase separation of the components. It is noteworthy that the content of non-extractable (insoluble) PE retained as the constituent of the polymer blend upon selective extraction of PE in decalin at 418 K and in xylene at 408 K lies between 20% and 30% PE. A possible explanation is as follows. Since the growing polymer particles are much larger than the effective pore diameter of the matrix ($4-15 \text{ nm}$), the fibrillae of the matrix phase penetrate the particles of the PAn phase, thus preventing them from being accessed by the solvent molecules.

In situ synthesis of conducting compositions can also be performed in the reverse order. In this case, the catalyst or initiator of polymerisation of the corresponding monomer is immobilised on the conducting component. For instance, doping of PAc with dihydronaphthalide sodium results in the formation of a charge-transfer complex²⁹³ $[\text{Na}_{0.057}(\text{CH})]_x$ which is used as initiator for grafting of blocks of PS, polyisoprene, PMMA, PEO, etc., onto the PA chains.²⁹⁴

The possibility of immobilisation of metal complex catalysts on graphite followed by the *in situ* preparation of conducting PPC²⁹⁵ makes this approach be particularly attractive. Here, the height of the potential barrier to the charge carriers injected into the dielectric polymeric component of the PPC reduces.²⁹⁶ The PE-soot composition also exhibits conducting properties;²⁹⁷ a sharp decrease in the electrical resistance begins as the content of soot reaches 6 vol.%. The conductivity of this PPC is independent of the soot particle size (on the average, 62 nm in diameter) and the melt flow index of PE. As the content of soot changes from 16 vol.% to 28 vol.%, the maximum conductivity increases from 1 to $3 \Omega^{-1} \text{ cm}^{-1}$ at a current density of up to 15 A cm^{-2} . The current-*vs.*-voltage curve passes through an extremum. The decrease in the electric current is due to stress relaxation and to scission of soot chains caused by the Coulomb forces at high voltages. The HDPE-based composition exhibits higher conductivity compared to the LDPE-based PPC; this is probably due to the lower volume fraction of the amorphous phase characterised by high concentration of soot in the former case.

Thus, different synthetic procedures developed in the framework of the *in situ* approach to preparation of PPC are convenient and promising for the synthesis of conducting composite materials.

X. Formation mechanism and the structure of *in situ* prepared polymer-polymer compositions

In the preceding sections of this review we have considered many aspects of the mechanism of formation of the *in situ* prepared PPC. In this section, we will sum up information on the morphology, formation mechanism of polyolefin molecular compositions and the role played by the interfacial layers.

The strength of adhesive interaction between the components of PPC is an important characteristic determining their mechanical properties and operating characteristics. The properties of various two-phase polyolefin-polymer compositions can essentially (and even abnormally) change irrespective of the nature of the polymeric constituents. Most often, the parameters of PPC are determined by peculiarities of the boundary (interfacial) layers characterised by effective interactions between the components of the PPC. In principle, the morphology of the interfacial layer can follow two patterns.⁷ First, the interfacial layer can comprise two regions adjacent to the one and only interface and having specific structures different from the structure of the bulk phases of each component (A and B). Second, a situation with two interfaces is possible. General and more detailed schemes illustrating the structure of the interfacial layers are shown in Fig. 18. If PPC are prepared by blending polymeric components that can be even virtually immiscible, the first pattern can be followed; however, in

Figure 18. The structure of intermediate layers in the formation of polymer blends (I) and synthetic (II) compositions (a) and the structure of the intermediate layers in polymer blends (I) and in synthetic (II) compositions iso-PP (1), triblock copolymer (2) and PE (3) (b).

this case the interfacial layers are formed due to the physical interparticle interactions and self-diffusion of macromolecular segments. The latter process is a kind of segmental dissolution of polymers accompanied by migration of the low-molecular-mass homologues-components towards the interface (this provides an explanation for the important role of the molecular mass distribution of the starting polymers in the formation of PPC).

As mentioned above, considerable attention is given to the methods for weakening the interface stress and improving adhesion between the immiscible phases.²⁹⁸ In the course of reactive blending (polymerisation of one monomer in the presence of the other component) such boundary layers are formed as a result of the appearance of interpenetrating polymer chains and, possibly, pseudointerpenetrating polymer networks, which favours the improvement of compatibility of the components.

Often, the interface is represented as a conventional, two-dimensional geometrical surface. However, in real binary compositions the interface can be rather thick and exhibit specific properties that differ from the properties of the bulk phases. These are not only lowered segmental mobility of macromolecules, reduced number of possible macromolecular conformations and loosened macromolecular packing, but also violation of identity of the chain building blocks and changes in the translational dislocation vectors and character of relaxation processes, *etc.* The properties of PPC are strongly dependent on how the interfacial layer is distributed within the compositions, *i.e.*, is it localised only at the interface or does it extend to the bulk phases of the polymeric constituents? The interfacial layer has a complex structure. It includes the adsorbed near-surface layer with specific properties and some transition layers in which the degree of ordering of the macromolecular packing varies with the distance from the surface of the polymeric matrix. If the content of one component is low (5% to 10%), the so-called threshold space of the interfacial layer takes on particular significance, since in this case the phase continuity can be violated, thus providing the possibility of direct contact between the macromolecules of the polymeric constituents. Under certain conditions, one bulk phase can 'penetrate' through the second bulk phase (Fig. 19), which leads to the formation of interfacial structures with improved adhesion.

As a rule, the mechanical characteristics of the interfacial layer are related to its adhesive properties, that is, an increase in the modulus of elasticity corresponds to an increase in the adhesive energy and to thinning down of the interfacial layer. When estimating the contribution of the boundary layers to the properties of a multiphase system, one should know the distance from the interface at which deviation of local properties from the bulk properties can be considered insignificant; an important point is, however, that the thickness of the interfacial layer determined by different methods depends on the sensitivity of a particular method.⁸ Nevertheless, the thermodynamic approach allows one to evaluate the minimum thickness of the interfacial layer ($\delta_{\min}$), which meets the criterion for its stability.²⁹⁹

Figure 19. A scheme illustrating interpenetration of polymer chains in compositions prepared by *in situ* polymerisation.

The density of the interfacial layer changes exponentially with the distance from the interface and can be controlled in a targeted manner. The volume of the interfacial layer, V_1 , can be found using the following equation³⁰⁰

$$V_1 = \frac{\rho}{\rho_1} V (1 - e^{-\alpha N}),$$

where ρ and V are the density and volume of the polymer matrix, respectively; ρ_1 is the effective density of the interfacial layer; α is the coefficient of proportionality; and N is the number of particles of a particular component.

The density of the interfacial layers in the composition of HDPE and PVC was qualitatively assessed using positron annihilation technique.⁶⁵ It was found that the *in situ* prepared PPC are characterised by dispersion of the PVC particles in disordered PE domains. A decrease in the density of macromolecular packing upon the formation of the interface was also pointed out by Chalykh *et al.*³⁰¹ The PE component of this PPC was found to form one crystalline phase and two amorphous phases (the surface phase and the intermediate phase).³⁰² NMR studies revealed the existence of domains characterised by different free induction decay parameters and relaxation times in the bulk of the PPC. The interaction between these domains is weaker than within each of them. The formation of the transition layer leads to loosening of the near-surface layer of the PE phase. The mean correlation time of intermolecular motions in this layer is 10^{-8} s.

Similarly to the filled systems, the interfacial layer in polymer–polymer compositions serves three main interrelated functions.¹ These are (i) stress redistribution from the phase contact region to the bulk phases (reduction of stress concentration in the more flexible component), or operation as a specific structural stress concentrator during the degradation of PPC; (ii) changes in the elastic and viscoelastic properties of PPC; and (iii) suppression of both cracking and formation of other defects (the interfaces prevent the samples from microcracking).

The type of the phase structure and the sizes of corresponding structural domains depend on the nature of the polymers under study (the surface tension at the interface and the viscosities of the components and their ratios, the volume fraction of the components and blending conditions). It is these characteristics that determine the properties of PPC. In particular, the formation of amorphous-crystalline structure leads to improvement of the impact toughness (see, *e.g.*, Ref. 303); PPC with fibrillar structure exhibit higher strength and improved strain–stress properties (see, *e.g.*, Refs 304 and 305); polymer compositions with lamellar structure are characterised by improved barrier properties³⁰⁶ while continuous structure favours achievement of an optimum combination of the properties of both components.³⁰⁷

If the formation of dispersed structures has been studied in much detail, the conditions for the appearance of domains with

continuous morphology have been little studied except, probably, for the PE–PS system.³⁰⁸ Recently, Tseng *et al.*¹⁸⁶ reported the results of scanning electron microscopy studies of the changes in the morphology of compatible and compatibilised incompatible PP–PA-6 (30:70) systems. The incompatible PPC were characterised by high surface tension at the interface, which led to the formation of a coarse-grained product. Even the addition of a rather large amount of the PP/MA phase (5 parts by mass) was insufficient for inhibition of the formation of this structure. On the other hand, the addition of the PP/MA–co-PPG copolymer (5 parts by mass) led to substantial reduction of the domain size of PA-6. The reduction magnitude was found to be a function of the diamine-modified PPG chain length. Finally, the reactions involving compatibilisers containing grafted MA (0.8 mass %) followed by the formation of the PP/MA–co-PPG copolymer result in the compatible compositions for which the longer the PPG chains, the higher the dispersity. Similar results were also obtained in studies of a compatible system PP–(PP/MA)–PA-12 (65:10:25), in which all the MA groups enter into reactions with the terminal NH₂ groups of PA-12 and the particle size lies between 0.1 and 0.5 μm or less.³⁰⁹

It should be noted that the particle size distribution of the dispersed phase in compatible systems is much narrower than in incompatible systems. In the latter, coarse-grained particles of PA-12 grow in the course of annealing at 453 K. This is accompanied by grafting a larger number of the PA-12 molecules onto the PP/MA phase and by an increase in the thickness of the interfacial layer. An increase in the content of the PP/MA phase favours an increase in the dispersity of PA-12. Despite the presence of excess MA groups, the (PP/MA)–g-PA-12 system is formed in these compositions. However, it should be kept in mind that thermomechanical treatment during processing of polymers has a strong effect on the mechanochemical processes in and, hence, on the morphology of these heterogeneous systems.

In addition to the interaction between the functional groups of different components (including grafted ones) of an *in situ* prepared PPC, grafting of the newly formed polymeric constituent (a polyolefin, polydiene or polyacetylene) of the PPC onto the surface of the polar component also plays an important role in the formation of the interfacial layer in this type of PPC. Grafting can occur, first, in the initiation stage of polymerisation (the multiple bonds of the surface reactive groups can be cleaved and these groups can undergo insertion into macromolecules in the form of end groups); second, in the growth stage, when the multiple bonds of a particular component are involved in the copolymerisation; and, third, in the stage of chain transfer to the surface of the polar component (the reaction between the propagating chain end or a functional group of the polymer and the specific surface group, resulting in the formation of a covalent bond). Specific reaction mechanisms and the relative contributions of particular reaction stages depend on the nature of the constituents of PPC.

Improvement of the properties of the PO–PO compositions prepared using the principle ‘compatibilisation *via* polymerisation’ as compared to polymer blends of the same chemical composition is rationalised by higher ordering of their morphology.¹²⁸ The synthesis of the PO–PO compositions involves coating of the catalyst with the polymeric constituents in rigorous order, that is, PP, SKEP and, finally, PE. In this case the adhesive, SKEP, is localised at the interface (*cf.* polymer blends with the same structural elements, in which SKEP is much more dispersed within the bulk of the dispersed phase). Therefore, the brittleness temperature of the compatibilised composition is reduced by 16°.

As a rule, one component of a polymer blend presents no obstacles to crystallisation of the other blend component.⁹⁹ Nevertheless, there are some exceptions. For instance, the crystallisation temperature of the PA-6 phase in the PP–PA-6 compositions is 2–3° lower than that of the starting polymer, which points to a lower nucleation rate.¹⁸⁶ In other words, the product of *in situ* polymerisation, PP–(PP/MA)–PA-6, prevents crystallisation of PA-6.^{310, 311} On the other hand, the crystallisa-

tion temperature of the PP phase of the composition is appreciably higher (by 6–9°) than the crystallisation temperature of the individual polymer. This means that PA-6 acts as a promoter for crystallisation of PP in the composition under consideration. No substantial changes in the melting temperatures of these semi-crystalline polymers in both compatible (437.5 K) and incompatible (494.5 K) PPC occur; however, the degree of crystallinity of the PA-6 phase in the compositions decreases. Probably, the presence of copolymers within the interfacial layer makes the crystallisation of PA-6 more difficult to proceed. On the other hand, the degree of crystallinity of the PP phase in compatible PP–PA-6 compositions remains unchanged.

Finally, yet another important structural feature of the interfacial layer should be pointed out. The macromolecules located within this layer adopt an extended conformation due to the orientational effect of the matrix. For instance, the macromolecular segments adjacent to the PVC phase in the molecular compositions of PE and PVC are oriented.³¹² This can be rationalised by the effect of the PE chain growth conditions, namely, by high density of the growing PE chains in the thin near-surface layer. Polymer chains growing in this case in a co-operative manner adopt an extended conformation. It is assumed^{7, 8} that crystallisation of one component near the phase boundary of the other component is accompanied by the formation of transcrystallites that are stronger and more rigid than spherulites. Interpenetration of the polymer blocks into the interfacial layer provides the possibility for the adhesive interaction (anchoring) between the constituent phases to occur. Such a submicrostructure contributes largely to improvement of the impact toughness of PPC.

Orientation of macromolecules at the interface between glassy polymers leads to transition of the polymers into a state typical of liquid-crystalline polymers.³¹³ Rigorous control of crystallisation conditions also allows the preparation of highly crystalline PE films (in this case, the polar component can act as nucleating agent for crystallisation) and polymer alloys. In particular, PE can undergo epitaxial crystallisation on oriented poly(oxyethylene) in spite of different crystal structures, macromolecular conformations and polarity of both polymers.³¹⁴ However, this is impossible if PP, cellulose, PVAIc or PA-6 are used instead of poly(oxyethylene). The formation rate of the *in situ* prepared PPC also plays a significant role. If macromolecules leave the reaction medium at a rate comparable with the chain propagation rate, no stacking occurs; rather, structures with extended conformations of the macromolecules are formed.³¹⁵ The so-called occlusion effect responsible for occlusion of the growing polymer chains within the ‘dead’ polymer domains should also be taken into account. Thus, by using the ‘compatibilisation *via* polymerisation’ strategy one can prepare structures with the nonequilibrium orientation of macromolecules.

From the aforesaid it follows that the interactions between the components of PPC at the interface, especially between crystalline polymers, should be considered in close relation to the changes in the molecular and supramolecular structure and taking into account the unique topology of such polymers. Not only physical immobilisation and chain entanglement, but also chemical interactions between different-type polymeric constituents can occur in the molecular compositions. The net effect of these factors leads to the formation of a common co-operative system, which includes several types of bonds and is characterised by additional structuralisation of PPC, which favours the achievement of a high degree of homogenisation. This complex system of interactions at the interface in the *in situ* prepared PPC takes over the breaking load in the case of destruction of the composite material.

Nevertheless, an ideal type of structural organisation of the PPC in question is provided by the IPN that represent molecular compositions formed in the *in situ* polymerisation of monomer 2 in preliminarily swollen polymer 1. The major difference between the classical IPN and the *in situ* prepared compositions based on crystalline polymers lies in the fact that the formation of IPN

involves substantial swelling of the polymer in the monomer. One of the most important features of the IPN consists in extremely strong (in essence, on the molecular level) mutual dispersion of the components.

The size, D , of the polymer 1 phase domains formed in the semi-IPN in the polymerisation of monomer 2 with the molecular mass M_2 can be estimated using the semiempirical Donatelli equation.³¹⁶ This equation takes into account the changes in the free energy of the system and is written as follows:

$$D = \frac{2\gamma\omega_2}{RTv_1[(1-\omega_2)^{-2/3} + \omega_2/v_1M_2 - 1/2]},$$

where γ is the surface tension at the interface, ω_2 is the mass fraction of the monomer and v_1 is the density of cross-links in polymer 1.

Under some assumptions we can estimate the domain size of the PS phase in the blends with PP, prepared by the *in situ* polymerisation of styrene in PP deformed *via* delocalised crazing.⁷⁵ This size is nearly 100 nm, which is in agreement with the results of electron microscopy studies. The aggregative stability of these systems is provided by the strong system of entanglements between two macromolecular networks (the so-called catenane links), *i.e.*, by a specific type of anchoring. Under optimum conditions this method allows one to achieve complete interpenetration of the components on the molecular level even for thermodynamically incompatible polymers.

Morphologically, the systems under study are also relatively close to the IPN. The point is that the second polymer phase is formed in the intercrystallite domains of partially crystalline PO. At temperatures below the melting temperature, PO exhibit rather high resistance to the action of the surface forces that cause phase separation, thus stabilising the newly formed structure. In other words, the crystal structure of PO, which plays the role of cross-links in the first network, reduces the possibility of the formation of extended phase domains of the second component and determines the dispersity of the system. Indeed, the synthesis of the HDPE–PMMA compositions *via* delocalised crazing⁷⁶ resulted in the formation of the structures characterised by phase co-continuity (selective extraction of the components led to the formation of a continuous porous framework rather than to phase separation of the composition). The formation of the PO phase within the amorphous polar component occurs in a more complex manner. In this case, release of heat (its amount can be rather large) in the formation zone of the PO component leads to softening of the matrix and to penetration of the PO phase into the polar component matrix under the action of mechanical stress.

A salient feature of the formation of IPN is the imposition of microphase separation that is due to the thermodynamic incompatibility of the polymer networks formed on the chemical reactions.¹² The chemical compositions of the separating phases depend on both the stoichiometry of the components and the IPN formation rate. The microphase structure is characterised by the degree of segregation of the two-component system in which phase separation into the polymeric constituents occurred (usually, no equilibrium phase separation is reached and the phases with variable chemical composition are formed). The most sensitive characteristic of the phase separation in polymer blends is the relative elongation at break.⁸⁴ Often, passage from compatibility to incompatibility is very sharp and occurs at a particular ratio of the components. Even if specific interactions between the macromolecules of PPC can occur at ambient temperatures, their thermodynamic compatibility deteriorates on heating and they are characterised by the lower critical solution temperature.

Since the components of molecular PPC are thermodynamically incompatible, the compositions prepared from them belong to nonequilibrium systems. To convince oneself that this is true, it is sufficient to give, *e.g.*, the PE–PMMA system molecular mobility (by annealing), which leads to melting of the PE phase

and devitrification of the PMMA phase and is exactly the same as what occurs usually in the case of mixing of polymer melts.

Thus, polyolefin-based PPC prepared by *in situ* polymerisation of one component do not represent typical interpenetrating polymer networks since they can be dissolved in appropriate solvents and are characterised by a wide range of variations in the yielding and creep. On the other hand, they also differ from conventional polymer blends. These PPC can be called molecular, pseudointerpenetrating, thermoplastic chemical polymer blends³¹⁷ that exhibit homogeneity on a microscopic level. Combinations of some specific properties of their components can lead to positive synergistic effects.

XI. Fields of application of *in situ* prepared polymer – polymer compositions

Almost without exception PPC and their individual polymeric constituents have found the same fields of application, the use of the former being often more advantageous. Polymer – polymer compositions belong to the class of hybrid composite materials with improved breaking strength. A salient feature of PPC is nonlinear dependence of their properties on the chemical composition due to unique structural peculiarities. As a rule, these materials are characterised by improved impact toughness (cold resistance), strength, wear resistance and exhibit good dispersability and processability. Many of them (*e.g.*, PVC–PE compositions) are suitable for production of plastic pipes and sheets, various profiles, moulded products and antifriction materials. Polymer compositions based on syndiotactic PP exhibit radiation-damage stability and can be used instead of plasticised PVC.¹¹⁶ Improved thermal stability of the *in situ* prepared HDPE–PVC compositions is rather unusual and sets them apart from polymer blends or untreated PVC.^{49,318} This property, which is also characteristic of the PVC–PS graft copolymers,³¹⁹ is thought to be due to the fact that the mobile chlorine atoms present in the allyl groups as impurities or bound to the tertiary carbon atoms of PVC are removed in the course of grafting. This again confirms the formation mechanism of the structure of interfacial layers in the *in situ* prepared PPC. Polymer – polymer compositions PVC–HDPE can find applications as high-strength, cold resistant polymer films for enclosing greenhouses.⁶³ These materials exhibit improved thermal stability and UV and IR radiation stability, *i.e.*, they favour the ‘greenhouse effect’. The ability of the PE films used for enclosing greenhouses to keep unsweated and retain transparency for long periods under conditions of excess moisture content is also of great importance.

Modification of PP with elastomeric and thermoplastic elastomer additives allows substantial improvement of the impact toughness of the materials and reduction of the brittleness temperature. Among conventional additives are PIB, butyl rubber, SKEP, SKEPT, polybutadiene rubbers, divinylstyrene-based thermoplastic elastomers, *etc.* Polymer – polymer compositions based on PP and ternary SKEPT have superiority in cold resistance (down to 223 K) and impact toughness compared to the untreated PP.³²⁰ The rheological characteristics of these PPC allow them to be processed using conventional methods for processing of thermoplastics, *viz.*, extrusion, injection moulding, blow moulding and pressing.

Blends of different types of PE exhibit improved processability and higher impact toughness compared to the individual components. Often, this leads to enhancement of the performance of production equipment. The PE–PB and PP–PB compositions prepared using the method of ‘compatibilisation *via* polymerisation’ are characterised by high modulus of elasticity, strength, thermal stability, crack resistance and tensile creep. These materials are promising for production of hot water supply pipes, heat exchangers and cable plasticates. In addition, blends of engineering polymers and commercially available thermoplastics are used for production of, *e.g.*, bumpers.

The thickness of the LDPE film used for production of containers should be at least 50 to 60 μm ; these values are mainly determined by the low strength of the polymer. Compatibilisation of several types of polyolefins (*e.g.*, LDPE and HDPE) allows substantial improvement of the properties of the polymer films and reduction of their thickness down to 20 to 30 μm without deterioration of the film strength. This result in more than doubling the performance of extruder reactors and reducing the specific consumption of materials.³²¹ Packaging films are also produced from PPC based on blends of PE with atactic PP, PIB, *etc.* The content of the recycled materials used for production of PE packaging films and containers reaches 50%.¹⁶ Recycled materials are used for production in those cases where no heavy demands are placed on the structural strength of products, but their environmental safety characteristics should meet stringent requirements (*e.g.*, decorative, insulating and sound-absorbing panels, *etc.*). To this end, one can use wood–polymer compositions based on wood waste and recycled thermoplastics (in particular, sawdust mixed with SKEPT-modified recycled LDPE).³²²

Polyolefins, and first of all HDPE, LLDPE, LDPE, PP and its copolymers, as well as PB are the main components of the PPC used for production of pressure pipelines. The properties of polymer–polymer compositions have a strong effect on the strength characteristics of pipes and the operating conditions. New types of LLDPE-based PPC were recommended³²³ for production of hot water supply pipelines (323 K, a pressure of 5 MPa) with a service life of 50 years. Compositions based on UMMPE ($M_w = 4.5 \times 10^6$) and low-molecular-mass PE ($M_w = 8.0 \times 10^4$) are used for production of high-strength, high-modulus fibres by single-stage and two-stage drawing techniques.^{324, 325}

Dilution of the blend with the main component is also used for recycling of multicomponent compositions.³²⁶ For instance, homogenisation of blends of LDPE, HDPE, PP and PVC followed by the addition of PP ($\sim 50\%$) resulted in phase inversion, so that the properties of the end product were mainly determined by the properties of multifilled PP.

As mentioned above, PO and PA, with somewhat different polarities, represent a typical example of immiscible polymers. Blending of PO and PA in the presence of appropriate compatibilisers improves the impact toughness of materials and provides a means of protecting the polymer surface from attack by atmospheric moisture and oxygen. The latter can be illustrated taking the *in situ* prepared PPC formed immediately on polymeric fibres as an example.⁴⁹ The PETP or PA fibres become covered with a specific kind of PE ‘coat’, which protects them from wear, thus improving the wear resistance of the materials, from moisture absorption, *etc.* (Fig. 20). *In situ* prepared polymer–polymer compositions have found an unusual field of application as supports for metal complex catalysts.⁵³ Specific properties of PPC based on HDPE and metal-containing polymers, *e.g.*, titanium, nickel, cobalt and other metal polyacrylates should also be pointed out.³²⁷ Interpenetrating polymer networks can be formed not only within the interfacial layer, but also in the bulk of these PPC. This is due to the fact that not all unsaturated groups are consumed in the polymerisation of metal diacrylates in PE melts. Since the PPC are processed at temperatures above the polymerisation temperature, the unreacted functional groups can be involved in the chemical interaction to form IPN. *In situ* prepared polymer compositions can combine the advantages of thermoplastics and thermosetting polymers. Often, the *in situ* method allows recycling of thermoplastics. The use of filled PPC, *e.g.*, a ternary system PP–LDPE–short glass fibres (up to 30%–40%) whose morphology was studied by Avalos *et al.*,³²⁸ is also expected to provide a way to substantially improve their properties.

Stable conductivity, good mechanical characteristics, high homogeneity, protective effect of the matrix and good processability of the compositions of PAc and PO open the possibility of

Figure 20. A SEM image of the surface of PETP fibre coated with a HDPE ‘skin’.

their use for production of moulded products, *e.g.*, semiconductor relays, thermistors, solar batteries, *etc.*³²⁹

The operating characteristics of PPC including their photo-degradation and photo-oxidation behaviour under natural conditions have been the subject of intensive research. For instance, it was found that the rate of ozone oxidation of oriented HDPE–PP compositions decreases as the content of PP increases.³³⁰ In studies of the blend of isotactic PP and SKEPT† it was shown that an increase in the content of PP leads to enrichment of the interfacial layer with rubber and that the structure of the interfacial layer is the determining factor in the thermal oxidation of blends and vulcanisates.³³¹ This manifests itself as changes in both the mechanism and kinetics of radical steps in the initial stage of oxidation which can affect inhibition of the oxidation process. Photo-induced oxidation of PPC based on commercially available LDPE and LLDPE is accompanied by scission of the polymer chains and cross-linking of the molecules, as indicated by the changes in the molecular mass and molecular mass distribution. If PPC contain polymeric sensitizer constituents, chain scission reactions become more important, while cross-linking of polymer chains, which can also occur, appears to be less significant. No preferential degradation of a particular component was observed in studies of the blends of LLDPE³³² or LDPE^{333, 334} and styrene–butadiene copolymer.

A unique possibility of controlling the properties of polymers has arisen after the preparation of blends of PO with non-olefin components by reactive blending. In particular, polyolefins co-calendered with PVC without using volatile plasticisers can be given such useful properties as elasticity and strength.³³⁵

Of course, the entire spectrum of applications of molecular polyolefin–polymer compositions is much broader.

XII. Conclusion

The use of molecular polyolefin–polymer compositions allows to a great extent the increasing industrial demands for novel materials to be met with reasonable cost:property ratio. Studies on interrelations between the compatibility of polymeric constituents, structure and properties of these PPC are of great theoretical and practical importance. In addition, the preparation of this type of PPC by reactive blending opens the possibility of re-use of plastic waste and degraded polymeric materials. Compatibilisation of the components of PPC requires improvement of interfacial adhesion and an increase in the phase dispersity, which can often be achieved by using interfacial modifiers. PO-Based compositions prepared by *in situ* polymerisation of one component do not belong to typical representatives of interpenetrating polymer

† SKEPT composition is ethylenenorbornene (4.0 mol %), propylene (32 mol %) and ethylene (the rest).

networks; on the other hand, they differ from conventional polymer blends. They can be classified as molecular, pseudointerpenetrating, thermoplastic chemical polymer blends.³¹⁷ In some optimum cases the *in situ* prepared PPC are characterised by homogeneity on a microscopic level, a valuable combination of specific properties of their constituents and by positive synergistic effects.

The structure of a real particle of the *in situ* prepared PPC is shown in Fig. 21. The particle is composed of the catalyst component or another precursor (1) coated with the newly formed polymer (3) and the interfacial layer (2). The topology and phase structure of the PPC can be controlled in the design stage. Determination of the structure of the PPC and finding out the methods for its control will allow targeted design of polyolefin-based composite materials with desired properties. Unfortunately, no analytical expressions relating the molecular parameters and the composition of a system to its properties have been derived as yet. Would they be proposed, this will favour the refinement and generalisation of the experimental relationships and the development of a well-substantiated approach to the preparation of PO compositions with desired properties.

A great advantage of the methods for preparation of PPC considered in this review is that they allow one to prepare operationally compatible polymer compositions from thermodynamically

Figure 21. General view (a) and simplified scheme (b) of the structure of a particle of molecular PPC (for details, see text).

cally incompatible components. These compositions exhibit stable properties and have superiority in some characteristics compared to traditionally used polymer blends. This approach follows a recent trend, according to which polymeric materials are given the desired properties by choosing appropriate combinations of the known components rather than by polymerisation of new monomers, since the potential of the organic synthesis of new monomers and polymers based on them are, after all, limited.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 01-03-97018) and the Ministry of Industry and Science of the Moscow Region.

Abstract. The current state of studies on the mechanisms of asymmetric hydrogenation, hydrosilylation and cross-coupling induced by metal complexes is considered. The possibilities for the identification of stages of catalytic reactions involving asymmetric induction are analysed. The classification of the types of asymmetric induction according to the differences in these stages is proposed. In most cases, asymmetric induction occurs in the stage of substrate coordination by catalytic complexes (the key–lock interaction). Evidence is presented in favour of the assumption that the asymmetric carbon atom is formed in the product in the stages of transformations of the asymmetric intermediate, even though the starting chiral catalytic complex is C_2 -symmetric. The bibliography includes 118 references.

I. Introduction

Asymmetric catalytic reactions involving prochiral substrates on chiral metal-complex catalysts proceed through the interaction of these species to form diastereomeric intermediate complexes. The rational description of the phenomenon of asymmetric induction (or diastereoselectivity)[†] in asymmetric synthesis can be given using empirical stereochemical rules and models¹ analogous to those proposed by Prelog, Cram, Cornforth, *et al.* Asymmetric induction can take place either in the stage of interaction (coordination) of a metal-complex catalyst with a substrate to form an intermediate complex or in the course of subsequent transformations of the resulting complex. The first alternative is sometimes called the steric control or the ‘key–lock’ interaction (the terms ‘chiral recognition’ and ‘chiral discrimination’ are also used).

For the reaction

where A is the substrate and B is the reagent (catalyst), the following general classification of the types of asymmetric induction is proposed:

- (1) prior to the reaction (due to a chiral medium);

- (2) the stage involving the interaction of A with B (coordination of the substrate by the catalyst);

- (3) transformations of the first ($[AB]^1$), second ($[AB]^2$) and subsequent intermediates already involving the coordinated substrate;

- (4) nonbonded diastereomeric interactions analogous to those existing between enantiomers in racemates.

Asymmetric induction of the first type is observed in reactions performed in a chiral matrix [for example, in cholesteric liquid crystals (CLC) in the mesophase temperature range, where a chiral helical structure is formed] or in a chiral solvent and, probably, under the combined action of the electric and magnetic fields.^{2,3} Asymmetric induction of the second type takes place in asymmetric metal-complex catalysis, in particular, on hydrogenation and hydrosilylation of aromatic ketones. Asymmetric induction occurring in the course of transformations of the first and second intermediates (the third type) has been examined in detail for catalytic allylic alkylation.⁴ The nature of asymmetric induction, which is caused by interactions between enantiomers in racemates (the fourth type) and due to which the racemates differ from the constituent individual enantiomers in some chemical and physical properties, is poorly known.

Asymmetric induction, if considered as a way of communicating stereochemical information, involves two components, *viz.*, static discrimination due to steric hindrance and dynamic discrimination resulting from kinetic or thermodynamic factors.⁵

Hydrogenation, hydrosilylation and cross-coupling are of importance from the practical standpoint because they comprise a minimal set of reactions, which provide the preparation of chiral products bearing many functional groups involved in pharmaceuticals.⁶ Because of this, the present review deals with the mechanisms of asymmetric induction occurring in these three reactions.

II. Asymmetric induction prior to the catalytic reaction

Asymmetric induction prior to the reaction should be considered as a manifestation of the chiral action of a medium both on the catalyst, which in this case can be achiral, and the prochiral substrate. Asymmetric reactions can proceed in a CLC medium

[†] The enantioselectivity can be considered as a measure of asymmetric induction in asymmetric catalysis where the enantiomeric product is isolated from a diastereomeric intermediate complex.

in the mesophase temperature range where a chiral helical structure is formed (for more detailed arguments in favour of asymmetric induction prior to the reaction, see below). However, the published data on asymmetric synthesis in a CLC medium as a chiral matrix are contradictory. The enantioselective Claisen rearrangement performed in a CLC mesophase has been reported.⁷

CNB is cholesteryl *p*-nitrobenzoate.

The authors judged the enantioselectivity of the reaction from the CD spectra of the product.

Ethyl(phenyl)malonic acid was decarboxylated in a CLC mesophase in an optical yield (*p*) of 18%.⁸

In the photochemical synthesis of hexahelicene performed in CLC within the mesophase temperature range of 20–25 °C, the enantioselectivity of the process was 1%, which was confirmed by the presence of a CD maximum in the absorption band of the hexahelicene obtained.⁹

However, photocyclisation of α -(*N*-methylanilino)styrene into *N*-methyl-2-phenylindoline in various CLC mesophases afforded a racemic product.¹⁰ When studying thermochemical interconversions of sulfoxides in a cholesteryl *p*-nitrobenzoate mesophase, a small enantiomeric excess (*ee*) of the product was observed.¹¹

It was concluded^{10,11} that asymmetric transformations in cholesteric mesophases, like those in standard chiral solvents, proceed in low optical yields. However, the authors of the cited papers noted that exceptions are possible in the case of strong specific interactions between the dissolved compound and CLC.

In another study,¹² even the theoretical possibility of the manifestation of the asymmetric effect in a CLC mesophase was

denied because the helical step of CLC (300–400 nm) is incompatible with the molecular sizes of standard reagents. These molecules do not ‘notice’ the helical structure of CLC, much as people do not notice the curvature of the earth’s surface. Nevertheless, CLC, owing to the chirality of their molecules, can exert a slight asymmetric effect on chemical reactions, if only as optically active solvents.

The asymmetric influence of the magnetic field is poorly known.[‡] Pasteur was the first to take an interest in this problem. He believed that if the magnetic field can induce rotation of the polarisation plane of light in the case of achiral compounds (the Faraday effect), it can generate the dissymmetry analogous to that possessed by chiral molecules. Kelvin reasoned that this idea is in error because the magnetic rotation does not possess the right- or left-handed quality, *i.e.*, it is not chiral. However, P Curie noted that the magnetic field parallel to the electric field can induce chirality because the mirror operation (which provides interchangeability of components) is applicable to the parallel and antiparallel molecular arrangements in this combined field.¹⁴ The above-considered enantiomorphism and the enantiomorphism of chiral molecules are distinguished as the ‘false’ and ‘true’ chirality, respectively.^{2,3} This raises the question of whether the ‘false’ chiral effect can cause asymmetric induction. It is known that the symmetry is broken at the level of elementary particles. It is assumed that the ‘false’ chiral effect can induce analogous symmetry distortions in chemical reactions. Changes in the symmetric (in the absence of this effect) energy barriers in the path of formation of enantiomers of the product can lead to differences between the rate constants of formation of enantiomers in the chemical reaction away from the equilibrium.^{2,3}

This theoretical reasoning has been supported experimentally. Thus Gerike¹⁵ discovered the enantiomeric enrichment (although small and irregular) of the product (*ee* < 1%) in alkylation of prochiral ketones with Grignard reagents, the addition of bromine at the double bond and some other reactions using various combinations (parallel, antiparallel and orthogonal mutual arrangements) of the electric (15–8100 V cm^{–1}) and magnetic (constant and alternating, 8 × 10³–1.17 × 10⁵ A m^{–1}, 0–50 Hz) fields. It was reported that reduction of ketones with Grignard reagents and lithium aluminium hydride in a constant magnetic field proceeded with high enantioselectivity.¹⁶ However, this conclusion was disproved by one of the authors.¹⁷ It is agreed^{2,3} that the concept of the asymmetric influence of the constant magnetic field is reasonable, but this influence can serve only as a ‘starter’ and must be combined with a chiral autocatalytic process. Apparently, this problem calls for further careful experimental investigation.

We also examined asymmetric induction in catalytic reactions proceeding in a liquid-crystal chiral matrix^{18,19} by studying hydrogenation of α -acetamidocinnamic acid (ACA) in the presence of achiral Wilkinson’s catalyst RhCl(PPh₃)₃ possessing a substantial molecular volume (this fact is of importance in imparting the helical ordering of the CLC molecules to the molecules of the catalyst). Since RhCl(PPh₃)₃ and ACA are insoluble in a CLC melt, *viz.*, in cholesteryl tridecanoate (CTD), the reaction was carried out in a CTD–BuⁿOH–C₆H₆ mixture. In this solution, the molecules of CTD, the substrate (ACA) and the catalyst RhCl(PPh₃)₃ have helical ordering at the mesophase temperature of 60–70 °C. This is evidenced by the fact that the CD spectra show maxima of induced circular dichroism of the same sign in the absorption bands of the substrate and the catalyst. Probably, the same sense of helical ordering of the substrate and catalyst molecules facilitates discrimination between the *Re*- and *Si*-sides of the C=C bond in the substrate coordinated to the catalyst in an intermediate complex. Actually, a moderate temperature-dependent enantioselectivity was observed in the reaction under consideration (Fig. 1).

[‡] The non-asymmetric influence of the magnetic field on chemical reactions has long been known (see, for example, the review¹³).

Figure 1. Temperature dependence of the optical yield of *N*-acetylphenylalanine in hydrogenation of ACA.

The dependence has a maximum in the middle of the temperature range of the CTD mesophase where the cholesteric liquid crystal is helically ordered. This effect could also be attributed to the effect of CLC as a chiral solvent. However, the fact that the maximum of enantioselectivity coincides with the middle of the temperature range of the liquid crystal mesophase counts in favour of the former explanation.

With the aim of investigating the effect of a combination of the electric and constant magnetic fields on chemical reactions, we[§] used a solenoid.²⁰ Acid- and base-catalysed mutarotation of D-glucose in water was examined. In the mutarotation of monosaccharides, the equilibrium was established between the α and β forms, which are diastereomers. In the initial stage, the reaction was far from the equilibrium (this is a necessary condition for the magnetic field to exert the asymmetric effect^{2,3}). The reaction was carried out in a temperature-controlled polarimetric tube placed in a solenoid and its course was followed from the change in the optical rotation. The rate constant of mutarotation k was calculated according to the first-order equation. The magnetic field strength (H) was calculated from the magnetic rotation of the polarisation plane of light under the action of water at $\lambda = 589$ nm. The direction of magnetic field was judged from the direction of the observed rotation of the plane of polarisation induced by water. To obtain a more accurate estimate of the dispersion of the rate constants, some experiments were repeated several times at the same temperature. The results are given in Table 1.

Presently, one cannot give an unambiguous answer to the question of how the rate constant is changed depending on the direction of magnetic field. However, the reaction at low temperatures in the field with (+)- α_D H₂O proceeds somewhat more rapidly than that in the field with (–)- α_D H₂O. At the same time,

§ The experiment was carried out in collaboration with E I Klabunovskii.

it can be said with reasonable confidence that the effect of a constant magnetic field (without combining with the electric field) is absent. The results of the investigation of D-glucose mutarotation in water in a constant magnetic field demonstrated that the changes in the rate constants depending on the direction of the magnetic field are comparable in value to the errors of the measurements (Table 2).

III. Asymmetric induction in the stage of substrate coordination by catalytic complexes

The elucidation of the nature of asymmetric induction and the identification of the stage where it takes place are closely related to the investigation of the general mechanism of asymmetric reactions. For the latter problem to be solved, it is necessary to reveal individual elementary stages, determine their rates, detect and characterise intermediates (including the establishment of their absolute configurations) and, finally, identify the key stage of asymmetric induction. If asymmetric induction occurs in the stage of substrate coordination by a chiral catalytic complex, this fact can be established using rather simple logical approaches considered below.

The mechanism of hydrogenation of the C=C bond in substrates was studied using rhodium phosphine catalysts, involving such ligands as dipamp,^{21–25} chiraphos,^{26–29} diop,^{21,29} bppm,^{30,31} dioxop^{32,33} and BisP*.³⁴

In studies on hydrogenation of itaconic, citraconic and mesaconic acids in the presence of [Rh(bppm)]⁺ giving rise to 2-methylsuccinic acid, an attempt was made to reveal the stage involving asymmetric induction (the optical yields of the products are given below the formulae of the acids).³⁵

In the event that the enantioselectivity of the reaction is controlled by intermediate **1** common to all the three substrates (which follows from Halpern's theory discussed below), the optical yields must be close, which is contradictory to the experimental data considered above. Hence, it was concluded that asymmetric induction occurred in the stage of substrate coordination (the 'key-lock' interaction).

S is the solvent

It should be noted that the chiral catalytic complex with the bppm ligand does not possess symmetry elements (except for C_1) and, hence, asymmetric induction in the stage of substrate coordination is performed by the asymmetric complex.

The hydrogen pressure influences the enantioselectivity of hydrogenation of acetyl- and benzoylaminocinnamic acids and their esters in the presence of rhodium complexes with the bppm, diop or dipamp ligands (with NEt_3 and without it). To explain this fact, Ojima *et al.*³⁵ offered the hypothesis that two reaction pathways compete with each other:

Path A

Path B

Paths A and B are favourable at low and high hydrogen pressures, respectively. Path B has been found previously in the studies of hydrogenation of alkenes on Wilkinson's catalyst. The authors of the cited study postulated³⁵ that paths A and B afforded different enantiomers. Hence, an elevation of the pressure, which facilitates path B, would be expected to decrease the enantioselectivity up to the inversion of the configuration. It is this situation that was experimentally observed. Interestingly, the addition of triethylamine weakened the influence of the hydrogen pressure on the enantioselectivity. The anion, which is generated upon the addition of NEt_3 to acid (the substrate), has a much higher tendency to form an adduct with the rhodium phosphine complex than the corresponding acid. Consequently, the contri-

bution of path B in the presence of a base is insignificant, which agrees with the experimental evidence that the enantioselectivity remained virtually unchanged at different hydrogen pressures. Hence, the hypothesis under consideration provides an adequate explanation for the effect of the hydrogen pressure and the influence of the addition of a base on the enantioselectivity.

However, this scheme, as applied to the hydrogenation of derivatives of amidocinnamic acid, does not allow one to reveal the stage responsible for asymmetric induction due to a lack of detailed stereochemical information on two competitive reaction pathways. Nevertheless, the hypothesis for two competitive reaction pathways is fruitful. It was found^{36–39} that the enantioselectivity of hydrogenation of ACA in the presence of the $[\text{Rh}((R)\text{-PheNOP})(\text{cod})]\text{ClO}_4$ complex

depends on the hydrogen pressure, the temperature, the ratio of the concentrations of ACA and the complex and the dielectric constant of the solvent (Fig. 2). These dependences can readily be explained within the framework of the above-considered concept. The contribution of the reaction path B becomes more significant and, correspondingly, the higher enantiomeric excess of the product adopting a certain configuration, *viz.*, (*S*)-AcPhe, is achieved as the hydrogen pressure is elevated, the concentration of the substrate with respect to the catalyst is decreased, the temperature is lowered and the dielectric constant of the solvent decreases. The role of the first two factors follows directly from the schemes of the reaction paths A and B. The influence of the two last-mentioned factors is in agreement with the observations made in the study.³⁵ The proposed explanation is also confirmed by the fact that rhodium hydride was observed in the reaction mixture at low temperature (-20°C).³⁷

Upon hydrogenation of the enamide substrate on complexes with bppm and PheNOP, asymmetric induction occurs during the transformation of an asymmetric intermediate.

The pure dihydride mechanism (path B), which is realised even at low temperature and hydrogen pressure, was considered in the study³⁴ devoted to hydrogenation of methyl α -acetamidocinnamate ($\text{Ac}\Delta\text{PheOMe}$) on a rhodium complex containing (*S,S*)-1,2-bis(*tert*-butylmethylphosphino)ethane (Scheme 1).

Asymmetric induction takes place during substrate coordination by the dihydride complex (major intermediate) present in an

Figure 2. The optical yield of the product (*S*)-AcPhe in hydrogenation of ACA vs. the hydrogen pressure (*a*), the reaction temperature (*b*), the ratio of the concentrations of ACA and the catalytic complex (*c*) and the dielectric constant of the solvent (*d*).

The reaction conditions: (*a*) — $T = 20^\circ\text{C}$, $[\text{ACA}]:[\text{Ph}] = 100:1$, $\text{C}_6\text{H}_6\text{--MeOH}$ (1:1); (*b*) — $p_{\text{H}_2} = 1$ atm, $[\text{ACA}]:[\text{Ph}] = 100:1$, $\text{C}_6\text{H}_6\text{--MeOH}$ (1:1); (*c*) — $T = 50^\circ\text{C}$, $p_{\text{H}_2} = 1$ atm, $\text{Pr}^\text{i}\text{OH}$; (*d*) — $T = 25^\circ\text{C}$, $p_{\text{H}_2} = 1$ atm, $[\text{ACA}]:[\text{Ph}] = 100:1$, the solvent: (1) DMF; (2) dioxane; (3) THF (4) EtOH — C_6H_6 ; (5) MeOH — C_6H_6 ; (6) EtOH; (7) MeOH.

Scheme 1

excess. As can be seen from Scheme 1, this intermediate is devoid of symmetry elements, *i.e.*, the asymmetric carbon atom is generated in the product in the stage of the transformation of the asymmetric intermediate although the starting chiral catalytic complex **2** possessed the symmetry C_2 .

The mechanism of asymmetric induction was investigated for hydrogen-transfer hydrogenation of aromatic ketones R^1COR^2

on rhodium and iridium complexes, which were generated *in situ* and contained Schiff bases, *viz.*, derivatives of (*S,S*)- (**3a–c**) and (*R,R*)-1,2-diaminocyclohexane (**4**).⁴⁰

3: Ar = Ph (**a**), C₆H₄OMe-*o* (**b**), Np-2 (**c**).

In all cases, the configuration of the product was determined by the configuration of the ligand and was independent of the nature of the metal atom. If ketones as substrates of this reaction are arranged in order of decreasing difference between the molecular volumes of two substituents (Fig. 3), it can be seen that *ee* tends to decrease in the series FICOMe > 2-NpCOMe > PhCOMe > PhCOEt > PhCOPrⁱ. In the case of rhodium complexes with the ligand **3a**, the corresponding series is as follows: FICOMe > 2-NpCOMe ≈ PhCOMe ≈ PhCOEt ≈ PhCOPrⁱ.

The most pronounced difference in *ee* is observed for FICOMe and PhCOMe. This fact can be interpreted using the quadrant rule.

The metal atom in the C_2 -symmetric chelate chiral complex (the catalyst) is oriented toward the intersection point of the

Figure 3. Influence of the difference between the molecular volumes of the substituents R^1 and R^2 in ketone R^2COR^1 ($R^2 > R^1$) on the enantioselectivity of hydrogenation.

(The catalytic system: (a) Rh/3a, Rh/4; (b) Rh/3b; (c) Rh/3c; (d) Ir/4; (e) Ir/3b. Ketone: (I) FlCOMe; (II) 2-NpCOMe; (III) PhCOMe; (IV) PhCOEt; (V) PhCOPrⁱ).

quadrants and the C_2 -symmetrically arranged aryl substituents fall in the quadrants related by the symmetry C_2 (left upper and right lower), thus 'blocking' them. The larger the difference between the molecular volumes of the substituents in the ketone involved in the intermediate complex (the average of two possible positions, which can occupy the ketone in the intermediate, is indicated by an empty arrow), the higher the probability of the bulky substituent of the carbonyl group of the ketone being located in the free quadrant and, correspondingly, the larger the chiral discrimination and, consequently, the higher the enantioselectivity. It is this situation that was experimentally observed and, hence, the data obtained can be considered as an argument in favour of the fact that asymmetric induction (chiral recognition) takes place in the stage of substrate coordination in an intermediate complex.

Other authors also support the idea that asymmetric induction in hydrogenation with the hydrogen transfer catalysed by rhodium and iridium complexes occurs in the stage of ketone coordination. Thus the following catalytic cycle (Scheme 2) was proposed⁴¹ for hydrogen-transfer hydrogenation of acetophenone catalysed by (S)-(+)-3-*sec*-butyl-, (S)-(-)-3-(1,2,2)-trimethylpropyl- or (S,S)-(+)-3,8-di-*sec*-butyl-1,10-phenanthroline complexes of rhodium(I) in a $Pr^iOH-KOH$ medium.

Scheme 2

As can be seen from Scheme 2, asymmetric induction occurs upon substrate coordination by asymmetric intermediate 7. However, this mechanism of hydrogenation needs additional evidence.

For the reactions catalysed by iridium complexes with Schiff bases, which were prepared from pyridine-2-carbaldehyde and α -phenylethylamine, a mechanism was proposed according to which asymmetric induction takes place in the stage of the hydrogen transfer from the donor (isopropyl) group to the acceptor molecule (ketone subjected to hydrogenation) in the cyclic transition state (Scheme 3).^{42,43}

Scheme 3

DH₂ is propan-2-ol; X = DH₂, OH⁻; R = Me, Et, Prⁿ, Prⁱ.

Scheme 4

The catalytic cycle proposed⁴⁴ for hydrogenation of benzylideneacetone in the presence of the $\text{HIr}[(R)\text{-Ph}.\text{CH}(\text{Me})\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_2]$ complex is shown in Scheme 4. The structure of the intermediate was established by X-ray diffraction analysis. According to this scheme, asymmetric induction occurs in the stage of coordination of the ketone by the asymmetric complex.

Scheme 3 involves direct hydrogen transfer, whereas Scheme 4 implies that the transfer proceeds with the participation of metal hydride.⁴⁴ Both schemes are to a large extent conventional, but the latter scheme seems to be better justified[†] because the hydride intermediate was found experimentally.⁴⁴

Therefore, there is some evidence that asymmetric induction takes place in the stage of ketone coordination by an asymmetric intermediate complex, which lost the symmetry C_2 (if it was present in the starting catalytic complex).

The complex, which is formed *in situ* based on CoCl_2 , semi-corrin ligand **10** and NaBH_4 in alcohol, serves as an efficient catalytic system for asymmetric reduction.^{46, 47}

Amides and esters of α,β -unsaturated acids are reduced by this system with high enantiomeric excess ($ee = 90\% - 99\%$).

$ee = 98.7\%$ ($R = (\text{CH}_2)_2\text{Ph}$), 98.9% ($R = \text{C}_6\text{H}_{11}$), 92.4% ($R = \text{Ph}$);

[†] At the same time, Scheme 4 ignores the reversibility of the reaction involving the hydrogen transfer from isopropanol⁴⁵ and, hence, Scheme 3 seems to be preferable.

The investigation of the reaction mechanism followed with the use of NaBH_4 in an $\text{EtOD} - \text{DMF}$ medium or using NaBD_4 in an $\text{EtOH} - \text{DMF}$ medium demonstrated that borohydride and EtOH serve as sources of hydrogen atoms at the β - and α -carbon atoms of the product, respectively.⁴⁷ Hydrogenation of substrates bearing a prochiral carbon atom in the α -position proceeds non-enantioselectively with respect to this atom.^{47, 48} The assumed structure of the intermediate complex is shown in Fig. 4.

Figure 4. Possible structures of the intermediate complex in reduction reactions on a cobalt-containing catalyst (the cobalt-hydride bond is omitted for clarity).⁴⁷

The involvement of the coordinated alkene in structure **B** is sterically hindered so that the transition state **A** is more favourable. Unfortunately, the authors did not indicate the $\text{Co}-\text{H}$ bond, whereas the latter, probably, provides an explanation for the fact that the asymmetric carbon atom is generated only in the β -position of the alkene and hydrogen is generated from NaBH_4 . Actually, the experimental observations mentioned above can readily be explained by assuming that the alkene containing the non-equivalent α - and β -carbon atoms is coordinated to the cobalt atom (whose hydride ion is, undoubtedly, generated from NaBH_4) as shown below

* P is chiral phosphine, S is the solvent.

Reduction of the C = C bond in substrates of the types

involves the enantioselective addition of the hydride ion at the C_β atom, which is controlled by an asymmetric Co hydride complex, whereupon the intact chiral C₂-symmetric metal complex fragment, apparently, cannot ensure the enantioselective attack on the α-carbon atom. This explanation agrees well with the conclusion made previously that asymmetric induction is realised in the stage of the transformation of an asymmetric intermediate. Hence, turning back to Fig. 4, it can be said that asymmetric induction takes place in the stage of coordination of alkene by the asymmetric monohydride complex of cobalt.

The mechanism of asymmetric hydrosilylation has been studied less thoroughly than the mechanism of asymmetric hydrogenation. It was suggested⁴⁹ that the enantioselectivity results from the competition between diastereomeric silyloxyalkyl(aryl)-rhodium intermediates (Scheme 5).

According to another assumption, asymmetric induction takes place in the stage of the addition of ketone to an intermediate complex^{50, 51} (Scheme 6).

Scheme 6

L* is (S,S)-(+)-2,3-O-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane [(S,S)-(+)-diop].

This scheme is similar to that proposed in the study⁵² where the following structure of the five-membered transition state was assumed

In all the above-considered cases, asymmetric induction is realised in the stage of substrate coordination by an asymmetric intermediate.

IV. Asymmetric induction in the course of transformations of the first or subsequent intermediates of the catalytic reaction

Research on the mechanism of catalytic hydrogenation of substrates like (Z)-α-acetamidocinnamic acid in the presence of rhodium phosphine complexes was started with the detailed investigation of the kinetics of hydrogenation of methyl (Z)-α-acetamidocinnamate catalysed by a rhodium complex containing achiral diphosphine, viz., 1,2-bis(diphenylphosphino)ethane (diphos).^{27, 53–55} The catalytic cycle of this reaction is shown in Scheme 7. The precursor of the catalytic complex, viz., an ionic adduct of diene with a catalyst (**11**), is involved in the catalytic cycle after reduction of the diene. The structure of complex **12** was determined by ³¹P NMR spectroscopy⁵³ and the structure of complex **13** was established by ³¹P, ¹³C and ¹H NMR spectroscopy and X-ray diffraction analysis.²⁴ At room temperature, the oxidative addition of hydrogen to the complex **13** is the rate-limiting step of the reaction, whereas reductive elimination of the product becomes the rate-limiting step at –40 °C. As a result, alkyl hydride complex **15** at –75 °C was accumulated in a concentration sufficiently high for analysis by ³¹P, ¹³C and ¹H NMR spectroscopy.^{29, 54}

Of compounds presented in Scheme 7, only intermediate **14** was not identified and its structure was proposed 'by analogy'.^{56, 57} Later on, the dihydride intermediate was found experimentally.⁵⁸ The intermediates **13**, **14** and **15** as well as the reaction product are racemates (both enantiomers of these intermediates are shown in Scheme 7).

The catalytic cycle of hydrogenation of the same substrate catalysed by {Rh[(R,R)-dipamp]}⁺ is shown in Scheme 8. In this catalytic cycle, the corresponding intermediates are diastereomers and it is reasonable that the reactions involving these intermediates proceed at different rates.⁵⁹ An analogous catalytic cycle was proposed^{26, 27} for hydrogenation in the presence of {Rh[(S,S)-chiraphos]}⁺. In both cases, ³¹P NMR spectroscopic studies demonstrated^{26, 29, 55, 59} that one of the diastereomers (**16**^{maj}) was present in a high excess with respect to the other diastereomer (**16**^{min}). The structure of the major diastereomer (**16**^{maj}) obtained in the reaction in the presence of {Rh[(S,S)-chiraphos]}⁺ was established by X-ray diffraction analysis²⁶ and circular dichroism spectroscopy.²⁷ However, the configuration of the resulting product was opposite to that, which would be expected to be realised if the reaction proceeds through this intermediate.^{23, 26, 60, 61} Hence, it was suggested^{26, 55} that the enantioselectivity is associated with the difference between the constants $k_2^{\min}$ and k_2^{maj} ($k_2^{\min} \gg k_2^{\text{maj}}$, see Scheme 8) due to which the reaction proceeded predominantly through the intermediate **16**^{min} whose concentration was small compared with that of **16**^{maj}. In the case of hydrogenation of methyl (Z)-α-acetamidocinnamate in the presence of {Rh[(R,R)-dipamp]}⁺ at 0 °C, the ratio of the constants $k_2^{\min} : k_2^{\text{maj}} \approx 1000$.⁵⁹ Halpern⁵⁵ assumed that this situation follows the Curtin–Hammett principle according to which

Scheme 7

Scheme 8

the ratio of the products depends only on the difference between the free energies of the transition states and is independent of the ratio of the conformers (intermediates). According to Halpern's theory, the chiral recognition (asymmetric induction) takes place in the transformation $16 \rightarrow 17$ involved in the catalytic cycle. Unfortunately, no explanation was offered for the differences in stability and reactivity of the intermediates 16^{maj} and 16^{min} , which could allow an understanding of the reason for the substantial difference in the rates of their transformations.

Halpern's theory provides an explanation for the effects of hydrogen pressure and temperature on the enantioselectivity of the reaction. It was demonstrated³⁵ that the enantioselectivity decreased and even the configuration of the product was changed as the hydrogen pressure was increased. According to Halpern's mechanism (see Scheme 8), the formation of the intermediates 17 is accelerated as the hydrogen pressure is increased. At some time, this step ceases to be rate-limiting and the process is controlled by the reversible formation of the diastereomeric adduct 16 , i.e., the enantioselectivity is determined by the ratio $k_1^{\text{min}}:k_1^{\text{maj}}$. Since $k_1^{\text{maj}} > k_1^{\text{min}}$, another catalytic cycle, which affords an opposite isomer of the product, becomes more favourable and the enantioselectivity is decreased. It is this situation that was experimentally observed.

The formation step of adduct 16 is characterised by a substantially higher enthalpy of activation than the next step of the addition of hydrogen (in the presence of $[\text{Rh-dipamp}]^+$ as the catalyst, 18.3 and 6.3 kcal mol⁻¹, respectively). What this means is the rate of the first step is decreased much more rapidly than that of the second step as the temperature is decreased and, consequently, the first step can become rate-limiting. Hence, the enantioselectivity would be expected to decrease with decreasing temperature. This situation was observed in reactions involving some phosphine catalysts.^{32,35}

Since Halpern's theory provides an explanation for many experimental observations, it was commonly accepted in the 1980s.^{62–65} However, this theory has a number of drawbacks.

1. According to Scheme 8, the coordination mode of enamide is not changed (*Re-Si*) and, consequently, the balance between the major and minor catalytic cycles remains unchanged on going from the planar-square complex 16 containing the C_2 -symmetric chiral (diphosphine)Rh(I) fragment to the octahedral complex 17 containing the asymmetric (diphosphine)Rh(III)H₂ fragment.

However, the real situation may be different. Moreover, intramolecular interconversions of the complex 16 are quite possible and even (see Ref. 66) the energy barrier for these interconversions is low. It is conceivable that the interconversion *Re-Si* occurs in the step $16 \rightarrow 17$, in which case the major enantiomer is formed in the major catalytic cycle.

2. Most likely, Halpern's theory is inapplicable in the case of rhodium complexes serving as catalysts of hydrogenation of enamides with *ee* = 99.0%–99.9%. In this case, with the generally observed ratio between the major and minor intermediates (10:1), the ratio of the rate constants $k^{\text{min}}:k^{\text{maj}}$ must be even several orders of magnitude larger than that in the case of the rhodium complex with the chiraphos ligand (*ee* = 88%,

$k^{\text{min}}:k^{\text{maj}} \approx 1000$). This difference in the rate constants of the transformations of diastereomeric intermediates seems to be unlikely. For the reaction involving the rhodium complex with the BisP* ligand, another mechanism was proposed³⁴ (see above).

3. Halpern's scheme provides no explanation for some experimental evidence, for example, for the difference in enantioselectivity of hydrogenation of the *E* and *Z* isomers.^{67,68} The enantioselectivities of hydrogenation of (*Z*)- and (*E*)- α -benzoylaminocinnamic acids using the Rh/(*S,S*)-diop system differ not only in magnitude but also in sign.⁶⁹ This may be associated with the different modes of coordination of the above-mentioned substrates by the rhodium atom (the *E* isomer is coordinated through the carboxy carbonyl group, whereas the *Z* isomer is coordinated through the amide carbonyl fragment).⁷⁰ Apparently, the *Re*- or *Si*-side of the coordinated double bond of the substrate may also be changed. Halpern's theory provides no explanation for the influence of bases on the value of *ee* in the reactions performed in the presence of catalysts for which this theory has been initially proposed.³⁵ Thus according to Halpern's hypothesis, the enantioselectivity of hydrogenation in the presence of diphosphine catalysts decreases as the temperature is decreased; however, this is not necessarily the case. Thus in hydrogenation of dehydroamino acids in the presence of rhodium complexes with the prophos, cycphos or diop ligands, the optical yields decreased as the temperature was raised.^{42,71} Apparently, Halpern's mechanism is only a special case.

The mechanism of hydrogenation of substrates, such as tiglic acid, catalysed by the Ru(OAc)₂[binap] complex has been studied in sufficient detail. It was demonstrated that hydrogenation proceeded through the formation of a ruthenium monohydride complex.⁷² The mechanism of hydrogenation of tiglic acid on this catalyst was detailed in the study.⁷³

The bis(carboxylato)ruthenium complex involving a substrate performs the heterolytic splitting of H₂ giving rise to a hydride. The hydride ion reduces the C=C bond in the coordinated substrate to form the chelate which contains the chiral product in the half-hydrogenated state. Protonolysis of the newly formed Ru–C bond affords the target product. According to this scheme, asymmetric induction takes place in the formation of the chelate complex with the substrate hydrogenated, i.e., in the step of the transformation of the intermediate devoid of symmetry elements (except for *C*₁). An analogous mechanism for hydrogenation of tiglic acid on the catalytic methallyl complex [binap]Ru. [η³-(CH₂)₂CHMe]₂ was proposed in the study.⁷⁴ In the cited study, it was also assumed that asymmetric induction occurs in the step of the transformation of the asymmetric intermediate, which already involves the substrate in the coordination sphere.

Asymmetric cross-coupling of Grignard reagents with alkenes has been less well studied. According to the presently accepted mechanism, the reaction proceeds through the formation of the intermediate π -allyl(aryl)ML₂ (Scheme 9).^{75–79}

Scheme 9

X = Hal; M = Ni, Pd; L₂ = P₂, P, P;

Y = Br, OH, OPh, COMe, OSiMe₃, CO₂Me.

The stages A → B, B → C or C → products may be responsible for asymmetric induction. With the aim of elucidating this problem, we studied the reaction of arylmagnesium bromides with derivatives of crotyl alcohol under the action of a nickel catalyst by increasing successively the molecular volume of the leaving group (OR).⁸⁰

Among the intermediates which confirmed the general reaction mechanism proposed previously, species involving π -coordinated alkene (the substrate) were identified by ³¹P NMR and CD spectroscopy. Probably, these intermediates, which exist in the equilibrium with intermediates **20**, are involved in the overall reaction (Scheme 10).

The chiral arrangement of the phosphine phenyl groups of the coordinated dpcp ligand presented in Scheme 10 is based on the results of X-ray diffraction analysis of the complex⁸¹ (the cyclopentane ring of the dpcp ligand is omitted). The crotyl ligands in the intermediates **20a–20d** involve the stereogenic⁸² carbon atom whose configurations are symbolised as (*R*) and (*S*). The π -coordinated crotyl ligand of this type can be subjected both to the (*R*)-(*S*)-inversion of the π -allylic chirality and the *syn-anti* transformation according to the π - δ - π mechanism.^{83–85} Hence, it can be assumed that all possible forms of the intermediate **20** (**a–d**) exist in the equilibrium. In turn, each intermediate can exist in equilibrium with the intermediates **21a–21d**. The interconversion **20d** ⇌ **21d** experiences the smallest of steric

Scheme 10

hindrances. The reaction proceeding through these intermediates affords a product whose configuration is identical with that observed experimentally. The larger the molecular volume of the leaving group, the more favourable this path and the higher the expected enantioselectivity. This fact was confirmed experimentally. Hence, asymmetric induction in the reaction under consideration takes place in the stage of the interconversion of the asymmetric intermediates $20(a-d) \rightleftharpoons 21(a-d)$.

This mechanism allows one to explain rather readily the characteristic features of the reaction observed experimentally, *viz.*, the dependence of the enantioselectivity on the molecular volume of the leaving group (the larger the molecular volume, the more favourable the path through the intermediate **21d** and the higher the enantioselectivity) and the fact that the enantiomeric excess of the product is independent of the temperature (because the equilibrium can be established even at low temperatures). Both intermediates responsible for asymmetric induction already involve the coordinated substrate and are asymmetric.

Another type of cross-coupling, for example, the reaction of a racemic mixture of 1-phenylethylmagnesium chloride with (*Z*)- β -bromostyrene catalysed by nickel complexes (the dynamic kinetic resolution) can be represented by Scheme 11.⁸⁶

Scheme 11

Asymmetric induction can take place both in steps *A* and *B* (in both cases, the intermediates are asymmetric).

V. Asymmetric induction caused by nonbonded diastereomeric interactions

Solutions containing one enantiomer or a mixture of enantiomers (a racemate) may differ in physical properties. Thus the NMR spectra of the racemate differ from those of the optically active compounds comprising this racemate.^{87,88} Analogous effects were also observed in calorimetric studies. These effects are attributable to diastereomeric interactions between enantiomers in solutions.^{89,90}

The enthalpies of interactions of amide derivatives of L- and D-alanine as well as of dipeptides containing the terminal L- and D-alanine residues in aqueous solutions are given in Table 3.

Table 3. Enthalpies of interactions of peptide fragments containing the terminal L- and D-alanine residues.⁹¹

^a This dimension was used by the authors of the cited study.⁹¹

The observed differences in *H* are indicative of the presence of nonbonded interactions between enantiomers in solutions, such as monomer–monomer, monomer–dimer and dimer–dimer containing the terminal L- and D-alanine residues.⁹¹

An impressive example of the separation of an enantiomer and a racemate by fractional distillation was reported.⁹² It appeared that the boiling point of the racemate of trifluorolactic acid differs from that of its enantiomers. This is indicative of the presence of strong nonbonded diastereomeric interactions. However, this effect was not observed for the ester of lactic acid. The differences in the physical properties of enantiomers and the racemate in solutions are generally rather small,[†] but they are sufficiently large for these substrates to exhibit different chemical activities.⁹⁴

The following general principle was stated: the reaction rate for a chiral compound and the ratio of the resulting products depend, among other things, on the enantiomeric composition of the starting compound.⁹⁵ The following reactions can be distinguished:

Below examples are given of reactions where one of the nonbonded interactions (or all these interactions taken together) leads to different compositions of the products.

[†] Differences in the physical properties of the enantiomers and the racemate in crystals have long been known and were described in handbooks (for example, see Ref. 93). These differences are due primarily to the differences in the molecular packings in the crystals.

If (*R*)- or (*S*)-camphor was used as the starting substrate, the excess of borneol in the resulting mixture was insignificant. However, the reaction starting from racemic camphor afforded borneol as the major product.⁹⁶ In contrast, reduction of (*R*)-camphor with LiAlH_4 gave rise predominantly to isoborneol, whereas borneol was obtained as the minor product (90.2% and 9.8%, respectively).^{95,97} A somewhat different composition of the mixture was obtained in the reaction starting from (*R,S*)-camphor (88.7% and 11.3%, respectively).

Reductive dimerisation of camphor

afforded a mixture of isomers

The reaction involving the (*R*)-monomers of camphor gave rise to the (*R,R*)-cis and (*R,R*)-trans dimers in a ratio of 34.8 : 65.2. In the product obtained from the racemate of camphor, (*R,S*)-cis [(*R,R,S,S*)-cis] and (*R,S*)-trans [(*R,R,S,S*)-trans] isomers were present in a ratio of 37.4 : 62.6.⁹⁵

Oxidative dimerisation of the (*S*)-monomer of a phenol derivative

afforded the (*P,S,S*) and (*M,S,S*) diastereomers in a yield greater than 97.5%.⁹⁵ The racemic monomer can, in principle, give eight diastereomers:

However, dimerisation of this monomer produced a mixture of the (*P,S,S*), (*M,S,S*), (*P,R,R*) and (*M,R,R*) diastereomers (*trans* dimers) in 66% yield, whereas the theoretically possible yield is 50%. This inconsistency can be considered as an argument in favour of active interactions between the enantiomers. The reaction

catalysed by chiral aminoalcohol yielded a chiral compound bearing an asymmetric centre in the terminal fragment.⁹⁸ (-)-Aminoalcohol catalysed the formation of (*R*)-alcohol with the diastereomeric excess $de = 97\%$ independently of its enantiomeric purity (100% and 21%), whereas the (*S*) product with $de = 87\%$ was obtained in the presence of (+)-aminoalcohol ($ee = 100\%$). This result is attributable to nonbonded diastereomeric interactions between the chiral substrate and the aminoalcohol.

The non-linearity of the changes in the optical and enantiomeric purities, which was observed in some cases, is accounted for by similar reasons.

The effect of the non-linear dependence of the enantiomeric excess of the product on the enantiomeric (or diastereomeric in the case of a diastereomer) purity of the catalyst (the reagent) can be manifested in asymmetric catalysis⁹⁹ (in asymmetric synthesis and in stereoselective reactions¹⁰⁰) if a chiral catalyst (or a reagent) can form a dimeric diastereomeric complex with one of the reagents of the catalytic (or non-catalytic) reaction.

Possible dependences of the enantiomeric excess of the product on the enantiomeric excess of the catalyst (the reagent) are shown in Fig. 5. A wide range of such reactions is presently known.^{99,100} These effects are attributed to the differences in the reactivity of homochiral and heterochiral dimeric complexes.

Figure 5. Possible deviations from the linear dependence of *ee* of the product on *ee* of the catalyst. (1) the linear dependence, (2) the positive non-linear effect, (3) the negative non-linear effect.

For example, in the reaction

the homochiral (–)·(–) dimer

is 1200 times more active than the heterochiral dimer,

which gives rise to the positive non-linear effect.^{101–103}

VI. Conclusion

Recent investigations demonstrated that the enantioselectivity of some metal-complex catalysts approaches 100%. Ligands for complexes, which ensure the record-breaking enantiomeric purity of the products in various reactions, are given in Table 4. All the listed ligands are conformationally rigid and possess a pronounced helical component bearing bulky groups at the ends of an incomplete helical turn.⁶

The investigation into the mechanism of hydrogenation of enamides in the presence of one of such complexes (the octahedral asymmetric rhodium dihydride complex containing the BisP* ligand) demonstrated that asymmetric induction takes place in the stage of substrate coordination by the complex. The high enantioselectivity of this catalytic reaction (99.9%) is determined by the 99.95% probability of the coordination of enamide by one side {the *Re*-side in the case of the Rh[(*S,S*)-BisP*] complex}.¹⁰⁶ This is indicative of a large difference between the free activation energies of substrate coordination through the favourable and unfavourable sides. The probability of the substrate being coordinated through a particular side is, evidently, determined by the helical component of the conformationally rigid ligand of the complex bearing bulky groups at the ends of the incomplete turn of the helix.

As an alternative mechanism for improving the diastereomeric purity of an adduct of a dihydride complex with enamide, intramolecular isomerisation is less probable due to the high reactivity (short lifetime) of this intermediate (such an isomerisation is more likely in the case of an adduct of the starting complex with the substrate,⁶⁶ which is not involved in the catalytic cycle³⁴).

	98.9	40, 47			
	98	113			

The relationship between the sense of the helical component of a ligand in a rhodium complex involved in hydrogenation of enamides and the configuration of the product⁶ either results from asymmetric induction taking place in the stage of substrate coordination or is a consequence of an alternative mechanism, which is most likely common to the overall series of reactions in which this regularity is observed.

The available experimental data indicate that the reactions proceeding under the action of chiral C₂-symmetric metal-complex catalysts generate the asymmetric carbon atom in the product in a step involving an asymmetric intermediate. Apparently, the Curie–Pasteur principle, which states that there is ‘no asymmetry without asymmetry’, has a literal sense.

Controlled synthesis of stereoblock polypropylene. New trends in the development of elastomers

N M Bravaya, P M Nedorezova, V I Tsvetkova

Contents

I. Introduction	49
II. Catalyst systems for the synthesis of elastomeric stereoblock polypropylene	50
III. Characteristic features of the structure of elastomeric stereoblock polypropylene and the nature of relaxation processes	65
IV. Conclusion	67

Abstract. The review generalises published data on the synthesis of elastomeric stereoblock polypropylene, a representative of thermoplastics, which are prepared by random or block copolymerisation of various co-monomers and are widely used in the manufacture of diverse mechanical rubber goods. New unique applications of metallocene and post-metallocene catalysts in the design of polyolefin elastomers with a broad spectrum of physico-mechanical characteristics are discussed. Particular attention is given to modern homogeneous catalyst systems based on Group IVB element metallocene complexes, which ensure highly efficient synthesis of polypropylene elastomers with various stereoblock structures. Data on the specific features of the structure and properties of the elastomeric stereoblock polypropylene are analysed. The bibliography includes 160 references.

I. Introduction

Homo- and copolymers of α -olefins currently rank as one of the most important industrial polymeric materials. The world manufacture of polyolefins such as high-density polyethylene (HDPE), linear low-density polyethylene (LLDPE), and isotactic polypropylene (IPP), estimated as tens million tons a year, constantly increases and now it accounts for more than 50% of the output of all manufactured plastics.¹ Expansion of the production of these materials was promoted by the discovery of metal complex Ziegler–Natta catalysts with high activity and regio- and stereospecificity.^{2–4} At present, industrial processes, mainly, the synthesis of IPP, make use of fourth-generation heterogeneous Ziegler–Natta catalysts containing TiCl_4 , $\delta\text{-MgCl}_2$, Et_3Al , and modifying additives.^{5–7} Due to replication (the reproduction of the shape of a catalyst particle by the growing polymer particle), the catalysts used ensure the formation of spherical polymer particles with specified size and porosity.

The range and the fields of application of homo- and copolymers of α -olefins are constantly extending. The consumption of

binary ethylene–propylene and ternary ethylene–propylene–diene copolymers permanently increases.^{1, 8, 9} The production volume of these materials exceeds a million tons a year. The industrial synthesis is performed most often using vanadium metal complex systems.^{10, 11} Highly effective two-stage processes for the production of heterophase copolymers based on IPP (1st stage) and ethylene–propylene copolymers (2nd stage)¹ are widely used in industry. By controlling the fraction and the composition of the copolymer and the molecular masses of polypropylene (PP) and the copolymer, one can obtain materials with enhanced elasticity and impact strength, thermoplastic polyolefins (TPO) and thermoplastic elastomers (TPE).^{2–6}

A special position among polyolefins is held by elastomers. They are usually prepared by statistic or block copolymerisation of various co-monomers. Elastomers are capable of being rapidly stretched and contracted; they exhibit high strength and high modulus of elasticity in the stretched state and return to the initial size as the load has been removed. The elastic properties of these materials are due to the formation of chemical or physical networks. The physical network junctions can be represented by crystalline regions joined by the transient chains of the amorphous polymer (Fig. 1). The fractions of amorphous and crystalline phase, the average size, the size distribution, the shape of crystallites, the network density, the possibility of changing the network structure under the action of load and several other factors determine the properties of elastomeric materials.

In the last two decades, the discovery of new highly effective homogeneous systems based on metallocene complexes of Group

IVB elements activated by poly(methylaluminoxane) (MAO) or by other compounds opened up new opportunities for the development of polymer technologies and for extension of the range and applications of homo- and copolymers of α -olefins. Various aspects of metallocene and post-metallocene catalysis of olefin polymerisation have been covered in monographs, special editions and reviews.^{12–20} Due to the uniformity of active centres, these catalysts make it possible to produce polymers with a narrow molecular mass distribution (MMD) and copolymers with a homogeneous composition. The narrow molecular mass distribution and structural and compositional uniformity result in enhanced mechanical strength, impact strength and clarity of materials and determine specific properties of homo- and copolymers. The successive or simultaneous conduction of polymerisation in the presence of a mixture of complexes having different structures ensures the synthesis of polymers with bi- or polymodal MMD and with a controllable composition.

When metallocene catalysts are used, the differences between the reactivities of ethylene, propylene, higher α -olefins and a number of other monomers are much less pronounced²¹ than in the case of heterogeneous or vanadium systems.²² By varying the composition, structure and the type of symmetry of metallocenes, one can control the stereospecificity of metallocene systems and prepare PP and higher poly- α -olefins with various microstructures. The use of metallocene systems not only ensures the formation of PP having different stereochemical compositions (iso-, syndio-, hemicis- and atactic polymers) at satisfactory rates but also extends the range of applicable monomers (for example, cycloolefins and polar monomers can be involved in reactions). A large number of new materials are currently produced in industry by metallocene-catalysed processes.^{23,24}

Metallocene catalysts also open up the way for the preparation of new polymers with diverse stereo- and regiochemical structures, in particular, synthetic blends of various PP, or for the selective synthesis of stereoblock PP (SBPP). The SBPP macromolecules either consist of alternating stereoblocks with different structures or have a uniform structure separated into blocks by regularly arising ‘errors’.

If the length of the co-crystallised stereoregular sequences (i) is relatively short, for example, $i \leq 10–12$ (Fig. 2 *a–d*), and the molecular mass of the polymer is high, the polymer exhibits elastomeric properties. The interest in the production of elastomeric stereoblock polypropylene (eSBPP) is caused by the fact that this is a way of one-pot synthesis of TPE from a single monomer, which has obvious advantages over the processes that require the use of at least two monomers. Due to the specific properties of metallocene catalyst systems and the possibilities they provide, the number of papers and patents devoted to various processes of eSBPP synthesis has substantially increased during the last five years. Quite recently, the range of PP-based elastomeric materials, presented in Fig. 2 and considered in this review, was extended by elastomeric PP (ePP), which is branched atactic PP with short regular, ordered (isotactic or syndiotactic) side chains.²⁵ These branches are organised in well dispersed crystal-

line domains connected by amorphous sections of the backbone, their presence preventing ‘sliding’ of the atactic chains under load, which is typical of atactic PP. Investigations by a number of companies aimed at the development of eSBPP-based materials which could replace plasticised PVC, and some other expensive elastomers are in progress, and this is largely related to the possibility of designing macromolecules in the presence of metallocene catalyst systems.^{25,26}

The present review surveys data on the influence of the structure of catalysts and conditions of synthesis of polypropylene on the activity of catalyst systems and the structure of eSBPP; the relationship between the structure and properties (strain, relaxation, thermal, *etc.*) of the SBPP produced. The attention is focused on the homogeneous catalyst systems based on metallocene complexes of Group IVB elements.

II. Catalyst systems for the synthesis of elastomeric stereoblock polypropylene

This section considers views on the mechanism of catalytic and stereospecific action of metal-complex catalysts and on the development of methods for the analysis of polymer microstructure and its relationship with the properties of catalysts; it describes the history of the discovery of eSBPP and the development of heterogeneous catalysts and highly effective homogeneous catalyst systems for the synthesis of eSBPP.

1. Characteristics of the mechanisms of catalytic and stereospecific action of metal complex catalysts

Elucidation of the mechanisms of catalytic and stereocontrolling action of catalysts is very significant for the target-directed and controlled synthesis of polyolefins. Research into the mechanism of action of Ziegler–Natta metal complex catalysts of polymerisation is the subject of a number of monographs and reviews.^{12,13–17,20,27}

The currently accepted mechanism of formation of an active centre (AC) based on Shilov’s and Dyachkovskii’s concept²⁸ includes the steps of coordination of catalyst components, alkylation and ionisation of a transition metal compound to give a coordinatively unsaturated cation containing an active metal–carbon bond. These views have been further developed after the discovery of highly effective homogeneous catalyst systems based on metallocenes in combination with MAO or weakly coordinating anions such as $B-(C_6F_5)_4$.^{13–20,24} The mechanism of action of the specific activating agents for metallocene systems is extensively studied.

Several alternative mechanisms of chain growth are described in the literature, namely, the coordinate-anionic mechanism, direct insertion of the monomer into the active metal–carbon bond and migration mechanism. On the basis of the results of recent investigations into propylene polymerisation catalysed by homogeneous syndio- and hemicispecific metallocene catalysts, preference is given to the migration mechanism. According to this mechanism, growth of the polymer chain occurs through its migration to the coordinated monomer and insertion of the monomer. The next monomer molecule is coordinated to the newly appeared vacancy, and migration of the polymer chain and insertion are repeated; thus, after each monomer insertion event, the growing polymer chain and the coordination vacancy exchange places (the Cossee mechanism). This mechanism also assumes the possibility of chain migration to the initial position without monomer insertion with retention of the AC geometry (the Cossee–Arlman mechanism). The symmetry of the AC and the ratio between the rates of the ‘monomer insertion–chain migration’ and ‘chain migration without monomer insertion’ processes largely determine the polymer microstructure.

In terms of the two-step mechanism of chain growth, the stereocontrol can take place both at the coordination step and during monomer insertion into the metal–carbon active bond.^{29–33} The insertion of the first monomer is usually not

Figure 2. Schematic views of various types of SBPP.

(*a*) Alternation of isotactic and syndiotactic blocks; (*b*) alternation of isotactic and atactic blocks; (*c*) isotactic blocks with a correcting ‘error’; (*d*) isotactic blocks with an extending ‘error’.

stereospecific.³¹ Stereocontrol is enhanced as a result of cooperative action of the AC, the ligand and the growing polymer chain. The views on the mechanism of stereocontrol by metal complex heterogeneous catalysts is based on the detailed investigation of the polymer microstructure and the properties of separate polymer fractions.

In conformity with the Bovey statistics,^{34,35} a polymer chain is regarded as a sequence of isotactic dyads characterised by identical arrangements of methyl groups relative to the plane of the carbon chain of the macromolecule (*m*-dyads) and syndiotactic dyads in which the methyl groups of propylene are located on different sides of this plane (*r*-dyads). Methods for determination of the contents of *m*- and *r*-dyads, triads (*mm*, *rr*, *mr*), tetrads (*mmm*, *rrr*, *mmr*, *rrm*), various pentads (iso — *mmmm*; syndio — *rrrr*, and hetero — *rmmr*, *mmrr*, *mrrr*, *rmrr*, *rrmr*, *mrmm*, *mrrm*, *mmrm*) and higher sequences (hexads, heptads, etc.) based on the use of high-resolution ¹³C NMR spectroscopy have been developed.^{12,13,17,29,33,36–38}

Analysis of the configuration statistics allows one to identify the stereocontrol mechanism. Two key mechanisms are possible according to which stereocontrol is determined either by the chirality of the catalytic site or by the last inserted monomeric unit in the growing polymer chain. Correspondingly, two simple statistical models have been developed to interpret the distribution of the stereosequences in the polymer, known as the enantiomorphic model and the Bernoullian model. According to the enantiomorphic model, high stereospecificity is attained when an accidental 'error' arising during the polymer chain growth is corrected in the next step. The following ratios hold in this case: *rr* : *mr* = 1 : 2 or *mmmr* : *mmrr* : *mrrm* = 2 : 2 : 1. When the stereocontrol is accomplished by the last incorporated unit of the polymer chain, $4[mm][rr][mr]^{-2} = 1$.³⁷

Methods for estimating the length of continuous isotactic sequences and the regiospecificity of catalyst systems have been developed. The degree of regiospecificity is normally determined from the ¹³C NMR spectra of polymer solutions by analysing the proportion of abnormal patterns of monomer addition (2,1- or 1,3- instead of the 1,2-addition). Depending on the type of system and polymerisation conditions, the frequency of abnormal addition patterns can vary from fractions of a percent to tens of percent.^{29,33}

The fraction of isotactic sequences with different numbers of monomer units and the pentad composition of the polymer can vary over a broad range, depending on the stereocontrol capacity of catalyst systems, while in the case of stereoblock polymers, it is determined by the content of monomer units in regular and atactic sequences. The formation of stereoblock fractions with the use of heterogeneous catalyst systems is usually explained by the presence of highly coordinatively unsaturated AC the structure of which changes repeatedly over the period of polymer chain growth, for example, due to different ways of coordination of the cocatalyst and modifying additives. The microstructure of these materials is described using parametric models, in particular, the enantiomorphic model, the Bernoullian statistic model and the first- and second-order Markov chains.

In analysis of the mechanism of the stereocontrolling action of catalyst systems, the method of polymer fractionation by extraction with solvents having increasing boiling points is often used. The fractionation at rather high molecular masses (> 50 000 g mol⁻¹) is mainly determined by the stereoregular structure of polymer chains, while at lower molecular masses, it is determined simultaneously by the molecular mass and the microstructure.³⁹

When polymerisation takes place under the action of modern highly active titanium magnesium catalysts (TMC), the content of irregular fractions in the product reaches ~ 50%. However, the introduction of electron-donating modifiers, for example, dibutyl phthalate as an internal donor or various dialkoxysilanes as external donors, markedly increases the isospecificity of the systems. High isospecificity of TMC is also attained by using

2,2-substituted dialkoxypyrans as modifying additives.⁶ The isotactic fractions of polymers obtained with these catalysts are characterised by high contents of *mmmm* pentads (≥ 94%–98%).

The discovery of highly effective stereospecific homogeneous catalysts made it possible to establish the relationship between the metallocene structure, the nature of the ligands, the type of symmetry, the mechanism of polymerisation and the microstructure of the resulting PP.^{37,40,41} An advantage of homogeneous metal complex systems is the possibility of direct investigation of the AC nature by various physical methods. Ewen⁴² has formulated the symmetry rule which establishes the relationship between the structure of the initial catalyst and the microstructure of PP synthesised using this catalyst. Thus *ansa*-metallocenes of C₂ symmetry can ensure the synthesis of IPP with a content of *mmmm* pentads of up to 99%, those of C_s symmetry provide the synthesis of syndiotactic PP with up to 94% of *rrrr*-pentads, C_{2v} symmetry leads to atactic PP, and C₁ symmetry provides hemi-isotactic, isotactic or stereoblock PP depending on the type of π-bonded ligands and substituents in them. Catalysts with C₂ symmetry are characterised by homotopic, C_s, by enantiotopic, and C₁, by diastereotopic coordination positions of the olefin and the growing polymer chain. The knowledge of the mechanistic details of the stereo- and regiocontrol of the polymer gives a key to the rational design of homogeneous catalysts. By changing the metallocene structure, the type of symmetry, the ligands and substituents in the ligands and in bridges and by varying the conditions of polymerisation, one can control the microstructure, the molecular mass, and the terminal groups of polymers in the desired direction and produce materials with necessary properties. In the case of metallocene catalysts, unlike heterogeneous catalyst systems, polymerisation conditions (reaction temperature and monomer concentration) influence appreciably the stereo and regio structure of the resulting polymers.

2. Heterogeneous Ziegler–Natta catalyst systems for selective synthesis of elastomeric stereoblock polypropylene

It was found in the first of Natta's studies that PP formed in the presence of isospecific catalyst systems based on the layered violet modifications of α- or δ-TiCl₃ and Et₃Al (or Et₂AlCl) as a cocatalyst contains ~ 80 mass % of the major substance, isotactic crystalline PP insoluble in boiling n-heptane,^{43,44} ~ 5% of amorphous low-molecular-mass atactic PP soluble in ether, and ~ 15% of an intermediate fraction soluble in boiling n-heptane. It was shown that fractions with degrees of crystallinity of 15%–30% and an intrinsic viscosity of ~ 1 dl g⁻¹, unlike isotactic fractions, exhibit 'stress–strain' curves typical of elastomers, namely, a low initial modulus of elasticity, its substantial decrease upon stretching to 200%–300% and an increase in the modulus and strength upon further stretching (Fig. 3). A number of other properties typical of elastomers have been noted. A stereoblock structure has been proposed for this polymer.^{43,44}

In 1982, the synthesis of high-molecular-mass elSBPP induced by tetraalkyl or tetraaryl derivatives of titanium, zirconium and

^a Catalyst loading expressed in mmol (g Al₂O₃)^{−1}. ^b Catalyst activity expressed in kg of PP (mmol M)^{−1} h^{−1}, where M is a transition metal. ^c Viscosity-average molecular mass (in g mol^{−1}) calculated from the intrinsic viscosities (taken from Ref. 46) using the Mark–Houwink equation with the parameters $K = 1.58 \times 10^{-4}$, $\alpha = 0.77$. ^d Macroscopic index of polymer samples determined from the intensities of the absorption bands at 993 and 975 cm^{−1} in the IR spectra. ^e Melting temperature. ^f Degree of crystallinity calculated from the heats of melting (taken from Ref. 46): $C = (\Delta H_m/209) \times 100$, where ΔH_m is the heats of melting (in J g^{−1}), 209 J g^{−1} is the specific heat of melting of crystalline polypropylene. ^g Content of the fraction soluble in diethyl ether. ^h During polymerisation, hydrogen was introduced (~3 atm). ⁱ Polymerisation was carried out with the addition of triisobutylaluminium (TIBA), Al:Zr = 1. ^j The catalyst was preliminarily hydrogenated for 20 min at 25 °C.

hafnium immobilised on Al₂O₃ [with a specific surface area (*S*_{sp}) of 100–150 m² g^{−1}] has been patented.⁴⁵ These catalyst systems allow the preparation of high-molecular-mass PP (with an intrinsic viscosity of 1.5–13.0 dl g^{−1}) with low or moderate degrees of crystallinity (5%–30%) and high melting points (135–155 °C).^{46,47} The glass transition temperature (*T*_g) of the polymers varies from −7 to −10 °C. The content of fractions soluble in ether and heptane ranges from 30% to 50%, depending on the catalyst and polymerisation conditions. The polydispersity coefficients of the polymer samples also vary over wide limits, $M_w : M_n = 6–23$ (M_w and M_n are the weight average and number average molecular masses of the polymer, respectively).

The influence of the nature of the transition metal, the ligands attached to it and polymerisation conditions on the activity and properties of the resulting polymer is illustrated by the data of Table 1.^{45–47} Zirconium complexes with bulky ligands (neopentyl or neophyl) lead to the formation of PP with a higher degree of isotacticity than ZrBn₄ (see Table 1, rows 8, 3, 1). The stereospecificity of tetranephyl and tetranepentyl complexes of zirconium depends appreciably on the concentration of the supported catalyst. An increase in the content of the complex on the support (correspondingly, an increase in the Zr:Al ratio) is accompanied by an increase in the isotacticity of the resulting polymer and simultaneous decrease in the catalyst activity (see, for example, rows 4, 5 and 7, 8).

When the zirconium complex is pre-hydrogenated, or polymerisation is conducted in the presence of hydrogen (to control the molecular mass of polymers), the catalyst activity substantially increases and the crystallinity of the resulting polymer decreases due to the increase in the content of the elastomer fraction. It should be noted that upon the addition of stoichiometric amounts of triisobutylaluminium or diisobutylaluminium hydride, the crystallinity of polymers markedly increases (see Table 1, rows 6, 4). Titanium complexes are more active than zirconium complexes. In the presence of hydrogen, the activity of titanium complexes decreases by about 20% and becomes comparable with the activity of zirconium complexes under similar conditions. The molecular mass of PP obtained under the action of titanium complexes is much higher. The crystallinity of polymers synthesised using titanium complexes in the presence of hydrogen is relatively high (see Table 1, rows 9, 10).

To characterise the elastomeric properties of polymers, most researchers use either the recovery or the residual elongation, which are determined by the following relations

$$\frac{l_{\max} - l_1}{l_{\max} - l_0} \cdot 100\% \quad \text{or} \quad \frac{l_1 - l_0}{l_0} \cdot 100\%,$$

where $l_{\max}$ is the maximum elongation, l_1 is the sample length after relaxation, l_0 is the length of the initial sample.

The results of mechanical tests of samples of elastomeric PP obtained in the studies by Collette are presented in Fig. 4. It can be seen that the polymers synthesised possess good elastomeric properties. Upon stretching by 300%, the residual elongation is 93%. However, it was found that mechanical compositions obtained by blending the high-molecular-mass fraction soluble in ether with the fraction insoluble in hexane exhibit similar properties (see Fig. 4, dashed lines). After blending for 10 min at 180 °C, the percentage of the ether-soluble fraction decreased from 69% to 37%.⁴⁶ It was concluded⁴⁶ that the key role is played by the high-molecular-mass atactic fraction, which can be co-crystallised with a more stereoregular fraction to give cross-linked structures, and the following criterion was introduced: a catalyst effective for the formation of elSBPP should possess relatively low

Figure 4. Hysteresis tests of elastomeric SBPP (1–4) and mechanical mixtures (1'–3') of ether-soluble ($M_n = 284\,000$ g mol^{−1}) and hexane-insoluble ($M_n = 1\,478\,000$ g mol^{−1}) fractions.⁴⁶ The rate of sample drawing and unloading is 51 cm min^{−1}. Draw ratio (%): (1, 1') 300; (2, 2') 500; (3, 3') 700; (4) 820.

stereospecificity and ensure the production of a high-molecular-weight polymer.

Later, Job⁴⁸ developed modified heterogeneous titanium magnesium catalysts for the synthesis of stereoblock ePP. The catalysts were prepared by the reaction of TiCl_4 with $\text{Mg}(\text{OAlk})_2$ in the presence of electron-donating substances (dialkyl phthalates) and activated by an organoaluminium compound with addition of a reagent to control stereoselectivity (heterocyclic aromatic nitrogen-containing compounds: 2,6-lutidine or pyrazine). In the absence of a nitrogen-containing modifying agent, these catalyst systems allow the synthesis of isotactic PP, while in the presence of this agent, stereoblock PP with short syndiotactic blocks is obtained. The specific activity (per g of the catalyst) of the TMC is 50–100 times as high as that of the Collette catalysts: $\sim 9 \text{ kg PP (g Cat.)}^{-1} \text{ h}^{-1}$ and $\sim 200 \text{ g PP (g Cat.)}^{-1} \text{ h}^{-1}$, respectively. The PP samples contained $\sim 50\%$ of isotactic pentads, the elongation at rupture reached 1000%, and the residual elongation after stretching to 300% was $\sim 70\%$ –85%.

It was shown^{49,50} that the use of heterogeneous vanadium systems, for example, VCl_3 together with TIBA, results in the formation of PP with an increased proportion of abnormal additions of the monomer (2,1- or 1,3- instead of the typical 1,2-addition) due to the lower stereo- and regioselectivity of vanadium systems. The resulting polymer possesses a number of properties typical of elastomeric PP, namely, low Young's modulus, the absence of yield point and high impact strength. In addition, it has a high frost resistance.

The elastomeric SBPP synthesised on heterogeneous catalyst systems has a broad MMD (Fig. 5) and can be separated into fractions by treatment with various solvents. The broadest MMD is observed for the most stereoregular fractions (see. Fig. 5). This property, common to heterogeneous catalyst systems, is a consequence of the multi-site nature of the AC formed in heterogeneous catalysts; it hampers the target-directed synthesis of polymers with specified characteristics.

Figure 5. The molecular-mass distributions of the fractions of elSBPP prepared with the Collette catalysts (1,3,5-trichlorobenzene, 135 °C).⁴⁶ (1) elSBPP soluble in ether; (2) non-fractionated elSBPP; (3) elSBPP soluble in heptane; (4) elSBPP insoluble in hexane, $[P_i]$ is the proportion of the polymer fraction.

3. Metallocene catalysts for the synthesis of elastomeric polypropylene

The next generation of catalysts used for the synthesis of elSBPP are homogeneous catalyst systems based on metallocene complexes of Group IVB elements activated by MAO. Advantages of these systems include high activity and the possibility of obtaining

elSBPP as the only reaction product or as the predominant fraction. In addition, by selecting metallocenes and polymerisation conditions, one can control the microstructure of the growing polymer chain and change the molecular-mass characteristics of PP over wide limits.¹⁹

There are several types of homogeneous metallocene catalyst systems efficient in the synthesis of elSBPP, which differ in the mechanism of action. Since the AC structure, the stereocontrol mechanism and the properties of the resulting polymer are interrelated for these catalysts, it is expedient to consider various types of catalyst systems and the proposed mechanisms of polymerisation and to analyse the properties of the resulting elSBPP. It should be noted, however, that most of the mechanisms, although based on modern views and confirmed by some experimental results and model calculations, are still under discussion and require more detailed experimental evidence.

The main types of homogeneous catalyst systems for the synthesis of elSBPP include *ansa*-metallocenes with C_1 symmetry in the presence of the MAO cocatalyst; bisindenyl 2-aryl-substituted metallocenes in the presence of MAO; 'hybrid' metallocene systems in which metallocenes of several types are used simultaneously; alkylated bisindenyl 2-aryl-substituted metallocenes activated by TIBA, and post-metallocene catalyst systems.

a. *ansa*-Metallocenes with C_1 symmetry activated by polymethylaluminoxane

The synthesis of elSBPP with macromolecules consisting of alternating short stereoregular crystallisable and atactic sequences catalysed by MAO-activated asymmetric titanocenes **1** and **2** was first reported by Chien and coworkers.^{51–55} Under certain conditions, the reaction gave PP completely soluble in ether. For the polymer obtained at 25 °C, analysis of the density of amorphous and crystalline PP blocks⁵² made it possible to estimate the lengths of atactic and isotactic blocks; they were 50 and 20 monomer units, respectively. Propylene polymerisation catalysed by a series of structurally homogeneous metallocenes **3–7** in the presence of the MAO cocatalyst has also been studied.^{56–58} The catalytic properties of these systems, their dependence on the nature of the metallocene and on the polymerisation conditions and some characteristics of the resulting elSBPP samples are presented in Table 2.

^a Polymerisation temperature. ^b Here and in Tables. 3, 7 and 8 the activity is expressed in kg PP (mmol M)⁻¹ [C₃H₆]⁻¹ h⁻¹, where M is a transition metal. ^c Content of isotactic pentads determined from the ¹³C NMR spectra. ^d Here and in Table 6, two T_m values are presented corresponding to two melting peaks observed in the DSC curves. ^e Polymerisation was carried out in the liquid monomer. ^f Amorphous polymer. ^g The sample is unstable.

Of the series of catalysts **1–7**, the hafnium complexes **5** and **7** are the most effective. They combine rather high activity and stability; they catalyse the formation of PP with fairly high molecular mass and good elastomeric and strength characteristics. An increase in the monomer concentration, all other conditions being the same, induces an increase in the molecular mass and some decrease in the content of isotactic pentads (see Table 2, rows 6, 8 and 9, 10). Note that in the presence of titanium metallocenes of this type, eSBPP is formed only in a narrow temperature range, 25 to 30 °C.⁵⁵ At –25 °C, the content of isotactic pentads reaches 72% (see Table 2, row 2). In addition, titanium complexes are much less stable than zirconium and hafnium analogs. Hafnium complexes give rise to PP with higher molecular masses than zirconocenes (see Table 2, rows 4, 6 and 5, 9); this is typical of metallocene catalysis. An unusual feature is that the activities of zirconocenes and hafnocenes are comparable. In the case of hafnium complexes, all other factors being the same, PP samples with higher degrees of isotacticity are formed (see Table 2, rows 4, 6 and 5, 9). The replacement of the propylidene bridging groups by dimethylsilylene groups results in an increase in the molecular mass and isotacticity of the PP (see Table 2, rows 6, 9; 7, 10 and 8, 11). An increase in the monomer concentration is

accompanied by a decrease in the isotacticity of the polymer for both hafnium and zirconium catalysts (see Table 2, rows 6, 7 and 9, 10), whereas an increase in the reaction temperature from 0 to 25 °C markedly decreases the isotacticity of the PP formed with the hafnium complex (see Table 2, rows 11, 10).

In a study of a stereoblock polymer prepared by anionic polymerisation of acrylates, an idea was put forward that two different states of the AC, aspecific (non-selective) and isospecific ones, may exist.⁶⁰ Subsequently, these views have been often used as the basis of the mechanisms of formation of stereoblock PP, in particular for the catalysts of C_1 symmetry.^{51–58} The key feature of asymmetric *ansa*-metallocenes is the presence of two inequivalent vacancies in the AC accessible for the monomer coordination and growth of the polymer chain. Usually, one vacancy is aspecific (non-selective) and the other one is isospecific. Chien and Collins explained the formation of a sequence of atactic and isotactic blocks in the presence of these catalysts in terms of models which take into account polymer chain growth in the active centre (the small square shows a coordination vacancy), whose stereospecific action changes as a result of slow (see Refs 51–55) or fast (see Refs 56–58) inversion (on the time scale of olefin coordination and addition), for example, due to migration of the polymer chain (P).

According to the Chien model, several steps of olefin coordination and insertion occur in turn in either of the active sites until its inversion takes place. However, within the framework of this model, it is difficult to explain the decrease in the content of the *mmmm* pentads following an increase in the monomer concentration on structurally similar Collins complexes. In conformity with the Collins model, the monomer is randomly coordinated

and inserted at the first or second accessible reactive active site. When two competing reactions are involved, namely, olefin insertion and chain isomerisation (migration without insertion), short isotactic sequences would regularly arise in the macromolecule; this would determine the elastomeric properties of the resulting PP; the length of these sequences would depend on the type of the coordination vacancies and the ratio of the chain growth rates in each site to the rate of active centre isomerisation. This model is also supported by the fact that hafnium complexes exhibit more pronounced stereocontrol action than the zirconium analogues, all other conditions being the same. The rate of polymer chain growth for hafnocenes is much lower than that for zirconocenes. Within the framework of this model, the replacement of zirconium by hafnium can result in a decrease in the ratio of the chain growth rate to the inversion rate.

A similar mechanism of the action of complexes with C_1 symmetry assuming the presence of two sites with different stereospecificities and competition between chain growth and migration without insertion (which also gives rise to elSBPP) has been proposed recently^{59,61} for a series of structurally rigid zirconocenes **8–15**.

A characteristic feature of these zirconocenes, as noted above, is 'stereoduality', i.e., the existence of two different coordination vacancies **a** and **b** (Scheme 1, small squares) in the cationic metal alkyl active site formed under the action of MAO.

Scheme 1

The non-selective coordination vacancy **b** is sterically less crowded than the isospecific vacancy **a**, and the processes of monomer coordination and chain migration to coordination vacancy **b** without insertion compete in the active centre. When the monomer concentration is low, chain migration without insertion can kinetically predominate. In this case, the reactions 'monomer insertion at vacancy **a** with chain migration (**a** → **b**) and subsequent chain migration without insertion (**b** → **a**)' will result in the formation of ...mmmm... sequences (see Scheme 1, cycle 1 → 2 → 3). When the monomer concentration increases, the probability of coordination and insertion at the sterically less hindered vacancy **b** becomes higher. The chain migration to the monomer that has added non-selectively gives rise to 'errors,' which are 'corrected' at the next step of monomer addition at vacancy **a**, and the...mrrm... sequences are thus formed (see Scheme 1, cycle 4 → 5 → 1). This type of polymer chain growth virtually excludes the propagation of 'errors' and, depending on the conditions, it can result in alternation of short isotactic sequences separated by single stereodeflects. Polypropylene formed by this mechanism is an isotactic macromolecule divided into short continuous isotac-

tic segments by regularly arising 'errors' (see Fig. 2 c, elSBPP with $k = 1$).

An increase in the polymerisation temperature and a decrease in the monomer concentration lead to a relative increase in the rate of chain migration without insertion and, correspondingly, to a higher content of isotactic pentads (see Table 2, rows 13, 14; 16, 17; 12, 13 and 15, 16). Conversely, an increase in the monomer concentration increases the probability of monomer insertion at coordination vacancy **b**, resulting in a decrease in isotacticity. It will be shown below that, in conformity with the proposed mechanism, the PP samples prepared with these catalyst systems are characterised by either the absence or low content of pentads of the ...mrrm... type with double 'errors'.⁶¹

It was also found for these types of catalyst systems that no 'errors' caused by isomerisation of the growing chain unit attached to the catalyst *via* β -hydride shift or the formation of allylic intermediates, typical of catalysts with C_2 symmetry,^{62–66} arise in this case. The absence of these reactions was confirmed experimentally by analysis of the pentad composition of the PP synthesised by polymerisation of $\text{CH}_2=\text{CDMe}$.⁵⁹

The catalysts of C_1 symmetry substituted at the 2-position make it possible to prepare PP with a very broad range of properties. Some parameters of the resulting polymers are presented in Table 2. An increase in the monomer concentration entails an increase in the molecular mass and a decrease in the content of isotactic pentads and in the degree of crystallinity of the polymer, while an increase in the reaction temperature is accompanied by lowering of the polymer molecular mass and an increase in the crystallinity. The best catalysts are 2-methyl-substituted complexes **8–10** with ethylene bridges because they exhibit high activity and ensure the formation of elSBPP with a relatively high molecular mass and a content of isotactic pentads at a level of 30%–50%.

These catalyst systems allow effective preparation of PP the properties of which vary over very broad limits, from those typical of highly crystalline rigid thermoplastics to those peculiar to low-crystallinity elastomers, which behave as viscous liquids under the action of load (Fig. 6). The samples combining high molecular mass ($\sim 200\,000\text{ g mol}^{-1}$) and moderate isotacticity ($[\text{mmmm}] = 30\%–40\%$) display good elastomeric and strength properties. The elongation at rupture for some samples reaches 1700%–2000%. However, a characteristic feature of elSBPP prepared on catalysts with C_1 symmetry is a relatively low melting

Figure 6. Drawing curves of PP samples prepared on the **10**–MAO catalyst system and exhibiting properties of viscoelastic (**1**), elastomeric (**2–4**) and stiff thermoplastics (**5, 6**).⁵⁹ M_w (g mol^{-1}): (**1**) 134 000; (**2**) 170 000; (**3**) 96 000; (**4**) 63 000; (**5**) 48 000; (**6**) 48 000.

point.⁵⁹ This indicates the presence of a substantial number of regiodefects in the polymer chain.

New metallocene complexes of C_1 symmetry for the synthesis of elastomeric PP have been described.²⁶ These *ansa*-metallocenes with strap-type $-(CH)_2-$ or $-(CH_2)_2-$ substituents at the 4- and 5-positions of the fluorenyl ligand possess high activity, 20–70 kg PP (g Cat.)⁻¹ h⁻¹ or 1–5 kg PP (mmol M)⁻¹ [C₃H₆]⁻¹ h⁻¹ (polymerisation in the liquid monomer medium); they provide the synthesis of PP with a molecular mass of 8×10^4 to 1.4×10^6 g mol⁻¹ and ensure very good elastomeric properties. Indeed, the residual elongation after stretching the sample by 300% is only 2.5%–10.0%. The greatest observed elongation of the sample reaches 5200%, the tensile strength is 0.8–2.5 MPa, and Young's modulus is 2.1–9.0 MPa. It has been assumed²⁶ that the unique properties of eSBPP prepared with these catalysts are determined by ultrasmall (nano-sized) crystallites which form the junctions of the polymer network.

A criterion of a 'good catalyst' of this new type for the synthesis of elastomeric PP has been proposed,²⁶ determined by the ratio between the parameters of the catalyst asymmetry (ratio of the van der Waals areas of the larger ligand and the smaller one) and parameters of stereoregularity of the synthesised PP (the ratio of *mm*- to *rr*-triads). The proportion of the *mmmm* pentads in the resulting polymers does not exceed 31%; however, unlike eSBPP formed in the presence of C_1 -symmetric catalysts considered above, these polymers contain substantial numbers of syndiotactic pentads ($[rrrr] \approx 28\%$).

b. The 'bis(2-substituted indenyl) metallocene – polymethylaluminoxane' catalyst systems

Bisindenyl metallocenes with aryl (**16–25**) and alkyl (**26–29**) substituents at the 2-position of the indenyl ring represent the most extensive and thoroughly studied class of metallocenes effective in the synthesis of eSBPP. In recent years, this series has been extended by zirconocenes with mixed hapto-bonded (**30–35**) and heterocyclic (**36–38**) ligands. Due to the intensive research, one can expect that new catalyst systems of this class effective in the synthesis of stereoblock PP would appear in the near future.

The 2-aryl-substituted dichloride complexes **16**, **19** were the first of the series of 'oscillating' metallocenes.^{67–72} Upon activation with MAO, these catalysts ensure the formation of stereoblock PP with high molecular masses.

R¹ = R³ = CF₃, R² = Me (**35**).

X = O (**36**), S (**37**), NMe (**38**).

X-Ray diffraction studies^{67, 73–75} showed that both the zirconocene **16** and the hafnocene **19** exist as two rotation isomers relative to the metal–hapto-ligand bond in the crystal unit cell. This attests to the energetic equivalence of both forms. This fact served as a pre-requisite for the proposed⁶⁷ 'oscillation' mechanism of the formation of stereoblock PP on catalysts of this type (Scheme 2, where the I and A stand for the isospecific and aspecific centres, respectively, k_{pi} and k_{pa} are the rate constants for polymerisation at the I and A centres, C_i^* and C_a^* are the concentrations of the I and A centres; and w_i and w_a are the rates of chain growth at the I and A centres, respectively).

Scheme 2

It was assumed that during polymerisation, the active cationic alkyl metal complex retains the ability to undergo barrier-free rotation. During the growth of the polymer chain, reversible isomerisation of the complex from the isospecific *rac*-form to the aspecific *meso*-form takes place repeatedly. The insertion of propylene during the period of existence of the *rac*-form of the active centre (the I centre) gives rise to isotactic sequences. On the *meso*-form of AC (the A centre), propylene insertion yields atactic blocks. To obtain the stereoblock structure of the polymer, it is necessary that the isomerisation rate be lower than the rate of olefin insertion but higher than the chain growth rate. Thus, chain growth on the 'oscillating' type AC gives macromolecules of the stereoblock structure. The length of the isotactic sequences is usually rather small and the stereoblock PP synthesised under the action of these metallocenes is distinguished by a low degree of crystallinity with a rather high molecular mass.

For a large number of complexes of this type, the influence of polymerisation conditions on the catalyst activity and characteristics of the resulting polymers (microstructure and fractional composition, molecular mass, MMD, elasticity) has been studied.^{67, 70, 72, 73, 76–78} Typical properties of catalyst systems and eSBPP prepared on these catalysts, and their dependence on the reaction conditions are presented in Table 3.

Table 3. Polymerisation of propylene induced by 'oscillating' catalysts (MAO cocatalyst).

Note. The catalyst concentration was varied in the range of 10^{-5} – 10^{-6} mol litre⁻¹. ^a Polymerisation was carried out in the liquid monomer.

The catalyst systems in question are characterised by a slight increase in the activity and a sharp decrease in the molecular masses with an increase in polymerisation temperature^{67, 70, 72, 73, 76–78} (see, for example, Table 3, rows 1, 4 and 2, 7). The temperature at which a high-molecular-mass eSBPP can be prepared usually does not exceed 30–40 °C. It has been noted⁷⁰ that the yield of the solid polymer formed upon polymerisation in the liquid monomer medium at 50 °C equals 30% based on the monomer consumed; the rest falls to low-molecular-mass products. The same sharp decrease in the molecular mass of the polymer upon an increase in the reaction temperature has been observed⁷² for the **20**–MAO catalyst system, which induces the formation of eSBPP with a higher molecular mass and a higher degree of crystallinity (see Table 3, rows 5, 6). From the temperature dependence of the activity of the complex **16** (liquid propylene, 0–40 °C) measured in several studies,^{70–72} the effective activation energy of polymerisation was found to be $E_a \approx 4$ kcal mol⁻¹.

Unlike a number of other metallocene catalyst systems, for these complexes, a marked decrease in the polymerisation rate with time was observed, even for low reaction temperatures (Fig. 7).⁷² The activity of catalyst systems and the molecular-

Figure 7. Effect of conditions of propylene polymerisation on the variation of the catalytic activity of the **16**–MAO system with time.⁷⁰ Polymerisation was carried out in the liquid monomer medium; $k_{cat} = w_p[C_3H_6]^{-1}[M]^{-1}$, where w_p is the rate of polymerisation. T_p (°C): (1) 2; (2) 8; (3) 30.

mass characteristics of eSBPP largely depend on the method used to prepare the catalyst.^{70, 73, 80} In many cases, the resulting polymers are characterised by a broad MMD ($M_w : M_n = 3–6$) and can be separated into several fractions by extraction with boiling ether and n-heptane. It is of interest that the differences in molecular masses and stereoisomeric compositions of the fractions prepared in the presence of these catalyst systems are much smaller than those obtained with the use of isospecific heterogeneous catalysts.^{82, 83} Comparison of the data obtained by different researchers^{70, 79, 80} allows the conclusion that the activity of complexes of this type increases with an increase in the Al:Zr ratio (see Table 3, rows 3, 7–9), which is typical of catalyst systems based on metallocenes.

An interesting feature of these catalysts is that the activities of the zirconium and hafnium complexes **16** and **19** are comparable.^{69, 72, 73} As noted above, hafnocenes with C_1 symmetry behave in a similar way.^{56–58} Normally, hafnium metallocenes of other types are much less active than zirconium analogues, all other factors being the same, and give polymers with much higher molecular masses. The 2-phenyl-substituted complexes **16**, **19** have approximately equal activities; in the case of eSBPP prepared on the hafnium complex, the molecular mass is higher and the polydispersity and the degree of isotacticity are much lower than those for eSBPP synthesised under the action of zirconium analogue (see, for example, Table 3, rows 11, 10 and 13, 12). Bruce *et al.*⁷³ believe that the comparable levels of activity of the complexes **16** and **19** are due to the more effective formation of AC in the case of the hafnium catalyst.

A number of publications have been devoted to the analysis of the influence of substituents on the catalytic properties of 2-aryl-substituted complexes and characteristics of the resulting eSBPP. The introduction of methyl substituents at the 3- and 5-positions of the benzene ring (complex **17**) causes some decrease in the catalyst activity and the polymer molecular mass; in addition, the isotacticity of the polymer substantially decreases.^{68, 69} The complex **18** containing trifluoromethyl substituents provides the formation of a crystalline PP (see Table 3, row 14). It is of interest that polymers prepared under the action of the complexes **16**–**18**, even with different contents of isotactic pentads, have rather high melting points (140–150 °C), which implies a small number of regiodefects in isotactic blocks. The introduction of various substituents into the *para*-position of the benzene ring (complexes

20–25) barely affects the activity of the system and the properties of the eISBPP formed.^{72, 78} Both *rac*- and *meso*-forms of the analogue of the complex **16** with the methyl substituent at the 1-position give rise to an amorphous low-molecular-mass PP with very high polydispersity coefficients, $M_w:M_n = 4–15$.⁸⁴ The eISBPP formed under the action of the complex **30** is close in stereochemical composition to the polymer formed with the **16**–MAO catalyst system; however, regarding the melting point and the macrotacticity index, it is close to the eISBPP prepared on catalysts with C_1 symmetry.⁷¹ Complexes **31–35** with mixed ligands and different substituents are less active catalysts than the bisindenyl complexes with identical ligands.⁸⁵

The main channel of chain transfer by the catalyst systems considered is the transfer of the β -hydrogen atom to the metal and the coordinated monomer.⁸⁰ An interesting feature of 2-aryindenyl systems is the clear-cut effect of the co-monomer, which was identified in a study of propylene copolymerisation with ethylene induced by the complexes **16** and **18**.^{79, 86} The activity of the catalyst system increases 2- to 8-fold even at a low ethylene:propylene molar ratio (0.05–0.08) in the monomer mixture. The increase in the activity is accompanied by a substantial (2–3-fold) increase in the molecular mass of the copolymer. The ethylene content in the copolymer varies in the range of 15 mol %–50 mol %. The system activity also increases appreciably upon the introduction of hydrogen. It has been assumed^{86, 87} that the co-monomer effect shows itself as the ability of ethylene to be inserted and to ‘wake up’ the AC after the formation of a regiodeflect of the polymer chain as a result of the monomer 2,1-addition.

Studies of the complexes **16** and **18** showed⁸⁷ that they are more regiospecific than the isospecific $\text{EtInd}_2\text{ZrCl}_2$ catalyst (Ind is indenyl). The non-bridged complex **16** produces PP containing 0.1 mol %–0.3 mol % of 2,1-added units. It is of interest that ‘regioerrors’ are detected only in isotactic sequences of the polymer, *i.e.*, they arise only in those cases where the ‘oscillating’ metallocene occurs in the isospecific state. This is confirmed by the fact that no ‘errors’ are found in the PP synthesised by the polymerisation of propylene in the presence of *meso*- $\text{Me}_2\text{Si}(2\text{-PhInd})_2\text{ZrCl}_2$, whereas the *rac*-analogue of this complex produces PP with ‘errors’ caused by the 3,1-addition.⁸⁸

A specific feature of the ‘oscillating’ catalysts is an increase in the content of the *mmmm* pentads following an increase in the monomer concentration (see, for example, Table 3, rows 15–17). Quantitative analysis of this phenomenon is based on the fact that the rate of polymerisation is proportional to the monomer concentration, while the rate of isomerisation does not depend on it and, since the content of isotactic pentads is determined by the ratio of the rates of these reactions, the regularity of the polymer increases with an increase in the monomer concentration. This has been observed in numerous experiments.^{67–69, 73, 78} As discussed above, an opposite dependence of the content of isotactic pentads on the monomer concentration was found for metallocenes with C_1 symmetry.

A mathematical model has been proposed to describe the oscillation mechanism of polymer chain growth.^{80, 89, 90} Computer generation of PP macromolecules has been carried out with variation of three parameters, namely, the stereoselectivity of the isospecific active centre (α), the selectivity of the aspecific centre (β) and the g/K parameter, which specifies the ratio of the relative reactivity to the stability for iso- and aspecific states ($g = k_{\text{pa}}/k_{\text{pi}}$, $K = k_1/k_2$). Thus $g/K > 1$ corresponds to the predominant existence of the isospecific AC. The dependence on the pentad composition on the monomer concentration for definite α , β and g/K values is determined by the parameter

$$\Delta = \frac{(k_{\text{pi}}/k_1 + k_{\text{pa}}/k_2)[\text{C}_3\text{H}_6]}{2}.$$

The best agreement between experimental and calculated pentad compositions was found for $\alpha = 0.97$, $\beta = 0.56$ and

$g/K = 0.6$. The Δ parameter varies in the 1–10 range as the propylene concentration changes from 1.2 to 11 mol litre^{−1}. However, the authors of the model admit⁸⁰ that the same kinetic dependence of the pentad composition on the monomer concentration can be described qualitatively and quantitatively by the Busico model,^{63, 64, 91} which takes into account the competition between the chain growth and epimerisation processes with the assumption that the AC have two active vacancies accessible for monomer coordination and the polymer chain growth.

Since the model of the ‘oscillating’ complex is widely recognised, several factors deserve attention, both those confirming the proposed mechanism and those conflicting with it. The mechanism in question is supported by the increase in the content of the *mmmm* pentads with an increase in the monomer concentration, which was observed experimentally for these complexes. The mathematical model describing this mechanism provides a quantitative correspondence between the polymer microstructures calculated and found experimentally depending on the polymerisation conditions (monomer concentration, temperatures) for reliable values of model parameters. The X-ray diffraction data for the complexes **16**, **19** are also a forcible argument in favour of the ‘oscillating’ complex. Theoretical studies^{92, 93} demonstrated the presence of two energy minima for the transition state corresponding to the *rac*- and *meso*-forms of the complex **16** and stabilised by the π -interactions between the phenyl substituents and the aromatic system of the indenyl ligands (π -stacking interactions); the two minima are energetically equivalent ($\Delta\Delta H = 0.6$ kcal mol^{−1}). Indeed, on passing to hydrogenated analogues of the complex **16**, (2-CyInd)₂ZrCl₂ (Cy is cyclohexyl), (2-Ph-H₄Ind)(2-PhInd)ZrCl₂ and (2-Cy-H₄Ind)₂ZrCl₂, all other factors being the same, a substantial decrease in the PP isotacticity has been noted: [*mmmm*] = 32%, 15%, 13% and 5%, respectively.⁷⁷

Direct investigation of isomerisation processes for ‘oscillating’ catalysts is of interest. The data of dynamic NMR for (2-PhInd)₂HfBn₂ (see Ref. 73) and structurally related (2-phenylcyclopenta[*l*]phenanthryl)₂ZrCl₂ (see Ref. 94) indicate a very high frequency of rotation of haptic-bonded ligands: 6800 s^{−1} for the former complex and $\sim 1 \times 10^8$ s^{−1} for the latter one. The latter zirconocene activated by MAO ensures (although with a low activity) the formation of a low-molecular-mass PP similar in stereoisomeric composition to the eISBPP prepared under the action of the complex **16**. The frequencies of ligand rotation about the axis passing through the M atom and the centroid of the Cp ring are several orders of magnitude greater than the frequency of olefin insertion estimated from the maximum rate of monomer absorption, which equals 0.1–10.0 insertions of C₃H₆ per second even with allowance for the low efficiency of the formation of AC. Evidently, such a fast rotation should average the stereospecific action of the AC and ensure the formation of PP with a narrow MMD. No data on the rate of isomerisation in real catalyst systems (MAO-activated metallocenes) are available. To explain the observed contradiction, it has been suggested⁹⁴ that the chain growth actually proceeds at a very high rate, which exceeds the rate of rotation of the haptic-bonded ligands but during the period of growth of the macromolecules, the AC pass many times into the ‘dormant’ state, perhaps, due to the formation of a contact ion pair with the counter-ion.

Note that only for the complexes **16** and **19**, was the existence of two energetically equivalent stereoisomers identified. Data from X-ray diffraction analyses of a number of other complexes which catalyse the formation of stereoblock PP indicate the presence of only one stereoisomer, for example, the *meso*-form of the complex **17**,⁶⁸ the *rac*-form of the complex **18**,^{68, 73} and its hafnium analogue⁷³ and the *meso*-form of the complex **21**,⁷⁸ which does not differ from the complex **16** in catalytic properties.

Although ¹³C NMR spectroscopy is a unique tool for analysing the structure of the polymer chain and, correspondingly, the catalytic properties of the AC, which allows one to evaluate its stereo- and regiospecificity, the stereocontrol mechanisms and so

on,^{34–37, 39, 40, 41, 95} this method still does not provide sufficient information for the analysis of the contents of sequences comprising 15–16 monomer units capable of crystallisation.

In the opinion of Gauthier and Collins,^{56, 58} the known data on the microstructure of elSBPP do not allow one to decide unambiguously in favour of one or another statistic model. For example, elSBPP formed under the action of the **19**–MAO catalyst system⁷² has a pentad composition that can be obtained by mathematical generation of the polymer chain in terms of the Bernoullian model with a probability of *m*-addition (*p_m*) equal to 0.58. However, no correspondence was attained between the calculated and experimental compositions for polymers with higher contents of isotactic pentads, which also exhibit elastomeric properties; this indicates that the given model is inapplicable to the description of the real mechanism of formation of stereoblock PP. Nevertheless, the possibility of existence of catalyst systems which form stereoblocks also by this mechanism cannot be ruled out completely.

A finding quite unusual for metallocene catalysis is that PP samples prepared by virtue of 'oscillating' catalyst systems are characterised in some cases by high polydispersity values *M_w* : *M_n* (Tables 3, 4). The correlation between the degree of isotacticity and the polydispersity of PP was first pointed out by Bruce *et al.*⁷³ This can be illustrated by the plots shown in Fig. 8 for the PP samples prepared using the [2-(4-RC₆H₄)Ind]₂MCl₂ and [2-(3,5-R₂C₆H₃)Ind]₂MCl₂ complexes with the MAO cocatalyst (Al : Zr = 1000) at 20–25 °C.^{68, 69, 73, 78} An increase in the polydispersity with an increase in the isotacticity can be followed in Fig. 8 for each type of complex. The hafnium analogues catalyse the formation of PP with a much lower crystallinity and polydispersity. Since the content of isotactic pentads is determined by the isospecific state of complexes of C_{2v} symmetry and can be regarded as a measure of activity, it is reasonable to suggest that this state is realised upon reversible coordination of a component (or components) of the reaction mixture (MAO, AlMe₃, solvent, monomer) by the cationic alkyl metal complex. These interactions might be responsible for broadening of the MMD of the elSBPP samples prepared in the presence of the catalyst systems.

In this connection, the following example is of interest. It has been reported⁸² that the elastomeric PP prepared in the presence of hydrogen (0.044 mmol of H₂ per mole of C₃H₆) in order to decrease the molecular mass differs appreciably from the elSBPP produced in the absence of hydrogen, all other conditions being the same (liquid propylene, 23 °C). The molecular mass of the product decreases and the polymer synthesised in the presence of hydrogen has the following composition: 72% of ether-soluble fraction, 13% of heptane-soluble fraction and 15% of a fraction

Figure 8. Polydispersity vs. isotacticity for PP samples prepared on 'oscillating' catalysts activated by MAO at 20–25 °C.^{68, 69, 73, 78} Catalyst: (1) **16**; (2) **20**; (3) **21**; (4) **22**; (5) [2-(4-Bu'C₆H₄)Ind]₂ZrCl₂; (6) **19**; (7) **17**; (8) **18**; (9) hafnium analogue of the complex **18**.

insoluble in heptane, whereas the fractional composition of the polymer obtained without hydrogen is completely different: 36%, 43% and 21%, respectively. The microstructures of the fractions are also markedly different, the isotacticity of all fractions being much higher in the case of the polymer prepared in the presence of hydrogen (Table 5, rows 11–14, 15–18).

In a recent study,⁸⁰ it was reported that the synthesis of PP induced by the complex **16** can yield elSBPP with a narrow MMD (*M_w* : *M_n* = 2.1–2.7). However, the polymerisation procedure employed in this study⁸⁰ results, with other conditions remaining the same, the formation of a PP in which the molecular mass is 2–4 times lower than that reported previously. The observed extension of the MMD was attributed⁸⁰ to the increase in the polymerisation rate following an increase in the monomer concentration and by a decrease in the rate of mass transfer and propylene solubility during polymerisation at high rates.

The catalytic properties of 2-alkyl-substituted complexes **26**–**29** in the propylene polymerisation in toluene have been studied.^{81, 96} At a propylene pressure equal to 1 atm, elSBPP with a rather high molecular mass can be formed only at low temperatures (–20, 0 °C). Thus at –20 °C, elSBPP with a molecular mass of 600 000 g mol^{–1} is formed under the action of the complex **26**. When more active catalysts are used, PP with a higher molecular mass is produced. The maximum activity is exhibited by the complexes **26** and **27** (see Table 3, rows 18, 19). The specific activity of the complex **26** is four times lower than that of the complex **16** at 0 °C. The activity of catalysts in propylene polymerisation increases 1.3–2.3-fold as the reaction temperature decreases from 0 to –20 °C. All 2-alkyl-substituted complexes, except for compound **26**, are inactive in ethylene polymerisation at low temperatures. Similar properties are found for complexes **36** and **37** with heterocyclic substituents at the 2-position in the presence of the MAO cocatalyst.⁹⁷ high-molecular-mass elastomeric SBPP is formed on these catalysts only at low temperatures (0, –20 °C); the catalyst activity increases as the reaction temperature decreases; and more active catalysts give rise to elSBPP with a higher molecular mass. Thus the activity of complex **38** at –20 °C equals 59 kg PP (mol Zr)^{–1} h^{–1} atm^{–1}, and the weight-average molecular mass of the resulting PP is 3600 g mol^{–1}. Meanwhile, under similar conditions, complex **36** exhibits an activity comparable to that of the complex **16** and leads to the formation of PP with a molecular mass of 720 000 g mol^{–1}. Dynamic NMR analysis of **36** and **37** identified fast rotation around the axis that passes through the Zr atom and the centroid of the Cp ring and the presence of a conformational equilibrium, fast on the NMR time scale, although an X-ray diffraction investigation of the complex **36** indicated that only *meso*-**36** exists in the solid state,⁹⁷ unlike the situation with the complex **16**. It can be demonstrated in relation to the elSBPP prepared with the complexes **26**, **27**, **29** and **36** that the isotacticity–molecular mass combination of properties is important for the strength and elastomeric characteristics of the polymer (see Table 4).

Table 4. Strain and elastic properties of elSBPP prepared under the action of bis(2-alkylindenyl)zirconium dichlorides in the presence of the MAO cocatalyst (*T_p* = –20 °C, toluene, *p*_{C₃H₆} = 1 atm, Al : Zr = 3500).^{96, 97}

Analysis of the microstructure of the PP samples prepared with the 26–MAO catalyst system led Naga and Mizunuma¹⁰⁰ to the conclusion that the formation of isotactic sequences during the growth of the polymer chain is dictated by the terminal unit ($4[\text{mm}][\text{rr}][\text{mr}]^{-2} \approx 1$) in the range of polymerisation temperatures of –20 to 40 °C. These results indicate that this stereocontrol mechanism may be involved in the propylene polymerisation under the action of 2-aryl-substituted metallocenes. The synthesis of the high-molecular-mass eSBPP on catalysts with C_2 symmetry,¹⁰¹ namely, *rac*-Me₂C(3-PrⁱInd)₂ZrCl₂ and *rac*-H₂C(3-PrⁱInd)₂ZrCl₂, should also be mentioned. In the presence of MAO, at 50 °C in liquid propylene, these complexes (Al:Zr = 1000–4000) actively $\{A \approx 2.5 \text{ kg PP (mmol Zr)}^{-1} [\text{C}_3\text{H}_6]^{-1} \text{ h}^{-1}\}$ form amorphous polypropylene with a molecular mass of 100 000–160 000 g mol^{–1} and with a content of isotactic pentads of 15.6% for the former catalyst and 25.5% for the latter catalyst. The formation of stereo blocks on these catalysts is determined by the presence of two enantiomers with different isospecificity and a noticeable contribution of the stereocontrolling influence of the terminal unit of the polymer chain to the enantiomeric stereocontrol. An increase in the reaction temperature is accompanied by a decrease in the content of isotactic pentads typical of metallocene complexes of C_2 symmetry (unlike catalysts of C_1 symmetry).^{59, 61, 102}

An increase in the Al:Zr ratio accompanied by an increase in the activity of the 16–MAO system reduces the content of

isotactic pentads in the resulting polymer (see Table 3, rows 3, 7, 9). In this connection, it is of interest to turn to the data of Petoff *et al.*¹⁰³ Analysis of the effect of AlR₃ additives (R = Me, Buⁱ) introduced in MAO demonstrated that aluminium alkyls decrease the activity of the *rac*- and, more appreciably, *meso*-form of Me₂Si(2-PhInd)₂ZrCl₂ but do not change substantially the microstructure of PP prepared on each complex alone. A pronounced increase in the polymer isotacticity upon the introduction of aluminium alkyls, accompanied by a decrease in the activity, was observed in the polymerisation guided by a mixture of *rac*- and *meso*-forms of the complex as the cationic *meso*-form became passive after coordination to TIBA. The addition of aluminium alkyls to the 16–MAO system (Al_{MAO}:Zr = 1000) brought about a decrease in the activity by factors of 1.4 and 1.7 for R = Buⁱ (Al_{AlBu₃}:Zr = 1000) and Me (Al_{AlMe₃}:Zr = 100), respectively, but induced an increase in the content of the *mmmm* pentads from 39% to 47% in the former case and a drop of this value to 19% in the latter case (similarly to polymerisation with a large excess of MAO). Thus, one cannot rule out the possibility of MAO participation in the stereocontrol through chain transfer between aspecific and isospecific sites by the AlMe₃ contained in MAO, as in the case of ‘hybrid’ metallocene catalysts considered below. Apparently, parameters of MAO (degree of oligomerisation, structural characteristics, Lewis acidity), which depend on the temperature and the presence and concentration of AlMe₃, are also important factors influencing the state of the active centre

Figure 9. Engineering (*a*, *b*) and true (*c*) stretching diagrams and hysteresis tests of the elSBPP samples obtained on **16**–MAO [*a* (curve 1), *c*], **19**–MAO [*a* (curve 2)], **20**–MAO (*b*) catalyst systems.^{70,72} σ_i is true stress, ε^H is the measure of relative deformation equal to $\ln(l/l_0)$.

(polarisation of the M–C bond, capacity for dissociation upon coordination and insertion of olefin).^{104,105}

The microstructure of stereoblock PP obtained in the presence of ‘oscillating’ catalysts differs from the microstructure of PP formed on catalysts with C_1 symmetry by a much higher content of heterotactic pentads, the average length of isotactic sequences being the same (see Table 5). It is also noteworthy that PP synthesised using ‘oscillating’ catalysts has a stereoblock structure even in samples with low contents of isotactic pentads. Thus a sample of elSBPP with good elastomeric properties formed on the **19**–MAO catalyst system contains only twice as many isotactic *mmmm* pentads as the ideal atactic PP and, correspondingly, half the syndiotactic *rrrr* pentads. In addition, the content of boundary *mmmr* pentads is higher, while that for *rrrm* is lower for stereoblock PP. The proportion of other pentads corresponds to atactic PP.

A lot of data on the strain, strength and elastomeric properties of elSBPP have now been accumulated.^{70,72,80,106–111} Figure 9 *a–c* shows the data on the relaxation dependences for stereoblock PP. It can be seen that polymer samples exhibit good elastomeric properties. The stretching curves follow a pattern typical of classical elastomers,¹¹² i.e., they show uniform deformation

Figure 10. Elongation at rupture (ε_p) vs. content of isotactic pentads in elSBPP samples obtained on metallocenes of C_1 symmetry (1)⁶⁰ and ‘oscillating’ catalysts⁷² (2).

mation upon stretching to great degrees of elongation and high reversibility of deformation.

Some properties of the elSBPP samples obtained on treatment with various types of catalyst are compared in Table 6. The elastomeric SBPP with macromolecules containing more uniform isotactic but also longer atactic sequences have higher melting temperatures but exhibit smaller elongation at rupture, while the molecular masses and the contents of the *mmmm* pentads are the same. Figure 10 illustrates the dependence of the elongation at rupture on the content of isotactic pentads for the PP samples prepared on metallocenes of various types. Figure 11 *a–c* presents the variation of the modulus of elasticity, tensile strength and the residual elongation vs. the molecular mass and the degree of crystallinity for the elSBPP samples synthesised in the presence of the metallocenes **16**, **19** and **20**. As can be seen from the data of Table 6 and Figs 10, 11, an increase in the molecular mass of polymers with invariant stereoregularity and degree of crystallinity results in a higher modulus of elasticity, tensile strength and a smaller residual elongation. A decrease in the stereoregularity for similar molecular masses and crystallinity degrees reduces the modulus of elasticity, the tensile strength and the residual elongation. An increase in the sample degree of crystallinity with invariant molecular masses and stereoregularity brings about an increase in the modulus of elasticity, the strength and the residual elongation. It can be seen that the strength and elastomeric properties are determined by several characteristics including the molecular mass, the degree of crystallinity and the stereoregularity of the polymer.

Presumably, the size and size distribution of the crystallites and the dynamic changes in the structure of the network junctions under the action of load at various temperatures are also signifi-

cant for strain and elastomeric parameters of eLSBPP. However, at present, it is impossible to perform a comparative analysis of the effects of these factors on the mechanical properties of eLSBPP samples obtained using different catalyst systems as no information needed for this purpose is available.

Thus, by varying the type of the catalyst or polymerisation conditions, one can prepare eLSBPP possessing a required set of properties.

4. Catalyst systems based on metallocenes with activators other than polymethylaluminumoxane

In the preceding sections, we considered metallocene catalysts for the synthesis of elastomeric PP activated by MAO. In these catalyst systems, MAO functions as an alkylating and a cation-generating reagent without being an effective controller of the microstructure or chain transfer agent.⁸⁰ The main factors that control the microstructure of the macromolecule in the catalyst systems considered above are the composition and structure of the initial catalyst and the monomer concentration. The catalyst systems containing MAO as a cocatalyst suffer from some drawbacks. The maximum activity of metallocene catalysts, in particular those considered in this review, is observed at great cocatalyst : catalyst ratios (see, for example, Table 3, rows 4 and 9). Due to the high cost of MAO, the catalysts are expensive. In this section, we give examples of metallocene catalyst systems in which other types of activating additives are used and also catalyst systems that provide additional possibilities of controlling the microstructure of the macromolecules formed.

a. The $(2\text{-PhInd})_2\text{ZrMe}_2$ –TIBA catalyst systems

Recently, we found a new class of homogenous catalyst systems in which TIBA serves as the activating additive. In terms of activity in ethylene and propylene polymerisation, these catalysts are commensurable with systems containing MAO as the cocatalyst; they also retain the stereospecific action.^{98,113} This group of complexes includes the dimethyl derivatives of 2-substituted

bisindenyl zirconocenes, in particular, the dimethylated analogue of the complex **16**.

Study of the catalytic properties of the $(2\text{-PhInd})_2\text{ZrMe}_2$ –TIBA system in toluene and in liquid monomer showed that its activity is similar to that of **16**–MAO, the molecular mass of the resulting eLSBPP being the same or higher (Table 7). Unlike the **16**–MAO catalyst, for this system, no increase in the content of isotactic pentads following an increase in the monomer concentration was observed (see Table 7, rows 4, 5 and 1, 2). The concentration of TIBA or, with a constant metallocene concentration, the Al_{TIBA}:Zr ratio is the factor which allows variation over broad ranges of the system activity, the kinetic characteristics of the polymerisation process and the properties of the PP formed. Thus an increase in the Al_{TIBA}:Zr molar ratio from 100 to 300 entails a 4-fold increase in the activity, a growth of the molecular mass from 80 000 to 220 000 g mol^{−1} and a decrease in the content of isotactic pentads (Fig. 12). Yet another feature of this catalyst system is the fact that it permits polymerisation to be carried out at relatively high temperatures (see Table 7, row 7). The increase in the activity of the given system with an increase in the reaction temperature is not accompanied by a sharp decrease in the molecular mass, as was observed for the MAO-activated

Figure 12. Pentad composition (1) and macro tacticity index (2) of eLSBPP obtained with the $(2\text{-PhInd})_2\text{ZrMe}_2$ –TIBA catalyst system vs. Al:Zr molar ratio ($T_p = 30^\circ\text{C}$).¹¹³

system, and makes it possible to change the isotacticity of eLSBPP (see Table 7, rows 6, 7). Thus, by varying the concentration of the activating agent and the reaction temperature, one can prepare eLSBPP with a specified set of properties.

Panin *et al.*⁹⁸ proposed a model which takes into account the participation of TIBA and the monomer in the formation of the AC (Scheme 3, initiation); this allows one to explain why the rate of polymerisation is first order with respect to TIBA and second order with respect to the monomer.

Another model explains the role of TIBA in the stereocontrolling action of the AC (Scheme 3, stereocontrol).¹¹³ This model

Scheme 3

implies repeated inversion of the AC (fast dynamic equilibrium) from the isospecific to aspecific state during chain growth as a result of coordination of an additional TIBA molecule or the generation of 'errors' due to fast exchange between the alkyl groups of TIBA and the growing polymer chain.

Computer simulation of the growing chain of stereoblock PP (~300 000 units) was carried out with the optimised parameters of probability of monomer addition to the active site in the isospecific (q) or aspecific ($1-q$) state and the probability of monomer addition with a definite orientation in the isospecific centre (p_m). In all model experiments, the last-mentioned value was taken to be unity. The probability of m - or r -addition ($p_{m,r}$) in the aspecific AC was taken to be 0.5. The pentad composition of experimentally obtained eLSBPP samples is consistent with the value calculated in terms of this model; in addition, a logical dependence of the q parameter on the TIBA concentration is observed.

It should be noted that eLSBPP formed under the action of the $(2\text{-PhInd})_2\text{ZrMe}_2$ -TIBA catalyst system is similar in pentad composition to the PP produced by the **16**-MAO system (see Table 5, 6) and exhibits similar elastomeric properties.

The attraction of this catalyst system for the synthesis of eLSBPP is in the use of cheap trialkylaluminium instead of expensive MAO as the activating agent and in the possibility of changing the molecular-mass characteristics and the microstructure of the resulting polymer by varying the Al:Zr ratio and the polymerisation temperature. Apparently, the $(2\text{-PhInd})_2\text{ZrMe}_2$ -TIBA system should be sensitive to the action of hydrogen and ethylene, like the **16**-MAO system described above.^{79, 82, 85, 86} This provides additional opportunities for the control of activity, molecular mass and stereo and fractional composition of the polymer.

b. 'Hybrid' metallocene catalyst systems

The mechanisms of action of the above-described homogeneous metallocene catalyst systems for the synthesis of eLSBPP have a common feature, *i.e.*, the possibility of the existence of a cationic AC in the isospecific or aspecific state. In recent years, publications appeared on the synthesis of stereoblock PP by polymerisation induced by mixtures of metallocenes with different stereospecificity, 'hybrid' homogeneous^{114–116} or supported¹¹⁷ catalyst systems.

In studies on homogeneous catalyst systems, a combined activator for zirconocene dichlorides, namely,

TIBA-CPh₃B(C₆F₅)₄^{114–116} or MAO¹¹⁶ was used. Zirconocene dichlorides on a MAO-treated support were activated by TIBA.¹¹⁷ Presumably, in the homogeneous system, TIBA acts as the alkylating agent in the initiation step, and the subsequent reaction of the alkylated catalyst with the borate gives rise to a cationic alkyl metal AC. The mechanism of activation of metallocene catalyst systems involving trialkylaluminium is currently open to question and its detailed discussion is beyond the scope of this review. Only some facts will be presented. Monoalkylation of a large series of zirconocene dichlorides induced by AlMe₃ has been confirmed experimentally.¹¹⁸ In the case of the Cp₂ZrCl₂-TIBA system (Al:Zr = 10), a ¹³C NMR study showed that the Cp₂Zr(Buⁱ)Cl·TIBA complex is the only identifiable product (19%), whereas in the (Me₅C₅)₂ZrCl₂-TIBA system, the (Me₅C₅)₂Zr⁺Cl...ClAl⁻Buⁱ complex is formed selectively.¹¹⁹ Preliminary reaction of zirconocene dichlorides with MAO at relatively low Al:Zr ratios (~10²) results in complexes that are effectively activated by TIBA in the polymerisation of propylene.^{120–122} The Me₂Si(Me₄C₅)NBuⁱZrCl₂-MAO, Me₂Si(Me₄C₅)NBuⁱZrCl₂-TIBA-CPh₃B(C₆F₅)₄ and Me₂Si.(Me₄C₅)NBuⁱZrMe₂-TIBA-CPh₃B(C₆F₅)₄ systems exhibit different catalytic properties in ethylene polymerisation under identical conditions.^{101, 123–125} Despite the fact that TIBA is widely used as an activator of immobilised metallocene complexes supported on MAO-treated materials,¹²⁶ no data on the mechanism of activation or the role of TIBA have been published. In a number of publications,^{123, 127–130} it is noted that TIBA is not a chain transfer agent in homogeneous catalyst systems for ethylene and propylene polymerisation but functions as an activator.

Propylene polymerisation using a mixture of dichloride metallocene complexes with different stereospecificity, namely, isotactic-atactic complexes **39–40** or **41–40**¹¹⁴ and isotactic-syndiotactic complexes **41–42**¹¹⁵ activated by TIBA-CPh₃B(C₆F₅)₄ gave¹¹⁴ high-molecular-mass products, which were mixtures of homopolymers with the composition corresponding to the stereospecific action of the initial catalysts and a stereoblock fraction. The catalyst systems studied by Chien *et al.*¹¹⁴ exhibit activities of up to 50 kg PP (mol Zr)⁻¹ h⁻¹ [C₃H₆]⁻¹. The content of the stereoblock fraction depends on the molar ratio of the complexes in the hybrid mixture and the TIBA concentration. The stereoblock fraction ensures the compatibility of the resulting polymers. An increase in the concentration of TIBA is accompanied by an increase in the activity of the systems and a decrease in the crystallinity of the polymeric product. At a definite composition, the resulting polymers exhibit good elastomeric properties: the elongation at rupture reaches 900% and the recovery is 97%–98%. The formation of the stereoblock fraction was attributed¹¹⁴ to the fast exchange of growing polymeric chain

fragments between the AC with different stereospecificities with participation of TIBA.

Recently, experimental data have been published confirming the possible formation of the stereoblock PP fraction by the 'hybrid' mechanism.¹¹⁶ Analysis of the terminal groups of the PP macromolecules formed under the action of zirconocenes with different structures, the isospecific complexes *rac*-Me₂Si.₂(2-MeInd)₂ZrCl₂ (**45**) and **43**, the aspecific complex **40** and the syndiospecific zirconocene **42** activated by MAO or by the TIBA–CPh₃B(C₆F₅)₄ system showed that chain transfer to the organoaluminium compound proceeds efficiently for some catalysts. This is indicated by the high content of the isopropyl groups in the polymer.

The efficiency of chain transfer during propylene polymerisation on MAO (or AlMe₃ present in MAO) is governed by steric parameters of metallocene and is maximum for the sterically most hindered highly stereo- and regiospecific zirconocene **43**. The introduction of an additional amount of AlMe₃ (Al:Zr = 500–5000) results in a considerable increase in the activity and a decrease in the molecular mass of isotactic PP. The efficiency of the chain transfer to the organoaluminium compound reaches 95%; evidently, this process takes place through alkyl–polymer chain reversible exchange reactions in heteronuclear cationic intermediates.¹¹⁶

The aspecific complex **40** is less capable of chain transfer by this mechanism. The introduction of an additional amount of AlMe₃ results in a lower molecular mass of the polymer and a lower system activity, apparently, due to the formation of coordinatively saturated 'dormant' active centres.^{131, 132} The chain transfer during polymerisation is less pronounced in the case of the syndiospecific complex **42** and does not take place when sterically open isospecific zirconocene **45** is used. On none of the zirconocenes studied, was transfer of the polymer chain to TIBA observed in the presence of a combined activator.

By combining complexes with different stereoselectivity (**40**–**43**) exhibiting the maximum capacity for chain transfer to the organoaluminium compound, it was possible to prepare PP with the highest (up to 30%) content of the stereoblock fraction (atactic–isotactic blocks) soluble in boiling hexane.¹¹⁶ The proportion of the stereoblock fraction increases upon an increase in the content of the catalyst more prone to chain transfer to the organoaluminium compound.

Unfortunately, the researchers cited¹¹⁶ did not analyse the dependence of the content of the stereoblock fraction on the concentration of the complexes **40** and **43** and TIBA. A decrease in the concentrations of these components should decrease the probability of exchange reactions and thus reduce the amount of the stereoblock fraction. However, in a recent study,¹³³ doubt is cast upon the widely recognised opinion regarding the nature of the AC (the cationic metal alkyl site stabilised by the counter-ion). Analysis by NMR spectroscopy of anion exchange reactions

(dynamic symmetrisation of ion pairs of zirconocene) which are accelerated in the presence of Li⁺...MeB[–](C₆F₅)₃ and upon an increase in the zirconocene concentration, mainly due to the entropy factor, provides grounds for belief that quadrupole ion–counter-ion dimers (or polynuclear complexes) act as AC for the ion-coordinate polymerisation of olefins. Proof of the existence of such intermediates would provide a new interpretation of exchange reactions involving zirconocenes with different stereospecificities.

Apparently, stereoblock PP is formed by a chain transfer mechanism between the AC with different specificity through TIBA or the monomer during propylene polymerisation induced by binary supported catalysts which have been reported recently.¹¹⁷ These catalysts were synthesised by co-precipitation of the isospecific zirconocene **41** and the syndiospecific complex **44** from a toluene solution onto silica gel treated with MAO (PQ-SiO₂–MAO). This method of deposition ensures homogeneous distribution of complexes on the surface of the support and creates the possibility for the arrangement of two AC possessing different stereospecific action in the close vicinity of each other. Comparison of the molecular-mass characteristics and the *xxxx/xxxxy* ratios of the pentad contents (*x*, *y* = *m* or *r*) for the PP samples prepared on the PQ-SiO₂–MAO–**41**, PQ-SiO₂–MAO–**44** and PQ-SiO₂–MAO–(**41** + **43**) catalyst systems with all other factors remaining the same showed that the polymer formed under the action of the binary supported catalyst contained a stereoblock fraction in addition to isotactic and syndiotactic fractions. On the basis of the analysis of ¹³C NMR spectra, it was concluded¹¹⁷ that the chain transfer to TIBA or to the monomer takes place, on average, after 75 steps of insertion. Apparently, due to the low activity of the catalyst and relatively low molecular mass of PP samples (40 000–50 000 g mol^{–1}), data on the properties of polymers are not presented in the publication. The melting temperatures of PP formed on the binary supported catalyst at 30–60 °C are close to those of IPP (*[mmmm]* ≈ 90%) prepared using the supported complex **41**. It should be noted that the use of 'hybridisation' with utilisation of procedures giving rise to highly effective immobilised catalysts¹³⁴ after optimisation of the conditions of their synthesis and polymerisation and with appropriate selection of metallocenes, can prove highly promising for the synthesis of eSBPP or polypropylene composites.

5. Catalyst systems of the post-metallocene type

Since the first publications^{135, 136} and to the present day, the interest in the catalyst systems for olefin polymerisation based on chelates formed by Group VIII elements, so called post-metallocene catalyst systems, has continually increased. Most publications are devoted to the study of catalytic activity, the mechanisms of formation and the properties of polyethylene (PE) formed under the action of these systems (see, for example, reviews^{137, 138}). In recent years, approaches to the design of chiral catalyst systems of this type effective for the synthesis of stereoregular PP have taken shape.^{139–143} The chelate complexes of Group IVB metals can also be regarded as post-metallocene catalysts. In a number of publications,^{144–146} high catalytic activity of these complexes activated by MAO in ethylene polymerisation has been reported. A number of publications have been devoted to the catalyst systems based on Group IVB metal chelate complexes efficient in the synthesis of eSBPP.^{99, 147, 148}

The catalytic activity of MAO-activated zirconium dichloride *rac*-bisacetylacetonate has been studied.⁹⁹ This catalyst system in toluene produces fractions of highly isotactic PP (76%) and eSBPP (24%), while in methylene chloride, eSBPP is formed as the only polymerisation product. It has been suggested⁹⁹ that the cationic metal alkyl complex with a coordinated toluene molecule exhibits an isospecific action. In methylene chloride, which is more polar than toluene, the electrophilicity of the cationic species is manifested as agostic interactions with the growing polymer chain, which result, however, in chain isomerisation rather than chain transfer.

Under certain conditions, this process competes with chain growth and acts a source of 'errors', which deteriorate the growth of isotactic sequences.

Unlike the mechanism realised on C_1 -symmetric catalysts and giving rise to single ...*mrrm*... stereodefects, this mechanism does not rule out the appearance of double 'errors' with the formation of short atactic sequences, which is indicated by the presence of intense signals corresponding to the *mrrm* + *rrmr*, *rmrm* and *rrrm* pentads in the ^{13}C NMR spectrum (see Table 5, row 25). An increase in the reaction temperature promotes more efficient isomerisation. To confirm the proposed mechanism, Shmulinson *et al.*⁹⁹ demonstrated that this system effectively catalyses isomerisation of oct-1-ene to oct-2-, -3- and -4-enes.

High-molecular-mass elastomeric SBPP ($M_w = 120\,000$ – $160\,000\text{ g mol}^{-1}$, $M_w:M_n = 1.7$ – 2.4) is formed on chiral $M(\eta^2\text{-NPhPPPh}_2)_2(\eta^1\text{-NPhPPPh}_2)_2$ complexes ($M = \text{Ti, Zr}$) upon polymerisation in the liquid monomer at 25°C .¹⁴⁷ Apparently, a reason for the formation of alternating isotactic–atactic sequences during polymerisation of propylene induced by these catalysts is reversible coordination of the phosphine ligand resulting in a dynamic equilibrium between the tetrahedral and octahedral isomers. The tetrahedral isomer is aspecific, while the octahedral one is isospecific. The ^{31}P NMR spectra recorded at room temperature point to the predominant formation of the octahedral isomer under the action of MAO, although the tetrahedral complex has also been identified.

The dynamic equilibrium between the tetrahedral and octahedral isomers during polymerisation can result in the formation of isotactic and atactic sequences whose relative lengths are determined by the activity of the complexes. However, in the case of this catalyst system, this is not the only factor deteriorating the growth of isotactic sequences. As in the previous case, Kuhl *et al.*¹⁴⁷ observed isomerisation of alk-1-enes into internal olefins.

The possibility of formation of stereoblock PP as a result of the change in the AC geometry in a dynamic equilibrium during the growth of the polymer chain has been studied¹⁴⁸ in propylene polymerisation in the presence of Ti(III) and Ti(IV) bisallyl chelate complexes, $[(\text{Bu}^t\text{Me}_2\text{SiCH}_2\text{CH}_2)_2\text{Ti}(\mu\text{-Cl})_2\text{Li} \cdot \text{TMEDA}]$ (where TMEDA is N,N,N',N' -tetramethylethylenediamine) and $[(\text{Bu}^t\text{Me}_2\text{SiCH}_2\text{CH}_2)_2\text{TiCl}_2]$. Similar complexes of zirconium induce the formation of isotactic PP under the same conditions. Several allylic complexes of Group IVB metals active in olefin polymerisation have been described.^{149–154} As a rule, these are half-sandwich zwitterion Ti(IV) and Zr(IV) complexes in which the allylic ligand stabilises the electronic state of the active site.^{149–151} The allylic intermediates are described most often as products of deactivation (or temporary deactivation) of the AC.^{152–154}

The Ti(III), Ti(IV) and Zr(III), Zr(IV) bisallylic complexes¹⁴⁸ present unusual examples of comprehensively characterised catalysts active in the polymerisation of ethylene and propylene, in which the M –allyl bond mimicks the type of binding in cene or chelating ligands, and the lability of the allylic bond (σ , η^1 , η^3)^{155–157} determines the stereocontrolling effect. An unusual

finding is that paramagnetic bisallyl Zr(III) ($\mu_{\text{eff}} = 1.5\text{ }\mu_{\text{B}}$) and Ti(III) complexes ($\mu_{\text{eff}} = 1.7\text{ }\mu_{\text{B}}$) are active in the polymerisation of ethylene and propylene upon activation by a slight excess of MAO. Polymers formed in the presence of MAO-activated M(III) complexes possess the same properties as the polymers obtained with M(IV)–MAO catalyst systems (Table 8, rows 4, 5 and 10, 12). It was suggested that, under these conditions, the olefin undergoes oxidative addition to the M(III) bisallyl complex with subsequent formation of the cationic M(IV) alkyl AC upon treatment with MAO. However, participation of the monomer at the active centre initiation step is debatable because the specific activities of M(III)–MAO systems normalised to the monomer concentration are similar (see Table 8, rows 1, 2 and 4, 6).

Table 8. These catalyst systems induce the formation of polyethylene with a very high molecular mass and a quite substantial polydispersity coefficient, especially in the case of zirconium complexes. Under the action of zirconium complexes, IPP is formed. An increase in the reaction temperature from 25 to 50°C is accompanied by an increase in the isotacticity from 56% to 96% (see Table 8, rows 2, 3). Catalyst systems based on titanium complexes give rise to eSBPP. Ray *et al.*¹⁴⁸ believe that the dynamic change in the geometry of the AC, $C_{2v} \rightleftharpoons C_2$, caused by reversible $\eta^1 \rightleftharpoons \eta^3$ isomerisation of the allylic ligands is responsible for the formation of stereoblocks. Meanwhile, an increase in the Al/Ti ratio is accompanied by a decrease in the molecular mass of the polymer and the content of isotactic pentads and by some decrease in the system activity. Apparently, these facts indicate that the chain transfer by titanium complexes to the organo-aluminium compound and the back reaction can account for the appearance of regular 'errors' in isotactic sequences, similar to the situation observed for the 'hybrid' catalyst systems. Unfortunately, the pentad composition of eSBPP prepared in the presence of Ti(III) and Ti(IV) bisallyl complexes was not reported in the study under discussion.¹⁴⁸

III. Characteristic features of the structure of elastomeric stereoblock polypropylene and the nature of relaxation processes

The possibility of preparing elastomeric materials by homopolymerisation of propylene has triggered considerable interest in these processes. For many elastomers, the influence of the microstructure and the molecular-mass characteristics on the strain, elastic and thermal properties of polymers has been studied. A number of publications have been devoted to the investigation of the rates and mechanisms of the relaxation processes using

differential scanning calorimetry (DSC),^{82, 110, 114} DSC performed in the quasi-isothermal stepwise mode,¹⁵⁸ dynamic mechanical analysis (DMA),^{26, 158, 159} dynamic thermomechanical analysis (DMTA),¹⁰⁷ birefringence,¹⁰⁷ IR polarimetry¹⁰⁸ etc. The structure of the materials has been studied by X-ray diffraction analysis,¹⁰⁷ solid-phase ¹³C NMR spectroscopy, scanning electron microscopy and atomic-force microscopy (AFM).¹⁵⁹ The elSBPP samples subjected to analyses were synthesised using different catalyst systems, both heterogeneous and homogeneous ones based on bridged and non-bridged metallocenes.

The materials prepared using heterogeneous catalysts, namely, non-modified TMC and supported catalysts based on tetraneophylzirconium have been studied.¹¹⁰ The contents of the isotactic pentads in the PP were 60 mass % and 40 mass %, respectively. The samples studied had similar values of melt flow index (0.5 g min⁻¹ at 230 °C under a load of 21.6 kg) and impact strength (280–300 kJ m⁻²). The polymer prepared using TMC was characterised by a higher modulus of elasticity and tensile strength. The DSC curves for homopolymers exhibited clear-cut peaks for melting (from 155 to 140 °C), crystallisation (from 110 to 80 °C) and glass transition (from 4 to -5 °C). The peaks observed at 50 °C correspond, evidently, to relaxation processes in the disordered phase. For the PP samples studied, the DMTA spectra were also measured; they indicated an increase in the material stiffness following an increase in the degree of isotacticity.

The DSC curves for compositionally homogeneous elSBPP samples completely soluble in ether (synthesised using *ansa*-metallocenes) display feebly pronounced melting and crystallisation peaks.^{55, 57, 114}

In a study of the properties of elSBPP produced under the action of homogeneous systems based on non-bridged metallocenes, both the initial samples and separate fractions were analysed, first of all, the fraction soluble in boiling ether, the fraction soluble in boiling n-heptane and that insoluble in boiling n-heptane. For the polymer synthesised using the 16-MAO catalyst system,⁸⁰ two melting peaks were detected (60 and 140 °C), whereas the ether-soluble fraction {36 mass %, [mmmm] = 0.19} showed no peaks in the DSC curves. In the case of the heptane-soluble fraction {43 mass %, [mmmm] = 0.33}, a broadened endothermic peak in the temperature range from 40 to 160 °C was found, pointing to broad size and stability distributions of the crystallites. According to ¹³C NMR spectroscopy, all fractions had a stereoblock structure. For the fraction insoluble in n-heptane {57 mass %, [mmmm] = 0.38}, a melting peak at 150 °C is clearly defined. It can be seen from Fig. 13 that non-fractionated elSBPP exhibits small melting peaks. The pattern of the melting curves depends not only on the method used to prepare the samples but also on their thermal pre-history.

X-Ray diffraction analysis, DSC, and solid-phase ¹³C NMR spectroscopy have been used to compare the structure of the crystallising and amorphous phases of non-fractionated samples and separate fractions of elSBPP prepared by polymerisation under different conditions and differing in the content of mmmm

Figure 13. Comparison of the DSC curves of elSBPP samples (16-MAO catalyst system) with different contents of isotactic pentads.⁸⁰ (1) 30% (crystallinity, 11%), (2) 19% (crystallinity, 2%).

pentads and in the molecular mass.¹⁰⁷ Unlike the other smectic fractions, fractions soluble and insoluble in n-heptane crystallise to give α - and γ -forms of PP. It is of interest that only formation of the α -form is noted for the initial polymer. To characterise the degree of ordering of amorphous phases, the influence of the temperature in the range of 20–80 °C on the peak intensity in the ¹³C NMR spectra was studied. The content of the crystalline phase in the elSBPP samples determined from the ¹³C NMR spectra in the solid phase is much higher than the values found by DSC or X-ray diffraction analysis. The results obtained attest to involvement of a synergistic effect in the crystallisation of polymers which contain easily crystallisable chains with high contents of isotactic sequences. The properties of polymers synthesised using the 'oscillating' catalyst and the catalyst containing *rac*- and *meso*-forms of *ansa*-zirconocene were compared as well as those of mixtures of isotactic and atactic PP. The materials were characterised by virtually equal contents of the mmmm pentads. The researchers noted¹⁰⁷ that the thermoplastic elastomers prepared by polymerisation, unlike blend compositions, possess excellent elastic properties even at elevated temperatures. In their opinion, the capacity for relaxation can be regarded as evidence for a multiblock structure of elSBPP. It has been shown by X-ray diffraction analysis, solid-phase NMR spectroscopy and birefringence that samples prepared in the presence of the 16-MAO catalyst behave as elastomers up to a temperature of 80 °C at which they are subject to shear deformation, unlike mixtures of isotactic and atactic PP, which have similar stereoisomer compositions and degrees of crystallinity.

In order to gain a better understanding of the domain structure of elSBPP, Kravchenko *et al.*¹⁵⁸ studied the thermal and morphological properties of PP obtained using the 16-MAO catalyst by the DSC method with temperature fractionation. The PP samples contained 25% and 30% isotactic mmmm pentad; their molecular masses were 240 000–260 000 g mol⁻¹. Preliminarily, the temperature of crystallisation for the studied samples varied from 160 to 50 °C with a step of 10 °C, and the samples were annealed at the appropriate temperatures for 12 h and then heated in the usual way. The resulting curves (Fig. 14) exhibit multiple peaks (Table 9) and differ substantially from the curves observed with fast scanning; this points to the influence of kinetic factors on the processes of crystallisation. Interesting results have been obtained by treating polymeric materials with hot nitric acid:¹⁵⁸ only ~10% of the polymer was insoluble (this corresponds to the content of perfect insoluble crystals). This method is widely used in the investigation of the structures of various polymeric materials. To characterise the domain structure of elSBPP samples, the AFM method was used.¹⁵⁸ Regions consisting of ribbon crystals distributed in the amorphous phase were found in the samples. It was also found¹⁵⁸ that the thickness of the lamellae in elSBPP equals 12 ± 4 nm, which corresponds to 54 monomer units. The elongation at rupture for the material

studied reaches 1000% and the tensile strength was 15 MPa. When deformations do not exceed 300%, the hysteresis is high and no destruction of crystals in the samples is observed. In the case of great deformation, the initial lamellar crystallites are destroyed and small blocks are produced, which are mainly contained in fibrils. These processes are similar in mechanism to those taking place in other segmented elastomers such as aromatic polyesters and polyamides. The nanofibrils formed upon drawing contain alternant structures of rigid crystallites and, possibly, initially amorphous segments crystallising under the action of stress with chains oriented in the direction of drawing for both types of segments. The length of these domains is several hundreds of nanometers and the width is ~ 12 nm. After relief of the stress and relaxation, the initial structure of the sample is not restored.

The results obtained in the studies of various samples of eSBPP and their fractions by DSC, DSC with temperature fractionation, by treatment with nitric acid and by AFM point to the cooperative nature of crystallisation processes and to the presence of diffusion and kinetic restrictions.

The rates of relaxation processes for compositionally inhomogeneous eSBPP and separate fractions have been studied by the birefringence method.¹⁰⁸ It was shown that the relaxation time and the size of the relaxation plateau depend on the temperature and shear deformation. In the case of 100% deformation, the relaxation time decreases as the temperature rises (2 h at 25 °C, 900 s at 80 °C, and 440 s at 115 °C), and the size of the relaxation plateau changes from 0.62 at 25 °C to 0.43 at 85 °C.¹⁰⁷ The effect of temperature on the rate of the relaxation processes for non-fractionated samples and for separate fractions of PP at different shear deformations (3% to 100%) was studied in detail. In the temperature range of 200–105 °C, complete isotropisation occurs rapidly. At 105 °C and at lower temperatures, the rates and the degrees of isotropisation for the initial samples and for separate fractions are markedly different. It is of interest that repeated application of shear strain resulted under some conditions in an increase in the rate and the degree of relaxation.

The results of studies^{107, 110} indicate that great shear deformations ($\geq 50\%$) are able to destroy the physical junctions at weak points; this gives smaller crystals. An increase in the deformation results in irreversible anisotropy of non-equilibrium crystals. The fractions insoluble in heptane exhibit properties typical of solid elastomers; they are able to induce co-crystallisa-

tion of fractions with lower isotacticity. This results in a higher cross-linking density. It was concluded that the composition and the cooperative role of different fractions determine the elastic properties of materials.

Madkour and Mark^{111, 160} arrived at analogous conclusions. The effect of the molecular mass, MMD and the length and length distribution of isotactic blocks on the moduli of elasticity of the materials have been studied by mathematical modelling. Modelling with allowance for co-crystallisation processes gave the dependences of the modulus of elasticity on the content of isotactic sequences similar to those established experimentally.

The results of an investigation of the fracture mechanism and examination of the fracture surface of eSBPP by scanning electron microscopy are rather interesting.¹¹⁰ The dependence of the fracture energy on the stereochemical composition was elucidated. When the content of the *mmmm* pentads decreases from 60% to 40%, the cohesion energy of fracture for the samples studied changes from 8 to 20.6 kJ m⁻², and the plastic energy, from 53.8 to 9.4 kJ m⁻². In the examination of the fracture surface, the formation of sinusoidal structures parallel to the sample surface and to the load axis has been observed for some samples (Fig. 15). Structures of this type have been described only for some thermoplastic elastomers.

**Figure 15.** Photomicrograph of the fracture surface of the eSBPP sample.¹¹⁰

Thus, it was shown that the regularities observed for eSBPP are similar to those typical of crystalline elastomeric materials. The structure and the properties of the elastomeric PP, as well as of a number of other elastomers are due to the formation of crystallites from thin lamellae or nanofibrils joined by straightened or bent transient chains, which form an amorphous phase in addition to the end chains. The number, volume and the structure of junctions in the physical networks and the degree of ordering of the amorphous phase, the surface free energy of lamellae (end faces), and the values of cohesion and plastic energy determine the sub- and microstructure, the elastomeric properties of these materials, and the patterns of the observed dependences.

IV. Conclusion

The information considered above shows that the discovery of highly effective homogeneous metallocene and post-metallocene catalyst systems has stimulated work on the synthesis of new materials based on polyolefins. Among these, thermoplastic elastomeric stereoblock PP occupies a special place. The interest in its synthesis is great because these polymers can be used as adhesives, binders or elastic films. Numerous catalyst systems and their mixtures have been developed, which allow targeted control of the microstructure and molecular-mass characteristics of elastomeric stereoblock polymers. The mechanism of catalytic

and stereospecific action of these catalysts has been studied. Data on the influence of the microstructure on the mechanical, thermal and relaxation properties of elastomers have been obtained.

This review surveys the state-of-the-art of the research along this line. The necessity of this generalisation is dictated by the vigorous development of the work dealing with the design of new polymeric and structural materials.

VIII. Conclusion	81

Abstract. The information on the structure and properties of peptide nucleic acids (PNA) is generalised. The use of PNA oligomers in biomolecular studies and biotechnology is exemplified. The published data on the most important methods for the chemical synthesis of PNA oligomers with the main emphasis on the efficiency of condensation reactions are considered. The methods for PNA synthesis are systematised; their advantages and disadvantages are discussed. Some recommendations for optimisation of the condensation procedure and synthesis of PNA are presented. The bibliography includes 153 references.

I. Introduction

Peptide nucleic acids (PNA, **1**) represent analogues of nucleic acids (NA, **2**),^{1–4} but, in contrast to the latter, contain neither carbohydrate nor phosphate residues and have uncharged pseudopeptide backbones.^{1,5–8} The monomeric unit of classical PNA comprises *N*-(2-aminoethyl)glycine and a heterocyclic base (purine or pyrimidine) bound through an acetyl linker. The monomers are linked by amide bonds. The geometry of the achiral backbone and its relative flexibility^{3,9} confer on PNA an ability to mimic, with striking exactness, the spatial structure of carbohydrate–phosphate backbones of NA.⁴

From the chemical standpoint, PNA represent a hybrid of an oligonucleotide wherefrom the nucleases have been adopted and a peptide, the structure of which gave birth to the structural principle of the PNA backbone. Thus, PNA possess properties of both these classes of compounds.^{8, 10} This structural-and-functional duality of PNA determines their unique property.⁴ Indeed, these molecules combine uniquely the strict recognising ability inherent in NA with the flexibility and stability of proteins.

It should be noted that the term 'peptide nucleic acids' is used to point to the structural similarity of these compounds to NA and to reflect the similarity of the PNA oligomeric backbone to that of

peptides, although neither the term ‘acid’ nor ‘peptide’ are applicable to PNA, for in contrast to nucleic acids PNA are not polymeric acids and in contrast to peptides they do not contain amino acids. Nevertheless, the abbreviation ‘PNA’ has now come into general use, although it would be more correct to refer to these compounds as polyamide analogues of oligonucleotides.¹⁰

II. Properties of peptide nucleic acids

Complementary PNA molecules form specific antiparallel PNA–PNA duplexes having helical structures^{4,11} similar to those of DNA and RNA duplexes but, which is even more important, they form highly stable specific (antiparallel and parallel) duplexes with complementary DNA and RNA sequences^{1,5–7,9,12–14} containing Watson–Crick base pairs.^{2,15,16} In all cases, antiparallel PNA–DNA duplexes are more stable than the parallel ones, *viz.*, their melting temperatures differ by ~ 1 °C for each base pair.² The circular dichroism spectra of PNA–DNA and DNA–DNA duplexes are similar,^{2,17} which points to the formation of right-hand helices during the formation of

PNA–DNA duplexes despite the fact that base pairs in PNA–DNA and DNA–DNA duplexes have slightly different geometries.¹⁷ NMR and X-ray crystallography studies of PNA–PNA and PNA–DNA complexes revealed that PNA–PNA duplexes possess broad, deep major grooves and narrow, shallow minor grooves; noteworthy, one complete turn of a helix in PNA–PNA duplexes corresponds to 18 base pairs, whereas that in PNA–DNA duplexes, to 13 base pairs.^{17–20}

PNA–PNA, PNA–DNA and PNA–RNA duplexes are considerably more stable than DNA–DNA, DNA–RNA and RNA–RNA duplexes of the same compositions.^{1, 2, 11–17, 21–23} Even four-membered PNA sequences produce highly stable duplexes with complementary DNAs.¹⁷ In contrast to NA–NA duplexes, the stabilities of PNA–NA duplexes are little dependent on the solution ionic strength.^{2, 24–27} PNA–DNA duplexes are formed faster than the corresponding DNA–DNA duplexes,^{14, 22} but high specificity of hybridisation is preserved.²⁸

The stabilities of PNA–DNA duplexes can be predicted based on a model which takes into account the interactions between only the nearest adjacent bases;^{17, 29, 30} however, this model describes adequately the stabilities of short duplexes comprising no more than eight units.¹⁷

The most essential property of PNA is their unique sensitivity to mismatches in the structure of NA targets.⁷ The difference in melting temperatures of a perfect PNA–DNA complex and a duplex containing one mismatch amounts to 20 °C and even more.³

Peptide nucleic acids form PNA–(DNA)₂ triplexes with double-stranded DNA.^{31–34} These triplexes are less stable than the classical (DNA)₃ triplexes.³⁴ On the other hand, PNA forms stable (PNA)₂–DNA and (PNA)₂–RNA triplexes with single-stranded DNA and RNA targets, respectively.^{5, 12, 14, 16, 33, 35–39} Such triplexes are often formed in the interaction of PNA with double-stranded NA.^{37, 40–44} In the latter case, the formation of triplexes leads to the displacement of one of the DNA strands resulting in complete separation or P-loop formation³⁸ with subsequent incorporation of PNA chains.^{5, 33, 37, 40–44} PNA form Watson–Crick pairs with DNA. The attachment of the second PNA chain is accompanied by the formation of Hoogsteen pairs.^{35, 39} It was found that Watson–Crick chains of PNA are antiparallel to DNA chains, while Hoogsteen strands are parallel to them.^{37, 39}

It is noteworthy that Hoogsteen strands stabilise Watson–Crick PNA–DNA duplexes which are formed first; the latter can be relatively unstable.³⁸

Homopyrimidine PNA molecules and PNA enriched with pyrimidine residues are especially prone to triplex formation.^{9, 35–39} The respective triplexes are extremely stable, *e.g.*, ten-membered (PNA)₂–DNA triplexes have the melting temperatures of ~70 °C.^{9, 39} The ability of cytosine-containing PNA to form triplexes is pH-dependent, since cytosine can form Hoogsteen pairs with guanine residues only in the protonated state.⁹ No triplexes with the composition (PNA)₃ have been found.⁴⁵

Recently, a new type of PNA-containing triplexes has been discovered.³⁷ Both PNA chains in the (PNA)₂–DNA triplex formed upon binding of the PNA oligomer 5′-T₄G₂(TG)₂-3′ to the oligonucleotide 5′-A₄C₂(AC)₂-3′ are in the antiparallel orientation relative to the DNA strand.

The binding potential of PNA with respect to NA is far from being exhausted. Studies of NA-binding properties of PNA aimed at the synthesis of novel PNA possessing improved structures and able to enhance the specific binding of PNA to complementary NA are currently under way.³⁷

The melting of short-chain (PNA)₂–DNA triplexes is a non-equilibrium process, *viz.*, the melting temperature depends on both the concentrations of components and heating velocity.³⁸ Thus, the stabilities of (PNA)₂–DNA complexes were found to be kinetic.³⁸ The dissociation of such triplexes occurs in two steps, *viz.*, the first (limiting) step includes separation of the Hoogsteen

strand of PNA, while the second step includes rapid separation of the Watson–Crick strands of PNA.³⁸

Peptide nucleic acids manifest high chemical and biological stabilities.^{25, 46} They are highly resistant against cell nucleases, proteases and peptidases.^{25, 27, 47} PNA oligomers undergo very slow enzymatic hydrolysis in both cell extracts and *in vivo*.^{25, 46} PNA molecules are distinguished by generally low toxicity and are not prone to non-specific binding to cellular proteins. Being immobilised on solid supports, PNA molecules preserve their hybridisation properties.²⁸

It is known that modifications of NA backbones by replacing phosphodiester or carbohydrate units by non-charged or cationic structures may confer useful properties on NA, *e.g.*, enhanced resistance against nucleases and effective penetration through cell membranes and more specific and stronger binding to complementary target NA.⁴⁸ Attempts are being made to improve the PNA structure in order to increase the ability of PNA for nonspecific binding to NA and their transport across cellular membranes.^{2, 3, 8–10, 36} Thus the addition of certain peptides,^{49–53} *e.g.*, the 16-membered peptide ‘transportan’,^{50, 51} to PNA increases considerably the rate of intracellular transport of PNA.^{9, 23, 49–53} α -Helical PNA (α PNA) have been obtained in which the role of the backbones is played by α -helical peptide structures.^{54–56} Such PNA analogues form highly specific stable Watson–Crick duplexes with complementary NA^{54, 55} and manifest very high biological stabilities.⁵⁶ PNA analogues with chiral backbones with positively and negatively charged groups, PNA–DNA chimeras, *etc.*, have been synthesised.³⁶

Comparative studies of structurally different PNA analogues have shown that classical PNA with *N*-(2-aminoethyl)glycine backbones first synthesised by Peter E Nielsen ten years ago¹ manifest optimum NA-binding properties.⁴ Therefore, the main attention in this review will be given to methods of synthesis of classical PNA molecules based on *N*-(2-aminoethyl)glycine residues.¹

III. Applications of peptide nucleic acids

By virtue of their unique properties,^{13, 37} PNA have found wide use in molecular-biological, biochemical, genetic engineering and clinical investigations.^{2, 3, 14, 26, 27, 36, 57–65} They represent attractive candidates for new-generation genetic therapeutic drugs which interfere selectively with gene expression.^{9, 14, 26, 36, 57, 62–71} The use of PNA oligomers in antisense^{9, 26, 27, 36, 57, 67, 69, 72–74} and antigen^{27, 36, 57, 67, 68, 72, 75, 76} biotechnologies is of considerable promise.

Antisense PNA selectively inhibit the expression of brain proteins.⁴⁷ The design of anticancer and antiviral drugs based on PNA seems to be a very promising approach.^{26, 57, 65} Some PNA derivatives manifest antibacterial³⁶ and antisense activities^{9, 47} towards eukaryotic cells and animal organisms.^{9, 47}

There is evidence that PNA interfere with all the key stages of gene expression.^{9, 46, 57, 77} Used in nanomolar concentrations, PNA cause a practically complete specific arrest of transcription of DNA templates.^{46, 78} The usefulness of PNA oligomers in gene-oriented technologies has been demonstrated with a PNA-dependent arrest of transcription elongation of RNA polymerase as an example.^{27, 46, 67, 68, 72} By virtue of their ability to induce effective blocking of transcription, PNA oligomers represent potential inhibitors of cell growth, which makes them a useful tool in the design of antitumour drugs.⁷⁸

PNA duplexes and especially triplexes with mRNAs, *e.g.*, PNA–RNA and (PNA)₂–RNA, effectively inhibit the translation of mRNA.^{67, 73, 74} Their potent antisense effects *in vitro* are due to high specificities and stabilities of triplex (PNA)₂–RNA.³⁸ The arrest of translation elongation of mRNA occurs even upon addition of six-membered complementary homopyrimidine PNA.⁷³

The antisense efficiencies of duplex-forming PNA are lower than those of triplex-forming ones; in this case, no less than 20-

membered PNA are required for the inhibition of translation elongation of mRNA (however, the translation initiation can be arrested due to formation of even short-chain PNA–RNA duplexes).^{73,74} Nevertheless, RNA molecules in hybrid PNA–RNA duplexes are not cleaved by RNase H.^{67,73,79–81} The antisense effect of duplex-forming PNA is largely due to steric hindrances upon formation of stable PNA–RNA complexes⁹ which hinder the translation of mRNA. PNA-induced degradation of mRNA, which is unrelated to the effect of RNase H, should not be ruled out either.⁹

Duplex-forming PNA can inhibit translation *in vitro*, being specifically directed against the binding sites of ribosomes, whereas triplex-forming PNA are more specific against polypurine sites located ‘below’ the translation initiation point.⁹

Peptide nucleic acids are used for mapping of RNA molecules in molecular biological studies, particularly for detection of RNA domains responsible for binding to other RNAs and peptides.⁸⁰ Their applications open up new possibilities for elaboration of novel approaches to the study of RNA–RNA and RNA–protein interactions and such processes involving non-translatable RNA molecules as splicing. There is evidence that PNA molecules behave as effective ‘traps’ for some DNA-binding proteins.⁸¹ PNA–DNA chimeras are convenient primers for DNA polymerases.⁸² In recent years, PNA have extensively been used as biomolecular tools for the studies of various intracellular processes.^{2,3,8,10,27,57,61–64,80–82}

The use of PNA in the design of efficient procedures for the detection of hybridisation, which are extremely sensitive to mismatches in NA targets, is a promising approach.^{28,83} Fluorescently labelled PNA are used as diagnostic probes for detecting specific NA sequences and for the study of penetration of PNA oligomers through cellular membranes and their intracellular distribution.^{84–87} The use of PNA in combination with ion-exchange HPLC (the detection limit is 150 pmol),⁸⁸ MALDI TOF mass spectrometry,⁸⁹ capillary electrophoresis⁹⁰ and other advanced analytical techniques⁸⁸ allows reliable identification of specific genetic sequences in various test samples.

The use of PNA in the design of electrochemical biosensors^{28,91–93} opens up new possibilities for fast screening of primary NA structures and helps overcome many problems of modern biotechnology.^{2–4,8,10,61} These compounds can be used as an outstanding basis for the construction of new generations of highly efficient diagnostic tools, *e.g.*, biochips.⁸³

In this context, the development and optimisation of versatile techniques for the synthesis of PNA oligomers are becoming currently central tasks. The condensation of PNA monomers and oligomers with formation of amide bonds induced by various activating reagents is the key step in PNA synthesis. The combination of protective groups, deprotection and capping conditions as well as post-synthetic work-up of synthetic PNA oligomers strongly depend on the condensation method used.

IV. Basic principles of chemical synthesis of peptide nucleic acids

The chemical synthesis of PNA molecules consists essentially in the oligomerisation of the monomers 3–6 comprising *N*-(2-aminoethyl)glycine backbones and acetic acid residues (acetyl linkers), each containing one of four nucleobases as a substituent.¹⁴ At present, a broad range of methods for the chemical

synthesis of PNA are available; the most efficient of them have become especially popular in the past decade.^{14,94–97}

First of all, a solid-phase methodology is applied for the synthesis of PNA. The synthesis of oligomeric molecules on the surface of polymeric supports was first developed by Merrifield for the synthesis of peptides and proteins in 1962. The strikingly simple idea to immobilise growing oligomeric chains on solid supports has brought biooligomer synthesis to a qualitatively new level. At present, the principle proposed by Merrifield⁹⁸ is widely used in the synthesis of peptides and proteins as well as of DNA and RNA fragments (oligonucleotides). In the overwhelming majority of cases, PNA oligomers are also synthesised on solid polymeric supports. In this review, the main emphasis will be laid on the problems related to the efficiency of solid-phase synthesis of PNA.

Although PNA oligomers can be synthesised by classical methods commonly employed in peptide synthesis,¹⁴ specially designed condensation procedures should be preferred, taking into account peculiarities of chemical structures of PNA monomers. In fact, of the different methods for the activation of carboxy groups based on the use of activated esters, symmetrical anhydrides, acid halides and *in situ* activating reagents, the *in situ* activation has become the most promising approach, which is currently especially popular.

This method envisages the use of reagents based on uronium and phosphonium salts which effect fast (within several seconds) activation of carboxy groups of PNA monomers. Owing to high activation rates, mixing of PNA monomers with an activating reagent can be performed directly in a column with a polymeric support to which the growing oligomeric chain is attached (it is this procedure that represents *in situ* activation) or immediately before the addition of the monomer to the reaction column. This makes it possible to conduct PNA synthesis in an automated regime.

The solid-phase procedure for PNA synthesis involving *in situ* activation will be considered below; its advantages have been corroborated by chemical practice. The data on the efficiencies of other activation techniques can also be useful and proper consideration will be given to them.

V. Factors determining the efficiency of condensation in the synthesis of peptide nucleic acids

The yields of condensation products in the synthesis of PNA using the *in situ* activation procedures depend critically on a number of factors. The most essential of them are as follows:

- the nature and concentration of the activating reagent;
- the nature and concentration of the PNA monomer;
- the nature of a nucleobase component of the PNA monomer and the nature of the nucleobase incorporated into the PNA oligomer in the preceding step;
- the nature and the concentration of a base (as a rule, tertiary amines);
- the nature of the solvent(s);
- the presence or absence of catalysts, *e.g.*, 1-hydroxybenzotriazole;
- the experimental procedure (*e.g.*, preactivation of the PNA monomer or mixing of the PNA monomer with the condensation reagent *in situ*);

— condensation conditions (reaction time and temperature);
 — other conditions (*e.g.*, the quality of reagents, dryness of solvents, inertness of the reaction atmosphere, *etc.*).

It should be noted that information concerning the dependence of the yields of the condensation products on the nature of the heterocyclic bases of PNA monomers is practically absent. This problem demands special investigation. The majority of literature sources cite average yields of PNA condensation products calculated per coupling cycle of a hypothetical monomeric fragment (irrespective of the nature of the monomer) or the total yields of the PNA oligomer.

It seems reasonable to consider all the factors mentioned above. Hence, it is expedient to discuss in detail the main aspects related to the efficiencies of PNA condensations inherent in particular synthetic strategies.

VI. The main strategies of peptide nucleic acid synthesis

Usually, PNA synthesis utilises conventional solid-phase peptide synthesis protocols.¹⁴ Three synthetic strategies are currently especially popular which produce PNA in high yields and purity. These strategies differ in the nature of protective groups blocking 5'-terminal primary aliphatic amino groups in PNA monomers. *tert*-Butoxycarbonyl (*t*Boc or Boc), 9-fluorenylmethoxycarbonyl (Fmoc) and 4-methoxyphenyldiphenylmethyl (monomethoxytrityl, MMT) groups are generally used as protective groups, and Boc,^{12, 94, 99, 100} Fmoc,^{77, 97, 101–106} and MMT strategies^{96, 107–112} of PNA synthesis are distinguished, correspondingly.

The chemical nature of these groups and the differences in the conditions for their removal determine the choice of optimum condensation reagents and condensation conditions for each particular strategy, although the main principles of PNA synthesis are the same.

The Boc strategy^{12, 94, 99, 100} was the first to be used for the PNA synthesis. In this case, exocyclic amino groups of heterocyclic bases are usually protected by the benzyloxycarbonyl (Z, Cbz) group (the Boc/Z version),⁹⁴ and *O*-benzyl groups are sometimes used as additional protective groups for guanine.¹¹³ The Boc/acyl version of the Boc strategy, where exocyclic amino groups of nucleobases are protected by acyl groups, has also been described.⁹⁵ One of the well-known disadvantages of the Boc strategy is the necessity to use strong acids for the removal of Boc groups (trifluoroacetic acid) and the cleavage of PNA oligomers from the polymeric supports (hydrofluoric acid, trifluoromethanesulfonic acid, *etc.*). Such drastic conditions limit the range of PNA synthesised according to the Boc protocol.

A search for milder conditions has led to the development of the Fmoc strategy of PNA synthesis.^{14, 77, 96, 97, 101–106, 114} Here, the Fmoc groups are removed by mild treatment with piperidine.¹⁴ The benzyloxycarbonyl (Z),⁹⁷ benzhydryloxycarbonyl (Bhoc)¹⁰⁶ or MMT groups^{12, 96, 114} are used to protect amino groups of nucleobases. The advantage of a Fmoc/acyl version of this strategy^{77, 102–105} is the possibility of selective removal of the Fmoc groups without affecting the acyl protective groups of the heterocyclic bases.^{102, 103} The use of this strategy ensures higher yields of PNA in comparison with the Fmoc/Z strategy, while the

conditions for PNA synthesis are compatible with those of peptide and oligonucleotide syntheses.^{104, 115} This opens up new opportunities for the synthesis of hybrid PNA–DNA and PNA–peptide molecules.

In addition to Boc and Fmoc protection, it was proposed to use MMT groups for protection of 5'-terminal primary amino groups.^{96, 107–112, 116} Although the MMT group, like the Boc group, is acid-labile, this can be cleaved under considerably milder conditions than the Boc groups (the MMT groups are split off by treatment with 3% trichloroacetic acid).¹⁰⁷ In the MMT strategy, the amino groups of heterocyclic bases of the PNA monomers are usually protected by acyl groups (*e.g.*, acetyl, isobutyryl, anisoyl, benzoyl, *tert*-butylbenzoyl) (MMT/acyl version of the MMT strategy).^{96, 107, 110, 116} The reaction conditions are mild, which makes it possible to perform automated synthesis of PNA oligomers using the oligonucleotide synthesisers, while their compatibility with oligonucleotide synthesis protocols allows one to obtain PNA–DNA chimeras.^{107–109}

The efficient condensation requires that the 5'-terminal amino groups were not protonated, since in the form of cations they do not manifest nucleophilic properties. However, under basic conditions where the amino group is not protonated and hence is active, the undesirable transfer of the *N*-terminal acetyl group with the attached heterocyclic base to 5'-terminal primary aliphatic amino group may take place.^{94, 97, 115, 117}

PNA — C-terminal fragment of the PNA oligomer.

This reaction can also occur under neutral conditions⁹⁴ resulting in the break of growing PNA chains and accumulation of short-chain oligomers. This affords a mixture of products and the isolation of target PNA presents a serious problem.

The formation of isomeric structures can be avoided provided the condensation is very fast. In this case, side products cannot be formed, since the *N*-acyl transfer is a rather slow process.^{94, 97, 100, 117} In the presence of reagents based on uronium and phosphonium salts, the condensation occurs so fast that even *in situ* activation of carboxy groups of PNA monomers is possible.

Splitting of the *N*-terminal monomeric unit¹² under the action of piperidine used for removal of Fmoc groups is yet another side reaction.

It should be stressed that the problem of side reactions and the efficiency of PNA synthesis on the whole depend critically on the combination of protective groups used. Indeed, the Boc and Fmoc strategies differ essentially in the conditions of deprotection of 5'-amino groups of the last added monomer. As mentioned above, the removal of Boc groups requires rather drastic acidic treatment, which leads to the protonation of 5'-amino groups. Therefore, this group should be neutralised before the addition of the next monomeric fragment, which is not required in the case of the Fmoc strategy.

On the other hand, the removal of Boc groups is always quantitative and rather fast, whereas splitting of Fmoc groups by basic treatment proceeds slowly and not always completely,^{118, 119} which negatively affects the efficiency of condensation.

Aggregation of growing oligomeric chains is an additional obstacle to efficient condensation. Interchain aggregation makes the deprotected terminal amino group only partly accessible for subsequent condensation, which decreases the efficiency of the process on the whole.^{120, 121} It should be noted that aggregation is only possible in the case of the non-protonated amino group.^{120, 121} Apparently, repulsion of positively charged amino groups prevents the aggregation of oligomers. Thus, the interchain aggregation never takes place in acidic media and terminal amino groups are more accessible to condensation. However, the amino group cannot efficiently react with the activated monomer, since its nucleophilicity is suppressed.

Deprotonation of terminal amino groups of PNA with simultaneous condensation (neutralisation *in situ*) is the most elegant approach to solving this problem. This methodology was first employed for peptide synthesis in 1987.¹²² The use of neutralisation *in situ* in the synthesis of peptides using Boc and Fmoc protocols results in a significant increase in the condensation rate.^{123–125} This effect was especially spectacular in the synthesis of 'problematic' sequences which are especially prone to undergo interchain aggregation. Their syntheses by conventional methods involving preliminary neutralisation of terminal amino groups face the most serious problems.^{126, 127}

At present, neutralisation *in situ* has become very popular for the synthesis of PNA along with conventional methods where deprotonation of 5'-amino groups of PNA oligomers precedes condensation. In some cases, the use of neutralisation *in situ* helps solve the problem of side reactions of PNA isomerisation and increases the yields of condensation products.

VII. Some regularities of condensation reactions in the synthesis of peptide nucleic acids

A detailed knowledge of condensation reactions associated with PNA synthesis and a search for efficient procedures for its optimisation demand that the data available should be interpreted with due regard to the nature of reagents used for the activation of PNA monomers. The methods for the synthesis of PNA–DNA chimeras are described separately, since in this case condensation has a number of specific features.

1. Activated esters and carbodiimide activation

For the first time, the method of activated esters has been successfully employed for the synthesis of thymidine PNA oligomers.^{1, 5} The synthesis of thymidine PNA using Boc-protected pentafluorophenyl (PFP) ester of a thymidine PNA monomer as a monomer was carried out in 1992.⁵ When the monomer concentration was 0.1 mol litre⁻¹, the yield of the condensation product was > 99%. However, an attempt to apply this method to the synthesis of cytidine PNA oligomers was without success: the yield of the target product did not exceed 50% under identical conditions.⁶

There are some examples of successful applications of the method of activated esters for the synthesis of heterogeneous PNA. Thus the synthesis of PNA oligomers from Fmoc/Z-protected monomers by ester activation has been described.⁹⁷

This was one of the first examples of the implementation of the Fmoc protocol to the synthesis of PNA. In this case, the use of the activated esters strategy ensured high efficiency of condensation.

The yields of condensation products in the synthesis of PNA oligomers with the chain lengths of up to 20 residues varied from 95% to 99%.⁹⁷ The average yields in the synthesis of PNA containing all the four types of nucleobases were 97% over each step, which corresponds to the 70% yield of target oligomers. With allowance for subsequent isolation, the yield of PNA oligomers was 43%.

It is of note that the choice of strategies for the synthesis of PNA is often determined by the necessity to obtain high yields of condensation products at low expenditures of expensive PNA monomers where the use of manyfold (fourfold and higher) monomer excess is undesirable. A combined use of the Fmoc protocol and PFP activation allows the use of as little as a twofold excess of PNA in a single condensation.⁹⁷ The use of threefold (or greater) excesses of PNA monomers did not result in further increase in the yields of condensation products. The dimethyl sulfoxide (DMSO)–*N*-methyl-2-pyrrolidinone (MP) mixture (1 : 4) appeared to be the solvent system of choice.⁹⁷ Apparently, this system favours rapid access of the reagents to the growing PNA oligomers.¹²⁸ However, for other activation procedures, other solvent systems were more efficient.

The use of the activated esters approach to PNA synthesis sometimes gives reasonable results;¹² however, in the majority of cases, higher (94%–99%) yields of condensation products were obtained using the *in situ* activating reagents.^{1, 5} In principle, the PNA synthesis can successfully be performed using the so-called carbodiimide activation involving, e.g., dicyclohexylcarbodiimide (DCC) or *N,N'*-diisopropylcarbodiimide,¹² which sometimes affords high (up to 98%–99%) yields of condensation products.^{6, 7} Low rates of PNA condensation is the main disadvantage of this activation procedure.⁹⁹

Carbodiimide activation by DCC made it possible to obtain addition products of thymidine and cytidine PNA monomers in quantitative yields. Purine monomers are only partly incorporated into PNA oligomers; repeated condensation does not result in quantitative yields of the addition products.

The use of *N,N'*-diisopropylcarbodiimide as the activating reagent has made it possible to obtain nearly quantitative yields even for purine monomers.⁹⁹ However, this required the use of a fourfold excess of the monomers and the activating reagent, and the condensation lasted no less than 60 min.⁹⁹ In addition, the introduction of the adenine and the guanine monomers into PNA oligomers required two and three condensation cycles, respectively.

The carbodiimide activation is a convenient procedure for obtaining PNA adducts with other molecules. Thus the synthesis of hybrid PNA peptides containing biotin residues, which confer on PNA the ability to penetrate cell membranes efficiently, has been described.¹²⁹ The peptide fragment of the chimeric molecule was prepared using a standard peptide synthesis protocol,¹³⁰ while the synthesis of the PNA fragment was carried out manually, using the Boc strategy based on the methods described in the classical work by Nielsen.⁹⁴ The activation with DCC was performed in the presence of 1-hydroxybenzotriazole, using a fivefold excess of a PNA monomer. The condensation was performed at an elevated (37 °C) temperature to increase the yield of the target product.¹²⁹

In other examples of the synthesis of hybrid PNA–peptide molecules,⁴⁹ the Boc protocol was combined with carbodiimide activation.^{94, 129} Such an approach to the preparation of chimeras is justified, since it ensures complete compatibility of syntheses of both the peptide and PNA fragments of the hybrid molecules⁴⁹ and overall yields of target products of no less than 50%.⁴⁹

A combined use of carbodiimide activation with the Boc/acyl protocol common in peptide synthesis,¹³⁰ allows one to obtain both classical PNA molecules with *N*-(2-aminoethyl)glycine backbones and molecules with non-canonical backbones containing

optically active monomeric fragments where the glycine residues are substituted by other amino acids, *e.g.*, lysine, serine, isoleucine and glutamic acid.¹³¹ Incorporation of D-lysine-based monomers into PNA oligomers increases the stabilities of PNA–DNA and PNA–RNA duplexes. With other amino acids, the stabilities of these types of duplexes are usually low.¹³¹

In some cases, such as in the synthesis of PNA–peptide chimeras and thymidine PNA oligomers, the activated esters and carbodiimide methodologies are employed. Sometimes, the yields of condensation products prepared by the activated esters (PFP) method even exceed those obtained by *in situ* activation.⁹⁷

Nonetheless, it is generally acknowledged¹² that PNA synthesis based on the use of *in situ* activation reagents, *viz.*, uronium and phosphonium salts, is the most reliable approach, since it ensures higher yields of the condensation products. This approach has considerably been developed in the recent years and it is this procedure that offers the broadest opportunities for the synthesis of PNA and their derivatives.

2. *In situ* activation by reagents based on uronium and phosphonium salts

The most popular activating reagents for PNA synthesis are *O*-(benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), (benzotriazol-1-yloxy)tris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP), *O*-(benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU), *O*-[(ethoxycarbonyl)cyanomethylideneamino]-1,1,3,3-tetramethyluronium tetrafluoroborate (TOTU) and (benzotriazol-1-yloxy)-tris(dimethylamino)phosphonium hexafluorophosphate (BOP), although other reagents are also known.

Since condensation strongly depends on the strategy used for PNA synthesis, in the first place, on the combination of protective groups, it seems expedient to classify the data on the *in situ* activation into three groups corresponding to Boc, Fmoc and MMT strategies.

a. The Boc strategy

The Boc/Z-modification of the Boc strategy is a classical approach to PNA synthesis. The dependence of the condensation efficiency of the Boc/Z strategy on different factors has been studied in sufficiently great detail.⁹⁴ This strategy makes it possible to obtain high yields of PNA containing > 15 units with all the four types of

heterocyclic bases. The use of the carbodiimide activation procedure for the synthesis of such oligomers is usually less efficient.⁹⁴

Studies of the effects of various factors, such as the nature of activating reagents, solvents, monomer concentrations, the nature of the organic base (tertiary amine), catalysts, *etc.*, on the efficiency of condensation in the *in situ* activation revealed that all of them are important for the optimisation of condensation conditions.⁹⁴

Comparison of the efficiency of condensations under the action of some uronium activating reagents, *viz.*, the most popular reagents HBTU and TBTU and the relatively new reagents HATU and *O*-(1,2-dihydro-2-oxo-1-pyridyl)-*N,N,N',N'*-bis-(tetramethylene)uronium hexafluorophosphate (HDPU), revealed that the condensation was efficient in all the cases under study, but the yields of addition products were the highest with HBTU.^{94, 100}

It should be noted that these results are valid exclusively for a DMF–pyridine solvent system and for the concentrations of the PNA monomer and the base [diethyl(cyclohexyl)amine, DECHA] of 0.05 and 0.1 mol litre⁻¹, respectively. Under these conditions, the average yields of the condensation products were 92.2%–97.1% irrespective of the nature of PNA monomers. However, conditions can be selected where other activating reagents will be more efficient than HBTU, *e.g.*, in other solvent systems or in the presence of other bases. This suggests that condensation conditions are to be chosen for each activating reagent.

Comparison of the efficiencies of HBTU and PyBOP has demonstrated the former to be superior under identical conditions. The overall yields of PNA oligomers using HBTU and PyBOP activation were 61% and 40%, respectively, which corresponds to average yields of 97.1% and 94.7% in each step.^{94, 100} It is of note that this comparative study was carried out under conditions optimum for HBTU.

An important role in efficient condensation is played by the solvent system used. Thus in a DMF–pyridine mixture, the overall yield of the condensation product was 61%, whereas those in DMF or DMF–DMSO were 55% and 22%, respectively.⁹⁴ However, it was not indicated which monomers determined the lowest yields of PNA. Noteworthy, virtually none of the works cited in this review provide these data.

Studies of the dependence of the yield of a PNA oligomer on the nature of an organic base (tertiary amine) have shown that 4-dimethylaminopyridine (DMAP), DECHA, (dicyclohexyl)methylamine and (dicyclohexyl) ethylamine were as efficient as (diisopropyl)ethylamine (DIPEA) which is widely used in peptide synthesis.⁹⁴

The nature of the tertiary amine only slightly affected the yields of the condensation product (93.7%–95.3%). The condensation in the presence of DIPEA in the DMF–pyridine system is not optimum, since this amine reacts with the monomers to give insoluble salts. Better conditions for this reaction can be found. The condensation in the presence of DIPEA is efficient in MP–DMSO.

Studies of relationships between the yields of condensation products and concentrations of PNA monomers revealed that acceptable yields can be obtained when the monomers are used at concentrations no less than 0.1 mol litre⁻¹. At lower concentrations (0.05 mol litre⁻¹), the condensation proceeds as a rule too slowly resulting in the accumulation of side products from competing reactions.⁹⁴

Addition of catalytic amounts of DMAP and 1-hydroxybenzotriazole to the reaction mixture may have a negative effect on the efficiency of condensation, although it is known that their addition sometimes favours the formation of amide bonds.⁹⁴

The loading[†] of the polymeric support should not exceed 0.1–0.2 mol-equiv. g⁻¹, which is essential for the maximum yield

[†] Here, loading is expressed as the number of functional groups per unit surface area.

of the PNA oligomer. With a higher degree of loading, the efficiency of PNA synthesis is lower.^{94, 100}

The use of the Boc/Z strategy ensures high (99.4%) yields of target products with *in situ* activation (HATU) in the presence of DIPEA.⁹⁵ In this case, the reaction mixture must contain a large (e.g., sevenfold) excess of the PNA monomer with respect to loading of the polymeric carrier.⁹⁵ The amount of the activating reagent is usually reduced by 10%, while the tertiary amine is taken in a twofold excess with respect to the PNA monomer.⁸⁸

Acceptable yields are obtained with a fourfold excess of the PNA monomer and by activation with HATU (the amount of HATU is 0.9 mol-equiv. with respect to a monomer) in the presence of DIPEA and lutidine.⁴⁷ The use of a fivefold excess of PNA monomers and a tenfold excess of DIPEA makes it possible to increase the overall yields of PNA oligomers to 92%.¹⁷

Very often, the yields can be increased upon preactivation of PNA monomers. To this end, the PNA monomer is mixed and incubated with the activating reagent for several seconds before being loaded onto the column.^{95, 96, 109, 110, 113, 115, 116} Strictly speaking, here we do not deal with the *in situ* activation, however, the term '*in situ* activation' is conventionally related to the nature of the activating reagent rather than to the order of mixing of the reagents. It is of note that the methodology of preactivation does not imply the isolation of activated monomers. Usually, the amount of the activating reagent is 5%–10% smaller than that of the monomer.

Preactivation of PNA monomers by incubating them with the activating reagent for 2 min and condensation in an MP–pyridine mixture make it possible to obtain PNA oligomers in overall yields of 90%. Depending on the length and composition of sequences, the yields of PNA vary from 68% to 90%.⁸⁸

In a search for the most rational technique for PNA synthesis, an investigator has to select between a rapid and cheap synthesis with the use of a small excess of PNA monomers and low (but acceptable) yields and lengthy syntheses with large expenditures of expensive monomers and activating reagents, but giving nearly quantitative yields.

Attempts to specify the conditions for effective synthesis of PNA have been undertaken time and again.⁹⁵ Primary attention in the optimisation of PNA synthesis is usually given to such factors as the low cost and ease of synthesis of PNA monomers, nearly quantitative yields of condensation products, the simplicity and efficiency of the procedure for isolation of PNA oligomers from the reaction mixture after completion of the synthesis and the possibility to obtain chimeric DNA–PNA duplexes and ligand-containing PNA molecules.

Such a choice of optimisation parameters seems to be justified, however, other factors, such as reaction rate and economy, are no less important. Thus the rate of condensation should be high enough to minimise side reactions. The synthetic strategy should first of all be efficient and allow for economic expenditure of expensive PNA monomers and activating reagents. The latter factor is of crucial importance in large-scale syntheses of PNA.

While comparing the Boc/Z and the Boc/acyl strategies of PNA synthesis, preference is given to the latter, since it is thought to be more promising. Although the average yields of oligomers calculated per one condensation cycle are high in both cases, *viz.*, no less than 98% (Boc/acyl) and about 99% (Boc/Z), the yields of PNA oligomers in the case of the Boc/acyl synthetic strategy and conventional isolation procedure do not exceed 65% (relative to the support loading), and are as low as 20% according to the Boc/Z protocol.⁹⁵ In addition, the Boc/acyl strategy allows one to synthesise PNA–DNA chimeras and to prepare addition products of acid-labile ligands to PNA, which is inattainable in the case of the Boc/Z strategy.⁹⁵

The synthesis of thymidine PNA oligomers makes use exclusively of Boc-protection of 5'-terminal amino groups, since the thymidine PNA monomer does not require protection of the heterocyclic base.^{77, 79} Such oligomers are conveniently synthesised by manual techniques.⁷⁹ In this case, by analogy with

previously developed procedures,^{94, 131, 132} the Boc strategy is combined with HBTU activation in the presence of DECHA. This approach affords high yields of condensation products, but requires the use of a fourfold excess of PNA monomers.⁷⁹

The Boc strategy is also used in the synthesis of PNA oligomers containing modified units.^{131, 133–135} Thus PNA molecules may incorporate units containing anthraquinone and acridine residues.¹³³ Such oligomers are used to study the melting behaviour of hairpin-shaped PNA of high-molecular-mass PNA–PNA duplexes by fluorescence quenching (the so-called 'molecular beacon' method). High yields of condensation products are obtained. Its repeated condensation is used for the attachment of a modified PNA monomer followed by a non-modified monomer to PNA oligomers.¹³³

The Boc/Z method combined with HBTU activation^{94, 134} allows synthesis of PNA molecules with fluorescent labels at their N-termini.¹³⁴ Such PNA derivatives can be used for detecting specific NA sequences. The fluorescence of the label may increase more than 50-fold upon hybridisation of PNA with the complementary NA target in comparison with that of the free PNA.¹³⁴

The classical Boc/Z strategy is also used for the synthesis of PNA chimeras containing clusters of modified fragments, *e.g.*, those with positively charged, chiral backbones built up of D-lysine residues.¹³⁵ The presence of such fragments in PNA confers useful properties on the latter.^{131, 135} In contrast with ordinary PNA, chimeric PNA form exclusively antiparallel duplexes with DNA; their stability depends critically on the presence of mismatches. Even one mismatch decreases sharply the stability of hybrid duplexes. If a mismatch is located in the middle of clusters containing three modified residues, ten-membered PNA–DNA duplexes are unstable even at 15 °C ($\Delta T_m = 28$ °C). Such PNA can serve as the basis for the development of genetic diagnostic tools, particularly, for the detection of point mutations.

Synthesis of these PNA derivatives by the Boc strategy combined with HBTU activation in the presence of DECHA,^{131, 136} affords chiral oligomers in overall yields of 80%–90%,¹³⁵ and optical purity of no less than 90%.

In the majority of cases, the Boc protocol includes the use of standard polymeric supports containing (4-methylbenzhydryl)-amino groups (MBHA).^{11, 131, 132, 135, 136}

PNA oligomers are cleaved from the solid phase by treatment with $\text{CF}_3\text{COOH} - \text{CF}_3\text{SO}_3\text{H}$.^{11, 131, 136}

The Boc strategy allows the use of various activating reagents including BOP.¹³⁷ The use of BOP and DIPEA as a base affords high yields of condensation products in various solvent systems, *e.g.*, DMF– CH_2Cl_2 and DMF–DMSO. In this case, the use of a twofold excess of PNA monomers is sufficient, but each condensation reaction should be repeated in order to provide more efficient binding of the monomers.¹³⁷

PNA can also be synthesised using the Boc/Z strategy combined with the *in situ* activation with TBTU in DMF–pyridine¹¹³ as described in the classical work of Nielsen.⁹⁴ However, it is more expedient to carry out the condensation in DMF in the presence of a twofold excess of DECHA as a base with respect to the monomer. This is associated with the good solubility of PNA monomer salts formed in DMF.¹¹³ The use of a threefold excess of PNA monomers is optimum. This approach allows one to use 2-amino-6-benzoyloxypurine with the non-protected amino group as a guanine precursor.¹¹³ The side reaction (capping) of the oligomeric chain can be avoided if the amount of TBTU is 10%

less than that of the PNA monomer¹¹³ or if the PNA monomer is subjected to 5-min preactivation.⁹⁶

Capping of oligomeric chains occurs both in PNA and peptide synthesis¹²³ provided the free activating reagent is present in the reaction mixture. This is possible owing to the fact that the terminal amino group of the peptide following deprotection reacts with both the activated amino acid derivative and the activating reagent.¹²³ Thus in the presence of an excess of HBTU, the tetramethylguanidine derivative was formed, which did not undergo subsequent elongation of the peptide chain.¹³⁸ This side reaction can be avoided if the amount of the activating reagent is smaller (by 5%–20%) with respect to the monomer.¹¹³

With TBTU as the activating reagent, another side reaction, *viz.*, the *N*-acyl transfer, can take place.^{94, 113, 123} To avoid this, neutralisation *in situ* is used.¹²³ In this case, condensation is carried out in the presence of a base without preliminary neutralisation of the 5'-terminal primary amino group of the oligomer.¹¹³ The efficiency of condensation is monitored by HPLC analysis of aliquots obtained by appropriate treatment of a small portion of a polymeric carrier (3–5 mg) following attachment of the next monomeric unit.¹¹³

In the synthesis of thymidine PNA oligomers based on the use of the Boc strategy and TBTU activation, a decrease in the yields of condensation products is observed sometimes after addition of the first 3–4 monomeric fragments.¹¹³ This leads to the accumulation of short chains, whereas the overall yield of PNA does not exceed 30% (in the case of a 10-membered oligomer). The same problem sometimes arises with HATU activation, presumably, due to aggregation of growing thymidine PNA oligomers. This can partly be overcome through the attachment of lysine residues at the C-ends of PNA chains, which prevents the interchain aggregation of the oligomers formed.

It is noteworthy that the synthesis of heterogeneous PNA oligomers containing monomeric fragments of all the four types is not accompanied by significant reduction of product yields in the PNA synthesis.¹¹³ In this case, the yield over each condensation step reaches 97%, which corresponds to 66% overall yield of the target 16-membered oligomer.

Similar problems, *viz.*, aggregation of PNA chains, may arise during the removal of protective Z groups after completion of PNA synthesis resulting in a significant decrease in the yields of PNA.^{11, 113} A crucial role in this process belongs to complementary interchain and intramolecular coupling of PNA oligomers. Even four-membered PNA–PNA duplexes significantly hinder post-synthetic work-up of PNA oligomers.¹¹³ Therefore, oligomeric PNA sequences should be analysed for the possibility of intramolecular hairpin and intermolecular cluster formation prior to the synthesis. It was found that the overall yields of PNA can be increased to 75% and even more through incorporation of a lysine residue into PNA heterooligomer, since the charged ϵ -amino group of lysine partly prevents the aggregation of PNA chains.

These data suggest that the efficiency of synthesis of PNA oligomers strongly depends on the properties of PNA sequences to be prepared irrespective of the synthetic procedure used.¹³⁹ Theoretically, PNA may contain any combination of monomers, while the synthesis of certain sequences in quantitative yields faces difficulties. Thus the attachment of a purine monomer to an oligomeric PNA sequence containing a 5'-terminal purine base is problematic. Therefore, if PNA containing purine clusters are to be synthesised, the synthetic protocol should include repeated condensations.¹³⁹ The lowest yields were obtained in the synthesis of PNA oligomers containing several consecutive guanine residues.

In conclusion, it may be said that the Boc strategy can be implemented in both manual and automated variants.¹³⁹ Although the former seems to be rather efficient and inexpensive,¹⁴⁰ automated synthesis using peptide and oligonucleotide synthesisers holds especially great promise.¹⁴¹ The reason is that the manual synthesis of PNA is not only lengthy and laborious, but also needs large-scale synthesis (not less than 5 mmol) in order to obtain acceptable yields of condensation products.

b. The Fmoc strategy

It is generally recognised that the Fmoc strategy of PNA synthesis^{14, 77, 96, 100–106, 114} requires milder conditions than the Boc strategy.¹² In particular, no treatment of PNA oligomers with strong acids before and after synthesis is necessary. This allows the use of other protective groups for exocyclic amino groups of heterocyclic bases of the PNA monomers. Correspondingly, the Fmoc strategy affords higher degrees of purity of reaction mixtures and higher overall yields of PNA oligomers. The Fmoc/acyl strategy of PNA synthesis is especially promising,^{77, 104, 105} since it can also be used for the synthesis of PNA–DNA and PNA–peptide chimeras.

Various versions of the Fmoc strategy are currently known. Thus Bhoc protection of heterocyclic bases of the PNA monomers and HATU activation allows automated synthesis on oligonucleotide synthesisers.¹⁰⁶ The use of a DIPEA–lutidine mixture seems to be more effective than the use of only one base, since it affords higher yields of the condensation products.¹⁰⁶

DMF is a suitable solvent for the Fmoc condensation, and HATU is one of the most potent activating reagents.¹⁴¹ However, in this case, too, the synthesis of individual PNA oligomers may face problems related to non-efficient condensation.¹⁴¹ Thus the synthesis of PNA oligomers with sequences containing several identical consecutive heterocyclic bases (not necessarily purines) yields short-chain products. This problem can partly be overcome through the use of repeated condensations.¹⁴¹

Two condensation cycles are carried out in the following cases: in the synthesis of sequences containing four or more identical consecutive residues after attachment of two or three identical PNA monomers to the oligomer, in the synthesis of PNA oligomers containing purine clusters and in the synthesis of 18-membered and more extended PNA oligomers independent of the composition of the sequence after the attachment of the 17th residue.¹⁴¹

The yields of PNA obtained using the Fmoc strategy and HATU activation vary from 26% to 38%.¹⁴¹ In some cases, the overall yields of PNA oligomers do not depend on the sequence lengths but are determined by the efficiency of the attachment of the first PNA monomer to the polymeric support, since the yield of the first condensation product can be lower than the yields of the products obtained in subsequent condensations.¹⁴¹

In the majority of cases, reversed phase HPLC is used for the analysis of reaction mixtures and isolation of target products under conditions for the separation of peptides rather than oligonucleotides.¹⁴¹ The condensation efficiency of the Fmoc strategy can also be estimated spectrophotometrically by measuring UV absorption of a product formed upon removal of Fmoc groups by piperidine in the range of 256–301 nm. This method is especially convenient for stepwise monitoring of PNA oligomerisation.⁹⁷

Thus, the Fmoc strategy can be used for the synthesis of PNA oligomers unattainable by other methods. This procedure allows modifications to the synthetic protocol aimed at increasing the yields of condensation products in separate synthetic cycles.¹⁴¹

The low efficiency of the condensation encountered in the Fmoc strategy of PNA synthesis seems to have the same reasons and solutions as those in peptide synthesis.¹⁴² It is known that many problems of automated solid-phase peptide synthesis are related to the nature of the sequence to be synthesised.¹⁴² Low condensation yields are due to the formation of bulky spatial peptide structures, which may interfere with the formation of amide bonds.

Those peptide chain fragments which are susceptible to interchain aggregation, can also decrease the accessibility of the amino group and thus prevent further elongation of the chain.¹²⁰

Spatial hindrances appear in the course of PNA synthesis which decelerate the removal of protective Fmoc groups from the 5'-termini of PNA oligomers and decrease the efficiency of subsequent condensation.¹⁴³

The synthesis of purine-rich PNA presents a special problem. If a PNA sequence contains more than two consecutive purine residues, the efficient attachment of the next purine monomer requires a longer reaction time and repetition of the condensation procedure three or four times. The attachment of the guanine monomer to the 5'-terminal guanine unit proceeds at a very slow rate.

Aggregation of PNA chains is the main reason for low condensation efficiency inherent in both Fmoc and Boc strategies. The synthesis of partly or fully self-complementary sequences may produce problems relevant to intrachain association of PNA oligomers. In addition, the solid-phase synthesis conditions favour intermolecular aggregation of growing oligomers. Thus purine-rich PNA and thymidine PNA oligomers (both four-membered and more extended ones) are prone to aggregation.

The condensation efficiency strongly depends on such factors as the loading of the polymeric support and the composition of the solvents. Thus, low densities of oligomers 'growing' on solid supports favour solution of the problem of intermolecular aggregation of PNA chains, whereas certain solvents prevent inter- and intramolecular aggregation of PNA molecules (*e.g.*, the formation of hairpin structures) and ensure effective diffusion of reagents to the N-termini of the growing PNA chains.

Studies aimed at optimisation of conditions for PNA synthesis are currently under way, since no ideal method for PNA synthesis has been developed so far. The Fmoc/acyl strategy of PNA synthesis seems to be the most advanced one, since it permits one to obtain oligomers of virtually any composition in high yields.^{104, 115}

Thus the synthesis of thymidine PNA oligomers by the Fmoc/acyl method combined with HATU activation requires only small (twofold) excess of the monomer¹¹⁵ and a 20% deficiency of the activating reagent. It is more expedient to use MP as a solvent and the DIPEA–lutidine mixture as a base. Preactivation of PNA monomers for 2 min is yet beneficial. The yield of the condensation product in each step is 85%–90%, the condensation time is 30 min and the overall yields of the 7-membered oligomer is no less than 50%.¹¹⁵ The efficiency of the reaction is most conveniently monitored spectrophotometrically.

Attempts have been made to optimise condensation conditions in solution using mixtures of PNA monomers and amino acid esters as model systems.¹¹⁵ Direct application of the data obtained in these model systems to solid-phase PNA synthesis is questionable, since the optimum conditions for the synthesis in solution and on polymeric supports may differ in principle. This circumstance should be taken into consideration when selecting model systems. On the other hand, these studies sometimes give valuable results.

The yields of condensation products in the reaction of PNA monomers with L-phenylalanine *tert*-butyl ester were not lower than 95% irrespective of the nature of the activating reagent (HATU or HBTU in the presence of 1-hydroxybenzotriazole), of the tertiary amine (*N*-methylmorpholine, lutidine or the DIPEA–lutidine mixture) and of the solvent (DMF or MP). The nature of the base and the activating reagent did not influence the efficiency of the reaction. The best result was obtained in the case of HATU activation in the presence of lutidine in DMF.¹¹⁵

As mentioned above, the overall yields of PNA oligomers may depend on the efficiency of attachment of the first monomer to the polymeric support. Thus the yield of the attachment product of the first cytosine monomer to the polymeric support (Tentagel) in the synthesis of heterogeneous PNA by the Fmoc/acyl strategy combined with conventional HBTU activation in the presence of 1-hydroxybenzotriazole and lutidine did not exceed 50%,¹¹⁵ whereas those obtained in subsequent condensation steps were no less than 80%. The efficiency of attachment of the first PNA monomer can be increased to 80% and even higher using repeated condensation. In this case, the time for each condensation can be reduced.¹¹⁵ Low yields of the attachment products of the first

monomeric unit to a polymeric support have also been reported.¹⁴¹

The best conditions for the PNA synthesis by the Fmoc/acyl strategy include the use of a twofold monomer excess (0.125 mol litre⁻¹), preactivation with HATU (0.8 mol-equiv.), DIPEA and lutidine (1–2 min), condensation (20 min) and repetition of the condensation procedure in each (with the exception of the first) reaction cycle. This provides an overall yield of heterogeneous PNA of 43% (for 16-membered oligomers), which corresponds to the average yield of the condensation product of 95% (in this case, the attachment of the first monomeric fragment occurs with high yield). The main disadvantage of this method is the necessity to repeat the condensation procedure in each cycle.¹¹⁵ The expedience of this approach is doubtful despite its obvious advantages, *viz.*, good reproducibility of experimental results.

c. The MMT strategy

This strategy of PNA synthesis is rather promising^{38, 96, 107–112, 116, 144, 145} particularly its MMT/acyl version,^{96, 107, 110, 116} which is fully compatible with oligonucleotide synthesis protocols. It allows the use of automatic DNA synthesisers without modification of their design or software, which is especially convenient for conducting the syntheses of PNA–DNA chimeras.

The MMT strategy allows the use of a broad range of activating reagents,^{38, 112, 144, 145} including mesitylenesulfonyloxybenzotriazole (TMSOBT)¹¹² and 3,4,6-triisopropylbenzenesulfonyloxybenzotriazole (TPSOBT).¹⁴⁴ The latter gives higher yields of the condensation products (the average yield in one cycle reaches 96%) than the commercially available activating reagent PyBOP.^{112, 144} Depending on the nature of the PNA monomer and the 5'-terminal oligomeric fragment, the yield in each condensation step varies from 91% to 99%.¹⁴⁴

The efficiency of condensation carried out by the MMT strategy can be estimated spectrophotometrically by measuring UV absorption spectra of the MMT⁺ cation formed upon removal of the protective MMT group from the 5'-terminal amino group of a PNA oligomer. The MMT strategy combined with TPSOBT activation is compatible with oligonucleotide synthesisers.¹¹² This approach was first used in the synthesis of PNA molecules containing uracil residues.¹¹² The 'manual' variant of the MMT strategy is also effective, *e.g.*, in the synthesis of thymidine PNA oligomers.³⁸

The use of PyBOP as an activating reagent allows one to reach 95%–99% yields in each step of the monomeric fragment coupling.⁹⁶ However, in this case, the use of concentrated (0.3 M) solutions of PNA monomers and PyBOP is necessary. It is more expedient to use *N*-ethylmorpholine as a base and to perform preactivation of PNA monomers.⁹⁶

The MMT strategy is used for the synthesis of phosphonate analogues of PNA (pPNA).^{110, 116, 146, 147} The presence of negatively charged groups in the pPNA backbone makes PNA analogues readily soluble in aqueous solutions in comparison with classical PNA oligomers. These molecules bind specifically to complementary fragments in DNA and RNA, although the melting temperatures of pPNA–NA complexes are somewhat lower than those of the corresponding PNA–NA complexes.

A combination of the MMT/acyl protocol with triisopropylbenzenesulfonylnitrotriazole activation is efficient in the synthesis of pPNA.^{110, 116, 146, 147} The condensation in the presence of *N*-methylimidazole as a nucleophilic catalyst permits one to obtain the average yields of 95% in the condensation step with a reaction time of 10 min.^{110, 116} However, the quantitative overall yields of condensation products are not achieved, although the use of dilute solutions of PNA monomers (0.05 M) and the activating reagent (0.06 M) together with preactivation (mixing of the PNA monomer with the activating reagent and *N*-methylimidazole), makes this procedure attractive.^{110, 116}

3. Some peculiarities of the synthesis of PNA–DNA chimeras

The interest in PNA–DNA chimeras has arisen in the past decade, which gave a strong impetus to the development of methods for their synthesis.^{77, 109, 111, 144, 148–150} The use of classical PNA in biochemical studies is limited due to their poor solubilities in aqueous solutions, proneness to self-aggregation^{4, 12, 34} and low penetrability through cell membranes.^{4, 9, 84, 151} The latter is the main obstacle for the use of canonical PNA oligomers as antisense agents *in vivo*.⁹

Chimeric PNA–DNA molecules are devoid of most of these drawbacks. They possess all the advantages of PNA together with valuable properties inherent in NA. Indeed, the PNA–DNA chimeras synthesised so far combine high biological stabilities, high affinities and selectivities of binding to NA targets typical of PNA with perfect solubilities and the ability to activate hydrolysis of RNA targets by RNase H, which are characteristic of DNA.^{9, 34} Chimeric PNA–NA molecules have various applications, *viz.*, they are promising therapeutic (including antisense) drugs⁹ and can be used as a basis for highly effective diagnostic tools and highly sensitive biomolecular probes.^{77, 96, 107–109, 144, 148, 149} Synthesis of hybrid PNA–NA molecules manifests specific features, which necessitates a consideration in a separate section.

The correct choice of linkers between PNA and DNA fragments of the chimeric molecules is one of the most important problems. Depending on whether the 5'-terminal fragment of the hybrid molecule belongs to PNA or DNA, the linker used is represented either by modified nucleosides (*e.g.*, 5'-amino-2',5'-dideoxynucleosides^{77, 149}) or modified PNA monomers [*e.g.*, *N*-(2-hydroxyethyl)glycine derivatives].¹⁴⁸

Syntheses of both types of PNA–DNA hybrids, *viz.*, 5'-PNA–DNA-3' and 5'-DNA–PNA-3', have been described. Owing to the charged backbones of their DNA fragments, PNA–DNA chimeras are perfectly soluble in aqueous solutions, which makes possible their isolation and analysis by standard methods, such as polyacrylamide gel electrophoresis and ion-exchange reversed phase HPLC.¹⁰⁸

In the case of 5'-terminal PNA fragments, PNA and DNA fragments are linked by the amide bond and 5'-amino-2',5'-dideoxynucleosides are used as linkers.⁷⁷ Such hybrid molecules are synthesised by various methods. Thus 5'-PNA–DNA-3' hybrids are prepared according to Boc/Z protocols commonly used in the synthesis of PNA-peptide conjugates.¹⁵² However, the use of this technique for the synthesis of PNA–DNA chimeras containing purine nucleotide residues may result in acid-catalysed apurination of the DNA fragment during deprotection of heterocyclic bases of PNA.⁷⁷ Therefore, this approach is used exclusively for the synthesis of PNA–DNA hybrids the DNA fragments of which contain more stable pyrimidine nucleotides, whereas 5'-PNA–DNA-3' chimeras are more efficiently synthesised using the Fmoc/acyl strategy.⁷⁷

If hybrid molecules contain 5'-terminal DNA fragments, the PNA and DNA parts can be linked by phosphoramidate bonds without any linkers. In this case, the synthesis of PNA fragments is carried out using the Fmoc/acyl protocol. With the thymidine monomer, Boc-protection of the 5'-terminal amino group is possible. The activation is performed with HATU in the presence of DIPEA and DMAP; the condensation is carried out in DMF. In this case, the use of acid-labile groups for protection of heterocyclic bases of PNA monomers is inadmissible because of easy acid hydrolysis of phosphoramidate bonds.⁷⁷

The synthesis of PNA fragments of such chimeric oligomers usually employs the MMT/acyl strategy. In this case, the conditions of PNA synthesis are compatible with those of oligonucleotide synthesis;^{36, 149} PNA fragments can be synthesised by manual techniques. The condensation is performed in the DMF–pyridine mixture with 2-[2-oxo-1(2*H*)-pyridyl]-1,1,3,3-bis(pentamethylene)uronium tetrafluoroborate (TOPPipU) as the activating reagent and DECHA as the base.¹⁵³ Under these conditions, the condensation of thymidine and cytidine PNA monomers proceeds smoothly, purine monomers are attached inefficiently to the growing PNA chain.¹⁴⁹ If HATU is used as the activating reagent, DIPEA as the base and acetonitrile as the solvent in the presence of a fivefold excess of PNA monomers (necessary to attain high yields of condensation products), the reaction time is no less than 15 min.³⁴ This method was used for the synthesis of chimeric molecules containing 5-bromouracil and 5-methylcytosine residues.³⁴ The incorporation of 5-methylcytosine residues into the PNA chains of chimeric molecules increases the stabilities of their duplexes and triplexes with complementary DNA.³⁴

The modified thymidine PNA monomer based on *N*-(2-hydroxyethyl)glycine^{34, 107, 148} is often used as a linker between DNA and PNA fragments of chimeric molecules of the 5'-DNA–PNA-3' type; the latter can be synthesised using both Boc¹⁴⁸ and MMT strategies.^{34, 107} If the Boc/Z strategy is used, the PNA synthesis is carried out on a solid phase; the linkers are attached under the same conditions.¹⁴⁸ Subsequent synthesis of DNA fragments of hybrid molecules should also be performed on the solid phase. It is inadmissible to perform the synthesis of DNA fragments in solution, since the solubility of PNA oligomers devoid of protective groups in organic solvents is insufficient to provide efficient condensation with phosphoroamidite derivatives of nucleosides.¹⁴⁸

The solid-phase MMT method is more suitable for the synthesis of the 3'-PNA fragments; after completion of PNA synthesis, solid-phase synthesis of the DNA fragment is continued without detachment of the oligomer from the support. This prevents the use of PNA monomers the heterocyclic bases of which are protected by acid-labile groups, since the DNA fragments will not withstand acid treatment used to remove protective groups. This synthetic procedure is inapplicable to chimeric molecules containing PNA monomers of all the four types, but can be used for the synthesis of hybrid molecules with the pyrimidine monomers constituting the PNA fragments.¹⁴⁸

The MMT/acyl modification of this method is devoid of these disadvantages and allows the synthesis of PNA–DNA hybrids containing all the four types of nucleobases in both DNA and PNA fragments.^{108, 109, 150}

The MMT/acyl strategy allows the application of the fully automated protocol on oligonucleotide synthesisers. The DNA fragments of hybrid molecules are usually synthesised according to a conventional phosphoroamidite protocol, which makes use of commercial 2'-deoxynucleoside phosphoroamidites.¹⁰⁸ This method of synthesis of PNA–DNA chimeras has practically no drawbacks.^{108, 150}

The synthesis of PNA fragments of 5'-PNA–DNA-3' oligomers may involve HBTU activation in the presence of DIPEA in DMF–acetonitrile.¹⁵⁰ Solutions of PNA monomers and activating reagents should be used at concentrations of no less than 0.1 M (preferably, 0.2 M); preactivation is also desirable. A commercially available aminohexanol phosphoroamidite derivative can be used as a linker between the PNA and DNA fragments; this is attached to the 5'-end of a DNA fragment by a standard oligonucleotide synthesis protocol. Then the synthesis of a 5'-terminal PNA fragment of a chimeric molecule is followed.¹⁵⁰

The MMT/acyl strategy is used in the synthesis of chimeric molecules with the composition 5'-PNA–DNA–PNA-3'.¹⁰⁹ In this case, both PNA fragments are synthesised in an automated regime using HBTU activation in the presence of DIPEA in DMF–acetonitrile mixture; this may require an eightfold excess

of the reagents with respect to the carrier loading. Preactivation of PNA monomers makes it possible to increase the condensation efficiency and the average yields in the attachment of monomeric fragments up to 96%.¹⁰⁹

Obviously, the problem of efficiency of each individual approach to the synthesis of PNA molecules has no unambiguous solution. The choice of the most adequate strategy for the PNA synthesis depends on the goal and facilities as well as on the number of PNA oligomers to be synthesised, the scale of synthesis, composition and purity of PNA oligomers.

VIII. Conclusion

The design of the most efficient method for the synthesis of PNA oligomers requires that a rational compromise between the efficiency and economy of the synthetic process be found.

On the one hand, one has to reach the maximum yields of condensation products and the choice of synthetic strategy must take into account both the nature of the activating reagent and other factors discussed in this review.

On the other hand, the synthesis of PNA should be rational. This implies that the synthetic procedure should not only be efficient, but also fast and as cheap as possible. Examples of both the approaches to PNA synthesis have been presented in this review.

In low-budget laboratories, where the primary goal is economic PNA synthesis, it is the 'slow' synthesis that is most commonly used. Although this procedure is rather laborious, it gives excellent yields in the condensation step.

'Fast' processes are utilised in the majority of large biotechnological companies which manufacture PNA oligomers for commercial purposes. Here, large excesses of PNA monomers and the most potent activating reagents are employed in order to ensure high yields of the condensation products. However, quantitative yields cannot be attained due to a reduction of the condensation time; therefore, pure PNA oligomers can be obtained by virtue of complex isolation procedures.

The most rational synthetic strategies combine the best features of both approaches, viz., the 'fast' and the 'slow' syntheses of PNA.

Oxygen compounds of halogens X_2O_2 (X is a halogen atom)

I V Nikitin

Contents

I. Introduction	85
II. Dioxygen difluoride and related compounds	85
III. Chlorine oxides Cl_2O_2	88
IV. Bromine and iodine oxides	92

Abstract. The results of studies on the structure and properties of the O_2F_2 , Cl_2O_2 , Br_2O_2 and I_2O_2 molecules and the FOO , $ClOO$ and $BrOO$ radicals obtained mainly in the past decade are surveyed. The bibliography includes 173 references.

I. Introduction

Compounds of the general formula X_2O_2 pertain to the class of high-energy compounds. Representatives of this class are thermally unstable and are characterised by low binding energies. Some of them are the most potent inorganic oxidants.

In my book¹ published in 1986 and devoted to the oxygen compounds of halogens, compounds with the general formula X_2O_2 were represented by only dioxygen difluoride O_2F_2 . Moreover, it was mentioned that this compound has no Cl -, Br - and I -analogues. Such a conclusion was drawn based on the fact that in the mid-80's, the works which admitted the existence of Cl_2O_2 were few, and virtually none dealt with Br_2O_2 and I_2O_2 . However, in recent studies on atmospheric chemistry it was reported that halogen oxides X_2O_2 (and halogen atoms, particularly, those of chlorine and bromine) are involved in depletion of stratospheric ozone. This fact has attracted the attention of researchers to these compounds, and new information appeared on this class of compounds, which allowed the X_2O_2 oxides to be characterised in more detail. Thus, this review supplements the book.¹

It should be noted that, as for other halogen–oxygen compounds, the distinctions between the structures and properties of X_2O_2 oxides override their similarities.

II. Dioxygen difluoride and related compounds

1. Dioxygen difluoride

Dioxygen difluoride exists only at low temperatures (m.p. = 119 K, b.p. = 216 K). It was obtained for the first time in 1933 by Ruff and Menzel² upon action of an electric discharge on a fluorine–oxygen mixture. The most probable mechanism of O_2F_2 formation is as follows:

Inasmuch as the synthesis of O_2F_2 was described in detail in the book,¹ this issue will not be discussed here.

Jackson³ established the structure of the O_2F_2 molecule in 1962 by using the method of microwave spectroscopy (MW). The dioxygen difluoride molecule was shown to represent spatially skewed chains of atoms $F-O-O-F$ with C_2 symmetry. This structure was confirmed later by electron diffraction (ED).⁴ Table 1 shows the bond lengths (r) and bond and torsion angles in the O_2F_2 molecule.

Being formally close to the hydrogen peroxide structure, the molecular structure of dioxygen difluoride, however, differs substantially in its details. For instance, the $O-O$ bond length in the H_2O_2 molecule is 1.48 Å, which is close to that of a single bond, whereas the bond length in the O_2F_2 molecule suggests a double-bond nature, being similar to the bond length in the O_2 molecule and the O_2^+ cation (1.208 and 1.12 Å, respectively, according to the data from Ref. 7). Thus, the following resonance structure was proposed for the O_2F_2 molecule:

Calculations of the structure of O_2F_2 molecules by the local density functional (LDF)⁵ method provided good agreement with the experimental⁵ data: the calculated $O-O$ and $O-F$ bond lengths differed from those found experimentally by no more than 0.01 and 0.015 Å, respectively (see Table 1). The geometrical parameters of the $FOOF$ molecule calculated using the Becke–Perdew–Wang B3PW91 functional⁶ fit less the experimental data, and the Hartree–Fock theory usually applied in calcula-

Table 1. Geometrical parameters of the O_2F_2 molecule.

Parameter	Experimental data		Quantum-chemical calculations	
	MW ³	ED ⁴	LDF ⁵	B3PW91 ⁶
$r(O-O)/\text{\AA}$	1.217(3)	1.216	1.215 ^a	1.222
$r(O-F)/\text{\AA}$	1.575(3)	1.586	1.562 ^a	1.523
$F-O-O/\text{deg.}$	109.5	109.2	110.5 ^a	109.2
$FOO/OOF/\text{deg.}$	87.5	88.1	88.4 ^a	88.1
Rotation barriers /kcal mol ⁻¹	30		36–42	

^a A mean value is given (averaged from nine values calculated using different Gaussians).

Uspekhi Khimii 71 (2) 99–112 (2002); translated by T Ya Safonova

tions of geometrical parameters of molecules gave unsatisfactory results for dioxygen difluoride (see Ref. 5).

According to calculations,⁵ the internal rotation barrier in the O_2F_2 molecule is $\sim 36\text{--}42\text{ kcal mol}^{-1}$, which exceeds substantially the value of 30 kcal mol^{-1} suggested by Jackson³, the value of $20.83\text{ kcal mol}^{-1}$ determined by the CNDO/2 method¹ and the energy of the $\text{O}-\text{F}$ bond dissociation equal to 20 kcal mol^{-1} (see Ref. 8).

Vibrational spectra (IR and Raman) of dioxygen difluoride samples in both solid state and solution are described in the book,¹ and the IR spectrum of gaseous O_2F_2 was measured with an IR Fourier spectrometer in a multipass cell at 175 K (Ref. 9). The O_2F_2 molecule is characterised by six normal vibrational modes active in the IR spectrum, *viz.*, $\text{O}-\text{O}$ stretching (ν_1), $\text{O}-\text{F}$ stretching symmetrical (ν_2) and antisymmetrical (ν_3), $\text{O}-\text{O}-\text{F}$ bending symmetrical (ν_4) and antisymmetrical (ν_5) and also torsion (ν_6) modes. The most intense absorption bands were obtained at 1210 cm^{-1} (ν_1) and 615 cm^{-1} ($\nu_2 + \nu_3$ combination). The ν_1 frequency in the spectrum of gaseous O_2F_2 is 100 cm^{-1} lower as compared with the spectrum of matrix-isolated O_2F_2 . The IR spectral band of gaseous O_2F_2 observed at 1490 cm^{-1} was attributed to $\text{O}-\text{O}$ stretches of the O_2F radicals present in equilibrium with O_2F_2 . It was noted⁹ that the half-life of O_2F_2 at a temperature below 180 K exceeds 2 h .

An experimental value for the enthalpy of formation of dioxygen difluoride $\Delta H_{298}^\circ(\text{O}_2\text{F}_2) = 4.73 \pm 0.30\text{ kcal mol}^{-1}$ first determined in 1959¹⁰ was never refined. It should be noted that this quantity was calculated by different methods (Table 2) in quite a number of studies (see, *e.g.*, Refs 6, 11–15). In 1996, Chase¹¹ tabulated the recommended thermodynamic constants for oxygen halides (NIST–JANAF) based on spectroscopic and thermodynamic data published up to 1994 inclusive, and the value of $4.6 \pm 0.2\text{ kcal mol}^{-1}$ was proposed for the enthalpy of formation of dioxygen difluoride. Later, this value was argued against by Kieninger *et al.*⁶ who calculated the thermodynamic characteristics of oxygen fluorides by the density functional method. Using the B3PW91 functional, they have obtained good agreement between experimental and calculated enthalpies of formation of the OF , O_2F and OF_2 molecules (the largest deviation was observed for the OF molecule and amounted to $\sim 0.6\text{ kcal mol}^{-1}$ at 0 K). However, the same calculation method gave overestimated values for the enthalpies of formation of O_2F_2 , namely, 7.3 kcal mol^{-1} (at 298 K) and 9.0 kcal mol^{-1} (at 0 K).⁶ The value for 298 K exceeded the recommended one¹¹ by 64%. At the same time, the high value of 9.0 kcal mol^{-1} did not differ dramatically from the values $\Delta H_0^\circ(\text{O}_2\text{F}_2) = 8.2\text{ kcal mol}^{-1}$ estimated¹⁴ by using the B3LYP functional and $\Delta H_0^\circ(\text{O}_2\text{F}_2) = 8.7 \pm 0.2\text{ kcal mol}^{-1}$ calculated in Ref. 15. Although the difference in experimental and calculated enthalpies of formation of the FOOF molecules cannot be called a dramatic one, however, further studies should be performed in order to refine the experimental value for the enthalpy of formation of FOOF.

Table 2. The enthalpy of formation of the FOOF molecule calculated by different methods.

T/K	$\Delta H^\circ/\text{kcal mol}^{-1}$	Ref.
298.15	4.6 ^a	11
	4.5	12
	5.0	13
	7.3	6
0	9.0	6
	8.2	14
	8.7	15

^a This value is included in the recommended NIST–JANAF Thermochemical Table.

Dioxygen difluoride is a strong oxidative-fluorinating agent, which reacts over a wide range of low temperatures.

Thus, fluorination of ClF_3 by O_2F_2 occurs at 195 K to give chlorine pentafluoride in a quantitative yield.¹⁶ All the other methods of ClF_3 synthesis require much higher temperatures and pressures.¹⁷ Xenon is fluorinated by an excess of O_2F_2 to give a mixture of XeF_2 and XeF_4 at $153\text{--}195\text{ K}$, repeated treatment producing pure xenon tetrafluoride.¹⁸ Fluorination of actinides by O_2F_2 can be carried out at ambient and lower temperatures.¹⁹

Due to low $\text{O}-\text{F}$ binding energy, the dioxygen difluoride molecules and O_2F radicals behave as more efficient sources of the fluorine atoms as compared with molecular fluorine and rank below krypton difluoride only.²⁰

Synthesis of dioxygenyl salts in the reaction of O_2F_2 with fluorine-containing Lewis acids is among the most important preparative reactions of dioxygen difluoride.¹ Here, dioxygen difluoride is a source of O_2F radicals, which react with Lewis acids to give salts, *e.g.*, $\text{O}_2^+\text{AsF}_6^-$.

The radicals O_2F can be obtained from this salt by thermolysis

and used, *e.g.*, for the preparation of electronically excited and vibrationally excited ClF , BrF and IF molecules in their ground electronic states, which are employed in various spectroscopic studies (see Ref. 17 and references cited therein).

2. The O_2F radicals

The O_2F radicals are formed upon a low-temperature impact (photolysis, radiolysis, *etc.*) on systems containing fluorine and oxygen. Following stabilisation in low-temperature matrices, they can be studied by various spectral techniques.

Recently, Bartlett and co-authors²⁰ reported the possibility of regenerating O_2F radicals from dioxygenyl salts at low temperature. Solvated O_2F radicals were formed from the salts ($\text{O}_2^+\text{AsF}_6^-$, $\text{O}_2^+\text{SbF}_6^-$) dissolved in anhydrous HF in the presence of an alkali-metal fluoride by the reaction

A nonlinear O_2F radical represents a prolate asymmetrical rotor^{21,22} with the rotational constants $A = 78.4301$, $B = 10.013935$ and $C = 8.855247\text{ GHz}$. The ground state of the O_2F radical is X^2A'' ; the energy of the $^2A'$ state exceeds that of the ground state by $\sim 1.07\text{ V}$ (8630 cm^{-1}).²³ The asymmetrical OOF isomer is by 100 kcal mol^{-1} (according to Ref. 23) or 85 kcal mol^{-1} (according to Ref. 24) more stable than the symmetrical OFO isomer. In contrast to OOF, the OFO radical has never been observed experimentally.^{23,25} In addition, as compared with the OFO^+ cation, the FOO^+ cation is more energetically favourable. The FOO^+ ion represents a charge-transfer complex $\text{F}(\text{P})-\text{O}_2^+(\text{P})$, which dissociates readily to F and O_2^+ (see Ref. 26).

Internuclear distances $r(\text{O}-\text{O})$ and $r(\text{O}-\text{F})$ in the O_2F radical are 1.200 and 1.649 Å , respectively, and the $\text{F}-\text{O}-\text{O}$ bond angle is 111.2° , which is somewhat larger²⁵ than in the FOOF molecule. An increase in the $\text{O}-\text{F}$ bond length in the O_2F radical as compared with the O_2F_2 molecule agrees well with a decrease in the $\text{O}-\text{F}$ bond strength when going from O_2F_2 to O_2F . The $\text{F}-\text{O}_2\text{F}$ bond strength in dioxygen difluoride is $\sim 19.6\text{ kcal mol}^{-1}$ at 0 K .²⁷ In the O_2F radical, the fluorine atom is less strongly bound to oxygen: the dissociation energy is $11.7 \pm 0.5\text{ kcal mol}^{-1}$ (0 K).²⁸ Virtually the same value $11.9 \pm 0.2\text{ kcal mol}^{-1}$ (0 K) was obtained in calculations²⁷ from the third law of thermodynamics when studying the thermodynamic properties of the $\text{F} + \text{O}_2$ reaction mixture.

Like peroxy radicals,²⁹ dioxygen monofluoride strongly absorbs in the UV range ($200\text{--}300\text{ nm}$). The absorption

maximum for the O₂F radical was shown³⁰ to lie at 206.5 nm (the absorption cross-section $\sigma = 1.35 \times 10^{-17} \text{ cm}^2$), at 215 or 220 nm.^{27,28,31} At 298 K,³¹ intense absorption of the O₂F radical was observed at 215 nm with the absorption cross-section $\sigma = 1.15 \times 10^{-17} \text{ cm}^2$ (for O₂F₂ molecules, $\sigma = 4.2 \times 10^{-18} \text{ cm}^2$).³¹ At 300 K, the absorption maximum was observed at 220 nm, the absorption cross-section being equal to $1.3 \times 10^{-17} \text{ cm}^2$ (Ref. 28) and $1.6 \times 10^{-17} \text{ cm}^2$ (Ref. 27).

The IR spectrum of the O₂F radicals in the gas phase has been studied.^{21,26,32,33} Using an IR Fourier spectrometer (resolution of 0.003 cm^{-1}) and a cell with an optical path of 100 m, the vibrational spectrum of the O₂F radical was obtained with the most intense absorption bands at 579.32 (ν_3), 940.22 ($\nu_2 + \nu_3$), 1142.46 ($2\nu_3$), 1486.93 (ν_1), 1495.60 ($\nu_2 + 2\nu_3$) and 2948.09 ($2\nu_1$).²¹ All vibrational frequencies of gaseous O₂F appeared to be lower than those of matrix-isolated O₂F. The bending vibrational frequency ν_2 was in the range of $365\text{--}370 \text{ cm}^{-1}$. An attempt⁹ to resolve the rotational structure of the O–O stretching band has failed; however, this structure was eventually resolved.²¹ These results show that detachment of a fluorine atom from the O₂F₂ molecule results in a substantial increase in the O–O stretching mode frequency, the latter approaching a vibrational frequency of 1580 cm^{-1} for the O₂ molecule.

In spectrokinetic studies²⁸ of the equilibrium in the gas-phase reaction

in a temperature range of 295 to 359 K, the enthalpy of formation of the O₂F radical was found to be $\Delta H_{298}^\circ(\text{O}_2\text{F}) = 6.24 \pm 0.50 \text{ kcal mol}^{-1}$ (the radicals were generated by pulse irradiation of a gas mixture with electrons of 2 MeV energy). A kinetic study of the reaction of fluorine and oxygen atoms³¹ gave a value of $5.49 \pm 0.40 \text{ kcal mol}^{-1}$ (298 K). A later study²⁷ showed similar values for enthalpy (Table 3). Table 3 lists $\Delta H_0^\circ(\text{O}_2\text{F})$ values calculated using B3LYP¹⁴ and B3PW91⁶ functionals and the QCISD(T)/6-31G(*d,p*) method³⁴ (QCI is quadratic configuration interaction).

Generally, the O₂F radical behaves as a mere source of fluorine atoms rather than as a radical. Its relatively low reactivity is explained by the fact that abstraction of the F atom, which represents the active part of the radical, requires an activation energy of $\sim 12.6 \text{ kcal mol}^{-1}$ (Ref. 35). The O₂F radical is inert with respect to other peroxy radicals, whereas the HO₂ radical reacts quickly at room temperature with RO₂ with the rate constants lying within $(4\text{--}12) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Ref. 29).

Table 3. The enthalpy of formation of the O₂F radical.

<i>T</i> /K	$\Delta H_{\text{exp}}^\circ / \text{kcal mol}^{-1}$	$\Delta H_{\text{theor}}^\circ / \text{kcal mol}^{-1}$	Ref.
298	6.24 ± 0.50	—	28
	5.49 ± 0.40	—	31

	—	8.9 ± 3.0	34
	—	6.5 ± 0.5^a	11

^a This value is included in the recommended NIST–JANAF Thermochemical Table.

Solutions containing O₂F radicals are stable at temperatures $\leq 223 \text{ K}$. They can be used for oxidative fluorination. For example, Au(III) is oxidised to Au(V)

Similarly, the Ag(II) ions are oxidised to Ag(III), Ni(II) is oxidised to Ni(IV) and Pt(IV) is oxidised to Pt(V).

Controlled hydrolysis of a solution of a dioxygenyl salt in HF at 195 K represents a rare example of the chemical synthesis of ozone.³⁶

The same result was obtained with other available and handy dioxygenyl salts, *viz.*, fluoroantimonates O₂⁺SbF₆[−] and O₂⁺Sb₂F₁₁[−]. It was assumed³⁶ that the reaction of dioxygenyl O₂⁺ with a water molecule gives an O₂ molecule and an H₂O⁺ cation, the latter decomposing with elimination of H⁺. Hydroxyl formed upon the H₂O⁺ decomposition reacts with O₂⁺ producing protonated ozone OOOH⁺, which transforms into ozone upon elimination of H⁺.

The recent active studies on the properties of dioxygen difluoride and the O₂F radicals were partly associated with the hazards of atmospheric contamination by halogen-containing refrigerants and propellants that produce halogen atoms upon photolysis. The reactions of the fluorine atoms with methane, water and other hydrogen-containing compounds present in the atmosphere of Earth have low activation barriers³⁷ and result in HF, *i.e.*, stable reservoir molecules rained out of the atmosphere. However, the main mechanism for transformation of the fluorine atoms in the atmosphere is the reaction

(hereinafter M is any species), which produces the O₂F radicals. Moreover, due to a high oxygen concentration and a high rate of fluorine atom reaction with oxygen, the ratio of the equilibrium concentrations [O₂F] : [F] in the stratosphere may exceed 10^4 (see Refs 35, 38, 39). The radicals O₂F in turn can take part in catalytic cycles of ozone destruction^{36,38–41}

The efficiencies of the reactions of oxygen, water and methane with F atoms in the atmosphere depends on the altitude: at altitudes of 4–42 km, the reactions with oxygen resulting in O₂F₂ prevail; below 4 km and above 42 km, the reactions with H₂O and CH₄, which produce HF, are predominant.⁴² At altitudes above 28 km, photolysis of O₂F proceeds actively, which inhibits accumulation of these radicals.³⁹

The reaction of the F atoms with the oxygen molecules is not the only source of the O₂F radicals. The following reaction has been hypothesised:⁴³

which, however, cannot play any noticeable role due to the lower chlorine dioxide content in the atmosphere as compared with oxygen.

Studies of certain reactions of the O₂F radicals at 295 K by means of pulse radiolysis coupled with UV absorption spectroscopy have shown³⁵ that the reactivity of the O₂F radical is relatively low, the upper limits of rate constants of its reactions with O₃, CH₄ and CO being 3.4×10^{-16} , 4.1×10^{-15} and $5.1 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively.³⁵ Whence it follows that O₂F radicals pose no threat to the ozone layer.

The reaction

proceeds virtually completely by the channel

probably, *via* an intermediate complex ON–FO₂. The rate constant for the reaction (1) is $(1.47 \pm 0.08) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. The reaction

proceeds at 295 K with the rate constant $k_2 = (1.05 \pm 0.15) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Ref. 40). Kinetic studies of reactions (1) and (2) under continuous flow conditions using microwave electric discharge and mass spectrometry have confirmed their bimolecular mechanisms.³⁹ At a total pressure of 1 Torr, the following rate constants were obtained ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$):

$$k_1 = (7.5 \pm 0.5) \times 10^{-12} \exp\left(\frac{-688 \pm 377}{T}\right) \text{ at } 190 \text{ K} < T < 298 \text{ K}$$

and

$$k_2 = (3.8 \pm 0.8) \times 10^{-11} \exp\left(\frac{-2042 \pm 456}{T}\right) \text{ at } 260 \text{ K} < T < 315 \text{ K}.$$

At room temperature, the upper limits of the rate constants for the reactions of O_2F with O_3 and CH_4 were 3×10^{-15} and $2 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively.

3. Compounds HOOF and ClOOF

The HOOF and ClOOF molecules are of particular interest for atmospheric chemistry. A reaction of OF with OH may result in a compound HOOF, which is kind of hybrid between hydrogen peroxide and dioxygen difluoride. A non-empirical estimate⁴⁰ has shown that the HOO/OOF dihedral angle in a skewed HOOF molecule (the C_1 group of point symmetry) is $\sim 83^\circ$ and the internuclear distance $r(\text{O}-\text{O}) = 1.339 \text{ \AA}$, these values being intermediate between those in H_2O_2 and O_2F_2 molecules. The HOOF molecule can be sufficiently stable and decomposes to F and HO_2 species. The enthalpy of HOOF formation can be estimated by using the following isodesmic reaction:

and was found to be $0.4 \pm 2 \text{ kcal mol}^{-1}$ (at 0 K).

Chlorine fluorine peroxide ClOOF can be an intermediate in the reaction of radicals $\text{ClO} + \text{OF}$. An estimate⁴³ gave a value of 85.1° for the dihedral angle in the skewed ClOOF molecule. The enthalpy of formation of ClOOF at 300 K was assessed to be $36.8 \pm 2 \text{ kcal mol}^{-1}$ (Ref. 43) and $18.5 \text{ kcal mol}^{-1}$ (Ref. 13). The presence of a stronger bond F–O in the ClOOF molecule as compared with HOOF, allows one to assume that ClOOF decomposes to Cl and O_2F . Dissociation of ClOOF to F and ClO_2 is energetically less advantageous.^{13,43} The peroxide ClOOF is by 18 kcal mol^{-1} more advantageous with respect to energy than the chlorite FOCIO.¹³

III. Chlorine oxides Cl_2O_2

In contrast to fluorine which forms a single compound, *viz.*, dioxygen difluoride, chlorine oxides with the composition X_2O_2 are of greater diversity.

The first mention in the literature of a compound with the formula Cl_2O_2 dates back to 1949. In the ^{38}Cl radiotracer investigations of mechanisms of reactions of chlorine with chlorous acid, of the chloride ion with the chlorate ion and of chlorous acid disproportionation, each of these reactions was assumed⁴⁴ to involve an intermediate which had an asymmetrical structure of either ClClO_2 or ClOCIO and decomposed to ClO_2 .

Of all possible structures built of two chlorine atoms and two oxygen atoms which include three-membered and four-membered cycles, only chloryl chloride ClClO_2 (C_s symmetry), chlorine peroxide ClOOCIO (C_2 symmetry) and chlorine chlorite ClOCIO (C_1 symmetry) can exist. Among these isomers, ClOOCIO is the most stable one. Chloryl chloride ranks higher in the energy scale as compared with chlorine peroxide (by $0.9\text{--}5 \text{ kcal mol}^{-1}$ according to different estimates^{45–48}) and chlorine chlorite (by $7\text{--}10 \text{ kcal mol}^{-1}$, see Refs 45–49).

An estimate⁵⁰ of the Gibbs energy for an equilibrium mixture of all Cl_2O_2 isomers in the ideal-gas state has shown that at low

temperatures the ClOOCIO isomer prevails, whereas at higher temperatures the fraction of ClClO_2 increases.

Temperature, K	100	200	300
Fraction of ClClO_2	0.4	8.8	21.6
in a mixture of Cl_2O_2 isomers (%)			

The yield of chlorine chlorite at $T \leq 590 \text{ K}$ did not exceed 1%; however, its content in the mixture increased substantially with further increases in the temperature.

1. Chloryl chloride

Attempts to obtain chloryl chloride by the reaction of chloryl fluoride ClO_2F or chloryl perchlorate ClO_2ClO_4 with certain chlorine-containing compounds (NOCl , NO_2Cl , AlCl_3 , BCl_3 , HCl) were undertaken as early as in the 1950's (see, *e.g.*, Ref. 51), but resulted in formation of products of chloryl chloride decomposition, *viz.*, ClO_2 and Cl_2 in a 2:1 ratio. Only in 1992, could the fluorine atom in ClO_2F be exchanged for a chlorine atom from AlCl_3 , BCl_3 and HCl to give chloryl chloride in amounts sufficient for spectroscopic measurements; however, an attempt to isolate pure ClClO_2 has failed.⁵² Chloryl chloride was synthesised by passing ClO_2F over AlCl_3 under a pressure of $0.1\text{--}1 \text{ mbar}$, the product being collected at 77 K .⁵² The reactions of ClO_2F with BCl_3 and HCl also resulted in ClClO_2 , while the reaction of ClO_2F with NOCl afforded predominantly NO_2Cl .

In a different preparation of ClClO_2 , stoichiometric amounts of ClO_2F and HCl were mixed in a reactor and then the mixture was expanded into an absorption cell, the temperature in the reactor and the cell being kept at $\sim 255 \text{ K}$.⁵³ Chloryl chloride was also formed in the reaction of photochemically generated chlorine atoms with chlorine dioxide and in the recombination of ClO radicals on ice.⁵⁴ At room temperature, with a ClClO_2 partial pressure of 1 mbar and a total gas pressure of 4 mbar, the ClClO_2 half-life is 1 min. Under stratospheric conditions, chloryl chloride is more stable, but easily undergoes photolysis.

The UV absorption spectrum of ClClO_2 in a neon matrix demonstrated two bands devoid of definite structures with maxima at 236 and 296 nm and half-widths of ~ 40 and $\sim 45 \text{ nm}$, respectively.⁵² The absorption maxima in the gas-phase ClClO_2 spectrum were at 231 ($\sigma = 1.3 \times 10^{-17} \text{ cm}^2$) and 296 nm ($\sigma = 1.5 \times 10^{-17} \text{ cm}^2$).

The IR spectra of matrix-isolated and gaseous ClClO_2 demonstrated six fundamentals $\nu_1\text{--}\nu_6$. Table 4 shows the vibrational frequencies for the matrix-isolated $^{35}\text{Cl}^{35}\text{Cl}^{16}\text{O}_2$ (neon matrix)⁵² and compares them with the vibrational frequencies calculated by the CCSD/TZ2P method⁴⁷ (singles and doubles coupled-cluster). Geometrical parameters of the ClClO_2 molecule (Ref. 52) were later refined based on the rotational spectra^{53,54} of chloryl chloride (Table 5). For comparison, Table 5 shows the geometrical parameters estimated by the MP2 method using 6-31G*

Table 4. Vibrational frequencies in the spectrum of the ClClO_2 molecule.

Frequency	Experimental data ⁵²	Calculations ^a using the CCSD/TZ2P method ⁴⁷	Mode
ν_1	1041.20	1039	Cl–O stretch, symmetric
ν_2	522.50	524	OCIO bend
ν_3	440.43	459	ClClO bend, symmetric
ν_4	271.37	285	Cl–Cl stretch
ν_5	1216.37	1205	Cl–O stretch, antisymmetric
ν_6	251.40	254	ClClO bend, antisymmetric

^a Of all the values calculated using the MP2, CCSD and CCSD(T) methods with TZ2P and TZ2Pf basis sets, the CCSD/TZ2P method provided the best agreement with experimental data.

Table 5. Geometrical parameters and dipole moment (μ) for the ClClO₂ molecule.

Parameter	Experimental data			Quantum-chemical calculations	
	IR ⁵²	MW ⁵³	MW ⁵⁴	MP2/6-31G* (see Ref. 46)	MP2/TZ2Pf (see Ref. 47) ^a
$r(\text{Cl}-\text{Cl})/\text{\AA}$	2.22	2.1966	2.1978	2.459	2.269
$r(\text{Cl}-\text{O})/\text{\AA}$	1.44	1.4367	1.4360	1.469	1.442
$\text{Cl}-\text{Cl}-\text{O}$ /deg.	103.5	104.14	104.06	104.2	103.8
$\text{O}-\text{Cl}-\text{O}$ /deg.	116.0	114.96	115.05	116.7	115.0
μ/D		1.570		3.378	2.20

^aThe values shown were calculated by the MP2/TZ2Pf method that provides the best agreement with experimental data.

(Ref. 46) and TZ2Pf (Ref. 47) basis sets. The internuclear distance Cl—Cl in a ClClO₂ molecule exceeds that in the Cl₂ molecule by almost 0.21 Å. Chloryl chloride molecules represent asymmetric prolate rotors with the rotational constants $A = 9450.9218$, $B = 3588.0617$ and $C = 2787.9468$ MHz (for ³⁵Cl³⁵Cl¹⁶O₂).

A non-empirical quantum-chemical calculation⁴⁶ of the enthalpy of formation carried out by the MP2 method using 6-31 + G(3d, 2p) and 6-31G* basis sets for the following isodesmic reaction:

gave values of $\Delta H_0^\circ(\text{ClClO}_2)$ equal to 33.8 [MP2/6-31 + G(3d, 2p)] and 34.6 kcal mol^{−1} (MP2/6-31G*). The enthalpy of formation of ClClO₂ was also calculated⁴⁷ using the second-order Møller–Plesset perturbation theory and the CCSD and CCSD(T) methods with TZ2P and TZ2Pf basis sets. The CCSD(T)/TZ2P method gave a value of 35.1 kcal mol^{−1}, which is most similar to the experimental one.

Photolysis of matrix-isolated ClClO₂ caused its rearrangement into ClOClO and ClOOCl.⁵⁵ A more detailed study⁵⁶ has shown that the effect of light with a threshold wavelength of 610 nm on argon-matrix-isolated ClClO₂ results in immediate transformation of the latter into chlorine chlorite ClOClO without formation of any long-lived intermediates. A chlorine atom formed upon ClClO₂ dissociation can attack the ClO₂ residue either at the chlorine atom giving ClClO₂ or at the oxygen atom to give ClOClO. The action of light with a threshold wavelength of 665 nm on ClOClO causes its dissociation to either Cl and OClO (with subsequent regeneration of ClClO₂) or two ClO radicals (with subsequent regeneration of ClOOCl). A scheme of photolysis of argon matrix-isolated ClClO₂ has been described⁵⁶ and the wavelengths at which dissociation of Cl₂O₂ isomers takes place were specified (Scheme 1).

Scheme 1

By using narrow-band filters (665, 610 and 360 nm), all three isomers, *viz.*, ClOClO, ClClO₂ and ClOOCl, respectively, could be identified. The calculated⁵⁶ values of dissociation energies (E_{dis})

for chlorine chlorite and chloryl chloride were substantially lower than the photon energy, which points to the excessive energy of the photofragments.

Reaction	$E_{\text{dis}}/\text{kcal mol}^{-1}$
$\text{ClOClO} \longrightarrow 2 \text{ClO}$	6
$\text{ClOClO} \longrightarrow \text{Cl} + \text{OClO}$	~9.5
$\text{ClClO}_2 \longrightarrow \text{Cl} + \text{OClO}$	~19

In the photolysis of neon matrix-isolated ClClO₂, only chlorine and oxygen are formed, and no photoisomerisation of ClClO₂ to ClOOCl takes place.

A study⁵⁷ of photoisomerisation of argon-matrix-isolated chlorine, bromine and iodine chlorites (XOClO, X = Cl, Br, I) obtained by addition of X atoms to OClO has shown that all three chlorites isomerised to the corresponding chloryl halides XClO₂. In turn, ClClO₂ and BrClO₂ were transformed into ClOClO and BrOClO; this process could be repeated many times until XClO₂ decomposed to oxygen and the halogen.

It was assumed⁵² that chloryl chloride takes part in stratospheric ozone destruction (Scheme 2),⁵² although one can simulate⁴⁶ a 'zero' cycle (Scheme 3), which does not result in ozone loss.⁴⁶

Scheme 2

Scheme 3

For decades, the ClO radicals were the subject of spectroscopic and kinetic studies (the first works on this subject were carried out as far back as 20–30 years ago); however, little attention was paid to their dimerisation (self-reaction). The possibility of Cl₂O₂ formation upon recombination of the ClO radicals and further involvement of the Cl₂O₂ molecules in the presumed catalytic cycle of ozone depletion (see Scheme 2) were the reasons for the appearance of numerous publications devoted to recombination of the ClO radicals and properties of the dimer formed.

2. Chlorine peroxide

An IR spectroscopic study⁵⁸ of recombination of the ClO radicals generated at 220–240 K under continuous flow conditions by the reaction of Cl atoms with ozone has shown that chlorine peroxide ClOOCl, which can take part in the aforementioned catalytic cycle, is the dominant recombination product. Although it was soon shown^{55, 59–62} that the IR spectral bands pertain most probably to dichlorine trioxide (chlorine sesquioxide Cl₂O₃), the main conclusion on the involvement of Cl₂O₂ in the catalytic cycle remained true.

When studying the spectrum of the ClO radical recombination products in the submillimetre range (415–435 GHz) at a temperature below 240 K, several Cl₂O₂ isomers and chlorine dioxide OClO were identified,⁶³ chlorine peroxide ClOOCl being the main product. The ClOOCl molecule has a chain structure with two equivalent chlorine atoms and two equivalent oxygen atoms (C₂

Table 6. Geometrical parameters and dipole moment (μ) for the chlorine peroxide molecule.

Parameter	Experimental data	Quantum-chemical calculations	
	MW ⁶³	MP2/6-31G* (see Ref. 46)	MP2/TZ2Pf (see Ref. 47)
$r(\text{Cl}-\text{O})/\text{\AA}$	1.7044	1.741	1.711
$r(\text{O}-\text{O})/\text{\AA}$	1.4259	1.420	1.407
$\text{Cl}-\text{O}-\text{O}/\text{deg.}$	110.07	109.0	108.9
ClOO/OOCl	81.03	85.0	83.0
μ/D	0.72	0.921	0.84

symmetry). Molecules of chlorine peroxide represent slightly prolate asymmetric rotors with the constants $A = 13109.4463$, $B = 2409.7892$ and $C = 2139.6786$ MHz.⁶³ Earlier,⁶⁴ the following constants were obtained: $A = 12967$, $B = 2333$ and $C = 2085$ MHz. Table 6 shows internuclear distances and bond angles for chlorine peroxide molecules (see also Ref. 65).

The calculated values of the internal rotational barrier for ClOOCl are as follows:

ClOOCl conformation	$E/\text{kcal mol}^{-1}$	
	data from Ref. 66	data from Ref. 67
<i>cis</i>	8.8	10.1
<i>trans</i>	4.9	5.4

According to Ref. 63, the dipole moment of a ClOOCl molecule is 0.72 D, although the value of 0.76 D was thought⁶⁷ to be the most reliable one for the dipole moment.

An IR spectrum of argon-matrix-isolated ClOOCl at 12 K demonstrated absorption bands at 752.6 (O–O, stretch), 649.8 and 647.6 cm^{-1} (Cl–O, stretches);⁵⁵ the absorption bands at 750 and 650 cm^{-1} were also present in the spectrum of gaseous chlorine peroxide.⁶⁰ In a later work,⁵⁶ the IR spectrum of ClOOCl isolated in an argon matrix was studied. For a molecule with an isotopic composition of $^{35}\text{Cl}^{16}\text{O}^{16}\text{O}^{35}\text{Cl}$, the frequencies 753.97 (ν_1), 543.0 (ν_2), 647.67 (ν_3) and 418.5 cm^{-1} (ν_6) were found and the values 310 (ν_3) and 127 cm^{-1} (ν_4) were calculated.

In the UV absorption spectrum of ClOOCl,⁶⁸ the absorption maximum was observed at 245 nm and the absorption cross-section (σ) was equal to $6.4 \times 10^{-18} \text{ cm}^2$ (at 350 nm, the absorption cross-section was $< 1 \times 10^{-19} \text{ cm}^2$). An adsorption maximum was also found⁶⁰ at 245 nm ($\sigma = 6.5 \times 10^{-18} \text{ cm}^2$), and measurable cross-section values could be obtained up to 410 nm. The fact that this UV spectrum pertained to chlorine peroxide was confirmed by calculations.⁴⁸ Later,⁶⁹ an UV spectrum of ClOOCl obtained by chlorine monoxide photolysis ($\lambda = 254 \text{ nm}$) was studied; the absorption maximum was found at 244 nm ($\sigma = 6.4 \times 10^{-18} \text{ cm}^2$). The measurements were carried out at 195 K in the 200–400 nm range.

In a number of studies, the enthalpies of ClOOCl formation and energies of bond dissociation were calculated, which did not coincide completely but did not differ dramatically from one another. The enthalpy of ClO dimerisation found⁶⁸ from the temperature dependence of the equilibrium constant

$$K_{\text{eq}} = \exp\left(\frac{\Delta S_1^\circ}{R}\right) \exp\left(-\frac{\Delta H_1^\circ}{RT}\right)$$

for the reaction

was equal to $-17 \pm 0.7 \text{ kcal mol}^{-1}$. An experimental value of the enthalpy of ClOOCl formation (ΔH_{298}°) was equal to $31.3 \pm 0.7 \text{ kcal mol}^{-1}$. A non-empirical calculation⁴⁶ of the enthalpy of ClOOCl formation carried out within the framework

of the second-order Møller–Plesset perturbation theory with the 6-31 + G(3d) and 6-31G* basis sets gave the values $\Delta H_0^\circ(\text{ClOOCl}) = 35.7$ (MP2/6-31 + G(3d) and 32.6 kcal mol^{-1} (MP2/6-31G*), and an estimate⁴⁷ obtained by the CCSD method was $\Delta H_0^\circ(\text{ClOOCl}) = 34.2 \text{ kcal mol}^{-1}$. Using an experimental value of the heat of ClO formation and a calculated value of $\Delta H_0^\circ(\text{ClOOCl})$ with a correction made for $T = 298 \text{ K}$, the energy of ClOOCl dissociation

was determined⁴⁷ to be $D(\text{ClO}-\text{OCl}) = 14.9 \text{ kcal mol}^{-1}$. The fact that the enthalpy value of $34.2 \text{ kcal mol}^{-1}$ calculated by using the isodesmic reaction

deviated from the experimental value may be due to an error introduced by determination of the heat of formation of Cl_2O .⁴⁷ Using another value for the heat of Cl_2O formation, the following parameters were obtained:⁴⁷ $\Delta H_0^\circ(\text{ClOOCl}) = 32.7 \text{ kcal mol}^{-1}$ and $D(\text{ClO}-\text{OCl}) = 16.4 \text{ kcal mol}^{-1}$, which were in better agreement with the experimental data.

According to an estimate,⁵⁸ dissociation of chlorine peroxide ClOOCl to ClO + ClO requires $\sim 16.7 \text{ kcal mol}^{-1}$, whereas the dissociation to Cl + ClOO requires more than 19 kcal mol^{-1} . The value of $\Delta H_0^\circ(\text{ClOOCl})$ was calculated⁷⁰ to be $33 \pm 2 \text{ kcal mol}^{-1}$. In a kinetic study⁷¹ devoted to reactions of ClOOCl thermal decomposition and ClO dimerisation, the energy of the O–O bond dissociation ($18.1 \text{ kcal mol}^{-1}$) was calculated and the enthalpy of ClOOCl formation ($30.5 \pm 0.7 \text{ kcal mol}^{-1}$) was determined. Apparently, without introducing a huge error, one can assume the dissociation energies of Cl–OOCl and ClO–OCl bonds to be 21 and 18 kcal mol^{-1} , respectively.^{69, 72}

Thus, the molecule of chlorine peroxide differs sharply from the FOOF molecule in the bond strength: the O–O bond in ClOOCl is much weaker as compared with that in FOOF. Ionisation of ClOOCl makes this bond still weaker: for an ionic dimer ClOOCl^+ , the values $D_{298}(\text{ClO}-\text{OCl}^+) = \sim 11.5 \pm 4.3 \text{ kcal mol}^{-1}$ and $\Delta H_{298}^\circ(\text{ClOOCl}^+) = 287.5 \pm 2.9 \text{ kcal mol}^{-1}$ were found.⁷³

3. The ClOO and OClO radicals

It was assumed⁵⁸ that the photolysis of ClOOCl in the polar stratosphere results in the formation of Cl atoms and ClOO radicals. An investigation⁷⁴ confirmed this assumption. It was found that it is these products that were formed upon laser pulse photolysis of chlorine peroxide ($\lambda = 308 \text{ nm}$, 235 K) with a primary quantum yield of 1.03 ± 0.12 . The photodissociation of ClOOCl to Cl atoms and ClOO radicals was also mentioned in Ref. 68; however, the possibility of another dissociation channel resulting in two ClO radicals⁵⁶ cannot be ruled out. In contrast to Cl atoms, ClO radicals do not catalyse the ozone destruction; hence, the ratio of the dissociation products $[\text{Cl}]:[\text{ClO}]$ is important when assessing the ozone-depletion effect of ClOOCl. Experiments⁷⁵ on the ClOOCl photolysis ($\lambda = 248$ and 308 nm) have shown that irradiation mainly cleaves the stronger Cl–O bond, the $[\text{Cl}]:[\text{ClO}]$ ratio being 0.88:0.12 (248 nm) and 0.90:0.10 (308 nm). Mass-spectrometric studies failed to detect the intermediate ClOO that forms in the Cl–O bond scission, because of its fast dissociation. Photolysis of chlorine peroxide at $\lambda = 308 \text{ nm}$ resulted in its dissociation to Cl atoms and O_2 molecules, whereas photolysis at 248 nm produced in addition ClO, O and ClOO.⁷⁶

Abstraction of a chlorine atom from the ClOOCl molecule results in a ClOO radical, which is an isomer of the well-known chlorine dioxide OClO. The possibility of existence of the ClOO radical as an intermediate product in the pulse photolysis of chlorine–oxygen mixtures was reported by Porter and Wright⁷⁷ as far back as the early 1950's. The ClOO radical was by 3–4 kcal mol^{-1} energetically more favourable as compared with the OClO radical, the former being very reactive, however, in contrast, chlorine dioxide was stable at room temperature and

could exist as a radical for an indefinitely long period without any sign of dimerisation. Association of OCIO with the formation of weakly bound dimers was observed only in the solid state.^{78,79} Both ClO₂ isomers can be involved in the stratospheric ozone destruction, which explains the attention they have attracted in recent years (photochemistry of chlorine dioxide is the subject of numerous studies, see, *e.g.*, Refs 80–111). Experiments on OCIO photolysis most frequently used radiation with wavelengths of 365–368 nm; the absorption of OCIO begins at ~510 nm.

Photolysis of OCIO can result in both dissociation of the molecule and its photochemical isomerisation. A model of concerted isomerisation of the OCIO molecule which proceeds *via* ClOO isomers in the lower excited state ²A' was proposed. From this state, the radical ClOO can either emit a photon and pass to the ground state ²A'' with the energy 25–30 kcal mol⁻¹ lower than the energy of the ²A' state or dissociate. The ground state ²A'' of ClOO radicals obtained by photoisomerisation of chlorine dioxide and stabilised in an aluminosilicate matrix at 77 K was confirmed by analysis of the ESR spectrum.⁸¹

Decomposition of photo-excited OCIO molecules results in Cl atoms and O₂ molecules. Chlorine atoms can destroy ozone. Decomposition of OCIO can proceed by a different pathway, namely, with ClO and O formation. The latter species can regenerate ozone; however, dimerisation of ClO is preferable. Dimerisation of ClO and photoisomerisation of OCIO result in the formation of ClOOC or ClOO which destroy ozone. The direction of OCIO reactions, *viz.*, isomerisation or dissociation, and the mechanisms of these processes depend strongly on the photolysis conditions. In low-temperature inert matrices, chlorine dioxide transforms almost completely to the ClOO isomer. The ClOO radicals represent the only photoproduct upon photolysis of OCIO in an amorphous ice matrix (360 nm, 80 K).¹⁰⁰ Photolysis of OCIO at 150 K also produced ClOO together with ClClO₂. The latter was formed in the reaction of Cl atoms with chlorine dioxide.^{97,103} Chloryl chloride was also observed among the photolysis products of thin OCIO films either condensed at 100 K (up to 70 monolayers) or adsorbed on ice (0.5–2 monolayers).¹⁰⁵

Photolysis of aqueous and other solutions of chlorine dioxide results in the formation of chlorine atoms. The quantum yield and the mechanism of Cl atom formation were the subjects of a discussion. Thus it was assumed⁹⁷ that chlorine dioxide is first isomerised to ClOO, which is decomposed to Cl and O₂. On the other hand, it was supposed⁸⁹ that nearly 90% of excited OCIO molecules dissociate to O and ClO in an aqueous solution at room temperature at $\lambda = 365$ nm and only 10% of the molecules isomerise to ClOO, the latter decomposing to Cl and O₂ (the rate constant is $\sim 6.7 \times 10^9$ s⁻¹). However, the possibility of chlorine atom formation as the primary photoproduct has not been ruled out

According to data from Ref. 98, the 10% yield of Cl atoms comprised 9.5% of Cl obtained upon ClOO decomposition and 0.5% of Cl formed upon direct photodissociation. The same conclusion was made by the authors^{110,111} who studied photolysis of an aqueous solution of chlorine dioxide at $\lambda = 400$ nm. They have found that nearly 90% of excited OCIO molecules dissociate to ClO and O with subsequent recombination of these fragments. In this process, the quantum yield of the Cl atoms was about 10%, of which 2% were formed upon decomposition of ClOO and 8% were formed upon dissociation. They managed to observe ClOO radicals with a lifetime of ~4 ns.

Chang and Simon¹⁰⁴ assumed that a 'hot' ClOO isomer formed upon photolysis of OCIO undergoes relaxation in 9 ps and then dissociates. Irradiation of ClOO with light with a wavelength of 365 nm increased the yield of Cl atoms owing to the photolysis of vibrationally excited ClO radicals formed by the dominant photodissociation channel¹⁰⁸

A femtosecond spectroscopic study of the photolysis of an aqueous solution of OCIO has shown that ClO and O fragments quickly recombine to give vibrationally excited OCIO which relaxed to the ground state in 10 ps. Irradiation of OCIO with light with $\lambda = 400$ nm produced only Cl and O₂ as the photolysis products with a quantum yield of 0.07 ± 0.03 .^{106,107}

Gas-phase photoisomerisation of OCIO molecules seems to be highly unlikely.^{90,101}

In the UV spectrum, the absorption maximum of ClOO radicals was found at 248 nm [$\sigma = (3.4 \pm 0.3) \times 10^{-17}$ cm², 298 K] (Ref. 112) and at 246 nm [$\sigma = (2.98 \pm 0.23) \times 10^{-17}$ cm², 191 K] (Ref. 113).

An IR spectrum of ClOO radicals generated by either photoisomerisation of argon-matrix-isolated OCIO or the reaction of Cl atoms with oxygen molecules at 17 K demonstrated the following vibrational frequencies: 1442.8 (ν_1), 408.3 (ν_2), 192.4 (ν_3) cm⁻¹ and an overtone of 375.6 cm⁻¹ ($2\nu_3$) (C_s point symmetry group).⁹⁵ IR-Fourier spectra measured for eight neon-matrix-isolated ClOO radicals with different isotope compositions contained all fundamental frequencies, four overtones and five combined frequencies.⁷⁹ For example, the spectrum of ³⁵Cl¹⁶O¹⁶O radicals contained the frequencies 1438.56 (ν_1), 413.73 (ν_2), 201.38 cm⁻¹ (ν_3) (anharmonicity-corrected frequencies were 1477.8, 432.4 and 214.8 cm⁻¹). The O–O stretch frequency for the ClOO radical (1477.8) was close to that for the O₂F radical (1487 cm⁻¹).

The exact values of geometrical parameters for ClOO radicals are unknown. Based on IR spectra measured during the photolysis of a Cl₂ + O₂ mixture at 4 K, estimates were made¹¹⁴ for bond lengths and bond angles in a ClOO radical (Table 7). For this radical, the following values were proposed:¹¹⁵ $r(\text{O}–\text{O}) = 1.31$ Å and $r(\text{O}–\text{Cl}) = 1.835$ Å. Noticeably different geometrical parameters of ClOO radicals were calculated by different methods, *viz.*, by the high-level nonempirical CMRCI (contracted multireference configuration interaction) method,¹¹⁶ by using the MP2 theory with different basis sets¹¹⁷ and by means of the density functional theory (DFT)¹¹⁸ (see Table 7). According to calculations,¹¹⁶ the dipole moment of ClOO is 1.113 D.

Table 7. Bond lengths and bond angle in the ClOO radical.

Parameter	Experimental data IR ¹¹⁴	Quantum-chemical calculations		
		CMRCI ¹¹⁶	MP2 ¹¹⁷	DFT ¹¹⁸
$r(\text{O}–\text{O})/\text{Å}$	1.23	1.201	1.174–1.247	1.2154
$r(\text{Cl}–\text{O})/\text{Å}$	1.83	2.139	1.923–2.203	1.9286
$\text{Cl}–\text{O}–\text{O}$ /deg.	110	115.7	114.1–118.6	115.74

In a kinetic study of the reaction of Cl atoms with O₂ molecules and the following equilibrium:

(181–200 K, oxygen pressure of 15–40 Torr), the rate constant for Cl + O₂ association was found to be $(8.9 \pm 2.9) \times 10^{-33}$ cm⁶ molecule⁻² s⁻¹ (186.5 ± 5.5 K).¹¹⁵ According to this study,¹¹⁵ the equilibrium constant (K_{eq}) of the reaction Cl + O₂ is 18.9 atm⁻¹ (185.4 K). A similar value ($K_{\text{eq}} = 20.4$ atm⁻¹) was found at the same temperature in a different study.¹¹² The enthalpy of formation of ClOO radical was found¹¹² to be $\Delta H_{298}^\circ(\text{ClOO}) = 23.4 \pm 0.5$ kcal mol⁻¹; calculations¹¹⁹ gave the value of 24.2 ± 2 kcal mol⁻¹. In experimental studies,^{112,115} calculations according to the third law of thermodynamics gave the following values for the dissociation energy $D_0(\text{Cl}–\text{OO})$: 4.76 ± 0.49 (Ref. 115) and 4.83 ± 0.05 kcal mol⁻¹ (Ref. 112). The calculated value of $D_0(\text{Cl}–\text{OO})$ was 4.0 ± 2 kcal mol⁻¹ (see Ref. 119). Quantum-chemical calculations using the density func-

tional method showed that the dissociation energy of the ClO—O bond is 62.4 kcal mol⁻¹. Thus, it is evident that the ClOO radical has a strong O—O bond and a weak Cl—OO bond and in this respect resembles the FOO radical. A rather weak Cl—O bond allows us to consider the ClOO radical as an O₂ molecule with a ‘chaperon’, viz., a chlorine atom.¹²⁰

4. Compound HOOCI

Substitution of a hydrogen atom for a chlorine atom in chlorine peroxide gives HOOCI. This compound has not yet been isolated, however, it is of interest for atmospheric chemistry. Reactions Cl + HO₂ and ClO + OH can result in the formation of HOOCI. The reaction of Cl with HO₂ probably produces an excited HOOCI molecule with the lifetime at 298 K estimated as 1 ns.¹²¹ HOOCI molecules can decompose by three channels, viz., to Cl + HO₂, HCl + O₂ and OH + ClO. A study¹²² of the Cl + HO₂ reaction under continuous flow conditions at 250–420 K and a pressure of 0.9–1.5 Torr have shown that in this temperature range its rate constant depends little on the temperature and is equal to $(4.2 \pm 0.7) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹. At 298 K, the reaction proceeds by roughly 20% by the channel

At 243–298 K, the reaction of OH and ClO radicals largely proceeds by the channel

probably, with the formation of an excited HOOCI intermediate.¹²³ The other reaction channel

is realised to a small degree due to the high energy barrier associated with rearrangement of the intermediate.

The probability of stabilisation of excited HOOCI molecules is low under both atmospheric and laboratory conditions.¹²⁴ However, a non-empirical calculation using the CCSD(T)/TZ2P method has shown¹²⁵ that the thermal stability of HOOCI even exceeds that of ClOOCl; hence, when studying atmospheric processes, one must bear in mind the possibility of the existence of HOOCI. In the same work,¹²⁵ geometrical parameters of the HOOCI molecule were estimated [$r(\text{O}—\text{O}) = 1.443$ Å, $r(\text{Cl}—\text{O}) = 1.746$ Å, $r(\text{H}—\text{O}) = 0.968$ Å, bond angles Cl—O—O and O—O—H were 108.6° and 100.6°, respectively, the dihedral angle ClOO/OOH was 98.1°] as well as the dipole moment (1.74 D). The enthalpy of HOOCI formation was shown to be 1.5 ± 1 or 0.2 ± 1 kcal mol⁻¹. The calculated frequencies of HOOCI harmonic vibrations ω_1 – ω_6 were 3744, 1399, 835, 633, 392 and 361 cm⁻¹, respectively. The skewed structure of HOOCI was also confirmed by calculations.¹²⁶ It was also found¹²⁶ that the HOOCI isomer is most stable among the isomers of the general formula HClO₂, the energies of branched Y-shaped HClO₂ and a chain HOCIO (chlorous acid) forms exceeding the energy of the HOOCI form by 51.0 and 8.3 kcal mol⁻¹, respectively. The calculated¹²⁶ enthalpies of formation of HOOCI, HOCIO and HClO₂ molecules were 1.6, 11.9 and 56.2 kcal mol⁻¹, respectively [according to other estimates,¹³ $\Delta H_{300}^\circ(\text{HOOCI}) = -0.1$ kcal mol⁻¹]. The geometrical parameters of the HOOCI molecule calculated using the MP2/6-31G(d,p) method [$r(\text{O}—\text{O}) = 1.408$ Å, $r(\text{O}—\text{Cl}) = 1.751$ Å]¹¹⁶ were similar to those found in Ref. 125.

5. Chlorine chlorite and Cl₂O₂⁺ cation

In studies of disproportionation of chlorine-containing compounds, it was assumed that chlorine chlorite ClOClO can be an intermediate in these reactions.¹²⁷ Apparently, chlorine chlorite is the intermediate¹²⁸ in the reaction

A mass-spectrometric study⁷³ of ClO dimers has shown that several Cl₂O₂ isomers exist, of which ClOClO is the least stable.

Table 8. Calculated values of bond lengths and bond and torsion angles for the ClOCl'O' molecule.

Parameter	Quantum-chemical calculations	
	MP2/6-31G* (see Ref. 46)	CCSD/TZ2P ⁴⁷
$r(\text{Cl}—\text{O})/\text{\AA}$	1.713	1.717
$r(\text{O}—\text{Cl}')/\text{\AA}$	1.909	1.739
$r(\text{Cl}'—\text{O}')/\text{\AA}$	1.512	1.517
$\text{Cl}—\text{O}—\text{Cl}'/\text{deg.}$	109.7	111.6
$\text{O}—\text{Cl}'—\text{O}'/\text{deg.}$	116.8	112.4
$\text{ClOCl}'/\text{OCl}'\text{O}'/\text{deg.}$	67.1	76.6

According to different estimates,^{13,46,47} the enthalpy of ClOClO formation is 40.8–44.3 kcal mol⁻¹. Table 8 shows the results of quantum-chemical calculations^{46,47} of geometrical parameters for the ClOClO isomer.

Salts that involve Cl₂O₂⁺ as a cation have been synthesised.¹²⁹ A reaction of hexafluoroantimonate O₂⁺SbF₆⁻ with chlorine in anhydrous HF at 195–233 K gave Cl₂O₂⁺SbF₆⁻; the addition of antimony pentafluoride to the same reactants resulted in the formation of Cl₂O₂⁺Sb₂F₁₁⁻. Black-violet crystals of both salts precipitated when the solutions were cooled to 193 K. Structural studies showed that the salts contain the Cl₂O₂⁺ cations shaped as flat trapezia in which the ‘chlorine part’ is spaced at 2.425 Å from the ‘oxygen part’, which amounts to ~75% of the sum of the van der Waals radii of Cl and O. The internuclear distances Cl—Cl and O—O were 1.916 and 1.185 Å, respectively. In the Raman spectrum of the Cl₂O₂⁺Sb₂F₁₁⁻ salt, an O—O stretch was observed at 1534 cm⁻¹ and Cl—Cl stretches were found at 586 and 593 cm⁻¹. Despite the apparent weakness of the cation structure, the salts are sufficiently stable: Cl₂O₂⁺SbF₆⁻ decomposes at 273 K, and Cl₂O₂⁺Sb₂F₁₁⁻ is stable up to 313 K. The dissociation energy of the Cl₂O₂⁺ cation

is equal to 12.8 kcal mol⁻¹. The formation of Cl₂O₂⁺ cations occurs as a result of chlorine oxidation by a dioxygenyl cation.

IV. Bromine and iodine oxides

1. Bromine oxides

Currently, bromine oxides remain insufficiently explored compounds despite the growing interest in them.¹³⁰ Probably, this is associated with their low stabilities. Only bromide monoxide Br₂O, bromine bromate BrOBrO₂ and bromic anhydride O₂BrO—BrO₂ have been characterised in most detail. Despite being known since the 1930s, BrO₂ has probably never been obtained in pure form. Moreover, a substance with this molecular formula is believed to be in fact either a mixture of Br₂O₃ and Br₂O₅ (see Ref. 130) or bromine perbromate BrOBrO₃ (Ref. 131).

The oxide Br₂O₂ has never been isolated either. However, this was probably observed¹³² in the IR spectroscopic studies of the products of atomic–molecular reactions of bromine and oxygen in solid argon. Moreover, it is most probable that this oxide is an intermediate in the recombination of the BrO radicals.

A study of disproportionation of the BrO radicals generated by photolysis of either bromine–ozone or bromine–oxygen mixtures

has shown¹³³ that reaction (3) is of the second order. The branching ratio for reactions (3a) and (3) k_{3a}/k_3 was equal to

Table 9. Geometrical parameters of the BrOOBr molecule calculated by different methods.

Parameter	Quantum-chemical calculations		
	BLYP, SVWN and B3LYP ¹³⁹	MP2, CCSD(T), B3LYP ¹⁴⁰	MP2/6-31 + G(2d) ¹⁴¹
$r(\text{O}-\text{O})/\text{\AA}$	1.264–1.335	1.359–1.410	1.4068
$r(\text{Br}-\text{O})/\text{\AA}$	1.922–2.082	1.861–1.900	1.8861
$\text{Br}-\text{O}-\text{O}/\text{deg.}$	113.3–115.6	109.6–112.6	111.46
$\text{BrOO/OOBr}/\text{deg.}$	79.2–85.6	82.2–84.6	84.75

0.84±0.03 (at 298 K). According to the data from Ref. 134, the branching ratio k_{3b}/k_3 is equal to 0.12±0.04. The vibrationally excited intermediate BrOOBr* either dissociates to BrOO and Br or passes to a more stable state and then dissociates to Br₂ and O₂ via a four-centred complex A.

Studies of the kinetics and mechanism of the self-reaction of the BrO radicals generated by pulse photolysis of bromine–ozone mixtures at 220 and 298 K and a pressure of different gases of 75–600 Torr have revealed¹³⁵ absorption at 312 nm, which was not reported earlier. The absorption at 220 K was attributed to the Br₂O₂ dimer. The rate constant for reaction (3) was equal to $(2.75\pm0.50)\times10^{-12}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$ at 298 K independent of pressure and changed from $(2.00\pm0.41)\times10^{-12}$ (100 Torr) to $(3.10\pm0.30)\times10^{-12}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$ (400 Torr) at 220 K. In the same work, the pressure-independent ratios $k_{3a}/k_3 = 0.84$ (298 K) and 0.68 (220 K) were found. Estimates¹³⁵ have shown that the lifetime of Br₂O₂ does not exceed 1 min in the stratosphere at 195 K.

In a kinetic study,¹³⁶ the absence of the OBrO radical among the products of the BrO + BrO reaction was reported. Apparently, the metastable intermediate BrOBrO the decomposition of which would have given OBrO either was not formed at all or quickly isomerised to BrOOBr. For reaction (3), the following rate constants were found ($\text{cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$):¹³⁶ $k_3 = (2.98\pm0.42)\times10^{-12}$, $k_{3a} = (2.49\pm0.42)\times10^{-12}$, $k_{3b} = (4.69\pm0.68)\times10^{-13}$ at 298 K and 760 Torr (oxygen as the buffer gas). These values are similar to those obtained in a different study.¹³⁵ According to data from Ref. 137, in the temperature range of 204–388 K, the rate constant for reaction (3) depends on the temperature in the following way:

$$k_3 = (1.70 \pm 0.45) \times 10^{-12} \exp\left(\frac{215 \pm 50}{T}\right).$$

At 298 K, $k_3 = (3.51\pm0.35)\times10^{-12}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$. When simulating the atmospheric processes, it is recommended (bearing in mind the results of previous studies) to use the value

$$k_3 = (1.50 \pm 0.46) \times 10^{-12} \exp\left(\frac{230 \pm 100}{T}\right) \text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}.$$

A detailed study¹³⁸ of the kinetics and mechanism of the self-reaction of BrO radicals in the temperature range of 220–298 K has shown that at $T < 250$ K a new reaction channel appears

At 222 K, the rate constants k_{3c} and k_{-3c} are equal to $8.2 \times 10^{-32}\text{ cm}^6\text{ molecule}^{-2}\text{ s}^{-1}$ and $2.5 \times 10^{-18}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$, respectively. The equilibrium constant is 1.937×10^5 (235 K) and $1.26 \times 10^6\text{ atm}^{-1}$ (222 K). An enthalpy change in the reaction

was estimated to be $-14\pm0.02\text{ kcal mol}^{-1}$.

The absorption maximum in the UV spectrum of the Br₂O₂ dimer was found at 305 nm, the cross-section $\sigma = 1.4 \times 10^{-17}\text{ cm}^2$ (at 350 nm, the cross-section was $1.28 \times 10^{-17}\text{ cm}^2$).¹³⁸

Like Cl₂O₂, compound Br₂O₂ can exist in several isomeric forms. Among three possible isomers of Br₂O₂, bromine peroxide

BrOOBr is the most stable.^{139,140} A calculation¹³⁹ using BLYP, SVWN and B3LYP density functionals have shown that the energies of BrBrO₂ and BrOBrO isomers are higher than that of the BrOOBr isomer by 8.4 and 11.3 kcal mol⁻¹, respectively. Table 9 shows the results of quantum-chemical calculations^{139–141} of geometrical parameters for the bromine peroxide molecule. Depending on the calculation method, the internuclear distance $r(\text{O}-\text{O})$ varies from 1.264 to 1.410 Å, and $r(\text{Br}-\text{O})$ varies from 1.861 to 2.082 Å, the bond angle Br–O–O varies from 109.6 to 115.6° and the torsion angle BrOO/OOBr varies from 79.2 to 85.6°. The vibrational spectrum of the BrOOBr molecule was also calculated.^{139–141} The frequencies of O–O stretches (1103, 1046 and 878 cm⁻¹) obtained¹³⁹ by three different methods differ substantially from the calculated frequencies 746 cm⁻¹ (Ref. 140) and 737 cm⁻¹ (Ref. 141).

The enthalpy of BrOOBr formation was estimated¹³ to be 41 kcal mol⁻¹ (300 K). Calculated within the framework of different approximations, the enthalpies of BrOOBr, BrBrO₂ and BrOBrO formation at 0 K are, correspondingly, 46.1, 52.9 and 54.8 kcal mol⁻¹ (Ref. 139) and 44±1, 57±6 and 56±4 kcal mol⁻¹ (Ref. 140).

It was shown¹⁴² that the reaction of bromine atoms with O₂ molecules in an argon matrix at 10 K gives BrOO radicals. The frequency of 1487.0 cm⁻¹ in the IR spectrum of the BrOO radicals was assigned to the O–O stretch. In a recent study¹⁴³ which analysed the IR spectrum of argon-matrix-isolated BrOO radicals with different isotope compositions at 17 K, the frequencies of 1485.1, 1444.0 and 1402.3 cm⁻¹ were attributed to the O–O stretches in Br¹⁶O¹⁶O, Br¹⁶O¹⁸O and Br¹⁸O¹⁸O, respectively. Non-empirical calculations using the QCISD(T) method¹⁴⁴ gave the frequencies of the Br–O stretch (450 cm⁻¹) and the Br–O–O bend (261 cm⁻¹).

Like its chlorine analogue, the BrOO radical is more stable than its symmetrical isomer OBrO by approximately 5 kcal mol⁻¹ (Ref. 145) or 17–18 kcal mol⁻¹ (Ref. 146).

By using five different density functionals, the internuclear distances Br–O and O–O and the Br–O–O bond angle were calculated¹⁴⁶ for the BrOO radical in its ground state ²A'' (Table 10). In the other studies,^{144,145} higher values were obtained for the Br–O bond length and lower values were found for the O–O bond length.

Table 10. Geometrical parameters of the BrOO radical.

Parameter	Quantum-chemical calculations			
	BHLYP ¹⁴⁶	BP86 ¹⁴⁶	QCISD(T) ¹⁴⁴	[UMP/2, CCSD(T)] ¹⁴⁵
$r(\text{Br}-\text{O})/\text{\AA}$	2.178	2.150	2.302	2.291
$r(\text{O}-\text{O})/\text{\AA}$	1.253	1.242	1.232	1.214
$\text{Br}-\text{O}-\text{O}/\text{deg.}$	118	118		116.4

According to estimates,¹⁴⁷ the strength of the Br–O bond is ~1 kcal mol⁻¹. A later estimate¹⁴⁵ gave practically the same value, viz., 1.2–1.7 kcal mol⁻¹. Dissociation of BrOO radicals to BrO and O requires more than 50 kcal mol⁻¹ (Ref. 145). The enthalpy of BrOO formation is 35.1 kcal mol⁻¹ (300 K).¹³

Irradiation of BrOO radicals isolated in a solid argon matrix at 275 nm resulted in reversible photoisomerisation to give OBrO.¹⁴³ If the matrix also contained oxygen, photolysis of BrOO produced O₃ and BrO. Apparently, in this case a reaction of excited BrOO radicals with oxygen molecules proceeds.¹⁴⁸

Contamination of the atmosphere of Earth with bromine-containing compounds proceeds both in a natural way and as a result of human activities. Methyl bromide is the main source of stratospheric bromine. Its content in the atmosphere was recently assessed to be ~10 ppt (1 ppt = 10⁻¹²).¹⁴⁹ The lifetime of CH₃Br in the atmosphere is less than two years, it readily photolyses in the lower stratosphere. It was concluded¹⁵⁰ that, of all possible bromine-involving catalytic cycles of ozone depletion, the cycle with the reaction BrO + ClO as the rate-determining step (Scheme 4) is the most efficient.

Scheme 4

This cycle is particularly remarkable due to the fact that the loss of two radicals that are inactive with respect to ozone results in appearance of very reactive bromine and chlorine atoms.¹⁵¹ The contribution of such a cycle into the halogen-controlled ozone depletion can reach 20%–25%.¹⁵² Many studies were devoted to the BrO + ClO reaction (*e.g.*, see Refs 153–161 and references therein).

2. Compounds BrOOCl, BrOCIO and HOOBr

The class of compounds covered by this review also involves BrOOCl and BrOCIO. These can form as intermediates in the BrO + ClO reaction

It was found^{154, 156} that the rate constant for reaction (4) is $(8.2 \pm 1.0) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and does not depend on the temperature in the range of 241–408 K. In the same studies, the following branching ratios were found: $k_{4a}/k_4 = 0.45 \pm 0.10$, $k_{4b}/k_4 = 0.55 \pm 0.10$ and $k_{4c}/k_4 < 0.02$. The presence of channel (4c) was concluded by Toohey and Anderson,¹⁵⁵ and the formation of BrCl in considerable amounts was experimentally observed,^{157, 158, 160, 161} which suggests that this channel makes a substantial contribution to reaction (4). Using the gas-discharge technique and mass spectrometry and a combination of pulse photolysis and UV absorption spectroscopy, the value $k_4 = (1.29 \pm 0.16) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (298 K) and the ratio $k_{4c}/k_4 = 0.08 \pm 0.03$ were obtained.^{158, 159} Like many other bimolecular radical–radical reactions, reaction (4) is characterised by an inverse temperature dependence. Thus the following values were obtained for the rate constant of reaction (4) in the temperature range of 220–400 K ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$):

$$k_4 = (4.70 \pm 0.50) \times 10^{-12} \exp\left(\frac{320 \pm 40}{T}\right) \quad (\text{Ref. 158})$$

and

$$k_4 = (6.1 \pm 1.2) \times 10^{-12} \exp\left(\frac{240 \pm 60}{T}\right) \quad (\text{Ref. 159}).$$

Values of rate constants for reaction (4) similar to the aforementioned values,^{158, 159} were found in the studies devoted to the kinetics of this reaction and involving mass-spectrometric detection of the products:¹⁶⁰ $k_4 = (1.13 \pm 0.15) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, $k_{4b}/k_4 = 0.43 \pm 0.10$ and $k_{4c}/k_4 = 0.12 \pm 0.04$ (298 K). Thus, the BrO + ClO reaction proceeds with formation of two intermediates, *viz.*, BrOCIO which gives OCIO [channel (4b)] and BrOOCl which either decomposes to Br, Cl and O₂ [channel (4a)] or rearranges to the four-centred state A with subsequent elimination of BrCl [channel (4c)].

A calculation¹⁴⁰ has shown that, of the mixed oxides XX'O₂ (X = Br and X' = Cl), the peroxide BrOOCl is the most stable; the enthalpy of its formation was found to be $39 \pm 2 \text{ kcal mol}^{-1}$ (0 K)¹⁴⁰ or $38.9 \text{ kcal mol}^{-1}$ (0 K).¹³⁹ In an earlier work,¹⁵⁵ the geometrical parameters of the BrOOCl molecule were estimated: $r(\text{Br}-\text{O}) = 1.8 \text{ \AA}$, $r(\text{Cl}-\text{O}) = 1.7 \text{ \AA}$, $r(\text{O}-\text{O}) = 1.2 \text{ \AA}$ and the BrOO/OOBr dihedral angle was ~70°. A calculation¹⁴⁰ using the MP2 perturbation theory gave the following values: $r(\text{Br}-\text{O}) = 1.859 \text{ \AA}$, $r(\text{Cl}-\text{O}) = 1.710 \text{ \AA}$, $r(\text{O}-\text{O}) = 1.412 \text{ \AA}$, bond angles Br–O–O and Cl–O–O were both equal to 109° and the dihedral angle was 84.5°. The values close to those mentioned above were also obtained in calculations using the B3LYP density functional.

It was assumed¹⁶² that the reaction of the BrO radical with hydroxyl involves the formation of a short-lived vibrationally excited complex HOOBr. The main and probably the only channel of this reaction is

The rate constant for this reaction was estimated to be $(7.5 \pm 4.2) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 300 K and 1 Torr.¹⁶² The enthalpy of HOOBr formation was determined to be 5 kcal mol^{-1} (298 K)¹⁶² which is similar to the value of $4.2 \text{ kcal mol}^{-1}$ (300 K)¹³ and to the calculated¹³⁹ value of $8.6 \text{ kcal mol}^{-1}$ (0 K). The formation of the HOBrO intermediate in the BrO + OH reaction cannot be ruled out either; however, isomerisation of HOOBr to HOBrO is hindered due to the high energy barrier.¹⁶³

3. Iodine oxides

An assumption of the existence of I₂O₂ and its hydrate H₂I₂O₃ as intermediates in the reaction of the iodate ions with the iodide ions in an acidic medium was put forward back in 1930 (see Ref. 164). In a study devoted to the mechanism of this reaction,¹⁶⁴ the following scheme of I₂O₂ formation (in the HIO₂ form) was proposed:

By analogy with the recombination of ClO and BrO radicals, one can assume that the reaction IO + IO also proceeds with the formation of I₂O₂ dimers as the intermediates, although the evidence of their existence is still insufficient.

When studying the recombination of IO radicals generated upon photolysis of CH₃I in the presence of ozone at 303 K at an atmospheric pressure (N₂ and O₂ as the diluent gases), the formation of the I₄O₉ aerosol was observed, which deposited on reactor walls as a yellow-white film.¹⁶⁵ It was assumed^{165, 166} that, at first, the bimolecular self-reaction of the IO radicals proceeds

The I₂O₂ formed reacts with I to give IO₂

and the latter transforms into amorphous I₄O₉.

The IO + IO reaction was studied by a combination of pulse photolysis and UV absorption spectroscopy in the temperature range of 250–373 K at a pressure of 650 Torr (nitrogen as the

diluent gas).¹⁶⁷ The rate constant for this reaction is independent of the temperature and has the following form:

$$k = 1.73 \times 10^{-12} \exp \left(\frac{1020 \pm 200}{T} \right).$$

At 298 K, its value was $(5.6 \pm 1.2) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹. The rate constant at 300 K was determined¹⁶⁸ to be $(6.6 \pm 2) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹. Later,¹⁶⁹ the rate constant $k = (8 \pm 1.7) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹ was measured at room temperature and a pressure of 60–600 Torr.

It was concluded¹⁷⁰ that I₂O₂ dimers can form in the self-reaction of the IO radicals, although this possibility has never been confirmed in spectroscopic studies. According to certain data,¹⁷⁰ the rate constant for this reaction is temperature-independent in the range of 220–320 K and is equal to $(9.9 \pm 1.5) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹.

A non-empirical calculation using the QCISD(T)/6-311 + G(3df) basis set¹⁷¹ has shown that all I₂O₂ isomers are unstable with respect to the elements at 298 K.

Below, four possible isomers of I₂O₂ are shown as well as the calculated bond lengths (in Å) in them

In this family, the IIO₂ isomer is the most stable (in contrast to the corresponding chlorine and bromine analogues). The stability of I₂O₂ isomers decreases in the following sequence:¹⁷¹ IIO₂ > IOIO > IOOI > OIIO. In the IIO₂ molecule, the internuclear distance $r(\text{I}-\text{O}) = 1.777$ Å [calculated using the MP2/6-311 + G(3df) method] is the shortest distance as compared with the other I₂O₂ isomers, and the frequency of the I–O stretch is the highest (about 960 cm⁻¹). The lifetime of IIO₂ with respect to its decomposition to I and OIO at room temperature was estimated to be ~4 s. The geometrical parameters of iodine peroxide molecules IOOI were also calculated:¹⁷¹ $r(\text{I}-\text{O}) = 2.037$ Å, $r(\text{O}-\text{O}) = 1.426$ Å, the bond angle I–O–O and the torsion angle IOO/OOI were equal to 110 and 86°, respectively. The frequency of the I–O stretch was ~510 cm⁻¹. Using the following isodesmic reaction

the enthalpy of IOOI formation was calculated to be 37.5 kcal mol⁻¹ (at 298 K).¹⁷¹ As suggested by the authors of this work,¹⁷¹ OIO may be among the products of the IO + IO reaction.

Apparently, IOO radicals are still less stable as compared with ClOO radicals.^{171, 172}

The reaction of IO and ClO radicals at 298 K and the total pressure of 1 Torr was studied by mass spectrometry¹⁷³

For reactions (5), the rate constant $k_5 = (1.1 \pm 0.2) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹ and the branching ratios $k_{5a}/k_5 = 0.55 \pm 0.03$, $k_{5b}/k_5 = 0.25 \pm 0.02$ and $k_{5c}/k_5 = 0.20 \pm 0.02$ were found.¹⁷³ The value $k_5 = (1.29 \pm 0.27) \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹ (298 K) was also obtained.¹⁷²

The channel

was assumed to be highly improbable.

The most important source of iodine in the atmosphere is methyl iodide, which is liberated by algae and phytoplankton of the ocean and is rapidly photolysed in the troposphere. Iodine compounds can get to the stratosphere as a result of convection. Nuclear stations can also be a source of atmospheric contamination with iodine. The activity of iodine in the atmosphere is associated particularly with the absence of a photolytically stable reservoir of iodine-containing molecules.

* * *

Until recently, insufficient attention has been paid, for very clear reasons, to halogen–oxygen compounds X₂O₂, with the exception of dioxygen difluoride. The interest which has been aroused in these and related compounds was associated with the problem of stratospheric ozone depletion. The use of traditional and advanced methods for studying the properties of unstable compounds, as well as theoretical calculations of different levels allowed certain characteristics of both existing and imaginary compounds with the general formula X₂O₂ to be obtained. In this review, an attempt is undertaken to draw their ‘portraits’ based on the data taken from literature sources in which these compounds are discussed. The work dealing with other oxygen compounds of halogens are beyond the scope of this survey.

VI. Conclusion	108

Abstract. The data on the synthesis and reactions of organic compounds containing bonds of Te to Group 14 elements are generalised and systematised. The use of these compounds in the synthesis of organoelement compounds, complexes with organotellurium ligands, tellurium-containing clusters and metal tellurides is reviewed. The bibliography includes 99 references.

I. Introduction

The existence of four types of true, *i.e.*, containing at least one $Te-C$ bond, organotellurium compounds with Group 14 elements, *viz.*, $(R^1Te)_4E$, $(R^1Te)_3ER^2$, $(R^1Te)_2ER_2^2$ and $R^1TeER_3^2$ ($R^1 = Alk, Ar$; $R^2 = H, Alk, Ar$; $E = Si, Ge, Sn, Pb$), is possible in principle. Tellurides $R^1TeER_3^2$ are the most well studied among them. Compounds $(TeR)_4E$ have not been described so far, while the other two types are represented by only a few examples. The derivatives $(R_3E)_2Te$, the methods of synthesis and reactions of which are similar to those of tellurides $R^1TeER_3^2$ are also considered.

The interest in compounds $R^1TeER_3^2$ and $(R_3E)_2Te$ is determined by the fact that these are currently acquiring an ever increasing importance in the synthesis of organic and inorganic tellurium derivatives. Perfluoroalkyl trimethylstannyl tellurides $(R_FTeSnMe_3)$ are used for the preparation of telluroketones and previously unknown telluracyles.^{1–3} Compounds $R^1TeER_3^2$ are used as synthetic equivalents of organyl telluroate anions RTe^- which are easily oxidised in air and are used exclusively *in situ*.^{4–9} These types of compounds have been used in the synthesis of aryl methyl tellurides,⁸ aryl tellurobenzoates⁹ and aryl telluroformates^{6,7} in high yields. Triphenylgermyl derivatives and their stannyl analogues, *viz.*, $ArTeEPh_3$ ($E = Ge, Sn$), are convenient starting compounds for the synthesis of metal telluroates $(ArTe)_nM$ (M is metal),⁴ whereas $BuTeSiMe_3$ is used for the synthesis of tellurium-containing clusters.⁵ The reaction of bis-(trialkylsilyl) tellurides with some organoelement compounds,

which enables low-temperature synthesis of practically important metal tellurides M_xTe_y , attracts special attention.^{10,11}

The use of other compounds with $Te-E$ bonds for the synthesis of organic tellurium derivatives and some organic and organoelement compounds are described in more detail in the sections devoted to reactions of tellurides $R^1TeER_3^2$.

Earlier data on the synthesis and reactions of compounds $R^1TeER_3^2$ and $(R_3E)_2Te$ are described in the monographs.^{12–14}

Spatially hindered (organoelement)telluroles of the type R_3ETeH ($R = Me_3Si$, $E = Si, Ge$; $R = Ph$, $E = Si$) as well as tin and lead telluroates $[(Me_3Si)_3SiTe]_2E$ ($E = Sn, Pb$), which also contain $Te-E$ bonds, are used as the starting compounds in low-temperature synthesis of tellurides of these metals and are considered in the reviews.^{15,16}

II. Synthesis and reactions of compounds $R^1TeER_3^2$ ($E = Si, Ge, Sn, Pb$)

1. Synthesis of compounds $R^1TeER_3^2$

The most common approach to the synthesis of compounds $R^1TeER_3^2$ (**1**) with any element E is based on the reaction of alkali-metal telluroates R^1TeM with chlorides R_3^2ECl .^{4,5,17–19} Lithium telluroates are usually prepared by insertion of tellurium into the $C-Li$ bonds of alkyl(aryl)lithium,^{5,17–19} whereas sodium telluroates can be obtained by reducing diaryl ditellurides with either sodium borohydride in $PhH-EtOH$ ^{4,19} or metallic sodium in THF.¹⁸ The yields of compounds **1** usually vary from 60% to 80% with the exception of *p*-methoxyphenyl (triphenylgermyl) telluride (**1g**) obtained in 23% yield.⁴ Bis(trimethylsilyl) telluride and dialkyl ditellurides are side products in the synthesis of alkyl trimethylsilyl tellurides **1a,b**.^{5,17} $Ph_3SiTePh$ could not be obtained by this method.⁴

$M = Li, Na$.

The silyl derivatives **1a–c** represent pale yellow fluids with an unpleasant odour; their analogues containing heavier Group 14 elements are colourless or pale yellow solids readily soluble in ordinary organic solvents.

The reaction of lithium ethanetellurolate with chlorosilanes was used in the synthesis of the silyl derivatives **2a,b** containing alkyl groups and a hydrogen atom at the silicon atom.²⁰

R = Me (**a**), Et (**b**).

Aryl trimethylsilyl tellurides **3a,b** are obtained in 30%–40% yields by treatment of aryl telluromagnesium bromides with chlorotrimethylsilane in THF.^{21, 22}

Ar = Ph (**a**), 4-MeC₆H₄ (**b**).

(Me₂Si)₂Te and Me₃SiO(CH₂)₄TePh were isolated along with compound **3a** in 10% and 45% yields, respectively.²¹ The latter seems to result from the tetrahydrofuran ring opening under the action of chlorotrimethylsilane and the reaction of Me₃SiO(CH₂)₄Cl formed with PhTeMgBr.

Yet another approach to the synthesis of compounds **1**, viz., the reaction of the lithium derivatives R₃ETeLi with alkyl halides, is represented by a single example. Thus butyl (triethylsilyl) telluride **1p** was synthesised²³ in 79% yield by treatment of tetrameric lithium triethylsilylanetellurolate (**4**) with butyl chloride. Compound **4** is prepared from ethyllithium and the corresponding tellurol.²³

Reactions of diorganyl ditellurides^{1–3, 24} and diorganyl tellurides^{6, 7, 25–27} with organoelement hydrides afford tellurides **1** containing Si, Ge and Sn atoms. The synthetic potential of this method is inferior to that based on the reaction of alkali-metal tellurolates with chlorides R₃TECl and is mainly employed for the synthesis of organyl (triorganylstannyl) tellurides **1** (E = Sn). The reaction of diaryl ditellurides with triphenylstannane proceeds under mild conditions (heating of the reactants at 60–70 °C without a solvent) and results in aryl (triphenylstannyl) tellurides **1i, 5a–c** in 50%–70% yields.²⁴

Ar = Ph (**1i**), 4-MeOC₆H₄ (**5a**), 4-EtOC₆H₄ (**5b**), 4-PhOC₆H₄ (**5c**).

If tributylstannane is used instead of triphenylstannane, no individual compounds similar to compounds **5** could be isolated. However, the mass spectra of oily reaction products contain peaks of molecular ions corresponding to aryl (tributylstannyl) tellurides ArTeSnBu₃.²⁴

The reaction of bis(perfluoroalkyl) ditellurides with trimethylstannane is employed in the synthesis of perfluoroalkyl trimethylstannyl tellurides **6a–e**.^{1–3} Thus trifluoromethyl trimethylstannyl telluride **6a** was obtained in ~90% yield on warming of a 1:3 (CF₃)₂Te₂–Me₃SnH mixture in diethyl ether from –196 to 0 °C (see Ref. 1).

Compounds **6b–e** were synthesised under nearly identical conditions.^{2, 3} The reaction of the corresponding ditellurides with Me₃SnH (molar ratio 1:1) affords perfluorohydrocarbons and Te together with perfluoroalkyl trimethylstannyl tellurides.

R_F = CF₃ (**a**), C₂F₅ (**b**), (CF₃)₂CF (**c**), C₃F₇ (**d**), C₄F₉ (**e**).

It is noteworthy that the yields of compounds **6** with a ditelluride:Me₃SnH molar ratio of 1:2 are much lower due to their reaction with Me₃SnH.²

Reactions of diorganyl tellurides with organoelement hydrides proceed with the cleavage of one or two C–Te bonds resulting in compounds **1** or bis[triorganylsilyl (germyl, stannyl)] tellurides (R₃E)₂Te **7**. Sometimes, mixtures of both types of compounds are formed. The nature of the reactants is the main factor which determines the direction of these reactions. Thus in the case of dialkyl tellurides, a crucial role is played by the nature of the hydrides R₃EH the reactivities of which increase in the following order: Si < Ge < Sn. The reaction of triethylsilane with diethyl telluride (200 °C, 7 h) affords a mixture of compounds **1q** and **7a** (yields 12% and 55%, respectively). The reaction of triethylgermane with the same telluride (140 °C, 7 h) gives a mixture of compounds **1r** and **7b** in comparable yields (39% and 59%, respectively), whereas a similar reaction of triethylsilane yields only telluride **7c** even at 20 °C.^{25, 26}

R¹ = R² = Et: E = Si (**1q, 7a**), Ge (**1r, 7b**), Sn (**7c**).

In contrast to dialkyl tellurides, the reaction of bis(perfluoroalkyl) tellurides with trimethylstannane (molar ratio 1:1) gives exclusively perfluoroalkyl trimethylstannyl tellurides **6b,d,e** in 50%–65% yields.^{2, 3}

R_F = C₂F₅ (**b**), C₃F₇ (**d**), C₄F₉ (**e**).

Irrespective of the nature of the hydrides R₃EH, their reaction with aryl cyclohexyl tellurides leads to the cleavage of only the C_{sp³}–Te bond. Thus tellurides **8a–f** were prepared by heating an equimolar mixture of the reactants in benzene in the presence of catalytic amounts of azoisobutyronitrile (AIBN).^{6, 7, 27, 28} Compounds **8** were not isolated due to their low stabilities and were used in subsequent conversions (see Section II.2) *in situ*.

Compound 8	Ar	E	R	Ref.
a	Ph	Si	Me ₃ Si	6, 7, 28
b	4-FC ₆ H ₄	Si	Me ₃ Si	6, 7, 28
c	Ph	Ge	Bu	28
d	4-FC ₆ H ₄	Ge	Bu	28
e	Ph	Sn	Bu	27
f	4-FC ₆ H ₄	Sn	Bu	28

In contrast to tris(trimethylsilyl)silane, triphenylsilane does not split the C–Te bonds in aryl cyclohexyl tellurides.²⁸

It is of note that reaction of alkyl (or cycloalkyl) phenyl tellurides with triphenylstannane was proposed²⁹ as an efficient preparative procedure for the synthesis of alkanes (or cycloalkanes) in high yields long before the publication of the works.^{6, 7, 27, 28}

In all probability, this reaction follows a radical mechanism.²⁹

Germlyl (**9**) and stannyl (**1h**) derivatives were prepared in nearly quantitative yields by exchange reactions of organyl trimethylsilyl tellurides with the corresponding fluorogermane or chlorostannane.¹⁷

A similar reaction was used in the synthesis of organyl silyl tellurides **10a,b**.¹⁷

R = Me (**a**), Ph (**b**); X = Br, I.

The attempts to synthesise compounds of the type **10** by the reaction of lithium methane(benzene)telluroate with BrSiH_3 were unsuccessful, bis(silyl) telluride $(\text{H}_3\text{Si})_2\text{Te}$ being the only reaction product.¹⁷

Other reactions resulting in compounds **1** are represented by single examples. Thus ethyl (triethylgermyl) telluride (**1r**) was synthesised by reaction of diethyl ditelluride with triethylgermyl-lithium (yield 89%)²⁰ or from the same ditelluride and bis(triethylgermyl)mercury (yield 73%).³⁰

Methyl tris(trimethylsilyl)silyl telluride (**1s**) was synthesised by treatment of lithium tris(trimethylsilyl)silanetelluroate with trimethyltelluronium iodide.³¹ Photolysis of a hexabutyldistannane–dimethyl telluride mixture yields methyl tributylstannyl telluride (**1t**).³²

2. Reactions of compounds $\text{R}^1\text{TeER}_3^2$

In most cases, reactions of compounds **1** were studied using silyl and stannyl derivatives as examples. Some of these reactions represent valuable procedures for preparative synthesis of various organotellurium compounds including those used in synthetic organic chemistry.

The Te–Si bond in organyl triorganysilyl tellurides is easily cleaved under the action of hydrohalic acids, alcohols and water to give organyl tellurols and halogenosilanes, alkoxy-silanes or siloxanes, respectively.¹⁷

$\text{R}^1 = \text{Me, Ph; X} = \text{Br, I, Oalk, OH}.$

Benzenetellurol *in situ* manifests strong reducing properties.^{33–35} Several methods for the synthesis of this compound are known, they include methanolysis of phenyl trimethylsilyl telluride^{33–35} and reduction of diphenyl ditelluride with hypophos-

phorous acid or sodium borohydride.³³ The former approach is especially convenient. Phenyltellurol thus generated reduces nitro compounds into amines (in benzene or chloroform),^{33,34} alkenes and alkynes into alkanes,³⁴ aldehydes and ketones into alcohols³⁴ and reduction of carbonyl compounds in alcohols in the presence of catalytic amounts of ZnI_2 affords ethers.³⁵ These reactions proceed under mild conditions and in high yields.

Compounds **1** readily undergo disproportionation. Thus methyl germly telluride disproportionates into di(germyl) telluride (**7d**) and dimethyl telluride, whereas disproportionation of methyl silyl telluride yields bis(methyltelluro)silane and silane.¹⁷

The disproportionation of methyl trimethylstannyl telluride upon long-term storage or irradiation at 488 nm follows the same scheme as in the case of methyl germly telluride, bis(trimethylstannyl) telluride and dimethyl telluride being formed.¹⁷

Pyrolysis of perfluoroalkyl trimethylstannyl tellurides **6** proceeds in quite a different manner.^{1–3} This results in trimethyl-fluorostannane and telluroketones **11**, which easily dimerise into the 1,3-ditellurethane derivatives **12** and **13**.^{1–3}

$\text{R}^1 = \text{F; R}^2 = \text{F}$ (**a**), CF_3 (**b**), C_2F_5 (**d**), C_3F_7 (**e**);

$\text{R}^1 = \text{R}^2 = \text{CF}_3$ (**c**).

Heating of tellurides **6a–d** in chloroform with a large excess of 2,3-dimethylbutadiene yields initially the telluroketones **11a–d**, which then enter into a [4 + 2]-cycloaddition reaction^{1–3} to give 5,6-dihydro-3,4-dimethyl-2*H*-tellurine derivatives **14a–d** in 70%–90% yields.

$\text{R}^1 = \text{R}^2 = \text{F}$ (**a**); $\text{R}^1 = \text{F, R}^2 = \text{CF}_3$ (**b**); $\text{R}^1 = \text{R}^2 = \text{CF}_3$ (**c**);

$\text{R}^1 = \text{F, R}^2 = \text{C}_2\text{F}_5$ (**d**).

Phenyl trimethylsilyl telluride cleaves lactones and ethers under mild conditions (dichloromethane, 20 °C) in the presence of catalytic amounts of ZnI_2 to give C-tellurination and O-silylation products.¹⁸ Thus acids **16** are prepared from lactones **15** and PhTeSiMe_3 in > 80% yields. Intermediate *O*-trimethylsilyl esters **17** are hydrolysed upon work-up of reaction mixtures.

Phenyl trimethylsilyl telluride markedly exceeds related sulfur- and selenium-containing compounds in reactivity. The lac-

tone ring opening under the action of telluride occurs at 20 °C (PhSSiMe₃ reacts at 70 °C,³⁶ whereas PhSeSiMe₃, at 80–100 °C).³⁷

Oxirane and other cyclic ethers are cleaved with the same efficiency under the action of phenyl trimethylsilyl telluride to give trimethylsilyloxy-substituted tellurides **18**.¹⁸ Other examples of such reactions have also been described.¹⁸

R = Me, Et, n = 0; R = H, n = 1–4; R = Me, n = 2.

Organyl trimethylsilyl tellurides RTeSiMe₃ are synthetic equivalents of organyl tellurolate anions RTe[−] (see Refs 4–9). In some cases, the use of tellurides gives better results in comparison with alkali-metal tellurolates. Thus the reaction of MeTeSiMe₃, generated *in situ* from MeTeLi and Me₃SiCl, with arylazo sulfones in MeCN containing catalytic amounts of 18-crown-6 afforded aryl methyl tellurides in 36%–62% yields.⁸

R = H, 4-Br, 4-COMe, 2-CO₂Me.

The use of MeTeLi prepared from MeLi and Te in THF does not lead to aryl methyl tellurides in this reaction. Deazosulfonation in THF does not take place, but substitution of MeCN for THF yields a mixture of dimethyl telluride and dimethyl ditelluride which are inert with respect to arylazosulfones.⁸

Under mild conditions (THF, 20 °C), phenyl trimethylsilyl telluride reacts with aryl chlorides to give phenyl tellurobenzoates **19a–i** (yield 62%–91%).⁹ The advantages of this procedure in comparison with the classical methods based on the use of sodium arenetellurolates lie in higher yields of the esters formed and the simplicity of their isolation from reaction mixtures.³⁸

Ar = 4-ClC₆H₄ (**a**), 3-ClC₆H₄ (**b**), 4-BrC₆H₄ (**c**), 4-NO₂C₆H₄ (**d**), 4-NCC₆H₄ (**e**), Ph (**f**), 4-MeC₆H₄ (**g**), 4-MeOC₆H₄ (**h**).

Aryl tris(trimethylsilyl)silyl tellurides **8a,b** used *in situ* react with chloroformates exclusively in the presence of catalytic amounts of tetrakis(triphenylphosphine)palladium(0) to give aryl tellurocarbonates **20a–j** (for the use of compounds **20a–j** as precursors of oxyacyl and alkyl radicals see Refs 39, 40). Aryl tellurocarbonates **20e,j** with a phenyl radical at the ester oxygen atom can be prepared^{6,7} only from compounds **8a,b**. They could not be obtained in the reaction of chloroformates with sodium arenetellurolate.^{6,7}

Compo- und 20	Ar	R	Compo- und 20	Ar	R
a	Ph	Me	f	4-FC ₆ H ₄	Me
b	Ph	Pr ⁱ	g	4-FC ₆ H ₄	Pr ⁱ
c	Ph	cyclo-C ₆ H ₁₁	h	4-FC ₆ H ₄	cyclo-C ₆ H ₁₁
d	Ph	C ₈ H ₁₇	i	4-FC ₆ H ₄	C ₈ H ₁₇
e	Ph	Ph	j	4-FC ₆ H ₄	Ph

Compounds **1** react with some metal halides to give the corresponding metal tellurolates. Thus the reaction of phenyl triphenylgermyl(stannyl) tellurides **1e,i** with the palladium(II) chloride–benzonitrile complex results in elimination of Ph₃ECl followed by the formation of red-brown palladium tellurolates **21** which seem to possess polymeric structures.⁴

E = Ge (**1e**), Sn (**1i**).

The reaction of compounds **1** with CuCl in chloroform⁴ or acetonitrile⁴¹ gives polymeric copper(I) tellurolates **22**.

Ar = Ph, 4-EtOC₆H₄; E = Ge, Sn, Pb.

Metal tellurolates are also formed in those cases where phenyl trimethylsilyl telluride is used as a source of the ligand PhTe. Thus reaction of this compound with dimethylcadmium in CH₂Cl₂ gave cadmium(II) benzenetellurolate (**23**).¹⁰

Reaction of organyl trimethylsilyl tellurides, particularly, BuTeSiMe₃, with copper(I) salts results in tellurium-containing clusters which were characterised by the X-ray diffraction method.⁵

X = Cl, OAc; (a) PPh₃, THF; (b) PPr₃, diglyme; (c) PET₃, THF; (d) PPh₃, diglyme.

The cluster **24** is the only reaction product of phenyl trimethylsilyl telluride with a complex cobalt(II) salt.⁵

It has been shown recently⁴² that compounds RTeEMe₃, similar to (Me₃E)₂Te (E = Si, Sn), enter into oxidative addition with triethylphosphine platinum complexes Pt(PEt₃)_n (n = 3, 4) to give complexes **25a–g** in 76%–100% yields.

E = Si: R = Ph (**a**), 4-PhC₆H₄ (**b**), Bu (**c**), Me₃Si (**d**);

E = Ge, R = Ph (**e**); E = Sn: R = Ph (**f**), Me₃Sn (**g**).

The structures of compounds **25** were confirmed by NMR spectroscopy and the X-ray diffraction analysis using complex **25b**⁴² as an example. They represent solid red-coloured substances stable under an argon atmosphere but extremely sensitive to oxygen and moisture.⁴²

The reactivities of phenyl trimethylsilyl chalcogenides PhM(SiMe₃)₃ (M = S, Se, Te) in this reaction increase in the following order: S < Se < Te. Thus phenyl trimethylsilyl sulfide does not react with Pt(PEt₃)₃ even after 5-h heating at 50 °C, whereas phenyl trimethylsilyl selenide reacts with the Pt(0) complex at 25 °C, albeit at a much slower rate than its tellurium analogue.⁴²

Complexes **25** are gradually decomposed in benzene even at 25 °C. The following decomposition products of compound **25a** have been identified:⁴²

The decomposition reaction is reversible, *i.e.*, the addition of even 1 equiv. of PEt_3 inhibits this process.⁴²

III. Methods of synthesis and reactions of compounds $(\text{R}_3\text{E})_2\text{Te}$ (E = Si, Ge, Sn, Pb)

Compounds containing two bonds of Te to Group 14 elements include both symmetrical $(\text{R}_3\text{E})_2\text{Te}$ (E is a Group 14 element) (**7**) and non-symmetrical derivatives of the type $\text{R}_3^1\text{E}^1\text{TeER}_3^2$ (**26**). The methods of their syntheses and reactions of both types of compounds are very similar and will therefore be considered in the same section.

1. Methods of synthesis

Two reactions affording tellurides **7** are described in Section II. The first of them is the reaction of hydrides R_3EH with diorganyl tellurides. Depending on the nature of substrates, this reaction gives compounds **1** and **7** or their mixtures.^{25,26} The second reaction is disproportionation of tellurides **1**.¹⁷

The addition of Me_3SiCl to an ethereal solution of PhTeMgBr leads to the formation of bis(trimethylsilyl) telluride,⁴³ apparently also as a result of disproportionation of PhTeSiMe_3 under the reaction conditions. It should be noted that the same reactants in THF (see Section II.1) give PhTeSiMe_3 .

The general method for the synthesis of both symmetrical (**7**) and non-symmetrical (**26**) tellurides is based on the reaction of organolithium derivatives $\text{R}_3^1\text{E}^1\text{TeLi}$ with chlorides $\text{R}_3^2\text{E}^2\text{Cl}$.^{44–48} However, this method is only seldom employed, *e.g.*, in the synthesis of phenyl derivatives containing various combinations of Ge, Sn and Pb atoms. This reaction was also used in the synthesis of bis(triphenylsilyl) telluride.⁴⁹

Compound	E ¹	E ²	Ref.
7e	Ge	Ge	46
7f	Sn	Sn	44, 45
7g	Pb	Pb	47
26a	Sn	Ge	46
26b	Sn	Pb	45
26c	Pb	Ge	46

Non-symmetrical derivatives **26d–f** are also obtained by reactions of triethyltin or -germanium hydrides with tellurides **1q,r** (yields 60%–90%)²⁶ or **7a,b**.⁵⁰

E¹ = Si (**1q, 7a**), Ge (**1r, 7b**); E¹ = Si, E² = Sn (**26d**); E¹ = Ge, E² = Sn (**26e**); E¹ = Si, E² = Ge (**26f**).

In these reactions, the reactivities of the hydrides decrease in the following order: Sn > Ge > Si. Thus the reaction of Et_3GeH with $(\text{Et}_3\text{Si})_2\text{Te}$ yields $(\text{Et}_3\text{Ge})_2\text{Te}$ (yield 79%) and Et_3SiH (yield 50%) at 235 °C for 6 h, while the reaction of Et_3SnH with

$(\text{Et}_3\text{Ge})_2\text{Te}$ results in $(\text{Et}_3\text{Sn})_2\text{Te}$ (yield 76%) and Et_3GeH (yield 57%) at 70 °C for 1 h.⁵⁰

Reactions of the mercury derivatives $(\text{Et}_3\text{E}^1)_2\text{Hg}$ with the hydrides $\text{R}_3\text{E}^2\text{TeH}$ also yield non-symmetrical tellurides **26**,⁵¹ however, this method has been studied relatively little. Reaction of bis(triethylgermyl)mercury with Et_3SiTeH (molar ratio 1 : 1) yields compound **27** with the Si–Te–Hg–Ge fragment, which can easily eliminate the mercury atom to yield the non-symmetrical telluride **26f** under mild conditions (–78 °C, 2–3 min).

It is of note that in contrast to compound **27**, bis(triethylsilyltelluro)mercury (**28**) formed with a tellurol:mercury molar ratio of 2 : 1 is thermally stable and is not decomposed even on heating to 130 °C for 7 h.⁵¹

The synthesis of symmetrical tellurides **7** has been studied in much more detail than that of the non-symmetrical analogues **26**. Reaction of sodium⁵² or lithium^{21,53–57} tellurides with the halides R_3EX is the most general approach to their synthesis. The yields of tellurides **7** vary from very low (5%)⁵⁷ to quantitative.⁵⁵

M = Na, Li.

Compound 7	E	R ₃	Ref.
h	Si	H ₃	53, 55
i	Si	Me ₃	21, 52–54, 56
j	Si	Bu ^t Me ₂	56
k	Ge	(CF ₃) ₃	57
l	Ge	Me ₃	52
m	Sn	Me ₃	52
n	Pb	Me ₃	52

Reaction of 1,1'-bis(chlorodimethylstannyl)ferrocene⁵⁸ with lithium telluride was used to obtain 1,3-distanna-2-tellura[3]ferrocenophane **29** (yield 28%).⁵⁹

Sodium hydrotelluride was employed in the synthesis of bis(triphenylstannyl) telluride (**7f**).^{19,60}

Some digermyl tellurides were prepared using hydrogen telluride as the tellurium-containing reagent.⁶¹ Thus warming of a mixture of carbodiimides **30** with an excess of H_2Te from –196 °C to room temperature results in bis(germyl) tellurides **31** in 60%–90% yields.⁶¹

$n = 1-3$.

Silicon analogues of carbodiimides **30** do not enter into such reactions.⁶¹

The symmetrical tellurides **7a–c** were obtained by heating hydrides R_3EH with tellurium powder.^{26,50,62,63} As in the previous cases, the reactivities of the hydrides increase in the following order: Si < Ge < Sn. Whereas the reaction of tellurium with

Et_3SnH proceeds at $130\text{ }^\circ\text{C}$ ^{26,62} and that with Et_3GeH , at $190\text{--}210\text{ }^\circ\text{C}$,^{26,62} the reaction of Te with Et_3SiH resulting in bis(triethylsilyl) telluride **7a** in 71% yield can be realised only at $280\text{ }^\circ\text{C}$.^{50,63}

E = Si (**a**), Ge (**b**), Sn (**c**).

The reaction of 1,1'-bis(dimethylstannyl)ferrocene⁵⁸ with tellurium powder was used for the synthesis of telluride **29** (yield 90%);⁵⁹ the same compound was obtained in 79% yield by reaction of 1,1,2,2-tetramethyl-1,2-distanna[2]ferrocenophane with tellurium.⁵⁹

Depending on the nature of the hydride and the chalcogen, reactions of sulfur and selenium with hydrides R_3EH yield either organoelement hydrochalcogenides R_3EMH [E = Si,^{50,63} Ge;²⁶ M = S,⁶³ Se (see Refs 26, 50 and 63)] or their mixtures with compounds $(\text{R}_3\text{E})_2\text{M}$. The stabilities of hydrides R_3EMH increase in the following order: $\text{Te} < \text{Se} < \text{S}$. Thus heating of sulfur with triphenylsilane at $200\text{ }^\circ\text{C}$ gives triphenylsilylanethiol Ph_3SiSH as the only product (yield 70%),⁶³ whereas reaction of selenium with triethylsilane ($260\text{ }^\circ\text{C}$) results in a mixture of Et_3SiSeH (yield 62%) and $(\text{Et}_3\text{Si})_2\text{Se}$ (yield 32%).^{50,63} The latter represents a symmetrisation product.⁶³

Whereas triethylsilylanetellurol Et_3SiTeH , which is the least stable of all chalcogenols, is symmetrised completely, the degree of conversion of more stable triethylsilylaneselenol into bis(triethylsilyl) selenide and H_2Se is only 40%.⁶³

It should be noted that reaction of selenium with germanes R_3GeH (R = Pr^i , cyclo- C_6H_{11}) yields predominantly germane selenols R_3GeSeH .

Tributylphosphine telluride $\text{Bu}_3\text{P}=\text{Te}$, a synthetic equivalent of metallic tellurium, was used instead of the latter in reactions with triorganylstannyl hydrides.⁶⁴ Its solubility in organic solvents makes it possible to synthesise bis(triorganylstannyl) tellurides, e.g., bis(tributylstannyl) telluride **7o**, under mild conditions in the presence of catalytic amounts (2 mol.%–10 mol.%) of Cp_2^*TiH ($\text{Cp}^* = \text{Me}_5\text{C}_5$). In the absence of a catalyst, the yield of the target product does not exceed 2%.⁶⁴

Tellurides **7** (E = Ge, Sn) were also synthesised by exchange reactions of compounds **7** containing more light weight Group 14 elements with the halides R_3EX . Thus bis[tris(pentafluorophenyl)stannyl] telluride **7p** was obtained (in 57% and 51% yields, respectively) by reaction of bis(triethylgermyl) (**7b**) or bis(triethylsilyl) tellurides (**7a**) with $(\text{C}_6\text{F}_5)_3\text{SnBr}$.⁶⁵ This reaction seems to involve stepwise exchange of Et_3E groups (E = Si, Ge) for $(\text{C}_6\text{F}_5)_3\text{Sn}$ groups and proceeds through four-membered transition states.

E = Si (**a**), Ge (**b**).

With an excess of germlyl bromide, di(silyl) telluride (**7q**) is quantitatively converted into di(germyl) telluride (**7d**), apparently, by the same mechanism.⁵⁵

Other methods of synthesis of tellurides **7** were studied in separate reactions, although some of them can be used for the synthesis of a larger number of compounds. Thus bis(triisopropylgermyl) telluride (**7r**) was obtained in 78% yield by reaction of bis(triisopropylgermyl)mercury with tellurium powder.³⁰

Bis(trifluorosilyl) telluride (**7s**) was prepared by reaction of trifluorosilyl radicals generated by decomposition of hexafluorodisilane with tellurium vapour in a low-temperature matrix.^{66,67}

The synthesis of silyl derivatives of the type **7**, which contain sterically hindered silane residues, requires special strategies. Thus bis(triphenylsilyl) telluride (**7t**) was obtained by protonation of lithium triphenylsilylanetellurolate (**32**) in THF or by oxidation of this salt with atmospheric oxygen.⁴⁹

It should be noted that oxidation of tris(trimethylsilyl)silane-tellurol ($(\text{Me}_3\text{Si})_3\text{SiTeH}$ or its lithium salt results in the ditelluride $[(\text{Me}_3\text{Si})_3\text{Si}]_2\text{Te}_2$.^{68,69}

The symmetrical telluride **33** is formed together with the corresponding metal tellurides by pyrolysis of tellurolates **34**.¹⁶

M = Zn, Cd, Sn, Pb, Yb.

The symmetrical and non-symmetrical tellurides considered above containing two $\text{Te}-\text{E}$ bonds have identical substituents on the Group 14 elements. Presumably, telluride **35**⁶⁹ synthesised from lithium tris(trimethylsilyl)silylanetellurolate and trimethylchlorosilane is the only compound which has different substituents on these atoms.

2. Reactions of compounds $(\text{R}_3\text{E})_2\text{Te}$

It should be noted that the majority of reactions of tellurides **7** and **26** have been studied for a limited number of compounds only; therefore, it is sometimes difficult to judge the general type of one or another reaction.

Most reactions of tellurides **7** (reactions of the non-symmetrical derivatives **26** have been studied relatively little) occur with elimination of tellurium. The hydride derivatives $(\text{H}_3\text{E})_2\text{Te}$ are photosensitive and are decomposed on rough glass surfaces even at room temperature,⁵³ while bis[tris(trifluoromethyl)germyl] telluride (**7k**) eliminates tellurium only at $115\text{ }^\circ\text{C}$.⁵⁷ Tellurides **7**

containing alkyl and trifluoromethyl radicals are rather easily hydrolysed.⁵⁷

Symmetrical (**7e–g**) and non-symmetrical phenyl derivatives (**26a–c**) are thermally and hydrolytically stable compounds. Their stabilities with respect to moisture and oxygen increase in the following order: $(\text{Ph}_3\text{Ge})_2\text{Te} < (\text{Ph}_3\text{Pb})_2\text{Te}$ and $(\text{Ph}_3\text{Ge})_2\text{Te} < \text{Ph}_3\text{GeTeSnPh}_3 < \text{Ph}_3\text{GeTePbPh}_3$.⁴⁷ The non-symmetrical aliphatic derivatives $\text{R}_3^1\text{E}^1\text{TeE}^2\text{R}_3^2$ easily disproportionate to give the symmetrical tellurides $(\text{R}_3^1\text{E}^1)_2\text{Te}$ and $(\text{R}_3^2\text{E}^2)_2\text{Te}$.⁷⁰

The Te–E bonds in tellurides **7** are easily cleaved under the action of various oxidants. Thus the silyl derivatives **7h,i** react with oxygen to give elementary tellurium and the corresponding siloxane.⁵³

R = H (**h**), Me (**i**).

The oxidation of tellurides **7** by halogens proceeds under mild conditions and gives halides R_3EX (yields 50%–85%) and Te; some amount of R_2SnX_2 is formed in the case of stannyl derivatives.^{56,71}

R = Et; E = Si (**a**), Ge (**b**), Sn (**c**); R = Me, E = Si (**i**); X = Cl, Br, I.

The reactions of the tellurides **7** with Ag(I) ⁴³ and Hg(II) ⁵¹ salts also afford halides R_3EX and, in addition, metal tellurides. Noteworthy, the reactions of these salts with diorganyl tellurides R_2Te give complexes with the compositions 1 : 1 or 1 : 2.⁷²

E = Si (**a**), Ge (**b**).

It has been shown for the first time⁶³ that the cleavage of E–Te bonds in compounds **7** is effected not only by free halogens but also by organic dihalides containing rather active halogen atoms. Thus boiling of ethyl derivatives **7a–c** with 1,2-dibromoethane leads to the formation of Et_3EBr , Te and ethylene.⁶³ The reaction with bis(triethylstannyl) telluride (**7c**) proceeds most smoothly.

E = Si (**a**), Ge (**b**), Sn (**c**).

It is this reaction in particular that underlies the synthesis of alkenes from vicinal dibromides using bis(triphenylstannyl) telluride (**7f**) and CsF as a dehalogenating reagent.⁷³

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Ph}$, $n\text{-C}_8\text{H}_{17}$, PhSO_2CH_2 ; $\text{R}^1 = \text{R}^2 = \text{Ph}$;
 $\text{R}^1-\text{R}^2 = \text{CH}_2\text{OCH}_2\text{OCH}_2$.

This reaction proceeds under mild conditions; alkenes are most frequently formed in virtually quantitative yields. Thus the reaction of *meso*-1,2-dibromo-1,2-diphenylethane with $(\text{Ph}_3\text{Sn})_2\text{Te}$ results in *trans*-stilbene in 94% yield.⁷³

Upon substitution of $\text{KF} \cdot \text{H}_2\text{O}$ for CsF, telluride **7f** effects dehalogenation of α -chloro(bromo) ketones under mild conditions (MeCN , 20°C).⁷³ With a molar reagent ratio **7f**: $\text{KF} \cdot 2\text{H}_2\text{O}$: α -halogeno ketone of 1 : 3 : 1, the ketones are formed in 60%–90% yields. The feasible mechanism of this reaction includes the intermediate formation of triphenylstannanetellurol.⁷⁴

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^3 = \text{Me}$, Et, Ph; $\text{R}^1 = \text{Me}$, $\text{R}^3 = \text{Ph}$; $\text{R}^2 = \text{H}$, Me;
 $\text{R}^1-\text{R}^3 = (\text{CH}_2)_4$, $\text{R}^2 = \text{H}$.

Cleavage of the Te–E bonds in tellurides **7a–c** proceeds smoothly under the action of symmetrical and non-symmetrical acyl peroxides.⁷⁵ This reaction gives high yields of elementary tellurium and triorganylsilyl (germyl, stannyl) esters of the corresponding acids.

E = Si (**a**), Ge (**b**), Sn (**c**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Ph}$, Me.

Reaction of bis(triethylgermyl) telluride (**7b**) with dicyclohexyl percarbonate yields CO_2 and cyclohexyloxytriethylgermane together with Te, apparently as a result of decomposition of the initially formed triethylgermyl cyclohexanecarboxylate.⁷⁵

Like diaryl tellurides Ar_2Te ,⁷² tellurides **7a,c** eliminate Te upon heating with sulfur or selenium to give sulfides and selenides, respectively.^{50,63} As in the reaction with diaryl tellurides,⁷² sulfur surpasses selenium in activity. Thus reaction of $(\text{Et}_3\text{Sn})_2\text{Te}$ with sulfur proceeds at 20°C (90 h), whereas reaction of the same telluride with selenium requires heating at 150°C for 30 h.^{50,63}

E = Si, M = S; E = Sn: M = S, Se.

Formally, reduction of diorganyl chalcogen oxides by bis(trialkylsilyl) tellurides is related to the same class of reactions.⁵⁶ This can be regarded as a preparative method for the synthesis of chalcogenides from chalcogen oxides because of their high yields (80%–100%) and easy separation from other products, *viz.*, hexaalkyldisiloxanes and elementary tellurium. It should be noted that bis(trimethylsilyl) sulfide and selenide are also rather efficient reagents.⁵⁶

$\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Ph}$, M = Te; $\text{R}^2 = \text{Me}$, M = S;
 $\text{R}_3^1 = \text{Bu}^t\text{Me}_2$; $\text{R}^2 = \text{Ph}$, M = Se; $\text{R}^2 = \text{Me}$, M = S.

The use of bis(triphenylstannyl) telluride (**7f**) for monodesulfurisation of organic trisulfides⁷⁶ and synthesis of aryl triphenylstannyl sulfides⁷⁷ is based on easy elimination of the Te atom from compounds **7**. Various types of organic trisulfides (aryl-, benzyl-, alkyl-) are readily converted into the corresponding disulfides under the action of $(\text{Ph}_3\text{Sn})_2\text{Te}$. The rate of the desulfurisation reaction increases with an increase in the solvent polarity.

R = FC₆H₄, MeC₆H₄, Bn, PhCHMe, Me(CH₂)₂.

Other bis(triphenylstannyl) chalcogenides (Ph₃Sn)₂M (M = S, Se) can monosulfurise organic trisulfides; the reactivities of chalcogenides (Ph₃Sn)₂M decrease in the following order: Te > Se > S. Bis(triphenylstannyl) selenide causes desulfurisation of only diaryl and dibenzyl trisulfides, whereas desulfurisation by bis(triphenylstannyl) sulfide proceeds with very low yields and only upon long-term boiling of the reaction mixture.⁷⁶

Reaction of telluride **7f** with diaryl disulfides under mild conditions (MeCN, 20 °C) results in aryl triphenylstannyl sulfides **36** in high, sometimes quantitative, yields.⁷⁷ Dialkyl and dibenzyl disulfides do not enter into such reactions. Compounds **36** can be synthesised from diaryl disulfides and bis(triphenylstannyl) selenide.⁷⁷ However, the latter is much less efficient than tellurides. 4-Methylphenyl triphenylstannyl sulfide is formed in a quantitative yield upon treatment of the corresponding disulfide with telluride **7f** and in only 28% yield when a selenium derivative is used, other conditions (solvent, temperature, reaction time) being the same.⁷⁷

Ar = 4-ClC₆H₄, 4-FC₆H₄, Ph, 4-MeC₆H₄, 2-C₁₀H₇.

If organyl trimethylsilyl tellurides RTeSiMe₃ represent synthetic equivalents of organytellurolate anions RTe⁻ (see Section II.2), compounds **7** and particularly bis(triphenylstannyl) telluride **7f** act as synthetic equivalents of the telluride anion Te²⁻ (see Refs 73, 78).

Bis(triphenylstannyl) telluride **7f** used in combination with CsF (4 equiv.) is a mild tellurinizing reagent.^{73, 78} Reactions of this reagent with organic bromides and iodides in MeCN at 20 °C afford symmetrical diorganyl tellurides in high yields.^{73, 78} Aryl iodides and alkyl chlorides are inert with respect to compound **7f**, which makes it possible to synthesise diorganyl tellurides containing chlorine atoms. It is believed⁷³ that the synthesis of diorganyl tellurides proceeds in two steps and includes an attack of the fluoride ion on the tin atom.

X = Br, I; R = Prⁱ, Bn, Cl(CH₂)₆, Me(CH₂)₉, PhCOCH₂, CH₂CO₂Et, CH₂CO₂Me, CH₂CO₂Prⁿ, CH₂CO₂Bu^t, (CH₂)₃CO₂Et.

Reactions of bis(trialkylsilyl) tellurides with certain organo-element compounds occur with the cleavage of both Te—Si bonds and lead to the formation of tellurides of the corresponding metals rather than elementary Te; these reactions are of special interest. Thus reactions of bis(trimethylsilyl) telluride (**7i**) with tris(dimethylamino)antimony or -bismuth occur under very mild conditions (hexane, -30 °C) and yield polycrystalline antimony and bismuth tellurides¹¹ which manifest semiconducting properties.

M = Sb, Bi.

Metal dialkyls can be used instead of dimethylamino derivatives. This method was used in the synthesis of Cd(II) telluride.¹⁰

Reaction of bis(trimethylsilyl) telluride (**7i**) with copper(I) chloride in the presence of phosphines results in the formation of cluster copper complexes⁷⁹ which differ from those obtained using butyl trimethylsilyl telluride (see Section II.2).

(a) PEt₃, Et₂O; (b) PPhEt₂, Et₂O; (c) PPr₃ⁱ, Et₂O; (d) PBU₃^t, THF.

Reactions of tellurides **7** with other than Sb, Bi and Cd organoelement derivatives occur with the cleavage of two (less frequently, one) Te—E bonds; in this case, tellurium becomes a constituent of one of the reaction products.

Bis(tributylstannyl) telluride undergoes transmetalation with trimethylaluminium.^{80, 81} Bis(dimethylaluminium) telluride (Me₂Al)₂Te used *in situ* is an efficient tellurinizing reagent. Treatment of aldehydes, ketones⁸⁰ and *N*-methylformanilide⁸¹ with this reagent results in telluroaldehydes (ketones)⁸⁰ and *N*-methyltelluroformanilide,⁸¹ respectively.

R¹ = H; R² = Prⁿ, Bu^t, Ph, N(Me)Ph; R¹R²CO — adamantanone, bicyclo[3.3.1]nonan-7-one.

Tellurides (H₃E)₂Te react with PF₂Br with the cleavage of one and two Te—E bonds to give a mixture of compounds **37** and **38**.⁸² These compounds were not isolated; their formation was deduced from the ¹H and ¹⁹F NMR spectra.

E = Si, Ge.

At the same time, reaction of bis(trimethylsilyl) telluride **7i** with Bu^tPCl₂ occurs with the cleavage of both Te—Si bonds resulting in a mixture of cyclic compounds **39** and **40**.⁸³

Reactions of bis(trialkylsilyl) tellurides with acyl chlorides and bisacyl tellurides have been considered in the recently published review.⁸⁴

The Te—E bond in tellurides **7** is easily cleaved by protic acids (HCl, anhydrous CF₃CO₂H).⁶³ Thus the first silanetellurol, *viz.*, triethylsilanetellurol, was obtained by treating bis(triethylsilyl) telluride (**7a**) with trifluoroacetic acid (molar ratio 1 : 1) at 20 °C. In the presence of an excess of the acid, the Te—Si bond of tellurol is cleaved to give triethylsilyl trifluoroacetate and elementary Te, presumably as a result of oxidation of the intermediate H₂Te.⁶³

M = Mn (**45a**), Re (**45b**); X = Br, Cl.

Reaction of germyl tellurides **31** with gaseous HI at 20 °C results in the cleavage of both Te–Ge bonds^{55,61} to give germyl iodides and H₂Te.

Silane- and germane-tellurols **41** are formed by an exchange reaction between the corresponding tellurides and H₂Te.⁸⁵ The equilibrium constants are equal to 0.90 (E = Si) and 0.95 (E = Ge).

E = Si, Ge.

The signals for the Te–H protons in the ¹H NMR spectra of tellurols **41** are observed at very high fields. Thus δ_{TeH} of silanetellurol is equal to –7.46 ppm, while that of germanetellurol is –7.44 ppm.⁸⁵

The Te–E bonds are not affected upon complexation of tellurides **7** with some Lewis acids. The stable complexes **42a–c** (1 : 1) were prepared from bis[tris(pentafluorophenyl)germyl]cadmium (**43**) and tellurides **7a–c**.⁸⁶ A complex with the composition 1 : 2 was also isolated in the case of the stannyl derivative.

E = Si (**a**), Ge (**b**), Sn (**c**).

The complexes **42a–c** are rapidly oxidised in air. It is noteworthy that tellurides **7a–c** form predominantly 1 : 1 complexes, while diorganyl sulfides R₂S react with compound **43** to give 1 : 2 complexes. This is attributed to the decrease in the donor activity of the Te atoms of tellurides **7a–c** as a result of *d*_π–*p*_π coupling of Te with the E atoms and steric hindrances.⁸⁶

Tellurides **7** react with chromium, molybdenum and tungsten carbonyls (CO)₅M·THF (M = Cr, Mo, W) resulting in the displacement of the tetrahydrofuran molecule and the formation of complexes **44** which are sensitive to oxygen and atmospheric moisture.^{52,87} The yields of the latter are relatively low (17%–45%). The attempts to obtain complexes **44** by irradiation of solutions containing metal hexacarbonyls and tellurides failed due to decomposition of tellurides upon illumination.

E = Ge, Sn, Pb; M = Cr, Mo, W.

Unlike bis(trimethylstannyl) selenide, which forms binuclear complexes **45** in high yields upon reaction with manganese and rhenium halogen carbonyls, bis(trimethylstannyl) tellurides (**7m**) react with these carbonyls to give complexes **45a,b** in very low yields (*e.g.*, the yield of compound **45a** is 11%, whereas the formation of complex **45b** followed only from spectroscopic data).⁸⁸ Treatment of complex **45a** with HCl in ether yields tellurol **46** (δ_{TeH} – 12.80 ppm).

IV. Other types of non-cyclic compounds containing Te–E bonds

Apart from R¹TeER₂³ and (R₃E)₂Te derivatives, several non-cyclic compounds containing Te–E bonds, *e.g.*, di(organyl-telluro)silanes (germanes, stannanes) (R¹Te)₂ER₂² **47** (see Refs 17, 19, 20) and tris(ethyltelluro)silane (**48**), have been described.²⁰ Synthesis of both types of compounds was performed by reactions of the corresponding chloro derivatives of Group 14 elements with lithium tellurolates in THF¹⁹ or ether.²⁰

47a: E = Sn, R¹ = Ph, R² = Me;

47b: E = Sn, R¹ = Ph, R² = Bu¹;

47c: E = Si, R¹ = Et; R₂² = Et, H.

Dimethylbis(methyltelluro)germane (**47d**) was prepared by reaction of dimethylchlorogermane with methyl trimethylsilyl telluride.¹⁷

Reactions of compounds **47a–d** and **48** have not been studied yet.

V. Cyclic compounds containing Te–E bonds

A series of three-, four-, five- and six-membered cyclic compounds with rings built exclusively of Group 14 elements (Si, Ge, Sn) and tellurium have been described. The methods for the synthesis of rings containing 4 to 6 atoms are similar to those for non-cyclic tellurides (R₃E)₂Te, whereas reactions resulting in three-membered cycles have no analogues.

The reaction of compounds R₂E=ER₂ **50a–d** with tellurium powder is a common procedure for the synthesis of three-membered cyclic compounds **49a–d** containing two Group 14 elements and one tellurium atom. Synthesis of telluradisilirane (**49a**)⁸⁹ and telluradigermirane (**49b**)⁹⁰ is performed in benzene at 20 and 80 °C, respectively; telluradistannirane (**49c**)⁹¹ is prepared by boiling the reactants in toluene for 2 h. The yields are 66%, 80% and 71%, respectively.

E = Si, R = 2,4,6-Me₃C₆H₂ (**a**); E = Ge, R = 2,6-Et₂C₆H₃ (**b**);

E = Sn, R = 2,4,6-Pr¹₃C₆H₂ (**c**); E = Ge, R = 2,4,6-Me₃C₆H₂ (**d**).

The synthesis of the Te,Ge-cycle **49d** was also carried out by boiling hexamethylcyclotrigermane (**51**) with tellurium powder in toluene.⁹⁰ Presumably, this reaction proceeds *via* the intermediate digermene **50** (E = Ge, R = 2,4,6-Me₃C₆H₂).

Compounds **49a–d** represent high-melting crystalline substances which are resistant against oxygen and atmospheric moisture. The germyl derivatives **49b,d** manifest thermochromic

properties: they are colourless at -196°C but become pale yellow (20°C) and orange (140°C) colour.⁹⁰ The structures of the cyclic compounds **49a–c** were studied by the X-ray diffraction method.

Reaction of compound **49c** with an excess of tellurium powder in toluene affords cyclo-1,3-ditellura-2,4-distannane **52** in a quantitative yield.⁹¹ The same cycle is obtained in 73% yield by boiling a mixture of the corresponding distannene **50c** with tellurium powder in toluene (molar ratio 1 : 3).⁹¹

R = 2,4,6-Pr₃C₆H₂.

The *tert*-butyl analogue of compound **52**, viz., cyclo-1,3-ditellura-2,4-distannane **53**, was synthesised by reaction of tetrameric di(*tert*-butyl)tin with tellurium as well as by reaction of Bu₂^tSnCl₂ with sodium telluride.⁹²

The reaction similar to that used in the synthesis of tellurides (R₃E)₂Te (see Section III.1) was used to prepare cyclo-1,3-ditellura-2,4-digermane **55**. Heating of the hydride **54** with tellurium powder gives a cyclic compound **55** in a nearly quantitative yield.⁹³ It is noteworthy that reaction of the hydride **54** with selenium yields a mixture of four- and five-membered cyclic products.⁹³

The synthesis of the five-membered derivatives R₈E₄Te (**56a,b**, E = Ge, Sn) was carried out using structurally similar derivatives of Group 14 elements. Octaphenyltelluratetragermacyclopentane (**56a**) was obtained by reaction of 1,4-diiodooctaphenyltetragermene with sodium hydrotelluride in a benzene–ethanol mixture.⁹⁴ Reaction of 1,4-diiodoocta(*tert*-butyl)tetrastannane with H₂Te in the presence of triethylamine leads to octa(*tert*-butyl)telluratetrastannacyclopentane (**56b**).⁹⁵ Since the reaction of triethylamine with H₂Te yields triethylammonium hydrotelluride Er₃NH⁺HTe[−], it may be assumed that the HTe[−] anion is a tellurium-containing substrate of this reaction. Sodium telluride is not suitable for the synthesis of the heterocycle **56b**, since it cleaves the Sn–Sn bonds in the starting compound. Compound **53** and the five-membered *tert*-butyl derivative of 1,3-ditellura-2,4,5-tristannacyclopentane **57** are by-products in the synthesis of telluratetrastannacyclopentane **56b**.⁹⁵

E = Ge, R = Ph (**a**); E = Sn, R = Bu^t (**b**).

Compound **56b** is rather stable upon storage, whereas its germanium analogue **56a** is rapidly oxidised in air to give

Ph₂Ge–Ph₂Ge–O–GePh₂–GePh₂.⁹⁴ According to X-ray diffraction analysis data,⁹⁵ the ring in compound **56b** is practically planar.

2,4,5-Hexamethyl-1,3-ditellura-2,4,5-tristannacyclopentane, a representative of yet another type of five-membered cyclic compound containing Te and Sn atoms, was prepared by reaction of tellurium powder with dimethylstannane which in turn was synthesised by reduction of dichlorodimethylstannane with lithium aluminium hydride in an Et₂O–DMF mixture (30 : 1, by volume).⁹⁶ It was characterised by mass spectrometry as well as by ¹H (see Ref. 96) and ¹¹⁹Sn NMR spectroscopy (see Ref. 97).

Reduction of dichlorodimethylstannane or Me₂SnO with lithium aluminium hydride in Et₂O and subsequent reaction of dimethylstannane with tellurium powder results in 2,2,4,4,6,6-hexamethyl-1,3,5-tritellura-2,4,6-tristannacyclohexane (**58**) in 58% yield.⁹⁸

Compound **59** was also synthesised in 62% yield by reaction of dimethyldichlorostannane with sodium hydrotelluride synthesised from Te and NaBH₄ in water⁹⁹ and was characterised by the X-ray diffraction method⁹⁹ and mass spectrometry.⁹⁸

VI. Conclusion

The data presented suggest that compounds containing bonds of Te with Group 14 elements belong to a synthetically promising class of organoelement compounds. They can be used for the synthesis of organotellurium derivatives of various types, *e.g.*, organoelement tellurols, alkyl aryl tellurides, aryl tellurobenzoates and aryl telluroformates, various telluroketones and heterocycles. A promising, although still insufficiently studied area of application of these compounds is the synthesis of various metal tellurolates and tellurium-containing clusters and low-temperature synthesis of metal tellurides. These are only a very few examples which illustrate possible applications of compounds containing Te–E bonds in organic synthesis, particularly, in the synthesis of organic sulfur derivatives and some other organoelement compounds.

The expansion of the range of well-studied reactions, primarily those resulting in tellurolates and metal tellurides, a search for novel procedures for the synthesis and characterisation of various compounds, *e.g.*, R₃ETeR² and (R₃E)₂Te, elaboration of synthetic procedures for and studies of reactions of other types of compounds containing bonds of Te with Group 14 elements, *e.g.*, (R₃E)₄Te and (R¹Te)_nER_{4−n}² (*n* = 2, 3), present indisputable interest for both organotellurium chemistry and organic chemistry in general.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 99-03-33132a and 00-15-97320) and Grant No. 2000-5-117 of the RF Ministry for Education.

Abstract. Data on the use of electrochemically generated metal complex catalysts in organic synthesis are analysed, systematised and generalised. The considerable potential of organic electrochemistry is shown. Some electrochemical methods provide advantages in the synthesis of compounds where conventional chemical methods fail, are experimentally complicated or have environmental limitations. Particular attention is given to the mechanisms of electrocatalytic reactions. The bibliography includes 333 references.

I. Introduction

The development of environmentally safe and resource-saving chemical and technological processes is one of the strategically important lines of research in science and engineering. Homogeneous catalysis is finding increasing use in organic synthesis because it offers advantages over heterogeneous catalysis, particularly, from the viewpoint of selectivity and efficiency. Actually, complexes of transition metals, such as Ni, Pd or Co in low oxidation states, can react with many functional groups thus catalysing the formation of C–C, C–P, C–Si and other bonds. Electrochemical methods enable one to synthesise many organometallic compounds, study the reactivities of coordination compounds and elucidate possible reaction mechanisms.

In recent years, the use of electrochemically generated catalysts in reactions of organic compounds has assumed great importance both in organic synthesis and in thorough investigations into electron transfer, bond cleavage, substitution, addition

and other reactions. The results of these investigations find application in many fields of physical, organic and analytical chemistry. The major breakthrough in the use of electrochemical reactions in industry, particularly, in low-tonnage chemistry, occurred in the past few years. From an industrial standpoint, electrochemical reactions have a number of advantages. Thus the conversion, the rate and, within certain limits, the selectivity of the process can be easily controlled by means of such parameters as the current density and the potential.^{1–3}

Methods of indirect reduction and oxidation of organic compounds where the formation and regeneration of reactants occurs at an electrode find increasing use in modern organic synthesis. These methods enable one to perform various transformations of organic compounds under conditions of efficient and environmentally safe processes.⁴ Presently, the electric energy cost is only an insignificant part of the cost price of the product and it is expected that it will grow more slowly than the price of chemical reagents.⁵ Electrochemical processes are environmentally non-polluting and the control over these processes can be easily automated. Electrochemical reactions can provide higher selectivity as compared to conventional chemical transformations with simultaneous reduction of energy consumption and attainment of higher current densities.

Electrochemical metal complex catalysis attracts interest because it enables one to carry out reactions under mild conditions (moderate temperature, ambient pressure) and in a virtually closed system with the use of a minimum amount of the catalyst (mediator), which is cyclically regenerated. It should be noted that mediator processes are not only of practical importance but also offer a unique possibility of studying reaction mechanisms of reduction and oxidation of various substrates by electrochemical methods. For the simple cases, the mathematical approach was elaborated. This approach is based on approximating formulae, which provide a way of determining the rate constants of individual steps of the overall process of formation, consumption and regeneration of the mediator and enable one to obtain information on the energy characteristics of these steps and on the influence of various external factors. For this purpose, the

dependencies of the current (its catalytic increase as a measure of the rate of the process) and the potential on the conditions of electrolysis are used.

The ever-increasing number of studies are aimed at replacing traditional catalysts based on toxic heavy metals with environmentally safer and cheaper compounds.

The present review surveys the principal results, which were obtained in organic synthesis with the use of electrochemical methods under the conditions of metal complex catalysis in the last 15 years. Some electrochemical reactions related to metal complexes, such as reversible haptotropic shifts, ligand exchange, modelling of molecular switches and modelling of the active sites of metalloenzymes as well as the architecture of electrochemically functionalised fullerenes are beyond the scope of the present review.

II. General principles of metal complex electrocatalysis in organic synthesis and methods of investigation of reaction mechanisms

1. General principles

Reactions involving transition metal complexes can be divided into two classes. One class includes reactions, such as isomerisation, dimerisation or oligomerisation of unsaturated compounds, in which no redox processes occur. In these reactions, the function of the catalyst is to control the kinetics and selectivity of thermodynamically possible processes. In this case, electrochemical methods employing transition metal catalysis are used as an alternative to conventional procedures for generation of some low-valent species that are difficult to access.⁶ However, the above-mentioned reactions are not, in essence, electrochemical processes because they require no electricity consumption and, hence, they are not considered in the present review.

The reactions of the second class involve both catalysts (transition metal complexes) and a stoichiometric number of electrons (either from a reducing agent or from an electrochemical source). This class can be subdivided into two groups according to the type of action of the catalyst.

In the first group of reactions, the transition metal complex can serve as a carrier of electrons from their source to the reagent. Generally, these processes proceed by the so-called outer-sphere mechanism without the formation of an intermediate complex of the substrate (**A**) with the catalyst (the redox P/Q pair) and the mediator is regenerated electrochemically.^{7–12}

where **P** is a mediator, **Q** is a catalyst, **A** is a substrate, **B** is a reduction product and **C** is the target product.

The function of the redox catalyst (mediator **P**) is to transfer an electron from the electrode to the substrate after which the initial product of reduction of the substrate **B** is transformed into the final product **C** in the course of the chemical reaction. In the case of the rapid irreversible conversion of **B** into **C**, the substrate can be reduced under the conditions of homogeneous electron transfer in the direction opposite to the standard potential drop ($E_{P/Q}^\circ > E_{A/B}^\circ$),^{7,8} which substantially extends the possibilities of redox catalysis. The apparent benefit of using redox catalysts is achieved only when these catalysts are stable and can be rapidly regenerated at an electrode in high current yield at potentials which are more positive than the potentials of direct electroreduction of the substrate, or at potentials which are less positive than the potentials of direct electrooxidation of the substrate. In addition, the catalysts must rapidly react with the substrate.

Hence, it is advantageous to use such metal complex catalysis in two cases: (1) if the employment of the homogeneous electron transfer leads to acceleration of the process as a whole, *i.e.*, if the

kinetic barrier of the electrochemical process is lowered and the potential approaches the thermodynamical value owing to transfer of the electron to the bulk of the solution and a decrease in the overpotential of the electrochemical reaction; (2) in processes involving substrates whose homogeneous redox reactions proceed more rapidly than heterogeneous reactions for one or another reason.

The second group of faradaic and catalytic reactions includes those proceeding by the inner-sphere mechanism, *i.e.*, processes involving the formation of various intermediate coordination compounds (**PA** or **QA**) in the course of the reaction. This approach was described for the first time 15 years ago and was considered in the reviews.^{13–19}

The inner-sphere electron transfer has some advantages over the outer-sphere mechanism for the following reasons.

1. Redox processes are independent of the difference between the potentials of the mediator and the substrate and, hence, a large reduction in the overpotential becomes possible.

2. The inner-sphere transfer has a lower activation barrier.

3. Only one electron can be transferred in the outer-sphere process, whereas two or more electrons can be transferred through the inner-sphere mechanism. This is of particular importance in biocatalysis and in activation of small molecules.

In the last decade, attempts have been made to provide theoretical justification for these processes and to extend the range of catalytic reactions. However, many details of the reaction mechanisms remain unclear.

The mechanism of action of metal complex catalysts can be represented by the following scheme

Since transformations of the substrate in the coordination sphere of the metal complex play a decisive role in the catalytic cycle, this type of catalysis is termed coordination electrocatalysis.¹³ The electrochemical step of the process and the chemical reaction of the substrate share a common catalyst–substrate complex. The function of the catalyst is to bind and activate the substrate in the coordination sphere of the metal complex with the resulting increase in the reactivity of the substrate in the electron exchange with the electrode. Unlike redox catalysis, coordination electrocatalysis requires that either the mediator **P** or the catalyst **Q** be coordinatively unsaturated or their ligands be readily leaving groups, which is necessary for the formation of the intermediate **PA** and **QA** complexes. Different approaches to investigation of mediator processes were first described approximately two decades ago and were covered in the reviews.^{7–19}

Abundant data on complex formation and activation of substrates that are kinetically inert in redox reactions are presently available,^{14,20} which facilitates the choice of an appropriate metal complex.

For the reactions considered below, electrochemical methods do not necessarily have advantages over conventional chemical methods. However, it should be noted that electrochemical methods make it possible to generate unusual low-valent intermediates, which cannot be prepared with the use of chemical reducing agents. In addition, many reactions require reduction of intermediates of the catalytic cycle, which can be readily accomplished in the electrochemical process by controlling the potential of the working electrode.

In recent years, electrochemical methods were substantially simplified and became cheaper. Many electrochemical reactions are carried out in the direct current mode with the use of constructionally simple current sources. Undivided cells find increasing use because divided cells are less efficient in polar aprotic solvents and require a large amount of a supporting electrolyte. Processes with the use of sacrificial anodes have

considerable promise both for direct and catalytic reactions. In the latter case, the conductivity is enhanced and metal ions generated at an anode can influence the reactivities of chemical intermediates.^{21, 22}

Data on the electrochemical and chemical behaviour of the simplest transition metal complexes were surveyed in the reviews and papers.^{22–33}

2. Methods of investigation of the mechanisms of reactions catalysed by transition metals

Reactions catalysed by transition metals proceed through catalytic cycles involving metal complexes in different oxidation states. Most of the metal complexes are either oxidised or reduced, or both. Consequently, they can be readily detected and characterised by electrochemical methods (voltammetry, amperometry, chronoamperometry, *etc.*). These methods also allow one to estimate the reactivities of metal complexes. Presently, stationary and transient voltammetry are the most readily available methods.

Stationary voltammetry is used for characterising a metal complex which is already present in solution and is characterised by the redox potential and its concentration is determined by the reduction or oxidation current. The reactivity of the complex with respect to the substrate can be examined by monitoring the change in its redox current as a function of time using, for example, the method of rotating disc electrode. If a new electroactive metal complex is formed in the course of the reaction, it can also be detected from its redox peak and its yield in the reaction is determined by the redox current. By this means, both the reagents and the products of the chemical step and its kinetics can be characterised. The stationary state method enables one to obtain kinetic data for chemical reactions whose half-lives $t_{1/2}$ are larger than several tens of seconds.

Transient voltammetry is used for proving the existence of the equilibrium between different complexes by estimating the relative change in the current at the redox peaks of different species as the scan rate is changed. The redox process of one species at the electrode surface leads to a shift of the equilibrium in the diffusion layer. The concentration of the species, which is measured from their redox current, reflects not their true concentration but the dynamic concentration [the CE (chemical–electrochemical) mechanism]. The scan rate fixes the time scale. The equilibrium is more difficult to shift as the time is decreased. In the limit, at very high scan rates, the dynamical equilibrium is frozen though it can be realised within longer periods of time (low scan rates). This method allows one to determine the equilibrium concentrations of different complexes and then their equilibrium constants. In these cases, the thermodynamics and kinetics of the equilibrium can be characterised using staircase transient voltammetry or chronoamperometry (the pulse duration θ) of redox waves of various species. In this case, electrochemical methods are similar to

NMR spectroscopy because progressive freezing of the equilibrium as the scan rate is increased (voltammetry) or as the pulse duration θ is decreased (chronoamperometry) is analogous to coalescence in NMR spectroscopy. In the equilibrium reactions, the major species observed in solution are not necessarily reactive because they can be involved in the endergonic equilibrium (which is established with energy absorption). Since conventional methods provide a way of controlling the reaction, efficient reactive species can be identified only in detailed kinetic studies.

Cyclic voltammetry can also be used for generation of stable or short-lived organometallic species through successive electron transfers and chemical reactions in the course of redox processes involving metal complexes. A knowledge of the absolute number of electrons involved in an electrochemical process enables one to determine oxidation states of a cascade of complexes, which can be generated from a particularly stable complex. The kinetics of reactions of electrogenerated species with a particular substrate can be controlled by increasing the scan rate in cyclic voltammetry (or decreasing the pulse duration in chronoamperometry), *i.e.*, by reducing the time scale of the chemical reaction. Analysis of the changes in the voltammogram as a function of the scan rate (or the time) makes it possible to obtain the kinetic data for chemical reactions whose half-lives $t_{1/2}$ range from 0.1 s to 10 ns. Hence, intermediate species can be generated and/or identified and their reactivities can be characterised.

However, although electrochemical methods provide a way of studying the kinetics and thermodynamics of reactions, they give no information on the structures of intermediates. Electrochemical methods in combination with NMR spectroscopy allow the elucidation of the characteristic features of the reaction mechanisms and provide detailed structural data. Other spectral methods can also be combined with electrochemical methods to obtain kinetic and structural parameters of the complex reaction system. The efficiency of this approach was demonstrated in many studies on elementary stages, such as oxidative addition, ligand exchange and reductive elimination.

III. Homocoupling of organic halides

1. Homocoupling of organic monohalides

Reductive dimerisation of organic halides is the first known reaction involving both faradaic reduction and catalysis by transition metal complexes. In 1976, Jennings *et al.*³⁴ reported electrodimersation of alkyl bromides in DMF by electrolysis between two metal electrodes (Ni, Al or Cu) in the presence of iron or nickel acetylacetonates and triphenylphosphine. Later on, other analogous reactions were carried out, the electrochemical properties of catalyst precursors were studied and the reaction mechanisms were investigated.^{35–44} The results published within the last decade are summarised in Table 1. Although dimerisation products can be obtained in high yields, these reactions are of

Table 1. Products of electroreductive coupling catalysed by Ni and Co compounds.

Substrate	Metal – ligand	Solvent	Product	Yield (%)	Ref.
EtBr	Ni – phen	DMF	C ₄ H ₁₀		35
n-C ₆ H ₁₃ Br	Ni – bipy	DMF or NMP	C ₁₂ H ₂₆	85	36
n-C ₅ H ₁₁ Br	Ni – bipy	DMF or NMP	C ₁₀ H ₂₂	89	36
MeOC ₂ H ₄ Br	Ni – bipy	DMF or NMP	(MeOC ₂ H ₄) ₂	60	36

Cl(CH ₂) ₄ Br	Ni – bipy	DMF or NMP	Cl(CH ₂) ₈ Cl	38	36
CH ₂ =CHCH ₂ Cl	Co – bipy	H ₂ O	(CH ₂ =CHCH ₂) ₂		37
PhCHCl ₂	Ni – salen	DMF	PhCH(Cl)CH(Cl)Ph + PhCH=CHPh		40
	Co – salen	DMF	PhCH ₂ CH ₂ Ph + PhCH=CHPh		41, 42
X(CH ₂) _n Cl (X = Br, I; n = 2–6)	Ni – salen	DMF	Cl(CH ₂) _{2n} Cl	80–90	43, 44

Note: phen is 1,10-phenanthroline; bipy is 2,2'-bipyridyl; NMP is *N*-methyl-2-pyrrolidone; salen is the bis(salicylidene)ethylenediamine dianion.

limited synthetic usefulness because most of them can be carried out using either chemical or electrochemical methods in the absence of catalysts.⁴⁵

The synthesis of biaryls from aryl halides attracts great interest because these compounds are of practical use, whereas they are difficult to prepare by chemical methods. First electro-syntheses were carried out in 1980s simultaneously by several research groups^{46–49} with the use of $\text{NiCl}_2\text{PPh}_3$ (1%–20%) as the catalyst precursor in the presence of an excess of PPh_3 . Later on, nickel complexes with 2,2'-bipyridyl and bidentate phosphines, *viz.*, 1,2-bis(diphenylphosphino)ethane (dppe) and 1,2-bis(dialkylphosphino)benzene, were prepared.^{50, 51}

The Ni(II) complex with bipy, which can be reduced to the Ni(0) complex, proved to be an efficient catalyst of dimerisation of aryl compounds.^{52, 53} In combination with sacrificial anodes, this process can be performed in an undivided cell under very simple experimental conditions in the presence of an excess of bipyridyl.

$\text{Ar} = \text{Ph}, 3\text{-MeC}_6\text{H}_4, 4\text{-MeCOC}_6\text{H}_4, 2\text{-naphthyl}; \text{X} = \text{I}, \text{Br}, \text{Cl}.$

Interestingly, biaryls were obtained in only slightly lower yields when the reactions were carried out in alcohols, such as methanol or ethanol, instead of DMF with the use of a sacrificial iron or aluminium anode.^{54, 55} A nickel complex with either bipy or di(2-bipyridyl)amine can serve as a catalyst. The results obtained in the cited studies evidence the possibility of formation of organonickel intermediates, which are stable in protic solvents and give rise to biaryls. Efficient arylation of activated alkenes was carried out under the same conditions.⁵⁵

The electrosynthesis of biaryls from bromo- or iodoarenes⁵⁶ can be carried out in the presence of $\text{PdCl}_2(\text{PPh}_3)_2$ as the catalyst precursor. Aryl triflate can also serve as the substrate,^{57, 58} but the latter process requires higher temperature. These homocoupling reactions catalysed by Ni or Pd complexes can also be performed using conventional chemical methods in the presence of zinc as a reducing agent to obtain biaryls in comparable yields.⁵⁸

$\text{Ar} = \text{Ph}, 4\text{-Bu}^t\text{C}_6\text{H}_4, 4\text{-MeCOC}_6\text{H}_4, 4\text{-Me}_2\text{NC}_6\text{H}_4; \text{X} = \text{I}, \text{Br}.$

$\text{Ar} = \text{Ph}, 4\text{-NCC}_6\text{H}_4, 4\text{-CF}_3\text{C}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4; \text{Tf} = \text{O}_2\text{SCF}_3.$

Catalytic reduction of cyclohexanecarboxylic acid chloride (**A**) in the presence of the electrochemically generated Ni(I)(salen) complex yielded the tetramer, *viz.*, 1,2-dicyclohexylethene-1,2-diol dicyclohexanoate (**B**).⁵⁹ The first step involves electron transfer from the Ni(I)(salen) complex to acyl chloride to form the acyl radical **C**. The radical anion **E** is generated from diketone **D** either by electroreduction or by the reaction with the Ni(I)(salen) complex. Subsequent reactions of the intermediates **E** and **F** with the initial acid chloride give rise to the reaction product **B**.

$\text{R} = \text{cyclo-C}_6\text{H}_{11}.$

However, the function of Ni(I)(salen) is conceivably more complex than the mere role of an outer-sphere electron carrier to form acyl radicals. Heterogeneous reduction of acyl chlorides RCOCl ($\text{R} = \text{Alk}$), which also proceeds through acyl radicals, yields aldehydes rather than the tetramers.

2. Homocoupling of organic dihalides

Electroreductive coupling of organic dihalides is one of the approaches to the synthesis of polymers. Polyynes were prepared from diiodoacetylene in the presence of the Ni complex with dppe.⁶⁰

Electroreductive coupling of aromatic and heteroaromatic dihalides was examined.⁶¹

The results of studies on reductive electropolymerisation of aryl dihalides are summarised in Table 2.^{51, 62–72} Depending on the experimental conditions, polymers either deposit from the bulk of the solution in the course of electrolysis or precipitate as films on the electrode surface. This method is also suitable for preparing copolymers from a mixture of two aryl dihalides. Recently, the mechanism of polymerisation catalysed by the Ni complex with bipy was investigated.⁷³

Homogeneous catalytic reduction of α,ω -alkanediyl dihalides under the action of electrochemically generated Ni(I)(salen) complexes was studied. Thus, 1,8-dichlorooctane was prepared from 1-bromo-4-chloro- and 1-chloro-4-iodobutane in a yield of higher than 88%. It was demonstrated that the reaction followed the radical pathway.^{73, 74}

Electrochemical reductive coupling of some *gem*-dihalides, in particular, of dimethyl dibromomalonate in the presence of the copper complex with 1,10-phenanthroline and a sacrificial copper anode gave rise to cyclopropanes.⁷⁵

Studies by cyclic voltammetry and chronoamperometry showed that reduction of dimethyl dibromomalonate with the Cu(I) complex is a catalytic process, which is kinetically controlled by the rate of concerted electron transfer and cleavage of the carbon–bromine bond. In the presence of styrene, cyclopropane is formed through the addition of $\text{R}_2\text{C}\cdot\text{Br}$ ($\text{R} = \text{MeO}_2\text{C}$) at the double bond.⁷⁵ The radical intermediate is subsequently reduced to the corresponding anion, no transformations into carbene or alkylcopper intermediates being observed. In the reactions with other *gem*-dihalides, the products are formed by the chain mechanism involving addition.

Table 2. Reductive electropolymerisation of aryl dihalides with the use of a nickel catalyst.

^a DMA is *N,N*-dimethylacetamide.

IV. Cross-coupling of organic halides

1. Cross-coupling of aryl halides

Asymmetrical biaryls, particularly, those containing electron-donating and electron-withdrawing groups in the aromatic nucleus, find use in nonlinear optics. Attempts were made to prepare these compounds, which are difficult to access, from mixtures of two different aryl halides employing electrochemical methods in combination with catalysis by Ni or Pd complexes. The chief drawback of this approach is the low selectivity of the process due to competitive cross- and homocoupling. It was demonstrated⁷⁶ that the reactions involving two aryl halides, which possess similar reactivities in the oxidative addition step, afforded three possible products (one asymmetrical and two symmetrical) in a ratio corresponding to statistical distribution (2:1:1). If the reactivities of the starting aryl halides differ substantially, an asymmetrical product can be obtained in satisfactory yield only upon slow addition of the more reactive aryl halide in the course of electrolysis.⁷⁶

$R^1 = \text{MeO}, \text{Me}_2\text{N}, \text{MeS}; R^2 = \text{F}, \text{CN}, \text{CF}_3; X = \text{Br}, \text{Cl}.$

Intramolecular cross-coupling catalysed by the Ni complex with 1,2-bis(diisopropylphosphino)benzene was reported.⁵¹

In the electrochemical syntheses of asymmetrical biaryls, high selectivity is achieved in two-step processes. The reaction involving a stoichiometric amount of the $\text{PdCl}_2(\text{PPh}_3)_2$ complex is an example.^{56, 77, 78} The Pd(0) complex generated at an electrode first reacted with a molecule of one aryl halide followed by electroreduction of the resulting σ -arylpalladium complex in the presence of another aryl halide to give asymmetrical biaryls in good yields.

Yet another two-step synthesis of biaryls was carried out with the use of the catalytic Ni – bipy system. Electroreduction of aryl halides in the presence of Zn^{2+} ions and an excess of bipy with the use of a sacrificial zinc anode afforded not biaryls but arylzinc compounds stable in the reaction medium.⁷⁹ The addition of another aryl halide and a catalytic amount of $\text{PdCl}_2(\text{PPh}_3)_2$ to this reaction mixture gave rise to asymmetrical biaryls in high yields (Table 3).⁸⁰

This method is also applicable to coupling reactions of aryl halides with allyl chlorides.⁷⁹ Functional substituents in aryl halides do not interfere with the reaction.

Table 3. Two-step cross-coupling of aryl halides catalysed first by Ni complexes and then by Pd complexes.⁸⁰

2-BrC ₆ H ₄ OMe	2-BrC ₆ H ₄ CN	55

2. Cross-coupling of aryl halides with activated alkyl halides

The syntheses of pharmaceuticals, agrochemicals and perfumes make use of arylacetic or arylpropionic acids and benzyl ketones as important intermediates. These compounds can be prepared by electrochemical methods. It was shown that esters of α -halocarboxylic acids can react with arylnickel compounds, which are generated electrochemically from aryl halide in a divided cell, to give esters of arylacetic or arylpropionic acids.⁸¹ The chief drawback of this two-step procedure is the use of a large excess of PPh_3 , which is necessary for preventing homocoupling.

$\text{R} = \text{H, Me; X}^1, \text{X}^2 = \text{Cl, Br.}$

Recently, a more efficient procedure, which combines the use of a sacrificial anode with catalysis by nickel complexes, was developed. To reduce undesirable homocoupling to a minimum, the most reactive substrate, *viz.*, activated alkyl halide, was slowly added to the reaction mixture at 60–80 °C. This procedure was applied to cross-coupling of aryl halides with α -chloro esters (Table 4),^{82,83} α -chloro ketones (Table 5)^{83–85} and allyl and vinyl derivatives (Table 6).⁸⁴

This procedure was also successfully used in the asymmetric synthesis of 2-arylpropionic acids.⁸⁶ The resulting compounds possess higher biological activities than those of *S*-enantiomers [for example, in the case of 2-(3-phenoxyphenyl)propionic acid (phenopropfen) or 2-(6-methoxy-2-naphthyl)propionic acid (**1a**, $\text{R} = \text{H}$) (naproxen)]. However, conventional procedures for the synthesis generally afford racemates. The electrochemical syn-

Recently, it has been demonstrated that cross-coupling of some aryl halides with heteroaryl halides proceeded in high yields under the action of the Ni(II) complex with *bipy*.^{87–89}

Products of cross-coupling of aryl halides are listed in Table 7. In the course of electrolysis, the nickel(II) complex was regenerated and its content in the electrolyte is at most 10 mol % with respect to Ar^1X . Organic halides were taken in equivalent ratios. In all cases, the electrosynthesis afforded asymmetrical biaryl as the major product. If aryl halides contain electron-withdrawing substituents in the aromatic nucleus, their cross-coupling reactions proceed in higher yields with the use of a zinc anode. Apparently, this is attributable to higher reactivity of magnesium

and its compounds with respect to electron-withdrawing functional groups resulting in transformations of the latter as side reactions. The mechanism of cross coupling was studied in detail and discussed in Ref. 89.

V. Formation of compounds containing the metal – carbon bond

Cathodic alkylation of catalysts upon reduction of alkyl halides is characteristic of various chelate complexes of transition metals, which form rather stable compounds with the alkyl–metal σ -bond (such as cobalamine, phthalocyanine, salen and dithiocarbamate complexes of Co, Fe, Ru, Rh, Ni and Cr).^{90, 91}

The electrochemistry of vitamin B₁₂ and reactions of its reduced form (B_{12s}) with organic halides have been studied extensively.^{92–99}

Schrauzer and coworkers^{95–97} examined alkylation of vitamin B_{12s}, cobaloximes and other chelate Co(I) complexes [including Co(I)(salen)] with alkyl halides. Generally, these reactions proceed through the S_N2 mechanism including the supernucleophilic derivative of vitamin B₁₂, viz., B_{12s}, in which cobalt exists in the Co(I) state. Alkylcobalt intermediates were demonstrated⁹⁷ to decompose either photolytically or pyrolytically to form alkyl radicals. Rusling and coworkers⁹⁸ studied electrocatalytic reduction of 1,2-dibromoethane and 1,2-dibromobutane under the action of vitamin B_{12s} and found that these vicinal dibromides were transformed into alkenes without the intermediate formation of the alkylcobalt(III) complex. Later on, the catalytic reactions involving B_{12s} were compared with those involving Co(I)(salen)⁹⁹ and the rate of reduction of 1,2-dibromocyclohexane was found to

depend on the formal potential of the Co(II)–Co(I) pair. In addition, it was demonstrated¹⁰⁰ that reduction of benzyl bromide under the action of Co(I)(salen) gave rise to either benzyl radicals or carbanions depending on the potential at which the intermediate benzylcobalt(III) complex is subjected to electrolysis.

Costa and coworkers^{101–103} examined electrochemical reduction of salen complexes of organocobalt(III) and catalytic reactions of organic halides with the electrochemically generated Co(I)(salen) species. Methyl- and ethylcobalt(III)(salen) were electrochemically reduced to Co(I)(salen) and the alkyl radical.¹⁰¹ It was shown that Co(I)(salen) slowly reacted with *tert*-butyl bromide or chloride to give 2-methylpropene and molecular hydrogen. Apparently, the initially formed unstable intermediate decomposed into Co(II)(salen) and the highly reactive *tert*-butyl radical due to steric hindrances induced by the *tert*-butyl group, no organocobalt(III) derivatives being generated.¹⁰³ Peters and coworkers¹⁰⁴ studied these reactions in most detail. Thus, the products of the reaction of Co(II)(salen) with iodoethane were identified and characterised, the reaction scheme was proposed, its kinetic and thermodynamical parameters were measured, the UV spectrum of the EtCo(salen) intermediate was recorded, the electrochemical reduction of this intermediate was characterised and simulation of the mechanism was performed. Preparative electrolysis showed that one electron was consumed per iodoethane molecule. The compositions of the reaction products depend primarily on the solvent. Thus the dimer, viz., n-butane, and ethane were obtained as the major products in acetonitrile and DMF, respectively (in all cases, ethylene was present in small amounts). The reaction scheme includes the following steps:

SolvH is the solvent.

It was suggested that the solvents have different effects on the relative rates of the last three steps [reactions (5)–(7)]. Dimerisation of ethyl radicals dominated over disproportionation (in acetonitrile, the yield of n-butane was 7.2 times higher than that of ethylene; in DMF, this ratio ranged from 3 to 4). In all cases, the yield of ethane was higher than that of ethylene because hydrogen atoms are readily detached from the solvent under the action of ethyl radicals, the detachment from DMF proceeding more readily than that from MeCN [reaction (7)]. To confirm the proposed mechanism, EtCo(III)(salen), which was prepared by the reaction of electrochemically generated Co(I)(salen) with EtI [reaction (2)], was reduced at a controlled potential. In this process, one electron was demonstrated to be consumed per molecule of the σ -complex with the resulting formation of the green Co(I)(salen) complex and the ethyl radical [reactions (3)–(4)].¹⁰⁴

Upon reduction of 1,8-diiodooctane under the same conditions,¹⁰⁵ two σ -complexes, viz., 8-iodooctylcobalt(III)salen and μ -(1,8-n-octyl)bis[cobalt(III)(salen)], were detected (both by electrochemical methods and UV spectroscopy) as intermediates, their relative amounts being dependent on the substrate : catalyst ratio.

The mechanism proposed in the study⁹⁹ was supported by the results of the investigation¹⁰⁶ on catalytic reduction of alkyl halides with the Co(II)(salen) complex at microelectrodes, the reaction scheme being supplemented by two more steps.

Electrochemical alkylation of mercury metal with butyl bromide in the presence of bis(dimethylglyoximate)(pyridino)Co(II) [Co(DH)₂Py₂] was examined.¹⁰⁷ It was suggested that Co(II) was initially reduced to Co(I). Then the Co(I) complex reacted with BuBr to give BuCo(III)(DH)₂Py under the action of which the alkyl group was transferred to mercury metal.

Cathodic alkylation of the catalyst is typical of various chelate complexes of transition metals, which form rather stable compounds containing the alkyl–metal σ -bond, for example, of cobalamine, phthalocyanine, salen and dithiocarbamate complexes of Co, Fe, Ru, Rh, Ni and Cr.⁹⁰ These compounds contain metal atoms, which can exist in three successive oxidation states (for example, +3, +2 and +1 for Co), and possess the external π -system of the ligand favourable for stabilisation of the anionic complex. However, the ability of metal to exist in three oxidation states ($n+1$), n and ($n-1$) and the presence of a chelating ligand are not necessarily sufficient for alkylation of metal complex anions. For example, attempts to subject the Ir dimethylglyoximate complex to either chemical or electrochemical alkylation failed¹⁰⁸ in contrast to the analogous Co and Rh complexes. The potential of formation of the nucleophilic anion interacting with alkyl halides plays a large role in this process. If this potential is more negative than the potential of reduction of the alkylation product, the latter is not formed because of its irreversible reduction accompanied by the cleavage of the metal–alkyl bond. The potential of formation of the metal complex anion and the potential of reduction of the alkylation product depend on the nature of the metal atom, the chelating ligand, the solvent and the σ -bonded organic group.¹⁰⁹ For example, reduction of most metalloporphyrins, which contain an organic group σ -bonded to the metal atom, occurs at more negative potentials than reduction of metalloporphyrins with coordinated ligands. However, some ironporphyrins containing the Fe–Alk bond are reduced more readily than the corresponding complexes with ionic ligands.¹¹⁰ Studies of the electrochemical properties of a series of Co²⁺ complexes with substituted phthalocyanines in DMF allowed the conclusion that alkylation of electrochemically generated mono-anionic complexes in the presence of n-butyl bromide proceeded at the metal atom.⁹¹

Electrochemical reduction of n-butyl bromide was studied in the presence of the cobalt phthalocyanine complex PcCo(II) (Pc is substituted phthalocyanine) and the catalytic cycle was proposed.¹¹¹ This catalytic cycle was called ‘chemical catalysis of electrochemical reduction of alkyl halides’.¹¹¹

The above scheme is common to many chelate compounds of transition metals and rare-earth elements. At potentials more cathodic than the potential of reduction of the Co–Alk bond, electrolysis resulted in regeneration of the highly reactive [PcCo(I)]⁻ anion, which was rapidly alkylated with n-butyl bromide present in the solution and then reduced thus resuming the catalytic cycle.⁹¹

Metalloenzymes are natural catalysts in which metal ions exhibit different coordination modes. Vitamin-B₁₂-dependent enzymes containing the cobalt atom as the catalytic site catalyse

different isomerisation reactions accompanied by skeleton rearrangements.^{112–123} New models were proposed^{115–123} for enzyme catalysis on the basis of a hydrophobic analogue of vitamin B₁₂ in which the peripheral amide groups of natural vitamin B₁₂ are replaced by ester groups and this complex was demonstrated to be an efficient catalyst of electrochemical rearrangements of the carbon skeleton of 1-bromopropane derivatives containing two electron-withdrawing groups (COMe, CO₂Et or CN) at position 2.

Among other catalytic processes, the electrochemical transformation of nitrate anions into ammonia was carried out in water under the action of the Co(I) complex with 2,3-dimethyl-1,4,8,11-tetraazacyclotetradeca-1,3-diene, which was prepared from the corresponding Co(II) complex.¹²⁴

Some theoretical and applied problems of the use of cobalt complexes with ligands, which can stabilise metals in low-valent states, in electrocatalytic dehalogenation, homocoupling and cross-coupling reactions and in functionalisation of white phosphorus were covered in the studies.^{125,126} It was shown that electrochemical reduction of organic halides proceeded under the action of either the Co⁺(bipy) or Co[–](bipy)₂[–] complexes. Intermediates of the catalytic cycle, *viz.*, cobalt σ -complexes, were isolated and characterised. It was demonstrated that arylation (alkylation) of white phosphorus occurred under the simultaneous action of electrochemically generated nucleophilic [Co(I)(bipy) or RCoX₂(bipy)] and electrophilic (Mⁿ⁺, RX) reagents. Functionalisation of P₄ can follow two pathways, *viz.*, P₄ can react with ArCoX₂(bipy) or it can be reduced with the Co(I)(bipy) complex to the δ -P₃-cyclotriphenylphosphorus complex of cobalt, which, in turn, reacts with organic halides to form compounds containing the P–C bond.

The Ni σ -complexes are difficult to access and little studied. However, these compounds can be readily synthesised by electrochemical methods under mild conditions. It is known⁸⁹ that these complexes are intermediates of electrocatalytic cycles of cross-coupling, functionalisation of alkenes and reactions of aldehydes proceeding in the presence of Ni(0) complexes. In some cases, Ni σ -complexes can be isolated in pure form and they can be considered as model compounds for gaining insight into the mechanisms of organometallic synthesis.⁸⁹ Recently,⁸⁹ several σ -complexes containing Ni in different oxidation states [for example, RNiX(bipy), R₂NiX(bipy) and R₂Ni(bipy)] and exhibiting different reactivities were found to exist.

VI. Addition of organic halides to unsaturated groups

1. Addition at double and triple carbon – carbon bonds

First studies of electroreductive addition of organic halides at double or triple carbon – carbon bonds go back to the 1980s. Two main procedures using various catalysts were developed. In both processes, the key step involves the radical addition to unsaturated hydrocarbons. The first approach, which was considered primarily by Scheffold *et al.*,^{127,128} is based on the use of vitamin B₁₂ or related cobalt complexes as mediators of indirect electroreduction (in some cases, in combination with photolysis). The second approach, which was proposed by Gosden and Pletcher,¹²⁹ is based on the use of nickel complexes with macrocyclic tetradentate ligands, which can stabilise Ni(I) species.

In recent years, various organonickel and organocobalt compounds were studied and their redox properties and reactivities were examined depending on the nature of the ligand coordinated to the metal atom. The reactions described earlier were investigated once again with the aim of optimising the conditions and improving their efficiency. In particular, the reactions using the Ni(cyclam) complexes (cyclam is 1,4,8,11-tetraazacyclotetradecane) were examined and carbanion analogues were generated using the Ni(0) complexes in the presence of Michael acceptors.

a. Reactions with electron-rich double and triple carbon–carbon bonds

Most of reactions with electron-rich double and triple carbon–carbon bonds occur as free-radical cyclisation processes, which are used primarily for the preparation of five-membered rings with the desired stereochemistry.¹³⁰

Electrochemical processes involving cobalt complexes were studied in detail.^{127, 131} In recent years, the results of new studies on the application of cobalt complexes other than vitamin B₁₂ and nickel complexes with tetradentate macrocyclic ligands were reported. In these reactions, complexes of both types generate radical species.

Direct cyclisation of bromoacetals through cobaloxime(I) complexes was described as early as 1985.¹³² The reactions were carried out in a divided cell in the presence of a base (40% aqueous NaOH) and (chloropyridine)cobaloxime(III) (50%) as a catalyst precursor. Later on, it was found^{133, 134} that the amount of the catalyst can be reduced to 5% (the number of the catalytic cycles is ~50) and the presence of a base is not needed if the reaction is performed in a divided cell with a zinc anode.

This method was applied¹³³ to the synthesis of condensed bicyclic derivatives from various ethylene and acetylene compounds in the presence of (chloropyridine)cobaloxime(III) or Co[C₂(DO)(DOH)_{pn}] (see Table 8). Either saturated or unsaturated cyclic products can be obtained depending on the amount of the catalyst used, the cathodic potential and the presence of the hydrogen donor, for example, RSH (see Table 8).^{136, 138} Studies of some model reactions showed that the electrochemical method is more selective and efficient than conventional reduction with the use of Zn.¹³⁵

Nickel compounds, for example, the Ni(cyclam) complexes,¹²⁹ can also be used for generating radicals in electroreductive processes, including free-radical cyclisation reactions.

The Ni complexes with cyclam and its analogues and also with Ni(CR) and Ni(tet a) serve as efficient catalysts in DMF in the presence of NH₄ClO₄ as a proton source.^{136–138, 141} Electrochemically generated Ni(I) species rapidly react with organic halides to form alkynyl, alkenyl or aryl radicals whose intramolecular addition at double or triple bonds gives rise to cyclopentane derivatives (see Table 8).^{136–138} These reactions can also be carried out in an undivided cell with a magnesium anode, as exemplified¹³⁹ by the reactions of aryl halides bound to an unsaturated hydrocarbon chain (see Table 8). Nickel complexes with cyclam and other tetradentate donor ligands are catalysts of choice.^{139, 142, 143}

The Ni(salen) complex is a good alternative to the Ni(cyclam) complex for generating Ni(I)-containing intermediates. Thus cyclisation of 1-halo-6-phenylpent-5-yne proceeded much more efficiently than direct electroreduction of the substrate in the presence of 10% of a catalyst (see Table 8).¹⁴⁰ Electroreductive cyclisation of *N*-alkenyl-2-bromoanilines with the use of the Pd complex with PPh₃ as the catalyst¹⁴⁴ and electrocatalytic dehalogenation of α -haloacetic acids under the action of the reduced form of vitamin B₁₂ were reported.¹⁴⁵

b. Addition to Michael acceptors

Radicals or carbanions and their equivalents, *viz.*, organometallic compounds, can be added to Michael acceptors. Free-radical reactions in the presence of nickel or cobalt complexes as catalysts have been studied previously.^{127–129}

The synthesis of ethyl 8-oxodec-2-enoate, which was isolated from honey queen bees, provides a good example of the potential of the electrochemical approach to the preparation of natural products. This process involves two major electrochemical steps, *viz.*, the formation of the C–C bond catalysed by vitamin B₁₂ and initiated by visible light and the Michael addition of intermediate 3 at the triple bond.¹²⁸

This approach was applied to the synthesis of the pheromone of California red scale,¹⁴⁶ prostaglandin PGF_{2 α} ,¹⁴⁷ the pheromone of house mice¹²⁸ and jasmonates.¹⁴⁸ Alkylation and acylation of activated alkenes was used for the preparation of amino acid derivatives (Table 9).¹⁴⁹

In some cases, protonation of an intermediate radical formed through the addition of alkyl halide to the Michael acceptor proceeds diastereoselectively. This situation is observed upon the addition of Bu^tBr to diethyl mesaconate catalysed by vitamin B₁₂.¹⁵⁰ However, standard reduction with zinc in the presence of vitamin B₁₂ proved to be more efficient because the stereoselectivity in the latter case was determined by the addition of amines.

The Ni(cyclam) complexes and related compounds can also be used for alkylation of Michael acceptors. For Ni(tet a) in acetonitrile, the number of catalytic cycles is small.¹⁵¹ However, this catalyst (2%) in DMF containing NH₄ClO₄ as the proton source shows efficiency in alkylation of unsaturated ethers, ketones or nitriles.¹⁵² In the case of terminal alkenes, the reaction products are obtained in good yields.

The nucleophilic addition can be performed in the presence of Ni(II) complexes, which are transformed into Ni(0) complexes upon cathodic reduction. The Ni(0)(bipy) complexes rapidly react with alkyl, alkenyl and aryl halides. However, in this case the organonickel intermediate generated through oxidative addition does not give the corresponding addition product in the presence of activated alkenes. In the presence of a Ni complex with a weaker bound ligand (for example, with pyridine, which prevents activated alkene from being coordinated to the metal atom), the regioselective 1,4-addition of aryl groups to activated alkenes was carried out under very mild conditions (60 °C, an undivided cell with a sacrificial aluminium or iron anode). Arylation products were obtained in 20%–63% yields,¹⁵³ which are comparable with those obtained in reactions using arylcopper or cuprates. The reactions performed in methanol or ethanol instead of DMF gave products in only slightly lower yields [the nickel complex with di(2-bipyridyl)amine as the catalyst].⁵⁵

Intramolecular nucleophilic addition can follow either the radical or carbanion pathway.^{51, 137, 138, 154} Some examples are given below.^{51, 137, 138}

Bicyclic ketones were synthesised in the presence of 5% of vitamin B₁₂.¹²⁷

Some other Co complexes as well as Ni complexes catalysed cyclisation of bromocyclohexenones **4a,b** and **5a,b** to form bicyclic ketones **6a,b** and **7a,b**, respectively,¹⁵⁴ but the numbers of catalytic cycles in these cases were rather small. These reactions afforded open-chain compounds **8a,b** and **9a,b** as by-products. The Ni(cyclam)(ClO₄)₂, Ni(CR)((ClO₄)₂ and Co(bpp)OAc [bpp = C₅H₅NC(O)N[−](CH₂)₃N[−]C(O)C₅H₅N] complexes proved to be most efficient as catalysts.¹⁵⁴

	5b	—	—	16	19
Co(bpp)OAc	5a	47	11	—	—
	5b	—	—	40	13

Intramolecular arylation of unsaturated amides gives rise to lactams. These reactions can follow either the radical or carbanion pathway. The carbanion mechanism is realised in the presence of the nickel triphenylphosphine complex to give a mixture of γ - and δ -lactams in a ratio of 3 : 1.⁵¹ The reactions through the radical mechanism [in the presence of the Ni(tet a) complex] proceed selectively to give δ -lactam, although in rather low yield.¹³⁷

The electroreductive addition of (*Z*)- or (*E*)-alkenyl halides to electron-deficient alkenes in the presence of a sacrificial iron anode proceeds in high yields with complete retention of the stereochemistry of the alkenyl fragment. These reactions can be used for functionalisation of isomerically pure (*Z*)- or (*E*)-alkenes.¹⁵⁵

X = Cl, Br, I; A = CO₂Et, COMe, CN.

The conditions were optimised using the model reaction of methyl vinyl ketone (A = COMe) with (*Z*)- or (*E*)-1-halohept-1-enes. It was found that high yields (up to 84%) can be achieved in the presence of 1,2-dibromoethane and an iron anode. The process involves preelectrolysis, *viz.*, oxidation of an iron anode and reduction of 1,2-dibromoethane, followed by electrolysis of a mixture of alkenyl halide and methyl vinyl ketone. The role of iron ions is not understood. Conceivably, they function as Lewis acids, activate electron-deficient alkenes and facilitate the formation of the C–C bond. The reaction mechanism is not entirely known. Presumably, it involves coordination of electron-deficient alkene by electrochemically generated Ni(0) species. Oxidative addition of vinyl halide to the complex **A** affords the organonickel compound **B**, which is either protonated by residual water (path *a*) to form an addition product or transmetalated with iron ions (path *b*) to release Ni(II).

Recently, it was found¹⁵⁶ that cobalt bromide, either in the free form or in the complex with 2,2'-bipyridyl, catalyses the electrochemical addition of aryl halides to activated alkenes in a DMF–pyridine or acetonitrile–pyridine mixture. The reactions proceeded only with the use of a sacrificial iron anode, whereas the addition products were not detected in the reactions performed with other anodes (Zn or Al).

R = 4-CO₂Et, 4-COMe, 4-CF₃, 4-CN, 4-CHO, H, 4-OMe, 2-COMe; X = Br;

(*b*) MeCN–PyH, CoBr₂, Fe anode, Ni cathode, 60 °C.

2. Addition to carbonyl compounds

Data on electrochemical allylation of carbonyl compounds and the Reformatsky reaction are presently available.

Some carbonyl compounds can be subjected to direct electrochemical allylation; however, coupling reactions catalysed by transition metals are more efficient, particularly, in the case of ketones.

One of procedures involves PdCl₂(PPh₃)₂ as the catalyst in the presence of the zinc salt (ZnCl₂). This procedure allows one to transform allyl acetates into the corresponding tertiary alcohols in good yields.¹⁵⁷

R ¹	R ²	R ³	Yield (%)
H	Ph	H	77
H	4-MeOC ₆ H ₄	H	84
H	4-ClC ₆ H ₄	H	68
H	(CH ₂) ₅	H	40
Me	Ph	H	62

Of two possible isomers, the more branched isomer **A** was obtained as the major reaction product.

R = Me (56%, **A** : **B** = 91 : 9); Ph (71%, **A** : **B** = 83 : 17).

The reactions with conjugated carbonyl compounds proceed as 1,2-addition.

Exploration into the mechanism of this reaction revealed the key role of ZnCl₂,¹⁵⁸ which is most readily reduced to give Zn(0). The latter is capable of reducing the π-allylpalladium intermediate. The reaction products are formed through addition of diallylzinc to carbonyl compounds.

Carbonyl compounds can be allylated with the use of a nickel catalyst.^{82, 159, 160}

X	R ¹	R ²	R ³	Yield (%)
Cl	Me	Ph	H	85
Cl	Me	Me(CH ₂) ₅	H	70
Cl	Me	Ph	Ph	86
Cl	Me	Bu ^t	Me	60
Cl	Me	CH ₂ =CH	Me	43
OAc	H	Ph	H	80
OAc	H	(CH ₂) ₅	H	83

When employing an undivided cell, this reaction proceeds efficiently only in the presence of a sacrificial zinc anode. The reactions of aromatic and aliphatic aldehydes or ketones give rise to the corresponding homoallylic alcohols in good yields. The reactions of branched ketones, such as diisopropyl ketone, afford products in lower yields. In the case of α,β-unsaturated carbonyl compounds, the addition occurs exclusively at the 1,2-position. The Pd–Zn catalytic system is also efficient in these reactions. It was suggested^{160, 161} that the process is accompanied by transmetalation of the allylnickel complex, which is formed upon the oxidative addition of allyl halide (acetate) to the Ni(0) complex, with anodically generated Zn(II) species.^{160, 161}

The Reformatsky reaction can also be carried out in an electrochemical mode either directly or with the use of a mediator.

Catalysis by nickel compounds provides an efficient way of transforming the corresponding α -chloro derivatives to β -hydroxy esters or nitriles.¹⁶² These reactions also involve the oxidative addition of cathodically generated Ni(0)(bipy) to a halogen-containing derivative as the first step. In this case, the nature of a sacrificial anode is also of importance although the formation of an organozinc derivative was not unambiguously confirmed.

R ¹	R ²	R ³	Yield (%)
H	Et	Et	77

Me	CH=CH(CH ₂) ₃		50

The reaction of carbonyl compounds with methyl chlorodifluoroacetate,¹⁶³ which cannot be activated by conventional chemical methods, provides an interesting example demonstrating the possibilities of this procedure. The best results were obtained with the use of a CH₂Cl₂–DMF mixture (9 : 1). The ¹⁹F NMR spectroscopic studies demonstrated that the reaction was accompanied by transmetalation.

R ¹	R ²	Yield (%)
Ph	Me	72
(CH ₂) ₅		63
Ph	H	70
Me(CH ₂) ₂	H	77
	H	45

Under analogous conditions, the reactions of methyl dichloroacetate with acetophenone or cyclohexanone afforded epoxides in high yields.¹⁶²

R¹ = Ph, n-C₆H₁₃, Bu^t; R² = H, Me, Ph; R¹–R² = (CH₂)₅.

The reactions of chloroacetonitrile and α -chloropropionitrile with ketones proceeded analogously.¹⁶²

R¹ = H, Me; R² = Ph, n-C₆H₁₃, Bu^t; R³ = H, Me, Ph; R²–R³ = (CH₂)₅.

The intramolecular addition to the carbonyl group has not been adequately investigated. Only the ring expansion reactions of α -bromomethylcycloalkanones, which were carried out in the

presence of Co[C₂(DO)(DOH)_{pn}]Cl₂ as the catalyst at 55–60 °C, were reported.^{133, 164} It was assumed that the reaction proceeds *via* the radical pathway in accordance with the usual behaviour of alkylcobalt intermediates. The use of a sacrificial zinc anode in combination with a cobalt catalyst leads to an increase in the number of catalytic cycles and improvement in the yield.¹³³

R = Buⁿ, n-C₆H₁₃, n-C₁₁H₂₃; n = 1–4.

Much attention has been given to the use of catalytic systems based on cobalt complexes in the organic synthesis, particularly, in the ring expansion reactions suitable for the preparation of natural compounds. The traditional electrolytic scheme of the synthesis was proposed. Under electrochemical conditions, Co(II) in heptamethyl cobyrinate perchlorate { [Cob(II)₇C₁ester]ClO₄ }, which is a catalyst simulating vitamin B₁₂, is readily reduced to Co(I) to give highly nucleophilic intermediates. The latter react with alkyl halides to form alkylated complexes containing the Co–C bond. The electrochemical reactions or photolysis of these complexes afford the final products. Torii and coworkers¹⁶⁴ studied the ring expansion reactions of 2-(bromomethyl)cyclopenta(hexa)nones with the use of cobaloxime (MeOH, 60 °C) in the galvanostatic mode under irradiation with visible light. Murakami and coworkers¹⁶⁵ used [Cob(II)₇C₁ester]ClO₄ as the catalyst of ring expansion reactions in the potentiostatic mode.

In different electrolytic modes, the ring-expansion product **10** was obtained as the major product (in yields of up to 56%). The course of the reaction was monitored by electronic and ESR spectroscopy, which made it possible to identify intermediates formed at different potentials either in daylight or in the dark. The potentials ≤ -1.5 V (with respect to a saturated calomel electrode) are optimum for electrolysis. The reaction cycle involves electrochemical reduction of the Co(II) complex to supernucleophilic Co(I) species, which react with the substrate to give the corresponding alkylated complex. The latter decomposes upon electrolysis (rather than photochemically) to the final product and the cobalt complex is recycled back to the catalytic cycle as the mediator. The ratio of the reaction products is determined by the strain energy of alicycles. Thus the highest yield of the ring-expansion product was achieved in the transformation of five-membered cyclic ketone to six-membered ketone.¹⁶⁵

Under particular conditions, electroreductive coupling of organic halides with aldehydes catalysed by the nickel(0) complex with 2,2'-bipyridyl proceeds in good yields (Table 10).¹⁶⁶

Alcohols can be obtained in high yields with the use of nickel, iron or stainless steel anodes. Aromatic aldehydes bearing the

4- $\text{ClC}_6\text{H}_4\text{CO}_2\text{Me}$	PhCHO		inox ^d	50 ^e
$\text{MeC}(\text{Br})=\text{CHMe}$	PhCHO		inox ^d	52

^a Reaction conditions: ArX, 15 mmol; $\text{R}^1\text{R}^2\text{CO}$, 7.5 mmol; Bu_4NBF_4 (10^{-2} mol litre⁻¹) as the supporting electrolyte; $I = 0.1$ A, a nickel cathode, 20 °C.^b The yields are given with respect to the carbonyl compound; ^c $\text{NiBr}_2(\text{bipy})$, 7 mmol; ^d inox is a stainless steel anode; ^e the yield is given with respect to ArCl (ArCl , 7.5 mmol, PhCHO, 30 mmol).

electron-donating groups in the ring, aliphatic aldehydes and cyclohexanone can be involved in these reactions. 2-Bromoaniline and 2-bromoanisole can serve as arylating agents, whereas other isomers cannot perform this function due, apparently, to stability of the arynickel intermediate $\text{ArNi}(\text{I})(\text{bipy})$. The reactions of aryl halides containing substituents at positions 3 and 4 yield predominantly biaryls, whereas the addition at the carbonyl group proceeds to only a small extent. The reaction of benzaldehyde with aryl halide containing the electron-withdrawing methoxycarbonyl group in the ring proceeded in satisfactory yield upon the replacement of Br by Cl. In this case, homocoupling of $\text{ArNi}(\text{I})(\text{bipy})$ with ArX was suppressed but a three- to fourfold excess of the aldehyde was required. The fact that aromatic aldehydes containing electron-withdrawing substituents in the ring, which are favourable for π -bonding, virtually do not enter into the reactions (whereas aliphatic aldehydes can be involved in these reactions) is indicative of the predominant σ -character of the bond between the organonickel complex and the carbonyl group of aldehyde.

Selective reduction of aryl propargyl ethers to the corresponding phenols in the presence of electrochemically generated nickel complexes proceeds under mild conditions and in good yields. This reaction provides the means of removing the allyl and propargyl protective groups.¹⁶⁷

The carbonyl group in allyl ether of salicylaldehyde was subjected to electrochemical intramolecular allylation [$\text{NiBr}_2(\text{bipy})$, Mg anode, -1.2 V with respect to a saturated calomel electrode] using nickel complexes as the catalyst.¹⁶⁸ It is believed that this process involves electrochemically generated $\text{Ni}(\text{0})$ complexes as active catalytic species capable of reacting with the allyl fragment of the ether to form the π -allyl nickel complex **A**.

The intramolecular transfer of the allyl fragment to the carbonyl group affords intermediate alkoxide, *viz.*, nickel(II) phenoxide **B**. Conceivably, the Ni^{2+} ions in this complex can be replaced by the Mg^{2+} ions to give the intermediate **C**, which is accompanied by liberation of the $\text{Ni}(\text{II})$ complex and completion of the catalytic cycle. Hydrolysis of the alkoxide **C** gives rise to the final product:

Later on, it was demonstrated¹⁶⁹ that the propargyl fragment in *o*-(propargyloxy)arencarbaldehydes was transferred to the carbonyl group under the action of electrochemically generated nickel complexes to produce homopropargyl alcohols.

It was believed that the C–O bond in propargyl ether was initially cleaved followed by the addition of the propargyl fragment to the carbonyl group. The reactions of ring-unsubstituted propargyl ethers afforded allene isomers as by-products.

Electrochemical reductive deprotection of the amino group in allylcarbamates containing several functional substituents in the presence of catalytic amounts of the Ni(II)(bipy)₃ complex proceeded selectively to give the corresponding amines in 40%–99% yields.¹⁷⁰

$R = \text{Ph, 4-MeO}_2\text{CC}_6\text{H}_4, 4\text{-NCC}_6\text{H}_4, 2\text{-MeCOC}_6\text{H}_4, \text{Bn, cyclo-C}_6\text{H}_{13}, (\text{MeO})_2\text{CHCH}_2.$

The reactions proceed under mild conditions (20 °C) in an undivided cell with a sacrificial zinc anode. The allyl groups in arylcarbamates are selectively removed in 70%–99% yields. Under these conditions, the ether, ketone, acetal and nitrile groups remain intact.

VII. Electrocatalytic reduction of carbon dioxide

The data on electrocatalytic reduction of nitrogen and its oxides, carbon oxides and small molecules containing triple bonds (acetylene, cyanides) were surveyed in the reviews.^{13, 171} All these substrates are electrochemically inactive and contain very strong bonds, which are rather difficult to cleave. Hence, activation of these molecules by inserting them into the coordination sphere of metal followed by (or preceded by) the electrochemical electron transfer is the most promising way for subjecting poorly reactive molecules to various chemical transformations. Besides, electrocatalytic procedures involving metal complexes attract considerable attention because they allow the use of vast biosphere reserves of N₂, CO₂ and O₂ as cheap and accessible starting materials in various chemical processes.

Direct reduction of CO₂ at a metal cathode, for example, at a mercury cathode, requires a high overpotential ($E_{\text{CO}_2/\text{CO}_2^{\cdot-}} = -2.21$ V with respect to a saturated calomel electrode, DMF). Other metal cathodes, for example, copper or gold cathodes, can reduce CO₂ in aqueous solutions at somewhat lower cathodic potentials (from –1.3 to 1.7 V). However, even these values are too high for practical applications because water is reduced at these potentials with hydrogen elimination. In principle, it is possible to use non-aqueous solvents, but these processes require larger energy consumption and are often accompanied by side reactions.

The use of various metal complexes as catalysts has the most promise for selective electroreduction of CO₂. Generally, these processes are carried out using complexes with nitrogen-containing macrocyclic ligands, *viz.*, porphyrins and their analogues, which are well known as biocatalysts.¹⁷² Compared to natural catalysts, artificially synthesised metal complexes with nitrogen-containing macrocyclic ligands (for example, with phthalocyanines) possess even more extended π -conjugated chains, whereas their catalytic activity is highly competitive with that of natural analogues. Metal complexes with phthalocyanines,^{173–185} Co(II)

complexes with porphyrins,⁹⁰ Ni(II) complexes with cyclam,^{186–191} bis- and polypyridyl complexes of Rh(II),¹⁹² Re(I),¹⁹³ Cu(II),¹⁹⁴ Co(II), Fe(II) and Ni(II),^{195–199} iron and cobalt complexes with 4,5-dihydroxybenzo-1,3-disulfonate and 2-hydroxy-1-nitrosonaphthalene-3,6-disulfonate^{200, 201} ligands proved to be catalysts of CO₂ reduction. Most of the above-mentioned complexes act as efficient catalysts of CO₂ reduction only in non-aqueous media because CO₂ reduction in water is preceded by proton reduction. Only the cobalt complex with phthalocyanine (PcCo)^{173, 174, 176–181, 201, 202} and the nickel complex with cyclam^{185, 195, 203, 204} proved to be efficient electrocatalysts of CO₂ reduction in water or aqueous acetonitrile, the latter being active only at a mercury cathode at which the overpotential of hydrogen elimination is higher than that at a platinum cathode. It was suggested^{186, 187} that higher selectivity of electroreduction of CO₂ compared to that of H₂O observed in these processes is associated with the larger size of the macrocyclic ligand and the presence of the NH groups in Ni(cyclam).

A considerable advantage of metal complexes as catalysts is the possibility of changing their reactivities by modifying the macrocyclic ligand with electron-donating or electron-withdrawing substituents. Thus the nickel(II) complex with a cyclam analogue containing two methyl groups in the macrocycle (3,10-dimethyl-1,3,5,8,10,12-hexaazacyclodecane) exhibits much higher catalytic activity than the nickel(II) complex with unsubstituted cyclam.²⁰⁵ It should be noted that the insertion of σ -acceptor substituents (for example, of fluorine) into the nitrogen-containing ring also leads to improvement in the catalytic activity and selectivity of CO formation (compared to hydrogen elimination). In these cases, the Ni(II) complex with 3,3,10,10-tetrafluorocyclam proved to be most efficient. The further increase in the number of the fluorine atoms in the macrocycle leads to deterioration of activity.²⁰⁶

Metalloporphyrins can also exhibit catalytic activity in reduction of CO₂ to CO in aqueous and non-aqueous media.²⁰⁷ However, porphyrins are rapidly consumed in the course of electrolysis and the catalysis ceases after a rather small number of catalytic cycles. Catalysts are poisoned due to carboxylation and hydrogenation of porphyrins (see Ref. 208).†

Mechanisms for formation of different products of CO₂ reduction catalysed by metallophthalocyanines have been proposed.^{173, 174}

The formation of carbon monoxide

The formation of formic acid

The formation of methane

† Undesirable cathodic processes can be prevented performing gas-phase reactions of CO₂ with electroactive films at solid electrolytes.²⁰⁹ In many cases, heterogeneous catalytic reduction of CO₂ was carried out with the use of an active catalyst, for example, metalloporphyrin or metallophthalocyanine, deposited on a solid electrolyte (graphite) and coated with a conducting film (Nafion), which prevents it from passing into solution.^{173, 174, 176–181, 210} However, these systems are beyond the scope of the present review.

It should be noted that the formation of the metal–CO₂ complex was postulated as the key step in virtually all studies devoted to catalytic binding of CO₂ by transition metal complexes.²¹¹ In most cases, this suggestion was supported only by indirect evidence obtained in IR and NMR spectroscopic studies because, first, the lifetime of these intermediates is short and, second, the presence of the solvent molecules, which are also capable of being coordinated, hinders the detailed analysis of the structure of the complex.

The reaction mechanism was investigated also with the use of semiempirical quantum-chemical calculations. For example, an attempt was made to relate the catalytic activity of phthalocyanines to the energy of the frontier orbitals of the complex.²¹¹ It appeared that the catalytic activity of phthalocyanine complexes correlates with the ability of the metal atom to coordinate an additional ligand, which, in turn, depends on the difference between the energy of the *d* orbitals of the metal atom and the energy of the frontier orbitals of the coordinated ligand.

Electrocatalytic reduction of CO₂ was examined in aqueous solutions at a graphite electrode, which was coated with PcCo bound to poly-4-vinylpyridine as a donor axial ligand.^{179, 183, 184} It was demonstrated that the presence of the latter leads to a substantial improvement in the catalytic activity of PcCo due, apparently, to a rise in the electron density on the metal atom. In this catalytic system, the selectivity of CO₂ reduction is much higher than that in the case of pure PcCo in spite of the fact that competitive water reduction persists. This is attributable to an increase in the local concentration of CO₂ in the near-membrane layer through hydrophobic interactions of CO₂ with polyvinylpyridine.¹⁷⁷ The reaction scheme was proposed.^{183, 184}

The catalytic process starts only at the second reduction wave of PcCo because the first reduction step is followed by rapid addition of H⁺ to the peripheral nitrogen atoms of the phthalocyanine ring and the active species capable of reducing both H⁺ and CO₂ to form H₂O and CO, respectively, are generated only at the second wave. However, no direct evidence for the formation of the PcCo–CO₂ adduct was obtained.

VIII. Synthesis of carboxylic acids

1. Carboxylation of organic halides

In the early 1980s, it was demonstrated that electroreduction of aryl halides catalysed by nickel complexes with PPh₃ (see Ref. 212) or dppe²¹³ in the presence of CO₂ affords predominantly arenecarboxylates rather than biaryls. Based on the results of electroanalytical investigation of the [Ni]–dppe system, the catalytic cycle was proposed.^{214, 215}

The Pd complex with PPh₃ also catalyses electrocarboxylation of aryl iodides and bromides.²¹⁶

In this reaction, CO₂ was assumed to react as an electrophile with [ArPd(0)(PPh₃)₂][–] generated upon reduction of the aryl-

palladium(II) σ-complex.²¹⁷ Aryl chlorides react with Pd(0) too slowly to ensure efficient carboxylation. Aryl triflate and aryl bromide possess higher reactivities and, hence, arylcarboxylic acids can be synthesised starting from the corresponding aryl triflate.^{57, 58}

Ar = 4-RC₆H₄ (R = Cl, CF₃, CO₂Et, F, Me), 1- or 2-naphthyl.

Nonsteroid anti-inflammatory drugs, *viz.*, α-arylpropionic acids, were prepared from the corresponding benzyl chlorides and CO₂ in the presence of the Ni–dppe or Ni–dppp system [dppp is 1,3-(diphenylphosphino)propane] and cyclooctadiene (COD).²¹⁸ There is no need to use a catalyst in these reactions, but it suppresses homocoupling, which becomes the main reaction at high concentrations of benzyl chloride and lower CO₂ pressure.²¹⁹

HMPA is hexamethylphosphoramide.

Product	Name	Yield (%)
PhCH(Me)CO ₂ H		89
	naproxen	81
	ibuprofen	80
	phenopropfen	76

There is also no need to use a catalyst in electrocarboxylation of aryl halides or various benzyl compounds in an undivided cell in the presence of a sacrificial aluminium²²⁰ or magnesium^{21, 221} anode. Organic halides containing functional groups, which make it impossible to apply direct electrochemical reduction, are subjected to electrocarboxylation using a catalyst simultaneously with a sacrificial anode.

Interest in transition metal complexes with tetraazamacrocyclic ligands as applied to electrocatalysis is associated with the fact that these complexes are similar to natural photosynthetic systems.²²² The mechanism of CO₂ reduction catalysed by tetraazamacrocyclic complexes of Ni(II) and Co(II) was examined by cyclic voltammetry and preparative electrolysis. Reduction affords CO, which then reacts with a Ni(I) complex to form Ni(0) carbonyl compounds, which eventually poison the catalyst.²²²

Electrocatalytic reduction of CO₂ under the action of trinuclear nickel cluster radicals was investigated by electrochemical methods and spectroelectrochemistry.²²³

2. Carboxylation of alkenes and alkynes

It is possible to subject unsaturated compounds to direct electrochemical carboxylation.^{18, 224} However, this procedure is of limited usefulness because only arylated or activated alkenes can be used as substrates. For alkynes, only a few examples of the successful application of this reaction have been reported.^{225–229}

Indirect electrochemical reductive coupling of alkynes with CO₂ gives rise to substituted acrylic acids through hydroxycarboxylation.^{60, 225–231} Electrolysis was carried out at 20–80 °C in an undivided cell in DMF containing a catalytic amount of a nickel complex in the presence of a sacrificial magnesium anode at

ambient or slightly elevated (5 atm) CO₂ pressure. Alkynes containing electron-donating groups are more readily subjected to carboxylation at elevated temperatures, whereas carboxylation of alkynes bearing electron-withdrawing groups proceeds more readily at room temperature.

(a) Ni(bipy)₃(BF₄)₂ (10%), e⁻, DMF, Mg anode; (b) hydrolysis.

R ¹	R ²	Yield (%)	Ratio A : B
n-C ₆ H ₁₃	H	65	90 : 10
Pr ⁿ	Pr ⁿ	93	
Ph	H	55	71 : 29
Ph	Me	72	38 : 62
Ph	CO ₂ Et	75 ^a	

^a The ratio between the di- and monocarboxylation products was 74 : 26.

The reactions proceed predominantly as the *cis*-addition with good regioselectivity (in the case of terminal alkynes, CO₂ reacts at position 2). Monocarboxylation takes place only in the absence of electron-withdrawing groups.

This procedure has advantages over the chemical method devised by Hoberg *et al.*,^{232, 233} which, for the most part, required stoichiometric amounts of air-sensitive Ni(0)(COD)₂; instead, readily accessible Ni(II) complexes are used in the electrochemical procedure.

In these reactions, the advantages of a sacrificial anode are evident, a magnesium anode being most suitable. Oxidation of the latter gives rise to Mg²⁺ ions, which can be involved in the catalytic cycle to decompose nickelacycle **A** thus liberating Ni for further transformations.

The formation of the nickelacycle **A**, which was established by cyclic voltammetry, confirms the proposed mechanism. In the absence of Mg²⁺ ions (the reactions were carried out in a divided cell in the presence of ammonium ions), the nickelacycle was not decomposed and the reaction was terminated once the starting nickel compound has been completely consumed. After the addition of MgBr₂ to a solution of the nickelacycle prepared electrochemically, Ni(II) was regenerated.²³⁴

Diacetylenes are used for the construction of polycyclic compounds. Thus bicyclic pyrones were prepared by electrochemical carboxylation in the presence of CO₂ and a stoichiometric amount of a Ni(0) complex.²³⁵ This procedure was also applied to the synthesis of linear and cyclic monocarboxylic acids from nonconjugated diacetylenes.^{236, 237} The composition of the reaction products depends on the nature of the ligand. Thus cyclic compounds **11** were prepared with the use of a nickel complex with bipyridyl at normal CO₂ pressure, whereas linear adducts **12** were obtained with the use of pentamethyldiethylenetriamine (PMDTA) as the ligand and elevated CO₂ pressure (5 atm).

L	Yield (%)	Ratio 11 : 12
bipy	35	59 : 4.5
PMDTA	30	9 : 45

The addition of CO₂ to diacetylenes containing both the terminal and internal triple bonds proceeds predominantly at position 2.

Electrochemical carboxylation of 1,3-diacetylenes in the presence of Ni(PMDTA) as the catalyst proceeded regio- and stereoselectively to give predominantly (*E*)-2-alkylidenealk-3-ynoic acids **13** (sometimes, with an impurity of isomeric products **14** and **15**).^{237, 238}

L = PMDTA.

R ¹	R ²	Yield (%)		
		13	14	15
n-C ₅ H ₁₁	n-C ₅ H ₁₁	58	25	—
Ph	Ph	40	0	—
MeOCH ₂	MeOCH ₂	60	1	—
Ph	Bu ⁿ	37	16	3
MeOCH ₂	Ph	50	0	11

In this process, double bonds proved to be less reactive than triple bonds.²³⁹ In nonconjugated as well as in conjugated alkenynes, only the triple bond is carboxylated with regio- and stereoselectivity analogous to those observed for acetylenes.²⁴⁰

According to this procedure, monocarboxylic acids were prepared in good yields starting from 1,2-dienes.²⁴¹ In the case of alkyl- and cycloalkallenes, the addition of CO₂ proceeds predominantly at the C(2) atom. In the case of arylallenes, the addition occurs predominantly at the C(3) atom.

R = n-C₈H₁₇, cyclo-C₆H₁₁; Ar = Ph, 4-MeOC₆H₄;

L = PMDTA; p_{CO₂} = 5 atm.

Some other examples of homogeneous electrochemical activation of CO₂ were also described among which are the synthesis of lactones by telomerisation of butadiene and CO₂,²⁴² synthesis of bicyclic lactones using nickel or cobalt complexes,²⁴³ trans-carboxylation²⁴⁴ and insertion of CO₂ into epoxides catalysed by Ni(cyclam)Br₂.²⁴⁵

IX. Carbonylation of organic substrates

Carbonylation of organic substrates is still a complicated problem because the presence of CO leads to deactivation of the catalytic system. The reactions of carbon monoxide with transition metals

in low oxidation states afford different metal carbonyls, which exhibit low reactivity with respect to the carbon–halogen bonds because of strong coordination with CO.

Some metal carbonyls can be activated by electrochemical reduction with generation of active anionic species. For example, aldehydes can be synthesised by electrolysis of a stoichiometric mixture of alkyl halides and iron pentacarbonyl.^{246, 247}

R = n-C₅H₁₁, Et, Bn; X = I, Br.

Carbon dioxide can be used as a CO source. It is well known that complexes of transition metals in low oxidation states catalyse chemical and electrochemical reduction of CO₂ to CO. This approach was applied to the generation of the mixed Ni(0)bipy(CO)₂ complex by electrochemical reduction of Ni(bipy)²⁺ in *N*-methylpyrrolidone or DMF in the presence of CO₂.^{248, 249} The resulting complex can react with alkyl, benzyl and allyl halides to form symmetrical ketones with regeneration of Ni(bipy)²⁺. The proposed two-step procedure for the synthesis of ketones involves electroreduction and chemical coupling.

It was demonstrated²⁵⁰ that carbonylation can also be carried out by electrolysis of a solution of organic halide containing a catalytic amount of bipy under an atmosphere of CO in an undivided cell with a stainless steel anode. This process produces symmetrical ketones in good yields.

RX	Yield (%)
BnCl	80
2-MeC ₆ H ₄ CH ₂ Br	70
4-MeC ₆ H ₄ CH ₂ Br	62
2-ClC ₆ H ₄ CH ₂ Cl	75
MeCH=CHCH ₂ Cl	65
Me(CH ₂) ₅ Br	62
4-CF ₃ C ₆ H ₄ Br	50

The anodic reactions afford the Ni(II)(bipy) and Fe(II)(bipy) complexes, which are reduced at a cathode to give intermediates catalysing the synthesis of ketones. In these processes, complexes of nickel coordinated both by bipy and CO serve as reactive species. Iron complexes, apparently, exhibit a synergistic effect.

Ketones were successfully prepared by electroreductive coupling of organic halides with CO using the Ni(bipy)²⁺ complex as the catalyst. Either CO entering the solution^{250–252} or metal carbonyls²⁵³ serve as a source of carbonyl groups. Electroreduction of CO₂ proceeded under the action not only of Ni(0)(bipy)^{248, 249} but also of iron porphyrinates in the presence of anodically generated Mg²⁺ ions.²⁵⁴

Ketones can be prepared not only by electrochemical carbonylation of organic halides but also by some other reactions catalysed by nickel complexes. Thus unsymmetrical ketones were obtained by NiBr₂(bipy)-catalysed electroreductive coupling of acyl chlorides with alkyl halides.²⁵⁵ Acid chlorides are transformed into symmetrical ketones in an undivided cell equipped with a nickel or stainless steel anode.

R = Bn, Ph, 3-FC₆H₄, 3-MeC₆H₄, 4-MeC₆H₄, 4-FC₆H₄,

It is believed that the first reaction step gives rise to alkynyl-nickel intermediates through oxidative addition of acid chloride to an electrochemically generated unstable low-valent nickel com-

plex. Regeneration of divalent Ni yields a bisacylnickel complex. Ketone is derived from the bisacylnickel complex by reductive elimination of Ni bound with one CO molecule.²⁵⁶

In the presence of the Ni(bipy) complex, arylzinc compounds, which are electrochemically generated from aryl halides and zinc salts, react with (CF₃CO)₂O to give the corresponding aryl trifluoromethyl ketones.⁷⁹

The reactions involving the electroreductive formation of the carbon–heteroatom bond under the conditions of transition metal catalysis are few in number. For example, mention may be made of electrochemical silylation of allyl acetates in the presence of the Pd–PPh₃ system²⁵⁷ and the electrochemical synthesis of aryl thioethers from thiophenol and aryl halides.²⁵⁸

Based on electrochemical activation of salts and complexes of some transition metals, catalytic systems were designed for carbonylation of methanol to form dimethyl carbonate.²⁵⁹ The reactions are carried out by passing CO through a methanolic suspension or through a solution of a complex under atmospheric pressure at 20 °C in an ion-exchange membrane cell. Metal complexes catalyse oxidative carbonylation of methanol.

The anodic process leads to regeneration of metal in a higher oxidation state.

The redox pairs, which are active in chemical carbonylation promoted by oxygen, viz., Cu(I)/Cu(II), Pd(0)/Pd(II) and Co(II)/Co(III), were tested as catalysts. However, the electrochemical conditions appeared to be milder than those used in conventional chemical reactions. In some cases, the complexes exhibited higher catalytic activity. In these complexes, bipy, salen, acac and PPh₃ were used as ligands. The highest faradaic yields (%) of dimethyl carbonate were achieved with the complexes CuCl(bipy) (84.8), PdCl₂(bipy) (64.0), CoCl₂ (26.0), RhCl₃ (25.0) and AgBF₄(bipy) (10.2). The VCl₃, Mn(salen), Mn(acac)₂, ReCl₃(bipy), Cr(acac)₃, NiCl₂(bipy) and RuCl₂(PPh₃)₂ compounds proved to be either poorly reactive or inactive at all. Only in the presence of the PdCl₂(bipy) complex, did more than one redox cycles occur.

It is known that many transition metals catalyse oxidation of CO to CO₂ in water. It is these transition metals that exhibit the highest activity in oxidative carbonylation of alcohols to form dialkyl carbonates. This reaction mechanism involves the formation of methoxycarbonylmethyl intermediates (MCO₂Me, where M = Cu, Co or Pd) whose stability and reactivity depends substantially on the structure of the complex and the nature of the ligands.^{260, 261} For example, CuCl exhibits activity only at 70 °C, whereas it is active even at 20 °C in the presence of bipy. Electroactivation of CuCl, PdCl₂, PtCl₂ and AgBF₄ occurs only in the presence of bipy. To the contrary, the addition of bipy as well as of acac, salen and PPh₃ to CoCl₂, NiCl₂ and AuCl₃ impairs the efficiency of the process.

X. Electrochemical synthesis of organophosphorus compounds from chlorophosphines or white phosphorus

The development of synthetic approaches to the preparation of compounds containing P–C bonds based on white phosphorus or phosphorus chlorides is of importance in the preparative chemistry of organophosphorus compounds. Considerable attention is given to the synthesis of tertiary phosphines, which are widely used in organometallic and coordination chemistry.

The promising process^{262–266} for the preparation of tertiary phosphines is based on electrochemical coupling of mono- or dichlorophosphines with aromatic and heteroaromatic halides catalysed by the nickel complex with bipy in an undivided cell using a sacrificial magnesium or zinc anode (Table 11).

ArX	Product	Yield (%) ^a	Anode
PhBr	Ph ₃ P	87	Mg

5-Cl-1,3-Me ₂ C ₃ HN ₂	Ph ₂ P(5-C ₃ HN ₂ -1,3-Me ₂)	25	Mg

^a The preparative yield is given with respect to chlorophosphine.

In recent years, the principles of indirect anaerobic electrochemical regeneration of galactose oxidase (GOase) were developed.²⁷¹ This enzyme oxidises the primary alcohol group of D-galactose to the corresponding aldehyde. The synthetic use of GOase is of interest because it is highly sensitive to the nature of the substrate and can perform selective oxidation of primary hydroxy groups in polyols. Thus xylitol is oxidised to L-xylose. Substituted ferrocenes exhibiting high catalytic activity were used as mediators. The iron(II) and ruthenium(II) complexes with the phenanthroline ligands appeared to be less efficient. For these processes, phosphate buffers with pH 10.8 are the media of choice. Electrochemical regeneration of GOase allows the pre-

vention of the undesirable formation of the enzyme inhibitor (hydrogen peroxide), which is generated under aerobic conditions in reactions involving GOase.

S is a substrate, P is a product, M is a mediator (ferrocene derivative).

XII. Characteristic features and mechanisms of reactions catalysed by nickel and palladium complexes

1. Kinetic regularities

The application of electrochemical methods to generation of complexes of Ni(0) and other metals in low oxidation states makes it possible to use catalytic amounts of complexes generated at an electrode. In addition, electrochemical methods allow one to obtain quantitative estimations of the rates of catalytic reactions and in some cases even to separate the overall process into individual steps and to evaluate the reactivities of intermediates and stability of different forms of metal complexes.

Based on the external morphological traits,^{24, 33, 272–274} in the $Ni(II)L_n-Ni(0)L_n$ system ($L = PPh_3$ or bipy) (Fig. 1). These are an increase in the current of reduction of the starting $Ni(II)L_n$ complex (see Fig. 1 a), the wave corresponding to reduction of the complex involving the substrate as the ligand (see Fig. 1 b) and the wave of catalytic reduction of the organometallic compound, which is a product of the reaction of the reduced form of the starting complex with the substrate (see Fig. 1 c). In all these cases, the observed pattern can be (with some reservations) considered as a classical pattern and, hence, the increase in the current (the ratio of the catalytic to diffusion current, i_c/i_d) can be used for calculating the rate constant of catalyst regeneration (k_{eff}), which describes the overall process.³³

Figure 1. Morphology of catalytic waves in the $Ni(II)L_n-Ni(0)L_n$ system;²⁴

(a) an increase in the current of reduction of the starting complex; (b) the wave corresponding to reduction of the complex with the substrate, (c) the wave of catalytic reduction of the organometallic compounds; (1) the $Ni(II)L$ complex, (2) and (2') the $Ni(II)L$ complex in the presence of increasing amounts of organic halides.

$$k_{eff} = \frac{k_1 k_2}{k_{-1}} \cdot \frac{[RHal]}{[bipy]}.$$

The lower the donor number of the solvent, the higher the efficiency of the catalytic process.³³

The nickel complex with bipy proved to be the most active and versatile catalyst, which exhibits a pronounced catalytic effect in reactions with various substrates containing the C–Hal, P–Cl or Si–Cl bonds.^{24, 33}

2. Relationship between electrochemical redox properties of nickel complexes and their reactivities in dehalogenation

The redox potentials of the complexes were used as the starting characteristics for predicting the reactivities and the reaction mechanisms of organometallic compounds.^{24, 26, 32, 33, 275} For a series of $Ni(II)$ and $Ni(0)$ complexes, the electrochemical gap $G = E_{ox} - E_{red}$, the electrochemical electronegativity $\chi = (E_{ox} + E_{red})/2$ and the degree of charge transfer $\Delta N = \Delta\chi/\Sigma G$ were estimated experimentally.^{24, 26, 32, 33} The G , χ and ΔN parameters can be used for evaluating the reactivities of the complexes in oxidative addition to organic halides.

These parameters are also suitable for estimating interactions between the complex and various ligands and substrates and for obtaining information on the complex-forming properties and donor-acceptor complex–substrate interactions. This is of particular importance in the case of organophosphorus substrates exhibiting both σ -donor and π -acceptor properties in interactions with transition metals. The largest electrochemical gap characterising the degree of ‘hardness’ of the complex was found for $Ni(II)Br_2$.^{24, 25, 32, 33} For phosphine and phosphite complexes of $Ni(II)$, the G values are much smaller. On the contrary, the electrochemical gap increases and, consequently, the donating ability and polarisability decrease in the series of the $Ni(0)$ complexes with bipy (0.60 V), phen (0.72 V) and Ph_3P (1.04 V). Based on these characteristics, the degrees of charge transfer between the complexes and substrates were calculated on the assumption that the $Ni(II)$ or $Ni(0)$ complex and the substrate act as an electron donor and an electron acceptor, respectively.^{24, 25, 32, 33} In the case of $Ni(II)$ complexes, the degrees of charge transfer are small, whereas these values are an order of magnitude higher in the case of $Ni(0)$ complexes. In the latter case, oxidative addition reactions are assumed to proceed. The sign of the degree of charge transfer indicates that the $Ni(0)$ complexes with all substrates exhibit pronounced donor properties ($\Delta N \gg 0$).

The reactivities of nickel complexes in catalytic processes were accounted for based on the data from voltammetric measurements, results of quantum-chemical calculations and estimations of the G , χ and ΔN values.^{24, 25, 32, 33} The reactivities of $Ni(0)$ complexes in reduction reactions of organic halides are determined by a number of factors among which are the electrochemical gap G , the degree of charge transfer ΔN , the strength of the Ni–P bond, the electronic and steric effects of the ligands and the occurrence of the subsequent redox processes. In the series of the $Ni(0)L$, $Ni(0)L^-$, L^- mediators ($L = bipy$ or phen) possessing reducing properties, the energy of stabilisation of the transition state decreases on going from the inner-sphere to outer-sphere reduction processes, which is accompanied by the corresponding decrease in the reaction rate, as compared to the inner-sphere mediator characterised by the same driving force for the process.³⁰

In the studies,^{26, 276–278} the mechanism of two-electron reduction of the complexes was proposed with consideration for competitive homogeneous redox reactions, the evidence for the

An analogous electrocatalytic cycle was suggested for the synthesis of hexa-1,5-diene from allyl bromide in the presence of nickel complexes with 2,2'-bipyridyl²⁹⁸ as well as from allyl

chloride under the action of the electrochemically generated cobalt complex with 2,2'-bipyridyl.³⁰⁵ However, the numbers of the catalytic cycles in these processes were rather low due to rapid decomposition of the catalyst.

Shiavon *et al.*⁴⁸ made an attempt to generalise the notions of the reaction mechanisms of organic halides under the conditions of homogenous catalysis by Ni(0) complexes with phosphine ligands. In this case, the efficient electrochemical process occurs through a lowering of the activation energy of RX reduction and cyclic regeneration of the catalyst. At less negative potentials ($|E_{RX}| > |E_{Ni(II)L}|$), a lowering of the activation energy and RX reduction lead to a change in the reaction pathway compared to that observed in non-catalytic conditions because heterogeneous reduction of RX proceeds at substantial overpotentials and high cathodic potentials. As a consequence, the radical generated upon the transfer of the first electron is reduced to the carbanion and the corresponding hydrocarbon RH and does not give coupling products.

In all cases, reduction can proceed *via* a series of simple steps involving electrochemical reduction of the nickel(II) complex to Ni(0), activation of organic halide through its oxidative addition to the Ni(0) complex and reductive elimination with the cleavage of the metal–carbon bond (either thermal decomposition or further cathodic reduction) as the key steps.⁴⁸

It should be noted that intermediates of the catalytic cycles were neither detected nor isolated.⁴⁸

The path *a* is realised if the σ -organonickel complex **A** is rather stable, as in the case of PhBr and BnCl at low temperature. For the catalytic process involving these halides to occur, the complexes **A** must be reduced. Later on, it was shown^{87, 301, 302, 306} that a Ni(0) complex serves as a reducing agent and the catalytic process takes place at $E_{Ni(II)/Ni(0)}$. The path *b* is typical of neopentyl bromide and benzyl iodide at 25 °C, the coupling product being formed *via* dimerisation of the radicals generated upon the homolytic cleavage of the nickel–carbon bond in the complex **A**. The reaction with butyl bromide follows the path *c*. In the latter case, thermal decomposition of an organonickel intermediate occurs through β -elimination involving the nickel hydride complex **B** as an intermediate. For homocoupling to proceed, the reaction must take the path *a*, which is realised at more negative working potentials, the composition of the products being determined by the ratio between the paths *a* and *c*.

Oxidative addition of organic halide to the Ni(0) complex is the rate-limiting step. An increase in catalytic current allows the comparison of the reaction rates for various halogen-containing derivatives. The reactivity was found to decrease in the series $Bu^tI > Bu^tCH_2I > BnCl > PhBr$ in parallel with the change in dipole moment.

Electroanalytical methods provide information on the reaction mechanisms of coupling of aryl halides. In the general case, a zero-valent nickel or palladium complex is formed at a cathode if PPh_3 , dppe or bipy serve as ligands. The first step of the catalytic cycle involves oxidative addition of aryl halide to a Ni(0) or Pd(0) complex giving rise to a σ -arylnickel or σ -arylpalladium inter-

mediate. Coordinatively unsaturated complexes of the Ni(0)(bipy),²⁷² Ni(0)(dppe)²⁹² or Pd(0)(PPh₃)₂ type²⁹⁵ proved to be much more reactive than the corresponding coordinatively saturated complexes. The reactivities of the Ni(0) or Pd(0) species depend also on the nature and the concentration of halide ions bound to the starting complex or added to the reaction medium.^{218, 238} The formation of biphenyl from bromobenzene catalysed by Ni(dppe) was examined in detail^{292, 293} and the catalytic cycle for this process was proposed. In this catalytic cycle, the σ -arylnickel intermediate **A** is initially reduced to the corresponding Ni(I) complex **B** followed by the transformation into the diarylnickel(III) complex **C**.

The complex **C** is subjected to reductive elimination to form the corresponding product and the Ni(0) complex from which Ni(0) is generated.^{292, 293} Hence, homocoupling proceeds through intermediate paramagnetic [Ni(I) and Ni(III)] and diamagnetic [Ni(0) and Ni(II)] species. The threshold potential (–2 V with respect to a saturated calomel electrode) was demonstrated to exist, which is necessary for the formation of biphenyl. At a less cathodic potential, the reaction affords the phenylnickel derivative PhNi(II)(dppe)Br, which needs to be reduced for the cyclic process to occur. It should be noted that the scheme proposed based on voltammograms^{292, 293} lacked experimental support because none of the postulated intermediates was isolated or identified. Equations describing the kinetic characteristics of the assumed sequence of the reactions were derived and the rate constants of different steps were calculated. It is believed that reductive elimination is the rate-limiting step.

The formation of biphenyl was completely suppressed upon introduction of CO₂ into the reaction system giving rise to a new catalytic cycle to form carboxylation products.

The reaction mechanism was proposed based on the results of an investigation of the reaction products, examination of the voltammetric behaviour of the starting complexes in the presence of the substrate and the behaviour of intermediates and kinetic calculations of individual steps of the process. Since the addition of CO₂ to ArNi(I)L₂ ($k = 1-2 \text{ mol}^{-1} \text{ litre s}^{-1}$) proceeds approximately 100–200 times faster than the addition of ArX, the formation of biaryls in the presence of stoichiometric amounts of CO₂ is completely eliminated.^{215, 294, 307}

By analogy with the reactions catalysed by Ni(dppe), two hypothetical catalytic cycles involving the formation of a σ -arylnickel intermediate were proposed for the reactions in the presence of the Ni(bipy) complex. In the catalytic cycle A, the Ni(I)X

complex (**16**), which is derived from the Ni(III) complex (**17**) in the reductive elimination step, undergoes disproportionation into Ni(0) and Ni(II) followed by reduction of Ni(II).³⁰⁵ An alternative mechanism assumes the formation of biaryl in the course of metathesis of σ -arylnickel(II) complex **18** accompanied by regeneration of Ni(II) (the catalytic cycle B).^{164, 230}

The reactivity of the nickel(0) complex with bipy with respect to carbon monoxide and organic halides under conditions of competitive reactions was examined by electroanalytical methods, which enabled the authors to devise a new procedure for the synthesis of ketones.^{251, 252} Reduction of Ni(bipy)²⁺ in the presence of an excess of CO rapidly afforded the inactive Ni(0)(CO)₂(bipy) complex. It was noted that RX remained intact when electrolysis was carried out with bubbling of CO through the reaction mixture, *i.e.*, when the solution was saturated with CO. Organic halides were efficiently converted into ketones when the concentration of CO was limited and the possibility existed of generating a mixture of Ni(0)(CO)₂(bipy) and Ni(0)(bipy). Based on the kinetic data, two alternative pathways for the formation of acylnickel complex **19** were proposed.

The first pathway involves oxidative addition of RX to Ni(0)(CO)(bipy) (the rate constant k_1), whereas the second pathway includes oxidative addition of RX to Ni(0)(bipy) (the rate constant k_2) followed by addition of CO from the mixed complexes Ni(0)(CO)₂(bipy) or Ni(0)(CO)(bipy) or from CO present in the solution (the rate constant k_4). The reactions of highly reactive organic halides (for which $k_2 > k_3$), such as aryl iodides, follow the second pathway. In contrast, benzyl chlorides, aryl bromides and alkyl halides are moderately reactive with respect to Ni(0)(bipy) ($k_2 \ll k_3$) and their reactions follow the first pathway.

The preparative synthesis of ketones was carried out in the presence of catalytic amounts of Ni(bipy)²⁺ (5% with respect to RX).²⁵⁰ Under these conditions, the constants k_2 and k_3 have similar values and the two pathways for formation of the acylnickel complex **19** compete with each other.²²⁸

The Pd-PPh₃ system is characterised by two-electron reduction of the σ -arylpalladium intermediate⁷⁷ analogous to reduction of the corresponding intermediate in the Ni-PPh₃-ArX system studied earlier.^{48, 231} In the presence of the Pd-PPh₃ system, the biaryl is formed, apparently, through reductive elimination from diarylpalladium(II) followed by regeneration of Pd(0).

Many key steps of the mechanisms of reactions catalysed by Ni(0) complexes were suggested without sufficient substantiation. In some cases,³⁰¹ the catalytic waves in voltammograms were incorrectly interpreted and the calculated rates of particular steps were in error.

The reaction mechanism of coupling of organic halides under the action of the electrochemically generated Ni(0)(bipy) complexes was investigated.³⁰³ *o*-Bromotoluene was chosen as a model aryl halide. Its reaction with Ni(0)(bipy) afforded the stable σ -complex 2-MeC₆H₄Ni(II)Br(bipy) (**20**) through oxidative addition.

Reduction of the complex **20** gave rise to a new complex, *viz.*, (2-MeC₆H₄)₂Ni(0)Br(bipy) (**21**), which was isolated and characterised. The stability of arylnickel σ -complexes containing the methyl group in the ortho position of the aromatic nucleus is attributed to the steric factors, which hinder the rotation about the Ar-Ni σ -bond and the axial attack of the reagents on the nickel atom.^{53, 308} The complex **21** was reversibly reduced to radical-anionic intermediate **22**.

As the outer-sphere electron carrier, the complex **22** can reduce 2-bromotoluene to toluene, which was confirmed by chromatography. Slow decomposition of [(2-MeC₆H₄)₂NiBr(0)(bipy)]^{-•} (**22**) in solution to form a biphenyl derivative was a competitive reaction. This reductive elimination was induced by electron transfer.

The mechanism of Ni(0)(bipy)-catalysed cross-coupling of aryl and hetaryl halides was investigated taking into account the notion of the mechanism of homocoupling reported earlier.³⁰³ It was demonstrated that a Ni(I) complex serves as the active form in cross-coupling.

A particular complex can either serve as an efficient catalyst of homocoupling of organic halides or be poorly active or even inactive in cross-coupling of two different RX. In the general case, the efficiency of the catalyst depends on the following factors.

1. The possibility of rapid regeneration of the catalyst, *i.e.*, the number of catalytic cycles.

2. The reaction rate of reductive addition of the arylnickel intermediate to aryl halide must be higher than the rates of its competitive decomposition, protonation, *etc.*

3. The reaction rate of reductive elimination of the $\text{Ar}^1\text{Ar}^2\text{NiX}$ complex must be rather high for regeneration of the catalyst (conceivably, promoted by the electron transfer) to be successful.

The electrochemically synthesised stable σ -complex $2\text{-MeC}_6\text{H}_4\text{Ni(II)Br(bipy)}$ (**20**) proved to be a convenient model for studying the mechanism of formation of tertiary phosphines.^{304–306} Thus it was demonstrated that the cross-coupling product containing the P–C bond was generated in the substitution reaction

$n = 0-3$.

The competitive pathway through nickel phosphides is not realised. Phosphines are generated primarily according to the following sequence of reactions

Reductive elimination of the (triarylphosphine)nickel complex $\text{ArPh}_2\text{PNi(II)Cl(bipy)}$ (**23**) affords the target compounds.

$\text{X} = \text{Cl}, \text{Br}$.

In the initial steps of electrolysis, products are formed through the reactions of the catalytic cycle A, whereas the reactions of the catalytic cycle B become dominant as the catalyst is consumed.

The use of the complex **20** as a model compound made it possible to follow the pathway of formation of secondary alcohols in electroreductive coupling reactions of organic halides with aldehydes catalysed by the nickel complex with 2,2'-bipyridyl.¹⁶⁶ The yield of the product was found to be proportional to the concentration of $\text{NiBr}_2(\text{bipy})$ in solution. It was suggested that nickel ions were involved in the corresponding nickel alkoxide thus being removed from the catalytic cycle. In addition, it was shown that alcohol was not generated at a potential of Ni(II)/Ni(0) reduction (-1.2 V with respect to a saturated calomel electrode). Cross-coupling proceeded only at more cathodic potentials corresponding to further reduction of the σ -complex $2\text{-MeC}_6\text{H}_4\text{Ni(II)Br}$ (-1.35 V).

4. Mechanisms and kinetics of reactions in the presence of palladium catalytic systems

Palladium serves as the most versatile catalyst because of its high efficiency in reactions of aryl halides, vinyl halides (triflates) and

allyl derivatives with nucleophiles (cross-coupling, Stille coupling, Suzuki coupling, Heck reaction, Tsuji–Trost reaction) to form the C–C, C–H, C–N, C–O, C–P, C–S and C–C(O)–C bonds.³⁰⁹ In the presence of an electron source, the reactions of these substrates with electrophiles can give rise to the C–C, C–H and C–CO₂ bonds.^{310,311}

The efficiency of palladium is associated with the fact that zero-valent palladium is capable of activating C–X bonds ($\text{X} = \text{I},^{312,313} \text{Br},^{313} \text{Cl},^{313} \text{O}^{314}$) by oxidative addition yielding organopalladium(II) complexes, which are able to react with nucleophiles.^{315–318} The nucleophilic reaction affords a new organopalladium(II) complex from which the final product is generated in one or several steps.³⁰⁹

The recent data published in the literature (see the review³⁰⁸ and references cited therein) allowed revision of the commonly accepted mechanisms of palladium-catalysed reactions. It appeared that the reactivity of the low-coordinate 14-electron Pd(0)L_2 complex, which serves as an active species initiating the catalytic cycle, depends not only on the nature of the ligand at the Pd atom but also on the precursor of the Pd(0) complex. With the aim of revealing the reasons for this specificity, the structures and reactivities of different Pd(0) complexes prepared by oxidative addition were studied. It was found that the oxidative addition to aryl halides afforded various arylpalladium(II) complexes (neutral, anionic or cationic).³⁰⁹ For example, the oxidative addition of aryl triflates to $\text{Pd(0)(PPh}_3)_4$ gave rise to the cationic $\text{ArPd(II)(PPh}_3)_2^+$ complexes, whereas the neutral $\text{ArPd(II)Cl(PPh}_3)_2$ complexes were obtained in the presence of chloride ions. These complexes can be related by the dynamical equilibrium. The structures of arylpalladium(II) complexes depend substantially on the structure of the efficient Pd(0) complex involved in the oxidative addition and on the nature of the anions bound to Pd(0) . Earlier, it was assumed^{295,309,312,313} that two-electron reduction of $\text{PdCl}_2(\text{PPh}_3)_2$ afforded the $\text{Pd(0)(PPh}_3)_2$ complex. However, the ³¹P NMR spectrum of this complex after its exhaustive electrolysis has three signals²⁹⁵ belonging to three different anionic complexes (**24–26**), which are at dynamical equilibrium.

$\text{L} = \text{PPh}_3$.

The dimer **24** is the most reactive species. Hence, the $\text{Pd(0)(PPh}_3)_2$ complex does not exist in solution. When generated in the presence of halide ions, this complex gives anionic Pd(0) complexes. Oxidative addition proceeds more rapidly in the presence of cations (Li^+ or Zn^{2+}).³⁰⁹ The reactions of the cations with the chloride anions bound to palladium(0) produce ionic pairs and improve the reactivity of the complex.

In the reactions with poorly reactive aryl bromides, the oxidative addition of aryl bromide to zero-valent palladium complex **27** is conceivably the rate-limiting step.^{315–317} For more reactive aryl halides, transmetalation [the nucleophilic attack on trans-ArPdXL_2 (**28**)] was considered as the rate-limiting step.^{318,319} Reductive elimination from cis-ArPdNuL_2 (**29**) gen-

erated upon the rearrangement of the *trans*-ArPdNuL₂ complexes (**30**) can also be the rate-limiting step.^{318, 320, 321}

The results of the study³²² provided convincing evidence that reduction of PdCl₂(PPh₃)₂ yielded the anionic palladium(0) complex Pd(0)(PPh₃)₂Cl⁻ and that the oxidative addition afforded the anionic five-coordinate arylpalladium(II) complex ArPdXCl(PPh₃)₂⁻, which was slowly transformed into *trans*-ArPdX(PPh₃)₂.³²² Under these conditions, the Cl⁻ anion was the best nucleophile and simultaneously the best leaving group. Hence, this rapid equilibrium is the degenerate S_N1 nucleophilic substitution. Based on the above-mentioned results, the new catalytic cycle was suggested.

L = PPh₃.

The nucleophile attacks the intermediate five-coordinate neutral arylpalladium(II) complex (**31**) to give the anionic five-coordinate complex [ArPd(II)XNuL₂]⁻ (**32**) in which the aryl group and the nucleophile are arranged in such a way as to provide rapid reductive elimination. Hence, the *trans*-ArPdXL₂ complex (**28**) may be ignored as an intermediate of PdCl₂(PPh₃)₂-catalysed cross-coupling. In the absence of nucleophiles, the formation of *trans*-PhPdI(PPh₃)₂ was demonstrated to be accelerated by cations³²² because the equilibrium **31** ⇌ **33** was shifted toward the complex **31**. In the presence of a rather strong nucleophile, the reaction follows the above-described scheme. Evidently, its mechanism can be changed in the catalytic cycle depending on the reaction conditions.

The reaction of alkenes with aryl halides catalysed by palladium complexes was discovered by Heck in 1968 (see the review³²³). In the presence of chiral ligands, enantioselective reactions can be carried out.^{323, 324}

[Pd] = Pd(OAc)₂ + nL.

The Heck reaction is performed in the presence of a base and, generally, in DMF. Of the catalytic systems, which were empirically chosen for the Heck reaction, mixtures of Pd(OAc)₂ and phosphines exhibit the highest efficiency. The catalytic cycle proposed for the Heck reaction in the study³⁰⁹ differs from that postulated earlier^{315–317} by the reduction of Pd(II) to Pd(0) under the action of phosphine^{325–327} and by the presence of the anionic Pd(0)(PPh₃)₂(OAc)⁻ complexes (**34**) generated *in situ*. The latter undergo oxidative addition to aryl halides yielding the short-lived five-coordinate arylpalladium (II) complex (**35**). Then the ArPd(II)(OAc)(PPh₃)₂ complex (**36**) is subjected to the nucleophilic attack by alkene. Reductive elimination of complex **37** affords the reaction product and hydride complex **38** from which the catalyst **34** is regenerated under the action of triethylamine.

The results of the cited studies provide evidence that the anionic complexes generated from precursors of zero-valent palladium complexes play a key role and account for the empirical data concerning the characteristic features of catalytic palladium systems.^{328–333}

XIII. Conclusion

To summarise, many interesting synthetic applications combining electroreduction with transition metal complexes were reported in the last 15 years. Electrochemical equipment and procedures for electrosynthesis become increasingly simple due to which many electrochemical methods compete with conventional chemical methods. Presently, some reactions, which have been previously described as catalytic processes, for example, carboxylation of organic halides or homocoupling of alkyl halides, can be carried out by direct electroreductive coupling in the presence of a sacrificial anode. However, electrochemical transition metal catalysis is often more selective. In recent studies, considerable attention has been given to the synergism between transition metal atoms of the catalyst and metal ions obtained upon dissolution of the anode.

Abstract. The possibility of quantitative and semiquantitative prediction of sorbents' behaviour in various physicochemical systems is discussed. The attention is primarily devoted to the investigation of elementary processes at different surface areas of a sorbent grain. It is noted that the achieved level of the description of sorption processes based on semiquantitative estimations provides sufficient information to predict sorption kinetics and equilibrium *a posteriori*. The possibility of sorption by both a separate sorbent grain and grain agglomerates is analysed. The peculiarities of sorption processes on biosorbents are considered. Steps in the search for an optimum sorbent for a given system are described. The bibliography includes 242 references.

I. Introduction

In the present review, sorption implies the transfer of a substance onto the surface or into the bulk of solids or liquids from the environment without formation of a separate phase of the substance. Such a viewpoint corresponds to a common sorption definition (see Ref. 1, for instance), though it is much broader than the interpretation of the process as the uptake of a substance from the medium by a specially prepared sorbent only. In real systems, any solid or liquid phase of a substance is a sorbent for the other substances being present in the environment. The character of such a sorption differs from that on a specially prepared sorbent in terms of quantity only.

Received 2 July 2001

Uspekhi Khimii 71 (2) 159–179 (2002); translated by A F Nasonov

The sorption accompanies any processes occurring in heterogeneous systems, and so researchers from almost all laboratories over the world deal with it to a greater or lesser extent. Information about sorption is mainly an incidental result of laboratories' work, although a vast number of studies specially cover the study of sorption and sorbents every year. The scope of sorption phenomena under investigation has significantly been extended^{2–11} during the last decade. Methods for the detailed and express analysis of sorbents' and sorbates' state have gained ground, efficient methods for the mathematical simulation of sorption processes have become available. Yet the main thing is that the possibility of observing the behaviour of separate adsorbed atoms and molecules *in situ* has arisen. The first observations of adsorbed atoms were made as early as 1958.¹² However, such observations became widespread as late as the present time. As a result, a transition to a new stage of sorption investigation is possible, which can be called the stage of visualisation of sorbed molecules.

A change in direction of many sorption investigations can be considered as the first indication of the advent of the new stage. If previously one aimed to create a macrokinetic model of sorption first and then make conclusions about molecules' motion, at present, one aims to obtain experimental data about behaviour of separate molecules first and, based on this, interpret macrokinetic sorption characteristics.¹³

The second indication is the introduction of a new research methodology avoiding application of *a priori* conceptions of the character of elementary processes. This methodology includes successive alternate implementation of laboratory, computing and, further, pilot experiments, based on the data obtained from observations *in situ* on connection of molecular motion with sorption macrokinetics.¹⁴

The fact that there is a tendency to predict the behaviour of sorbing bodies quantitatively by solution of kinetic equations describing the state change of these bodies and the medium during sorption can be considered as the third indication. The prediction can be incorrect if the kinetic equations employed ignore a number of necessary factors. However, methods for composing and solving kinetic equations of sorption are presently being improved rapidly.

This review considers only new studies giving an idea of the recent achievements in the investigation of elementary processes

with an emphasis on the data obtained by visualisation of molecular motion. The matter of the synthesis and usage of sorbents to solve applied problems is not concerned here.

II. General pattern of sorption

Consider a system which consists of sorbing bodies and a liquid or gaseous environment containing a sorbate. The 'bodies' can be represented by single crystals; microcrystals' agglomerates accreted so that the medium can penetrate into pores remaining between them; aggregates of particles of the amorphous substance; globules of polymeric molecules; pieces of tissue from sorbing fibres, *etc.* The bodies can form dense layers, localise in certain parts of the system or move freely in its bulk.

The sorbate molecules (ions) migrate from the bulk of the medium to the surface of each body and transfer into its adsorption layer during sorption. The adsorbed molecules migrate in this layer, diffuse into the bulk of the body or desorb. Molecules in the adsorption layer interact with each other and with the sorbent atoms located in the near-surface monoatomic layer of the bodies (Fig. 1). If the interaction of sorbate molecules with each other is sufficiently strong, they assemble into two-dimensional clusters that can grow over the surface until they contact neighbouring clusters. The two-dimensional clusters do not form on weak interaction of absorbed molecules with each other, while the influence of surface atomic relief on adsorption increases.

Migrating over the surface, molecules stay on an adsorption centre for some time, then jump to an adjacent centre. Molecule's dwell times on vertices, edges or steps of single crystal faces can differ by factor of tens in this process. This difference is the case for molecules' dwell times on adsorption centres located at different crystal faces with different atomic relief. Therefore, faces with an unequal number of steps have different sorbing abilities. Each face is characterised by its own local adsorption factor and sorptive capacity.¹⁵

The difference in sorbing properties of different faces is levelled if a body represents an agglomerate of microcrystals with pores between them. In that case, the sorbate first gets into pores between the microcrystals and subsequently adsorbs on their surfaces and diffuses into the bulk. Microcrystals have usually various habits and differ in composition, defectiveness, faces' relief and mutual arrangement. Hence, agglomerate properties can vary significantly.¹⁶ Considerable distinctions in properties are observed for aggregates of amorphous particles, globules of polymeric molecules, *etc.*^{17, 18}

Taking into consideration the discussion above, one should operate with a distribution function of sorbing bodies (sorbent particles) over properties (state parameters) to describe sorption

Figure 1. Scheme of the arrangement of adsorbed molecules on the surface of the sorbent crystal.

(1) Single molecule, (2) two-dimensional cluster on a face, (3) cluster at the vertex, (4) molecule at the adsorption site on the step end, (5) molecule that passed to the near-surface monolayer, (6) molecule at the edge, (7) single molecule at the vertex.

$$\varphi(\{x_i\}, t) = \frac{\partial^p N}{\partial x_1 \cdots \partial x_i \cdots \partial x_p},$$

where x_i ($i = 1, 2, \dots, p$) is one of the state parameters of the particles at the moment t , p is the number of the state parameters considered, N is the number of particles in a volume unit of the system, which have values of state parameters not exceeding $\{x_i\}$.

The state of each body is being changed during sorption: they undergo Ostwald curing and structural ordering,^{19–21} the bodies dissolve partly and sorb extraneous agents.^{21, 22} If bodies are in a stirred medium, they are partly destroyed upon collisions with each other and with walls of the system (vessel) and decompose at high temperature.²³ Bearing this in mind, one should define the state of each body with external parameters, among which are the spatial coordinates of its centre of gravity $\{X_i\}$, the velocity of movement relative to the walls ($\vec{v}_k$) and the mass m_k , and with internal parameters, the habit, characteristics of surface relief, and the phase and elemental composition. Each sorbing body can be presented as an aggregate of several species of structural elements. The structural element implies an aggregate of similar sorbing centres, and the sorbing centre is a group of atoms in the bulk or on the surface of a body, which can hold one molecule of the sorbate. Hence,

$$\{x_i\} = X_i, \vec{v}_k, m_k, \{n_j\}, \{\theta_j\},$$

where n_j is the number of adsorbing centres in the same state, which is determined by the centre's location in the body, the composition and configuration of molecules forming it, θ_j is the fraction of centres of a given sort occupied by the sorbate.

A conservation condition for the number of sorbent particles and all species of adsorbing centres can be written in the form^{24–26} (taking into account the continuous change of their states)

$$-\frac{\partial \varphi}{\partial t} = \sum_{i=1}^p \frac{\partial}{\partial x_i} \left[G_i \varphi - \sum_{j=1}^p \frac{\partial}{\partial x_j} (D_{ij} \varphi) \right] + Q(x_i, \varphi), \quad (1)$$

where

$$G_i = \lim_{\Delta t \rightarrow 0} \frac{\langle \Delta x_i \rangle}{\Delta t}, \quad (2)$$

$$D_{ij} = \frac{1}{2} \lim_{\Delta t \rightarrow 0} \frac{\langle \Delta x_i \Delta x_j \rangle}{\Delta t}.$$

In these equations, G_i is the rate of the change of parameter x_i for particles with approximately the same properties, D_{ij} is the fluctuation factor of the rate G_i upon the influence of random changes of the parameter x_j ; $Q(x_i, \varphi)$ is the frequency of particles' dissociation upon collisions with each other, thermal decomposition or phase transitions in the particles' bulk; Δx_i is the increment of x_i over the interval Δt ; averaging is performed for an ensemble of particles.

Equation (1) reflects the concept that every particle can with a certain probability move from one state to another, which is consistent with the conservation laws. The probability of some transitions is negligibly small, but they must be taken into account within the framework of a general pattern of sorption.

Another conservation condition has the form

$$-\frac{\partial(\varepsilon c)}{\partial t} = \text{div}[\varepsilon(\vec{v}_L c - D \text{grad} c)] + \frac{dM}{dt}, \quad (3)$$

where M is the number of moles of a substance extracted by the sorbent from a volume unit of the medium,

$$M = \int_{-\infty}^{+\infty} q \varphi dx_i,$$

$$\varepsilon = 1 - \int_{-\infty}^{+\infty} V_k \varphi dx_i,$$

ε , c and $\vec{v}_L$ stand correspondingly for the local porosity, the concentration of the sorbate, and the velocity of medium movement in the interval where particles have distribution $\varphi(x_i, t)$, D is the molecular diffusion constant for the sorbate in the medium, q is the sorbate quantity in a particle with parameters $\{x_i\}$, V_k is the volume of the particle, integration is performed over all parameters x_i .

Variable q is usually represented as a sum of sorbate quantities in the near-surface layer of a body

$$q_s = \sum_j q_{sj}$$

and in its bulk

$$q_v = \sum_j q_{vj},$$

where index j belongs to the adsorption centres of the j th species. If a body is a single crystal, then the layer of adsorbed molecules (sometimes along with one or two additional monolayers of crystal atoms) is regarded as a near-surface one.²⁷

If a body is composed of accreted microcrystals, then one includes both those which have at least one facet contacting the medium and the pores between them in the near-surface layer.

For the near-surface layer which is homogeneous along a normal to the surface, we have

$$\frac{dq_s}{dt} = \sum_j [\omega_j a S c - (\lambda_j + v_j) q_{sj}], \quad (4)$$

$$\frac{dq_v}{dt} = \sum_j \lambda_j q_{sj},$$

where ω_j , v_j are correspondingly the probabilities of the sorbate intake from the medium into the near-surface monolayer through sorption centres of the j th species and its leaving from these centres for the medium in a time unit, a is the normalising factor (effective width of the layer, from which sorbate molecules can get into the near-surface layer as a result of unit translation), S is the surface area, λ_j is the probability of a sorbate molecule transfer from the adsorption centre of the near-surface layer into the bulk of the body in a time unit.

Terms in the second member of Eqn (4) can differ in the order of magnitude, which will reveal itself in the stepwise character of sorption.²⁸

If a body is homogeneous, a transition of a sorbate from the near-surface layer into the bulk can approximately be described as a convective transfer with the effective diffusion constant D_v upon ordered motion of sorbate particles relative gravity centre of the body with velocity $\vec{v}_v$. The velocity $\vec{v}_v$ rides on the shift of the near-surface boundary due to dissolution and swell (compression) of the body upon sorption. If a body is highly porous, $\vec{v}_v$ is associated with the flow in pores caused by external pressure or phase transitions in the body.²⁹

The change with time of the sorbate concentration c_v in each region of the body in which the position is fixed relative to the body's surface is described by the equation

$$-\frac{\partial c_v}{\partial t} = \text{div}(\vec{v}_v c_v - D_v \text{grad} c_v) + W(t), \quad (5)$$

where $W(t)$ is the rate of a sorbate transition into a motionless state in the bulk of the body.

In terms of D_v , $\vec{v}_v$, c_v quantities, we have

$$\sum_j \lambda_j q_{sj} = \lim_{r \rightarrow 0} \oint_S \left(v_v c_v - D_v \frac{\partial c_v}{\partial r} \right) dS, \quad (6)$$

where r stands for the distance from the near-surface layer to the point where the sorbate concentration is equal to c_v , v_v is the normal component for the velocity of a surface shift to the centre of the body over the area dS .

Quantities included in Eqns (1)–(6) are functions of medium properties $\{y_i\}$, from which the following are usually defined:

$$\{y_i\} = T, c_i, \vec{v}_L, H_i, \rho_L, \mu_L,$$

where c_i is the concentration of the system components in the medium, $\vec{v}_L$ is the medium velocity, H_i is the field strength for an external field, ρ_L and μ_L are the medium density and viscosity, respectively.

Equations (1)–(6) are applied in a simplified form. For example, one assumes that $D_{ij} = 0$ (considering sorption as a purely determinate process) and $\vec{v}_v = 0$. If one takes into account the fluctuations of bodies' properties, then one assumes that $D_{ij} = \text{const}$, and changes in state parameters $\{x_i\}$ are independent of each other.^{30–32} This makes the solution easier, but excludes 'cross effects' reflecting the mutual influence of the body's state parameters and the medium's ones^{33,34} from the consideration. The cross effects are indirectly taken into account by the introduction of functions $G_i(x_i, y_i)$ and $D_{ij}(x_i, y_i)$ reflecting all the elementary processes.

III. Sorption gas dynamics and hydrodynamics

Velocities $\vec{v}_k$ and $\vec{v}_L$ determine the bodies' positions in the system. The sorption systems are heterogeneous as a rule, therefore, the position of a body is its most important state parameter.

1. Motion of an individual body in the flow of the medium

Any component of the instantaneous velocity of a body's movement can be represented as a sum of the velocities of the ordered motion $G_i = v_{ki}$ and the random fluctuations characterised by coefficient $D_{ij} = D_{ki}$, i.e.

$$\frac{dZ_i}{dt} = v_{ki} + D_{ki} \xi_{ki}(t), \quad (7)$$

where Z_i is the coordinate of the gravity centre of the body, $\xi_{ki}(t)$ is a random function of time,

$$D_{ki} = D_B + v_{ki} p_{ki},$$

v_{ki} is a component of the velocity $\vec{v}_k$, averaged over time, D_B is the diffusion constant when $v_{ki} \rightarrow 0$, and p_{ki} is the characteristic scale for fluctuations of the body's position.

Velocity v_{ki} is formed from the velocities of the body sedimentation in the field of terrestrial gravity, the approach of the bodies under the action of molecular interaction forces, the bodies' shifts in electric and magnetic fields, the thermo- and diffusiophoresis, the drift caused by the flow of medium and the chemoreactive movement. These kinds of motion are investigated with regard the sorbing bodies of simple form with little internal porosity.^{35–38} The movement of the bodies of complex forms has not been adequately studied.

Quantity D_B is determined by the Brownian motion. Functions $\xi_{ki}(t)$ and $p_{ki}(x_i, y_i)$ have different shapes. Theoretical approaches to their determination have been developed for the movement of particles in homogeneous suspensions.^{38–41}

The experiment has repeatedly been confirming the propriety of using correlation (7). As a result of the observations of trajectories of particles with dimensions of 1–5 μm in a liquid medium, it was established in recent time that the motion of the particles is really the sum of the ordered sedimentation in the field of terrestrial gravity and the random fluctuations characterised by coefficient D_B invariable with time.^{42,43}

2. Liquid flow near the surface of a body

The motion of a liquid near the surface of a solid determines in many respects the mass transfer to the surface of the solid.^{35, 42–46} The motion of a liquid whose molecules' interaction with each other and with molecules of the body is described by the Lennard–Jones potential, has been calculated by the molecular dynamics method^{47, 48}

$$v(r') = 4\varepsilon_i \left[\left(\frac{\sigma_i}{r'} \right)^{12} - \left(\frac{\sigma_i}{r'} \right)^6 - \left(\frac{\sigma_i}{r_{0i}} \right)^{12} + \left(\frac{\sigma_i}{r_{0i}} \right)^6 \right], \quad (8)$$

where r' is the distance between the gravity centres of the molecules, ε_i , σ_i are correspondingly the energy parameter and the dimension parameters of the potential of the interaction of molecules of the liquid with each other ($i = 1$) and with molecules of the solid ($i = 2$), r_{0i} is the boundary of the potential action area.

It was assumed in calculations that the body's surface is molecular smooth, and the molecules of the liquid move chaotically with a resulting shift along the direction of the stationary flow.

The calculations showed that in a broad interval of flow velocities, when $\varepsilon_2/\varepsilon_1 > 0.6$ and $\sigma_1 = \sigma_2$, the liquid moves along the surface so as the liquid's molecules in the layer of width σ practically do not move along the flow, and so this layer is motionless. The molecules which are more remote from the body surface move in accordance with the velocity gradient of the shear flow. Provided that $\varepsilon_2/\varepsilon_1 \leq 0.6$ and $\sigma_2 < \sigma_1$, a jump in the flow velocity takes place at a distance σ from the surface, in other words, the liquid 'slides' over the body's surface. This result means that numerous considerations of the near-surface motion of the liquid that do not take into account the slide motion and the existence of a 'motionless' layer need refinement.

When motion velocity increases, 'vortexes' are produced near the surface, which, multiplying, form wave structures disintegrating into chaotic vortexes in velocity flows l .⁴⁹ The most important peculiarity of the liquid's motion relative to a body is the anisotropy of motion velocity that leads to an unequal accessibility of different surface areas to the sorbate.^{35, 50, 51} Figure 2 illustrates the results of the calculations of velocities of medium motion near a body of size d at different flow velocities $\vec{v}_L$.⁵² In this case, there are several critical values of the Reynolds numbers

$$Re = \frac{1.6d |\vec{v}_L|}{\mu_L},$$

Figure 2. Results of calculations for solution streams flowing around a single grain of the sorbent (a) or a group of grains fixed on the support (b) by numerical solution of the Navier–Stokes equation for $Re = 10$.⁵² (1) Frontal vortex, (2) grain, (3) rear vortex; y and x are the spatial coordinates, x_1 is the size of the body.

changing the character of the velocity distribution of medium motion near them. If $Re < 0.1$, the flux flows around a body without producing vortexes; a stationary 'rear' vortex is produced near each body in the interval of $0.1 < Re < 100$; provided that $Re > 100$, vortexes break periodically away from the body. [An analogous vortex forming occurs for a body being in an ascending current (the Karman track) and for other motion regimes.⁵³]

Vortexes magnify anisotropy of the sorbate concentration field around the body and, therefore, increase unequal accessibility of its surface areas. If a body is fixed, its surface is unequally accessible at any Re values; if not, the difference in the area accessibility is substantial upon the laminar medium motion. In the latter case, the body orients in the flow in such a way that the medium makes a minimum resistance to the motion. The body retains such orientation (if we neglect re-orientation shifts caused by the rotary diffusion).⁵⁴ Thereby, the body retains unequal accessibility of its surface. It chaotically migrates and rotates in a turbulent flow so that its surface becomes equally accessible on average.

The concept of accessibility of different surface areas of bodies is fundamental to describe the external-diffusion regime of sorption. The consideration of this regime requires the determination of velocities of bodies' motion and medium flows around the bodies with high accuracy.

3. Chemoreactive movement

Chemoreactive movement is added to the common forms of the body's motion if the surface of a body is sorptively heterogeneous, in other words, if there are active sites distributed irregularly over the surface.^{55–60} Such a movement was discovered, for example, for sorbing water vapour on Al_2O_3 grains. The bodies' movement was investigated in a release reactor of which a scheme is shown in Fig. 3. Sorbent grains are introduced into section 1 for sorbent preparation, then they are blown in pre-reactor 2. A portion of the grains gets over channel 3 into adsorber 4, where they fall freely down in a sorbate gas. Flying through the adsorber, the grains deflect from the vertical trajectory if their velocity has a horizontal component.

The bodies were of size $d = 30 \pm 5$ microns and represented agglomerates of microcrystals. They were one by one introduced into the reactor filled with a mixture of water vapour and air. The agglomerates fell freely down reaching the bottom in several seconds. After that, distribution functions of agglomerates were determined with respect to motion velocities in the horizontal direction over the falling time. The measurements demonstrated that the distribution of the bodies over the velocities was the same as in the case of a dry sorbent in dry air if the bodies were brought to an equilibrium with water vapour before introduction into the reactor. If the bodies contained a non-equilibrium amount of water and fell in a humid medium, the velocity of their motion was considerably higher (Fig. 4). There were areas with a high rate of adsorption of water on the bodies' surfaces, which was caused by the capillary condensation started to proceed there. These sites adsorbed water vapour at the same rate as the other sites did, but desorbed it to a lesser degree, since a portion of the adsorbed water

Figure 3. Scheme of the release reactor.⁵⁵

Figure 4. Distribution of Al_2O_3 grains according to the movement velocities in water vapour (from Refs 55 and 56). N is the fraction of grains that move in the horizontal direction at a rate lower than v . Partial vapour pressure, kPa: (1) 2.0, (2) 3.0.

was removed as a condensate. As a result, the momentum flux of recoil from desorbed water molecules over such sites was less than the momentum flux over the other areas, and this caused the bodies' movement.

4. Motion in an ensemble of sorbing bodies

The motion of bodies in an ensemble of them is affected by the superposition of fields of velocities in the environment around the bodies and by direct contacts of different bodies. Interaction in the vortex medium furthers the approach and coordinated movement of bodies. For instance, if a homogeneous suspension of glass balls of diameter $\sim 50 \mu\text{m}$ in a water–glycerol medium ($\mu_L = 5 \times 10^{-2} \text{ Pa s}$, $\varepsilon = 0.5\text{--}0.9$) is poured into an empty vessel, the coordinated motion of aggregates of hundreds of balls will take place in different directions against a background of slow sedimentation after the cessation of the motion caused by pouring.^{61,62} The bodies can stick together, undergo a plastic deformation and even be destroyed if the velocity of their approach is great.^{63–65}

The dimensions and shapes of the aggregates produced in ensembles of moving bodies depend on the flow velocity, the medium composition, the sizes, shapes, and relief of the bodies' surfaces. Any suspension flow is characterised by its own distribution function of aggregates over dimension and shape parameters. This function shifts to smaller dimensions of the aggregates on increasing the flow velocity and decreasing the concentration of particles in the flow. In contrast, the function shifts to large aggregates on increasing the concentration of the particles, and the aggregates can change their shapes from fractal ones to colloid crystals depending on the movement regime. All these results follow from the observations of moving suspensions with an optical or atomic force microscope *in situ*, and also from the observations of 'preserved' suspensions with an electronic microscope (see Refs 66–69, for example).

The force of resistance to the flow changes upon aggregation of particles and, therefore, so does the regime of their motion. One can make conclusions about the scale of such changes from data on effective viscosities μ_{ef} of sorbent–medium suspensions. Thus, the effective viscosity of a suspension of polystyrene spherical particles with sizes of $d = 70 \text{ nm}$ in an aqueous solution of gelatin (1 mass %) with particles' concentration $q_0 = 2.7 \times 10^{20} \text{ m}^{-3}$ and shearing strain $p_s = 0.1 \text{ Pa}$ in the shearing strain of the suspension is 500 times greater than in the absence of the particles.⁶⁷ The dependence $\mu_{\text{ef}}(p_s)$ shows that the suspension is a single 'loose' aggregate which moves as a whole at the indicated concentration q_0 and $p_s < 0.3 \text{ Pa}$. This aggregate dissociates into smaller fragments upon increasing p_s , and most particles move at $p_s > 30 \text{ Pa}$ almost independently from each other. The value of μ_{ef} keeps at the level of 10^8 Pa s in the shearing flow of SiO_2 particles in an ester ($T = 300 \text{ K}$, $d = 14 \text{ nm}$, $q_0 = 1.7 \times 10^{20} \text{ m}^{-3}$) at $p_s < 10 \text{ Pa}$,

while at $p_s \rightarrow 10 \text{ Pa}$ it undergoes a jump until $\sim 0.1 \text{ Pa s}$, at which it stays in the interval of $p_s = 10\text{--}100 \text{ Pa}$ (see Refs 67 and 68). This jump indicates a mechanically stimulated rearrangement of the suspension, resembling a first-order phase transition. The accessibility of the surface of bodies to a sorbate on such a rearrangement changes with a jump too.

The possibility of aggregation of bodies in an ensemble depends on the composition of the adsorption layer. The sorption can both accelerate and suppress the aggregation.^{67,70} This dependence becomes of particular significance in the presence of a sorbate whose molecules can adsorb on two close particles at once, producing 'molecular bridges' between them.⁷⁰ Such sorbates are employed to control the aggregation.

These facts highlight the change in the velocity of a stationary flow of a suspension due to a change in its effective viscosity caused by the adsorption-induced acceleration or the deceleration of aggregation. It seems that such 'adsorption-dependent destabilisation' of a flow is more intensive for concentrated suspensions of small particles.

Dissipative structures reflecting cooperative interactions of bodies arise in moving suspensions.^{71–73} For example, if a mixture of glass balls of diameter of $\sim 0.27 \text{ mm}$ and sucrose crystals of size $\sim 0.80 \text{ mm}$ is discharged to an empty vessel with the form of a rectangular parallelepiped with dimensions of $5 \times 200 \times 300 \text{ mm}$ along one of the long edges, a texture is formed of inclined layers of the glass balls alternating with layers of the sucrose crystals. The widths of the layers and their angles of inclination relative to the bottom of the vessel will depend on the form and subtle peculiarities of the surface relief of sucrose crystals.⁷³ Separation of the initial mixture of particles with the formation of a spatially dissipative structure occurs at a comparatively low input of mechanical energy in the system. The grounds of such separation could be explained after a considerable specification of conditions of particles' contacts in the flow.

The examples above indicate that the variety of hydrodynamic phenomena accompanying sorption increases nonlinearly with an increasing number of bodies in the system. Each of these phenomena can influence or depend on sorption under certain conditions as it takes place for the adsorption destabilisation of a suspension flow. The phenomena in question can be described by the motion equation of solids in the flow and by Navier–Stokes equation by detailed accounting of the forces affecting the sorbing bodies.

5. Prediction possibilities

A complete *a priori* prediction of the hydrodynamic behaviour of a system of sorbing bodies in the medium is still impossible in the general case (although it can be made with an acceptable accuracy under some sorption conditions^{74,75}). To make the complete prediction, one needs to have methods to calculate the parameters of Eqns (5)–(7) based on data on molecular motion as well as methods to solve the equations specified by accounting for the variety of hydrodynamic behaviour of an ensemble of bodies in the medium. However, no universal methods for such a calculation exist so far.

The methods of molecular dynamics allow prediction of properties of flows of bodies based on data on potentials of interatomic interactions. However, specification of the kind of interatomic potentials is necessary to apply these methods widely to describe flows of particles and the medium. Observations of adatoms of gold in the contact area of two crystals in a tunnelling microscope has shown that atoms' behaviour cannot be explained by using the Lennard–Jones potential [see Eqn (8) or other known potentials].^{76,77} Therefore, the contemporary conceptions of the potentials of interatomic interactions are approximate. Nevertheless, this does not exclude successful semi-empirical prediction of motion of particles and a medium in narrow intervals of sorption conditions, for instance, upon sedimentation in reactors of different shapes^{78,79} or in shearing flows of concentrated suspensions.⁶⁷ However, such calculations require expenses which are commensurable to those for experimental

work. Hence, one has to restrict oneself to the estimations obtained using various models, *e.g.* the cell model,^{80,81} if the geometry of a system is complex.

IV. Adsorption kinetics

It is convenient to present the velocity of sorption in the form

$$\frac{dM}{dt} = \sum_j \int_{-\infty}^{+\infty} (\omega_j a S c - v_j q_{sj}) \varphi dx_i, \quad (9)$$

where

$$v_j = \frac{kT}{h} \chi_j \exp\left(-\frac{E_j \beta_j}{kT}\right). \quad (10)$$

Here k and h are the Boltzmann and Planck's constants, respectively, χ_j is the frequency factor, E_j is the detachment energy of a sorbate molecule from an adsorption centre, β_j is the ratio of an excess of the activation energy of desorption to the detachment energy. Correlations (9) and (10) demonstrate that it is necessary to take adsorption centres of all sorts into account, although adsorption centres do not always differ by values of v_j as sharply as, for example, for the sorption of antimony by the faces (001) of a GaAs crystal. (Three forms of the antimony are discovered in this case with $E_j \beta_j$ values differing by almost 1 eV.⁸²) Nevertheless, three species of adsorbed molecules were also found upon an exploration⁸³ of the sorption of a 5,10,15,20-tetrakis[3,5-di-*tert*-butylphenyl]porphyrin complex of copper onto the surface of a gold crystal at 420 K from a gaseous environment by scanning tunnelling microscopy *in situ*. The central porphyrin part of the molecule was not observable in the microscope against a background of the substrate while the *tert*-butyl groups manifested themselves as bright spots. The conformations of molecules of all species could be judged from the location and the intensity of the spots. The kinetics of mutual conversions of the forms could be deduced from the change in the number of the images. It turned out that one form localised on the steps, the second one on the breaks of rectangular terraces, the third on the terraces. The *tert*-butylphenyl groups of the second form localised at an angle of 65° to the plane of the porphyrin part of the molecule, and those of the third form at an angle of 45°. Heating the substrate till 520 K over 12 min led to the disappearance of the second form from the substrate without any observable desorption of the third form. In this case, the energy of gold atoms on the breaks of the terraces and far from them differed by a few millielectronvolts only.⁸⁴ However, such a difference causes a noticeably distinct behaviour of the second and the third forms of the mentioned molecules.

Therefore, an estimation of the role of the centres of all sorts is necessary in any case. Yet it is hard to measure the values of $\omega_j = \omega_j(\bar{v}_L, D)$ for the centres of all sorts, and an *a priori* calculation of these quantities is only possible after a specification of the form of interaction potential.

Specification can be achieved by a search for quantities which are independent of the form of the potential. Such invariants will restrict the possibility of changes in the potential. One of these invariants can be connected with the diffusion constant, D , of the sorbate in the medium and, hence, with ω_j .^{85,86} Indeed, D along with self-diffusion constant D_s characterises thermal motion of molecules

$$D = \gamma(y_i) D_s,$$

where $\gamma(y_i)$ is a function that does not depend on D_s explicitly. The coefficient D_s calculated by the method of molecular dynamics for 1.6×10^4 atoms at different forms of a potential of molecules' interactions can be presented in the following form for a dense monoatomic liquid:^{85,86}

$$D_s = \frac{B \exp(S_0)}{g_0 r_0^4},$$

where B is a coefficient that does not depend on the form of a potential, S_0 is the difference between the entropy of a liquid and a gas of the same composition, and g_0 is the value of radial distribution function of liquid's atoms at the point of the first maximum of the distribution for which the interatomic distance is equal to r_0 .

This correlation indicates the possibility of searching a correlation of coefficient D and, therefore, frequency ω_j with the potential of the interaction of medium molecules through the invariants resembling coefficient B .

Functions $q_{sj} = q_{sj}(y_i, t)$ and $\chi_j = \chi_j(y_i, t)$ reflect the kinetics of all the elementary surface processes leading to sorbate migration between centres of different sorts, chemical transformations of adsorbed molecules and a sorption change of the state of the surface. Rates of elementary processes usually differ significantly, and so functions q_{sj} change with time stepwise. Some steps can be slow in this case.

For instance, a three-step process proceeds during adsorption of oct-1-ene by crystals of aluminosilicate zeolite H-ZSM-5 at 290 K over $10^2 - 2 \times 10^5$ s. A transfer of the oct-1-ene into the adlayer occurs at the first step, the adsorbed oct-1-ene reacts with hydroxy groups of the zeolite, producing carbenium ions at the second step, and at the third step, the carbenium ions undergo a rearrangement

These steps were identified by observing ¹³C NMR spectra *in situ* (in magnetic fields up to 18 T with the sample spinning at a 2–5 kHz frequency at a magic angle, using cross-polarisation). It follows from the intensities of lines in the NMR spectrum at 14.3 ppm which correspond to the terminal groups ¹³CH₃ and are given in the study⁸⁷ that the third step is determined by the relation

$$\left(\frac{q_{sj}}{q_{0sj}}\right) = 0.31 + 0.69 \exp(-\sqrt{\omega_q t}),$$

where q_{0sj} and q_{sj} stand for the amount of cabenium ions in the adlayer at the beginning of the third step and at moment t , correspondingly, $\omega_q = 4.5 \times 10^{-5} \text{ s}^{-1}$ stands for the characteristic frequency of rearrangements.

The three-step nature of the process in question can be explained by the fact that centres of three sorts exist on the surface of the zeolite that differ in composition and mutual location of atoms. The centres of the first sort have a much larger value of ω_j than the other centres, thus, sorption mainly starts with transition of molecules onto these centres. At the second step, the molecules move to the centres of the second sort, which have hydroxy groups reacting with the oct-1-ene. The carbenium ions rearrange in the slow third step, remaining on the centres of the first sort or moving to the centres of the third sort.

The surface processes are so varied that one has to consider their peculiarities at a qualitative level. This has been done below using the sorption by single crystals as an illustration and the level of details of description achieved to date is also presented.

1. Accommodation of sorbate molecules

Different sorbing centres have different probabilities of accommodation, so that

$$\omega_j = \alpha_j \frac{S_j}{S} \xi_j, \quad (11)$$

where α_j is the local factor of accommodation at centres of the j th sort, S_j is the area of the body's surface containing these centres, S is the total area of the body's surface, ξ_j is the probability that a sorbate molecule contacts the surface in a unit time as a result of transition of molecules from a gas or a liquid.

A sorbate molecule is promoted to an excited state upon collision with the surface.⁸⁸ The promotion proceeds in a period τ_0

in the order of 10 fs. It is accompanied by deformation of electron density and activation of vibrational motion of both the molecule and the body in the contact point and sometimes by a configuration change of the molecule.^{89,90} Then the relaxation of the electronic excitement of the molecule proceeds in 10–100 fs, and the relaxation of the vibrations in $\tau_s = 1–10$ ps. Vibrations of atoms of a body can accidentally synchronise giving a molecule sufficient momentum to break it away from the surface. Molecules dwell at the surface of a body for different time τ owing to the accidental character of the synchronisation process and

$$\alpha_j = 1 - \int_0^{\tau_s} \bar{\varphi}_j(\tau) d\tau,$$

where $\bar{\varphi}_j(\tau)$ is the density of the distribution of molecules occupying centres of the j th sort over τ .

Function $\bar{\varphi}_j(\tau)$ implicitly characterises the dependence of τ on molecule's velocity and orientation at the beginning of the contact. An elastic reflection of the molecules from the surface is observed and $\alpha_j \rightarrow 0$, if all the molecules have the velocity and the orientation at which function $\bar{\varphi}_j(\tau)$ is localised in the region of $\tau \approx \tau_0 < \tau_s$. If most molecules have $\tau \approx \tau_s$, then almost complete accommodation takes place and $\alpha_j \rightarrow 1$. Coefficient α_j can be determined for the adsorption of a rarefied gas on a homogeneous surface with high accuracy based on the data on a molecular beam reflected from a body. When considering sorption from a liquid medium, one has to content oneself with rough values of α_j . It is of some use to determine the function $\bar{\varphi}_j(\tau)$ characterising the first step of sorption by methods of femtochemistry.⁹¹

2. Migration on the surface

The sorbate molecules fixed on the surface jump from one adsorbing centre to another. The frequency of the long distance jumps which are accompanied by re-orientation of the molecules increases with increasing temperature. It is established by observation with the tunnelling microscope that the jumps of acetylene molecules on faces (111) of a lead crystal occur with a change of orientation at $T > 70$ K, and all six orientations are realised.⁹²

Superficial mobility of molecules depends on their configuration.^{93,94} Molecules can move from one centre to another due to conformational changes. Increasing the number and the strength of bonds of a molecule with an adsorbing centre weakens the tendency to such changes. This results, for instance, in sorption of a dendritic DNA on a graphite crystal, where DNA molecules can bind to the crystal through numerous guanidine bridges.⁹⁵ In the case of adsorption of 1,4-bis[β -(2-pyridyl)vinyl]benzene on face (100) of a silicon crystal, the sorbate molecules that are sufficiently strongly bound to silicon atoms migrate with low velocity so that their motion cannot be detected even on a sufficiently long observation in a tunnelling microscope. Molecules of this sorbate exist as four conformational species on the surface, however, motion with an observable velocity is not a specific feature for any of them. The migration proceeds much faster if it occurs at the face (100) of silicon where every near-surface silicon atom is blocked by a hydrogen atom.⁹⁶

Cooperative effects reveal themselves upon increasing the fraction θ_j of the surface occupied by the sorbate. The mobility gets smaller with the rise of θ_j if the attraction dominates in lateral interaction of sorbate molecules. The mobility increases first and then diminishes if the repulsion dominates.⁹⁷

Thus, the detailed description of molecules' motion over the surface requires that possible changes in their configuration upon jumping from one centre to another and their collective motions be taken into account.

Migration is quantitatively characterised by quantity D_j

$$D_j = \frac{kT}{h} \sum_i \chi_{ji} \exp \left[-\frac{(E_j - E_i)\beta_{ji}}{kT} \right], \quad (12)$$

where χ_{ji} is the frequency function for the transition of a molecule from the j th sorbing centre to the i th one, E_j and E_i are the energies of interaction of the molecule with the crystal on the j th and the i th sorbing centres, respectively, and β_{ji} is the correction function reflecting cooperative effects of activation.

It is assumed while calculating D_j that the shifts to the nearest vacant sorbing centre dominate among jumps of each molecule, and $E_j = n_j E_{j2}$ and $E_i = n_i E_{i2}$, where n_j and n_i are the number of the crystal's atoms in the nearest neighbourhood of the molecules on the j th and the i th sorbing centres, correspondingly, E_{j2} and E_{i2} are the average energies of the pairwise interaction of the molecules with the nearest neighbours.⁹⁸ It is also taken that $\beta_{ji} = 1$ and $\chi_{ji} = \text{const}$.⁹⁹ The calculation of E_j and χ_{ji} is attempted based on 'the first principles', but it is a success for the simple sorbates only.¹⁰⁰ It was possible to calculate these quantities for the migration of H_2 on the face (001) of a nickel crystal with a 10% discrepancy with the experimental data. However, one failed to explain the absence of an observable isotope effect in the superficial diffusion of hydrogen at low temperatures.¹⁰¹

If the energy of adsorption is sufficiently high, the near-surface layers of a crystal get disordered, molecules come to the surface from these layers, which leads to acceleration of superficial migration.¹⁰² One can get an idea of the scale of such acceleration based on the data on superficial migration of atoms during the adsorption of hydrogen and benzene on the crystals of iron and nickel. For instance, the hydrogenation of the adsorbed benzene is accompanied by a 10^4 – 10^5 -fold increase in the intensity of the superficial migration of iron and nickel atoms.

3. Formation of superficial clusters

Adsorbed molecules can join into clusters that grow up to the size of a whole face for large θ_j .^{103–105} The rate of the formation of the clusters increases quickly if the concentration of the sorbate in the medium achieves a critical value, which is substantially different in the case of the weak and strong bonds of the sorbate molecules with the crystal and with each other.

For example, the clusters can be observed in the sorption of hexadecyltrimethylammonium bromide by the surface of clinoptilolite crystals only at the concentration for which $\theta_j \rightarrow 0.25$. In the case of a lesser extent of the adlayer filling, the sorbate exists on the surface as separate molecules, which are observed as oblong knobs of 0.4 nm height in the atomic force microscope.¹⁰⁶ The heights of some knobs double at $\theta_j \rightarrow 0.25$, which can be interpreted as the formation of clusters.

The probability of their formation and growing up depends on the extent of conformity between the structures of the sorbate molecules and the near-surface monolayer of the body. In the case of the adsorption of simple molecules, this probability is higher for the sorbates whose crystal lattices have planes with an arrangement of atoms close to that in the near-surface monolayer of the body. The formation of clusters is facilitated in the case of the adsorption of complex molecules at certain configuration of the sorbate molecules.^{107,108} This is confirmed by the observation of the adsorption of oligosaccharide polymers on the face (100) of a graphite crystal from an aqueous solution in atomic force microscopy *in situ*.^{109,110} The molecule of the polymer, representing a polyvinylamide backbone with numerous dextran and hexanoyl branches, adsorbs so that its backbone is stretched along the surface. The hexanoyl chains contact the carbon atoms of graphite, and the dextran ones are directed outwards.

The orientation of molecules on the surface of a body depends on the ratio between the numbers of the hexanoyl chains and the dextran ones (q_m). The majority of molecules orients along one of two crystallographic directions of the crystal lattice at $q_m = 1/5$. In the case of a sufficiently high concentration of oligosaccharides in solution, a number of molecules successively attach to each molecule fixed on a free surface area, producing a two-dimensional cluster. The clusters spread out over the surface until they merge into a continuous monolayer of 0.7–1.2 nm width. The

orientation of molecules is arbitrary, and no two-dimensional clusters form at $q_m = 1$.

The two-dimensional clusters, enlarging, can turn into three-dimensional formations. For example, the clusters turn with time into epitaxial incrustations¹¹¹ upon adsorption of cadmium arachidonate $\text{Cd}[\text{CH}_3(\text{CH}_2)_{12}\text{CO}_2]_2$ from the vapour on the face (001) of a crystal of KCl.

Clusters can change their compositions and structures,^{112, 113} and successive monolayers of an adsorbed substance can be deposited over the produced ones¹¹⁴ at certain values of θ_j . Such a phenomenon was *in situ* observed in tunnelling and atomic force microscopies. The conclusions from the observations were confirmed by calculations using the methods of molecular dynamics.^{115, 116} In particular, it was established that multi-layer crystals arise, which can have different structures varying in the mutual orientation of molecules, upon the adsorption of H_2O on the face (100) of a crystal of MgO at $\theta_j \rightarrow 1$. One of the orientations dominates at $T < 200$ K, and the other one at higher temperatures.¹¹⁶ Structural transitions occur in the monolayer of lead on the face (100) of a copper crystal: the first one at $\theta_j \rightarrow 0.38$, the second, at $\theta_j \rightarrow 0.5$, and the third, at $\theta_j \rightarrow 0.6$. In this case, each of the structures undergoes 'two-dimensional' fusion¹¹⁷ on heating. The structural rearrangement of monolayers is accompanied by significant acceleration of adsorption over the adsorption of dodecanethiol and butanethiol on the face (111) of a gold crystal at 298 K.¹¹⁸

4. Two-dimensional solid solutions

Adsorbed atoms can be incorporated into near-surface interstices or occupy vacancies in the near-surface monolayer of crystal atoms, *i.e.* form two-dimensional interstitial solid solutions or substitutional ones.²⁷ This could be observed directly in the case of the sorption of InAs from its vapour on the faces (100) of a crystal of InP by atomic force microscopy.¹¹⁹ The sorption of vanadium oxide on the face (001) of a crystal of TiO_2 was detected by emergence of an additional component in the band $\text{V}2P_{3/2}$ of the photoelectronic spectrum at 623 K. (This band is caused by the transition of a vanadium atom into the lattice of TiO_2 .¹²⁰) It was possible not only to detect solid solutions, but also to determine their structures by means of X-ray diffraction analysis while studying the sorption of bismuth from its vapour on the face (001) of a copper crystal.¹²¹ It turned out that the bismuth atoms substitute the copper ones at small θ_j chaotically, and each bismuth atom transferred into the near-surface monolayer is shifted towards the vapour with respect to the copper atoms by 0.06 nm. The sorbed atoms of bismuth form a two-dimensional structure of the type $C(2 \times 2)$ at $\theta_j \rightarrow 0.35$, their radius is equal to 0.163 nm, which is considerably smaller than that of a bismuth atom in the bulk of its crystal (0.182 nm). Thus, the structure of two-dimensional solutions can change with increasing θ_j .

The mobility of molecules in the near-surface monolayer of the crystal is far lower than that in the adlayer.^{27, 122} Hence, the sorbate transfers to the adlayer at the first stage rather rapidly and forms a two-dimensional solid solution at the second stage slowly. The third stage arises after large periods of sorption, which consists of the transfer of the sorbate to the bulk of the sorbent.

5. Change in the properties of a sorbing body

All properties $\{x_i\}$ of the body change during sorption, and the scale of these changes is nonlinearly connected with the body's state and can be great in a narrow interval of sorption conditions. For example, a change in velocity of the body's motion under the influence of sorption becomes detectable if the body can freely move in the sorbed gas for a long time and the sorption is localised on a portion of the body's surface.⁶⁰ The change in temperature is considerable if the medium is characterised by the low thermal conductivity and the great heat of sorption. Sorptive changes in electroconductivity, magnetic, thermophysical and optical properties can turn out to be substantial for porous bodies, which is employed in sensor devices.¹²³

There can exist both positive and negative feedback between the sorption and the properties of a sorbing body. For instance, the feedback of the quantity of an adsorbed substance q with the velocity of chemoreactive movement $\vec{v}_k$ is positive since increasing $\vec{v}_k$ leads to growth in ω_j , and growth in ω_j facilitates the acceleration of the movement.⁵⁵ The feedback between q and T is usually negative since increasing the temperature leads to growth in the rate of desorption dominating over increasing α_j .¹²⁴

The character of the feedback between q and parameters $\{x_i\}$ is of great significance in the development of sensors.^{123, 124}

6. The possibilities of computational experiment

The direct observations of the motion of adsorbed molecules encouraged the application of the methods of molecular dynamics and Monte Carlo for the simulation of elementary processes of sorption under the quantum-chemical interpretation of interatomic interactions or the usage of atom-atomic potentials of the type (8). Simultaneously, the computational methods of chemical kinetics based on differential equations of the type (4) become more widely applied in investigating the sorption processes. As a result, separate elementary processes of sorption could approximately be described for some of the simplest molecules, based on the 'first principles'. It has become clear at the same time that some elementary processes can *a priori* be excluded from the consideration only in the case if we limit ourselves to a narrow set of conditions when modelling sorption. A complete kinetic model of sorption which is applicable for a broad set of conditions must take into account all the details of elementary superficial processes. However, the complexity of the model does not allow making computational experiments *in corpore*.

V. Sorbate migration into the bulk of a body

1. Diffusion into the bulk of crystals

Sorbate migration into the bulk of a body is usually characterised by coefficient D_v reflecting all elementary processes leading to the translation movement of sorbate molecules (ions).¹²⁵ Function $W(t)$ can be excluded from Eqn (5) while the sorption at the crystals is described. Coefficient D_v can be considered as a tensor taking into account the anisotropy of crystals' properties in this case. To solve Eqn (5), one should reflect the polyhedral form of crystals and the possibility of their formation with different faces in edge conditions. One also has to take into consideration the fact that the sorbent crystals have 'biographical' structural defects affecting D_v . Besides, the crystals acquire new defects during sorption that are distributed irregularly in their bulk. For example, the defects are localised at the periphery of each crystal for the crystals of K_2SO_4 or NaCl being in an intensely agitated aqueous solution. In this case, the sorbate accumulates significantly faster at the defect areas than at the other ones.^{63, 64} The values in the order of D_v of $10^{-25} \text{ m}^2 \text{ s}^{-1}$ are a characteristic of the perfect crystals of BaSO_4 with an ion-covalent bond of atoms at 300 K; for the sorption of SrSO_4 , in particular, by the crystals of BaSO_4 with high defectiveness of growing, $D_v = 10^{-16} \text{ m}^2 \text{ s}^{-1}$ (see Refs 126 and 127).

The molecules of sodium ethylenediaminetetraacetate and trinitrophenol diffuse into interlayer spaces of the crystals of hydrotalcite $\text{Mg}_3[\text{Al}(\text{OH})_8][\text{CO}_3]_{0.5}$, which have a lamellar structure with the ion-covalent bond of atoms within the layers and the van der Waals one between the layers, with the diffusion constant $D_v \approx 10^{-16} \text{ m}^2 \text{ s}^{-1}$ at 300 K.¹²⁸

Diffusion rate is especially high for sorption by the organic analogues of zeolites. The crystals of organic zeolites consist of groups of covalently bound atoms producing ring-shaped formations (blocks).¹²⁹ Closing each other up, the blocks produce channels whose width can reach several nanometres. Atoms of the crystal occupy not less than half volume of a channel, the rest space is occupied by molecular pores. Sorbate molecules can migrate along the channels with high values of D_v , which, for example, takes place in the crystals of $\text{C}_{72}\text{H}_{98}\text{N}_{12}\text{O}_{40}\text{Zn}_3$ with a

trigonal lattice (the diameter of a channel ~ 1 nm, the channels orient along axis c).¹³⁰ The channels accounting for 47% of the crystals' volume are filled with water molecules in an aqueous medium. Migration, for instance, of Na^+ ions over the channels proceeds at 300 K with the diffusion constant $D_v \approx 10^{-14} \text{ m}^2 \text{ s}^{-1}$, which was estimated from the data on the rate of ion exchange between the crystals and the solution.

One can judge elementary acts of sorbate migration in molecular crystals by the results of calculations made by the molecular dynamics method.^{131–133} The calculations showed a sharp change in the frequency of jumps of sorbate molecules over the channel and the number of molecules in the channel at small changes of the potential of interactions with atoms of the channel's 'walls'. The motions of sorbate molecules lead to significant fluctuations of the number of the molecules localised per length unit of the channel. The scale of such fluctuations also depends on the potential of interaction of molecules with atoms of the channel's walls. Thus, if a carbon nanotube with a diameter of 0.81 nm and a length of $l = 1.34$ nm is placed in a medium containing 10^3 molecules of H_2O , these molecules get into the nanotube and move inside it. If the interaction potential is of the type (8) and $\varepsilon_i = 0.549 \text{ kJ mol}^{-1}$ and $\sigma_i = 0.328 \text{ nm}$, the molecules of H_2O , having passed through the channel, get out of the tube with the frequency $\omega_e = 2 \times 10^{10} \text{ s}^{-1}$ (see Ref. 133), which corresponds to the coefficient D_v of the order $l^2 \omega_e = 3.6 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$. Frequency ω_e proves to be lower by several times if $\varepsilon_i = 0.272 \text{ kJ mol}^{-1}$ and $\sigma_i = 0.341 \text{ nm}$. In the channel of the nanotube, H_2O molecules form a monomolecular chain of 2–7 molecules arranged with higher order than in the medium. The molecules of the chain approach each other to a distance at which the hydrogen bond forms much more frequently, existing in such a state for $\tau_e = 5.6 \text{ ps}$ ($\tau_e = 1.0 \text{ ps}$ in water) on average. In addition, the H_2O molecules possess not only the axial mobility but also the radial one (less frequently). In this case, the average number of molecules in a chain varies from 4 to 6 when $\varepsilon_i = 0.549 \text{ kJ mol}^{-1}$ and $\sigma_i = 0.328 \text{ nm}$, and from 1 to 2 for $\varepsilon_i = 0.272 \text{ kJ mol}^{-1}$ and $\sigma_i = 0.341 \text{ nm}$. This example demonstrates the possibility of a sufficiently detailed description of the movement of a sorbate in channels when data on interaction potential of atoms are available.

2. Migration into polymeric grains

Coefficient D_v of the polymeric sorbents has as a rule a complex dependence on their structure, values of θ_j , T , composition of the medium and preliminary swelling of the grains, and this dependence is difficult to predict. For example, $D_v = 3.4 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at pH = 1.0 and $D_v = 1.65 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at pH = 2.0 for the sorption of CdCl_2 by grains of formaldehyde resin from an aqueous solution at 300 K.¹³⁴ The value of D_v grows with increasing θ_j first, and then diminishes during the sorption of LiCl by a resin containing sulfo groups.¹³⁵ Sorbents based on dendrimers and hydrogels have been obtained in recent years. Their coefficient D_v is almost the same as in the medium surrounding a body.¹³⁶ Two models are usually employed to describe sorption by polymeric grains.^{137, 138} The first model implies that all grains are quasi-homogeneous and isotropic, *i.e.*, characterised by a unique value of D_v when $\bar{v}_v = 0$ and $W(t) = 0$; the second one assumes a grain to be a population of small polymeric globules jointed by rare molecular bridges. In this model, a grain is characterised by the constants of the sorbate diffusion over the interglobule bulk (the channels) and from the interglobule space into the bulk of a globule. In this case, function $W(t)$ is determined as a total diffusion flux through surfaces of all the globules being in a volume unit, into their bulk. Both models reproduce basic features of the process only approximately.

The calculations³⁰ have shown that if sorbing bodies are homogeneous and have a Gaussian size distribution, then the time $\tau_{0.9}$ for which they capture 90% of an equilibrium quantity of the sorbate, is

$$\tau_{0.9} = \frac{(0.182 + 0.255\sigma_0 - 0.190\sigma_0^2)\bar{l}^2}{D_v}, \quad (13)$$

where σ_0 is the ratio of the root-mean-square deviation of distribution of particles' sizes to their average size $\bar{l}$. The deviation varies in the interval from 0 to 0.45.

For the lognormal distribution over sizes, we have

$$\tau_{0.9} = \frac{(0.1943 + 0.057\sigma_0)\bar{l}^2}{D_v}. \quad (14)$$

Correlations (13) and (14) characterise reversible sorption (Fig. 5). It follows from these correlations that it takes sufficiently great time to achieve the sorption equilibrium. One has to restrict oneself to the adsorption if it is required to perform the sorption sufficiently rapidly, *i.e.* within the time $t_k \ll t_{0.9}$. At small t_k , the adsorption behaves as a process with a slight deviation from the reversibility, which is related to the transfer of the sorbate into the bulk of grains. Such a deviation is often revealed in practice.^{139, 140}

Figure 5. Results of the numerical experiment on sorption by a sorbent with different size distributions of grains.³⁰ Normal distribution at $\sigma_0 = 0$ (1), 0.1 (2), 0.2 (3), 0.3 (4). $\tau = \pi^2 D_v t / \bar{l}^2$ is dimensionless time, M_∞ is the equilibrium amount of the sorbate in grains.

3. Sorption by the agglomerates of microparticles

If a body consists of accreted microparticles, coefficient D_v depends on their shape, size, and the character of their packing.^{141, 142} The relief of the surface of the particles also affects the value of D_v , which was demonstrated with the use of the molecular dynamics method, employing the diffusion of N_2 and isobutane in a cylindrical space between microparticles of 0.4–1.4 nm size at 200–800 K as an illustration.¹⁴³ In addition, the value of D_v can be reduced by infilling the space by the sorbate.

All this suggests that the description of sorption by the agglomerates with the use of coefficient D_v provides little information and shows a necessity to work Eqn (5) out, taking into account the structures of the agglomerates.

Bodies consisting of multiple accrete macroparticles retaining free spaces (macropores) between them are widespread among the agglomerates. In this case, each of the macroparticles is a combination of microparticles divided by the micropores provided that

$$V_k \gg \bar{V}_{k1} \gg \bar{V}_{k2}, \quad (15)$$

where $\bar{V}_{k1}$ and $\bar{V}_{k2}$ are the average volumes of macro- and micro-particles, respectively.

If the state of every particle in an agglomerate is characterised by its size l_i and the volume (V_{pi}) of pores surrounding it, then one can write condition (15) in a continuum approximation

$$c_v = \varepsilon_1 c_{v1} + \int_0^\infty \int_0^\infty m_1 \varphi(l_1, V_{p1}) dl_1 dV_{p1}, \quad (16)$$

$$m_1 = \int_{V_{k1}} \left[\varepsilon_2 c_{v2} + \int_0^\infty \int_0^\infty m_2 \varphi(l_2, V_{p2}) dl_2 dV_{p2} \right] dV,$$

where ε_1 is the total volume of macropores in a volume unit of a body, c_{v1} and c_{v2} are the bulk concentrations of the sorbate in macro- and micropores, m_1 and m_2 are the quantities of the sorbate in a macroparticle in state $\{l_1, V_{p1}\}$ and in a microparticle in state $\{l_2, V_{p2}\}$, ε_2 is the porosity of the microparticles, $\varphi(l_1, V_{p1})$ and $\varphi(l_2, V_{p2})$ are the distribution functions of the particles over their states.

Concentrations c_{vi} ($i = 1, 2$) change during sorption according to a transfer equation, which is analogous with relation (5)

$$\frac{\partial c_{vi}}{\partial t} = \text{div} [\varepsilon_i (D_i \text{grad } c_{vi} - \vec{v}_i c_{vi})] - \int_0^\infty \int_0^\infty \beta_i l_i^2 J_i \varphi(l_i, V_{pi}) dl_i dV_{pi}, \quad (17)$$

where D_i is the diffusion constant of the sorbate diffusion into the bulk of pores, $\vec{v}_i$ is the velocity of ordered motion of a liquid or a gas filling the pores, β_i is the shape factor for the particles, J_i is the sorbate flux from the pores through the surface of a particle.

In relations (16) and (17),

$$m_2 = \beta_2 l_2^2 \int_0^t (J_2 + J_{2s}) dt, \quad (18a)$$

$$J_1 = (\omega_{l1} c_{v1} - v_{l1} c_{a1}) a (1 - \varepsilon_2) + D_2 \varepsilon_2 \left(\frac{\partial c_{v2}}{\partial r} \right)_{l_1}, \quad (18b)$$

$$J_2 = (\omega_{l1} c_{v2} - v_{l1} c_{a2}) a, \quad (18c)$$

where J_{2s} is the intensity of the sorbate transfer into the bulk of microparticles, ω_i and v_{li} are the specific frequencies of the adsorption and desorption, respectively, c_{a1} and c_{a2} are the concentrations of the sorbate in the adsorption layer of microparticles localised on the surface of a macroparticle and in its bulk, $(\partial c_{v2}/\partial r)_{l_1}$ is the normal component of the gradient of sorbate concentration in pores near the surface of the macroparticle, and r is the distance from the centre of the macroparticle to the point where the sorbate concentration is equal to c_{v2} , a is the effective width of the adsorption layer.

Equations (17)–(18a–c) contain only those parameters which can be measured by experiment. Thus, $\varphi(l_i, V_{pi})$, ε_i and β_i can be determined by sectioning the bodies and measuring the sizes of particles and pores on the cuts with the use of optical and electronic microscopy. Frequencies ω_{li} and v_{li} can be measured upon adsorption by the microparticles which are not assembled into agglomerates. The intensity of sorbate transfer J_{2s} can be determined by the use of single crystals with the same molecular relief that the microparticles have. In addition, quantity J_{2s} can be measured directly observing the motion of adsorbed molecules in atomic force or tunnelling microscopy. The motion of individual molecules and atoms could repeatedly be observed in the tunnelling microscopy.^{144, 145} To tell the truth, their trajectories were determined by the electric field of the microscope to a great extent, but there are all reasons to consider that the influence of the field on the surface movement of molecules can be taken into account.

It is not difficult to determine the coefficient D_1 , while to determine D_2 is more complicated. This can be made by the conductometric method in the case where the size of sorbate molecules is not more than 0.5 nm. The current strength fluctuates at limits that are proportional to D_2 if two conductive microparticles of size 5–10 nm are approached so as to retain a space of 1–10 nm width between them, and the space is filled up with a sorbate solution containing NaCl, and the current is passed through the electric circuit formed.^{146, 147} The volume of the solution determining the electrical resistance of the circuit is very

low at the given size of microparticles. Thus, if even one molecule of the sorbate gets into the space, this results in a jump of the electrical conductivity and, therefore, the fluctuation of the current. It appears that a way to conductometric determination of the rate of sorbate accumulation in the bulk and on the walls of an individual micropore was suggested by Bezrukov *et al.*^{146, 147} Therefore, a way to the direct measurements of ω_{li} , v_{li} and coefficient D_2 for molecules of an arbitrary size is also open. It was shown¹⁴⁸ that the value of D_2 amounts to $(1-2) \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ at 300 K for the diffusion of polyethylene glycol of a mass of 200–10³ a.u. over a channel filled with an aqueous solution of NaCl in the lipid–peptide membrane with a channel radius of 1 nm. This value is lower than that in a free solution by an order of magnitude. This fact confirms the necessity to describe the sorption with Eqns (16)–(18a–b) taking into account possible differences in the values of D , D_1 , and D_2 .

The use of the functions contained in the indicated equations is complicated by the fact that some of them are unknown even for the most common sorbents. Simplifying assumptions are made for these functions, hence, the description of the sorption kinetics becomes semi-quantitative even if it agrees with the experimental data. The following assumptions are the most widespread:

$$\vec{v}_i = 0,$$

$$\varphi(l_i, V_{pi}) = \text{const} \cdot \varphi(V_{pi}) \delta(\bar{l}_i),$$

$$D_i \neq D_i(\bar{l}_i),$$

$$\beta_i \neq \beta_i(\bar{l}_i),$$

$$\omega_{li} = v_{li} = 0,$$

$$c_{a2} = B_a c_{v2},$$

where $\varphi(V_{pi})$ is the distribution function of pores over the bulk, $\delta(\bar{l}_i)$ is the Dirac function, and B_a is the equilibrium coefficient of adsorption. As can be seen, the number of *a priori* assumptions is large. Nevertheless, one has to employ most of them even in the most consistent descriptions.^{149, 150}

4. Possibilities of prediction

Quantum-chemical methods and correlative empirical dependences give an opportunity to estimate coefficient D , *a priori* with a relatively small error for the bodies whose structure is near-equilibrium. But the acting sorbents are non-equilibrium as a rule. The structures of their particles depend on the ‘biography’ of the sorbent. Therefore, the problem of the estimation becomes complicated, and one has to solve it experimentally. Some peculiarities of the migration into the bulk of a body can be predicted by the molecular dynamics method. However, the predicting possibilities of this method are restricted to nanoparticles and small periods of sorption.

VI. Equilibrium sorption

The equilibrium sorption is usually characterised by a distribution coefficient

$$K = (V_f c N_A)^{-1} \sum_j \int_{-\infty}^{+\infty} \theta_j n_j \varphi(x_f, t) dx_f,$$

where V_f is the volume of the sorbing phase, and N_A is the Avogadro constant.

Approaching the equilibrium, function $\varphi(x_f, t)$ converges, and parameters θ_j and n_j become independent from $\{x_j\}$, the number of all the centres except the most stable diminishes, and coefficient K tends to a value

$$K_e = \theta_1 N_1 (c N_A)^{-1} = K_0 \exp\left(-\frac{\Delta F}{kT}\right), \quad (19)$$

where θ_1 is the fraction of the most stable filled centres, N_1 is the number of such centres in a volume unit of the sorbent phase, K_0 is

the ratio between the coefficients of thermodynamic activity of the sorbent in the sorbent phase and in the medium, ΔF is the standard change in the free energy of the sorbent during sorption.

A dynamical quasi-equilibrium is achieved between the centres sorbing most rapidly and the medium in the system upon completion of the first step if the sorption proceeds in several steps and adsorption centres of only one type are involved in the process at each step. Many examples of adsorptive quasi-equilibrium on the 'external' surfaces of bodies or on the surfaces of micro-particles in the bulk of bodies with a successive transition to the equilibrium in the bulk have been described.

Equilibrium coefficients K_e are determined for several thousands of systems (though often without proof of their equilibrium). K_0 and ΔF are calculated for many systems by the methods of statistical mechanics and molecular dynamics. The matter connected with the differentiation of the partial and total equilibrium and the identification of centres that are responsible for the quasi-equilibria still remains unclear.

Functions $\Delta F(\theta_j, y_i)$ and $K_0(\theta_j, y_i)$ that can be converted into isotherms of sorption are diverse.^{151–154} The Langmuir, Freundlich, Frumkin, Totte, Dubinin–Serpinsky isotherms describing a variety of experimental results are applicable in a narrow range of conditions, as a rule. They are special cases of more complex isotherms. Systems are widespread both with a small entropy contribution in ΔF and with a great one.^{155, 156} The great contribution of entropy has been found upon investigation of the sorption of bovine serum albumin and ovalbumin on a series of ion-exchangers.¹⁵⁵ The sorption process of these proteins is endothermic, and coefficients K_e are great.

1. The variety of equilibrium forms

Sorptive centres of several sorts can retain commensurable quantities of a sorbate at the quasi-equilibrium. For instance, it has been proved by the methods of scanning electronic and tunnelling microscopy and also by the diffraction of slow electrons that CO molecules are retained on centres of two sorts on the face (111) of a platinum crystal. In this case, the adsorption on both centres is commensurable if θ_j is high, and the adsorption on one of them dominates if θ_j is low.¹⁵⁷

Four forms of the sorbate, being present in commensurable quantities and manifesting themselves in its magnetic properties, were discovered in the study of the adsorption of Cu(II) salts at TiO₂ single crystals.¹⁵⁸ Three forms of the sorbate with the adsorption heat of 101.6, 112.4, 178.1 kJ mol⁻¹, respectively, were observed upon the adsorption of NH₃ on crystals of CdSO₄·0.66H₂O.²³ The presence of these forms can be interpreted as a result of sorbate localisation at the centres of different type. The presence of several adsorptive forms can be related to the different orientation of molecules on the surface in the case of the adsorption of complex molecules.

The forms whose orientations are favourable to produce the largest number of bonds with the surface dominate over the others. This was demonstrated by Diaz *et al.*,¹⁵⁹ for instance, who compared the sorption ability of the SiO₂ surface covered with an alkyl monolayer with respect to eight polyacrylate specimens (sorbates) to which different number of dodecyl radicals was grafted.

2. The role of complex formation

Coefficient K_e increases if centres arise on the surface and in the bulk of a body which act according to the laws of complex formation: the more stable sorptive complexes, the greater values of K_e .¹⁶⁰ This was cogently shown for the sorption of actinides by sorbents containing organophosphorus substances¹⁶¹ and for the sorbent intended to remove bilirubin from the blood plasma.¹⁶² This fact makes possible the use of ideas of the chemistry of coordination compounds for the interpretation of the sorption, taking into account the fact that the stability of complexes in the bulk or on the surface of the body differs from that in the environment.

Sorbents with centres forming complexes can be selective. For example, the selective adsorption of a lanthanum salt at tetracycline centres is observed if tetracycline hydrochloride is sorbed at zirconium phosphate, and then the resulting sorbent is introduced into a solution of lanthanum, cerium, barium, and thorium salts.¹⁶³ If functional groups based on ethylenediamine or diethylenetriamine are grafted to a matrix of mesoporous molecular sieve MCM-41, a possibility will arise to extract Co²⁺ from its aqueous solution selectively due to the formation of amino complexes in the bulk of grains.¹⁵⁹ The selectivity of sorption depends on the difference in the stability of sorptive complexes. The mechanisms of the processes leading to different stability are similar to those determining the selectivities of homogeneous reactions.

3. Deformation of the electronic structure over adsorption

The electronic structures of sorbate molecules change upon sorption of any type, and the changes can be as substantial as for the formation of chemical compounds.^{140–145} Thus, the deformation of electronic structure of potassium atoms upon the adsorption of the potassium vapour on the face (110) of a GaP crystal is so strong that lines 2p(P) and 3d(Ga) in X-ray electron spectra shift by 1.6 eV at $\theta_j \rightarrow 0.1$.¹⁶⁴

Changes of electronic structure over adsorption affect all atoms of an adsorbed molecule to a greater or lesser extent. However, they are mainly localised on one or several atoms. As a result, some atoms can have great mobility, remaining within a molecule or breaking away from it. In particular, the change of electronic structure affects several atoms connecting the sorbate to the surface over the adsorption of the H₈Si₈O₁₂ clusters at the face (100) of a silicon crystal. The evidence for this is the coincidence of a measured reflection IR spectrum and a calculated one (by the method of density functional).¹⁶⁵

Calculations have shown that an H₂O molecule changes its configuration insignificantly upon its transition on regular adsorption centres localised at the faces (100) of NaCl crystals. But if a molecule of H₂O gets near an anion vacancy in the near-surface monolayer of the crystal, its electronic density changes so much that the molecule dissociates.¹⁶⁶

It has also been shown by the method of density functional that the electronic structure of a thiophene molecule changes to the configuration η^5 upon the sorption on the (010) surface of a crystal of MoS₂.¹⁶⁷ A cleavage of the C–S bond and the hydrogenation take place in this case. It was established by the same method that a hydrogen bond is formed between hydrogen atoms of the molecule of H₂O and any oxygen atoms of the near-surface monolayer (mostly the oxygen atoms of the vanadyl group) upon the adsorption of H₂O molecules on the face (010) of a perfect crystal of V₂O₅. If the sorbent is non-stoichiometric, the electronic structures of H₂O molecules are deformed so that some of adsorbed molecules dissociate.¹⁶⁸ It was shown by the X-ray electron spectroscopy and temperature-programmed desorption that the adsorption of H₂S on the face (100) of a crystal of FeS₂ at 500 K is accompanied by a strong deformation of electron shells of atoms and dissociation of the sorbate molecules. The hydrogen comes further into the bulk of the crystal and sulfur localises near the vacancies of the near-surface monolayer.¹⁵² The molecules of water adsorbed at the surface containing silicon and aluminium oxygen tetrahedra, are deformed to a lesser extent so that one of the protons of H₂O has an increased mobility without the dissociation of the molecules. Such a conclusion was made as a result of the calculation of configuration and normal vibrations of the molecule of water by the Hartree–Fock method.¹⁶⁹

The changes of the electronic structure of the sorbate are specific for the centres of a different sort. This manifests itself, for instance, in the adsorption of CO on the surface of crystals with the composition Cs₂HPW₁₂O₄₈, where the electronic structure of CO changes in different ways depending on whether it is localised on the atoms of cesium or hydrogen. Adsorption bands with maxima at 2165 and 2145 cm⁻¹ emerge in the IR spectra of the sorbate.

The intensity of the former band increases if some of the cesium atoms are replaced with hydrogen ones by changing the conditions of the synthesis of the sorbent.¹⁷⁰

The examples considered above indicate the variety of the forms of adsorption-induced deformation of the electronic structures of sorbate molecules. Information of such deformation is accumulated rapidly, though the general regularities of the response of an electronic structure to the adsorption are not defined concretely.¹⁵⁴

It is worth noting that the observation of $R^1-NHCONH-R^2-NHCONH-R^1$ molecules adsorbed on the graphite by scanning tunnelling microscopy revealed that the contrast in the images of carbamide groups is the same if the hydrocarbon chain contains an odd number of carbon atoms. If the number of the atoms is even, the contrast of these images is different.¹⁷¹ The contrast of the images of the carbonyl group is directly connected with its electronic structure. Therefore, one can conclude that the electronic structure of the sorbate's molecule becomes unsymmetrical with an even number of carbon atoms in the chain. This observation indicates the possibility of a direct microscopic study of some of the peculiarities of the intramolecular distribution of the electronic densities of adsorbed molecules.

4. The relationship between the distribution coefficient and the properties of a body to be sorbed

Experiments have demonstrated that the following condition holds true for some series of sorbates¹⁷²

$$K_e = K_1 \left(\frac{P_s}{P} \right)^m + K_2, \quad (20)$$

where K_1 , K_2 , and m are the characteristic parameters of a series of sorbates, P_s and P are the solubilities (for the sorption from a liquid) or the pressures of saturated vapour (for the sorption from a gas) of the sorbent and sorbate, respectively.

As a rule, $m > 1$ and $K_2 = 0$ in the investigated series. Nevertheless, $m = 1$ and $K_2 > 0$, for instance, for the sorption of α -naphthylamine by the crystals of naphthalene from solutions in various solvents.¹⁷³ Series for which $m = -1$ have appeared in the literature, but this can only be explained by the absence of the equilibrium in the system.¹⁷² Correlation (20) reflects a general tendency for substances with low solubility or pressure of saturated vapour to be sorbed predominantly. The results of quantum-chemical calculations do not conflict with such a tendency, though they show that one can expect a monotonic dependence of coefficient K_e on quantities P_s and P in the case of similar properties of sorbed substances only.^{174, 175}

Numerous facts indicate the importance of the similarity of sorbate's and sorbent's properties. For example, substances whose crystal lattice is similar to the sorbent one for at least one crystallographic direction adsorb better owing to favourable conditions created for the formation and growth of two-dimensional clusters in this case.¹⁷⁶

Inert gases dissolved in water are sorbed by the crystal solvate $SO_2 \cdot 6H_2O$ at $T = 268$ K. In this case, coefficient K_e is monotonically reduced by increasing the difference between the molecular mass of SO_2 and the atomic mass of a gas — Ar, Kr, Xe, and Rn (Fig. 6).¹⁷⁷

A number of admixtures are sorbed by the crystals of germanium and silicon from a melt at the melting point. The smaller the difference in sublimation enthalpy between the sorbed substance and the sorbent, the greater K_e for the formation of solid solutions.¹⁷⁸

Summarising the results of studies,^{172–178} one should note the absence of a determining property, which would uniquely characterise coefficient K_e , among the investigated properties of the sorbate and sorbent. Ratio P_s/P can be considered as such a property as a first approximation. This is indicated by the prevalence of correlation (20). However, the connection of K_e with this correlation is not always unequivocal.

Figure 6. Coefficients of equilibrium sorption by the $SO_2 \cdot 6H_2O$ crystals at 268 K of radon (1), xenon (2), krypton (3) and argon (4) vs. the sorbate atomic mass;¹⁷⁷

m_0 is the atomic mass /a.u.; K_3 is co-crystallisation coefficient.

5. Ways of prediction

The qualitative prediction of function $K_e(y_i, \theta_j)$ is possible based on the regularities of equilibrium sorption mentioned above. The semi-quantitative prediction is performed by analogy, using correlation dependences that are similar to Eqn (20). Another way is to employ approximate calculations of functions $\Delta F(y_i, \theta_j)$ and $K_0(y_i, \theta_j)$ with subsequent application of correlations of the type (19). The calculations are performed with the use of statistical thermodynamics and quantum chemistry.^{179–181}

One aims to determine the values ΔF regarding the resulting interaction of the sorbate and sorbent as a sum of interactions of different types, by considering their influence to be additive.¹⁸² For example, the dispersion, dipole, and pairwise electronic interactions are discriminated while describing sorption.¹⁸³ However, more precise information about the interaction potentials of atoms is required in such a method.

Especially great attention is paid to the calculation of function $K_e(y_i, \theta_j)$ for porous grains.^{184–187} Pores of different diameters and configurations have different sorptive capacities usually. In other words, each of them represents a specific sorbing centre. The assumption that pores and adsorbing centres are distributed over the free energy of sorption continuously could be used without a loss of accuracy if there exist many pores.^{188–190}

The calculations of sorption are carried out for many systems. Nevertheless, some of them deviate from the experimental results sharply.¹⁹¹ Other calculations allowed quantitative explanation of the existing experimental results only, but the new data could be explained at the qualitative level only.

VII. Accompanying phenomena

1. Cosorption on the surface and in the bulk

If a sorbent takes several sorbates up simultaneously, the sorption of each sorbate is rarely additive.^{15, 192} Sorbate particles usually not simply compete with each other for sorbing centres, but also change the sorptive capacity of these centres with respect to their competitors.¹⁹³ If these changes are great, one can speak about negative or positive cosorption of substances. Each cosorption type can be divided into a kinetic one, at which competitors speed up or slow down the sorption of each other, and an equilibrium one, at which they affect not only the rate, but also significantly change the value of K_e .

The range of the kinetic cosorptive effect can be considerable. For example, the rate of the formation of mixed adsorptive layers of $Cu(ClO_4)_2$ and KBr on the faces (100) of a copper crystal in the aqueous medium is so much greater than the rate of the formation of the pure layers of $Cu(ClO_4)_2$ that the adsorption proceeds from the kinetic regime to the diffusion one under the influence of KBr.¹⁹⁴ A powerful negative kinetic effect has been revealed⁹⁰ for

the cosorption of H_2 and Cl_2 on the rearranged (2×1) (001) surface of silicon at 300–1500 K, the initial temperature being 300 K. The molecules of HCl are produced in such an excited state upon the reaction of chlorine and hydrogen adatoms that most of them desorb in picoseconds after the beginning of the contact of the adatoms. The probability of desorption increases to 0.18 in a temperature range from 300 to 1000 K. After that, the probability remains constant, which indicates complex forms of functions $\chi_j(T)$ and $\beta_j(T)$ in formula (10). These functions point out the possibility of cleaning the surface from molecules of one sorbate by the molecules of another one owing to the interaction of the sorbates.

The equilibrium cosorption takes place in different systems. Thus, the sorption of strontium from a hydrothermal solution by Montmorillonite increases by 30% if the Sr^{2+} ions sorb together with Li^+ ions.¹⁹⁵ An analogous positive cosorption of these elements by soils was described by Chitra *et al.*¹⁹⁶

The adsorption of carbon monoxide on SiO_2 from a gaseous phase is negligible under ordinary conditions if the sorbent is not doped with a silver salt. The adsorption is enhanced if the sorbent contains silver. A band at 2169 cm^{-1} has appeared in the IR spectra of the system, which is a characteristic of the Ag–CO bond.¹⁹⁷

The adsorption of polyvinylpyrrolidone on the crystals of $\alpha\text{-Al}_2O_3$ from an aqueous solution at pH 5–7 is enhanced in the presence of polyacrylic acid.¹⁹⁸ The adsorbed molecules of the acid form hydrogen bonds with the polyvinylpyrrolidone. This results in a positive coadsorption. Such a bond changes the conformations of sorbate molecules, which was proved for samples with a spin label by ESR.

At the same time, the biomass of pine bark sorbs substances from a mixture of aqueous solutions of cadmium, copper, and nickel worse than from an individual solution of each salt.¹⁹⁹ A sterilised soil suppresses the sorption of phenanthrene if the soil contains pyrene in a concentration of $5 \times 10^{-4}\text{ mol g}^{-1}$. The pyrene affects the rate of adsorption slightly, but increases the rate of desorption sharply.²⁰⁰

Some sorbents interact with the sorbates, producing microcrystals. This is the case, for instance, for the sorption of $AgNO_3$ from an aqueous solution by copper hexacyanoferrate $Cu_2[Fe(CN)_6]$ (see Ref. 201) or for the sorption of SeO_2 from a gaseous flow by calcium hydroxide.²⁰² An abnormally strong sorption is observed in the latter case in the interval 770–970 K owing to the formation of $CaSeO_4$.

Thus, cosorption is a consequence of chemical reactions between the sorbates in the bulk or on the surface of sorbing bodies where the conditions of reactions of molecules differ from those in the medium surrounding the bodies. Investigating sorption, one can obtain information about the specificity of the interactions of the sorbate molecules in a force field of the sorbent molecules, which is necessary for a directed search for sorbents.

2. Specific features of biosorbents

Biosorbents consist of plant biomass or microbial cells immobilised on supports.^{203–210} Formally, the behaviour of biosorbent grains or separate cells does not differ from that of particles of inorganic sorbents. For example, Madrid *et al.*²⁰⁵ properly predicted the variation of the concentrations of a number of sorbates in a well-stirred reactor containing algae as sorbents. It was found that biosorbents can be characterised by particular diffusion coefficients D_v and by sorption isotherms and that the surface and volume sorption processes can be simulated in the usual way. If the sorbent is a set of identical cells, the membrane, cytoplasm and internal cell organelles should be regarded as its structural units.^{209,210} Sorbate accumulation by cell membrane can be treated as adsorption, while migration of the sorbate inside the cell, as bulk sorption.

Many biosorbents demonstrate selective sorption by separate structural units.²¹¹ For example, redwood bark and moss cells accumulate cadmium, copper and nickel ions from aqueous

solutions by membranes almost without involvement of the cytoplasm.²¹²

The sorption capacities of cells depend on their physiological state but, generally, their 'preferences' do not change.^{213–215} For example, the sorption sequence $Au^{3+} > Cu^{2+} > Ag^+$ always holds for the *Chlorella vulgaris* cells in aqueous solutions. Inside the cells, the sorbed substance undergoes chemical transformations and passes to the colloidal state.

In a study of sorption of various compounds by seeds of legume crops, it was found⁵² that the coefficient K decreases along the series of chromates, molybdates and tungstates: $Cr(VI) > W(V) > Mo(VI)$.

However, no general relationship between the nature of the biosorbent and the D_v or K values has been found so far. Elucidation of this relationship is complicated by strong influence of sorbates on one another^{204,208} and by changes in the sorbate state in the cells or in the physiological state of the cells themselves. The cells or destroyed biomass are to be regarded as 'black boxes'; thus, prediction of sorption becomes groundless, although formally it can provide some results.²⁰⁷

3. Structural memory of sorbents

If sorbate molecules are introduced into particles of a sorbent during its synthesis so that the former can escape to the medium, 'imprints' of the sorbate molecules can be retained in the sorbent structure and may play a role of specific sorption sites for this particular sorbate. The sorbent can 'remember' that the sorbate was present in the system during its synthesis. The 'memory' of inorganic sorbents was discovered long ago.²¹⁶ It has now been proved that organic polymeric sorbents also possess 'memory'; this fact is used successfully for selective and complete removal of side products of organic syntheses.²¹⁷

4. The influence of external fields on sorbents

Recent studies showed that the sensitivity of a sorbent with respect to an electric field can be increased to a practically significant level without deterioration of their sorption properties. For example, sorbents based on titanium phosphate have been developed the sorption capacity of which changes dramatically upon application of an electric field; these sorbents absorb a number of metal ions from aqueous solutions by the ion exchange mechanism and, after that, desorption can be accomplished by merely changing the potential sign.²¹⁸ The application of an electric field accelerates sorbate diffusion inside the bulk of grains.²¹⁹ The field also influences the surface mobilities of atoms; this has been demonstrated, for example, by direct observation in a tunnelling microscope of the behaviour of potassium and sodium atoms on the (100) surface of aluminium.²²⁰

Multiphase sorbents sensitive to acoustic fields have been prepared.^{221,222} The sorbent grains consist of a heat-sensitive polymeric hydrogel, which can undergo a structural phase transition at some temperature T_0 . Microcrystals of a poorly soluble substance with high density are introduced in the polymeric matrix, together with particles of a sorption-active phase. When $T < T_0$, the polymer molecules form a three-dimensional network with large cells, which ensures fast diffusion of the sorbate into the grains.

If the acoustic power is relatively low, the properties of the polymer network do not change on direct exposure to an acoustic field but the microcrystals inside the matrix are heated. They absorb most of the field energy and function as 'internal heaters' for the grains. If the grain temperature increases to T_0 , the polymer molecules are compacted to form denser stacks and the grain permeability decreases abruptly. Once the sound has been switched off and the grain has been cooled to $T < T_0$, the permeability increases again. Thus, the grain responds to acoustic treatment by a triggered transition from one permeability level to another.

New magnetite-containing sorbents have also been prepared. Particles of such a sorbent can move on exposure to a magnetic field.²²³

5. Phase antagonism and synergism in multiphase sorbents

If a sorbent grain contains several phases, they can compete for a sorbate. In this respect, sorbent phases are antagonists. The points where particles of different phases contact with one another can give rise to specific sorption sites with increased K_e values. If this effect predominates over the antagonistic effect, these phases exhibit a synergistic effect.^{224–227} For example, synergism was attained in the synthesis of a fibrous sorbent based on cellulose and zinc or copper ferrocyanide.²²⁴ This sorbent proved to be especially efficient for extraction of cesium salts from aqueous solutions and was recommended for deactivation of natural and technological waters contaminated by ^{137}Cs .

A sorbent based on CuO and $\gamma\text{-Al}_2\text{O}_3$ phases with a large internal surface area of microparticles and a high porosity of grains having a narrow size distribution was prepared by the sol–gel procedure.²²⁷ At 790 K, this sorbent showed a sorptive capacity toward sulfur dioxide of no less than 22.5 mass %, which is much greater than the values observed for other sorbents.

6. The molecular electrical conductivity of adsorbed species

If an adsorbed molecule (a two-dimensional cluster) occurs in a flow of electrons coming to the surface from the bulk, then, with some probability, the electrons adhere to a molecule, remain in contact with it for some period, and then pass to the substrate. Thus, the adsorbed molecule influences the electron flow. This influence can be described by attributing to each molecule an individual electrical conductivity. This parameter can be found by observing separate adsorbed molecules through a tunnelling microscope or by measuring the electric current between electrodes bridged by individual adsorbed molecules. For example, by applying a dilute solution of DNA (the length of the molecule is 10.4 nm) onto two platinum nanoelectrodes located at a distance of up to 8 nm using a special application procedure, one can ensure that one end of the molecule is adsorbed to the cathode and the other, to the anode, thus forming a ‘bridge’ across the gap between the nanoelectrodes.²²⁸ When the electrodes have been dried in a nitrogen flow and the voltage $U = 1\text{--}5\text{ V}$ has been applied, the cathode–DNA–anode circuit carries the current

$$I(U) = \sigma(U - U_\omega), \quad U > U_\omega, \quad (21a)$$

$$I(U) = 0, \quad U < U_\omega, \quad (21b)$$

where $\sigma = 5.3 \times 10^{-10} \Omega^{-1}$ is the molecular electrical conductivity at voltages higher than the threshold value $U_\omega = 1\text{ V}$.²²⁹

The electrical conductivity σ of the DNA molecule is due to tunnelling of electrons through the contact surface between the molecule and the anode and to their one-dimensional diffusion along the molecule.^{228, 230} However, it is not clear yet what are the contributions of these processes to the DNA conductivity.

Relations (21a) and (21b) reflect the threshold character of the molecular electrical conductivity of DNA. Apparently, this is a typical character of the electrical conductivity of molecules of different nature, as follows from the data on the interaction of adsorbed molecules with a flow of tunnelling electrons.

If a molecule is located on the surface of the substrate electrode, a second electrode represented by a spike with a ‘monoatomic’ tip is placed at a distance $R = 1\text{--}5\text{ nm}$, and the voltage U is applied to the spike, then current would flow from the spike to the substrate.^{231–233} The current intensity can be expressed by the relation

$$I(U) = \omega \rho_0 \varepsilon(\rho_0, U, R) [U \eta_1 + (U - U_\omega) \eta_2],$$

where ω is the probability for an electron to pass from the spike to the molecule per unit time, ρ_0 is the electron density of the substrate under the spike before application of the field, $\varepsilon(\rho_0, U, R)$ is the function characterising transition of electrons from the molecule to the substrate, U_ω is the voltage corresponding to the change in the η_1 and η_2 values from $\eta_1 = 1$ and $\eta_2 = 0$ for $U < U_\omega$ to $\eta_1 = 0$ and $\eta_2 = 1$ for $U > U_\omega$.

The threshold voltages U_ω were found for C_2H_2 , CO , benzene and pyridine molecules adsorbed on the surface of copper crystals.^{233–235}

The ω value usually depends slightly on ρ_0 and in the $kT < Ue < \varphi_e$ range (e and φ_e are the charge and the work function of an electron), it can be described by the exponent

$$\omega = \exp\left(-\frac{U_0}{U}\right),$$

where $U_0 = 10\text{--}100\text{ V}$ is the characteristic voltage of the tunnelling field emission.²³⁶ The $\varepsilon(\rho_0, U, R)$ function has a discontinuity at $U = U_\omega$. For $U > U_\omega$, it has several maxima; the $\{U_i\}$ values corresponding to these maxima comply with the condition

$$eU_i \rightarrow \omega_{hi} h,$$

where ω_{hi} is the frequency of a vibrational transition of the molecule or of the substrate below the molecule. This implies that the tunnelling electrons provide a resonance stimulation of vibrations of atoms in the adsorbed molecule, and the vibrations excited by the electrons are synchronised in such a way as to increase the probability of electron transition onto the substrate. The resonance excitation of intramolecular vibrations was found, for example, in the H_2O molecules adsorbed from vapour at 300 K on the surface of titanium oxidised in air.^{231–233} In this case, prior to H_2O adsorption, the $I(U)$ function exhibited maxima corresponding to the stretching vibrations in TiO_2 ($\omega_{hi} h \approx 0.1\text{ eV}$). After adsorption, this function acquired large-scale maxima at

$$e(U_2 - U_1) \approx 0.2\text{ eV},$$

$$e(U_3 - U_1) \approx 0.5\text{ eV},$$

$$e(U_4 - U_1) \approx 0.7\text{ eV},$$

$$e(U_5 - U_1) \approx 1.0\text{ eV}.$$

The first two of these values are close to the quantum energies of bending (0.2 eV) and stretching (0.46 eV) vibrations of adsorbed water molecules (from IR-spectroscopic data). Hence, the other maxima can be attributed to two-quanta and combined vibration transitions.²³³

When H_2O is replaced by D_2O , the positions of the $I(U)$ maxima shift in conformity with the expected isotope effect. This attests unambiguously to the stimulation of intramolecular vibrations by the tunnelling electrons.

VIII. Sorbent degradation

The properties of a sorbent change inevitably during operation as sorbent bodies are gradually dissolved and destroyed upon collisions and chemical reactions with admixtures. The mass of each grain m varies at the rate

$$\frac{dm}{dt} = \beta_{k0} S(c - P_s) - \gamma_k \omega_k m_f + G_k, \quad (22)$$

where β_{k0} is the kinetic coefficient of dissolution, γ_k is the probability of grain fragmentation, ω_k is the frequency of collisions of the grain with other grains or with reinforcing structures, m_f is the average mass of the chopped-off fragments, G_k is the rate of mass variation caused by chemical reactions between the sorbate and the reagents present in the system as impurities.

Each of the above-mentioned paths of the change in the sorbent properties is characterised by the proper time τ_i :

$$\tau_1 = \frac{\bar{m}}{\beta_{k0} S(c - P_s)},$$

$$\tau_2 = \frac{\bar{m}}{\gamma_k \omega_k m_f},$$

$$\tau_3 = \frac{\bar{m}}{G_k},$$

where $\bar{m}$ is the average mass of grains.

The τ_i values can be predicted;^{237, 238} however, the β_{k0} coefficients are unknown for most substances. They should be determined experimentally.

The γ_k value can be estimated using the theory of contact plastic deformation, the frequency ω_k can be determined using the collision theory and m_f is found from the model of fracture of solids.^{239, 240} These values can be appreciably different, depending on the reactor shape and the method of stirring of the suspension. If one deals with a block crystal, chopping-off of blocks is the most probable way of destruction. As a result, the m_f value is similar to the average mass of blocks. If the particle is an agglomerate, the points of accretion of microcrystals are the first to be destroyed upon collisions, thus, m_f becomes equal to the average mass of the separate microcrystal.

IX. The search for an optimum sorbent

The quest for the optimal sorbent is carried out more and more often according to the principle: 'a specific sorbent for each system.' An individual system is characterised by a unique set of $K_e(y_i)$, $\tau_{0.9}(y_i)$ and $\tau_1(y_i)$ functions. The sorbent of choice is one ensuring the specified values of these functions. The best sorbent for a given system is usually selected by searching through the sorbents optimum for similar systems.^{241, 242} If none of these materials is appropriate, the following multistep procedure is executed.

1. Identification of the substance to form the basis of the desired sorbent

At the stage of looking for the substance that would form the basis of the desired sorbent, correlations such as relation (20) are used and the array of materials with rather high K values and low solubility P_s is identified. The K values for each of these materials are determined experimentally and the material with the greatest K is chosen. This material would form the basis of the optimum sorbent.

2. Study of the kinetics of sorption by the disperse phase of the chosen material

When investigating the kinetics of sorption by the disperse phase of the material chosen as the basis for the optimum sorbent, the kinetics of sorbate absorption by the material particles moving freely in the medium should be measured over a broad range of conditions $\{y_i\}$. Using kinetic equations such as Eqns (3)–(11), the $\alpha_j(y_i)$, $v_j(y_i)$, $\lambda_j(y_i)$, and $\tau_{0.9}(y_i)$ functions are determined, while relations of type (13) and (14) are used to determine the $D_v(y_i)$ function. The $\mu_L(y_i)$ and $\rho_L(y_i)$ functions are also found. Using experimental data on sorption for long sorption times and high concentrations of the sorbate and relations of the type (19) and (20), the $K(\theta_j)$ and $\Delta F(\theta_j)$ values are determined and the isotherms of sorption $\theta_j(y_i)$ by the disperse phase are elucidated. The results of measurements are summarised as $G_i(x_i, y_i)$ and $D_{ij}(x_i, y_i)$ dependences [see relations (1) and (2)]. This stage results in quantitative descriptions of the adsorption and desorption, the formation of two-dimensional solid solutions and surface clusters, the formation of multiautomic layers and particles of the sorbate phase on the surface of freely moving sorbent particles, and migration of the sorbate inside the bulk of the chosen sorbent.

3. Study of the role of agglomeration

Agglomerates of particles differing in porosity are studied to identify the effects of contacts between the particles, capillary condensation and crystallisation in the pores on the $K(\theta_j)$, $\Delta F(\theta_j)$ and $\theta_j(y_i)$ functions. By simulating the sorbate interaction with pore walls, the $D_v(x_i, y_i)$ and $K_e(y_i, \theta_j)$ values for agglomerates can be determined.

The results of investigation of the kinetics of sorption by the disperse phase of the material chosen as the basis of the optimum sorbent and study of the role of agglomeration are generalised as kinetic equations of sorption of the type (1)–(13) devoid of arbitrary assumptions concerning the parameters of elementary steps in the sorption by separate particles and their agglomerates.

4. Determination of the rate of sorbent degradation

The rates of dissolution, fragmentation and chemical degradation of the sorbent for the most drastic operation conditions are determined using Eqn (22), and the $\beta_{k0}(y_i)$, $\gamma_k(y_i)$ and $G_k(y_i)$ functions are found. The ways of sorbent modification aimed at increasing its chemical and mechanical stability are developed.

5. Numerical experiment

The kinetic equations of sorption supplemented by edge conditions for the whole range of $\{y_i\}$ parameters formulated as a closed boundary problem are usually solved by numerical methods. The results are presented as the following functions:

$$K_e(x_{0i}, y_i, t_k), \tau_{0.9}(x_{0i}, y_i, t_k), \tau_i(x_{0i}, y_i, t_k),$$

where x_{0i} are parameters for the state of sorbent grains before use, t_k is the time period during which operation of the sorbent is planned.

These functions allow one to answer the question what properties are demanded of the initial sorbent for this sorbent to be regarded as optimal. At the stage of numerical experiment, the $\{x_{0i}\}$ values are found.

6. The nearest goal of the search

The stepwise procedure outlined above has been implemented thus far only for systems that are most important for practical purposes. Most often, in choosing the sorbents, the material that provides the most complete, fast and selective sorption and can be recovered from the medium over the shortest period of time is assumed to be the sorbent of choice.

These conditions are met by a sorbent with dendrite-shaped grains consisting of accreted filamentary nanocrystals forming a highly porous texture. The surface of nanocrystals bears functional groups capable of forming complexes as stable as possible with the given sorbate. The structure of nanocrystals allows the sorbate molecules to be inserted into interstices with a high K coefficient. Judging by the experimental results presented above, grains of such a sorbent would form highly porous filter layers characterised by low fluid-flow resistance, high velocity $\vec{v}_L$ and approximately equal accessibilities of grain surfaces for a sorbate and would ensure favourable conditions for adsorption of sorbate molecules on nanocrystals and diffusion of molecules into their bulk.

X. Conclusion

Analysis of the published data shows that the research into sorption is approaching a new stage of development which can be termed as the molecule visualisation stage. There are grounds to expect that the gap between macroscopic and molecular description of sorption would be filled. By the beginning of this stage, conditions have been created for experimental investigation of all elementary processes taking place on the surface and in the bulk of sorbent bodies. To date, these opportunities have not been exploited to a degree sufficient for the elaboration of a theory of sorption able to describe the whole set of elementary processes. Therefore, it is still impossible to predict quantitatively the behaviour of sorbents over a broad range of sorption conditions.

The current level of detail in the description of sorption makes it possible to compose a particular plan for the accumulation of data sufficient for quantitative prediction of the sorbent behaviour under various sorption conditions on the basis of *a priori* semiquantitative estimates ('by analogy').

This plan should include theoretical analysis of the possible variants of implementation of sorption processes and accumulation of missing experimental results. Theoretical analysis implies the solution of evolution equations that describe the variation of the sorbent state during the synthesis and operation, while experimental studies are aimed at 'information loading' of the evolution equations.

The authors are grateful to V E Bozhevol'nov and S S Berdonosov for assistance and active discussion of the work.

VII. Conclusion	171

Abstract. Data on the sorption properties of polyurethane foams including their modified forms are surveyed. Examples of application of polyurethane foams for the separation and preconcentration of inorganic and organic compounds are given. The mechanisms of sorption on polyurethane foams described in the literature are analysed. Advances in the development of combined and hybrid methods of analysis with the use of these sorbents are discussed. The bibliography includes 259 references.

I. Introduction

Polyurethane foams (PUF), or foamed polyurethanes, represent an extensive class of synthetic materials prepared from polyurethanes — heterochain polymers that contain urea, amide, ether, ester, or other groups in addition to urethane groups. Polyurethanes were first synthesised by Bayer and co-workers in 1937.¹

Later, industrial production of PUF was started on the basis of these polymers and polyesters or their analogues (Germany, 1944) and, subsequently, on the basis of cheaper polyethers (USA, 1957). Currently, PUF are produced in large amounts (millions of tons a year) in many countries all over the world. Polyurethane foams (in the household, these materials are called foam-rubbers) are widely used for domestic purposes: to produce soft furniture, car seats, mats, sponges, toys, and so on. In industry, PUF are employed as damping and heat insulating materials. Some similarity between the characteristic functional groups present in polyurethane molecules and in macromolecules forming living tissues provides grounds for assuming that PUF-based materials would be promising for use in medicine, all the more so, because polyurethane fibres have long been used in surgical practice as sutures and for the manufacture of vessel prostheses.

The possibility of using PUF as sorbents for extraction of metal ions and organic compounds from water and air was first established by Bowen in 1970.² Two years later, Braun and Farag

proposed the use of PUF as solid polymer matrices for immobilisation of various organic reagents.^{3,4} Since the mid-1970s, PUF have been used in analytical chemistry for preconcentration of inorganic and organic compounds from aqueous solutions or air and for the development of combined or hybrid analytical techniques. During the elapsed time, vast amounts of experimental information dealing with sorption by means of unloaded and loaded PUF has been accumulated and data on sorption mechanisms have been gained. The following practical applications of PUF have become traditional and most important: separation of mixtures in which elements and compounds are present in comparable amounts; isolation of components for preconcentration and subsequent determination directly in the sorbent phase using neutron-activation analysis, X-ray fluorescence, photometry, or another method; and isolation of components for preconcentration and subsequent determination in the eluate phase using chromatography, spectroscopy, or some other analytical technique.

The application of PUF in analytical chemistry is the subject of a monograph⁵ (difficult to access for a Russian reader) and several reviews,^{6–10} which, however, do not cover all applications of this class of sorbent. In addition, after the publication of the latest of the above-mentioned works (1992), the number of studies dealing with this topic has substantially increased and new trends in the use of PUF in chemical analysis have taken shape. This has stipulated the need for generalisation of the accumulated data at a qualitatively new level taking into account, first of all, the modern views on the mechanisms of sorption on PUF and the properties of these sorbents.

II. General characteristics of polyurethane foams

Polyurethane foams are prepared by polycondensation of isocyanates with polyols (glycols, triols, polyethers, or polyesters) followed by foaming of the polymer bulk by carbon dioxide. Polyether and polyester foams can be distinguished. In the industrial synthesis, polyethers with terminal OH groups and molecular masses of 400–6000 are used most often as the initial compounds, together with mixtures of 2,4- and 2,6-toluylene diisocyanates in 65:35 or 80:20 ratio. In the one-step process, diisocyanate, polyether resin, water, catalysts, stabilisers, and emulsifiers are mixed simultaneously. The reaction takes place immediately; foaming starts several seconds after mixing and is over after 1–2 min. Toluylene diisocyanates play an especially important role in the synthesis of PUF. The reaction between

polyhydric alcohol and isocyanate is a chain propagation reaction, resulting in urethane derivatives

The reaction of isocyanate with water yields amine and carbon dioxide, which foams the polymer. Amine can react with excess isocyanate to give substituted urea derivatives

Isocyanate can also react with urea and urethane derivatives giving rise to allophanate and biuret, which induce additional cross-linking of the polymer:

Depending on the number of cross-links, flexible and rigid PUF are distinguished. The materials with low cross-linking density are called flexible PUF, while rigid polymers are characterised by high cross-linking density. Flexible PUF are usually synthesised from polyhydric alcohols with not very high molecular mass and low degrees of branching, while rigid ones are prepared from highly branched alcohols with low molecular mass. Detailed information on the synthesis of PUF can be found in monograph.¹

Foamed polyurethanes contain different functional groups, namely, urethane [$-NHC(O)O-$], ether ($-O-$), ester [$-C(O)-O-$], amide [$-C(O)-NH-$], urea [$-NH-C(O)-NH-$], and terminal toluidine [$-C_6H_3(CH_3)NH_2$] groups and also both aromatic ($-C_6H_4-$) and aliphatic ($-CH_2-$) groups. The diversity of functional groups in the flexible polymer chains of PUF creates favourable conditions for the formation of intermolecular (secondary) bonds of various chemical natures and with different energies (ranging from van der Waals to hydrogen bonds), which has a substantial influence on the physicochemical properties of the materials.^{11, 12} The hydrogen bonds arising upon the interaction of hydrogens of the proton-donating urethane groups with oxygens of the proton-withdrawing ether, ester or carbonyl groups play an especially important role. The type of hydrogen bond depends on many factors, in particular, on the proton-donating and proton-withdrawing capacity of groups, their concentrations and distribution along the polymer chain and on the steric conditions of the formation of the H-bonds. Exhaustive information on the types of hydrogen bonding has been obtained by IR spectroscopy.¹³ Study of IR absorption of polyurethanes of different chemical structures in the region of NH stretching frequencies showed that most of the NH groups in polyurethanes are involved in hydrogen bonds. The vibration frequencies of NH groups perturbed by hydrogen bonding are different in the spectra of PUF based on polyethers and polyesters. This may be due to different types of H-bonding in these systems. From analysis of the IR spectra, it was concluded that the major type of hydrogen bond in polyester-based polymers is that between the hydrogen atom of the urethane group and the carbonyl oxygen of the ester group, while in the polyether foams, this is the bond between the urethane-group hydrogen and oxygen of the polyether chain; the hydrogen bond involving ether oxygen is stronger.¹³

Due to the strong hydrogen bonds which form in PUF a continuous three-dimensional network, in certain cases, linear polyurethanes, cross-linked only through physical bonding exhibit properties normally typical of chemically cross-linked linear chains.¹³ Yet another structural feature of the three-dimensional network formed in PUF is lability. The ability of the

network to be destroyed and reconstructed on heating, treatment with solvents or mechanical stresses suggests that this network can be likened to thixotropic structures, well-known in colloid chemistry. The presence of the labile structural network accounts for many specific properties of PUF. For example, the tensile and compression strengths of PUF are believed to be mainly due to the presence of intermolecular interaction. In the case of pronounced deformations (bending, stretching, *etc.*), the secondary bonds are destroyed, while the primary (chemical) bonds remain intact. Evidently, the ability of polyurethanes to 'heal' the defects arising upon deformations can be explained by the relative ease of network destruction and subsequent restoration. Therefore, after multiple compression, PUF is softened and its initial strength is restored after a certain 'rest'.¹¹

Polyurethane foams are foamed plastics in which some of the solid has been replaced by gas, usually air, which exists in the polymer as numerous bubbles (cells). Depending on the relationship between the rate of the macromolecule growth and the rate of gas evolution at the foaming stage, the cell walls are either broken (ruptured) or not; this gives rise to polymers with open-cellular or closed-cellular structure, respectively. As a rule, flexible PUF have an open-cellular structure and rigid ones are characterised by a closed-cellular structure. If the volume occupied by gas bubbles is less than 76% of the total volume of the specimen, the bubbles can be spherical; if this volume is greater than 76%, the bubbles are shaped most likely as quasi-spherical polyhedra, mainly, pentagonal dodecahedra.^{5, 6, 9} The polymer itself forms the walls of the bubbles, which are actually polyurethane membranes. In open-cellular PUF, at least two membranes (faces of the pentagonal dodecahedron) are ruptured.

Among the properties of PUF, one should mention the lightness (the apparent density is $0.015-0.045 \text{ g cm}^{-3}$), enhanced stability against thermooxidative destruction ($180-220^\circ\text{C}$), and chemical and radiation stability. The properties of PUF do not change (not counting the reversible swelling) on contact with hydrochloric (up to 6 M), sulfuric (up to 4 M), nitric (up to 2 M), or glacial acetic acid, solutions of sodium hydroxide or ammonia (up to 2 M), and many organic solvents such as benzene, tetrachloromethane, chloroform, diethyl ether, other ethers or esters, methyl isobutyl ketone, alcohols. Polyurethane foams based on esters are less stable in acidic or alkaline media than those based on ethers because the former are more susceptible to hydrolysis. Both types of PUF are soluble in concentrated sulfuric acid or a hot solution of arsenic(III) chloride; they are destroyed on treatment with concentrated nitric acid and oxidised by an alkaline solution of $KMnO_4$.²

Estimation of the purity of PUF of various brands showed that the content of inorganic impurities in them is comparable with or even less than that in other sorbents such as active (activated) carbons, synthetic ion exchange resins or chelating sorbents.⁵ It was found by neutron activation analysis that the major impurity in PUF is tin, its content being substantially lower in polyester PUF.¹⁴ This may be due to the fact that organotin catalysts are used in the synthesis of PUF based on ethers. In addition, small amounts of Na, Mg, Al, Mn, V, Cl, Br and I have been found in PUF.

The organic impurities extracted from industrial PUF specimens by various methods, namely, on treatment with solvents,^{15, 16} by thermodesorption^{17, 18} or by supercritical fluid extraction¹⁹ have been identified by a combination of gas chromatography and mass-spectrometry techniques. The impurities were mainly toluylene diisocyanates,¹⁵ various aliphatic and aromatic amines^{16, 18} and fluorocarbons (Freons).^{17, 19} The composition of the impurities depends on the solvent used and on the features of the PUF manufacturing process.[†]

[†] It is known¹ that amines and Freons are used as catalysts and as additional foaming agents, respectively, in the production of some sorts of PUF.

The specific surface area of PUF can be determined from isotherms of low-temperature adsorption of nitrogen^{20, 21} or carboxy-¹⁴C-stearic acid.²² The specific surface areas of the PUF specimens studied were 0.007–0.035 m² g^{−1}, which is much smaller than the values found in sorbents such as Tenax GC (6.4–25 m² g^{−1}) or XAD-2 (300–360 m² g^{−1}).

As applied to PUF, a method for the estimation of the microenvironment hydrophobicity, based on the interfacial partition of pyrene between water and the medium to be tested, has been developed.²³ The partition coefficient of pyrene between the sorbent and water, aqueous acetonitrile or aqueous ethanol is used as a measure of hydrophobicity. A comparative estimate of the surface hydrophobicities for six industrially manufactured specimens of PUF based on ethers and esters and for other sorbents such as Diasorbs C₄, C₈, C₁₆, phenyl and carboxyl, XAD-8, cellulose, cellulose triacetate and activated carbon AX-21 showed that the PUF specimens studied are characterised by approximately equal surface hydrophobicities and that, regarding this parameter, they should be placed between Diasorb C₁₆ and activated carbon AX-21.

Fluorescence spectroscopy has been demonstrated to provide extensive possibilities in investigations of the properties of polyurethane foam membranes.^{24, 25} Using pyrene as the fluorescence probe, the polarity of the pyrene microenvironment (ϵ_{ef}) in the matrix of various PUF has been estimated.²⁴ For low degrees of filling of the sorbent phase (0.3–0.9 $\mu\text{mol g}^{-1}$), the ϵ_{ef} value ranges from 24 to 39, polyether PUF being less polar than polyester PUF; for high degrees of filling of the sorbent phase (4.2–5.6 $\mu\text{mol g}^{-1}$), the polarity of the pyrene microenvironment decreases, the ϵ_{ef} values being 10–19 for polyester PUF and ~ 2 for polyether PUF. The polarity of the pyrene microenvironment in the matrices of protonated PUF proved to be higher than those for the initial PUF. The data on quenching of the fluorescence of pyrene sorbed on PUF by quenchers of different natures, namely, potassium iodide and bromoform, gave rise to the suggestion that solid-phase foamed polyurethane membranes contain polar and hydrophobic microregions characterised by different physical properties.²⁵ Lower values for the calculated Stern–Volmer constants for pyrene in the PUF matrix compared to the values for aqueous solutions point to a decrease in the mobility of pyrene and quencher molecules, related, first to the their transition to a thicker medium and, second, to the rigid fixing of these molecules at particular sections of the polymer chain. The fact that the pyrene molecule is rigidly fixed in the PUF matrix is also indicated by the absence of the excimer band in the fluorescence spectra of pyrene sorbates, even when it is sorbed from suspended media.²⁵

In a study of the protolytic properties of PUF, it was shown that stepwise protonation of PUF takes place in aqueous solutions of mineral acids (pH < 3).^{25, 26} The protonation constants were calculated; it was suggested that the terminal toluidine groups in the PUF molecules are the first to be protonated.

Thus, PUF are foamed plastics with a ‘membrane-like structure’ characterised by a relatively low specific surface area and high chemical stability and purity.

III. Sorption of elements and organic compounds on unloaded polyurethane foams

1. Sorption of elements

At present, the sorption of ~ 50 elements on unloaded PUF has been studied. Most often, PUF adsorb elements as metal acido complexes,[‡] more rarely, as heteropolyacids, ion associates or metal chelates. Sorption in the form of metal acido complexes is observed for most elements able to form negatively charged halide, cyanide, and thiocyanate complexes (Table 1). Sorption of chloride and thiocyanate metal complexes is the most wide-

Table 1. Sorption of elements by unloaded PUF from solutions in mineral acids.

spread. Data on the sorption of fluoride,^{27–30} bromide,^{2, 49, 52} iodide^{39, 53} and cyanide⁵⁴ complexes are scarce.

The sorption of metal acido complexes is carried out both from solutions of hydrohalic acids and from mixtures of alkali metal salts with mineral acids, for example, LiCl–HCl, KNCS–HCl and KNCS–H₂SO₄. The use of these mixtures is especially typical of sorption of thiocyanate complexes. The time required for sorption equilibrium to establish depends on the nature of the sorbed acido complex and varies from several hours (for metal chloride complexes) to 10–30 min (for thiocyanate complexes).

It should be noted that the conditions for sorption of metal acido complexes on PUF are the same as conditions for extraction of these complexes with oxygen-containing solvents, in particular, diethyl ether. Polyurethane foams adsorb metal acido complexes as one- and two-charged anions of the composition MF₆[−], MX₄[−] [X = Cl, Br, I, CN, NCS and M(NCS)₂^{2−}] with high partition coefficients ($n \times 10^2$ – $n \times 10^4$ ml g^{−1}). The sorption capacity is also high, varying from ~ 0.2 to ~ 2 mmol per gramme of the sorbent, which makes up to 10% of the sorbent weight. As a rule, PUF based on polyethers sorb metal acido complexes better than polyester foams. The metal acido complexes can be quantitatively desorbed from PUF on treatment with acetone or dilute solutions of hydrohalic acids.

[‡] Acido complexes are complexes containing only acid anions as the ligands.

Sorption on PUF of acido complexes of platinum group metals has some specific features. Thus Rh(III) and Ir(IV) are poorly collected from thiocyanate solutions at room temperature; however, after short-term heating to 90 °C, sorption of these metals becomes quantitative.⁷⁶

The selectivity of PUF with respect to chloride and, especially, thiocyanate metal complexes is relatively low and depends on sorption conditions, namely, solution acidity, supporting salts and other substances present in the solution. The sorption of metals from fluoride solutions proved to be more selective. Polyurethane foams quantitatively collect Ta(V) and Sb(V) from 0.1–5 M HF as MF_6^- complexes and do not adsorb Co, Zn, Fe(III), Hf, Zr, Sn(IV), Nb, Pa, As(V), Mo, or W.^{27, 28}

Apart from metal acido complexes, PUF quantitatively sorb some elements, for example, As, Ge, P and Si, as heteropolyacids (see Table 1). In this case, too, the conditions of sorption of heteropolyacids on PUF coincide with conditions of their extraction with oxygen-containing solvents.

Like crown ethers and acyclic polyethers, PUF collect alkali and alkaline earth metals^{59, 96–98} as well as Ag, Pb and Tl(I)^{59, 98} in the form of ionic associates with large hydrophobic anion partners such as picrate or anilidonaphthalenesulfonate. The sequence of sorption of metal picrates is in agreement with the series of extractability of these metals with crown ethers, for example, 18-crown-6 or dicyclohexyl-18-crown-6. Polyether foams are better sorbents for these metals than polyester-based PUF.

The possibility of sorption of metal chelates on unloaded polyether type PUF has been demonstrated. Thus Hg, Pt(II) and Zn are sorbed as complexes with dithizone,^{2, 99} Y is sorbed as a complex with 8-hydroxyquinoline,^{100, 101} and Cd, Fe(II) and Eu, as complexes with 1,10-phenanthroline.^{102–106}

2. Sorption of organic compounds

The interest in the use of PUF as sorbents for preconcentration of organic compounds is in many respects due to a study¹⁰⁷ demonstrating that ether-based PUF collect quantitatively polychlorinated biphenyls (PCB) from large water samples. In the subsequent years, several dozens of publications have been devoted to sorption on PUF of polycyclic aromatic hydrocarbons (PAH), PCB, phenols and some other organic compounds from various water^{108–112, 125–127, 137–145, 147, 150–174} and air^{113–124, 128–136, 146, 148, 149} samples (Table 2).

It was found in relation to aromatic compounds that the partition coefficients of substances between PUF and the aqueous phase are proportional to their partition coefficients for the extraction into diethyl ether.¹⁰⁸ Similar results were obtained in a comparison of sorption of 59 organic dyes (triphenylmethane, xanthene, sulfophthalein) by polyurethane foams from water or aqueous ethanol with the extraction of the same compounds into diethyl ether or ethyl acetate.¹⁶⁰ Sorption of dyes depends on the nature, the structure, and polarity of the dye. The pattern of the dependence of sorption of ionising organic compounds (phenols and carboxylic acids) on the solution pH attests that these compounds pass to PUF as neutral species.^{108, 137, 138, 141, 142}

The efficiency of sorption of anionic^{105, 171} and cationic surfactants¹⁷² and 4-nitrophenylazo derivatives of phenols^{161, 163, 164} increases if they are collected as ionic associates with large hydrophobic counter-ions. In this case, sorption is substantially dependent on the hydrophobicity of the cationic and anionic components of the associate, the size and charge of the ions they contain, the concentration and the nature of the counter-ion, the composition of the aqueous medium, and the chemical structure of the sorbent.^{25, 105, 167–169}

The capacity of PUF with respect to volatile organic compounds sorbed from air has been studied to elucidate the dependence of the volume before breakthrough on the key parameters of the process: flow rate of the mobile phase, temperature, sample volume and some other.^{114, 115, 119–121, 129, 130} The relationship between the size of the PUF block, the volume of the air under analysis and the volume before breakthrough has been elucidated in relation to PCB. It was found that PUF blocks with thicknesses of 4 and 7 cm collect 90% of PCB from 500- and 900-m³ air specimens, respectively.¹³⁰ It was noted¹³² that a 15 cm-thick PUF block completely absorbs hexachlorobenzene, 3,3'-dichlorobiphenyl and 2,4',5-trichlorobiphenyl impurities from air specimens with volumes of 250, 330, and 2880 m³, respectively. Pankov¹¹⁹ demonstrated that the relationship between the specific retention volume of a compound on PUF ($v_{g, 293}$) and the vapour pressure ($p_{L, 293}^0$) of the pure target compound is described by correlation equations:

$$\log v_{g, 293} = -1.195 \log p_{L, 293}^0 - 1.884 (r^2 = 0.989, \text{PAH})$$

and

$$\log v_{g, 293} = -1.059 \log p_{L, 293}^0 - 1.764 (r^2 = 0.950, \text{PCB}),$$

where r is the correlation coefficient.

Table 2. Sorption of organic compounds by unloaded PUF.

Type of compound	Sorbable compounds	Ref.
Aromatic hydrocarbons	monocyclic aromatic compounds	2, 108
	polycyclic aromatic compounds	109–125
	polychlorinated biphenyls	107, 124, 126–136
Hydroxy-containing aromatic compounds	phenols	2, 108, 122, 137–142
	carboxylic acids	108
	alcohols	143, 144
Esters	esters of phthalic acid	145, 146
	esters of acetic acid	147
Insecticides	organochlorine	127–129, 133, 148–150
	organophosphorus	133, 151–157
	acaricides	158, 159
Dyes	azo dyes	160–166
	xanthene	160, 167
	acridines	160, 168
	sulfophthalein	160, 169
	other	160, 166
Other compounds	anionic surfactants	105, 170–172
	cationic surfactants	172, 173
	alkylammonium salts	174
	bilirubin	175

A number of studies have been devoted to the transport of phenols¹⁴¹ and organic dyes¹⁶⁶ through thin polyurethane membranes. Using a polyurethane membrane, ethanol has been isolated from aqueous solutions.¹⁴⁴

3. The mechanisms of sorption on unloaded polyurethane foams

A critical analysis of the views on the mechanisms of sorption of metal complexes on PUF has been reported in a monograph⁵ and in a review.¹⁰ The mechanisms discussed as the most probable ones include extraction, anion exchange, cation chelation, ligand exchange and ligand addition mechanisms.

The views on the extraction mechanism, proposed by Bowen in his first study² and confirmed subsequently by other researchers are underlain by the fact that the conditions of extraction of metal acido complexes into diethyl ether are similar to the conditions of sorption of these complexes on PUF. The relatively high sorption capacity of PUF calculated on the basis of sorption isotherms of Au(III),² Fe(III),^{2, 38} Hg,⁷³ Sb(V)⁴⁸ and Te⁴⁹ halide complexes and some ions (0.5–1.5 mmol g⁻¹) with relatively low specific surface area (0.03–0.08 m² g⁻¹) is regarded as evidence supporting this mechanism. Experimental data concerning the transport of Ga,^{20, 36} Fe(III)^{36, 37, 40} and Au(III)³⁴ halide complexes and uranyl nitrate^{36, 86} through polyurethane membranes indicate that the membranes collect compounds not only due to adsorption but also due to absorption processes. A layer-by-layer microscopic study of polyurethane foam membranes after sorption of coloured compounds, for example, iodine showed that they are uniformly distributed throughout the sorbent bulk rather than concentrated on the surface.² In several studies devoted to sorption of Ga,^{20, 35} Fe(III),^{35, 38} Sb(III, V)⁴⁸ Sn(II, IV)²¹ chloride complexes and Co and Fe(III)⁵⁶ thiocyanate complexes, PUF are characterised as solid polymeric analogues of oxygen-containing solvents.

Extraction of metal acido complexes by polyurethane foams increases in the presence of alkali metal salts, *i.e.*, a salting-out effect is observed, which is usually typical of liquid extraction. For example, when polyether-based PUF are used, the partition coefficient of Sn(IV) from 3 M HCl does not exceed 140 cm³ g⁻¹, whereas for a solution containing 10 M LiCl and 0.12 M HCl, this value is 5600 cm³ g⁻¹ (see Ref. 21). A similar increase in the partition coefficient was also observed for PUF based on polyesters; however, the values are much lower in this case, namely, 120 and 730 cm³ g⁻¹, respectively.

Actually, the extraction mechanism proposed in early studies^{20, 35–37, 48} reflected the known ability of polymers to dissolve metal salts and organic compounds, which was later (1982) called solid-phase extraction,¹⁷⁶ but did not disclose the factors that made this dissolution possible.

Even the first investigations of the sorption properties of PUF showed that these sorbents possess low anion-exchange capacity. It has been suggested^{2, 20} that these properties appear due to protonation of the electron-donating nitrogen and oxygen atoms incorporated in PUF macromolecules. Since the basicity constants of the groups present in the foamed polyurethane units are rather low, it has been considered that PUF can exhibit anion exchange properties only in highly acidic solutions.

In 1982, a cation chelation mechanism was proposed,⁵⁹ which provided a different interpretation of the anion exchange properties in PUF. In a study of sorption of thiocyanate metal complexes and some organic anions (in particular, picrate) in the presence of various salts, the researchers concluded⁵⁹ that polyester-based PUF exhibit complexing properties with respect to alkali and alkaline earth metal cations, Ag, Tl(I), Pb, NH₄, RNH₃⁺, and H₃O⁺. When binding cations, neutral macromolecules of foamed polyurethane are converted into macrocations with variable charge density. To maintain neutrality, an anion should be bound (or exchanged) together with the cation. Sorption of metal acido complexes and organic anions by polyether-type polyurethane foams increases in the sequence

Li < Na < Cs < Rb < K < NH₄ < Ag, Tl(I) << Ba < Hg < Pb. Since the same sequence was observed for the sorption of these substances by many crown ethers¹⁷⁷ and acyclic ethers,^{178, 179} it was suggested⁵⁹ that the selective binding of cations is ensured by the polyether segments of PUF, which are able to form a helix around the sorbed cation. To confirm the selectivity of cation binding, the sorption properties of PUF of various types were compared with the extraction capacity of macrocyclic ethers containing polymeric units similar to those found in foamed sorbents.⁵⁹ It was shown that the cation-binding capacity of PUF based on poly(ethylene oxide) is higher than that of PUF based on poly(propylene oxide). The results of a study of sorbates by IR spectroscopy attest in favour of the cation chelation mechanism of sorption of organic compounds on PUF. This study showed the presence of strong interactions between the ether units of PUF and sorbed thiocyanate metal complexes.⁵⁹ The presence of ester groups, which are conformationally more rigid, in the polymer chain of PUF has an adverse effect on the cation binding. This is confirmed experimentally by the facts that the sorption properties of polyester-based PUF are poorer than those of polyether-based PUF and that the pattern of influence of alkali metal halides on sorption changes. The sorption of anions by polyurethane foams based on esters varies according to Hofmeister lyotropic series: Li < Na < K < Rb < Cs.

The cation chelation mechanism has found quite a few advocates. This mechanism is believed to be responsible for the sorption on PUF of Cd,⁵⁵ Co,^{59, 61} Fe(III),⁵⁵ Mo, W, Tc,⁷⁷ Os,⁷⁸ Pd,⁸¹ Pt,⁸² Ru,⁷⁹ Zn,⁵⁵ Zr and Hf⁷² thiocyanate complexes from slightly acidic aqueous solutions and hexachloro platinum and iridium complexes from acetone and ethyl acetate.⁴²

In the ligand exchange or addition mechanism, the polymer segments containing electron-donating nitrogen or oxygen atoms act as ligands able to coordinate metal ions. This 'ligand addition' has been considered to interpret the sorption of yttrium hydroxy-quinolate complexes¹⁰¹ and iron thiocyanate complexes³⁹ on PUF. It was proved using IR spectroscopy that the role of the ligand is played by the urethane group (–CO–NH–).

Sorption of organic compounds on PUF is explained in most cases in terms of the extraction and cation chelation mechanisms. According to the extraction mechanism, PUF are regarded as solid polymeric extractants which dissolve organic molecules in the polymer films that form the framework of these sorbents.¹⁰⁸ A piece of evidence supporting the extraction mechanism is provided by the fact that the efficiency of extraction of organic compounds by polyurethane foams can be increased by introducing inorganic salts in the aqueous solution–PUF system.¹⁰⁸ In the presence of alkali metal salts, sorption efficiency increases in the series: K < Na < Li. Double-charged cations influence the extraction efficiency to a markedly greater extent than single-charged ones, *i.e.*, a salting-out effect typical of extraction is involved. The extraction mechanism has also been used to interpret sorption by polyurethane foams of PAH,¹²⁵ phenols,^{108, 138, 141, 142} cationic dyes^{160, 167, 168} and organophosphorus and organochlorine acaricides.¹⁵⁸

Negatively charged forms of organic compounds such as anionic surfactants,¹⁷² sulfophthalein dyes^{160, 169} and azo dyes^{160, 161} are extracted by PUF by the cation chelation mechanism. This is indicated by the data on the influence of alkali metal and ammonium salts on sorption. Sorption of these compounds increases in the following order: Li < Na < Cs < Rb < K ~ NH₄.

In some publications, the important role of hydrophobic interactions and interactions giving hydrogen bonds in the sorption of organic compounds is noted. A reliable correlation has been established between the main parameter of PAH sorption, the partition coefficient (log *D*), and the hydrophobicity parameter of their molecules [the Hansch parameter defined as the partition coefficient in the 1-octanol–water system (log *P*_{ow})].¹²⁵ Two-parameter correlation equations relating the partition coefficients of phenols to their hydrophobicity parameters and

Scheme 1

medium pK_a values have been proposed.¹⁴² The logarithms of the partition coefficients of cationic surfactant homologues were found to follow a linear dependence on the number of carbon atoms in the alkyl groups of these compounds.^{25, 172}

Thus, various mechanisms of sorption of metal complexes and organic compounds by polyurethane foams have been proposed; each mechanism has its own adherents and has been confirmed by experimental data. A common drawback of the views in these mechanisms is that sorption is idealised. In most cases, consideration actually refers to special cases in which only one process takes place in the system, other processes being entirely suppressed. Meanwhile, real systems normally provide favourable conditions for the simultaneous occurrence of several processes.

4. Chemisorption processes involving polyurethane foams

Experimental data attesting to a previously unknown ability of the terminal toluene groups of PUF to be involved in oxidation, diazotisation and azo coupling reactions have been reported.^{180–182} When PUF samples are brought in contact with aqueous solutions of free active chlorine, sodium nitrite and 4-nitrophenyldiazonium tetrafluoroborate, chemisorption processes take place to give intensively coloured products. The composition of the products was determined using diffuse reflection spectroscopy, elemental chemical analysis and other techniques. The optimal conditions of heterogeneous chemical reactions with participation of PUF and the conjectural composition of the products are shown in Scheme 1.

The introduction of the diazo group into PUF provides activation of these materials toward covalent attachment of functional groups to their surface.¹⁸² Diazotised PUF enter into azo coupling reactions with azo components such as 8-hydroxyquinoline (Scheme 1), 1- and 2-naphthols, phenol, aniline and other compounds to give intensely coloured products. Heterogeneous chemical reactions involving PUF proceed under relatively mild conditions (aqueous solutions, room temperature, atmospheric pressure), the coloured products being rapidly formed at relatively low concentrations of compounds present in the aqueous phase. Therefore, PUF were recommended as new polymeric reagents for determination of free active chlorine and nitrite ions.^{180, 181}

IV. Sorption of elements on polyurethane foams loaded with organic reagents

Polyurethane foams can collect and retain substantial amounts of inorganic and organic compounds. This provides the possibility of

modifying PUF to improve their sorption properties, while preserving the required hydrodynamic characteristics of the material. This is done using oxygen- and nitrogen-containing extractants or chelating organic reagents. The general information about sorption of elements on PUF loaded with various oxygen- and nitrogen-containing extractants and chelating reagents is presented in Table 3. The major application of loaded PUF is preconcentration with subsequent determination of metal ions and organic compounds in waters.

Two ways of immobilising reagents, differing in the method of fixing of compounds in the PUF matrix, have been described, namely, physical and chemical immobilisation. Physical immobilisation is used most often because chemical fixing of reagents, which is carried out during the polymer synthesis, is a more laborious procedure. Organic compounds can be introduced into the foaming material owing to the hydrophobic nature of the polymer matrix and its dissolving capacity with respect to various compounds. Immobilisation of liquid extractants is an exceptionally simple procedure; this is attained by keeping PUF pellets or small cubes in an appropriate liquid extractant or in its mixture with some organic solvent. Excess liquid is then removed and the PUF samples are dried between sheets of filter paper. Foams obtained in this way contain 50 mass % to 80 mass % of an organic compound. Immobilisation is performed for liquid extractants, for example, tributyl phosphate,^{3, 183, 184, 187} trioctylamine,^{196, 197} bis(2-ethylhexyl) hydrogen phosphate,¹⁹² and for solutions of these compounds: tributyl phosphate in benzene,¹⁸⁵ trioctylphosphine oxide in diethyl ether, bis(2-ethylhexyl) hydrogen phosphate in nitrobenzene^{190, 191, 193} or in dichlorobenzene.^{194, 195}

Immobilisation of solid chelating reagents on PUF is carried out using two procedures. According to one procedure, the reagent is dissolved in a non-volatile organic solvent (plasticiser) and physically immobilised on PUF as described above. The other method consists of keeping the polymer in a solution of the reagent in a highly volatile solvent followed by removal of the solvent. In both procedures, it is required that the reactant solubility be rather high. This requirement is readily fulfilled in the second procedure because there is a wide choice of volatile solvents; however, the range of solvents suitable for the first procedure is substantially narrower. The solvents play a dual role in this case: they should efficiently dissolve the reagents and should also act as plasticisers for the polymeric sorbent. Tributyl phosphate^{57, 192, 213, 215} and α -dinonyl phthalate^{57, 209, 225} are used most often as plasticisers.

Table 3. Sorption of elements by polyurethane foams loaded with organic reagents.

Organic reagent	Element	Ref.	Organic reagent	Element	Ref.
Tributyl phosphate	Au	14, 183, 184	dithizone	Ag	211
	Bi	4, 57		Bi	212, 213
	Cr	185		Cd, Cu	214
	Nb	186		Hg	215–217
	Pd	4		Pb	218, 219
	U	162, 187		Zn	212, 218
Trioctylphosphine oxide	U	188, 189	diethyldithiocarbamates	As, Bi, Hg, Pb, Sb, Se, Sn	220–222
Bis(2-ethylhexyl) hydrogen phosphate	Ce	190, 191		Cd, Co, Cr, Cu, Fe, Mn, Ni	222–224
	Th	192		Hg	225, 226
	U	193–195		Sb	227
Trioctylamine	Co	196		REE	228, 229
	U	197, 198	diphenylcarbazide	Cr	230–232
Dibenzoylmethane	U	199, 200	benzoylhydrazone	Cu, Pd	233
Thenoyltrifluoroacetone	Co, Fe	201–203	phenylhydrazine	Mo	234

	Fe, Mn	57, 209			
	Hg	14, 57, 73, 208			
	In	14, 73			
	Zn	57, 73, 208			

^a AM are alkali metals.

Immobilisation of various chelating reagents on PUF has been described, for example, dimethylglyoxime,^{204–207} 1-(2-pyridylazo)-2-naphthol,^{14, 57, 208–210} dithizone,^{211–219} ammonium pyrolydinedithiocarbamate,^{220, 221, 223} hexamethylenammonium hexamethylenedithiocarbamate,²²⁴ and sodium,²²² diethylammonium²²⁵ and potassium²²⁸ diethyldithiocarbamates. It was shown using numerous examples that the conditions of formation of compounds with PUF-immobilised reagents do not differ from the conditions of reactions taking place in aqueous solutions.

Parameters such as the strength of retention and the uniformity of distribution of the organic reagent in a polymer matrix are little studied. It was only found that on contact with large amounts of an aqueous phase (up to 1 litre), not more than 15% of the reagent is desorbed, whereas on treatment with acetone, ethanol and other organic solvents both the reagent and the resulting complex are removed from PUF almost completely.²¹⁷ It was shown in a study of operational characteristics of PUF loaded with 1-(2-pyridylazo)-2-naphthol,²¹⁰ that an increase in the reagent content leads to a poorer retention of the reagent on contact with water. The optimal amount of the reagent is 1 mass %.

As in the case of unloaded PUF, isolation and preconcentration of compounds on loaded PUF are carried out in either a static or dynamic regime. In the latter case, the flow rate of the analysed solution through the column can vary over a broad range, from 0.1 to 250 ml min⁻¹. The scope of the dynamic preconcentration technique can be extended by using plasticised PUF,^{210, 225} as this allows quantitative collection of the analyte for flow rates exceeding 100 ml min⁻¹. Nevertheless, the solution flow rates used most often are 0.1–10 ml min⁻¹.

Physical immobilisation of organic reagents is usually carried out for polyether-type PUF. No results of comparative studies of the properties of different PUF have been found in the literature; only in one study,²⁰⁹ was it noted that the use of polyether-type PUF allows a 4-fold increase in the solution flow rate with respect to that for the polyester foam in the collection of Co, Mg and Fe using the polymer loaded with 1-(2-pyridylazo)-2-naphthol.

V. Classification of sorption processes involving polyurethane foams

A classification of sorption systems involving PUF has been proposed,²⁵ based on the views of various types of sorbent–sorbate intermolecular interactions developed by Kiselev.²³⁷ According to this classification, three types of sorption systems with participation of PUF can be distinguished, depending on the type of intermolecular interactions between the sorbent and the sorbate (Table 4).

The first type includes unloaded PUF in the polymer chains of which the active centres are represented by hydrophobic hydrocarbon chains and aromatic groups and electron-donating nitrogen and oxygen atoms contained in urethane, amide, ester, ether or terminal toluidine groups.

The second type comprises PUF loaded with alkali metal ions and mineral acids. This modification becomes possible due to protonation of nitrogen atoms incorporated in polar groups (first of all, terminal toluidine groups), which takes place in acidic solutions, due to introduction of cations capable of complexation with polyether (polyester) units in the polymer macromolecule. Upon binding alkali metal or ammonium cations or some other ions, polyurethane foams are converted into macrocations with variable charge density, which depends on the nature of the cation involved, salt concentration, and the nature of the PUF unit. Since this binding is less typical of PUF based on esters, it is possible to increase the selectivity of sorption on passing from polyether foams to those based on polyesters. The properties of the initial polymers would differ from the properties of PUF loaded in this way; thus, the latter can be used to recover negatively charged species.

Finally, PUF, loaded with various organic reagents upon immobilisation of the reagent without covalent bonding with the sorbent belong to the third type.

In the majority of cases, the main role in binding the sorbates on unloaded polyurethane foams is played by hydrophobic interactions and hydrogen bonds. Hydrophobic interactions play

Table 4. Classification of sorption systems with PUF according to the main types of sorbent–sorbate intermolecular interactions.

Type of sorption system	Main types of intermolecular interactions	Groups of compounds sorbed
Unloaded PUF	hydrophobic	polycyclic aromatic hydrocarbons ionic associates containing large hydrophobic cations ionic associates containing large hydrophobic cations and anions ionic surfactants phenols heteropolyacids alkali metal and ammonium salts
PUF loaded with alkali metal ions and mineral acids	hydrophobic + H-bonding H-bonding + donor–acceptor ion–dipole ion–ion ion–ion + donor–acceptor ion–ion + hydrophobic	metal acido complexes heteropolyacids sulfophthalein dyes anionic surfactants 4-nitrophenylazo-derivatives of phenols
PUF loaded non-covalently with organic reagents	chemical bond between the metal and the functional group of the organic reagent	metal complexes with organic reagents

a crucial role in the collection of PAH, associates containing simultaneously large hydrophobic cations and anions and associates containing hydrophobic cations. Compounds of the two first-mentioned groups are sorbed quantitatively on unloaded PUF (95%–99.9%); this can be used to develop procedures for preconcentration followed by spectroscopic determination of these coloured (luminescing) compounds.

The efficiency of sorption of compounds the molecules of which contain polar groups together with hydrophobic fragments is determined by a number of factors, which was demonstrated convincingly in relation to phenols.¹⁴² Of the group of compounds under consideration, either molecules incorporating hydrophobic fragments with Hansch parameters ($\log P_{ow}$ in the octanol–water system) greater than 3 (e.g., 1-naphthol), or relatively strong acids (e.g., 2,4,6-trinitrophenol) can be of interest from the practical standpoint. The main types of intermolecular interactions involved in the binding of strong acids and alkali metal salts include hydrogen bonding and donor–acceptor and ion–dipole interactions. In the case of chemical interactions taking place due to high reactivity of the terminal toluidine groups, chemical individuality of the sorbed molecules is lost upon the formation of surface compounds and, thus, sorption becomes irreversible, unlike the cases described above.

Ion–ion interactions make a crucial contribution to the sorption on PUF loaded with alkali metal ions and mineral acids of compounds such as thiocyanate metal complexes, heteropolyacids, single- and double-charged anions of sulfophthalein dyes, anionic surfactants and 4-nitrophenylazo derivatives of phenols. Binding of negatively charged species to PUF, which has an electrostatic nature, can be enhanced by hydrophobic interactions of anions containing hydrophobic groups. Usually, the compounds listed above are quantitatively sorbed on PUF; most of them, are intensively coloured, which accounts for their high practical significance.

In sorption systems of the third type, PUF function as hydrophobic polymeric matrices that fix organic compounds, the key interactions being due to the formation of chemical bonds between metal ions and functional groups of the reagent.

VI. Analytical application of polyurethane foams

Polyurethane foams are of substantial interest for analytical chemistry. These sorbents are characterised by high efficiency combined with sorption capacity with respect to many classes of sorbates, chemical and mechanical strength and stability against organic solvents. The advantages of PUF include the presence of a membrane structure, which ensures good hydro- and air-fluid dynamics of the sorbents and allows preconcentration of trace

elements and organic compounds from large samples of water and air. These sorbents are relatively inexpensive and readily available.

Sorption on PUF is used for separation, preconcentration and determination of trace elements and organic compounds from water and air. Determination of elements and organic compounds after preconcentration or separation can be carried out by a variety of methods. Most often, preconcentration by sorption is combined with photometry, diffuse reflection spectroscopy, atomic-absorption spectroscopy and chromatographic techniques. Determination can be done either directly in the sorbent or in a solution after desorption of the target components using an appropriate eluent. In some cases, determination is carried out after decomposition of the sorbent on treatment with mineral acids, for example, HNO_3 ¹⁸⁴ or its mixture with HCl .^{44, 54, 192}

1. Separation and preconcentration

The success of preconcentration and separation by sorption on PUF depends on a rational choice of the sorption system, the composition of the aqueous phase and on the procedure used for separation and preconcentration. The practice of preconcentration by sorption on PUF has some specific features differing from those used with other sorbents. Preconcentration and separation of elements and organic compounds on PUF can be performed in either a static or dynamic regime.

Static sorption can be performed in two ways. The traditional procedure is based on shaking (mixing) of the solution to be analysed with a known amount of the sorbent; air bubbles should be necessarily removed from the sorbent. Usually, PUF are used as cubes, cylinders, cylindrical discs or pellets cut out or knocked out of a polymer sheet. According to the second procedure, PUF blocks or discs situated in the solution under analysis are squeezed at some intervals either manually, for example, by the bottom of a glass measuring cylinder, or using a special automatic device.[§]

In the dynamic version of sorption, the solution under analysis is passed through a chromatographic column packed with PUF cubes or cylinders. Various methods for packing the columns have been developed; a vacuum procedure is used most often. In yet another specific method of preconcentration on PUF, called the pulsating column technique, the solution to be analysed is pumped through a sorbent layer located in a glass or plastic medical syringe. Since the sorbent is flexible, the cylindrical polyurethane foam plug can be easily compressed (or released) when the syringe

§ The automatic device consists of an eccentric shaft operated by an engine, which makes one or several glass or plastic pistons move up and down and thus forces the solution through the PUF sample placed under the piston.

piston moves. The pulsating column technique is very convenient regarding process automation in the sorption–desorption regime. More detailed information about different procedures of sorption on PUF from aqueous solutions can be found in the monograph⁵ and in reviews.^{9,10} Various types of samplers used for the collection of organic compounds from air by sorption are described in the same publications.

Numerous studies have been devoted to PUF for the separation and preconcentration of metals, mainly, as acido complexes. Some examples are presented below.

The separation of the Ta–Nb (from 1 M HF), Mo–Re, Mo–Tc (from 0.1 M HF + 1 M NH₄F) pairs on 4.5 × 0.9 cm columns packed by polyether-based PUF (0.27 g of the sorbent) has been described.²⁸ It was shown that Ta, Re and Tc are desorbed quantitatively from the column on treatment with 1 M HNO₃.²⁸ Separation of Ga and Fe in the presence of large amounts of aluminium (1:1000) is attained by sorption from 6–7 M solutions of HCl by polyether-based polyurethane foams.³⁵ Procedures for the separation of binary and ternary mixtures (W–La, W–Al, La–Ga, La–W, Ga–Al, Al–W–Ga and Mo–La–Al)⁷¹ under dynamic conditions using columns packed with 1 g of PUF at a flow rate of 1–5 ml min^{−1} have been developed. The separation is based on different sorbability of elements from thiocyanate solutions, which increases in the series Al < Ga < La < Mo < W. The Mo and La ions are desorbed from the column with acetone, while Al, Ga and W, by 1 M HCl, 2 M NH₃ and an HCl–acetone mixture, respectively.

The difference between the rates of sorption of elements on PUF underlies the procedure of separation of Te and Se.⁴⁹ Tellurium is sorbed quantitatively (> 99%) over a period of 2 min from a solution containing 1 M HCl and 5 M NaBr, while quantitative sorption of selenium requires that the contact time be increased to 2 h.

Procedures for separation of Os from Ru,⁷⁸ Pd from Pt,⁸² Rh from Ir⁷⁶ and Ru from Rh⁷⁹ based on the difference between the rates of formation of thiocyanate metal complexes have been developed. It was found that palladium can be collected at room temperature from a solution (0.002–0.006 M KNCS and 2 M KCl) in the presence of a large amount of platinum (1:20).⁸² To separate Ru from Os or Rh, a 0.3–0.4 M solution of KNCS containing 2 M NaCl is heated for 5 min at 90 °C and the Ru(NCS)₆^{3−} complex is sorbed by polyether-based polyurethane foams. The degree of recovery of Ru is 95%, while Os and Rh are sorbed under these conditions to not more than 5%.^{78,79} For separation of Rh and Ir (0.2 M KNCS + 0.2 M LiCl), the solution is heated for 30 min at 90 °C; as this takes place, rhodium is transferred quantitatively in the Rh(NCS)₆^{3−} complex. The complex is sorbed by PUF to 94 ± 1% and iridium, to not more than 5%. The procedure allows separation of rhodium in the presence of a large amount of iridium (1:5).⁷⁶

The preconcentration of cobalt and iron as thiocyanate complexes from large (up to 1 litre) samples on a PUF-packed column at a flow rate of 30 ml min^{−1} has been described.⁵⁶ The recovery of metals present in a concentration of 1 µg litre^{−1} was 96%. An efficient method for preconcentration of Co, Fe and Zn on 5 × 2 cm columns packed with 1.5 g of PUF (*v* = 5 ml min^{−1}) has been proposed.⁵⁷ It was shown⁷³ that Zn, Hg and In are sorbed quantitatively on a PUF column from a 0.2 M solution of KNCS at pH 2–3 and at flow rates of 25–50, 10–25 and 20–50 ml min^{−1}, respectively. Zinc is desorbed using 1 M HNO₃, and mercury and indium, by 1 M KNCS in 80% acetone. Molybdenum is recovered from sea water using sorption of its thiocyanate complexes on PUF with subsequent desorption with acetone.⁷⁷

A number of studies have been devoted to the use of PUF for the preconcentration of PCB,^{107, 126–128, 153} PAH,^{109, 110, 125} phenols,^{139, 140, 165} organophosphorus and chlorinated acaricides^{158, 159} and organophosphorus insecticides from water. It was noted that PUF offer a number of advantages over other polymeric sorbents and carbons for preconcentration of PAH,

PCB, and chlorine- and phosphorus-containing insecticides present in water.^{118, 127, 132, 135, 136} Polyurethane foam sorbents provide highly efficient recovery and allow a very high sampling rate (up to 800 litres min^{−1}).

2. Photometry

Two variants of using PUF in photometric analysis can be distinguished. The simplest, although not the most popular method is based on the sorption of elements on PUF as coloured compounds, desorption by acetone and spectrophotometric determination in the eluate. A classical example of using this method is determination of Co, Fe, Mo and Cu,⁶⁶ Ti,⁸³ Co,²³⁸ Fe²³⁹ as intensely coloured thiocyanate complexes after desorption from PUF on treatment with acetone. This technique was used to determine iron in glass and ceramic materials.¹⁰³ The method includes the preparation of Fe(II) phenanthroline, its sorption on PUF as an ionic associate with perchlorate ions, desorption by acetone and spectrophotometric determination at 510 nm. The range of iron concentrations determined in this way is 0.05–3 µg ml^{−1}. The method for cadmium determination in industrial zinc oxide specimens is based on the sorption of the [Cd(Phen)₂]²⁺ associate with dithizone as the counter-ion.¹⁰² A method for platinum determination in glass with a limit of detection of 0.1 µg ml^{−1} has been developed.⁹⁹ This includes sorption of the complex with dithizone on PUF, desorption by HCl-acidified acetone and spectrophotometric determination at 530 nm.

In some cases, a different, more suitable reagent is added to the eluate to increase the sensitivity and selectivity of the spectrophotometric determination. A method for determination of cobalt in nickel salts and in steels is based on the collection of cobalt on PUF from thiocyanate solutions, desorption with 80% ethanol and the subsequent determination in the eluate using 2-(2-benzothiazolylazo)-2-cresol.²⁴⁰ The method allows determination of cobalt in the presence of large amounts of Ni, Mo and Fe. A photometric method was described for arsenic determination in glass; the method includes preparation of the oxidised form of molybdoarsenic acid, its sorption on PUF, desorption with 0.1 M HNO₃ and determination in the eluate as the reduced form after the addition of SnCl₂.⁸⁹ A reported⁸⁴ method for determination of zinc in cadmium salts is based on sorption of zinc thiocyanate complexes on PUF, desorption on treatment with water and subsequent determination using 4-(2-pyridylazo)resorcinol. The same principle underlies determination of cobalt in natural waters.²¹⁰ The procedure includes preconcentration of cobalt from a 10-litre sample by sorption under dynamic conditions on a column with PUF loaded with 1-(2-pyridylazo)resorcinol.

The second variant is associated with the techniques of thin layer spectrophotometry, which rationally combines the preconcentration of elements on PUF with direct determination of the absorption of light by the solid phase.^{53, 62, 94, 185, 214, 216, 230} The essence of the method is in the sorption of coloured compounds by a PUF specimen shaped like a thin parallelepiped with dimensions corresponding to those of the cell (2 × 1 × 0.1 cm), transfer of the sorbent into a cell filled with an organic solvent and measurement of the optical density. The solvent serves as an immersion liquid reducing light scattering. Methods have been reported for determination of bismuth as an iodide complex,⁵³ cobalt as the thiocyanate,⁶² phosphate ions as the reduced form of the molybdophosphoric heteropolyacid,⁹⁴ zinc and bismuth,²¹² divalent mercury chloride and phenylmercury chloride²¹⁶ as dithizonates; and chromium as blue peroxochromic acid and a complex with diphenylcarbazine.^{185, 230} However, these methods are characterised by relatively narrow ranges of linearity of calibrating plots and relatively low reproducibility of the results.

Good prospects for the use of PUF in a flow-injection system were first demonstrated in relation to photometric determination of zinc in specimens of biological origin.⁸⁵ In this system, zinc is collected in the 'on-line' mode as the thiocyanate complex on a

microcolumn with PUF (0.3×3 cm, 100 mg of the sorbent), eluted with water and determined with 4-(2-pyridylazo)resorcinol. A flow-injection system has been used²⁴¹ for the photometric determination of aluminium with methyl thymol blue after separation of the interfering ions as thiocyanate complexes by sorption on a microcolumn with PUF (0.3×7 cm, 200 mg of the sorbent). The calibration plot is linear in the $0.25\text{--}2.0$ $\mu\text{g ml}^{-1}$ range, the productivity of the method is 17 samples per hour. Determination of 1 $\mu\text{g ml}^{-1}$ of aluminium can be carried out in the presence of large amounts of iron (1 : 170), zinc (1 : 100), copper and cobalt (1 : 50). This method has been used to determine aluminium in silicates and ores. The same procedure is employed to separate Fe, Cu, Zn and Co in a flow-injection method of determination of nickel in brasses, bronzes and silicates.²⁴² A method for determination of carbaryl with a limit of detection of 12 $\mu\text{g ml}^{-1}$ after collection on a PUF microcolumn and desorption by dichloromethane has been proposed; on-line spectrophotometric detection was carried out at 280 nm.²⁴³

3. Diffuse reflection spectroscopy

The combination of preconcentration on PUF and subsequent determination of the sorbed substances by diffuse reflection spectroscopy is a promising expedient for analytical chemistry. The possibility of this combination was first discussed by Dmitrienko and coworkers.^{63,64} It was shown²⁵ that PUF offer a number of advantages over other sorbents regarding their use in sorption–photometric and sorption–luminescence procedures and in test methods. First of all, this facilitates the final stage of analysis because the sorbate can be easily separated from other components present in the sorption system, which looks like a coloured tight pellet; owing to the uniform distribution of the analyte over the sorbent matrix, PUF pellets can be used without any additional operations.

In diffuse reflection spectroscopy, the Kubelka–Munk function (F) is related to the analytical signal, diffuse reflection (R), and the sorbate concentration in the following way:

$$F = \frac{(1 - R)^2}{2R} = 2.3 \varepsilon c s^{-1},$$

where $\varepsilon = n \times 10^4$ is the molar extinction coefficient of the sorbate ($n = 1\text{--}10$), c is the sorbate concentration, s is the light scattering coefficient. Methodical aspects of the quantitative measurements of the diffuse reflection of sorbates on PUF are considered in a paper.²⁴⁴ The main factors influencing the accuracy and reproducibility of diffuse reflection measurements, namely, sample layer thickness, sample humidity, the brand of the PUF used and the sorbate concentration, have been studied. For all the compounds studied, the Kubelka–Munk function was found to be linearly related to the sorbate concentration not only in the PUF matrix but also in aqueous solution within the limits of the linear sections of sorption isotherms. The limits of detection of intensely coloured ($\varepsilon \approx n \times 10^4$) compounds in the PUF matrix reach $n \times 10^{-2}$ μg in a $0.04\text{--}0.07$ g PUF pellet or $n \times 10^{-4}$ $\mu\text{g ml}^{-1}$ for a sample volume of $25\text{--}100$ ml.

Various methods are used to obtain a coloured compound in the sorbent phase. One method is based on the sorption on PUF of the coloured compounds formed in the solution under analysis upon the reaction between a specially added analytical reagent and the target component. Numerous publications have been devoted to determination of metal ions and organic compounds by this method. For example, in a sorption–photometric determination of cobalt^{63–65} and iron,^{63,64,69} they are transferred into coloured thiocyanate complexes and sorbed on PUF. The limits of detection are $n \times 10^{-3}$ $\mu\text{g ml}^{-1}$. To increase the selectivity of analysis, sorption is carried out in the presence of various masking compounds. A similar method was used to determine silicon as the oxidised and reduced forms of molybdosilicic acid with limits of detection of 3×10^{-3} and 1×10^{-2} $\mu\text{g ml}^{-1}$, respectively. A sorption–photometric procedure for determination of ionic sur-

factants using PUF is based on sorption of the associates formed by surfactants and coloured hydrophobic counter-ions. Sulphothalein dyes are used as the counter-ions in the determination of cationic surfactants,¹⁷³ while tris(1,10-phenanthroline)iron(II) was used for anionic surfactants.^{105,171} This procedure makes it possible to determine ionic surfactants present at a level of $n \times 10^{-2}$ $\mu\text{g ml}^{-1}$. A sorption and photometric method for determination of phenols and 1-naphthol is underlain by sorption of their coloured azo derivatives.^{161,163–165} Azo derivatives of phenols were synthesised by azo coupling with 4-nitrophenyldiazonium tetrafluoroborate. To enhance the recovery, sorption was carried out in the presence of cetyltrimethylammonium bromide. This procedure provides determination of phenols with limits of detection of $n \times 10^{-3}$ $\mu\text{g ml}^{-1}$.

The second method is related to the use of loaded PUF. In this case, the coloured compound is formed directly in the sorbent phase due to complexation or redox reactions between the target component present in an aqueous solution and an analytical reagent immobilised on PUF. Polyurethane foam loaded with dimethylglyoxime was proposed for sorption–photometric determination of nickel,^{64,206} and diphenylcarbazide-loaded PUF was proposed for chromium(VI) determination.^{64,231,232} A sorption–photometric determination of ascorbic acid is based on reduction of heteropolyacids immobilised on PUF.²⁴⁵ The procedure allows determination of 0.3 to 2.4 $\mu\text{g ml}^{-1}$ of ascorbic acid. The time of analysis is 75 min. When the reduction of heteropolyacid is carried out on exposure to microwave radiation, the duration of the analysis decreases to 6.5 min.²⁴⁶

The third method for preparation of coloured analytical forms in the PUF phase is based on chemisorption processes involving the terminal groups of these polymers. In this case, a higher selectivity is to be expected. This technique was used, for example, to determine nitrite ions¹⁸⁰ and free active chlorine¹⁸¹ in water.

4. Luminescence

A number of studies have been devoted to the use of PUF in luminescence analysis. The key factors influencing the intensity of fluorescence of sorbed molecules such as the thickness of the sample layer, sample humidity, the structure of the polymeric framework of PUF and the sorbate content have been studied in relation to the $[\text{Ru}(\text{Phen})_3]\text{Cl}_2$ complex, pyrene, rhodamine 3B, rhodamine 6G and butylrhodamine sorbed on PUF.^{244,247} It was found that the polymer framework of PUF has virtually no influence on the fluorescence emission and fluorescence excitation spectra of the sorbates; the spectra of sorbates on different PUF normally do not differ from one another and in most cases, they are similar to the spectra of these substances in aqueous solutions. The limits of detection of compounds with intense fluorescence in the PUF matrix are $n \times 10^{-3}$ μg (the weight of PUF $\approx 0.04\text{--}0.07$ g) or $n \times 10^{-5}$ $\mu\text{g ml}^{-1}$ for a sample volume of $25\text{--}100$ ml. The range of linearity of calibrating plots coincides, as a rule, with the initial linear sections of sorption isotherms and holds up to a change in the sorbate concentration by one to two orders of magnitude.

In most cases, compounds that luminesce on the sorbent surface (for example, metal complexes with organic ligands) are obtained by sorption from the solution in which they have been synthesised. A sorption–luminescence method for yttrium determination includes the formation of a complex with 8-hydroxyquinoline, sorption of the complex on PUF and measurement of the luminescence intensity at $510\text{--}513$ nm ($\lambda_{\text{excit}} = 398$ nm). The method was applied for determination of yttrium in lanthanum¹⁰⁰ and scandium¹⁰¹ oxides. In a highly sensitive sorption–luminescence method of selenium determination in soil, the target element is sorbed as 4,5-benzodiazoselenol, which is prepared by the reaction with 2,3-diaminonaphthalene.²⁴⁸ In a method for determination of Eu in scandium oxide, the mixed-ligand complex of this element with thenoyltrifluoroacetone and 1,10-phenanthroline is sorbed by polyurethane foam and then Eu is determined by luminescence directly in the sorbent, the limit of detection being

$1 \times 10^{-6} \%$.¹⁰⁶ Thallium is sorbed on PUF as the chloride complex, then the sorbate is treated with rivanol, a diamino derivative of acridine, and the fluorescence intensity is measured at 497 nm ($\lambda_{\text{excit}} = 367 \text{ nm}$).⁵¹ Only gallium is sorbed together with thallium. The analysis of these elements is not interfered with by the presence of large amounts (1 : 1000) of Cu, Co, Ni, Cd, Zn, Hg, In and La and alkali and alkaline earth metals; the limit of detection is $0.5 \mu\text{g litre}^{-1}$.

A method for determination of Cr(III) based on the quenching of fluorescence of rhodamine 6G sorbed on PUF has been described.²⁴⁹ The limit of detection equals 8 ng ml^{-1} for a sample volume of 25 ml.

A scheme of analysis has been proposed to perform fast screening of water samples for the content of PAH. According to this procedure, PAH are collected on PUF and their total amount is determined by the sorption-luminescence method.¹²⁵ Individual PAH are determined in the eluate after desorption of the sorbed impurities by acetonitrile using high-performance liquid chromatography (HPLC) with a fluorescence detector.²⁵

5. Atomic-absorption and atomic-emission spectroscopy

The preconcentration of elements by sorption on PUF is often combined with determination in eluates by atomic-absorption spectroscopy (AAS) and atomic-emission spectroscopy with inductively coupled plasma (ICP AES). The flame AAS method was applied to determine platinum⁴⁴ and thallium⁵⁰ after preconcentration of the elements as halide complexes on PUF followed by desorption on treatment with acetone.

Combination of group preconcentration of elements by sorption on PUF loaded with ammonium pyrrolidinedithiocarbamate (PUF-APDTC),^{220, 221, 223} a mixture of hexamethylenammonium hexamethylenedithiocarbamate with methyltriethylammonium chloride (MTOA)²²⁴ or on PUF loaded with sodium diethyldithiocarbamate²²² followed by determination of elements by non-flame AAS or ICP AES proved successful. A procedure for determination of As, Bi, Sb, Hg, Sn and Se in natural waters²²⁰ includes collection by sorption on columns with PUF-APDTC, elution of the element pyrrolidinedithiocarbamates with methanol, generation of hydrides directly in a methanol solution by the reaction with NaBH_4 and subsequent determination by ICP AES. The limits of detection of elements are, ng ml^{-1} : 0.2 (As), 30 (Bi), 0.03 (Se, Sb and Sn).

In determination of Cd, Co, Cu, Fe, Hg, Ni and Pb in high-purity oxalic acid,²²⁴ trace elements are concentrated under dynamic conditions on columns with PUF-APDTC or PUF-APDTC-MTOA; the degree of recovery of elements is higher than 97%. The components are desorbed by methyl isobutyl ketone (for AAS determination) or 4 M HNO_3 (for ICP AES determination). The limits of detection are 0.1 (Cd), 0.3 (Pb), 1 (Ni), 2 (Co and Cu) ng g^{-1} and 0.1 (Hg) $\mu\text{g g}^{-1}$ for non-flame AAS and 0.05 (Cd), 0.1 (Cu), 0.2 (Ni) and 1 (Pb) $\mu\text{g g}^{-1}$ for ICP AES.

The column version of the solid-phase extraction using PUF loaded with APDTC was used²²¹ to collect As, Bi, Hg, Sb, Se and Sn impurities in waters of various types. The degree of recovery of elements on passing of 150 ml of a sample ($\text{pH} \sim 4.5$) at a flow rate of 2 ml min^{-1} through a column was 97%–100%. After elution with methanol, the concentrate was analysed by ICP AES; the limits of detection were, ng ml^{-1} : 3 (As, Se), 8 (Bi), 0.12 (Hg), 2 (Sb) and 6 (Sn). It should be noted for comparison that the use of non-flame AAS after desorption of the elements with methyl isobutyl ketone decreased the limits of detection of elements down to 0.06 (As and Sb), 0.1 (Bi and Sn), 0.08 (Se) and 0.3 (Hg) ng ml^{-1} .

A method for lead determination in sea food has been proposed;²⁵⁰ lead is collected on a microcolumn packed with PUF loaded with 2-(2-benzothiazolylazo)-2-cresol, desorbed with 0.1 M HCl and determined by flame AAS. The limit of detection of lead by this method is $1 \mu\text{g l}^{-1}$.

A flow-injection system has been used²⁵¹ for atomic-absorption determination of zinc in waters and biological materials after preconcentration by sorption on a microcolumn packed with PUF.

6. X-Ray fluorescence spectroscopy

X-Ray fluorescence spectroscopy has been used to determine Ga,⁴¹ Co,^{58, 60} Fe, Pd, Pt and Zn.⁶⁰ As,⁸⁸ Ge,⁹⁰ PO_4^{3-} (see Refs 92, 93) methyl- and phenylmercury chloride, inorganic mercury²²⁶ and U.²⁵² Indirect determination of phosphorus on the basis of molybdenum or antimony after preconcentration on PUF as phosphomolybdate⁹² or molybdoantimonylphosphoric acid⁹³ has fairly low limits of detection (0.1 and $0.02 \mu\text{g ml}^{-1}$, respectively). The latter procedure is more selective: large amounts of silicon do not interfere with the determination of phosphorus. The relative standard deviation does not exceed 0.05. In an X-ray fluorescence determination of arsenic⁸⁸ and germanium,⁹⁰ they are transformed into arsenomolybdate and molybdogermanate, which are sorbed on PUF. The range of concentrations determined in this way is fairly broad: 0.5 – 3.5 and 0.25 – $35 \mu\text{g ml}^{-1}$, respectively. Arsenic can be determined in the presence of large amounts of PO_4^{3-} and SiO_4^{2-} (1 : 10) and an equal amount of germanium. The limits of detection are 40 and 70 ng ml^{-1} and the relative standard deviations do not exceed 0.07 and 0.09 for arsenic and germanium, respectively.

Determination of Co, Zn, Pd, Pt, Fe is carried out using sorption of their thiocyanates from acid solutions in the presence of NH_4Cl .⁶⁰ The ranges of linearity of the calibrating plots are rather narrow: 1–5 (Co, Zn, Fe) and 1–10 $\mu\text{g ml}^{-1}$ (Pd, Pt), the corresponding relative standard deviation being not more than 0.05. In sorption–X-ray fluorescence determination of chloride, methyl- and phenylmercury chloride, PUF loaded with sodium diethyldithiocarbamate is used.²²⁶

7. Neutron activation method

Direct determination of sorbed elements by neutron activation analysis (NAA) was shown to be, in principle, possible in a number of studies.^{14, 31, 227} The NAA method with a neutron flux density of $3 \times 10^{13} \text{ neutron cm}^{-2} \text{ s}^{-1}$ (irradiation for 10 min) allows determination of Au, In, Hg and Zn in the polyurethane foam matrix after collection of these elements from thiocyanate media.¹⁴ It was noted that irradiation of PUF for more than an hour results in polymer destruction; irradiation in H_2SO_4 leads to complete dissolution. Determination of gold in natural waters after sorption from 6 M HCl on ether-based polyurethane foams has been described.³¹ Neutron-activation determination of antimony is preceded by its isolation using PUF loaded with potassium diethyldithiocarbamate.²²⁷

8. Enzymic methods

In enzymic methods of analysis, PUF are used as polymeric supports for immobilised enzymes. A method for the immobilisation of cholinesterase comprising capture of an enzyme into a starch gel followed by impregnation of the gel into the PUF matrix has been proposed.²⁵³ An analytical system in which an enzymic minireactor is combined with an electrochemical sensor within one unit has been developed²⁵⁴ to determine toxic substances of the anticholinesterase action (for example, insecticides) in air and in liquid media. As the air or solution sample under analysis is pumped through the minireactor, the inhibitor is collected on the immobilised enzyme and inhibits it. The combination of preconcentration and analytical reaction in one unit with the sensor increases the method sensitivity and shortens the response time. The limit of detection of organophosphorus insecticides by such a system is 0.1 – 4.5 ng ml^{-1} , that for carbamates is 0.5 – 20 ng ml^{-1} .

A method for immobilisation of horse-radish peroxidase^{255, 256} and alkaline phosphatase²⁵⁷ in a chitosan film followed by impregnation into PUF has been developed. This procedure was used to develop highly sensitive test methods for

determination of mercury²⁵⁵ and organomercury compounds.²⁵⁶ The oxidation of *o*-dianisidine in the presence of thiourea by hydrogen peroxide is used as the indicator reaction. This procedure provides mercury(II) determination at a level of 1 ng ml^{-1} ; the lower limits of determination of methyl-, ethyl- and phenylmercury are 0.008, 0.01 and $25 \text{ } \mu\text{mol litre}^{-1}$.

A test procedure for determination of $0.05\text{--}10\,000 \text{ ng ml}^{-1}$ of lead has been described.²⁵⁷ In the development of this procedure, the inhibitory action of lead on the activity of PUF-immobilised alkaline phosphatase in the hydrolysis of *p*-nitrophenyl phosphate was utilised. It was noted that the key advantages of PUF over polystyrene and chromatographic paper used previously for enzyme immobilisation include a long (1–1.5 years) period of maintenance of enzyme activity; the researchers also noted good metrological characteristics of the developed procedures.

9. Chromatographic methods

The most important applications of PUF in chromatographic methods of analysis include preconcentration and isolation from waters and air of PAH,^{110–113, 117, 122, 124} PCB^{107, 121, 124, 131, 133, 153} and chlorine- and phosphorus-containing insecticides.^{127, 128, 133, 134, 152} After collection on PUF, organic compounds are determined using gas chromatography (GC) and HPLC in combination with various types of detector: flame ionisation (FID), electron capture (ECD), mass-spectrometric (GC/MS technique), N/P-selective and UV and fluorescence detectors. The existing chromatographic methods for the determination of trace amounts of organic compounds consist of several stages: collection of the trace elements on PUF, desorption, evaporation of the solvent and analysis of the concentrate.

Various solvents have been proposed for desorption of compounds from PUF: acetone,^{11, 107, 110, 117, 152} hexane,^{107, 133, 134, 153} methanol,¹¹⁷ an acetone–hexane mixture,¹³³ diethyl ether and petroleum ether.¹²¹ Solvent desorption is carried out in the Soxhlet apparatus for 18–24 h.^{107, 113, 115, 116, 118, 130, 132–134, 149} In some cases, samples are treated with ultrasound to intensify the process.¹²² Supercritical fluid extraction (SFE), which makes it possible to shorten the desorption time to 10–20 min,^{124, 156} and a method based on extraction of impurities with a small amount of an organic solvent after compression of PUF to 10% of its initial volume in a special column can provide alternatives to the prolonged and cumbersome procedure of Soxhlet desorption.¹²³ It has been shown¹²³ that 4 ml of dichloroethane or 6 ml of a 10% solution of acetone in hexane is sufficient for quantitative elution of eighteen PAH from a PUF sample with an initial volume of 115 cm^3 .

The preconcentration of organic compounds from waters is carried out in a dynamic regime; the flow rate reaches 270 ml min^{-1} . Traces of PAH are collected from water samples having large volumes (4–60 litres) using columns filled with one or several cylindrical inserts of PUF ($45 \times 45 \text{ mm}$).^{109, 110} A water sample heated to $62 \pm 2 \text{ }^\circ\text{C}$ is passed through a column at a flow rate of $250 \pm 10 \text{ ml min}^{-1}$. It was noted that pre-heating decreases the loss of PAH caused by co-precipitation on the suspended particles present in water samples.¹⁰⁹ For most of PAH including 3,4-benzopyrene, the degree of recovery amounts to 90%–98% for the model samples prepared from distilled water and 65%–85% for real potable or river water samples.^{109, 110} It was demonstrated in relation to 3,4-benzopyrene that PAH samples sorbed on PUF are stable for 7 days when the storage temperature is $4 \text{ }^\circ\text{C}$.¹⁰⁹ The PAH are desorbed by successive treatment with acetone and cyclohexane and determined by GC with a FID or by HPLC with a luminescence detector.^{110, 111}

The efficiency of PUF as sorbents for the isolation of PCB ($2\text{--}20 \text{ ng litre}^{-1}$) from natural water with a view to subsequent GC determination has been evaluated.^{107, 126–128, 135} When large sample volumes (up to 1790 litres) are passed through columns packed with PUF cylinders ($3.8 \times 2.2 \text{ cm}$) at a flow rate of

250 ml min^{-1} and then elution with acetone or hexane is carried out in a Soxhlet apparatus, 80%–100% of PCB is recovered. The influence of the flow rate on the degree of recovery of organic compounds under dynamic conditions has been studied. It was noted that an increase in the rate from 10 to 100 ml min^{-1} has no influence on the completeness of PCB recovery; however, an increase in the flow rate to 250 ml min^{-1} decreases the degree of recovery to 30%–60%.¹²⁸

Polyurethane foams are used to collect thirteen organochlorine insecticides (DDT, Lindane, Aldrin, *etc.*) and polychlorinated biphenyls by passing water through a ($20 \times 2 \text{ cm}$) column packed with PUF at a flow rate of 100 ml min^{-1} .^{127, 128} The collected compounds were washed out from the column by successive treatment with acetone and hexane and determined by chromatography.

Several types of samplers which allow a flow rate of $800 \text{ litres min}^{-1}$ to be reached have been developed for analysis of air.^{117, 118, 121, 128, 133–135} The samplers are stainless-steel, glass or plastic tubes filled with cylindrical inserts made of PUF, in some cases, in combination with other sorbents or with glass-fibre filters. Prior to the use, sorbents are subjected to prolonged (up to 24 h) purification by means of various organic solvents and water in the Soxhlet apparatus.^{113, 117, 133, 134} A large potential of portable samplers based on combination of PUF with other sorbents such as Tenax CG^{121, 135} and XAD-2^{118, 121, 128} for preconcentration of PAH, PCB and chlorine-, phosphorus- and nitrogen-containing insecticides in urban air samples has been demonstrated. For a sampling velocity of $0.1\text{--}0.3 \text{ m}^3 \text{ min}^{-1}$, the recovery of compounds is not less than 75%.¹²¹ After desorption with a diethyl ether–petroleum ether mixture (15 : 85)¹¹¹ or 5% diethyl ether in hexane¹³³ in a Soxhlet apparatus and evaporation of the solvent, the concentrate was analysed by various chromatographic methods: HPLC with UV detector and GC with ECD, PID and N/P-selective detectors. One sampler of this type was used to determine organochlorine compounds in the air above the Arctic.¹³⁴ Air samples with a volume from $300\text{--}600 \text{ m}^3$ to $2000\text{--}4000 \text{ m}^3$ were pumped through a sampler for a period from 8 h to 2–7 days at a flow rate of $750\text{--}800 \text{ litre min}^{-1}$. Solid particles were retained on the glass-fibre filter, while the vapours of organochlorine compounds were sorbed in two cylindrical PUF inserts. The impurity components were desorbed by 100–300 ml of hexane for 8 h in a Soxhlet apparatus, then the solvent was partially removed and the concentrations of the impurities were determined using GC with an ECD, GC/MS and HPLC with an UV detector. The Arctic air was found to contain various PCB isomers, DDT and other organochlorine compounds whose concentrations are several pg m^{-3} .

A method developed¹¹³ for determination of PAH in air at the ng m^{-3} level includes the following stages: preconcentration by sorption on PUF for 24–48 h at a flow rate of $0.5 \text{ m}^3 \text{ min}^{-1}$, successive elution with pentane and a mixture of dichloromethane (30%) with pentane, solvent evaporation from the eluate and analysis of the concentrate by GC/MS or by HPLC with a fluorescence detector.

A procedure for isolation, preconcentration and identification of volatile mutagens present in air has been described.¹¹⁷ The procedure includes sorption on PUF, elution with methanol or acetone, removal of the solvents, bioassays and analysis of the concentrate by GC/MS or by HPLC with a fluorescence detector.

Eighteen PAH were determined using GC/MS in exhaust gases after preconcentration for 20 min on a PUF-packed column and desorption with a small volume of dichloromethane or 10% of acetone in hexane.¹²³

Combination of the desorption of components collected on PUF using supercritical fluid extraction with subsequent determination of these components by the GC/MS technique was reported to be efficient.¹²⁴ This combination underlies a scheme for determination and identification of PAH, PCB and n-alkanes present in exhaust gases and the cigarette smoke. The scheme implies preconcentration of organic impurities on PUF followed

by desorption by the CO₂ fluid directly to the separating chromatographic column and allows gas-chromatographic analysis to be carried out over a period of less than an hour.

10. Test methods

The high efficiency of preconcentration by sorption on PUF of many compounds, the intensive colour of the sorbent observed in some cases, the ready availability and low cost of the sorbent are attractive features stipulating the use of PUF in test methods of analysis — simple and cheap methods for detection and determination of substances.²⁵⁸ A colour change of the sorbent after the reaction indicates the presence of the target component, and the content of the component is found by comparing the intensity of the sorbent colour with the appropriate scale or by measuring the length of the coloured zone or the time it takes for the characteristic colour to appear. The reliability of visual detection can be improved in some cases using portable miniphotometers which record light reflection from solid samples.

The possibility of using PUF in test methods of analysis was first mentioned by Braun and Farag.²¹⁸ Determination was preceded by element preconcentration on chromofoams (the term was introduced by Braun²¹⁸), *i.e.*, PUF loaded with photometric reagents. When these foams, as small cubes, are brought in contact with the solution under analysis, the white polymer acquires a colour typical of the given photometric reaction. These reactions are highly sensitive, for example, for sorption in the static regime, tenths (Co,²¹⁸ Cu,^{214, 218, 233} Cd,²¹⁴ Pd,²³³ Pb,^{218, 219} Cr,²³⁰ Mo²³⁴) and in some cases, even hundredths (Ag,²¹¹ Ni,²⁰⁵ Cu,²¹⁴ Zn,²¹⁸ PO₄⁹⁴) of a microgram of an impurity can be determined in a sample volume not exceeding 1–2 ml. The sensitivity of determination increases by at least an order of magnitude when Co,²¹⁸ Cu,²¹⁸ Cd,²¹⁴ Cr²³⁰ and Mo²³⁴ are sorbed in the dynamic regime. Detection of metals at a level of several nanograms in ml is attained by passing relatively large volumes of a solution (~1 litre) through a chromofoam filled column. The use of these materials ensures higher sensitivity of analysis than the use of impregnated paper or than drop reactions.^{205, 214, 218, 219, 230} Chromofoams are also suitable for a semi-quantitative determination, which implies either comparison with standard colour scales after sorption in the static regime or measurement of the length of the coloured zone in the column after letting-through the solution under analysis. Usually, the colour intensity of chromofoams is linearly related to the metal concentration in the aqueous solution.

One more way of using these sorbents in test methods of analysis, not associated with the preparation of loaded PUF, is also possible. Pellets of unloaded PUF complete with ampoules containing solutions of reagents have been used as test kits.^{105, 163, 165, 172, 180, 181} The reproducibility of the results of visual detection based on a colour scale (*s_r*) varies in the range of 0.1–0.5. Test kits based on PUF for determination of Co, Ni, Fe(III), nitrite ions, free active chlorine, total content of phenols, and anionic and cationic surfactants have passed metrological certification, have been registered as a type of test system²⁵⁹ and are currently produced in industry. The test systems based on PUF are simple to produce, reliable in operation and suitable for determination of toxic substances in waters of various types including potable and mineral waters, extracts from soils or juices. If necessary, the test form can be retained and analysed in a laboratory using diffuse reflection spectroscopy or, after desorption of compounds, HPLC.¹⁶⁵

VII. Conclusion

The presented data demonstrate that polyurethane foams are of considerable interest for the analytical chemistry of inorganic and organic compounds. Characteristic features of these sorbents include high efficiency in combination with versatility, chemical and mechanical strength, stability against organic solvents, relatively low cost and ready availability. The unique sorption

properties of synthetic polymeric materials are largely due to their cellular membrane-like structure, which allows the molecules being sorbed to penetrate inside the sorbent, and to the combination of various hydrophilic and hydrophobic active sites and reactive terminal groups.

The applications of PUF in analytical chemistry are diverse. These sorbents are used for preconcentration of elements and organic substances from water and air and in spectroscopic, sorption–spectroscopic and chromatographic methods of analysis. The good prospects of using PUF in flow-injection analysis are demonstrated. Other applications of these materials are also noted, including the use as polymer matrices for enzyme immobilisation in enzymic methods of analysis.

Polyurethane foams are of interest not only regarding practical use but also in purely scientific aspects. In our opinion, the scope of application of PUF in analytical chemistry has not been adequately appreciated because most studies are aimed at the solution of applied problems of substance preconcentration and only few publications deal with investigation of physicochemical processes that proceed during sorption. Too little attention is devoted to elucidation of the relationship between sorption parameters and the properties of the sorbed molecules and evaluation of the contributions of intermolecular sorbent–sorbate interactions. Virtually no works are related to the study of physicochemical properties of the polyurethane foams themselves.

The study of heterogeneous chemical reactions involving the PUF surface are of considerable interest. This line of research, which is successfully developing in other fields of chemistry, can provide important results that would allow one to approach the problem of target-directed change of the properties of PUF by surface modification.

One may hope that PUF would be used more and more extensively in hybrid methods of analysis based on the combination of preconcentration by sorption with the subsequent determination in the sorbent matrix using diffuse reflection spectroscopy, luminescence or X-ray fluorescence spectroscopy and in test methods of analysis.

This review was supported by the Russian Foundation for Basic Research (Project No. 01-03-33102).

Abstract. The discovery of a new allotropic form of carbon, extended nanometre-sized quasi-unidimensional tubular structures (carbon nanotubes), as well as broad prospects for the use of nanomaterials based on them initiated numerous studies in the search for, and design of, nanotubular structures based in other compounds. Some properties and the main methods for the synthesis of non-carbon nanotubes are considered. Studies on the simulation of the electronic structures of these unique objects are analysed. Results of experimental and theoretical studies along these lines are discussed. The bibliography includes 328 references.

I. Introduction

Intense studies on the nanotubular form of matter [tubulenes or nanotubes (NT)] have started following the discovery in 1991 of hollow cylindrical carbon-based structures, the lengths of which were several orders greater than their diameters, in cathodic condensates formed upon electrical arc discharge between graphite electrodes.¹ The new quasi-unidimensional carbon cluster was called 'fullerene tubulene' and its electronic spectrum (ES) was calculated.² It was found that the electronic spectrum of the carbon tube studied was characteristic of metals.

From the very beginning, considerable attention by experimenters and theoreticians was given to nanotubes as representatives of a new quasi-unidimensional allotropic modification of carbon in the series of previously known modifications, *viz.*, 3D (diamond) → 2D (graphite) → 1D (carbyne) → 0D (fullerene). With time, nanotubes, which were exotic objects of unique experiments and theoretical calculations, became the subject of numerous physicochemical studies; their unusual properties became the basis for many daring technological solutions. At present, NT find broad practical application; now they are commercial products and are subject to marketing studies.

Data on the structures and properties of carbon nanotubes, on the methods of their synthesis and on their uses can be found in many publications; they have been generalised in a number of monographs (see, *e.g.*, Refs 3–7) and in many reviews (see, *e.g.*, Refs 8–32).

In a number of reviews recently published in Russian scientific journals,^{15, 16, 21, 24–27} the methods of synthesis and study of carbon NT were discussed.^{15, 16} The main principles of the theoretical simulation of the geometrical and electronic structures of NT were described in a monograph⁷ and in papers.^{21, 26} The methods for the synthesis of such NT were described in detail by Rakov.²⁴ He also reported the most recent data on the chemistry and application of carbon NT considered as promising materials for modern technologies. Tarasov *et al.*²⁵ discussed the possibility of use of NT as 'tanks' for the storage of hydrogen. Basic information about carbon NT can be found elsewhere.^{33, 34}

Shortly after the paper by Iijima¹ was published, scientists were challenged by a number of questions that are of major importance to the development of the physics and chemistry of NT and for the prospects of their practical application.

1. What is the nature of NT and what is the mechanism according to which they are formed? Are there any physical or chemical restrictions limiting the scope of compounds which can be obtained in a nanotubular form?

2. What physicochemical properties should a compound possess to be a potential initial substance for the synthesis of NT?

3. What are the specific features of methods that can be used to obtain non-carbon NT? What is their value in materials science and technology?

From the very start, the concept of non-carbon NT was developed due to combined efforts of experimenters (syntheses of NT and studies of their functional characteristics) and theoreticians (simulations of new nanotube forms, prediction of their structures and properties).

In 1992, the first non-carbon NT based on lamellar molybdenum and tungsten disulfides were synthesised.³⁵ In 1994, the possibility of existence of tubulenes based on hexagonal boron nitride (BN-nanotubulenes) was predicted.^{36–38} Their dielectric properties were presumed to remain stable upon changes in their geometrical characteristics. This prediction was very important for the development of nanoelectronics; it initiated numerous studies on the synthesis of such NT.

A large number of non-carbon NT have been synthesised to date or their existence has been predicted. In addition to the NT mentioned above, others based on germanium silicide and tran-

A L Ivanovskii Institute of Solid State Chemistry, Urals Branch of the Russian Academy of Sciences, ul. Pervomaiskaya 91, 620219 Ekaterinburg, Russian Federation. Fax (7-343) 274 44 95. Tel. (7-343) 274 53 31. E-mail: ivanovskii@ihim.uran.ru

sition metal dichalcogenides, sulfides and chlorides have been synthesised. The molecular and electronic structures of various hypothetical NT containing boron, phosphorus, silicon, germanium and transition metal diborides were simulated; the mechanisms of their growth were discussed and the properties of certain nanotubular structures were studied.

Boron–nitrogen and dichalcogen-containing NT were the subject of special analysis.^{12, 29} Some data on the synthesis and properties of non-carbon NT can be found in monographs^{5, 7, 8} and reviews^{11, 14, 19, 21, 24} devoted to carbon tubulenes.

The present review discusses the general state of studies on the synthesis and simulation of the molecular and electronic structures of non-carbon NT which were developed most intensely in the last years.

Along with the ‘purely non-carbon’ NT listed above, we also consider the class of ‘transitional’ nanotubular structures containing both carbon and other *p*-elements (boron, nitrogen and silicon). These NT possessing diverse properties can either be obtained together with carbon NT within the same synthetic procedure or synthesised using methods specifically developed for this purpose. Of these, chemical substitution is the most promising method in which carbon NT are used as the starting material.

The overwhelming majority of non-carbon NT have been obtained (or their synthesis is anticipated) on the basis of compounds that, like carbon, have lamellar (quasi-two-dimensional) crystal structures. Therefore, classifications and descriptions of atomic structures of non-carbon NT are performed, and their geometrical models are built,^{7, 12, 21, 29} on the basis of the concepts and methods developed for carbon NT.^{3–10, 15–32} Let us summarise briefly those to be employed below.

Ideal carbon NT have the form of cylinders whose walls are formed by hexagons, with carbon atoms in the vertices. The process of formation of a nanotubulene can be visualised as the rolling of a ‘band’ of carbon atoms cut out of a graphite monolayer (graphene network). A graphite layer can be ‘cut’ in different ways: along lines which are perpendicular to the C–C bonds or pass through these bonds, or else at a definite angle, namely the so-called chiral angle θ (Fig. 1*a*). As the resulting ‘bands’ roll and their edges are linked together, two main NT types appear, *viz.*, non-chiral and chiral. The so-called zigzag and dented non-chiral NT are distinguishable. The structures of the main NT types are shown in Fig. 1*b*.

Using the base vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ of the graphene network, the following vector can be defined:

$$\mathbf{c}_h = n\mathbf{a}_1 + m\mathbf{a}_2.$$

The main geometrical parameters of a tubulene, *i.e.*, the diameter (D) and the chiral angle (θ), are related unambiguously to the base vectors of the graphene network through the following relationships involving the indices n and m :

$$D = \frac{|\mathbf{c}_h|}{\pi} = a\sqrt{\frac{3(n^2 + m^2 + mn)}{\pi}},$$

$$\theta = \arctan\left(-\frac{\sqrt{3}m}{2n + m}\right),$$

where a indicates the interatomic distances in the planar network.

In terms of these indices, the corresponding NT are denoted as (n, m) -NT. All (n, m) -NT with $0 < \theta < 30^\circ$ are regarded as chiral (spiral). Non-chiral NT have $\theta = 0$ and 30° . At $\theta = 0$, a family of zigzag-shaped $(n, 0)$ -NT is formed; these were named according to the type of tube ‘cross-section’ (see Fig. 1). The chiral angle for the dented (n, n) -NT equals 30° .

The NT ends may be open or closed by ‘caps’ formed by fullerene hemispheres. Other (*e.g.*, conical) ‘cap’ types are also possible. Single-layer and multilayer NT are known. The latter can consist of a system of concentric tubulenes or have a scroll-type structure. Nanotubes can be single or form diverse aggregates

Figure 1. Model for the NT formation upon graphene layer rolling into a cylinder (*a*) and nanotube types (*b*).

NT: (1) non-chiral dented (n, n) ; (2) chiral (n, m) ; (3) nonchiral zigzag-like $(n, 0)$.

(braids, splices, *etc.*) that may involve other nanospecies (fullerenes). Many possible aggregates formed by carbon NT are described in a review by Rakov.²⁴ The majority of NT contain various defects (topological defects, rehybridisation defects, ‘broken’ bonds). Directed introduction of defects into NT makes it possible to adjust flexibly their functional properties. More detailed information about NT types, their geometry, and their properties mentioned above can be found in a number of papers.^{3–32}

The material of this review is organised according to the following scheme. First, modern methods for the synthesis of non-carbon NT are considered. Further, we describe methods for the preparation of nanotubulenes from *p*-element compounds (BN, BC_x , CN_x , $\text{B}_x\text{C}_y\text{N}_z$), which are most structurally similar to carbon NT, and other classes of chemical compounds (transition metal dichalcogenides and oxides). Finally, we characterise methods (template synthesis and film ‘folding’) which are rather versatile and can be suitable for the synthesis of NT based on various melts and inorganic compounds.

After that, we discuss the results of theoretical simulation of the molecular and electronic structures of non-carbon NT by the methods of quantum chemistry and molecular dynamics. Data on the structural features and possible methods for the synthesis of hypothetical NT based on boron, silicon, phosphorus, CN_x , GaN, transition metal dichalcogenides and diborides and ‘hybrid’ nanotubular structures are considered. Special attention is paid to predictions of NT stability and properties. Data on the electronic properties of a number of NT formed in the B–C–N system are briefly discussed.^{7, 21}

Data about the physicochemical properties of non-carbon NT are far from being exhaustive yet, and their analysis is beyond the scope of this review. Some of the most interesting parameters of certain groups of non-carbon NT are briefly mentioned in the corresponding sections.

II. Methods for the synthesis of non-carbon nanotubes

1. Synthesis of nanotubes in the B–C–N system

The structures of nanotubes formed in the B–C–N system are similar to those of carbon tubulenes. The review of the methods for the synthesis of such non-carbon NT is given using the sequence in which the methods for the synthesis of carbon NT were considered by Rakov.²⁴ This will allow us to compare the potential of ‘traditional’ (for carbon NT) synthetic methods to that of new methods suggested for the synthesis of non-carbon NT.

a. Electric arc synthesis

Electric arc synthesis is the simplest method widely used for the synthesis of carbon NT (see Refs 9, 11, 15, 16, 24, 32). Numerous attempts to use this method for the synthesis of nanotubulenes in the B–C–N system have been reported. Of course, the standard method^{11, 15, 24} should be modified so as to ensure the introduction of not only carbon but also boron and nitrogen into the reaction zone. As a rule, this is done using an appropriate composition of air (*e.g.*, the synthesis is performed in a flow of nitrogen) and/or of the electrode.

Since boron nitrides are insulators,^{7, 36–38} in pure form they are unsuitable for the preparation of electrodes. BN-Nanotubulenes were first obtained in an electric arc discharge (in a helium atmosphere) between a copper cathode and an anode made of boron nitride enclosed in a tungsten shell.³⁹ The cathodic deposit was found to contain a wide variety of boron–nitrogen nanostructures with diverse morphology, including BN-nanotubulenes. The tubes consisted of a number of layers (the inner and outer diameters varied from 1 to 3 and from 6 to 8 nm, respectively, and the distance between the walls was ~ 0.33 nm); their lengths exceeded 200 nm. The ends of NT were ‘capped’ with tungsten-containing nanoparticles (which presumably consisted of tungsten borides or nitrides). The growth mechanism of BN-nanotubulenes was assumed³⁹ to involve catalysis by metal atoms.

A number of boron-containing phases, *e.g.*, ZrB₂ and HfB₂, have been studied as electrodes for the electric arc synthesis of NT in a flow of nitrogen.^{40–43} In the latter case, the plasma contained metal atoms, which could serve as growth catalysts for BN-nanotubulenes.

Cumings⁴⁴ reported a high-performance method for the synthesis of NT based on BN; the electrodes consisted of elementary boron (99 at.%) and admixtures of cobalt or nickel (up to 1 at.%), which served as catalysts. The pressure of nitrogen in the chamber was kept at 380 Torr; the current was 60 A. The residue on the cathode arranged on the bottom of the chamber was grey; a thin layer of the product was also found on the chamber walls. Analysis of the structure of the product obtained showed that it contained only double-layer NT (with diameters of the outer and inner BN-cylinders equal to 2.9 and 2.2 nm, respectively, and with a distance of ~ 0.37 nm between their walls). These tubes formed bunches (bundles). No metal admixtures were found in the NT; the stoichiometric composition of the tubes matched the ratio B:N = 1:1. It should be noted that double-layer NT were also obtained from BN using HfB₂ cathodes.⁴⁰ The growth mechanism and kinetics of such double-layer NT have not been ascertained.

Using scanning electron microscopy (SEM), it was found that NT bundles are often joined to form ‘knots’ that have their own structures. These junctions consist of boron nanocrystals coated by multilayer shells, *i.e.*, the specific cocoons. Nano-cocoon layers are formed by graphite-like boron nitride. Cumings⁴⁴ suggested a method for removal of boron nanocrystallites from nanococoons; as a result, the latter become empty and resemble the well-known carbon ‘onion-bulb’ structures, the so-called onions.^{3–6} It was suggested that hollow BN-nanococoons should be considered as a new nanomaterial for chemical and electrochemical industries. It

is possible to vary the properties of such material deliberately by filling the cocoons with definite atoms or molecules.

Vaporisation of porous BC₄N was accompanied by simultaneous formation of carbon, BN- and mixed BNC-nanotubulenes;⁴⁵ however, homogeneous boron carbonitride NT could not be obtained, probably, because of differences between the vapour pressures of gaseous boron nitrides and carbon.

b. Laser synthesis

In addition to such methods to obtain carbon NT as vaporisation of the target (graphite) under electron and ion beams, sunlight, Joule heat (resistance vaporisation), yet another method became popular,²⁴ *viz.*, ablation of targets under laser irradiation. Attempts to use laser irradiation for the synthesis of nanotubulenes containing B, C and N have been reported.^{46, 47} Hexagonal BN served as the target and high pressure of nitrogen was maintained in the chamber. The products contained BN-nanotubulenes and particles of cubical boron nitrides. A CO₂ laser was used to synthesise single-layer BN-nanotubulenes on a multigram scale.⁴⁸ It was found that the zigzag-shaped tubes form bunches; furthermore, small amounts of double-layer BN-nanotubulenes and fullerene-like clusters of boron nitride were detected.

Nanotubes (and nanoparticles) containing B, C and N atoms were also obtained by other methods of target irradiation. For example, electron microscopy allowed Golberg *et al.*⁴⁹ to observe *in situ* the formation of single- and multi-shell fullerene-type nanoparticles of boron carbide upon exposure of lamellar BC₃ to an electron beam; it cannot be ruled out that a densely packed structure, *viz.*, diamond doped with boron, was formed inside these particles. Proton–ion bombardment of boron pyronitride resulted in a microcomposite material which incorporated blocks of BN-nanotubulenes and possessed enhanced plasticity.⁵⁰

c. Pyrolytic synthesis

Catalytic pyrolysis of hydrocarbons in the presence of metal catalysts is becoming one of the most widespread and promising methods for the synthesis of carbon NT.²⁴

Pyrolysis of a CH₃CN–BCl₃ system in the presence of a cobalt powder at ~ 1270 K was first used⁵¹ to obtain nanotubulenes and nanofibres with diverse morphologies and compositions. More detailed studies⁵² of the reaction

showed that its products contained NT whose composition was close to BC₂N. However, the composition homogeneity was violated considerably in the NT walls and spontaneous separation occurred (presumably, during the NT growth) to give C/BN ‘islets’. The most stable NT contained BN layers separated by graphite-like carbon layers.⁵²

Sen *et al.*⁵³ found systems suitable for the synthesis of BCN- and CN-nanotubes using the pyrolytic method. These were obtained using the 1:1 (CH₃)₃N–BH₃ adduct and pyridine, respectively. The reactions were carried out at ~ 1270 K with cobalt as a catalyst. The products contained nanotubes with diverse chemical compositions and morphologies.

Pyrolysis of a mixture of acetylene with diborane (in an atmosphere of helium and hydrogen)⁵⁴ gave boron-containing carbon NT whose compositions varied from C₃₅B to C₅₀B. The boron content in such tubes was close to the nitrogen content in CN-nanotubulenes.⁵³ Nitrogen-containing carbon NT were also found in products of catalytic pyrolysis of triazine.⁵⁵ Ma *et al.*^{56, 57} used B₄N₃O₂H as the precursor for the synthesis of BN-nanotubulenes.

d. Substitution reactions

Han *et al.*^{58–60} described a new chemical method for the synthesis of NT based on replacement of carbon atoms by nitrogen and/or boron atoms in carbon NT. Carbon tubes obtained by one of the known technologies were used as the starting materials. This

method was employed to obtain a wide variety of boron–carbon (B_xC_{1-x}), boron–carbon–nitrogen ($B_xC_{1-x-y}N_y$) and boron–nitrogen (BN) multi- and single-layer NT, as well as their bundles.^{58–66}

For example, Han *et al.*⁶⁰ synthesised ($B_xC_{1-x-y}N_y$)-nanotubes using a mixture of B_2O_3 with a product of arc synthesis which contained up to 70% carbon NT, together with fullerene-like nanoclusters and amorphous carbon with an admixture of particles of the metal catalysts (Fe/Ni). The reactions were carried out in a flow of nitrogen in the temperature range 1523–1803 K. The products were analysed using transmission electron microscopy and electron energy loss spectroscopy (EELS) (Fig. 2).

Figure 2. Electron energy loss spectra for the original carbon NT (a), NT with the composition B_xC_{1-x} ($x \approx 0.1$) (b), 'stoichiometric' BN-nanotubulenes (c), nanotubes $B_xC_{1-x-y}N_y$ ($x = y \approx 0.1$) (d) obtained by chemical substitution.⁶⁰

The characteristic peaks in the spectra correspond to the presence of the respective elements, *viz.*, B, C and N.

Heating at 1523 K for 30 min resulted exclusively in boron–carbon NT (with the ratio B:C ≈ 0.1) joined as bundles. A mixture of single-layer (B_xC_{1-x}), ($B_xC_{1-x-y}N_y$)- and BN-nanotubulenes was obtained at higher temperatures (~ 1623 K). On subsequent increase in temperature (to 1803 K), the original carbon NT was destroyed completely; the resulting major fraction was a mixture of hexagonal, rhombohedral and turbostratic boron nitride with insignificant admixtures of nano-sized BN-structures: nanocones, polyhedral nanoclusters and nanofibres. No formation of BN-nanotubulenes was detected. The morphology of the BCN-nanotubulenes obtained resembled that of the original carbon NT in many respects. ($B_xC_{1-x-y}N_y$)-Nanotubulenes were also obtained⁶⁷ as reaction products of carbon nanotubulenes and CN_x -nanotubulenes with B_2O_3 and ammonia. The reactions leading to BC- and BN-nanotubulenes can be described^{58,59} by the following equations:

The maximum boron content in (B_xC_{1-x})-nanotubulenes did not exceed ~ 10 at.%. The bundles in ($B_xC_{1-x-y}N_y$)-nanotubulenes differed in the C : (B + N) ratios (Fig. 3). In certain cases, the 'stoichiometry' of N : B ≈ 1.0 was reached. This is due to the selective character of substitution:⁶⁰ the probability that 'pure' BN-nanotubulenes (or, at least, boron–nitrogen clusters in the

Figure 3. Composition histogram of multilayer BCN-nanotubulenes synthesised by chemical substitution from carbon NT (at 1773 K in a flow of nitrogen),⁶³ (a) without oxides, (b) in the presence of MoO_3 .

walls of the original carbon NT) are formed is much higher than the probability of NT formation if the replacement of carbon atoms by boron and nitrogen is purely statistical.

An interesting result was obtained by Han *et al.*⁶⁰ Inside single-layer BN-nanotubulenes, endohedral polyhedral BN-nanoclusters, described as four-shell octahedral BN-fullerenes with the composition $B_{12}N_{12}@B_{76}N_{76}@B_{208}N_{208}@B_{412}N_{412}$ (resembling carbon onion structures), were detected.⁶⁸ Similar hybrid nanotubular structures consisting of fullerenes located inside carbon NT ($C_n@C$) and carbon NT incorporating endofullerene chains ($M@C_n@C$) were also reported.^{69,70}

Attractive features of the method suggested by Han *et al.*^{58–61} are its ease and efficiency. The potential of the method is only limited by the amount of the original material available, *viz.*, carbon NT. Yet another important factor is the fixed size of the NT obtained in the system B–C–N, which is determined by the parameters of the matrices, *i.e.*, the carbon NT. The obvious drawback of the method is that it is difficult to synthesise NT with homogeneous chemical compositions.

This method was further developed^{63,65,66} and used for the synthesis of bundles of multilayer BN-nanotubulenes. A mixture of carbon NT and boric anhydride was complemented with MoO_3 (see Ref. 63) or a mixture of MoO_3 with PbO (see Ref. 65) or MoO_3 with V_2O_5 ;⁶⁶ the process was conducted in a flow of nitrogen at 1503–1773 K. Analysis of the reaction product involving molybdenum trioxide by transmission electron microscopy (TEM) showed that it contained bundles of multilayer BN-nanotubulenes, the major fraction of which (up to $\sim 82\%$) had non-chiral zigzag geometry.⁶⁶ The ends of such NT were open in contrast to the NT obtained^{58–60} in the absence of metal oxides.

The following scenario of the growth of BN-nanotubulenes was suggested,⁶⁶ taking into consideration that transition metal oxides are efficient oxidants for carbon. In the first stage, the terminal structures ('caps'), which close the carbon NT, are removed.

As a result, the gas phase can access the intra- and interlayer space of multilayer carbon NT. Further, carbon is simultaneously replaced outside and inside the carbon NT (Fig. 4). These

Figure 4. Scheme of the reaction of oxides and N_2 with multilayer carbon NT (a) in the reaction with its 'open' end (b) and its side surface (c) during chemical substitution in the synthesis of BN-nanotubulenes.⁶⁶

processes mostly involve the diffusion mechanism;⁷¹ as a result, growth of BN-nanotubulenes occurs.

High-resolution TEM was used to study the structure of BN-nanotubulene bundles obtained in the presence of PbO as the activator.⁷² All NT had zigzag geometry, their diameters ranged from 20 to 30 nm and their axes were arranged strictly parallel. It was suggested to consider this product as a new nanomaterial. It is characterised by invariable dielectric parameters and low chemical reactivity (in comparison with carbon NT).

High-resolution TEM analysis of the structures of multilayer BN-nanotubulenes showed that 'packs' of adjacent layers with hexagonal and rhombohedral types coexist, the wall structure changes from dented to zigzag-shaped and noticeable polygonisation of NT cross-sections takes place.⁷³

The substitution method was also used to obtain 'nanocables', i.e., BN-nanotubulenes filled with an alloy of Ni (40%) and Fe (60%).⁷⁴ In the first stage, carbon NT with nanoparticles of the alloy at the ends were obtained. These NT were then placed in a mixture of gaseous B_2O_3 and N_2 and kept for 30 min at the melting point of the alloy (1723 K). Two processes occurred simultaneously, viz., filling of the cavities with the iron–nickel alloy (due to the capillary effect), and change in the composition of the tube ('shell') due to chemical substitution.

It should be noted that the first SiC-nanotubulenes were obtained using the substitution reaction.⁷⁵ Large-diameter carbon NT and gaseous SiO were used as the starting materials.

e. Miscellaneous methods

A number of methods for the synthesis of BCN-nanotubulenes based on thermal reactions have been suggested.

Carbothermal reduction of amorphous boron oxide with simultaneous nitridation (at 1373–1723 K)⁷⁶ gave a product containing cylindrical BN-nanotubulenes with various configurations (including bent or kinked ones, T-shaped, 'bamboo-shaped') and nanostructures in the form of concentric truncated cones. The overall reaction can be described by the following equation:

Cylindrical (closed) multilayer NT formed bundles; their junctions contained multi-shell onion-type BN-particles which served as growth centres. The tube diameters ranged from 10 to 500 nm; the length-to-diameter ratios ranged from 3 to 30. Nanotubes grew both in the gas and in the solid phase. The growth of bamboo-shaped NT involved alternation of cylindrical and onion-type fragments:

It was assumed that certain structures incorporated B_3N_4 heptagons, which ensured contacts at the junctions of cylindrical fragments. The obvious drawback of this synthetic method is that the forms of the nanotubulenes obtained are too diverse and that no method to control the formation of NT with required parameters is available.

Nanotubes and nanocones based on BN were also obtained by thermal treatment of rhombohedral β -boron at 1470 K in the presence of graphite-like boron nitride and lithium vapour.⁷⁷ Growth of zigzag-shaped NT was observed at the edges of graphite-like BN particles. BN-Nanofibres were found to appear upon annealing (~ 2000 – 2370 K) of BN powder in the presence of iron.⁷⁸

2. Dichalcogenide nanotubulenes

Transition metals dichalcogenides MX_2 ($X = S, Se, Te$) were the first inorganic compounds to attract the attention of researchers as compounds that are potentially suitable for the synthesis of tubular nanostructures. These compounds have a distinct quasi-two-dimensional structure. For example, molybdenum and tungsten disulfides have lamellar structures (of the MoS_2 type, space group $P6_3/mmc$) consisting of packs of $S-(Mo,W)-S$ layers; the metal atoms are in a trigonal-prismatic environment⁷⁹ and the layers are packed due to van der Waals forces.

Numerous NT based on tungsten, molybdenum and niobium dichalcogenides have been synthesised to date, mostly by chemical methods.

The formation of fullerene-like species and fragments of cylindrical nanostructures consisting of WS_2 and MoS_2 was first observed upon thermal treatment of tungsten or molybdenum films on quartz substrates in a flow of H_2S/H_2 .^{35,80} Remskar *et al.*^{81,82} used chemical transport reactions to obtain MoS_2 and WS_2 cylindrical nanocrystals and tubular structures (MoS_2 microtubes several millimetres long with wall thickness smaller than 0.1 μm). Galvan *et al.*^{83–85} proposed a low-temperature ($< 100^\circ C$) activation method to obtain WS_2 -nanotubulenes involving treatment of condensed tungsten disulfide with concentrated nitric acid. A new material consisting of WS_2 -based NT was obtained using WO_x nanoparticles.⁸⁵

In the synthesis of fullerene-like molybdenum disulfide particles, a gas phase reaction of MoO_{3-x} with H_2S at 1073–1223 K gave MoS_2 -nanotubulenes as side products.^{86,87} The tubes consisted of 5–10 MoS_2 layers on average, were several micrometres long and were mixed with MoS_2 (2H-polytype).

The methods for the preparation of dichalcogenide nanotubes (and nanofibres) and for the synthesis of fullerene-like polyhedral particles of these compounds are being developed in parallel.⁸⁸ Both NT and polyhedral hollow or filled nanoparticles of d -metal dichalcogenides are often obtained in a single experiment.

Molybdenum disulfide particles with 3–5 nm diameters were synthesised⁸⁹ by laser ablation of MoS_2 targets. Laser-induced vaporisation of tungsten and molybdenum disulfides in argon at 720–1320 K gave⁹⁰ various hollow and metal-filled multilayer nanoparticles. For example, the major fraction obtained upon vaporisation of WS_2 at 1320 K consisted of nanoparticles with 10–15 nm diameters containing 4–8 concentric layers of WS_2 . The bulk of filled nanoparticles was found to contain a stabilised β -W phase, which is unstable under ordinary conditions, as the filler metal. In addition, the products contained tubular nanostructures.

Certain properties of dichalcogenide NT were summarised in a review by Zhu *et al.*⁸⁸ Hollow WS₂-onions are promising as solid lubricants;^{89,91} their tribological properties can be optimised by filling the cavities with tungsten carbide. The synthesis of such 'composite' particles is based on the pyrolysis of WC nanoparticles in hydrogen sulfide.⁹²

The properties of MS₂-nanotubulenes have not been studied in sufficient detail. It was found that disulfide nanotubes are semiconductors; they possess low chemical reactivities.⁹³ Normally, multilayer NT contain numerous defects in the outer layers, whereas the inner walls generally have nearly ideal structures, which is reflected in the conducting properties of NT.^{94–96} The coalescence and the growth mechanism of WS₂-nanotubulenes to give 'braids' have been studied;⁹⁷ a method for changing the conducting properties of these NT under the effect of the substrate was suggested.⁹⁸ The application of WS₂-nanotubulenes in scanning microscopy was discussed;⁹⁹ several versions of the growth mechanism of these NT were suggested¹⁰⁰ and the adsorption of methane on their surfaces was studied.¹⁰¹

In addition to the syntheses of nanotubulenes based on transition metal disulfides, attempts were undertaken to obtain nanostructures of other dichalcogenides as well. For example, bombardment of niobium diselenide with electrons resulted in NbSe₂-nanotubulenes, a few nanometres long, closed on one end.^{101,102} By varying the accelerating voltage and the current density, NbSe₂-onions were obtained as well. A similar technique was used successfully to synthesise MoTe₂- (Refs 103–106) and WSe₂-nanotubulenes.¹⁰² Nath and Rao¹⁰⁷ considered a method to obtain NT by reduction of tungsten and niobium triselenides or by decomposition of ammonium selenometallates in an atmosphere of hydrogen. Recently, methods for the preparation of CuInS₂-nanotubulenes¹⁰⁸ and Bi₃Se₄-nanorods¹⁰⁹ were proposed.

3. Oxide nanotubes

Transition metal oxides are widely used to construct diverse nanostructured functional materials in the form of films, nanorods, and mesoporous materials.^{110–122} Some of these nano-objects are obtained with the use of carbon NT. For example, filling the internal cavities of carbon NT with V₂O₅, MoO₃, PbO, or Bi₂O₃ particles followed by chemical removal of the carbon shell gave oxide nanofibres and nanotubular ceramics.^{123–125}

Nanotubulenes of transition metal (vanadium and titanium) oxides have not been synthesised until recently.^{126–133} The sol–gel method was found to be efficient for this synthesis^{126–129} (for more detail about colloid methods to obtain nanostructures, see Refs 134 and 135).

Krumeich *et al.*¹²⁶ used the sol–gel method to obtain multilayer vanadium oxide NT (VO_x-nanotubulenes). Ethanolic solutions of vanadium(V) triisopropoxide and an amine C_nH_{2n+1}NH₂ (4 ≤ n ≤ 22) or α,ω-diamine H₂N[CH₂]_nNH₂ (14 ≤ n ≤ 20) in the molar ratio 2:1 were stirred for 1 h in an inert atmosphere and hydrolysed. Ageing of the system for 12–96 h resulted in an orange composite, which gave a black product upon hydrothermal treatment for 2–7 days (at 450 K) in an autoclave. The composition, structure and certain properties of the product obtained were examined by X-ray diffraction, XPS and TEM and by magnetic susceptibility measurements.

It was found that the major components of the composites were nanostructures with tubular morphologies, whose outer and inner diameters were 5–50 and 15–150 nm, respectively, and whose lengths were up to 15 μm. Special experiments to study the cross-sections of the resulting VO_x-nanotubulenes showed them to be multilayered.^{127,128} Both spiral (scroll-shaped) NT and those in the form of a set of concentric cylinders with organic molecules intercalated between the cylinders were detected. Spiral NT are formed most commonly. Mixed structures were also observed. Figure 5 shows the cross-section types of multilayer NT. The figure shows the defects of NT packs. Certain NT contain regions with parallel arrangement of VO_x-layers, both inside the tubes and

Figure 5. Models (1–3) and different cross-section structures (4–11) of multilayer NT;¹²⁷

(1) concentric cylinders ('Russian matreshka'), (2) scroll, (3) 'papier-mache'; (4–11) typical cross-sections of vanadium-oxide NT.

in the vicinity of junctions between the adjacent tubes. The number of NT layers varies from 2 to 30; they are built of tetrahedra (VO₄) and of square pyramids (VO₅).¹²⁶ These polyhedra also serve as structural elements of the crystalline phases α-V_{1.08}P_{0.92}O₅, (NH₄)₂V₃O₈, K₂V₃O₈ and BaV₇O₁₆·nH₂O. The distance between the adjacent NT layers (1.6–3.8 nm, Table 1) changes proportionally to the length of the alkylamine molecule serving as the intercalant. The overall molecular formula of NT can be written as VO_xO_{y/2}[C_nH_{2n+4}N]_y. Attempts to obtain 'pure' VO_x-nanotubulenes by removal of organic molecules upon thermal treatment are probably hopeless, as the tubes undergo complete degradation at temperatures > 520 K. It is more likely that amines can be replaced by cations of alkali or alkaline-earth metals (*e.g.*, Na⁺, K⁺, Mg²⁺, Ca²⁺, Sr²⁺). This method may become efficient for modifying the properties of VO_x-nanotubulenes. Replacement of monoamines by diamines in NT results in a noticeable decrease in the interlayer distances (from 1.6–3.8 to 0.9–1.0 Å). Specimens of the composite manifest semiconducting properties.

Table 1. Chemical composition, distances between the VO_x-layers, magnetic moments of vanadium atoms (MM) and relative concentrations of V⁴⁺ ions in VO_xO_{y/2}[C_nH_{2n+4}N]_y-nanotubulenes.¹²⁶

^a Data obtained by X-ray (XRD) and electron (ED) diffraction.

Two new methods for the preparation of VO_x -nanotubulenes from vanadium oxotrichloride and pentoxide as the starting compounds have recently been proposed.¹³⁰ Both processes are carried out in two stages. In the first stage, a solution of VOCl_3 (or V_2O_5) with the amine $\text{C}_n\text{H}_{2n+1}\text{NH}_2$ ($11 \leq n \leq 20$) is hydrolysed to give a gel; in the second stage, hydrothermal treatment is conducted to yield NT. If V_2O_5 is used, amines are directly intercalated between the pentoxide layers. The resulting NT can be described by the general formula $\text{VO}_{2.42 \pm 0.03} \cdot (\text{C}_n\text{H}_{2n+4}\text{N})_{0.27 \pm 0.01}$ ($11 \leq n \leq 20$). If VOCl_3 is used, the general formula of the NT is $\text{VO}_{2.45 \pm 0.05}(\text{C}_n\text{H}_{2n+4}\text{N})_{0.27 \pm 0.01}$ ($11 \leq n \leq 16$). The NT morphology is similar to that described above. The low cost of the product obtained is worth a special note.¹³⁰

Pillai *et al.*¹³¹ succeeded in synthesising a unique type of multilayer vanadium oxide NT with periodically alternating distances between the VO_x -layers by changing pH of the medium. Ammonia was added to the reaction mixture obtained upon hydrolysis of an ethanolic solution of vanadium(V) triisopropoxide to pH 10. The final product was obtained in accordance with the procedure described above (see Ref. 126). It was found that the outer diameters of the resulting NT (> 250 nm) were much larger than those of the NT obtained without ammonia (at pH 4–8); however, the lengths of the former (2–5 μm) were much smaller than those of the latter. The walls of the NT obtained in the presence of NH_3 are composed of regularly alternating VO_x layers; between these, amine molecules and NH_4^+ are intercalated alternately (the VO_x – VO_x interlayer distances are 2.0 and 0.9 nm, respectively). The NT structures contain various defects, for example, violation of periodic alternations of the interlayer distances; in certain cases, breakdown of layers (both inner and outer ones) occurred. The fact that NT contain defects was interpreted¹³¹ as an indication of their high stability. The overall chemical formula of the new NT could be expressed as $[(\text{NH}_4)_y\text{VO}_x][(\text{C}_n\text{NH}_3)_z\text{VO}_x]$; the defects are present in the $[(\text{C}_n\text{NH}_3)_z\text{VO}_x]$ layers. It is possible to control the structure of vanadium-oxide NT by changing the pH of the gel. It is assumed¹³¹ that ‘pure’ $[(\text{NH}_4)_y\text{VO}_x]$ -nanotubulenes with small interlayer distances can be synthesised at pH ~ 12 . On the other hand, it is known¹²⁷ that it is ammonium vanadate $[(\text{NH}_4)_2\text{V}_3\text{O}_8]$ that is formed under these conditions.

In addition to particles with well-shaped tubular morphologies, products with ribbon-like structures and intermediate forms could be revealed by SEM in these composites.

Syntheses of TiO_2 -nanotubulenes from solution¹³² and with the use of mesoporous Al_2O_3 (see Ref. 133) were reported.

4. NiCl_2 -Nanotubulenes

Hacohen *et al.*¹³⁶ were the first to synthesise halogen-containing nanotubular structures, namely, NiCl_2 -nanotubulenes. Nickel dichloride has lamellar structure (of the CdCl_2 type, space group $R3m$); its specific feature is that it has ferro- and antiferromagnetic types of spin ordering inside the layers and between them, respectively. Multilayer NT were obtained; their cross-sections were up to ~ 7 nm, while the lengths were several micrometres. The tubular structures remained stable for a few days. It is assumed¹³⁶ that the most interesting applications of such structures may be related to their unusual magnetic characteristics.

5. Miscellaneous methods for the synthesis of non-carbon nanotubes

a. Template synthesis

The template method of synthesis is used to obtain nanotubular composites, *i.e.*, multilayer NT containing layers with different chemical compositions. Stable NT (normally, carbon nanotubes) are used as the support, which is then coated with layers of various metals or compounds.^{124, 137–141}

The interest in nanotubular composites is due both to the possibility of preparation of tubular forms of those materials which are as yet unknown as isolated NT, and to specific proper-

ties of the composites themselves (*e.g.*, they behave as ‘interfaces’ between the adjacent cylinders of different chemical nature).

It should be noted that the method for the application of coatings on carbon NT is similar to that for the chemical modification of their surfaces, in which the composition of the outer layers of multilayer carbon NT is carried out by doping (substitution).^{142–146}

Seeger *et al.*¹⁴² proposed a method for the application of SiO_x -coatings on multilayer carbon NT at room temperature (in addition to the high-temperature method¹³⁸). The low-temperature (colloid) method is based on the formation of positively charged centres on the surface of multilayer carbon NT followed by deposition of negatively charged colloidal SiO_x particles onto this surface. The high-temperature method¹³⁸ is based on the thermal decomposition ($T > 503$ K) of tetraethoxysilane

adsorbed on multilayer carbon NT.

The low-temperature SiO_x coatings had the form of continuous amorphous layers 3–10 nm thick with included nanocrystallites; the high-temperature process resulted in a non-uniform SiO_x layer, ~ 10 nm thick (complete covering of the support surface could not be reached). In both cases, no chemical interaction occurred between the contacting SiO_x layers and the multilayer carbon NT; the oxide film coated the NT directly without formation of any intermediate (*e.g.*, carbide) layers.

The method used to obtain ZnS-nanotubulenes¹⁴⁷ may be regarded as a combination of the template and substitution approaches. Highly structured semiconducting zinc oxide films which incorporated single-crystal ZnO columns obtained by non-equilibrium electrodeposition on a conducting substrate (glassy SnO_2) were used as the support.^{148–150} The columns (several micrometres high, with diameters of 100–300 nm) were oriented orthogonally to the substrate.

The process of formation of ZnS-nanotubulenes is based on the ion-exchange reaction

After exposure for 15 min, the thickness of the ZnS layer on the ZnO columns was ~ 15 nm; complete transformation of ZnO-columns into ZnS-nanotubulenes did not occur. The untransformed column matrix (ZnO) was removed by treatment with dilute H_2SO_4 . The resulting hollow ZnS tubes (open or closed) with wall thickness of ~ 10 nm maintained the surface morphology of the original crystallites; their cross-sections had polygonal shapes.

It is expected that other types of substitution may result in a wide range of NT with diverse chemical compositions, *e.g.*, tubular forms of semiconducting CuO, CuS, CdS, CdTe, ZnTe, *etc.*

b. Film ‘rolling’

As noted above, it is compounds which form phases with quasi-2D structures under equilibrium conditions that are usually considered as potential candidates for the synthesis of NT.

A fundamentally new approach to the problem of obtaining the nanotubular form of matter has been developed.^{151, 152} It was proposed to form NT from thin films. The principle of this method (which is subdivided¹⁵¹ into the ‘general’ and ‘special’ methods) is demonstrated in Fig. 6.

‘General’ method. A thin film is applied on a double-layer support the top layer of which can be removed by selective etching. Following the etching, an edge of the film is detached from the support, bent and placed atop the film. The tubular structure is formed in the bent region (see Fig. 6). For instance, this method was used to obtain silicon–germanium NT up to 12 μm long and with a diameter of ~ 230 nm. The thickness of one layer was 16 nm and was determined by the conditions of the film deposi-

Figure 6. General (a) and special (b) film 'rolling' methods for obtaining NT;¹⁵¹

(1) single-layer (double-layer) film that forms nanotubes; (2) a top support layer removed upon selective etching; (3) a bottom support layer. Arrows show the force directions when a double-layer film is rolled.

tion. Yet another procedure of the synthesis of SiGe films¹⁵¹ gave NT with up to 50 nm diameter and a wall thickness of ~6 nm.

'Special' method. Double-layer films made of different materials are used; the interatomic distances in the material of the outer film layer (l') should be larger than those in the inner film layer (l'') (see Fig. 6). After etching and detaching a film edge from the substrate, each material tends to restore its original structure; owing to the resulting mechanical stress, the free film edge bends upwards, makes a full turn and forms a tube. In the case of prolonged etching, the film edge can make several turns to give specific rolls that resemble the familiar 'scroll'-type carbon tubes. This method made it possible to obtain tubes up to 20 μm long and with a diameter of 530 nm from double-layer InAs/GaAs,¹⁵² InGaAs/GaAs¹⁵³ and SiGe/Si films¹⁵⁴ and from epitaxial SiGe films.¹⁵⁵

It is important that the thickness of NT 'walls' obtained by this method, *i.e.*, the number of layers in the multilayer NT, depends exclusively on the film technology used and can vary over a wide range, down to a monoatomic layer. The approach suggested^{151, 152} does not impose fundamental restrictions on the chemical compositions of individual NT layers, which allows tubular hetero-structures to be formed from multilayer films. Yet another important advantage is that it is possible to set exactly the location of the NT on the support: it is defined by the position of the film edge and by the etching time. Thus, the main factors in the manufacturing of NT within this approach are the choice of the film deposition method (which defines the size and chemical composition of the resulting NT), the time of chemical etching and the elastic properties of the material of the NT-forming film. It is expected¹⁵¹ that this approach will provide single-crystal NT of many semiconductors.

III. Simulation of the structures and prediction of the properties of nanotubulenes based on boron, silicon, germanium and phosphorus

The search for new methods for the synthesis of non-carbon NT is performed in parallel with active studies on theoretical simulation of their configuration and electronic structure. Generally, the majority of studies employ zone or cluster models, as well as modern methods of density functional theory (DFT). Furthermore, structural features and kinetics of NT formation are studied by molecular dynamics methods. Details on specific approaches and computational schemes can be found in the original studies discussed below.

In addition to the conventional energy and electronic characteristics of NT, such as energy bands, electronic state densities (SD), interatomic interaction parameters and charge states, the

so-called strain energy is often calculated (E_{str}). This parameter is defined as the difference between the energy of the flat atomic layer and the corresponding NT. It is considered as an estimate of the energy required to transform a compound in crystalline (lamellar) modification to the tubular form. By comparing the E_{str} for the known (carbon) NT and hypothetical non-carbon NT, it is possible to make conclusions on the probability of accessing the latter.

Compounds that have stable or metastable lamellar phases become the most common subjects of a theoretical search for non-carbon NT. In general, the methods used to build geometrical models of such NT resemble those for the carbon NT.^{7, 21, 26, 30} Their classification is also carried out by analogy with carbon NT (using n , m indices).

1. Boron-based nanotubulenes

A number of studies^{156–165} deal with prediction of the tubular structures of boron, which are electron-deficient in comparison with carbon NT. A number of techniques were used to simulate the boron NT formation process.

The formation of B-nanotubulenes was simulated by the 'cluster assembling' method. In the first calculation stage, the Hartree–Fock and DFT methods were used to determine the sizes and configurations of small (several atoms) isolated boron clusters; after that, their association was considered. For example, starting from a B_7 hexagonal pyramid, a large number of topologically different B_n clusters were constructed: quasiplanar (quasi-2D), convex and three-dimensional. Planar structures were found to be most stable (see also Refs 166 and 167). Convex structures are less stable. The stability of these structures increases^{156, 159} if they incorporate a combination of two base clusters, *viz.*, hexagonal and pentagonal pyramids.

Boustani *et al.*¹⁶⁴ and Gindulyte *et al.*¹⁶⁵ simulated boron-based NT. They evaluated the stability of the isomers of the tubular form of the B_{32} cluster, the structures of which are shown in Fig. 7. It was found that the stability of these isomers decreases with a decrease in the diameter. In contrast, as the diameter increases (the curvature of the cylinder walls decreases), their energies approach that of the most stable planar form of boron.

Figure 7. Model structures with C_{2h} (a), C_2 (b), D_4 (c, d) symmetry types for cylindrical B_{32} clusters with different diameters.¹⁶⁴

A competition between the following factors affecting the stability of the isomers was noted:¹⁶⁴ first, the high deformation energy of the planar layer, which increases abruptly with an increase in the curvature and prevents the formation of tubes with small diameters; second, the energy gain due to the coupling of broken (side) bonds in planar layers when they are rolling into a cylinder. Thus, it is quite possible to synthesise boron NT, but their diameters should be relatively large. Examples of such extended boron NT built like carbon NT were considered by Gindulyte *et al.*¹⁶⁵

The formation of NT in the bulk of α -boron quasi-crystals may be expected.¹⁵⁸ Calculations of local structural deformations for a 'compressed' boron quasi-crystal with rhombohedral lattice showed that closed hollow structures considered as precursors of the growth of extended NT are possible in this system.¹⁶⁸ The formation of boron NT may be critically affected by admixtures of various elements, *e.g.*, carbon or nitrogen.

2. Nanotubulenes based on silicon and germanium

The possibility of preparing NT consisting of silicon, which is a carbon analogue, still remains debatable. This is explained by great differences in the energy states of the atoms of these elements. It is known¹⁶⁹ that the most stable electronic configuration for the carbon atom is sp^2 , whereas for silicon it is sp^3 . Therefore, graphite is the most energetically favourable crystalline form for carbon, whereas a diamond-like structure is the most favourable for silicon. In the nano-state, carbon exists as atomic chains, hollow fullerene-like clusters and NT, whereas silicon does not form any polyhedral nanoparticles.¹⁷⁰

The first calculations of the energy and electronic states of hypothetical silicon-based NT formed by rolling of ribbon-shaped graphite-like structures of a layer composed of silicon atoms [nonchiral (6,6)- and (10,0)-NT and chiral (8,2)-NT] were carried out by the DFT method.¹⁷¹ The dependence of the electronic properties of such NT on their types is similar (see the corresponding reviews^{7,21,26,30}) to that of similar carbon NT. This is evident from the state densities for silicon NT shown in Fig. 8: the zigzag (10,0)-NT is a semiconductor with narrow energy gap, whereas the dented (6,6)-NT has metallic conductivity. Of interest are comparative energy evaluations of various carbon and silicon structures. The total energies (E_{tot}) of a silicon atom within a graphite-like network and in an NT are 0.79 and 0.83 eV lower than in crystalline silicon. The energy of cohesion (E_{coh}) of silicon atom in NT is only 82% of E_{coh} in a diamond-like crystal, whereas the E_{coh} of carbon atom in NT and in crystal (graphite) differ by no more than 1%. According to estimates,¹⁷¹ the energies required for rolling of networks consisting of carbon and silicon atoms into tubular structures are very similar (0.04–0.05 eV per atom). Presumably, the main problem in the synthesis of silicon NT is that it is difficult to obtain silicon in a lamellar (graphite-like) form.

Figure 8. Full densities of states for silicon (6,6)- (a) and (10,0)- (b) nanotubulenes.¹⁷¹

Vertical lines show the Fermi energy.

Calculations on mixed carbon–silicon NT showed¹⁷² that the Si $\rightarrow$ C replacement energy within carbon NT is ~ 3.1 eV per atom. If a silicon admixture is present, it generates resonance states ~ 0.7 eV above the Fermi level in the electronic spectrum of a metallic carbon (6,6)-NT. A silicon atom within a semiconducting carbon (10,0)-NT gives rise to a local electronic level arranged ~ 0.6 eV above the valence band.

Seifert *et al.*^{173,174} calculated the electronic states and analysed the stability of silicon-containing NT based on silanes and siloxanes with complex composition. In such NT, the silicon atoms forming the tube frame are surrounded by hydrogen atoms or by hydrogen atoms and OH groups.

Like silicon, crystalline germanium has a diamond-like structure with sp^3 bond type; its quasi-2D modifications (of the CaSi_2 type¹⁷⁵ or CaGe_2 type¹⁷⁶) are also known. Recently, polymers containing networks of germanium atoms (GeH hexagonal layers) were synthesised.¹⁷⁷ According to calculations,¹⁷⁸ these compounds should be semiconductors (the width of the forbidden band is $E_g \approx 1.4$ eV). The DFT method was used¹⁷⁹ to simulate the electronic properties of hypothetical ($n,0$)- and (n,n)-NT ($n = 6-10, 20$) based on GeH. The cross-sections of (8,0)- and (8,8)-GeH-nanotubulenes, which are the most stable of those described above, are shown in Fig. 9. It was shown^{7,21,26,30} that the dependence of the energy deformation of NT on its diameter (D) has the form:

$$E_{\text{str}} \approx \frac{1}{D^2}. \quad (1)$$

All of these tubes are semiconductors; the forbidden band width varies considerably depending on the NT diameter [from 1.33 to 1.16 eV for (20,20)- and (7,0)-NT, respectively]. Possible methods for the synthesis of these NT include¹⁷⁹ topochemical reactions and synthesis from molecular GeH_4 .

Figure 9. Structures of cross-sections (8,0)- (a) and (8,8)- (b) for GeH-nanotubulenes.¹⁷⁹

3. Phosphorus nanotubulenes

Orthorhombic black phosphorus is the most stable allotropic form of elementary phosphorus. The crystals of black phosphorus consist of graphite-like networks, the distance between which (0.36 nm) is much longer than the length of the P–P bonds in the network (0.223 nm). Unlike the planar graphene layers, the networks of phosphorus atoms are 'bulged'; this is explained by the repulsion of unshared electron pairs in the neighbouring atoms.

Seifert and Hernandez¹⁸⁰ compared the electronic and energy characteristics of an isolated network of black phosphorus with those of a number of hypothetical single-layer NT. In the initial stage, the structures of P-nanotubulenes (of zigzag and dented types) were constructed from ribbons of planar graphite-like layer of phosphorus atoms rolled to make a cylinder. After that, their geometry was optimised with respect to the axial displacements of atoms. Generally, relaxed structures of P-nanotubulenes are

similar to the structures of carbon NT and only differ in the type of six-membered rings. In the case of P-nanotubulenes, these rings have the form of cyclohexane rings consisting of phosphorus atoms.

The strain energy (E_{str}) of phosphorus NT is considerably higher than the E_{str} of carbon NT with similar diameters. This difference increases as the tube diameter decreases, which is explained¹⁸⁰ by changes in the electronic configurations of the carbon and phosphorus atoms in the networks. As a graphene network consisting of sp^2 carbon atoms folds, the increase in the wall curvature increases the contribution of the sp^3 orbitals.¹⁸¹ For a phosphorus network consisting of sp^3 phosphorus atoms, minimisation of the repulsion energy of unshared electron pairs of adjacent atoms occurs due to the maximum increase in the distances between adjacent phosphorus atoms upon their displacement from the network plane (the network ‘bulging’ mentioned above). As such a ‘bulged’ network is folded, the distances between the unshared electron pairs of certain phosphorus atoms decrease, resulting in rapid increase in E_{str} . However, the E_{str} of phosphorus NT at $D > 1.23$ nm is no higher than 0.1 eV per atom, which is comparable with the deformation energies of the corresponding carbon NT.

These energy estimates suggest that there are no obstacles to the existence of P-nanotubulenes. However, it should be expected that NT with rather large diameters will be formed. The following methods may be used to obtain P-nanotubulenes: the template method, a modification of the method for the synthesis of thin phosphorus films upon luminescent decomposition of PH_3 ¹⁸² and sublimation of phosphorus in the presence of catalysts.

It was noted¹⁸⁰ that phosphorus NT should have semiconducting characteristics invariable with respect to diameter changes (E_g changed in the range from 0.9 to 1.99 eV). Considering that the properties of phosphorus and arsenic are similar, the possibility that As-nanotubulenes may exist cannot be ruled out.

IV. Theoretical models of nanotubes based on *p*- and *d*-element compounds

1. Models of nanotubes consisting of B, C and N atoms

It was found in early studies^{4–8} of carbon NT that their properties could be affected by doping.

The cyclic cluster model and the semiempirical quantum-chemical MNDO method were used to study the charge distribution in carbon (6,6)-NT doped (one atom per unit cell) with one of the atoms: B, N or Si, in neutral, anionic and cationic state.¹⁸³ It was found that the distortions introduced by the dopants propagated along the NT to longer distances than across the NT. Distortions from charged dopants have a longer range than those from neutral atoms.

The local structural deformations of carbon NT appearing upon doping with single boron or nitrogen atoms were estimated.¹⁸⁴ In the case of nitrogen, the effects of structure relaxation are weak. Doping with boron resulted in displacement of the nearest carbon atoms by ~ 0.011 nm along the B–C bonds.

Scanning tunnelling spectroscopy and calculations within the DFT were used to study the effect of boron atoms on the properties and growth of carbon NT.^{185,186} Doping of multilayer carbon NT with boron confers on them metallic properties; the boron atoms are segregated to form separate islets in NT walls.¹⁸⁵ A boron admixture prevents the formation of ‘caps’ and favours the preferable growth of $(n,0)$ type NT.¹⁸⁷ This mechanism does not apply to dented NT; this fact can be used for growing selectively NT of certain geometries. Electrophysical studies¹⁸⁸ showed that doping of carbon NT with boron increases the paramagnetic susceptibility of the latter. Furthermore, their thermal factors of electrical conductivity are positive.

a. Boron nitride

Boron nitride was the first compound suggested for the synthesis of non-carbon NT. Quantum-chemical methods^{36–38} revealed a

number of interesting features of BN-nanotubulenes. Unlike carbon NT, the conducting properties of which are determined by their diameters and chiralities,^{4–8} BN-nanotubulenes are wide-gap semiconductors ($E_g \approx 5.5–6.0$ eV), which is important for the development of materials with predetermined properties. More detailed information about the electronic and energy characteristics of ‘ideal’ single- and multilayer BN-nanotubulenes can be found in a monograph⁷ and in a number of reviews.^{21,29,30}

In recent years, BN-nanotubulene structures were mostly simulated using the molecular dynamics method.^{76,189} The properties of the following tube types were compared:⁷⁶ chiral, zigzag-shaped, dented (built of graphite-like networks of B_3N_3 hexagons) and those built of four- (B_2N_2) and eight-membered (B_4N_4) rings. The latter type of BN-nanotubulenes were found to be the less stable.

The elastic properties of BN-nanotubulenes were estimated:¹⁹⁰ their Young modulus (Y) was 14 times higher than that for crystalline graphite-like BN, and comparable to the extremely high Y predicted^{191,192} for carbon NT (1–6 TPa). This agrees with the subsequent measurements¹⁹³ of the Young modulus for multilayer and single-layer carbon NT (0.4–4.0 TPa). The experimental studies¹⁹⁴ on the elastic properties of multilayer BN-nanotubulenes give values which are in good agreement with calculations¹⁹⁰ ($Y \approx 1.22 \pm 0.24$ TPa). Of the currently known elongated nanostructures with dielectric properties, BN-nanotubulenes are characterised by extreme values of the Young modulus comparable to those of glassy fibres.^{195,196}

The growth mechanisms of BN-nanotubulenes depend on their structures and differ considerably for $(n,0)$ - and (n,n) -nanotubes.^{197,198} The determining role in the growth process belongs to the specifics of the formation of terminal structures by virtue of B–N binding, these bonds being much more favourable than the B–B and N–N bonds. Zigzag NT stop to grow once ‘caps’ have formed. Dented NT grow by addition of extra atoms near the NT ends. The role of BN-rings of different types (in particular, five-membered rings) in the formation of BN-nanotubulene ‘caps’ and polyhedral boron nitride clusters, which are heteroatomic fullerene analogues, was discussed.^{199–207}

b. Boron carbides

Unlike BN-nanotubulenes, the type of electronic properties of BC_3 -nanotubulenes changes from metallic to semiconductor-type with the increase in their diameters.²⁰⁷ It is possible to increase the conductivity (hole concentration) of such NT by partial replacement of carbon atoms by ‘superstoichiometric’ boron atoms. Halogen atoms can serve as electron donors, as is observed for a number of intercalated graphites. The value of E_{str} for BC_3 -nanotubulenes is lower than that for carbon NT, which is in agreement with experimental data on their syntheses (see above).

c. Carbon nitrides

The existence of condensed carbon nitride (CN_x) and the extreme (comparable to that of diamond) hardness of $\beta\text{-C}_3\text{N}_4$ (the $\beta\text{-Si}_3\text{N}_4$ structure type) were predicted.^{208,209} Subsequently, CN_x was synthesised successfully (in amorphous, film and nanocrystalline states^{210–217}) and both various polymorphous modifications of crystalline CN_x and its tubular nanostructures were simulated theoretically.

Fundamental electronic properties of CN_x with the structures of the $\alpha\text{-Si}_3\text{N}_4$,^{218–220} Zn_2SiO_4 and $\alpha\text{-CdIn}_2\text{Se}_4$ ^{219,220} types and of a series of its quasi-2D modifications^{219–222} were considered. A lamellar structure containing graphite-like networks formed by a combination of triazine rings with nitrogen bridges was suggested for C_3N_4 .²²¹ Each carbon atom in the network is bound to three nitrogen atoms; each of the latter has only two closest neighbours. Planar C_3N_4 -networks can be packed according to $ABAB\dots$ type (the Bernal structure) or $ABCABC\dots$ type (the rhombohedral graphite structure).²²² The mean C–N bond length is ~ 0.136 nm (which is close to the sum of the Sleyter radii for the carbon and nitrogen atoms), the C–N–C bond

Figure 10. Planar networks used to simulate NT with compositions CN (a) and C₃N₄ (b).²²⁵

angle is 116° (see Ref. 221). It was found²²³ that vacancies appearing in the N-sublattice of cubic C₃N₄ favour its transformation into a pseudoplanar form. A number of other densely packed and lamellar modifications of carbon nitride have also been suggested (see the review²²⁴).

The structures of non-chiral single-layer (*n,n*)- and (*n,0*)-CN-nanotubulenes with different stoichiometry are described by networks similar to those of the C₃N₄ layers mentioned above and a hypothetical graphite-like layer with the composition CN (Fig. 10).^{225,226} All CN_{*x*}-nanotubulenes, irrespective of their structures and diameters, have metallic conductivity. Their deformation energy increases with a decrease in diameter, but it is smaller than that of carbon NT. In turn, E_{str} for CN-nanotubulenes is smaller than E_{str} for NT based on C₃N₄ (Fig. 11). It is assumed²²⁵ that the interlayer distances in multilayer CN_{*x*}-nanotubulenes will be ~0.04 nm smaller than those in multilayer carbon NT. The *sp*²-configuration of nitrogen atoms favours the stability of NT.

Figure 11. Deformation energy – diameter relationships for C- (1), C₃N₄- (2) and CN-nanotubulenes (3).²²⁵

The formation of fullerene-like molecules, NT and CN_{*x*} crystals was simulated by the molecular dynamics method.²²⁷ The simulation started from a planar fragment of a graphite network forming a cluster of 96 carbon atoms; in this system, the structural deformation upon replacement C → N in the N:C range 0.07–1.00 was studied. The CN_{*x*} layer remained planar up to the nitrogen content of ~20%; then it became ‘corrugated’ due to deviation of atoms (up to ~0.07 nm) away from the plane. It is believed²²⁸ that this results from occupying the antibonding π^* -orbitals (which is visible in photoelectron spectra) and formation of new, rather stable N–N bonds. The CN_{*x*} crystals may have various types of the layered packing of such deformed nitrogen–carbon networks. In should be noted that when a critical nitrogen content (~20%) is reached, a different type of structural evolution of this system is possible to result in NT or a fullerene-like molecule.²²⁷ It is important that stabilisation of the tubular and molecular states is attained at different system stoichiometry, *viz.*, CN and C₃N₄, respectively.

It is of note that only CN_{*x*}-nanotubulenes and nanofibres with relatively small *x* values ($x \leq 0.04$ –0.05) are known.^{229–236} Their electronic properties are interpreted on the basis of calculations for carbon NT containing nitrogen admixtures.^{236,237} In the general case, replacement of some carbon atoms in an NT by nitrogen atoms (electron dopants) increases the population of the energy bands and ‘metallisation’ of the NT. Admixtures of nitrogen create donor levels near the edge of the conduction band in carbon NT.^{236,237} Introduction of nitrogen atoms results in the formation of local pyridine-like fragments within NT walls; this explains the subtle features of electronic state distribution near the Fermi level, which may be important when creating nano-sized devices with hetero-transitions based on these NT.²³⁶

d. Boron carbonitrides

Theoretical construction of nanotubular structures was carried out based on a lamellar form of boron carbonitride BC₂N the electronic spectrum of which has been studied previously.^{238–240} It was assumed that the intralayer charge anisotropy, which causes the formation of ‘channels’ with increased and decreased electron density in BC₂N networks,^{238–243} would be preserved when these networks are rolled into cylinders (according to the chiral type) and would result in spiral motifs. As a result, circular currents would appear in BC₂N-nanotubulenes, and such NT may be considered as nano-solenoids (Fig. 12).

Figure 12. A variant of the atomic structure of a BCN-tube (a) and the scheme of circular currents therein (b).²⁴¹ E_z is the direction of the external field.

Nanotubes with small diameters maintain the conductivity type characteristic of the original BC_2N monolayers. The metallic type of conductivity of (n,m) -NT can change to the semiconductor type at certain diameters and chirality. The most stable are those (n,n) -NT which contain the maximum number of strong C–C and B–N bonds. Miyamoto *et al.*²⁴³ analysed the conditions required for the appearance of circular currents in such NT.

Attempts were made to describe the role of defects in the properties of BC_2N -nanotubulenes.^{241, 243} Partial replacement of carbon atoms by boron (or nitrogen) resulted in donor (or acceptor) admixture states for $\text{B}_{1+x}\text{C}_{2-x}\text{N}$ (or $\text{BC}_{2-x}\text{N}_{1+x}$) in the electronic spectra. Miyamoto *et al.*²⁴³ considered the role of electron (or hole) carriers in the formation of chiral currents in BC_2N -nanotubulenes.²⁴³

Analysis of the general trends in the formation of the atomic structure of BC_2N -nanotubulenes performed on the basis of results of theoretical studies showed that such nanotubulenes are characterised by the formation of BN- and C-islets.^{244, 245} The BC_x -nanotubulenes should undergo similar spontaneous segregation into regions consisting of carbon atoms and BC_3 fragments. These phenomena can give rise to quantum dots and hetero-transitions.

2. Nanotubes based on gallium nitride and selenide

The possibility of obtaining tubular structures for other compounds of Group III–V elements, which do not form lamellar structures under equilibrium conditions, was analysed for GaN (Ref. 246) and GaSe.²⁴⁷

In the first stage, the structures of a hypothetical crystalline graphite-like GaN were simulated by the DFT method and the equilibrium distances Ga–N in the layer were determined (0.178 nm).²⁴⁶ The difference between the bond energies of sphalerite-like (s) and graphite-like (g) phases of gallium nitride was found to be small, namely, 0.36 eV per atom. This value is smaller than the energy difference between s-GaN and its metastable cubic (sodium chloride-like) modification (0.5 eV per atom), which is considered²⁴⁶ to be evidence of the possibility of obtaining a lamellar allotrope of GaN.

The next simulation stage involved calculations of the electronic structure and E_{str} of gallium–nitrogen (n,n) - and $(n,0)$ -NT as a function of their diameters. Sawada and Hamada²⁴⁸ estimated the minimum possible NT sizes corresponding to zigzag-like (5,0)- and dented (2,2)-NT. It was found that E_{str} changes inversely to the square of the NT diameter; the geometry type of the walls of such tubes (unlike carbon ones²⁴⁹) only slightly affects E_{str} . On the contrary, this factor becomes important for the dielectric properties of GaN-nanotubulenes: although both tube types are wide-gap semiconductors [e.g., the values of E_g for (5,5)- and (9,0)-GaN-nanotubulenes are 2.15 and 2.16 eV, respectively], dented (n,n) -NT, like the hypothetical g-GaN, have indirect type of inter-band transitions. Zigzag-like $(n,0)$ -NT have direct type of the transitions. The E_g of $(n,0)$ -tubes decreases most significantly with a decrease in diameter. The GaN-nanotubulenes (like BN-nanotubulenes⁷) were found to manifest a relaxation effect: the atoms of the cationic (Ga) and anionic (N) sublattices are displaced by ~ 0.005 nm from the surface of an ideal cylinder: the gallium atoms are displaced towards the tube axis, whereas the nitrogen atoms are displaced in the opposite direction. Similar properties are also typical of GaSe-nanotubulenes.²⁴⁷

It is assumed that GaN-nanotubulenes can be obtained by template synthesis using carbon NT as the substrate.²⁴⁶ This will probably result in multilayer tubes with various chemical compositions (C/GaN nanotubular composites) with a metal–semiconductor interface. To date, tubular composites which are carbon NT partially filled with GaN, as well as separate GaN rods with 7–10 nm diameters and up to 40 μm long, have been synthesised.²⁵⁰ These specimens were obtained in an electric arc in an atmosphere of nitrogen with a graphite cathode and an anode containing a mixture of gallium nitride, graphite and nickel powder.

‘Pure’ GaN-nanotubulenes [with E_g values ~ 0.45 eV higher than those of the cubic phase of GaN (see Refs 246, 251, 252)] can be used in nanosized optoelectronic devices that are necessary, e.g., in colour displays.

3. Sulfide nanotubes

Nanotubes based on lamellar molybdenum and tungsten disulfides were constructed^{253, 254} from fragments of triple-layer packages S–(Mo,W)–S rolled into cylinders along certain chosen directions of the two-dimensional lattice. The tubes were classified (by analogy with the carbon NT) as non-chiral zigzag-like (n,n) - and dented $(n,0)$ -NT. The theoretical electron diffraction patterns built for these structures²⁵³ well describe the experimental data.²⁵⁵ Seifert *et al.*^{253, 254} used the DFT method in the strong bond approximation to study the dependence of the electronic properties and stability of a series of disulfide NT on their diameters. For example, the diameters of $(n,0)$ - and (n,n) - WS_2 -nanotubulenes ($n = 6, \dots, 22$) ranged²⁵⁴ from ~ 1.1 [for (6,6)- and (10,0)-NT] to ~ 3.1 nm [for (18,18-NT)]. For MoS_2 -nanotubulenes, the diameters ranged from 0.8 to 2.6 nm.²⁵³ The maximum diameters of model NT used in these studies were close to the minimum diameters of the disulfide NT synthesised.

The energy and electronic characteristics of all disulfide NT have certain common features,^{253, 254} which are also characteristic of crystalline phases.^{255, 256} Three bands are observed in the valence band of WS_2 -nanotubulenes, viz., A, B and C (Fig. 13), which result from contributions of quasi-framework $\text{S}3s$ - (band A), hybridised $\text{S}3p$ – $\text{W}5d$ - (band B) and $\text{W}5d$ -states (band C). The $\text{W}5d$ -states dominate in the vicinity of the lower edge of the conduction band. All (W,Mo) S_2 -nanotubulenes are narrow-gap semiconductors. However, $(n,0)$ -NT are semiconductors with direct transition in point Γ , whereas the family of (n,n) -NT is characterised by indirect transition type (Fig. 14). The forbidden band width increases with a decrease in the tube diameter, but it

Figure 13. Full density of states for (18,18)- WS_2 -nanotubulene. $E_F = 0$.²⁵⁴

Figure 14. Energy zones for (22,0)- (a) and (18,18)- (b) WS_2 -nanotubulenes.²⁵⁴

Horizontal lines show the Fermi energies.

remains smaller than the E_g for three planar S–(W,Mo)–S layers. This result agrees with optical experiments²⁵⁶ which showed that E_g in the electronic spectrum of WS₂-nanotubulenes was smaller than that for crystalline tungsten disulfide.

Charge transfer in disulfide NT occurs in the direction W(Mo) → S.^{253,254} For MoS₂-nanotubulenes, the effective charges are ~0.9 e (0.44 e per sulfur atom), which is much smaller than the formal ionic charges in the crystal (Mo⁴⁺, S²⁻). The deformation energies for disulfide NT are higher than those of carbon NT with the same diameters. In turn, the E_{str} of zigzag-like (Mo,W)S₂-nanotubulenes is somewhat higher than the E_{str} for dented ones.

Seifert *et al.*²⁵³ studied the effect of topological defects (in the form of four- and eight-membered rings) on the structure of the ‘caps’ on closed NT and polyhedral nanoparticles (Mo,W)S₂ (see also Ref. 257). Milosevic *et al.*²⁵⁸ considered the general geometrical aspects of the structure of dichalcogenide NT, determined the symmetry groups of single-layer NT based on 2H- and 3R-polytypes of MoS₂ and WS₂ and discussed some of their properties that depend on the system symmetry (in particular, such as splitting of the energy bands, rules of selection and structures of the phonon spectra).

It is assumed²⁵³ that the semiconductor conductivity type of (Mo,W)S₂-nanotubulenes can be changed to the metallic type if the constituent molybdenum or tungsten atoms are partially replaced by niobium atoms. Recently,²⁵⁹ annealing of Nb₂O₅-coated W₁₈O₄₉ nanorods at 1100 °C in H₂S atmosphere gave the first ‘mixed’ NT with the composition W_{1-x}Nb_xS₂ ($x \leq 0.2$). Their properties have not been studied so far.

The DFT method was used to evaluate the stabilities and simulate the electronic properties of hypothetical (*n,n*)- and (*n,0*)-NbS₂-nanotubulenes²⁶⁰ ($n = 6, \dots, 22$, the NT diameters ranged from ~1.0 [for (6,6)- or (10,0)-NT] to ~2.4 nm [for (14,14)-NT]). It was found that the strain energy E_{str} of NbS₂-nanotubulenes obeys Eqn (1), and that it is higher than that of carbon NT with the same diameters. This fact was explained by a higher energy consumption for rolling of a fragment of an S–Nb–S triple-layer sheet into a tube, in comparison with similar consumption required for rolling of a graphene monolayer. The energy bands of the tubes considered above differ only slightly from each other and from the energy bands of planar niobium disulfide layers.²⁶¹ The states of these bands near the Fermi level (predominantly of Nb4*d*-type) have high density, which determines their metallic properties; this, in turn, gives a reason to expect²⁶⁰ that NbS₂- and NbSe₂-nanotubulenes may manifest superconductivity. It was noted²⁶⁰ that the onset of superconductivity may be due to an increase in the electron–phonon interaction and an increase in the critical temperature (T_c) in tubular niobium disulfide structures in comparison with the T_c for its crystal [~ 5.6 – 6 K (see Ref. 262)].

It was suggested that NbS₂-tubes could be obtained by thermal treatment of NbO_x nanorods in an H₂S atmosphere or by using template synthesis on carbon NT as the templates. The latter method gave²⁶³ long nanostructures, *viz.*, niobium disulfide tubes and rods.

4. Boride nanotubes

A broad class of lamellar materials comprises metal diborides (MB₂) and other MX₂-phases (X = Be, Si, Ga, Hg, Zn, Cd, Al, Cu, Ag, Au) with the AlB₂ type structure (space group $D_{6h}^{19} - P6/mmm$).^{264,265} These materials aroused particular interest due to the discovery, in 2001, of a superconducting transition in MgB₂ ($T_c \approx 40$ K).²⁶⁶ Since then, superconducting MgB₂ has been obtained as single crystals, dense and porous ceramics, films, long wires and bands, as well as in a nano-structured state; numerous studies of its properties have been carried out (see the reviews^{267,268}).

Chernozatonskii²⁶⁹ analysed whether MgB₂ can exist as an NT. Double-layer MgB₂-nanotubulenes were simulated by rolling

(by the chiral and non-chiral types) ribbon-like fragments cut from two adjacent layers of a MgB₂ crystal. It was assumed that stabilisation of the electron-deficient boron layer occurred due to partial electron transfer (Mg → B); the bond between the coaxial, oppositely charged Mg- and B-cylinders is partially ionic, and the distance between them is similar to the interlayer distance in an MgB₂ crystal. According to molecular dynamics estimates, diboride (*n,n*)-NT, which have a minimum deformation energy if the diameter of the ‘outer’ B-tube is ~19 Å [for (11,11)-MgB₂-nanotubulenes], are more stable. The author’s conclusions are based on estimates of the lattice instability of the MgB₂ and AlB₂ type structures²⁷⁰ formed by alternating (in the sequence ...MXMX...) planar hexagonal metal networks (M) and graphite-like non-metal layers (X).

Synthesis of magnesium-diboride NT is most likely to give tubes of a dented type. Considering the results of calculation of the electronic structures of crystalline MgB₂ (see Refs 267, 271–274), it is assumed²⁶⁹ that such tubes should have metallic conductivity. It is also assumed that they may have superconducting properties (see Refs 7 and 272 on the superconductivity in carbon NT).

A number of NT structures based on ZrB₂ have been reported. It is assumed²⁶⁹ that the ‘caps’ of closed MB₂-nanotubulenes can have the form of structures with defects in the M- and B-shells as five- and four-membered rings. Probably, diborides may also exist as multilayer structures, such as multilayer NT, or as onions. Such systems as (7,7)@(11,11)@(15,15)-NT and (MgB₂)₁₈₀@(MgB₂)₂₈₈, the so-called bifullerene, may serve as examples.

The DFT method was used to calculate several structures,²⁷⁵ the prototypes of AlB₂-nanotubulenes. It was found that all diboride NT should have metallic conductivity.

V. Models of hybrid nanotubular structures

1. Intercalated BN-nanotubulenes

Particular interest is attracted to the control of the properties of NT and synthesis of new nanocomposite materials with nontrivial functional properties based on these. Chemical modification of NT is one of the most effective methods to solve these problems. The properties of NT can be changed in various ways, for example,

(1) by introducing compounds — intercalants (atoms or molecules) — into the internal cavity of single-layer or multilayer NT, into the space between layers (neighbouring walls) of multilayer NT or into cavities between the adjacent NT in NT braids or in nanotubular crystals;

(2) by adding foreign atoms or molecules to the broken bonds of atoms belonging to the terminal groups of open NT, to atoms of the ‘caps’ of closed NT or to atoms of the outer surface of NT walls (adsorption on NT surface);

(3) by replacing partially the NT atoms by atoms of some other kind (NT ‘doping’).

These modification methods became most popular for carbon NT (see the reviews^{15–17,21–28}). For non-carbon NT, simulations of intercalated nanotubulenes and ‘symbiotic’ tubular structures are used most frequently. In the latter case, this idea was used for the possible formation of various 1D-heterostructures [the so-called symbiotic boron carbonitrides, *viz.*, (C + BN)-nanotubulenes] in addition to ‘ideal’ NT with a regular distribution of different kinds of atoms over the nodes in a B–C–N system.²⁷⁶ It is expected that the conducting properties of such NT would vary widely. Certain experimental data on their synthesis were mentioned above.

Chernozatonskii *et al.*²⁷⁷ considered hypothetical BCN-nanotubular structures consisting of alternating C- and BN-fragments as representatives of ‘symbiotic’ NT. Considering the similarity of the bond lengths C–C (0.142), C–N (0.150) and B–N (0.145 nm in graphite-like planes), such heterostructures can be formed,²⁷⁶ *e.g.*, as a result of the growth of carbon NT on

substrates containing BN nanocrystallites, or as a result of the formation of BN-nanotubulenes on diamond crystallites, or due to both processes occurring simultaneously. Yet another way to obtain these kinds of structures is chemical doping; as the carbon atoms are replaced by B and N, the latter form BN-‘islets’ within the original carbon NT.

Simulation of symbiotic tubular structures in the B–C–N system made it possible to predict a number of interesting properties for them.^{277, 278} It was suggested to consider C–BN-nanotubulenes containing rings of carbon atoms as a new class of quasi-one dimensional systems with quantum dots in which the local disturbance of the energy of electronic states exceed a certain characteristic value (usually $kT_{\text{room}} \approx 0.024$ eV). The crystal orbital method in one-orbital approximation was used to calculate the electronic spectrum of zigzag-like $(n,0)$ -BN-nanotubulenes ($n = 5, 6, 9, 27, 72$) in which a number of (B,N)-atomic rings in the bulk or at the ends of open tubes were replaced by rings of carbon atoms. The states of the terminal carbon rings form a number of discrete levels around the dielectric gap of BN-nanotubulenes; as the number of carbon atoms increases, these levels are transformed into mini-bands. For example, the spectrum of carbon states (in the dielectric gap) for $(27,0)$ -CBN-nanotubulenes consists of two groups of levels the widths of which are 0.7 and 1.7 eV. A similar effect (Fig. 15) was noted for the states of bridging carbon rings between the fragments of neighbouring NT. It is assumed that the existence of ‘quantum dots’ (or ‘quantum rings’,^{278, 279} *i.e.*, conducting carbon rings at the ends or between dielectric BN-nanotubulenes) can result in unusual properties of these structures, *e.g.*, lead to resonance effects in external magnetic fields. Lammert *et al.*²⁸⁰ discussed the results of doping of carbon NT with boron and nitrogen admixtures carried out in order to obtain structures containing chains of quantum dots. Such structures can be regarded as models of novel quantum nano-devices.

Figure 15. Energy zones for $(\text{BN})_3\text{C}_2(\text{BN})_3$ fragments of ‘symbiotic’ $(n,0)$ -nanotubes;²⁷⁷ $n = 9$ (a), 24 (b), 72 (c).

The electronic characteristics of the hetero-transitions in NT consisting of the C/BN, $\text{BC}_2\text{N}/\text{BN}$ segments (the superlattice model) were found²⁷⁹ to be stable against changes in the radii, chirality type and the number of layers in these NT.

Intercalated boron-nitride NT present yet another type of ‘tubular composites’. Rubio *et al.*²⁸¹ calculated the electronic spectra of $(4,4)$ -BN-nanotubulenes which incorporated potassium or aluminium ‘fibres’ arranged along the cylinder axis. The evaluated intercalation energies (the differences between the full energies of the composite and its constituents, namely, the NT and the metal ‘fibre’) were much smaller than the intercalation energies for similar systems with carbon NT. In the system $\text{K}@ (4,4)\text{-BN-nanotubulene}$, no new states appear in the electron energy spectrum. In the system $\text{Al}@ (4,4)\text{-BN-nanotubulene}$, additional

levels of Al s, *p*-type appear in the energy gap, and the electronic spectrum of this system becomes similar to a superposition of the spectrum of a monoatomic chain of aluminium atoms and the spectrum of $(4,4)$ -BN-nanotubulene. The density of electron carriers, which define the conductivity of intercalated BN-tubes, is concentrated inside the cylinder, hence such NT are preferable (as compared to carbon NT) when making nano-wires with predefined parameters. It is deemed possible to intercalate silver and gold atoms into BN-nanotubulenes.

Hernandes *et al.*²⁸² presented a new idea that a molecular diode can be created on the basis of carbon NT intercalated with boron and nitrogen. A nano-diode consists of a carbon $(10,0)$ -NT (with metallic conductivity). A ‘fibre’ along the axis of this tube has two parts, *viz.*, one formed by boron atoms (*p*-dopants) and the other formed by nitrogen atoms (*n*-dopants). According to calculations, *n*–*p*-doping results in a potential barrier (~ 1 eV) between the adjacent sections of the tube containing the boron and nitrogen parts of the ‘fibre’, respectively. Jishi *et al.*²⁸³ discussed the electronic states of (n,n) - BC_3 -nanotubulenes ($n = 2, 3, 4$) intercalated with a chain of bromine atoms.

2. ‘Symbiotic’ nanostructures: metal – carbon cages (met-carbs) in nanotubes

The effect of intercalation on the properties of NT for more complex systems was considered by Ivanovskii *et al.*^{284, 285} It was noted²⁸⁴ that the formation processes, stabilities and properties of $\text{M}@ \text{C}$ type nanosystems obtained upon intercalation of NT with atoms of various metals depends on the nature of the intercalant and the atoms that form the NT. For example, lead, zinc, nickel and copper atoms readily penetrate the carbon NT (these metals are either inert to carbon under equilibrium conditions or form unstable carbide phases²⁸⁶). On the contrary, introduction of atoms of Group IV – VI *d*-metals, which readily form carbides, is hindered: their strong interactions with the carbon atoms in the NT walls would result in the deformation and destruction of the latter. Obviously, similar reasons should prevent the synthesis of $\text{M}@ \text{NT}$ type nanostructures (where M are atoms of the Group IV – VI *d*-elements) based on BN-, BC- and BCN-nanotubulenes.

It is assumed^{284, 285} that new nanostructures incorporating Group IV – VI *d*-metals can be prepared if the latter are introduced into NT as their ‘own’ stable nanostructures. For example, these are represented by polyhedral clusters containing metal atoms along with carbon atoms, the so-called met-carbs, discovered not so long ago (in 1992).^{287, 288} Metallocarbohedranes with the composition M_8C_{12} are the most stable of them. Metal – carbon nanoparticles with other compositions and structures have also been obtained (see, *e.g.*, the reviews^{289–293}).

Ivanovskii *et al.*^{284, 285} calculated the energy and electronic characteristics of hybrid quasi-one-dimensional nanosystems ($\text{M}_8\text{C}_{12}@ \text{NT}$), *i.e.*, crystals formed by regular chains of met-carbs $\{[\text{M}_8\text{C}_{12}]_\infty$, where $\text{M} = \text{Sc}, \text{Ti}, \text{V}, \text{Zr}, \text{Nb}\}$ arranged along the axis of single-layer C-, BN-, BC_x -, $\text{B}_x\text{C}_{1-x-y}\text{N}_y$ -, Si- and GaN-nanotubulenes.

Analysis of the electronic structures of a number of systems belonging to quasi-unidimensional $\text{M}_8\text{C}_{12}@ (12,0)\text{-NT}$ type (Fig. 16) was carried out with consideration of the chemical composition of the NT, mutual arrangement of met-carbs and NT (displacement of the met-carbs along the axis and rotation around the tubulene axis were simulated) and the electron concentration (EC) in the system defined by the nature of the transition metal.²⁸⁴ 1D-Crystals incorporating the following met-carbs were considered: Sc_8C_{12} , Ti_8C_{12} , V_8C_{12} , Zr_8C_{12} and Nb_8C_{12} . It was found that the electronic spectrum of a quasi-1D $\text{Ti}_8\text{C}_{12}@ \text{BN}$ crystal consists of five occupied bands formed by the $\text{N}2s$ -, $\text{C}2s, 2p$ -, $(\text{C}2s, 2p + \text{N}2p)$ -, $(\text{N}2p - \text{B}2s, 2p + \text{Ti}3d)$ -, $\text{C}2p$ - and $\text{Ti}3d$ -states. The first four bands contain the states responsible for the chemical bonds in Ti_8C_{12} nanostructures and in BN-nanotubulenes. The states of transition metals around the Fermi level are responsible for the bonds of the neighbouring met-carbs in the chain and for the chain – NT interactions.

Figure 16. Models of 1D-crystals of $\text{Ti}_8\text{C}_{12}@\text{C}$ - (a) and $\text{Ti}_8\text{C}_{12}@\text{BN}$ -nanotubulene (b);²⁸⁴ (c–f) possible mutual orientations for met-carb-nanotube.

It should be noted that stabilisation of a $[\text{Ti}_8\text{C}_{12}]_\infty$ polymeric chain occurs in a 1D-crystal of $\text{Ti}_8\text{C}_{12}@\text{BN}$ -nanotubulene. However, the interatomic bonds in the NT and met-carbs change by no more than 1%–3%. In other words, the main types of the bonds which make these structures stable in the ‘isolated’ state are preserved in the crystal, which is evidence in favour of the stability of the simulated ‘symbiotic’ nanosystems. Ivanovskii *et al.*^{284,285} analysed the stability of this type of 1D-crystal depending on the position of the met-carbs and the NT and on the nature of the metal atom. Calculations for 1D-crystals incorporating Sc_8C_{12} and BN-nanotubulene in which the number of electrons per met-carb is less than 8 [as compared to the number of electrons per met-carb for $\text{Ti}_8\text{C}_{12}@(12,0)\text{-BN}$ -nanotubulene] showed that there are no bonds between the met-carbs. In contrast, the increase in EC on going to the $\text{V}_8\text{C}_{12}@(12,0)\text{-BN}$ -nanotubulene system favours a noticeable increase in the population of these bonds (by ~54%). Thus, it is possible to control both the bond strength and the stability of a system as a whole, as well as its dielectric properties, by changing the EC in the system (for example, by changing the chemical composition of the met-carbs by ‘doping’ them²⁹³).

It should be noted that a number of hybrid systems incorporating two types of stable nanostructures, *viz.*, fullerenes enclosed into an NT ($\text{C}_n@\text{C}$ type)⁶⁹ and NT incorporating endofullerene chains ($\text{M}@\text{C}_n@\text{C}$ type),⁷⁰ have recently been synthesised.

VI. Conclusion

Development of methods for the synthesis of non-carbon NT is now the leading direction in experimental studies on these unique subjects. Along with attempts to apply the methods known for the synthesis of carbon NT to the synthesis of other inorganic compounds in nanotubular form, elaboration of many ‘special’ synthetic methods is currently in progress.

In addition to physical methods, such as electric arc synthesis and laser ablation,^{3–6,15,16,24} which are particularly popular for producing carbon NT, chemical synthesis is becoming more and more important. In many cases, carbon NT serve as starting materials for the synthesis of non-carbon NT (chemical substitution, template synthesis).

It is difficult at the moment to compare the methods existing for the synthesis of non-carbon NT with respect to their productivity and effectiveness. It is possible that, even in the future, it will be hard to prefer some specific ‘versatile’ method, because the efficiency of each synthetic method depends on the chemical nature of the non-carbon NT.

The stage at which experimental studies are today is characterised by research into the synthesis of as wide a range of non-carbon NT as possible. The majority of studies describe the synthetic procedures and report the chemical compositions and morphology of the products. However, studies on physicochemical and functional properties are only occasional. These are only reported in selected studies and are far from being comprehensive.

Although it is possible to speak now of inorganic, physical, colloid, polymer and analytical chemistry of carbon NT,²⁷ it is too early to distinguish any particular areas of chemistry of non-carbon NT. The materials science of non-carbon NT is also in its infancy. Many suggestions to use them in practice are based on theoretical simulations and are far from technological solutions. The wide-scale production of non-carbon NT is also a problem yet to be solved.

Theoretical models have been developed for those non-carbon NT which have (or assumed to have) the closest similarity to carbon tubulenes. Ideal models of non-carbon NT in the shape of ideal cylinders rolled from a monoatomic sheet (or a polyatomic layer) remain the basis for describing these structures. Problems of describing various defects in non-carbon NT, processes of their growth and association into ‘braids’, films and crystals still need to be solved. There are no published data on the electronic and energy characteristics and properties of composite NT (*e.g.*, oxide NT that comprise oxide layers and an organic component). Problems of theoretical simulation also include NT reactivity and deviation of non-carbon NT from ideal morphology.

* * *

When this review was being prepared for publication, new interesting results appeared dealing with the synthesis and study of the properties of new non-carbon NT and materials based on them, as well as with their theoretical simulation. The most important studies are briefly considered below.

Tang *et al.*²⁹⁴ proposed a simple method for the synthesis of boron–nitrogen NT by thermal treatment of a mixture of elementary boron and iron oxide (in the ratio 15 : 1) in a flow of gaseous NH_3 . Chemical deposition from the gas phase onto a support containing Al_2O_3 particles with sizes of several micrometres gave multilayer (containing from two to five concentric layers) BN-nanotubulenes with unusually large inner diameters (8–10 nm).²⁹⁵ Guo *et al.*²⁹⁶ developed a two-stage process for chemical deposition from the gas phase, which allowed them to obtain Y-shaped splices of boron–carbon–nitride NT. Ma *et al.*²⁹⁷ obtained a ‘coaxial cable’, *i.e.*, a carbon NT filled with iron ‘core’ and containing dielectric boron–nitrogen nanotubulenes as the housing. It was confirmed by EELS that the carbon and boron–nitrogen layers in such heterostructures are separated from each other.

Studies on dichalcogenide NT were continued. Thermal decomposition of $(\text{NH}_4)\text{Mo}_{1-x}\text{W}_x\text{S}_4$ in an inert atmosphere or in hydrogen gave single-layer and multilayer NT with ‘mixed’ composition $\text{Mo}_{1-x}\text{W}_x\text{S}_2$ ($x < 0.1$)²⁹⁸ containing new defect types. A method for the synthesis of sulfide NT with the composition $\text{Cu}_{5.5}\text{FeS}_{6.5}$ was suggested.²⁹⁹ Pyrolysis of a mixture of WO_{3-x} with carbon NT in an $\text{N}_2 + \text{H}_2\text{S}$ atmosphere gave new composite structures, *viz.*, single-layer carbon NT encapsulated in multilayer WS_2 -nanotubulenes.³⁰⁰ Problems of hydrogen accumulation in MoS_2 -nanotubulenes were discussed.³⁰¹

Synthesis of silicon NT, both open and closed on the ends, with inner diameters of ~60–80 nm was reported.³⁰² They were obtained by deposition of a mixture of SiCl_4 with hydrogen onto a $\text{Ni}_x\text{Mg}_y\text{O}$ support that served simultaneously as a catalyst.

Interesting results were reported by Bao *et al.*³⁰³ who obtained nano-sized nickel tubes by electrochemical deposition of metallic nickel in pores of an alumina membrane. These nanostructures manifest magnetic properties. Li *et al.*³⁰⁴ were the first to obtain gallium-nitride NT.

Progress was also achieved in methods for the synthesis of oxide nanotubulenes. New schemes for the preparation of vanadium-oxide NT were discussed.^{305, 306} Doble *et al.*³⁰⁶ were the first to obtain mixed NT with the composition $\text{Mn}_{0.1}\text{VO}_{2.5+\delta}$ by ion-exchange reactions. A method for the synthesis of TiO_2 , ZrO_2 , Nb_2O_5 and Ta_2O_5 metal-oxide nanotubulenes using organic crystallites as templates was discussed.³⁰⁷ Reactions of crystalline TiO_2 (anatase or rutile) with a NaOH solution gave a multilayer titanium-oxide NT with distances of ~ 0.75 nm between the adjacent layers.³⁰⁸ The chemical compositions of the tubes (*viz.*, the Ti:O ratio) vary widely. A compacted set of titanium oxide-based NT was found in a product of anodic oxidation of pure titanium.³⁰⁹ The NT diameters range within 25–65 nm; their ends closed on the support side form a barrier layer resembling porous Al_2O_3 .

GeO_2 nanorods of 50–150 nm diameters and a few hundred micrometres long were obtained.³¹⁰ Studies of the photoluminescent properties of these nanostructures showed that they are promising as materials for optoelectronic nanodevices. The sol–gel method was used to obtain semiconducting Ga_2O_3 and In_2O_3 nanotubulenes with ~ 100 nm diameters.³¹¹

Maurin *et al.*³¹² studied the electrochemical doping of carbon electrodes built of NT with lithium; a number of other issues of the electrochemistry of lithium-doped carbon NT were considered elsewhere.^{313, 314} The positron annihilation method was used to study multilayer carbon NT doped with potassium, rubidium and cesium.³¹⁵ A review paper³¹⁶ discussed methods for the synthesis of composites containing metal atoms intercalated in carbon NT and the role of metal atoms as NT growth catalysts, as well as the results of studies of these composites by molecular dynamics and quantum-chemical methods.

A new composite material consisting of multilayer carbon NT in amorphous SiO_x has been obtained.³¹⁷ Furthermore, the SiO_x/NT structure was simulated by a strong-bond DFT method. The sol–gel method was used to obtain yet another new composite containing vanadium pentoxide and carbon NT, which may be promising as lithium battery electrodes.³¹⁸

Studies on $\text{C}_n@C$ -nanotubulene hybrid systems (fullerenes in nanotubes) were continued.^{319–321} The local electronic states of the $\text{C}_{60}@C$ -nanotubulene system were studied by scanning tunnelling microscopy³¹⁹ and EELS.³²⁰ It was concluded³²⁰ that fullerene–NT interactions occur due to weak van der Waals forces. The methodological aspects of the use of EELS spectroscopy for studies on the optical and electronic structures of $\text{C}_n@C$ -nanotubulenes were analysed.³²¹

Interesting results were obtained in theoretical simulation of the systems in question.³²² For example, calculations for a set of hypothetical SiC-nanotubulenes by DFT made it possible to suggest that they can be synthesised by injection of holes.³²³ The type of the interband transition in these metastable tubular structures (*i.e.*, whether direct or indirect transitions occur) depend on their chirality. The E_{str} of these NT were found to be smaller than the E_{str} of the corresponding carbon NT.

Much attention is paid to the development of microscopic models of ‘hybrid’ nanostructures. Based on calculations of the potential energies for systems containing spherical and ellipsoid fullerenes inside carbon NT, the ‘optimum’ sizes for the fullerenes to be incorporated were discussed.³²⁴ The molecular dynamics method was used to calculate the energy states and the elastic and tribological parameters of fullerenes in (n,n) -C-nanotubulenes (where $n = 5 - 10$).³²⁵ A very interesting problem was considered by Liu *et al.*³²⁶ they optimised model ‘hybrid’ nanostructures in the form of carbon NT containing a monoatomic ‘fibre’ of carbon atoms inside (along the axis). It was shown that for the NT with

diameters larger than ~ 0.43 nm the fibre turns into a spiral along the NT axis.

Non-empirical DFT calculations of the energy states of C_{60} fullerene in boron–nitrogen NT were carried out.³²⁷ It was estimated that incorporation of fullerenes into (9,9)- and (10,10)-NT is exothermic, which implies that such ‘hybrid’ structures can actually be synthesised. It was shown that they would be semiconductors.

The formation mechanism of yet another type of ‘hybrid’ structure, *viz.*, small-size ionic KI crystallites inside carbon NT, was studied by molecular dynamics methods.³²⁸

This study was partially supported by the Russian Foundation for Basic Research (Project No. 01-03-32513).

VI. Conclusion	217

Abstract. Procedures for the synthesis of captodative aminoalkenes, which were developed primarily over the last 15 years, are systematised. The influence of the structural and stereoelectronic effects of the substituents both at the nitrogen atom and at the double bond on the reactivity of these systems is considered. Particular emphasis is given to regio- and stereoselectivity of electrophilic, nucleophilic and radical reactions of captodative aminoalkenes as well as to processes of the construction of carbo- and heterocyclic compounds based on these aminoalkenes. A special section is devoted to the chemistry of methylidene- and arylmethylidenequinuclidin-3-ones. The bibliography includes 327 references.

I. Introduction

Two decades ago, Viehe^{1–4} proposed the concept of the captodative effect. Later on, the notion of captodative alkenes was introduced for compounds characterised by the simultaneous presence of electron-withdrawing (captive) and electron-donating (dative) substituents at the same carbon atom of the double bond. Alkenes containing the electron-donating and electron-withdrawing substituents in the vicinal position are termed push-pull.

Among captodative alkenes, enamines containing the geminal electron-withdrawing group (EWG) attract the most attention. Since these alkene derivatives possess special chemical properties, they were regarded as a separate group of organic compounds. Recent studies demonstrated that cross-conjugated isomers exhibit specific and much more versatile reactivities as compared to fully conjugated push-pull aminoalkenes.

Many captodative aminoalkenes have already found wide application. It will suffice to mention that these compounds are structural fragments of bioorganic molecules and serve as building blocks in the synthesis of various biologically active heterocycles and analogues of natural compounds. In the solution of some natural-science problems of the prebiotic chemistry and philosophical questions about the origin of life on Earth, much attention has been focused on the simplest representatives of captodative

alkenes (see, for example, the studies^{5–9} devoted to 2-aminoacrylonitrile).

However, while the chemistry of push-pull aminoalkenes **1** has been studied in sufficient detail and its various aspects were surveyed in a series of fundamental reviews,^{10–16} captodative aminoalkenes **2**, on the contrary, remained poorly studied until recent years.

EWG = CN (**a**), CO₂R (**b**), C(O)R (**c**), CHO (**d**).

The first effort to systematise the main procedures for the preparation of 2-aminocycloalk-2-enones and consider their most remarkable properties was made in the review,¹⁷ which covered the data published up to 1983. In the review¹¹ devoted to the chemistry of β -aminoenones, a special section was concerned with the data on the chemical behaviour of captodative aminoalkenes (mainly, cyclic), which have been reported only in 30 scientific sources. In the last 15 years, some important aspects of the chemistry of captodative aminoalkenes were developed substantially owing, primarily, to elaboration of simple and efficient procedures for the synthesis of such systems. The present review generalises the data on the chemistry of captodative aminoalkenes. The first section of the review is dedicated to procedures for the preparation of captodative alkenes containing an unsubstituted, mono- or disubstituted amino group and one electron-withdrawing group (carbonyl, alkoxy carbonyl or cyano group) at the same centre. In the second section, the spectroscopic characteristics of captodative aminoalkenes are analysed, including the data on their structures. In the third section, the major types of transformations characteristic of these compounds are classified. A special section is devoted to the chemistry of 2-methylidene- and 2-arylmethylidenequinuclidin-3-ones belonging to bicyclic captodative aminoalkenes, which do not exhibit properties of enamines due to their structural characteristic features. Quinoid structures, which formally contain the $C=C(NR_2)CO$ fragment, and activated alkenes bearing the geminal acylamino group are beyond the scope of the present review. Data on some compounds of this type (in particular, dehydroamino acids) were surveyed in a number of publications (see, for example, the review¹⁸).

II. Synthesis of captodative aminoalkenes

1. Insertion of the double bond into systems containing geminal amino and electron-withdrawing groups

a. Olefination of carbonyl compounds

One of the classical ways for inserting a double bond into a molecule involves Wittig-type olefination of aldehydes and ketones. Various captodative aminoalkenes were successfully prepared according to this procedure. Costisella and Gross demonstrated that cyanophosphonate **3** reacted with aromatic or aliphatic aldehydes and ketones in the presence of a strong base (BuLi, THF;¹⁹ NaH, dioxane or DMSO²⁰) to form 1-cyanoenamines **2a** in moderate yields.

$\text{R}^1 = \text{H, Me, Et, Pr}^i, \text{n-C}_6\text{H}_{13}, \text{Ph, 4-NO}_2\text{C}_6\text{H}_4, (\text{EtO})_2\text{P(O)CH}_2, \text{2-furyl};$
 $\text{R}^2 = \text{H, Ph; B is a base.}$

Later on, it was found that this reaction could be performed by electrolysis of phosphonates **3** on platinum or glassy-carbon electrodes,²¹ the carbanion being generated on the cathode. This carbanion reacts with the carbonyl compound to give finally the target alkenes **2a** in satisfactory yields.

In addition to the aminonitriles **3**, the reactions were successfully performed with esters. Thus methyl (dimethoxyphosphoryl)piperidinoacetate (**4**) reacted with benzaldehyde to form unstable methyl 3-phenyl-2-piperidinoacrylate (**5**), which was transformed into β -ketophosphonate **6** without isolation.²²

The 1-cyanoenamines **2a** were also prepared from aminoacetonitriles **7** and aliphatic (including α,β -unsaturated) or aromatic aldehydes by the Peterson reaction^{23–27} or condensation in the presence of a strong base (KH, KOH–K₂CO₃).^{24, 28} Both procedures appeared to be extremely sensitive to the nature of the amino group in the starting substrate **7**. In the case of dimethylamino-, diethylamino- or pyrrolidinoacetonitriles, the reactions either did not take place at all or proceeded in very low

$\text{R}^1 = \text{Me, CH}_2=\text{CHCH}_2, \text{MeCH}=\text{CHCH}_2; \text{R}^2 = \text{Ph, Bn};$
 $\text{R}^3 = \text{H, Me, Pr}^n, \text{Pr}^i, \text{n-C}_5\text{H}_{11}, \text{Ph, 4-MeOC}_6\text{H}_4, \text{MeCH}=\text{CH},$
 $\text{EtCH}=\text{CH, PhCH}=\text{CH, 2-thienyl, 1-naphthyl};$
 $\text{R}^4 = \text{H, Me, Et, Ph; B = KH, LDA or KOH–K}_2\text{CO}_3\text{–Bu}_4\text{NBr.}$

yields.²⁴ (*N*-Methylanilino)acetonitrile [**7**, $\text{NR}^1\text{R}^2 = \text{N(Me)Ph}$] proved to be the only substrate, which was almost quantitatively transformed into the corresponding 1-cyanoenamine.

Aldol condensation of α -aminoketones bearing the active methylene group with aromatic aldehydes afforded the corresponding captodative aminoalkenes **2c**.^{29, 30}

b. Elimination

A wide range of captodative aminoalkenes were prepared by elimination reactions, which very readily proceed in the case of β -heterosubstituted ketones, aldehydes, nitriles and esters.

Elimination of hydrogen halide from α -amino- β -haloketones or derivatives of carboxylic acids is a valuable approach, provided that the corresponding starting compounds are readily accessible. The idea of the use of haloaldehydes as building blocks in the synthesis of captodative aminoalkenes has long been known. More than 40 years ago, Temin³¹ developed an original synthesis of α -morpholinoacrylonitrile from chloroacetaldehyde (**8**, $\text{R}^1 = \text{R}^2 = \text{H, X} = \text{Cl}$), which was generated *in situ* from dimethylacetal.^{32, 33} This classical procedure (with small modifications) continues to be used for the preparation of the 1-cyanoenamines **2a**.^{34–36}

$\text{R}^1 = \text{H: R}^2 = \text{Pr}^n, \text{Pr}^i, \text{Ph; R}^1 = \text{Me: R}^2 = \text{Et, Ph; R}^1 = \text{R}^2 = \text{H, Me, Et, Cl; R}^1 - \text{R}^2 = (\text{CH}_2)_4, (\text{CH}_2)_5, \text{CH}_2\text{CH}=\text{CHCH}_2; \text{X} = \text{Cl, Br};$

$\text{NR}^3\text{R}^4 = \text{NH}_2, \text{NMe}_2, \text{NEt}_2, \text{pyrrolidino, piperidino, morpholino, N(Me)Ph, N(Me)C}_6\text{H}_{11}\text{-cyclo};$
 $\text{R}^4 = \text{H: R}^3 = \text{Me, Et, Pr}^i, \text{Bu}^t,$
 $\text{cyclo-C}_6\text{H}_{11}, \text{CH}_2\text{Bn; B} = \text{Et}_3\text{N or NaOH.}$

De Kimpe *et al.*^{37, 38} extended the scope of application of this method using α -chloroaldehydes **9** as the starting compounds. The latter are prepared from aliphatic aldehydes by successive imination with primary amines and chlorination with *N*-chlorosuccinimide. The reactions of the aldehydes **9** with KCN in methanol afford the 1-cyanoenamines **2a** in high yields. It was assumed^{37, 38} that the synthesis proceeded through 2-(*N*-alkylamino)-3-chloro-substituted nitriles as intermediates, which were readily dehydrochlorinated under the reaction conditions.

There are also other examples where the resulting 2-amino-3-halopropionitriles **10** were subjected to dehydrohalogenation to give the corresponding 1-cyanoenamines **2a**, including those with the unsubstituted,³⁹ mono-⁴⁰ or disubstituted amino group.^{41, 42} For these reactions, Et₃N^{32–36, 39–41} or NaOH³¹ are the reagents of choice.

An elegant preparative procedure proposed recently for the synthesis of various 1-cyanoenamines **2a** is based on the involvement of (*N*-methylanilino)phenylthioacetonitrile (**11**) in the tandem alkylation–elimination process.^{43, 44} The reaction proceeds stereospecifically to form the *E* isomer, which is accounted for by

anti-elimination of PhSH from intermediate **12**. The latter was isolated and characterised by spectroscopic methods.⁴³

R = H, Me, Pr, Br(CH₂)₂, I(CH₂)₄, Ph, CH₂=CH, PhCH=CH, MeCH=CH, BrCH=CH, PhSCH₂CH=CH, PhSCH=CH;

X = Cl, Br, I.

An attempt to reduce ester **13** with Raney nickel led to unexpected elimination of PhSH giving rise to methyl 2-amino-3-phenylacrylate (**14**).⁴⁵

In my opinion, the above-considered reactions are of considerable synthetic value. In addition, there are other examples of the synthesis of captodative aminoalkenes resulting in elimination of hydrogen halide,⁴⁶ alkanethiol,⁴⁷ amine,⁴⁸ hydrogen cyanide,⁴⁹ water⁵⁰ or alcohol.^{51,52} Dehydrogenation of *N,N*-disubstituted 2-aminocycloalkanones is also worthy of mention. Thus 2-aminocyclopent-2-enones were obtained in high yields by passing gaseous 2-aminocyclopentanones over Pd/C.⁵³

NR₂ = NEt₂, N-piperidyl, N-morpholyl.

c. Rearrangements

In some unsaturated compounds, double-bond migration readily occurs under the action of strong bases. The driving force for this process is the formation of a thermodynamically more stable isomer due to interaction between the π -system of the double bond and the electron-withdrawing group.

Treatment of β,γ -unsaturated α -aminonitriles **15** with strong bases (Bu^tOK or MeONa) under mild conditions afforded the corresponding 1-cyanoenamines **2a**.^{26,27,54–56} It should be noted that the stereochemistry of the reaction product depends both on the conditions of its preparation and the structure of the starting substrate. In addition, thermally initiated isomerisation can take place in these systems, as, for example, upon distillation of the nonconjugated aminonitriles **15**.³⁴

R¹ = H; R² = Me, Pr, Ph; R¹ = R² = H;

NR³R⁴ = N(Me)Ph, N(All)Ph, N(Me)C₆H₄Br-2; B = Bu^tOK, MeONa.

Under the action of strong bases, the β,γ -unsaturated *N,N*-disubstituted α -aminonitriles **15** produce ambident anions, which can undergo alkylation either at the α or γ position.⁵⁷ This property was used for the preparation of various 1-cyanoen-

amines **2a**.^{54,58–63} It was established that regioselectivity of alkylation is determined by different factors, among which are the steric parameters of the electrophilic reagent, the amino group and the γ -substituent in the substrate.⁵⁸ The formation of the captodative aminoalkenes **2a** is favoured by the presence of a bulky amino group in the substrate molecule. For example, alkylation of the nitriles **15** containing the N(Me)Ph or N(cyclo-C₆H₁₁)Ph groups always proceeds regioselectively to form the 1-cyanoenamines **2a**.⁶¹ The stereochemistry of addition depends also on the reaction conditions. Thus the reactions performed at low temperatures (–78 °C) afforded predominantly or even exclusively the *Z* isomers of the compounds **2a**.^{60,61}

R¹ = H, Me, Ph, MeCH=CH; R² = H, Me; NR³R⁴ = N(Me)Ph, NMe₂,

N-piperidyl, N-morpholyl; R⁵ = Me, Et, Prⁱ, Bu, Bn, All, Br(CH₂)₃,

Cl(CH₂)₃, 2-BrC₆H₄CH₂; X = I, Br; B = LDA or Bu^tOK.

In some cases, the initially formed β,γ -unsaturated α -aminonitriles or esters also undergo double-bond migration to the α,β position with respect to the electron-withdrawing group.^{64–67} For instance, the reaction of methyl 2-chloro-3-methylbut-3-enoate (**16**) with piperidine started with the attack on the allylic carbon atom to give finally the conjugated amino ester **17**.⁶⁵ It is reasonable to assume that intermediate **18** generated through the replacement of the chlorine atom is isomerised to the more stable alkene **17** under the action of the amine.

When developing a general procedure for the synthesis of esters of β,γ -unsaturated α -amino acids using organozinc compounds, the French research team^{66,67} found that the reaction of aminoacetal **19** with divinylzinc afforded amino ester **20**, which underwent isomerisation to give methyl 2-diethylaminobut-2-enoate.

Prototropic isomerisation of β -allenic amino esters, ketones or nitriles **21** under the action of strong bases [MeONa–DMSO,⁶⁸ Bu^tOK–HMPA (HMPA is hexamethylphosphoramide)⁶⁹ or Bu^tOK–THF⁷⁰] proceeded rapidly to give conjugated aminoalkenes **22** in high yields.^{68–70}

R¹ = H, Me, Et, Pr, Bu, Ph;

NR₂ = NMe₂, NEt₂, N-piperidyl, N-morpholyl;

EWG = CO₂Me, CO₂Et, C(O)Me, CN.

Generally, tautomeric transformations are not considered as preparative reactions. However, unlike simple enamines with unsubstituted or monosubstituted amino groups, which exist predominantly in the imino form, captodative aminoalkenes **2** are much more stable in the enamine form. This allows their isolation either in the individual form or as a tautomeric mixture in which the enamine form dominates. Examples of such syntheses of aminoalkenes containing the activating carbonyl,^{71, 72} alkoxy-carbonyl⁷³ or cyano group⁷⁴ are available in the literature.

A series of captodative aminoalkenes were prepared from the corresponding substituted aziridines.^{45, 75–77} In some cases, their formation was absolutely unexpected. For example, treatment of aziridinecarboxylate **23** with sodium azide in methanol gave rise to the unsaturated ester **14** instead of the expected methyl 2-amino-3-azido-3-phenylpropionate.⁴⁵

It was reported that 2-amino-3-methoxy-1,3-diphenylprop-1-en-1-one was transformed into α -aminochalcone under the action of strong bases.⁷⁸ The authors assumed that this reaction proceeded through intermediate aziridinoketones. However, the formation of unsaturated α -aminoketones has not subsequently been confirmed.⁷⁹

Recently, α -aminoenone **24** was synthesised by photooxidation of cyclopropanol **25**.⁸⁰ Photolysis was carried out in the presence of photosensitising agents, viz., 9,10-dicyanoanthracene or triphenylpyrylium tetrafluoroborate, for 0.5–5.2 min. It was noted that the enone **24** decomposed when the reaction time was increased.

2. Insertion of the amino group into the conjugated C=C–EWG system

The reaction of acrylonitrile with formaldehyde dimethylhydrazine produced 2-dimethylaminopropenenitrile regardless of the reaction conditions.⁸¹

Apparently, this is the only example of the formal synthesis of captodative aminoalkene from unsubstituted activated alkene.

a. Nucleophilic substitution

Nucleophilic substitution of a particular leaving group is most commonly used for the insertion of the amino group into the conjugated C=C–EWG fragment.

Although the replacement of the functional group X in the conjugated C=C(X)EWG system by the amino group seems at first glance to be the shortest pathway to captodative aminoalkenes, the reactions of N-nucleophiles with haloalkenes activated with the geminal electron-withdrawing group are complicated processes and do not necessarily afford the desired products. The results of these studies were critically analysed in the review.⁸²

All the aforesaid is clearly exemplified by the data from the recent study,⁸³ which demonstrated that the results of the reac-

tions of primary amines with bromo(cycloalkylidene)acetates **26a,b** depend substantially on the reaction conditions, the nature of the amine and the size of ring in the starting substrate. Under superhigh pressure, these reactions afforded spiroaziridines **27a,b** in high yields (and with high diastereoselectivity in the case of the derivatives **27b**). Under the same conditions, amines containing an aromatic or bulky substituent at the nitrogen atom produced predominantly α -amino- β,γ -unsaturated esters **28a,b**. Thermal activation of the compounds **26a,b** was accompanied by migration of the exocyclic double bond followed by the replacement of the allylic bromine atom to form exclusively the esters **28a,b**. Only in the case of the derivatives **28a** containing the five-membered ring, back migration of the endocyclic double bond was observed giving rise formally to *ipso*-substitution product **29**.

$n = 0$, $R^1 = \text{Et}$, $R^2 = \text{H}$ (**a**); $n = 1$, $R^1 = \text{Me}$, $R^2 = \text{Bu}^t$ (**b**);

$R^3 = \text{Pr}^n, \text{Pr}^i, \text{Ph}, \text{Bn}, \text{PhCHMe}$.

In the reactions with N,N- or N,O-binucleophiles, compounds **26a,b** underwent a cascade of transformations. Both upon thermal activation and under high pressure, the reactions involved double-bond migration and substitution of the halogen atom followed by condensation to form oxazinones (in the case of N,O-dinucleophiles) or piperazinones (in the case of N,N-dinucleophiles).⁸⁴ As in the case of reactions involving primary amines, the captodative system can be constructed only with the use of the bromo(cyclopentylidene)acetate **26a** and aminoethanol derivatives.⁸⁴

$R = \text{Me}, \text{Bn}$.

Since the halide ion is one of the best nucleofuges, it is not surprising that this ion is most generally used as the leaving group. Nevertheless, examples of the replacement of other groups at the sp^2 -carbon atom are also available in the literature. These reactions often proceed very readily.

In spite of the ambiguous results of the reactions of 2-amino-cycloalk-2-enones with N-nucleophiles,⁸⁵ 2-morpholinocyclohex-2-enone (**30**) is recognised as a convenient substrate in transamination.¹⁷

Ar = Ph, 4-MeOC₆H₄, 4-BrC₆H₄, 2-HOC₆H₄, 2-HO₂CC₆H₄.

2-Morpholinocyclohex-2-enone (**30**) was prepared by the reaction of 3-nitrocyclohex-2-enone with morpholine, isomeric β-aminoketone being obtained as the minor product.⁸⁶

Refluxing of an equimolar mixture of 2-(*p*-tolylsulfonyloxy)-tropone (**31**) and azacrown ether **32** in benzene in the presence of pyridine afforded the corresponding substitution product.⁸⁷

Competitive *ipso*- and *tele*-substitution of various leaving groups in other troponoid systems has been well studied as well.^{88–90} For example, isocolchicides **33a–f** readily reacted with piperidine, the ratio between the *ipso* (**34**) and *tele* isomers (**35**) being determined by the nature of the leaving group X. The reactions of the compounds **33a–c** afforded exclusively the isomers **34**, whereas the compounds **33d–f** produced the *tele* isomers **35** in 10%–25% yields. In the case of colchicides containing a substituent at position 10, only *ipso*-substitution was observed regardless of the nature of the leaving group.⁹⁰

X = Cl (**a**), SOMe (**b**), SMe (**c**), OMe (**d**), F (**e**), OTs (**f**).

Finally, it should be noted that none of the attempts to replace the alkoxy group in α-alkoxyacroleins afforded the α-formyl-substituted enamines **2d**⁹¹ although the reactions of amines with 3-alkoxy- or 3-phenoxypropenals are accepted to be a procedure of choice for the synthesis of their push-pull isomers **1d**.^{12, 92, 93}

b. Synthesis of captodative aminoalkenes bearing the unsubstituted amino group

Undoubtedly, captodative aminoalkenes containing an unsubstituted amino group are of particular interest. The classical approach to their synthesis is based on reduction of the corresponding nitro and azido derivatives. It was recommended to use hydrogen on a metal catalyst,⁹⁴ hydrogen sulfide⁹⁴ or aluminium amalgam^{94–96} for reduction of the azido group. In addition, α-amino-α,β-unsaturated ketones and esters were prepared by electrolysis of solutions of ene azides activated with geminal carbonyl or ester groups.^{97–100} Refluxing of azidoesters in toluene in the presence of catalytic amounts of iodine also afforded esters of unsaturated α-amino acids.^{18, 101, 102}

EWG = CO₂Me, CO₂Et, MeCO, 4-MeC₆H₄CO, 4-ClC₆H₄CO;

R = Me, Et, Prⁿ, Prⁱ, Ph, PhCH=CH, 4-MeC₆H₄, 4-HOC₆H₄,

4-MeOC₆H₄, 4-ClC₆H₄, 2,4,6-Me₃C₆H₂, 2-BnC₆H₄, 2-MeC₆H₄,

2-PrⁱC₆H₄, 2-furyl, 2-thienyl, 3-thienyl, 3-indolyl.

An unusual synthesis of α-aminoenone **36** from α-bromo-ketone **37** and sodium azide has been reported.⁷¹ In the first step, the bromine atom was replaced to give azidoketone **38**. Subsequent elimination of N₂ afforded imino ketone, which underwent rapid isomerisation into the unstable alkene **36**.

Nitroalkenes are readily reduced with aluminium amalgam to the corresponding amino derivatives.^{103–107} However, this procedure allows the preparation only of esters of β,β-disubstituted α-amino acids **39**. Reduction of β-methoxy-β-alkyl- or β-alkyl-substituted substrates gave rise predominantly to hydroxyimino esters **40**.^{104, 107}

R¹ = Me, Et, Prⁿ, Prⁱ; R² = H, Me, MeO; R³ = Me, Et, Buⁿ.

Careful removal of various protective groups also made it possible to prepare the captodative aminoalkenes **2a–c** containing the unsubstituted amino group (see, for example, Refs 108–112).

Procedures were developed for the synthesis of captodative aminoalkenes containing the unsubstituted amino group along with the keto, ester or cyano group. The exceptions are the formyl derivatives **2d**. Recent attempts to synthesise these compounds based on 2-haloalk-2-enals and hexamethyldisilazane or (diphenylmethylidene)amine failed.¹¹³ Admittedly, the question about the possibility of the existence of the aminoalkenes **2d** containing the unsubstituted amino group as well as of all aminoaldehydes with the unprotected amino group^{114, 115} remains open.

3. Simultaneous insertion of the double bond and the amino group

a. Syntheses based on diketones and ketoesters

One of the most general methods for the synthesis of captodative aminoalkenes is based on condensation of primary and secondary amines with readily enolizable 1,2-dicarbonyl compounds. As a rule, the reactions are carried out at room temperature or on refluxing of equimolar amounts of the reagents in an appropriate solvent (benzene, toluene, more rarely, chloroform or alcohol) in the presence or absence of a base or acid catalyst. The liberated water is removed either by azeotropic distillation or using molecular sieves.

Examples of the syntheses of 2-aminocycloalk-2-enones containing the disubstituted amino group were given in the review¹⁷ and in a number of recent publications.^{116–119} The use of chiral pyrrolidines in reactions with five–eight-membered cyclic 1,2-diketones allowed the preparation of optically active α -aminoenones.¹²⁰ Primary amines can also produce α -aminoenones in the reactions with cyclic diketones.^{121–124} Along with usual alkyl- and arylalkylamines [BuNH₂, cyclo-C₆H₁₁NH₂, Ar(CH₂)₂NH₂], esters of some α -amino acids, such as glycine, alanine and tyrosine, were also successfully used in these reactions.^{125, 126}

$n = 0, 1, 2, 3$; $R^1 = \text{H, Alk, All, Ar}$; $R^2 = \text{Alk, All, CH}_2\text{CO}_2\text{Et, CH(Alk)CO}_2\text{Et}$.

Since acyclic analogues of aminoketones are much less stable, the structures of the starting substrate and the reaction conditions are of particular importance in their synthesis. Acyclic α -aminoenones containing the internal or terminal double bond were prepared from α -diketones according to a classical procedure,¹²⁷ the yields being at most 30%. All attempts to purify the products led to their resinification.^{128, 129}

Conventional procedures for the preparation of enamines containing the geminal alkoxy carbonyl group offered considerable promise.

It appeared that prolonged refluxing of 2,2-diethoxyethylamine with ethyl (3-chloro-2-nitrophenyl)pyruvate in toluene actually afforded the corresponding enamine in quantitative yield.¹³⁰ Taking into account the high sensitivity of alkyl pyruvates both to acidic and basic reagents, Arnold¹³¹ improved this procedure. He proposed that TiCl₄, which is traditionally used in the synthesis of enamines, should be changed for softer AsCl₃. In essence, this modification allowed the first synthesis of the terminal aminoalkenes **2b** ($R^1 = \text{H}$). In spite of low stability, all products were prepared in the pure form in high yields.

EWG	R ¹	NR ² R ³	Catalyst	Yield (%)	Ref.
MeCO	H		TiCl ₄	—	128, 129
EtCO	H		TiCl ₄	30	129
EtCO	Me		TiCl ₄	25	129
PhCO	Ph		TiCl ₄	—	129
CO ₂ Me	H	NMe ₂	AsCl ₃	82	131
CO ₂ Me	H		AsCl ₃	73	131

EWG	R ¹	NR ² R ³	Catalyst	Yield (%)	Ref.
CO ₂ Me	H		AsCl ₃	75	131
CO ₂ Bu ^t	H	NMe ₂	AsCl ₃	68	131
MeCO	H		AsCl ₃	100	133

The sole exception is the pyrrolidine derivative, which was not isolated by the author. It should be noted that methyl α -piperidinoacrylate has been obtained previously from the corresponding chlorine-substituted ester and piperidine¹³² in very low yield (5%–10%). Later on, the procedure proposed by Arnold¹³¹ was successfully used for the synthesis of optically active acyclic α -aminoenone, viz., 3-[(*S*)-2-(methoxymethyl)pyrrolidino]but-3-en-2-one.¹³³

The reaction of *o*-phenylenediamine with pyruvic acid in a 0.1 M HCl solution at 20 °C gave rise to a mixture of the corresponding α -amino derivative of acrylic acid and its tautomer with the imine structure.¹³⁴ Both isomers can be isolated in the individual form.

An attempt to prepare the captodative enamines **2d** by direct condensation of methylglyoxal with two equivalents of secondary amine was doomed to failure because the reaction proceeded with the involvement of the more reactive aldehyde group.¹³⁵

Not only amines but also their derivatives serve as N-nucleophiles in condensation with dicarbonyl compounds giving rise to the aminoenones **2c**.^{136, 137} For example, trialkylgermylamines were found to react at one of the carbonyl groups of α -diketones **41a,b** to form α -amino- α -triethylgermyloxy ketones **42a,b**. The latter compounds appeared to be thermally unstable. Thus the compound **42a** decomposed to give aminoenone **43**.¹³⁶

$R = \text{Me (a), Ph (b)}$.

Recently, an ingenious procedure was developed for the synthesis of esters of unsaturated amino acids **2b** from esters of hetarylpyruvic acids **44**.¹³⁸ The esters **44** exist only in the enol form and are very reactive. These compounds are readily transformed to give the unsaturated amino esters **2b** in high yields upon refluxing with ammonium formate in ethanol. However, all attempts to obtain the compounds **2b** from the esters **44** under the action of other aminating reagents (aniline, benzylamine, ammonium chloride or ammonium acetate) failed.

b. Oxirane-ring opening

The oxirane-ring opening under the action of amines is widely used only for the preparation of cyclic aminoenones. These reactions have been surveyed in the review.¹⁷ Since then, no modifications of this procedure were proposed. Noteworthy only are the studies,^{139, 140} which were not included in the cited review, and the investigations^{141, 142} reported at a later time.

4. Formation of an electron-withdrawing group in aminoalkene

Examples of the insertion or generation of an electron-withdrawing group for the construction of captodative systems are few in number. In addition, these reactions are of limited application and of no particular preparative value.

The formation of the aminoalkenes **2c** containing the geminal carbonyl group was observed upon hydrolysis of enediamines,^{143, 144} oxidation of enamines^{145, 146} or aminoalcohols¹⁴⁷ and removal of protective groups.^{148, 149} Thus analogues of one of the natural components of the smell of freshly baked bread, *viz.*, compounds **45a,b**, were synthesised by careful acid hydrolysis of the corresponding ketal **46**¹⁴⁸ or azomethine derivative **47**.¹⁴⁹

A more general and efficient procedure for the synthesis of the 1-cyanoenamines **2a** is based on the nucleophilic substitution of the halogen atom by the cyanide ion.^{150, 151} For example, prolonged refluxing of 1-chloro-1-(dimethylamino)alkenes **48** with potassium cyanide in acetonitrile or with zinc cyanide in chloroform afforded the 1-cyanoenamines **2a** in good yields.¹⁵⁰ Unfortunately, this procedure is inapplicable to the synthesis of β-monosubstituted analogues of the compounds **2a** (R¹ = H) because the starting chloro derivatives are much less accessible and, in addition, they readily undergo dechlorination under the action of bases or upon heating.

Finally, one activating function in compounds of the type **2** can be transformed into another one. Thus 2-(*N*-methylanilino)-pent-2-enitrile was transformed into the enamines **2c** containing the geminal carbonyl group under the action of organolithium, -magnesium or -zinc compounds.⁵⁴

5. Other procedures

Other reactions giving rise to the captodative aminoalkenes **2a–d** have also been described in the literature. The results of investigations for a series of activated alkynes were the basis of several publications. It is known that the reactions of ethynylcarbonyl compounds with N-nucleophiles are among procedures most commonly used for the preparation of amino derivatives of the push-pull type **1**.¹² However, it was unexpectedly found that dialkylamines containing bulky substituents added not only at the β position but also at the α position with respect to the aldehyde group of 4,4-dimethylpent-2-ynal (**49**) to give a mixture of the unsaturated aminoaldehydes **1d** and **2d**.¹⁵² Thus the

proportion of the isomer **2d** reached 50% and 10% in the reactions of PrⁱNH and BuⁿNH, respectively. The authors related the regioselectivity of the addition to the spatial structure of the nucleophile.

Analogously, the reactions of methyl 4-nitrophenylpropiolate (**50**) with some secondary amines afforded the corresponding α-amino derivatives **51**.¹⁵³

In the synthesis of pyrimidine derivatives from triazines and 1-diethylaminoprop-1-yne (**52**), HCN, which was eliminated in the course of the reaction, added to the starting alkyne to produce 2-diethylaminocrotononitrile (**53**) in yields of up to 76%.¹⁵⁴

Cyclic α,α'-dibromoketones **54a–c** reacted with primary¹⁵⁵ and secondary amines^{17, 156} to give either Favorskii rearrangement products **55b,c** or the corresponding 2-aminocycloalk-2-enones **56a–c** depending on the ring size of the ketone and the structure of the nucleophile. The ratio of the reaction products is substantially affected by the nature of the solvent. The formation of the enamines **56a–c** is favoured by polar aprotic solvents.

In spite of the fact that treatment of α,α-dihaloketones with amines generally afforded the corresponding diamino derivatives,¹⁵⁷ the reactions of ethyl 1-alkyl-3,3-dibromo-2-oxocyclohexanecarboxylates **57a,b** with a tenfold excess of morpholine gave rise to aminoalkenes **58a,b**.¹⁵⁸

Recently, 2-aminocyclohex-2-enones **59a–c** were prepared¹²⁶ by oxidation of saturated ketones **60a–c**. Oxidation proceeded

even upon storage of the starting substrates without a solvent in air. The same results were obtained by bubbling oxygen through a solution of the ketones **60** in chloroform.

The most reactive captodative aminoalkenes **2d** were first synthesised by L Duhamel and co-workers.^{159, 160} The reactions of Grignard reagents with formylated or acylated enediamines **61** produced the corresponding aminoalkenes **2c,d** in good yields.

Ingenious methods were proposed for the synthesis of esters of dehydroamino acids with the free amino group.^{161–164} Alkyl 2-aminoalk-2-enoates **62a–e** were prepared by alcoholysis of anhydrides **63a–e** under mild conditions.^{161, 162} In the studies,^{163, 164} aldimines **64e–l** (which were prepared by condensation of glycine esters with aldehydes) were used as the starting reagents, which were transformed into the target compounds **62e–l** upon refluxing in toluene in the presence of triethylamine or upon storage in the MeCN–DBU system (DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene) at room temperature. Spectral analysis demonstrated that the esters **62a–l** were always generated only as the *Z* isomers.

Other reactions giving rise to captodative aminoalkenes have also been reported. However, they are of limited application, cannot be used for preparative purposes, and hence, are beyond the scope of the present review.

III. Structures and spectroscopic characteristics of captodative aminoalkenes

In the analysis of the structures of captodative aminoalkenes, one should first of all answer the question of how the combination of the electron-withdrawing and electron-donating groups is reflected in the degree of *p*, *π*- and *π*, *π*-conjugation in such systems.

Captodative aminoalkenes can be represented by superposition of the structural fragments of enamines, on the one hand, and of α,β -unsaturated aldehydes, ketones or derivatives of carboxylic acids, on the other hand. This approach assumes that three canonical structures must be taken into account in the description of the reactivities of these compounds.

If the structure **65** makes a larger contribution to the total electronic state of the molecule compared to that of the resonance form **66**, the β -carbon atom would be expected to possess higher

nucleophilicity. In contrast, if the structure **66** predominates, captodative aminoalkenes must approach the corresponding activated alkenes in their chemical properties.

It is well known that the degree of conjugation between the π -electrons of the double bond and the lone electron pair of the nitrogen atom or the π -system of the activating group is manifested by the chemical shift of the olefinic proton in the ^1H NMR spectrum.^{165–167} Apparently, this correlation can be made only if the steric parameters of the substituents at the nitrogen atoms are identical or similar to those at the β -carbon atom, whereas the differences in their chemical shifts are rather large. The ^{13}C NMR spectra are less dependent on the influence of the medium and the anisotropic effects and directly reflect the state of both the π and σ electron density in the molecule. For a series of push-pull alkenes, the difference in the chemical shifts of two adjacent carbon nuclei was used for estimating the degree of polarisation of the double bond.^{165–167} However, it should be emphasised that ^{13}C NMR spectroscopy provides only qualitative estimates of the degree of polarisation of the double bond in the captodative aminoalkenes **2**. An effort to perform spectral analysis of 2-aminocycloalk-2-enones was made in the studies.^{17, 168}

The spectroscopic characteristics of captodative aminoalkenes containing the terminal double bond are given in Table 1. In the ^1H NMR spectra of these compounds, the signals for the

^a In CCl_4 . ^b The author's own data.

protons of the $\text{H}_2\text{C}=\text{}$ group are observed in the ‘olefinic region’ between the signals typical of vinylamines ($\delta = 3.40\text{--}3.78$)¹⁷¹ and the corresponding activated alkenes ($\delta = 5.75\text{--}6.36$).^{172–174} It should be noted that the chemical shifts of the olefinic protons depend on the nature of the captodative substituents. For example, the shifts $\delta(\text{H}_2\text{C}=\text{})$ in the spectra of α -aminoacrylonitriles bearing the nitrogen-containing heterocycles with similar steric parameters (see Table 1, the compounds **c–i**) are changed as the electron-donating ability of the amino group changes. As in the series of unsubstituted enamines,¹⁷⁵ the strongest orbital interaction between the lone electron pair of the nitrogen atom and the double bond is observed in the pyrrolidine derivative **e**.

The insertion of the alkyl or aryl substituent at the β position enhances deshielding of the olefinic proton and provides the possibility for the existence of the geometric isomers (Table 2).

As in the case of unsubstituted enamines,¹⁷⁵ the signal for the olefinic proton of the *E* isomers of captodative aminoalkenes is always observed at higher field. The results of the study⁴⁸ showed that this regularity is violated by some formyl-substituted enamines. However, I thoroughly checked the molecular geometry by NMR spectroscopy using the Overhauser effect and found that the assignment of the signals made in the cited study⁴⁸ was incorrect. To a first approximation, the larger value of $\delta(\text{HC}=\text{})$ for the *Z* isomers can be considered a result of strengthening of π,π -conjugation with a simultaneous decrease in p,π -conjugation due to the steric interaction between the β -substituent and the tertiary amino group. For this reason, the *Z* isomer is generally thermodynamically more stable.

Factors other than the structural characteristics of the molecule are also responsible for the ratio between the *E* and *Z* isomers.

^a In CCl_4 . ^b The assignment to the *E* and *Z* isomers was made based on the author's own data. ^c The author's own data.

Example of *E,Z* isomerisation of captodative aminoalkenes, which proceeded rather readily either in the course of the reactions^{48, 128, 129, 177} or upon subsequent purification (for example, upon distillation)¹⁷⁹ and even upon storage over a short period at room temperature,¹²⁹ are available in the literature.

For captodative aminoalkenes bearing the internal double bond, the chemical shift of the olefinic proton is also sensitive to variations in the nature of the electron-donating and electron-withdrawing substituents. Generally (although not necessarily), the stronger are the electron-withdrawing properties of the activating group and the weaker are the electron-donating properties of the amino group, the more substantial is the downfield shift of the signal for the olefinic proton. If the nitrogen atom possesses substituents capable of being involved in conjugation with the lone electron pair of the nitrogen atom, the chemical shift of the olefinic proton is increased further by 0.3–0.8 ppm. This fact also indicates that in these compounds conjugation between the double bond and the electron-withdrawing group typical of activated alkenes is virtually completely restored.

In the ¹³C NMR spectra of captodative *N,N*-disubstituted aminoalkenes, the signal for the C² atom is observed at a higher field as compared to the signal for the C¹ atom. It should be noted that this regularity is also true for the series of enamines bearing such a powerful electron-withdrawing substituent as the formyl group.¹⁷⁶ The difference in the chemical shifts of the adjacent carbon atoms of the alkene fragment observed in these systems is comparable with that for unsubstituted enamines (30–45 ppm). These data are unambiguously indicative of high polarisation of the double bond and are a strong argument in favour of the predominant contribution of the structure **65** to the ground electronic state of the molecule.

In the case of *N*-methylaniline derivatives containing the geminal electron-withdrawing group, an inversion of the usual order of the chemical shifts of the C¹ and C² nuclei is observed. The difference $\delta(C^2) - \delta(C^1)$ reaches +14.3 ppm (see Table 2, compounds **o**, **p** and **s**). The exceptions are enamines bearing the carbonyl group for which the positions of the resonance signals for the carbon nuclei are less dependent on the nature of the amino group (see Table 2, compounds **h**, **i**, **k** and **l**). A satisfactory explanation for this phenomenon is lacking.

The presence of conjugation in the C=C–EWG system of the carbonyl-containing captodative aminoalkenes **2d** is evidenced by the presence of intense absorption bands at 1655–1690 (C=O) and 1585–1620 cm^{−1} (C=C) in their IR spectra.¹⁸⁰ The former spectral region is close to the stretching vibration frequencies characteristic of the conjugated carbonyl group, whereas the frequencies belonging to the latter region are somewhat lower than the vibration frequencies of the double bond in the corresponding unsubstituted enals and enones and are noticeably lower than the vibration frequencies of the C=C bond in simple enamines.

Analysis of the IR spectra of captodative carbonyl-containing enamines by comparing the intensities of the absorption bands of the C=C and C=O groups led Arnould *et al.*¹⁷⁷ to the conclusion that the *E* isomer in the ground state adopts the *s-cis* conformation, whereas the *Z* isomer has the *s-trans* conformation.

Finally, the efficiency of *p,π*-conjugation in 2-aminocycloalk-2-enones depends dramatically on the ring size (Table 3). For example, the shifts $\delta(HC=)$ in the ¹H NMR spectra of piperidine and morpholine derivatives of cycloalkenones increase substantially on going from seven- to six- and then to five-membered rings. As in the spectra of acyclic enamines bearing the geminal carbonyl group, the resonance signals for the C³ atom in the spectra of 2-aminocycloalk-2-enones containing mono- and disubstituted amino groups are shifted upfield as compared to the signals for the C² atom. The difference between the chemical shifts

Table 3. Chemical shifts of the olefinic protons in 2-aminocycloalk-2-enones.

Compound	R	Chemical shifts of the olefinic protons /ppm	Solvent	Ref.

		5.86 ^d	CDCl ₃	86
		5.23	CCl ₄	183
		5.13	CCl ₄	183

The chemical shifts of the carbon nuclei: ^a $\delta(C^3) = 120.61$, $\delta(C^2) = 145.13$ (see Ref. 155); ^b $\delta(C^3) = 121.04$, $\delta(C^2) = 142.62$ (see Ref. 155); ^c $\delta(C^3) = 126.1$, $\delta(C^2) = 148.1$ (see Ref. 146); ^d $\delta(C^3) = 133.7$, $\delta(C^2) = 150.8$ (see Ref. 146).

of the β - and α -sp²-hybridised carbon atoms varies between −22 and −27 ppm, whereas this difference for unsubstituted cyclic α,β -unsaturated ketones ranges from 21 to 33 ppm. Undoubtedly, this effect should be related to the fact that *p,π*-conjugation between the nitrogen atom and the double bond dominates over the π,π -interaction between the double bond and the carbonyl group. All the aforesaid send one in the critical review of the conclusion made previously¹⁷ that the canonical structure **66** is more appropriate for the description of the ground state of 2-aminocycloalk-2-enones.

Hence, the spectroscopic data provide evidence for the presence of competitive *p,π*- and π,π -conjugation in the captodative aminoalkenes **2a–d**, the efficiency of the conjugation being determined by the nature of the functional groups. In the general case, the compounds under consideration are intermediate between unsubstituted enamines and α,β -unsaturated aldehydes, ketones or derivatives of carboxylic acids. What this means is these systems would be expected to exhibit dual reactivity with respect to nucleophilic and electrophilic reagents.

IV. Reactions of captodative aminoalkenes

Being polyfunctional systems, the captodative aminoalkenes **2a–d** are not only valuable starting reagents for organic synthesis but are also excellent models for solution of some problems of alternative reaction centres. Analysis of the data available in the literature shows that insignificant (at first glance) changes in the structure of the substrate or the reagent and variations in the reaction conditions can give rise to radically different reaction products. In addition, the polyfunctional properties of the compounds under consideration are often responsible for their unexpected and surprising cascade transformations.

1. Reactions with electrophilic reagents

a. Protonation and hydrolysis

Apparently, the nitrogen atom, the β -carbon atom and the heteroatom of the activating group serve as the nucleophilic centres in captodative aminoalkenes. Consequently, the regioselectivity of the electrophilic attack is the central problem of the reactions of the compounds **2a–d** with electrophilic reagents.

Protonation serves as the simplest test for the reactivity of such systems. Unlike simple enamines generating stable immonium salts¹⁷⁵ and the push-pull aminoenones **1c**, which are protonated predominantly at the oxygen atom,¹⁰ the captodative aminoalkenes **2a,c,d** can add the proton at each of three major nucleophilic centres depending on the structure of the substrate, the nature of the protonating reagent and the reaction conditions.

Thus the reactions of mineral or strong carboxylic acids with the aminoalkenes **2**, which are activated by the geminal cyano,¹⁸⁴ carbonyl,¹⁸⁵ formyl^{186,187} or azomethine group,¹⁸⁸ generally afford the corresponding enammonium salts **67a,c–e**. It should be emphasised that the hydrochlorides **67a,c,d** ($X = \text{Cl}$) were isolated and completely characterised.

EWG = CN (**a**), C(O)Ph (**c**), CHO (**d**), CH = NMe (**e**);

$R^1 = \text{H}$, $R^2 = \text{Me}$, Ph; $R^1-R^2 = (\text{CH}_2)_5$;

$\text{NR}^3\text{R}^4 = \text{NHBu}^t$, NEt_2 , , ; $X = \text{Cl}$, CF_3CO_2 , CCl_3CO_2 .

The regioselectivity of protonation of the 2-aminocycloalk-2-enones **56a–i** is determined by the ring size and the nature of the amino group.^{121,189} For example, the reaction of a solution of trifluoroacetic acid in CDCl_3 with morpholinocyclohexenone **30** afforded exclusively enammonium salt **68b** (NR^1R^2 is morpholino), whereas the reaction with the seven-membered homologue **56c** (NR^1R^2 is morpholino) performed under the analogous conditions led to protonation both at the heteroatom to give compound **68c** (NR^1R^2 is morpholino) and at the β -carbon atom to generate the corresponding immonium salt **69c**.¹²¹ Protonation of aminocyclopentenones (**56a**) as well of the cyclohexenone **56b** containing the monosubstituted amino group ($\text{NR}^1\text{R}^2 = \text{NHC}_6\text{H}_4\text{Me-4}$) afforded immonium salts **69a,b**, which underwent subsequent enolisation.¹²¹ The dependence of the regioselectivity

$Y = \text{CH}_2$: $n = 0$ (**a**), **1** (**b**), **2** (**c**); $Y = \text{CHMe}$: $n = 0$ (**d**), **1** (**e**), **2** (**f**);

$Y = \text{NH}$: $n = 0$ (**g**), **1** (**h**), **2** (**i**); $\text{NR}^1\text{R}^2 = \text{NHBn}$, $\text{NHC}_6\text{H}_4\text{Me-4}$,

, NMe_2 , ; $X = \text{CF}_3\text{CO}_2$, Cl .

of protonation on the ring size was also observed in the case of the enammonolactams **56h,i**.^{190,191}

The formation of nitrogen-protonated captodative aminoalkenes is a rare example of the existence of enammonium salts, which, as a rule, readily undergo isomerisation to the corresponding immonium salts.¹⁷⁵ A rather stable enammonium salt was first synthesised in 1976.^{192,193} However, really stable compounds with the enammonium structure were prepared only upon protonation of the captodative aminoalkenes **2c,d**. Apparently, their stability is associated with the powerful influence of the electron-withdrawing geminal substituent and the stabilising effect of the intramolecular hydrogen bond that is formed.[†] This assumption is supported by the fact that protonation of (*s-cis*-diethylamino)-benzylideneacetophenone gave rise to the enammonium salt adopting the *s-trans* conformation.¹⁸⁵

The salts **67d** are so stable that they were not transformed into immonium salts at all.^{186,187} As shown in the previous section, a decrease in the electron-withdrawing ability of the activating group in the captodative aminoalkenes **2** leads to an increase in the proportion of the resonance form **65** bearing a negative charge on the β -carbon atom. As a consequence, these aminoalkenes exhibit properties of simple enamines. Actually, unlike the formyl-substituted enamines **2d**, their azomethine analogues **2e** generated the enammonium salts **67e**, which underwent slow isomerisation in CDCl_3 solution to give the more stable C-protonated derivatives **70e**.¹⁸⁸

$\text{NR}_2 = \text{N} \begin{smallmatrix} \diagup \text{O} \diagdown \end{smallmatrix} \text{O}$, ; $X = \text{CF}_3\text{CO}_2$, CCl_3CO_2 .

The result of the reaction of the acyclic aminoenones **2c** with acids depends substantially on the nature of the protonating reagent and the reaction conditions. Thus the reaction with anhydrous HCl was accompanied predominantly by protonation at the nitrogen atom, whereas the formation exclusively of immonium salts was observed in a solution of trifluoroacetic acid.¹⁸⁵ The difference in the behaviour of inorganic and carboxylic acids is accounted for by the bifunctional catalytic action of carboxylic acids in the course of proton transfer from the nitrogen atom to the carbon atom.¹⁹⁴

In the enammonium salts **67**, *p*, π -conjugation becomes impossible. Moreover, the donor fragment NR^3R^4 is transformed into the acceptor $\text{N}^+\text{HR}^3\text{R}^4$ upon quaternisation. The formation of the system with the geminal electron-withdrawing substituents results in the essential electron density redistribution. This is the reason that the multiplicity of the C=C bond is somewhat decreased and, as a consequence, the barrier to rotation about this bond is substantially lowered. Examples of *E,Z* isomerisation of enammonium salts (**67c–e**), which proceeded very readily, were cited in Refs 185–188.

In spite of the fact that enammonium salts do not necessarily undergo tautomeric transformations into immonium salts, the

[†] The author's own data.

captodative aminoalkenes **2b–d** are hydrolysed to give the corresponding α -dicarbonyl compounds. For example, the aminoesters **62a–e** were virtually quantitatively transformed into esters of 2-oxocarboxylic acids **71a–e** in a 1 M solution of hydrochloric acid at room temperature during 0.5 h.¹⁶²

$\text{R}^1 = \text{Me}$ (**a**), Et (**b**), Pr^n (**c**), Pr^i (**d**), Ph (**e**); $\text{R}^2 = \text{Me}$, Et .

The acyl- and formyl-substituted enamines **2c,d** are also hydrolysed in an acidic medium.^{160, 186} Various α -diketones can be prepared from the compounds **2c** by varying the substituents in the starting substrate.

$\text{R}^1 = \text{Alk}$, Ar ; $\text{R}^2 = \text{H}$, Alk , Ar .

Protonation and hydrolysis of the captodative aminoalkenes **2** are used in a number of simple and efficient synthetic procedures. An example is hydrolysis of the 1-cyanoenamines **2a** containing the unsubstituted, mono- or disubstituted amino group to give the corresponding carboxylic acids **72**.^{20, 110, 150} The reactions of the cyanoenamines **2a** with Lewis acids (AlCl_3 or ZnCl_2) in ethanol followed by hydrolysis gave rise to monosubstituted amides **73**.^{184, 195}

$\text{R}^1 = \text{H}$, Me , Et ; $\text{R}^2 = \text{Me}$, Et , Ph , $4\text{-MeOC}_6\text{H}_4$; $\text{R}^1-\text{R}^2 = (\text{CH}_2)_5$;
 $\text{R}^3 = \text{R}^4 = \text{Me}$; $\text{R}^4 = \text{H}$: $\text{R}^3 = \text{H}$, Me , Pr^i , Bu^t , $\text{cyclo-C}_6\text{H}_{11}$.
 (a) H_2O , H^+ ; (b) AlCl_3 , EtOH or HCl , PhH ; (c) H_2O .

b. Alkylation and acylation

Alkylation of captodative aminoalkenes requires more drastic conditions and affords the corresponding enammonium salts regardless of the nature of the alkylating reagent. It is not surprising that the nature of the amino group exerts a pronounced effect on the ease of the reaction. Thus prolonged refluxing of 2-aminocycloalk-2-enones **56a,b** with alkyl halides afforded *N*-alkyl derivatives **74a,b**.^{181, 189}

$n = 0$ (**a**), 1 (**b**); $\text{NR}^1\text{R}^2 = \text{NMe}_2$, $\text{N}(\text{C}_6\text{H}_{11})_2$, $\text{N}(\text{C}_6\text{H}_5)_2$; $\text{R}^3 = \text{Me}$, Et ;
 $\text{X} = \text{I}$, Cl , BF_4 .

The cyanoenamines **2a** containing a bulky substituent on the monosubstituted amino group do not react with alkyl halides or alkyl *p*-toluenesulfonates. However, aminoalkenes bearing the disubstituted amino group can be prepared with the use of

stronger alkylating reagents, for example, of dialkyl sulfates, alkyl fluorosulfonates or triethyloxonium tetrafluoroborate.¹⁹⁶ In the latter case, alkylation proceeded under mild conditions and was not accompanied by side processes.

(62%–95%)

$\text{R}^1 = \text{Me}$, Et ; $\text{R}^2 = \text{Me}$; $\text{R}^1-\text{R}^2 = (\text{CH}_2)_5$; $\text{R}^3 = \text{Me}$, Pr^i , Bu^t , $\text{cyclo-C}_6\text{H}_{11}$.

'Magic methyl' was successfully used for quantitative *O*-alkylation of 2-aminotropone (**75a**) and 2-methylaminotropone (**75b**).¹⁹⁷ It is reasonable to assume that the driving force for this reaction is the formation of the aromatic system of tropylium cation **76a,b**.

$\text{R} = \text{H}$ (**a**), Me (**b**).

The primary, secondary and tertiary captodative aminoalkenes **2** are difficult to acylate. Thus attempts to perform the reactions of the primary aminoalkenes **2b** with acetyl chloride or acetic anhydride failed.¹³⁸ However, some reactions of the compounds **2b** with acid chlorides or anhydrides of strong carboxylic acids produced *N*-acylated products in moderate yields.^{95, 96, 104, 105, 107, 198–200} These reactions were used in the peptide synthesis.^{200–204}

(8%–60%)

$\text{R}^1 = \text{H}$, Me ; $\text{R}^2 = \text{Me}$, Et , Pr^n , Pr^i , Ph , $\text{MeOCH}_2\text{OC}_6\text{H}_4$, Het ;
 $\text{R}^3 = \text{Me}$, Et ; $\text{R}^4 = \text{ClCH}_2\text{CO}$, BnOCO , $4\text{-MeC}_6\text{H}_4\text{SO}_2$, CF_3CO ,

N-Acylation of 3-aminocoumarin derivatives was successfully carried out under the action of phthalic anhydride and 2-chloronicotinoyl chloride.^{205, 206} Perfluoroacyl fluorides proved to be excellent acylating reagents for the formyl-substituted aminoalkenes **2d**.²⁰⁷ The reaction of 2-*tert*-butylaminocyclohex-2-enone with ethyl chlorocarbonylacetate in the presence of pyridine and 4-dimethylaminopyridine afforded a mixture of *N*-acylated derivative **77** and the product of its subsequent intramolecular condensation **78**.²⁰⁸

The formation of diester **79** in the reaction of methyl 2-dimethylaminoacrylate with methoxalyl chloride is a rare example of C-acylation of captodative aminoalkenes. The compound **79** is readily hydrolysed to the symmetrical ester of dioxo acid **80**.¹³¹

Unsymmetrical amino groups in captodative aminoalkenes are sufficiently basic and nucleophilic that they can be subjected to condensation with carbonyl compounds. These aminoalkenes smoothly react with aldehydes or dimethylformamide dimethyl acetal to form the corresponding azomethines.^{94, 106, 110, 138, 209} Even the unstable cyanoenamines **2a** were readily transformed into 2-aza-3-cyanobuta-1,3-dienes **81** and **82** upon refluxing in benzene with azeotropic distillation of water.¹¹⁰

$\text{Ar} = \text{Ph}, 4\text{-MeOC}_6\text{H}_4$.

The reactions of the aminoalkenes **2b** with 5-formylpyran-2-one, which begin with the ring opening, provide the convenient means for preparing dihydroazepines **83**.²¹⁰

$\text{Ar} = \text{Ph}, 4\text{-ClC}_6\text{H}_4$.

In reactions with some carbonyl compounds, captodative aminoalkenes containing mono- and disubstituted amino groups act as C-nucleophiles. For example, the reactions of the 2-aminocycloalk-2-enones **56b,c** with quinones afforded various heterocyclic compounds.¹²² Their structures depend on the ring size and the nature of the amino group of the substrate. It was believed^{11, 122, 211, 212} that the first step of the reaction gave rise to derivative **84**.

The first investigations into the involvement of the captodative aminoalkenes **2** in aminomethylation demonstrated that the structure of the resulting Mannich base depends dramatically on the ring size of the substrate and the reaction conditions.^{181, 213} Thus the 2-aminocyclopent-2-enones **56a** produced bis-aminomethylated compounds **85** in moderate yields,¹⁸¹ whereas the reaction of the aminoalkene **30** gave rise only to monoaminomethylated product **86** even in the presence of a twofold excess of paraformaldehyde and morpholine hydrochloride.²¹³

$n = 1, \text{X} = \text{CH}_2$; $n = 2, \text{X} = \text{CH}_2, \text{O}$.

c. Reactions of electrophilic reagents with carbanions generated from captodative aminoalkenes

As mentioned above, the β -substituted captodative aminoalkenes **2a,b** are capable of being deprotonated under the action of strong bases to give allylic anions **87**, which can react with various electrophilic reagents (alkyl halides, aryl halides and carbonyl compounds) either exclusively at the γ -carbon atom or simultaneously at the α - and γ -carbon atoms.^{34, 57, 151, 178, 214–218} The fact that the attack proceeds predominantly at the γ -position is attributed primarily to the steric characteristics of the substrate and the electrophile. These reactions are preparatively valuable because they allow modifications of captodative aminoalkenes to obtain compounds, which are used in the synthesis of various polyfunctional systems.

EWG = CN (**a**), CO₂Me (**b**); R¹ = H, Me, PhS, PhSO₂; R² = H, Me;

R⁵ = Me, Et, Prⁱ, Buⁿ, n-C₅H₁₁, Ph, Bn, CH₂=CHCH₂, MeCH=CHCH₂,
Me₂C=CHCH₂; X = Hal; R⁶ = H, Me; R⁷ = Me, Prⁱ, Ph;
R⁶-R⁷ = (CH₂)₅; B = BuⁿLi, LDA, Bu^tOK.

Some tertiary enamines **2a,b** react with aldehydes in the presence of strong bases to give five- or six-membered lactones depending on the nature of the activating group.^{20, 214}

R¹ = H, Me; R² = Ph, Me(CH₂)₃, Me(CH₂)₅, MeCH=CH, , , .

The Michael addition of various anions to 2-(*N*-methylanilino)acrylonitrile afforded initially anions **88**.^{23, 35, 58} Their subsequent reactions with electrophiles gave rise to bifunctional

R¹ = Bu^t, Ph, PhCOCH₂CH₂, PhCH=CHCHPh, Bu^tC(O)CH₂;

R² = H, Me, Et, Bn; X = OH, I, Br.

derivatives **89**, which were hydrolysed to the corresponding carbonyl compounds **90**.^{23, 35, 58}

When developing this methodology and varying the nature of the electrophile and the organolithium derivative, Ahlbrecht and co-workers unveiled the considerable synthetic potential of one of the simplest captodative aminoalkenes, viz., 2-(*N*-methylanilino)acrylonitrile. This compound proved to be a versatile and readily accessible starting reagent for the one-pot synthesis of ketones,²³ β-, γ- and δ-diketones,^{179, 219–221} γ- and δ-oxoaldehydes,^{221, 222} β-phenylthioketones, which were transformed into α,β-unsaturated carbonyl compounds²²³ upon pyrolysis, as well as of derivatives of oxocarboxylic acids (nitriles,^{224, 225} esters and amides²²⁶). The efficient syntheses of bicyclic diketones²²⁰ and pyrroles¹⁷⁹ based on 2-(*N*-methylanilino)acrylonitrile are worthy of notice.

X = H, Alk, Ar, OR, NR₂; Y = H, Alk, Ar.

2. Reactions with nucleophilic reagents

Taking into account the electronic structure of captodative aminoalkenes, one would expect that these compounds will act as poor Michael acceptors and the attack of nucleophilic reagents will proceed predominantly either at the electrophilic centre of the activating group or at the α-carbon atom.

Actually, attempts to perform the 1,4-addition of some C- and N-nucleophiles to 2-aminocycloalk-2-enone have not met with success. Only nitroalkanes produced Michael adducts in moderate yields (see Ref. 17).

In the study on the cyanoenamines **2a**,⁵⁴ it was concluded that the direction of the addition of nucleophiles generally follows the rule of hard and soft acids and bases (HSAB). However, some of nucleophilic reactions of captodative aminoalkenes do not obey the HSAB principle.

The 1,2-addition of organometallic compounds to form a new C–C bond is the most extensively used nucleophilic reaction of captodative aminoalkenes. The reactions of the 2-aminocycloalk-2-enones **56a–d** with Grignard reagents proceeded regioselectively to produce 2-hydroxycycloalkanones **91a–d** in good yields.^{120, 227–230}

$n = 0$ (a), 1 (b), 2 (c), 3 (j); $\text{R}^1 = \text{H}, \text{Me}$;

$\text{R}^3 = \text{Me}, \text{Et}, \text{Ph}, \text{CH}_2=\text{CH}, \text{CH}_2=\text{CMe}$.

1,4-Adducts were detected in no cases. The reactions with the use of chiral substrates afford hydroxyketones with high enantioselectivity, which depends on the solvent used. Thus the enantiomeric excess (*ee*) achieved in the reaction of the aminoenone **56a** [$\text{R}^1 = \text{H}$, NR_2^2 is (2*S*)-2-methoxymethylpyrrolidino] with $\text{CH}_2=\text{CHMgBr}$ in tetrahydrofuran was only 33%, whereas it reached 84% in a $\text{Et}_2\text{O}-\text{THF}$ mixture (9:1).²³⁰ Interestingly, the absolute configuration of the optically active α -hydroxycycloalkanones **91** depends on the nature of the substituent R^2 . For example, the aminoenone **56b** [$\text{R}^1 = \text{H}$, NR_2^2 is (2*S*)-2-methoxymethylpyrrolidino] reacted with methyl- or ethylmagnesium bromide to give the compounds (2*R*)-**91b** ($\text{R}^3 = \text{Me}$ or Et) with an optical purity of 92%–95%, whereas the hydroxyketones **91b** ($\text{R}^3 = \text{CH}_2=\text{CH}, \text{Ph}$), which were obtained by the reactions of the same substrate with vinyl- or phenylmagnesium bromide, adopt an opposite configuration (*ee* 58%–95%).¹²⁰ The authors attributed these stereochemical results to the difference in the structure of an intermediate complex of the organometallic compound with the aminoenone.

Like 2-aminocycloalk-2-enones, acyclic captodative aminoalkenes react with organometallic compounds to form predominantly 1,2-adducts. Thus the formyl-substituted enamines **2d** are readily transformed into acylins **92**, which provides the basis for a new efficient procedure for the preparation of these synthetically important compounds.[‡]

$\text{R}^1 = \text{Me}, \text{Ph}$; $\text{R}^2 = \text{Alk}, \text{Het}$; $\text{R}^3 = \text{Et}, \text{Ph}$.

Analogously, the reactions of 2-(*N*-methylanilino)pent-2-enonitrile with organomagnesium and organozinc reagents proceed as the 1,2-addition. However, the reaction of the same substrate with benzylmagnesium bromide gave rise to 1,4-addition product **94b** along with 1,2-adducts **93b** in comparable amounts.⁵⁴

$\text{RMX} = \text{MeMgI}, \text{BnMgCl}, \text{AlI}_2\text{ZnBr}$; $\text{R} = \text{Me}$ (a), Bn (b), Al (c).

In the case of the secondary cyanoenamines **2a**, Grignard reagents serve as strong bases. These reactions afford trialkylketenimines **95** as the major reaction products.²³¹

$\text{R}^1 = \text{R}^2 = \text{Me}, \text{Et}$; $\text{R}^3 = \text{Pr}^i, \text{Bu}^i$.

In the reactions with captodative aminoalkenes, N-nucleophiles attack either the electrophilic centre of the activating group or the α -olefinic carbon atom. For example, 2-amino-3,3-dichloroacrylonitrile (**96**) reacted under mild conditions with primary and secondary amines to give amides **97** and **98**.²³² The mechanism of formation of these compounds involves the nucleophilic attack at the carbon atom bound to the cyano group followed by hydrolysis of the amidines generated in the first step. Curiously, the chlorine atoms were not replaced even in the presence of a fourfold excess of the amine (*cf.* Ref. 82). At the same time, the reaction of the substrate **96** with more nucleophilic thiophenol proceeded regioselectively with the replacement of both chlorine atoms.²³²

$\text{NR}^1\text{R}^2 = \text{N-pyrrolidine}, \text{N-piperidine}, \text{NHPy}$.

Condensation of primary amines and hydrazine derivatives with the captodative aminoalkenes **2c,d** proceeded exclusively at the carbonyl group. Under the action of the liberated water, the initially formed azomethinoenamines **99c** were hydrolysed in a basic medium to give oxo derivatives **100**.²³³ Under these conditions, the compounds **99d** were converted into bis-azomethines **101**. The ratio **99d**:**101** depends on the reaction conditions and the nature of the starting reagents.²³⁴ Under analogous conditions, guanidine and thiourea did not react with the aminoalkenes **2c**.²³³

$\text{R}^1 = \text{Me}, \text{Ph}$; $\text{R}^2 = \text{Ph}$ (c), H (d); $\text{NR}_2^2 = \text{NEt}_2$, N-pyrrolidine , N-piperidine ; $\text{R}^4 = \text{Me}, \text{Bu}, \text{NH}_2, \text{NHEt}$.

[‡] The author's own data.

2-Morpholinocyclohex-2-enone (**30**) undergoes condensation with ethanolamine acting as a N-nucleophile to give the corresponding azomethine derivative.²³⁵ As mentioned in Section II.2.a, 2-aminocycloalkenones are involved in *ipso*-substitution reactions under the action of primary aromatic amines and even ammonia.^{17, 88}

Unlike N-nucleophiles, S-nucleophiles can be involved in the intra- or intermolecular conjugated addition to captodative aminoalkenes. For example, prolonged refluxing of 2-(*N*-methylamino)pent-2-enonitrile with sodium thiophenoxide and thiophenol in THF gave rise to 1,4-addition product **102**.⁵⁴

The reactions of the aminoalkenes **2d** with alkane- or arene-thiols or dithiols afforded neither 1,2- nor 1,4-adducts; instead, the compounds **2d** were unexpectedly transformed into the corresponding thiol esters of α -amino acids **103** in yields of up to 87%.²³⁶ Neither changes in the structures of the reagents nor variations in the reaction conditions have an effect on the direction of the reaction.

$R^1 = \text{Me, Ph; } NR_2^2 = \text{NEt}_2, \text{N-morpholinyl; } R^3 = \text{Et, Bu, Ph, CH}_2\text{CH}_2\text{SH.}$

This methodology, which allows the construction of the $\text{CH}(NR_2)\text{CO}$ fragment, was further developed in the synthesis of esters of α -amino acids containing the disubstituted amino group. It is well known that these compounds are important precursors for the design of new pharmaceuticals and for the preparation of polyfunctional compounds.

It appeared that the reactions of the formyl-substituted enamines **2d** with an equimolar amount of dialkyl phosphonate in the presence of sodium alkoxide afforded esters of *N,N*-disubstituted α -amino acids **105** rather than the expected phosphonates **104**.^{237–239} The moderate yields of the esters **105** were accounted for by competitive anionic polymerisation of the starting substrate or one of the intermediates under the action of sodium alkoxide. In the absence of the catalyst, the reaction of the phosphonate with the aminoalkene **2d** did not take place.

$R^1 = \text{Me, Pr, Ph; } NR_2^2 = \text{NEt}_2, \text{N-morpholinyl, N-piperidinyl; } R^3 = \text{Me, Et.}$

Unlike the formyl-substituted enamines **2d**, the aminoenones **2c** containing the terminal double bond are involved in the regioselective 1,4-addition to dimethyl phosphonate. Thus 3-piperidinobut-3-en-2-one smoothly produced the Michael adduct.²³⁹

The 1,2-adduct was not detected even in trace amounts. 2-Diethylaminobenzylideneacetophenone did not react with dimethyl phosphonate.

The scheme providing an explanation for the generation of the amino acid derivatives **103** and **105** was proposed in the studies.^{236–240} Undoubtedly, the first step involves the addition of the nucleophile to the formyl group of the aminoalkene **2d**. The key step of the scheme involves isomerisation of the initially formed 1,2-adduct to give thermodynamically more stable tetrasubstituted alkene **106**, which is rapidly transformed into the thiol ester **103** (in the case of S-nucleophiles) or ketophosphonate **107** (in the case of P-nucleophiles). Heterolysis of the C–P bond in the intermediate **107** readily proceeds under the action of alkoxides to give the ester of α -amino acid **105**.

The proposed hypothesis was strongly supported by isolation of the enol **106** [$\text{Nu} = \text{P}(\text{O})(\text{OMe})_2$] as a stable silyl ether generated in the reaction of the α -formyl-substituted enamine **2d** ($R^1 = \text{Ph}$, $\text{NR}_2^2 = \text{NEt}_2$) with dimethyl trimethylsilyl phosphite.²³⁹ The above-described reaction of the substrates **2d** with dialkyl phosphonates is one of the first examples of the vicarious nucleophilic addition. From the practical standpoint, the reactions of soft nucleophiles with the aminoalkenes **2d** provide a new convenient procedure for the one-pot synthesis of derivatives of *N,N*-disubstituted α -amino acids.

3. Radical reactions

Aminoalkenes containing a geminal activating group are excellent radicalophiles. The stabilising effect of captodative substituents on the radical centre has been postulated more than 20 years ago¹ and was subsequently confirmed by numerous experiments.

Ito *et al.*²⁴¹ carried out the kinetic study of the addition of arylthiyl radicals to acrylonitriles bearing the electron-donating group X at the α position. It appeared that the rate constant of this reaction decreases in the series $\text{NR}_2 > \text{OR} > \text{Cl} > \text{OAc} > \text{Me} > \text{H}$. This sequence correlates well with their electron-donating ability and indicates that captodative substituents exert the synergistic effect on stability of the radical. It should be noted that the relative activity of amino derivatives is ~ 20 times higher than that of their alkoxy analogues and ~ 550 times higher than the reactivity of unsubstituted acrylonitrile. Consequently, the aminoalkenes **2** proved to be the most efficient radical traps of all the known compounds.

This ability of captodative systems finds versatile synthetic applications.^{4, 132, 242} Below are given the possible pathways of transformations of the radical intermediate giving rise to various polyfunctional compounds with high selectivity.

EWG = CN (**a**), CO₂R (**b**), C(O)R (**c**), CHO (**d**); R = Alk, Ar.

The behaviour of captodative aminoalkenes in photolysis is very sensitive to insignificant structural changes in the substrate and primarily to the nature of the substituents at the nitrogen atom. Conceivably, that is why it is difficult to make generalisations and predict the direction of the reaction based on the available data.

In most cases, photolysis of the 2-aminocyclohex-2-enones **56b** [$R^1 = \text{Et}$, $R^2 = \text{Me}$; $R^1 - R^2 = (\text{CH}_2)_4$, $(\text{CH}_2)_2\text{OCH}_2$] containing the α -hydrogen atoms in the substituents at the nitrogen atom is accompanied by elimination of one of these hydrogen atoms. Subsequent cyclisation of the resulting biradical intermediate affords bicyclic azetidine derivatives **108**.^{189, 243} Analogues of the compounds **56b** bearing the methyl group at position 3 produced the azetidines **108** in low yields.¹⁸⁹ In some cases, the reactions of the aminoalkenes **56b** performed under the same conditions unexpectedly gave rise to spiroaziridines **109**, which were isolated as alcohols **110** after reduction of the carbonyl group.^{119, 244} It is believed that the aziridines **109** were formed through α -hydrogen abstraction followed by the rearrangement of unstable azabicyclooctenol.¹¹⁹

108: $R^1 = \text{Et}$, $R^2 = \text{Me}$; $R^1 - R^2 = (\text{CH}_2)_4$, $(\text{CH}_2)_2\text{OCH}_2$;

109, 110: $R^1 = \text{H}$, $R^2 = \text{Ph}$; $R^1 = \text{Bn}$, $R^2 = \text{Ph}$;

$R^1 = \text{Me}$, All, $R^2 = \text{CH}=\text{CH}_2$.

Photochemical cyclisation of *N*-arylaminoalkenones afforded carbazole derivatives **111** and **112**.¹⁴⁰

R = Me, Et.

Radical cyclisation of 2-(haloarylethyl)aminocycloalk-2-enones proceeds both at the C² atom of the enone fragment to form aminoalkenes, which are azepine derivatives, and at the nitrogen atom to produce compounds of the indole series.²⁴⁵

The reactions of 2-aminotropones with palladium acetate, which are considered to be a catalytic radical process, differ essentially from the reactions of other troponoid compounds performed under the same conditions.²⁴⁶ Depending on the substituents at the nitrogen atom, either acetoxylation ($\text{NR}_2 = \text{NMe}_2$, NEt_2) or arylation [$\text{NR}_2 = \text{N}(\text{Me})\text{Ph}$] were observed.

The photochemical behaviour of the acyclic aminoalkenones **2c** differs from that of the 2-aminocyclohex-2-enones **56b**. Thus in photolysis of aminoalkenone **113** in ether or pentane, allylic hydrogen abstraction proceeded more efficiently to give isomeric nonconjugated alkene **114** as the only reaction product.¹⁷⁷ In the absence of the allylic hydrogen atom, for example, in aminoalkene **115**, the substrate underwent rapid *E,Z* isomerisation followed by slow formation of a mixture of compounds consisting primarily of cyclisation product **116** and elimination product **117**.¹⁷⁷

$R^1 = \text{Et}$, $R^2 = \text{Me}$; $R^1 - R^2 = (\text{CH}_2)_4$, $(\text{CH}_2)_2\text{OCH}_2$.

Intramolecular photocyclisation of 2-anilinoalkenonitriles gave rise to 2-cyano-1-methyl-3-*R*-indoles ($R = \text{Me}$, Ph , $\text{CH}=\text{CHMe}$). Under the action of Bu_3SnH in the presence of azoisobutyronitrile, radical cyclisation of 2-anilinoacrylonitriles containing the haloalkyl (alkenyl) substituent at position 3 gave rise to substituted cycloalkanes or cycloalkenes.^{63, 247}

4. Captodative aminoalkenes in the synthesis of carbo- and heterocyclic compounds

Due to the presence of multiple carbon–carbon and carbon–heteroatom bonds, captodative alkenes can be used in the synthesis of carbo- and heterocyclic compounds. Cycloaddition reactions are apparently the most important transformations of captodative aminoalkenes. These reactions have been extensively studied in the last decade. The aminoalkenes **2a–c** can be involved in [2 + 2]-, [3 + 2]- and [4 + 2]-cycloaddition reactions, the latter reactions being most common.

It is well known that dienophiles containing electron-withdrawing substituents are readily involved in the Diels–Alder

reactions with electron-rich dienes. It is not surprising that [4 + 2]-cycloaddition of simple enamines to nonactivated dienes occurs very rarely. Unlike simple enamines, captodative aminoalkenes successfully react with various dienes, including nonactivated compounds.

The reactions of the 2-aminocycloalk-2-enones **56a,b** with electrophilic diazenes **118** are formally classified as [4 + 2]-cycloaddition.^{248–253} Stability of 1,3,4-oxadiazines **119** thus formed depends both on the nature of the amino group and the ring size of the substrate as well as on the presence of the functional groups in the diazene **118**. Generally, aminoenones bearing a disubstituted amino group form rather stable cyclic derivatives **119**, which are slowly transformed into acyclic isomers **120** at room temperature or upon heating.^{248–250} Analogous [4 + 2]-adducts were also obtained from *N*-aryl-substituted aminocycloalkenones.²⁵² In other cases, the formation of the heterocycles **119** is not necessarily detected and the enediamines **120** are the only reaction products, which are readily rearranged into more stable isomers.^{251–253} Benedetti *et al.*²⁵¹ assumed that the compounds **120** can also be formed immediately from the starting substrates.

$n = 0$ (**a**), 1 (**b**); $R^1 = H$; $R^2 = Bu^n, Bu^t, Ph$; $NR^1R^2 = N$ (cyclopentyl), N (morpholinyl); $X = Ph, 4-NO_2C_6H_4, PhCO, CO_2Me, CO_2Et$; $Y = Ph, 4-NO_2C_6H_4, OEt$.

The reactions of the cyclic and acyclic aminoalkenones **56b** and **2c** (as dienophiles) with nitroalkenes (as heterodienes) were used for the synthesis of various carbo- and heterocyclic systems, *viz.*, tetrahydroindoles,¹⁴¹ polyquinanes^{254,255} and pentalenes.^{129,256–258} In most cases, the authors of the cited studies postulated that 1,2-oxazine *N*-oxides **121** were formed as intermediates whose subsequent transformations depend primarily on the nature of the substituents and the reaction conditions. Some heterocyclic derivatives **121** were so stable that they can be isolated in quantitative yields.^{141,257–259} In a number of studies,^{129,141} [2 + 2]-cycloaddition products or Michael adducts were detected along with the compounds given below.

$R^1 = Et, Ph$; $R^2 = H, Me, Ph$; $R^1-R^2 = (CH_2)_3$; $NR^3R^4 = NHBu^n, NHBu^t, NHPh, N$ (cyclopentyl), N (morpholinyl), N (piperidinyl); $R^5, R^6 = H, Me, Ph$.

$R^5 = H, Me, Ph$; $R^6 = H, Me$.

$R^5 = H, Me, Ph$; $R^6 = Me, Ph$.

Döpp and co-workers^{260–264} performed extensive studies on cycloaddition of various captodative alkenes to unsaturated systems over many years. The Diels–Alder reactions of the cyanoenamines **2a** with 1-naphthaldehyde (**122a**), 1-acetonaphthone (**122b**), 1-naphthophenone (**122c**) or methyl 1-naphthoate (**122d**) proceeded with high regio- and stereoselectivity to form adducts **123a–d**.^{36,170,261–263} By-products of [2 + 2]-cycloaddition were obtained in negligible yields (< 1%) (in some cases, these compounds were not detected at all). In contrast, the cyanoenamine **2a** (NR_2 is morpholino) is involved in [2 + 2]-cycloaddition with naphthalene-1-carbonitrile **122e** to give a mixture of isomeric polycyclic compounds **124** and **125** in low yields.²⁶⁴

$X = CHO$ (**a**), $C(O)Me$ (**b**), $C(O)Ph$ (**c**), CO_2Me (**d**), CN (**e**);

$NR_2 = N$ (morpholinyl), N (piperidinyl), N (piperidinyl)- Ph , N (piperidinyl)- NPh , N (piperidinyl)- $NC_6H_4CF_3$ -3,

The reactions of the aminoalkene **2a** (NR_2 is morpholino) with substituted 1-acetonaphthones afford the [2 + 2]- and [4 + 2]-cycloaddition products in a ratio which depends on the position of the substituent. The reaction with 2-methoxy-1-acetonaphthone produced only the [2 + 4]-adduct, whereas derivatives bearing a substituent at position 4 gave rise to [2 + 2]-cycloaddition products.²⁶⁵ Under the conditions of photolysis, 2-morpholinoacrylonitrile was involved in the [2 + 2]-cycloaddition reaction with 3-acetylthianaphthene.²⁶⁶

Unlike unsubstituted enamines, the cyanoenamines **2a** react with a number of nonactivated conjugated dienes to give [4 + 2]-cycloaddition products **126** and **127** (Scheme 1). The acrylonitrile **2a** (NR_2 is morpholino) proved to be more reactive as a dienophile than its analogue containing the aromatic amino group, the regioselectivity of the addition being dependent on the nature of the substituents in the diene (see Scheme 1).

The above-considered reactions clearly demonstrate that captodative aminoalkenes are good dienophiles, which are much superior to the corresponding alkoxy and thio analogues in reactivity.²⁶⁹ These compounds are equally efficient as dienes provided that the β -substituent contains one or several multiple bonds.^{25, 26, 270}

The reactions of dienes **128a,b** with derivatives of acrylic acid afforded unexpected cyclisation products.^{69, 271} Aminonorbornones **129a,b** were formed through the [4 + 2]-cycloaddition of methyl acrylate or acrylonitrile to aminocyclopentadienones **130a,b** generated upon intramolecular condensation of the dien-amino esters **128a,b**. The [2 + 2]-cycloaddition products **131a,b** were obtained as by-products. The proportion of the [4 + 2]-cycloaddition products **129a,b** depends on the nature of the

EWG = CO₂Me, CN; R¹ = Me (**a**), Et (**b**); NR₂² = NMe₂, NEt₂, .

amino and activating groups, *viz.*, the highest yields were achieved in the case of the dienes **128a,b** containing the piperidine substituent.

The captodative alkenes **2a–d** are excellent substrates in [2 + 2]-cycloaddition. The reactions of these compounds with substituted alkenes or carbonyl compounds produced respectively cyclobutanes²⁷² or oxetanes (the Paterno–Büchi reaction).^{273, 274} Thus the addition of symmetrical 1,2-diketones to the cyanoenamines **2a** proceeded regio- and stereospecifically to give head-to-head [2 + 2]-adducts with the *cis*-oriented amino and aryl groups (the configuration of the resulting diastereomer determined in the study²⁷³ is, apparently, in error). Under irradiation of a mixture of unsymmetrical diones and the cyanoenamines **2a**, the addition at the carbonyl groups proceeded with comparable rates to give a mixture of isomeric oxetanes in 9%–90% yields.²⁷⁴

Ar¹ = Ar² = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-CF₃C₆H₄, 2-C₁₀H₇; Ar¹ = Ph: Ar² = 4-MeOC₆H₄; 2-C₁₀H₇;

NR₂ = , , , , .

Examples of head-to-head and head-to-tail photochemical dimerisation of captodative aminoalkenes are available in the literature,^{5, 6, 275} the type of dimerisation being dependent on the structure of the substrate. The result of the reaction depends also on the reaction conditions. For instance, 2-aminoacrylonitrile underwent dimerisation in the presence of benzophenone as a photosensitising agent to form a mixture of diastereomers **132**.⁵ However, the formation of the cyclobutanes **132** was not observed in the absence of Ph₂CO. In the latter case, the main reaction involved fragmentation of the starting substrate to yield HCN and MeCN accompanied by competitive isomerisation into aziridine-2-carbonitrile.⁶

The captodative aminoalkenes **2a** are much more reactive than their push-pull isomers **1a**. These compounds react with dimethyl acetylenedicarboxylate or dibenzoylacetylene by being involved in the so-called ' α -cyclisation of tertiary amines'.^{276–278} Depending on the nature of the amino group in the aminoalkenes **2a** and the activating group in the acetylene derivative, either furans **133a,b** and **134c–f** or dihydropyrroles **135a–g** were obtained as the final reaction products. The preparation of dihydropyrroles, which were formed with high stereoselectivity, required more drastic conditions (refluxing in acetonitrile or DMSO).^{276, 279} The reaction mechanism includes [2 + 2]-cycloaddition and rapid recyclisation of adducts **136** into dienes **137**, which are the key intermediates for all products. The dienes **137a,c** are involved in 1,3-dipolar addition reactions with dipolarophiles, such as acrylonitrile, yielding finally a mixture of cycloadducts **138a,c** and the dihydropyrroles **135a,c** (Scheme 2).²⁷⁸

Scheme 2

$R^1 = R^2 = H$ (a), Me (b); $R^1 - R^2 = (CH_2)_2$ (c), $(CH_2)_3$ (d), $(CH_2)_4$ (e), $(CH_2)_5$ (f), CH_2OCH_2 (g); $X = C(O)Ph$, CO_2Me .

In [3 + 2]-cycloaddition, captodative aminoalkenes behave analogously to common enamines. Like enamines,¹⁷⁵ these compounds add aryl azides to give the corresponding dihydrotriazoles.^{11, 33, 280, 281} However, some of these cyclic derivatives are unstable and cannot be isolated. For example, dihydrotriazoles **139** formed in the reactions of the cyanoenamines **2a** underwent

$NR^2 = N$ (pyrrolidine), N (piperidine), N (morpholine); $X = H$, 4-Me, 3- NO_2 , 4-Br, 3-Cl.

spontaneous HCN elimination to generate 1,2,3-triazoles **140**.^{3, 280} The reactions always proceed regiospecifically to yield the only isomer.

Like enamines, the β -oxophosphonate **6** reacted with tosyl azide to give diazo compound **141**, which underwent cyclisation into pyridazine **142**.²²

In spite of the fact that the reactions of 2-morpholinoacrylonitrile with aldonitrone **143** afforded morpholides **144**, Döpp and Walter²⁸² considered these reactions as 1,3-dipolar cycloaddition. Actually, the formation of the amides **144** can be attributed to elimination of HCN from intermediate isoxazolidine **145** followed by the ring opening. Hence, this cycloaddition reaction is also regiospecific, the terminal carbon atom of the starting aminonitrile being nucleophilic. Keto nitrones did not react with 2-morpholinoacrylonitrile.²⁸²

Cycloaddition of 1,3-dipolar compounds **146a,b** to 2-pyrrolidino-cyclohept-2-enone afforded initially compound **147b**, which lost amine upon acid treatment to form pyrazolone derivative **148a** or isoxazolone derivative **148b**.²⁸³

$X = NPh$ (a), O (b).

5. Other reactions most typical of captodative aminoalkenes

The captodative aminoalkenes **2a–c** are involved in some reactions, which cannot be unambiguously classified with the above-considered types. The most typical reactions, which are not

associated with the presence of a particular specific substituent, are considered in this section.

The aminoalkenes **2a–c** are rather readily subjected to hydrogenation. Under traditional conditions of heterogeneous catalysis, selective reduction of the C=C double bond generally takes place.^{17, 126, 284} In some cases, the reactions are accompanied by simultaneous reduction of the activating group. For example, the addition of hydrogen to the enamines **59a,b** afforded the corresponding 2-aminocyclohexanones **60a,b**. However, hydrogenation of the substrate **59c** performed under the same conditions gave rise to a mixture of diastereomers of *cis*-1,2-aminoalcohols **149** in quantitative yield.¹²⁶

R = H (**a**), Me (**b**), 4-HOC₆H₄CH₂ (**c**).

Of a wide variety of different activated alkenes, only the captodative aminoalkenes **2b** appeared to react with hydrosilanes with reduction of the C=C double bond.²⁸⁵

NR₂ = NEt₂, N(CH₂)_nO; n = 1–3.

The reactions with the use of metal aluminium hydride or borohydride as reducing agents either proceeded only at the activating group (C=O or CN)^{17, 150} or resulted in simultaneous reduction of both functional groups.¹⁵⁹

Wittig olefination of optically active 2-(methoxymethyl)pyrrolidinobut-3-en-2-one afforded chiral 2-amino-substituted buta-1,3-diene **150**. This compound is the first representative of the compounds, which have previously been difficult to access.¹³³

Noteworthy are the palladium-catalysed reactions of 2-(*N*-methylanilino)alkenenitriles with iodobenzene.²⁸⁶ Owing to the studies performed by De Kimpe and co-workers,^{184, 195} this transformation of cyanoenamines became an efficient procedure for the synthesis of the corresponding amides.

Captodative aminoalkenes readily undergo isomerisation. As mentioned above, the aminoenones **2c** and the aminoenals **2d** can be very readily subjected to *Z,E* isomerisation, which either occurs in the course of their preparation or subsequent transformations or takes place upon storage. In addition to *Z,E* isomerisation, examples of rearrangements of these compounds under the action of both acidic²⁸⁷ and basic reagents¹⁸³ are available in the literature.

Analysis of the most typical transformations of the captodative aminoalkenes **2a–d** shows that these compounds can exhibit the properties of either enamines or activated alkenes depending on various factors. The balance in favour of the canonical structure of enamine can be rather easily disturbed upon insignificant changes in the nature of the activating or amino group.

V. Methylidene- and arylmethylidene-quinuclidin-3-ones

Methylidene- and arylmethylidenequinuclidin-3-ones **151** not only serve as the key intermediates in the design of new pharmaceuticals but are also of interest in theoretical organic chemistry. These compounds can formally be considered as bicyclic captodative aminoalkenes. However, they cannot exhibit properties of enamines because of the fixed spatial orientation of the lone electron pair of the nitrogen atom. This is the essential distinction between the compounds **151** and the above-considered systems.

The 2-arylmethylidenequinuclidin-3-ones **151** are generally prepared by base-catalysed condensation of quinuclidin-3-one **152** with various arene- or hetarenecarbaldehydes.^{288–299} The compounds **151** are obtained as individual isomers or as mixtures of geometric isomers in yields from moderate to quantitative. The same methodology was successfully applied to the synthesis of ferrocenylmethylidene-substituted³⁰⁰ and tricyclic analogues of quinuclidinone.³⁰¹

R = Ph, 2-PhC₆H₄, 2-HOC₆H₄, 2-MeOC₆H₄, 2-FC₆H₄, 2-ClC₆H₄, 3-HOC₆H₄, 4-HOC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-NO₂C₆H₄, 4-Me₂NC₆H₄, 4-PhOCH₂CH₂OC₆H₄, 2,4-(MeO)₂C₆H₃, 3,4-(MeO)₂C₆H₃, 3,4,5-(MeO)₃C₆H₂, BnOC₆H₄, C₅H₅FeC₅H₄,

The cyclopropane-ring opening in spirocyclic quinuclidinone derivative **153**, which occurs under the action of C-, N- or O-nucleophiles, provides an interesting example of the preparation of β,β-disubstituted methylidenequinuclidones.³⁰² Thus the reaction of the compound **153** with lithium diphenylcuprate afforded a mixture of isomers **154** and **155**. The compound **154** was completely transformed into the quinuclidinone **155** during 20 h (the ratio *Z* : *E* = 3 : 1).³⁰²

The quinuclidinone **151** (R = H) containing the terminal double bond was smoothly generated from the ketone **152** under the conditions of the Mannich reaction³⁰³ as well as by dehydra-

tion of 2-hydroxymethyl-3,3-dihydroxyquinuclidine hydrochloride (**156**).³⁰⁴

The orthogonal arrangement of the lone electron pair of the nitrogen atom hinders p,π -conjugation as a result of which the amino group exerts only the inductive effect on the double bond. This characteristic feature of the arylmethylidenequinuclidinones **151** is reflected in the observed downfield shifts of the signals for the olefinic proton ($\delta = 6.80\text{--}7.50$) in the ^1H NMR spectra and for the β -carbon atom ($\delta = 125\text{--}146$) in the ^{13}C NMR spectra as compared to the signals of the above-considered captodative aminoalkenes **2c** or **56b**. Hence, the quinuclidinones **151** would be expected to exhibit properties of strong amines in reactions with electrophilic reagents and properties of Michael acceptors in reactions with nucleophiles.

Like captodative aminoalkenes, the arylmethylidene- and ferrocenylmethylidenequinuclidinones **151** are protonated and alkylated at the nitrogen atom.^{299, 305–307} However, the same regioselectivity of the electrophilic attack is accounted for by different reasons. Thus enammonium salts of captodative aminoalkenes are highly stable due primarily to the stabilising effect of an intramolecular hydrogen bond, whereas N -protonation (alkylation) of the quinuclidinones **151** is associated only with the basicity of the nitrogen atom.

Bubbling of dry HCl through a solution of methylidenequinuclidinone led to quaternisation of the nitrogen atom to form compound **157** ($R = \text{H}$) along with the anti-Markovnikov addition of hydrogen halide to the double bond.³⁰⁵ In the case of the ferrocenylmethylidenequinuclidinones **151** ($R = \text{Fc}$), two heteroatoms are simultaneously protonated. The formation of the dications **158** was confirmed by NMR spectroscopy.^{299, 307}

$R = \text{H, Ph, 4-FC}_6\text{H}_4, 2,4\text{-(MeO)}_2\text{C}_6\text{H}_3, \text{Fc}$;

$X = \text{Cl, BPh}_4, \text{PhCO}_2, \text{CF}_3\text{CO}_2$.

Under the action of gaseous HCl in chloroform^{288, 290, 295, 308} or of NaBPh_4 in acetic acid,^{299, 307} the compounds **151** underwent reversible Z,E isomerisation. For example, Z -2-aryl-methylidene- and Z -2-ferrocenylmethylidenequinuclidinones are readily (often

quantitatively in a matter of minutes) transformed into the corresponding E isomers.^{295, 299, 307} In this case, there is the evident analogy with enammonium salts of captodative aminoalkenes, *viz.*, isomerisation becomes possible due to a decrease in the double-bond character of the alkene fragment.²⁹⁹ These transformations of the quinuclidinones **151** provide the means of performing the selective synthesis of their individual geometric isomers, which is of importance in studying the structure–properties relationships (including, the structure–biological activity relationships).

The fact that the quinuclidinones **151** cannot exhibit the properties of enamines is reflected in their reactions with nucleophilic reagents. For example, the majority of the reactions of the compounds **151** and their tricyclic analogues with various C-nucleophiles proceed as conjugated 1,4-addition.^{294, 301, 302, 309–314} In some cases, Michael adducts **159–162** are obtained in moderate yields, which is attributable to competitive 1,2-addition giving rise to compounds **163**. The latter compounds were obtained as the major products in the reactions of the quinuclidinones **151** with aryl- or alkyl lithium derivatives (Scheme 3).^{299, 300, 307, 315, 316} As mentioned above, numerous attempts to perform the Michael addition to captodative aminoalkenes failed almost without exception (see Section IV.2).

Alcohols serve as O-nucleophiles in the Michael addition reactions with methylidenequinuclidin-3-one, the reactions pro-

Scheme 3

$R^1 = \text{H, Ph, 2-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, \text{Fc}$; $R^2 = \text{CO}_2\text{Me}$, $R^3 = \text{CN}$;

$R^2 = \text{Ph}$, $R^3 = \text{CN}$; $R^2 = \text{Ph}$, $R^3 = \text{N=CHPh}$; $R^2 = \text{H}$, $R^3 = \text{NO}_2$;

$R^2 = \text{C(O)Me}$, $R^3 = \text{CO}_2\text{Et}$; $R^2 = \text{C(O)Me}$, $R^3 = \text{C(O)Ph}$;

$R^2 = R^3 = \text{C(O)Me}$, $R^2R^3\text{CH}_2 =$; $B = \text{NaOH, MeOH, BuLi}$.

ceeding slowly.³⁰⁶ As expected, aniline forms the corresponding Schiff's base with the latter compound.³¹⁷

The presence of two electrophilic centres, *viz.*, the carbon atom of the carbonyl group and the β -carbon atom of the double bond, allows the use of the quinuclidinones **151** for the construction of various heterocyclic systems. For example, the reactions of the ketones **151** ($R = H, Ph$ or Fc) with hydrazine afforded quinuclidine derivatives **164** or **165** depending on the reaction conditions. Under the action of basic reagents (KOH or an excess of hydrazine), the latter compounds were decomposed upon heating to give pyrazoles **166**.^{290–292, 296, 297, 300, 317, 318} Analogous transformations were observed in the reactions of the compounds **151** with thiosemicarbazide.³¹⁸ Phenylhydrazine reacts analogously to primary amines to produce phenylhydrazone.²⁹⁰

$R = H, Ph, Fc$.

The reactions of hydroxylamines with the arylmethylidenequinuclidinones **151** bearing a substituent at the double bond afforded oximes **167**,^{298, 319, 320} whereas the reaction of the unsubstituted methylidenequinuclidin-3-one **151** ($R^1 = H$) with hydroxylamine gave rise to oxime **168**, which was isolated as dihydrochloride.³²¹ It was assumed that this reaction proceeded through the intermediate formation of 4a-hydroxyisoxazolidino[4,5-*b*]quinuclidine **169**. The *N*-substituted derivatives of the isoxazolidine **169** were prepared in high yields by the reactions of quinuclidinone **151** ($R^1 = H$) with *N*-arylhydroxylamines.³²¹

$R^1 = H, Ph, 2-HOC_6H_4, 3-HOC_6H_4, 4-HOC_6H_4, 2-MeOC_6H_4, 4-MeOC_6H_4, 4-Me_2NC_6H_4, 4-NO_2C_6H_4$;

$R^2 = H, Ph, 4-MeC_6H_4, 4-ClC_6H_4, 3-ClC_6H_4$.

The compounds **151** equally readily reacted with thiourea and phenylthiourea to produce pyrimidinethiones **170**³¹⁸ or **171**.^{290, 300, 322} Finally, cyclisation of the ketones **151** with cyanothioacetamide gave rise to the corresponding thiones **172**.³²³

$R^1 = H, Ph, 4-MeOC_6H_4, Fc$; $R^2 = H, Ph$.

$R^1 = Ph, 4-FC_6H_4$.

As in the case of captodative aminoalkenes, reduction of methylidene- and arylmethylidenequinuclidinones can be directed with high selectivity toward either the $C=C$ double bond or the carbonyl group by varying the nature of the reducing agent. When subjected to platinum- or palladium-catalysed hydrogenation, methylidene- and arylmethylidenequinuclidinones were transformed into saturated ketones **173**.^{288, 291, 292, 298, 305} The corresponding allylic alcohols **174** were selectively obtained with the use of $NaBH_4$.^{288, 308, 324, 325} Stereospecific reduction of both functional groups in the benzylidenequinuclidinone **151** ($R = Ph$) with lithium aluminium hydride afforded benzylquinuclidinol *trans*-**175** ($R = Ph$).³²⁶ Catalytic hydrogenation of the same compound **151** ($R = Ph$) followed by reduction with $NaBH_4$ gave rise to *cis*-**175** ($R = Ph$).³⁰⁸

$R = H, Ph, 2-ClC_6H_4, 4-MeOC_6H_4, 3,4-(MeO)_2C_6H_3$.

VI. Conclusion

Recent progress in the chemistry of captodative alkenes allows the preparation of many aminoalkenes containing the geminal activating group, which can be considered as polyfunctional building blocks. Various transformations characteristic of this type of compounds, such as electrophilic or nucleophilic addition and, in particular, cyclisation, can be used in organic synthesis. Unlike the push-pull enamincarbonyl compounds **1c** for which a special type of non-cyclic aromatic stabilisation was assumed,³²⁷ the cross-conjugated aminoalkenes **2a–d** act as 'chemical chame-

leons'. The latter compounds are able to exhibit the properties of either enamines or activated alkenes resulting from insignificant changes in the structure of the substrate and the reaction conditions. Owing to these properties, captodative aminoalkenes are unique building blocks and there is reason to hope that they will find increasing use in organic synthesis.

V. Electrochemically activated reactions involving ‘electron sponges’	233

Abstract. Data on the electrochemical activation of various reactions involving organometallic compounds are generalised. Primary attention is devoted to the key types of transformation that can be performed using electrochemical electron transfer, namely, redox activation of 16- and 18-electron complexes of transition metals as the first step of a broad range of reactions, electrocatalysis, mediator processes, and electrosynthesis of compounds containing carbon–metal σ -bonds. The bibliography includes 188 references.

I. Introduction

The problem of increasing the reactivity of compounds arose as soon as chemists became engaged in targeted synthesis. Numerous methods for the increase in the reactivity are currently known, ranging from simple methods (introduction of an appropriate substituent into the molecule) to more complex ones that have become classical (for example, catalysis) and, finally, to the most advanced techniques (in particular, photochemically or electrochemically induced electron transfer). Figure 1 presents classification of the activation processes proposed by Chanon.¹ The diagram axis can be continued without limit because new ways of solving this problem would certainly appear with the progress of science.

Activation through electron transfer is rather effective. In this case, very high process selectivity can be attained because it is possible to specify precisely the potential needed for the generation of a particular active species.

The transformation of a molecule into a reactive radical cation or radical anion (Scheme 1) initiates a wide range of chemical reactions. This is due to the following factors: (1) usually, charged species react with nucleophiles or electrophiles more readily than neutral molecules; (2) the presence of the unpaired electron activates homolytic reaction pathways; (3) further redox processes, disproportionation and so on are also possible.

Scheme 1

S is the substrate, Nu is the nucleophile, E is the electrophile, P is the product; a is a redox reaction; b is dissociation, etc.

Activation of reactions through electron transfer was first employed by Taube² and Basolo and Pearson^{3–6} for inorganic systems. In organic chemistry, the development of this line of research was triggered by Kornblum's discovery^{7,8} of radical nucleophilic substitution ($S_{RN}1$) the mechanism of which has been later studied in detail by Bunnett⁹ and Russel.^{10,11} Saveant¹² was the first to use electrochemical electron transfer for the activation of organic reactions. Since then, the French electrochemical

Figure 1. Multilevel diagram of the activation methods of reactions.¹

school has held a leading position in the research along this line. A great number of examples in which diverse organic reactions are activated by electrochemical electron transfer have been reported (see, for example, Refs 1, 13).

The intense use of electrochemical electron transfer in reactions involving organometallic compounds started approximately in the early 1980s. Most of the transition metal π -complexes are able to undergo reversible electrochemical redox transitions to give active species with odd numbers of electrons; therefore, electrochemically induced electron transfer can be used efficiently to facilitate ligand exchange, isomerisation, insertion and other reactions.^{14–19}

It is of interest to compare the behaviours of mononuclear metal complexes and supramolecular species containing these complexes as structural units.²⁰ Systems of this type are able to undergo electrochemically induced reversible structural changes, and they can be regarded as prototypes of ‘molecular machines.’ In this case, the electron transfer involving one structural unit entails changes over the whole supramolecular system (for example, electrically induced charge separation, migration of structural fragments, *etc.*).²⁰

A relatively new field in the use of electrochemical electron transfer for changing the reactivity of transition metal complexes is the design of redox-switchable ligands. The introduction into the ligand of ferrocenyl, cobaltocenyl, anthraquinone or other groups prone to reversible redox transitions allows the formation of complexes with switching reactivity.²¹ A change in the redox state of the ‘switch’ induces a change in the electronic properties of the ligand and, hence, the nature of the metal–ligand bond. This promotes various types of reaction, for example, ligand exchange. This approach appears highly promising for the design of ‘redox-switchable’ catalysts. Chiral metal complexes with ‘redox-switchable’ ligands can be used in asymmetric synthesis, for the separation of enantiomers, *etc.*²¹

Yet another extensive field of application of the electrochemical electron transfer in reactions involving organometallic compounds is electrochemical generation of labile complexes of transition metals in low oxidation states and involvement of these species in subsequent chemical transformations *in situ*, most often, as catalysts. The combination of catalysis by metal complexes with the electrochemical electron transfer has opened up almost unlimited scope for performing various mediator processes (see, for example, Refs 22–24).

Numerous examples of reactions activated by electrochemical electron transfer have now been reported in the literature. Since it is impossible to embrace them all within a single review, we intended first of all to show what types of transformations can be accomplished by virtue of the electrochemical electron transfer and how the use of electrochemical methods extends the synthetic capacity of a chemist in the field of organometallic chemistry. Primary attention has been devoted to the studies published during the last decade and not covered in earlier reviews.

II. Reactions of odd-electron complexes of transition metals

The transfer from relatively stable 16- and 18-electron configurations to 17- and 19-electron configurations of transition metal complexes can be attained *via* electrochemical oxidation or reduction. The odd-electron complexes thus formed are much more reactive; therefore, they can be involved in reactions that either do not proceed at all or proceed too slowly for complexes with 16- and 18-electron configurations. Research into the chemical transformations of odd-electron complexes has been the subject of numerous studies (see, for example, reviews^{15, 18, 22}). If the transformations are classified in terms of the reaction type, the main types are ligand exchange, isomerisation, insertion, extrusion, chelation/dechelation and dimerisation.

1. Ligand exchange

Ligand exchange reactions can be initiated by both oxidation and reduction of mono- or polynuclear metal complexes.

Initiation by oxidation				Initiation by reduction			
ML	$-e^-$	$\rightarrow$	$ML^{+\cdot}$	ML	$+e^-$	$\rightarrow$	$ML^{-\cdot}$
18 e			17 e	18 e			19 e
$ML^{+\cdot} + L'$		$\rightarrow$	$M(L')^{+\cdot} + L$	$ML^{-\cdot} + L'$		$\rightarrow$	$M(L')^{-\cdot} + L$
17 e			17 e	19 e			19 e
$M(L')^{+\cdot} + ML$		$\rightarrow$	$ML' + ML^{+\cdot}$	$M(L')^{-\cdot} + ML$		$\rightarrow$	$ML' + ML^{-\cdot}$
17 e			18 e 18 e 17 e	19 e			18 e 18 e 19 e

Upon reductive activation, an electron passes to an unoccupied orbital; this is accompanied by weakening of the $M-L$ bond. In essence, a similar reaction takes place during oxidation, because an associative mechanism of ligand exchange including the intermediate formation of a 19-electron complex with an additional ligand has been proven for 17-electron complexes by Kochi and coworkers.^{23, 25}

Cp = C₅H₅.

A second ligand present in the solution is coordinated to the 17-electron complex to give a 19-electron intermediate (as in the case of reductive activation) in which cleavage of the $M-L$ bond is facilitated.

A large number of examples of electrochemically activated ligand exchange have been described (see, for example, the reviews^{15–18, 26} and the monographs^{27, 28}). We shall dwell only on some publications that appeared during the last three to four years.

An interesting example of replacement of the arene ligand in binuclear fulvalene (Fv) complexes of iron has been reported.²⁹ The doubly reduced 38-electron complex readily reacts with CO or with different phosphine ligands.

Preparative electrolysis of the fluorenyl complex of cobalt (at a potential of $-2.56\text{ V vs. Fc/Fc}^+$, where Fc is ferrocene) in the presence of various phosphine or phosphite ligands also results in ligand exchange.³⁰

An unusual ligand exchange in the metal coordination sphere accomplished by virtue of a ‘redox switch’ connected to the reaction centre of the molecule has been reported.³¹ The role of the ‘redox switch’ is played by a ferrocenyl fragment linked by a covalent bond to the arene ligand of the chromiumtricarbonyl complex. Since the ferrocene fragment is oxidised first, the reaction takes place at an anodic overpotential substantially lower than that required for oxidation of the chromiumtricarbonyl group. Thus the partial destruction of the complex is avoided and the process selectivity is increased. Although the

chromium atom has formally an 18-electron configuration, the adjacency of the strong electron acceptor results in easy replacement of the carbonyl group by a phosphorus-containing ligand.

The subsequent transfer of an electron from the Cr atom to the Fe atom turns off the 'redox switch'. Upon further displacement of the potential to the anodic region, the 'redox switch' is actuated once more, the Cr atom is activated again, and the reaction gives a purple complex, which was isolated.

Electrochemical cleavage of the metal–halogen covalent bond with subsequent replacement of the halogen atom by another ligand has been described in detail.³² Upon single-electron reduction of the rhenium complex with diphenylphosphinoethane (dppe) $[\text{ReCl}_2(\text{dppe})_2]^+$ [the $\text{Re}(d^4) \rightarrow \text{Re}(d^5)$ transition], the Re–Cl bond length increases by 0.1 Å; the transfer of one more electron induces cleavage of this bond, and another ligand present in the solution enters the coordination sphere of the metal.

Oxidation of the central metal atom in the complex results in strengthening of bonds with σ -donor ligands (ammonia, amines, pyridine, *etc.*) and weakening of bonds with π -acceptor ligands (CO, nitriles, cyanides, *etc.*); this stipulates the required type of electrochemical activation (cathodic or anodic) in each particular case.

Actually, chelation/dechelation reactions can also be classified as ligand exchange. Some organic groups, for example, the dithiocarbamate group, act as chelating ligands in the coordination sphere of unsaturated complexes. However, they can also occur in the metal coordination sphere as monodentate ligands. It was shown³³ that the monodentate dithiocarbamate ligand can be readily converted into a chelating ligand upon oxidative activation.

In principle, the inverse problem can also be solved. If it is required to change electrochemically the oxidation state of the central metal atom in a complex but to avoid ligand exchange or coordination of additional ligands, it is expedient to use a so-called cage ligand.²⁰ For example, oxidation of 1,10-phenanthroline complexes of Cu(I) is irreversible because it is accompanied by a structural rearrangement with coordination of solvent molecules to the copper atom giving rise to an octahedral geometry typical of Cu(II) complexes. If 2,9-dimethyl-1,10-phenanthroline is used as the ligand instead of 1,10-phenanthroline, the oxidation of the

Cu(I) complex is completely reversible because the presence of substituents at the α -position relative to nitrogen prevents the coordination of solvent molecules to the metal and, hence, the geometry does not change.³⁴

2. Isomerisation

When considering the electrochemically activated isomerisation of transition metal complexes, one can distinguish three main types of transformations encountered most often, namely, *cis*–*trans* isomerisation, change in the hapticity of aromatic π -ligands to the metal in various sandwich and half-sandwich structures and metal migration in complexes with polydentate aromatic ligands.

The first example of electrochemically activated *cis*–*trans* isomerisation was described by Rieke *et al.*³⁵ The reaction follows the scheme

Since then, numerous examples of both cathodically and anodically activated *cis*–*trans* isomerisations have been reported.²⁷ In particular, the rate constants for anodic isomerisation of the thiolate isocyanate complexes *cis*– $[\text{M}(\text{SC}_6\text{H}_2\text{Pr}_3\text{-2,4,6})_2(\text{NCR})_4]$ ($\text{M} = \text{Mo}, \text{W}; \text{R} = \text{Me}, \text{Bu}^+$) have been calculated from the data of cyclic voltammetry.³⁶

Isomerisation can be accompanied by a change in the type of metal bonding to the ligand: the terminal ligand passes to a bridging position or *vice versa*. For example, the 48-electron cluster $\text{Cp}^*\text{IrCp}_2\text{Co}_2(\text{CO})_3$ ($\text{Cp}^* = \text{C}_5\text{Me}_5$) can exist as two isomers, one containing a terminal and two bridging carbonyl groups (A) and one with three bridging CO ligands (B), the second isomer being thermodynamically more stable.

The rate of isomerisation depends appreciably on the number of electrons in the cluster³⁷ and varies in the following sequence: $48e \ll 49e < 47e$ (the ratio of the corresponding rate constants is 1 : 104 : 108). Thus, anodic activation is the most efficient.

Anodically activated isomerisation of diene ligands, for example, cyclooctadiene (cod), is known.³⁸

The trimetallic carbonyl clusters $\text{M}_3(\text{CO})_7(\text{dppm})(\text{tolan})$ ($\text{M} = \text{Os}, \text{Ru}$; dppm is diphenylphosphinomethane; tolan is diphenylacetylene) can also exist as two isomers which differ in the position of the alkyne ligand with respect to the triangle formed by the metal atoms.³⁹ The interconversion of the two isomers can be performed through electrochemical redox isomerisation because one of them is more stable in the reduced form and the other one, in the oxidised form.

Numerous examples of the change in the type of hapticity of the π -ligand to the metal atom induced by electrochemical electron transfer are known. For example, two-electron oxidation of a trinuclear ruthenium complex induces haptotropic isomerisation giving rise to an unusual μ^3 - η^3 : η^3 -coordination of the benzene ring.^{40, 41}

The structure of the resulting complex was confirmed by X-ray diffraction data.

The change in the hapticity upon oxidative or reductive electrochemical activation has also been reported for indenyl, cyclopentadienyl and some other aromatic ligands⁴¹ (see also the review²⁶ and references therein).

Of special interest are redox-induced reactions of complexes with polydentate ligands having, at least, two possible sites of coordination to the metal. In this case, redox switching of the metal from one coordination site to the other has been observed.²⁶

$\text{ML}_n = \text{FeCp}, \text{FeCp}^*, \text{Mn}(\text{CO})_3, \text{Cr}(\text{CO})_3$.

The ring–ring haptotropic isomerisation of 18-electron fluorenyl complexes with the d^6 metal configuration proceeds very slowly even at high temperatures, and the equilibrium is shifted towards the η^5 -isomer. In the case of 19-electron complexes, isomerisation rapidly takes place at -80°C , the equilibrium being shifted towards the η^6 -isomer:

Detailed analysis of the mechanism of ring–ring haptotropic tautomerism and a survey of published examples of these processes have been reported.²⁶

3. Insertion and extrusion

The electrochemical migrational insertion of a carbonyl group into the $\text{Fe}-\text{C}(sp^3)$ bond can be used to synthesise the corresponding acyl complexes; this reaction is carried out with either reductive⁴² or oxidative⁴³ activation.

If both anodic and cathodic types of activation are possible, one should prefer the method for which the ratio of the currents of the inverse and forward electrochemical processes ($I_{\text{inv}}/I_{\text{for}}$) in the cyclic voltammogram of the product is closer to unity, *i.e.*, a classical electrochemically reversible process should be the method of choice.¹⁵

The Kochi cathodic activation has provided the possibility of the back reaction, *i.e.*, CO extrusion from formyl metal complexes.⁴⁴

4. Electrochemically activated reactions in the ligand sphere of the metal

Transition metal complexes tend to undergo reactions accompanied by electrochemical activation of π -bonded ligands, resulting in ligand modification. The activation of C–H bonds followed by substitution in π -coordinated aromatic ligands provides an example.⁴⁵

Examples of reactions of this type can also be found in Walder's monograph.²⁸ A convenient method for building-up the hydrocarbon side chain during electrochemical reduction of acetyl derivatives of ferrocene, cymanthrene and benzenetricarbonylchromium has been proposed.⁴⁶

Of recent publications devoted to this topic, a study by Gusev *et al.*⁴⁷ deserves attention. The researchers identified the main regularities of the redox-induced activation of the C–H bonds in Pd and Pt η^4 -pentamethylcyclopentadiene complexes. Single-electron oxidation of these compounds proceeds selectively as homolysis of the C–H bond at the sp^3 -hybridised carbon atom of

the Cp ring, while its single-electron reduction results in activation of the C–H bonds of the methyl groups.

Dimerisation of organometallic radicals according to the ‘ligand–ligand’ type can also be regarded as a reaction in the ligand sphere of the metal. Reductive dimerisation of the $[\text{Mn}(\eta^6\text{-C}_6\text{H}_6)(\text{CO})_3]^+$ cationic complex, resulting in the formation of a new C–C bond, is an example.⁴⁸

Dimerisation giving a new C–C bond in the ligand sphere of a metal was observed in a two-electron reduction of sandwich iridium complexes.⁴⁹

A similar approach has been used to prepare ‘molecular wires’ consisting of polyyne chains with ferrocenyl and ruthenocenyl groups at the ends.⁵⁰

In solutions, 19-electron arenecyclopentadienylruthenium radicals either undergo dimerisation involving the six-membered ring (Scheme 2, pathway *b*) or capture a hydrogen atom from the reaction medium (Scheme 2, pathway *a*). It was found that a decrease in the electron-donating capacity of ligands or an increase in the ligand bulk enhances the stability of radicals and dimerisation becomes the preferential process over the addition of a hydrogen atom.^{51, 52}

Scheme 2

5. Disproportionation

Disproportionation can also take place with intermediate formation of 19-electron complexes. For example, the $\text{Mn}_2(\text{CO})_{10}$ dimeric complex can disproportionate in the presence of highly electron-donating nitrogen-containing tridentate ligands. This reaction is subject to both electrochemical and photochemical initiation⁵³

The overall reaction is as follows:

III. Electrocatalysis: combination of catalysis by metal complexes with electrochemically induced electron transfer

An important application of the electrochemical electron transfer in reactions involving metal complexes and proceeding *via* organometallic intermediates is electrocatalysis. This line of research has been vigorously developing during the last 15 years and combines the advantages of catalysis by metal complexes and activation through electrochemical electron transfer. When the reaction is carried out at an electrode, electron transfer does not require additional oxidants or reducing agents, and the process is highly selective. Modification of the electrode surface by metal complexes (or the addition of complexes as mediators to the solution) provides the possibility of conducting electrochemically activated reaction at a substantially lower overpotential.

The processes that combine catalysis by metal complexes with electrochemical transfer of an electron can be conventionally classified into two types. One type includes so-called mediator processes in which a complex is first reversibly reduced (or oxidised) at an electrode and then it passes the electron to an organic substrate (S) (or withdraws the electron from it in the case of oxidative activation). In this case, the electron transfer usually follows an outer-sphere mechanism, *i.e.*, no bond between the metal complex and the organic substrate is formed. The mediator electron transfer yields an active form of the organic substrate (either reduced or oxidised form), which is then converted into product (P); as this takes place, the mediator (A) is regenerated.

Reduction	Oxidation
$A + e^- \longrightarrow A^{\bullet-}$	$A - e^- \longrightarrow A^{+\bullet}$
$A^{\bullet-} + S \longrightarrow A + S^{\bullet-}$	$A^{+\bullet} + S \longrightarrow A + S^{+\bullet}$
$S^{\bullet-} \longrightarrow P^{\bullet-}$	$S^{+\bullet} \longrightarrow P^{+\bullet}$
$P^{\bullet-} - e^- \longrightarrow P$	$P^{+\bullet} + e^- \longrightarrow P$

In the second type of process, an electron transfer from the catalyst (Cat) to the organic substrate is an inner-sphere process, *i.e.*, it proceeds *via* the formation of an intermediate activated complex, decomposition and subsequent transformations of which afford product P.

Reduction	Oxidation
$\text{Cat} + e^- \longrightarrow \text{Cat}^{\bullet-}$	$\text{Cat} - e^- \longrightarrow \text{Cat}^{+\bullet}$
$\text{Cat}^{\bullet-} + S \longrightarrow \text{CatS}^{\bullet-}$	$\text{Cat}^{+\bullet} + S \longrightarrow \text{CatS}^{+\bullet}$
$\text{CatS}^{\bullet-} \longrightarrow P^{\bullet-} + \text{Cat}$	$\text{CatS}^{+\bullet} \longrightarrow P^{+\bullet} + \text{Cat}$
$P^{\bullet-} - e^- \longrightarrow P$	$P^{+\bullet} + e^- \longrightarrow P$
or	or
$P^{\bullet-} + \text{Cat} \longrightarrow P + \text{Cat}^{\bullet-}$	$P^{+\bullet} + \text{Cat} \longrightarrow P + \text{Cat}^{+\bullet}$

An advantage of mediator processes⁵⁴ is a decrease in the kinetic barrier to electrochemical reactions; the potential approaches the thermodynamic value. This is valid for processes that include a fast chemical step, $S^{+(-)} \rightarrow P^{+(-)}$. The mediator participating in these reactions should satisfy the following conditions: (1) the ability to undergo reversible oxidation or reduction; (2) $|E_m| \ll |E_s|$ (where E_m and E_s are the potentials of the mediator and substrate, respectively), the optimal potential difference is usually 0.3–0.5 V; (3) structural correspondence between the mediator and the substrate to ensure the electron transfer. The

mediator can occur in the solution or, alternatively, be chemically bound to the electrode (chemically modified electrode).

The inner-sphere electron transfer has a number of advantages over the outer-sphere process.²⁷

1. The redox process does not depend on the potential difference between the mediator and the substrate; therefore, a much more pronounced decrease in the overpotential is possible.

2. The inner-sphere transfer is characterised by a lower activation barrier.

3. An outer-sphere process allows the transfer of only one electron, while in the case of the inner-sphere mechanism, transfer of two or more electrons is possible. (This is especially important for bioelectrocatalysis and for activation of small molecules.)

In real processes, the consumption of electricity is determined by the contributions of various competing reactions involving radical cations or radical anions derived from the catalyst. Moreover, apart from the classical cases in which an inner-sphere or outer-sphere mechanism of electron transfer is regarded as proven, there exist a large number of intermediate processes for which it is difficult to draw a conclusion about the nature of the transition state. In the case of metal complexes with an inner-sphere or a similar mechanism of electron transfer, the activated molecule enters the metal coordination sphere, which increases its reactivity.

Numerous examples of electrocatalytic processes involving transition metal complexes are known.^{55–61} The greatest number of studies have been devoted to the activation of small molecules and to various reactions of C–C bond formation (homo- and cross-coupling, carboxylation and carbonylation, the addition to multiple bonds).

1. Electrocatalytic reduction of small molecules

A series of reviews and original papers (see, for example, the studies^{22,56–61}) have been devoted to electrocatalytic reduction of nitrogen and its oxides, carbon oxides, and molecules or ions with triple bonds (acetylene, cyanide ion). A common feature of all the above compounds is that they are electrochemically inactive and contain very strong bonds that are fairly difficult to cleave. Therefore, activation of such molecules through introducing them into the metal coordination sphere followed (or preceded) by electrochemical electron transfer is the most promising way of involving these compounds in various chemical transformations. In addition, considerable attention to electrocatalytic processes with participation of metal complexes is inspired by the idea of utilisation of the enormous reserves of N₂, CO₂ and O₂ present in the biosphere as a cheap and readily available feedstock for various chemical transformations.

Since it is impossible to cover the tremendous number of publications devoted to various processes of this type, in this review, we consider only examples of electrocatalytic binding of CO₂. These data, first, provide an idea of the main principles and features of electrocatalytic reactions and, second, they are fairly important from the practical standpoint.

Direct electroreduction of CO₂ at a metallic (for example, mercury) cathode requires a high overpotential: $E_{\text{CO}_2/\text{CO}_2^-} = -2.21 \text{ V vs. a saturated calomel electrode (SCE) in DMF}$.⁶² Other metallic cathodes, for example, copper or gold ones, are able to reduce CO₂ in an aqueous solution at somewhat less cathodic potentials (–1.3 to –1.7 V vs. SCE), but these values are also too great for practical application of this process^{63,64} because water is also reduced at these potentials with hydrogen evolution. This could be avoided by using non-aqueous solvents;^{65–71} however, such a process is unfavourable due to a high energy expenditure and undesirable reduction of components present in the solution.

A lot of data on the use of transition metal complexes for the electrocatalytic reduction of CO₂ can be found in the literature (see, for example, studies^{7,58,72,73}). As a rule, these are complexes with nitrogen-containing macrocyclic ligands such as porphyrins and their analogues, well-known as biocatalysts. Synthetic metal

complexes with nitrogen-containing macrocyclic ligands, for example, phthalocyanines (Pc) or 1,4,8,11-tetraazacyclotetradecane (cyclam) derivatives, are often not inferior to enzymes in their catalytic activity.

Metal phthalocyanines^{3,8–11,15,74–84} and metal porphyrins,^{2,12,13,19,58,73,85–87} Ni(II) complexes with cyclam derivatives,^{88–94} bis- and polypyridine complexes of Rh(II),⁹⁵ Re(I),⁹⁶ Cu(I),⁹⁷ Co(II), Fe(II) and Ni(II),^{76,84,98–101} iron and cobalt complexes with the 4,5-dihydroxybenzene-1,3-disulfonate and 2-hydroxy-1-nitrosonaphthalene-3,6-disulfonate ligands^{102,103} and other complexes can serve as catalysts for CO₂ reduction.

An important advantage of using metal complexes as catalysts for the reduction of CO₂ is the possibility of changing their reactivity by modification of the macrocyclic ligand either by introducing electron-donating or -withdrawing substituents or by replacing the central metal atom.¹⁰⁴ Indeed, a Ni(II) complex with a cyclam analogue, 3,10-dimethyl-1,3,5,8,10,12-hexaazacyclotetradecane, exhibits a much higher catalytic activity than the unsubstituted Ni(II)(cyclam) complex.¹⁰⁵ Surprisingly, the introduction of σ -acceptor substituents, for example, fluorine, into the nitrogen-containing ring also increases the catalytic activity and the selectivity of CO formation (with respect to hydrogen evolution). The Ni(II) complex with 3,3,10,10-tetrafluorocyclam proved to be the most efficient. Further increase in the number of fluorine atoms at the macrocycle leads to a lower catalytic activity.¹⁰⁶

The influence of the nature of the central metal atom on the catalytic efficiency of CO₂ electroreduction has been studied. In the case of metal complexes with *meso*-tetraphenylporphyrin, the highest current yield of CO was observed for Co, Fe and Zn complexes, while the catalytic activity of Ni, Cu, Mg and Mn compounds was fairly low.¹⁹

A wide range of monophthalocyanine complexes of various metals have been tested in the electrocatalytic reduction of CO₂ at a gas-diffusion electrode in an aqueous solution.^{3,15} The electroreduction of carbon dioxide gave CO, HCOOH and CH₄, the ratios and the current yields of which depended appreciably on the properties of the central metal atom in the phthalocyanine complex. With Group VIIIA transition metals such as Co, Ni, Fe and Pd, the reaction usually gives CO as the major product. The electrolysis of CO₂ in the presence of Sn, Pb, In and Al phthalocyanine complexes affords mainly HCOOH, and in the case of Zn phthalocyanine, approximately equal amounts of HCOOH and CO are formed. Under the action of phthalocyanine complexes of Group IIIB and IVB elements, In and Sn, formic acid is produced with the highest selectivity, and in the case of Cu, Ga and Ti, methane is formed, although in a low yield. Metal-free phthalocyanine proved to be almost inefficient in the reduction of CO₂. Thus, coordination of CO₂ to the metal atom in the complex plays an important role. The data on the use of metal phthalocyanines in reactions of CO₂ reduction (see Refs 3 and 15) are listed in Table 1.

It is of interest that the cathodic electrocatalytic activity of cobalt complexes with macrocyclic ligands increases if the Co atom is bound to the axial electron-donating ligand, for example, pyridine or imidazole.^{107–109} Thus CO₂ electroreduction in water at a glass-carbon electrode coated by Co tetraphenylporphyrin with the axial pyridine ligand occurs with a high selectivity.¹⁰⁷

Recently,¹¹⁰ investigations of diphtalocyanine complexes as catalysts for carbon dioxide electroreduction in protic media have been started. The major reaction products were CO and HCOOH (or methyl formate if electroreduction is carried out in methanol).

It is worthy of note that the formation of a metal–CO₂ complex is postulated as the key step in almost every study devoted to the catalytic fixing of CO₂ by transition metal complexes.^{3,9,109–114} In most cases, this is supported only by the data of IR or NMR spectroscopy because, first, the lifetime of these intermediates is short and, second, the presence of solvent molecules, also capable of coordination, hampers detailed analysis of the structure of the complex.

Table 1. Results of cathodic reduction of CO₂ in water in the presence of phthalocyanine complexes of transition metals (PcM).^{3,15}

M	<i>E</i> / V (vs. SCE)	Current efficiency (%)

A number of calculations for ligand-free complexes MCO₂ (M is an alkali or transition metal) have been carried out (see Ref. 115 and references therein). The first systematic study into the geometry, configurational interactions and electron density distribution for a wide range of MCO₂ complexes (where M is a metal of the 3-rd period: Ca–Mn, Cu, Zn) showed the occurrence of electron transfer from the metal atom to the CO₂ group, the electron density being concentrated on the carbon atom and the M–C bond being nearly ionic. The electron transfer from the metal to CO₂ is accompanied by redistribution of electrons in the internal levels and, in particular, results in a higher electron density on the oxygen atom. Thus, coordination to the metal increased the basicity of the oxygen atoms in the CO₂ group.

Mechanisms for the electrocatalytic reduction of CO₂ have been proposed in a few publications.^{79,109} These studies deal with the reduction of CO₂ in an aqueous solution at a graphite electrode coated by PcCo bound to poly-4-vinylpyridine (PVP), the latter acting as a donor axial ligand (Scheme 3).

It can be seen from Scheme 3 that the catalytic process starts only in the second step of PcCo reduction because the first reduction is followed by the fast addition of H⁺ to one of the peripheral nitrogens of the phthalocyanine ring, and only the second step gives an active species capable of reducing both H⁺ and CO₂ to H₂ and CO, respectively. Nevertheless, researchers^{79,83} who studied electrocatalysis by pure PcCo adsorbed on graphite, were unable to observe directly the PcCo–CO₂ adduct.

An interesting sequence of steps taking place during CO₂ reduction catalysed by iron porphyrins has been proposed and confirmed by kinetic data.^{112,113} The key step of this process is the formation of the Fe–C bond (Scheme 4, the porphyrin ligands are omitted, AH is a Brønsted acid).

It has been shown¹¹⁶ that a rotating ring–disk electrode, in which the disk electrode is represented by graphite coated by cobalt(II) *N,N',N'',N'''*-tetramethyltetra-3,4-pyridoporphyrine and protected by a polymeric film (Nafion) and the ring electrode is represented by platinum, can be used for quantitative determination of CO₂ in aqueous solutions (the concentration range is 10^{−4}–3.2 × 10^{−2} mol litre^{−1}). The method is based on the fact that CO₂ is reduced quantitatively at the disk to give CO (at −1.15 V vs. SCE), while the latter is detected on the basis of the typical oxidation peak at the platinum ring (0.4 V vs. SCE):

2. Electroreductive coupling, addition, carboxylation and carbonylation

Electroreductive coupling reactions are extensively used in synthesis. Phosphine, tetraazamacrocyclic and polypyridyl complexes of transition metals (mainly, Ni, Pd and Pt) are used most often as catalysts. Electrochemical electron transfer can play different roles in these reactions — an electron can participate directly in the catalytic cycle, or/and labile complexes of transition metals in low oxidation states can be generated electrochemically and participate in the reaction *in situ*.

The general scheme of the electroreductive coupling can be represented in the following way:^{27,55,117,118}

X = I, Br, Cl, OTf; M = Ni, Pd;

L = PPh₃, dppe, bipyridyl (bipy), *etc.*

The activity of Ni(0) and Pd(0) complexes in coupling reactions of organohalogen compounds was shown^{119, 120} to depend on a number of factors: the size of the electrochemical gap, the strength of the metal–ligand bond, and electronic and steric effects of the ligands. The first step of the catalytic cycle is the oxidative addition of an organic substrate to a zerovalent metal complex, resulting in the formation of a σ -arylnickel or σ -arylpalladium intermediate.

M = Ni, Pd.

Numerous reactions of this type have now been described (see the monograph²⁷ and the papers^{55, 118, 121, 122}). Among these, electrochemical synthesis of substituted 3-phenylthiophenes is noteworthy.¹²³ The reduction of a mixture of 3-bromothiophene and ZnBr₂ in the presence of the bipyridine nickel complex gives rise to 3-thienylzinc bromide, which enters into cross-coupling reactions with various aryl halides (PhI, *p*-NCC₆H₄Br, *o*-MeOC₆H₄Br, *p*-MeOC₆H₄Br).

The synthesis of optically active 1,3-dienes containing chiral substituents from alkenylstannanes by electrooxidation and homocoupling with participation of CuCl₂ has been reported.¹²⁴

Phosphine and bipyridine Ni complexes serve as the catalysts of the electroreductive coupling of aryl and hetaryl halides with mono- and dichlorophosphines, which allows the synthesis of tertiary phosphines in high yields.^{125, 126}

L = PPh₃.

Under the action of electrochemically generated Ni(0) or Sm(II) compounds, arylation of white phosphorus takes place.¹²⁷

The intramolecular reductive coupling of allyl 2-halophenyl ethers catalysed by the Ni(cyclam)Br₂ complex provides the preparation of 3-methyldihydrobenzofuran in 90% yield.¹²⁸

X = Cl, Br, I.

If CO₂ or CO is introduced in the reaction mixture containing an organic halide and the electrochemically generated Ni(0) complex, the reaction gives carboxylic acids or carbonyl compounds, respectively, instead of the homocoupling products.

Carbon dioxide adds to Ni(I)ArL₂ approximately twice as fast as ArX; therefore, the side reaction giving biaryls scarcely takes place.^{129–133} In the presence of CO₂ and catalytic amounts of electrochemically generated Pd(0) complex, aryl and vinyl triflates are converted into aromatic and α,β -unsaturated carboxylic acids, respectively.¹³⁴ Carboxylic acids can also be prepared from allyl and benzyl halides using Co complexes as catalysts.¹³⁵

R = PhCH₂, Ph(Me)CH, MeCH = CHCH₂;
salen is bis(salicylidene)ethylenediamine.

Recently,¹³⁶ electrosynthesis of ketones from organic halides and CO catalysed by Ni(0) bipyridine complex was carried out. Study of the process mechanism showed that the reaction involves the intermediate formation of the acyl nickel complex.

The use of electrochemical electron transfer makes it possible to 'invert' the polarity of aryl halides ArCOX and introduce them into reactions with electrophiles.¹³⁷

The process includes the formation of the PdArX complex and the subsequent CO insertion, resulting in the intermediate PdArCOX complex, which is reduced more readily than the initial aryl halides; after activation by electrochemical electron transfer, this species can react with electrophiles, for example, with H⁺.

Electrocatalytic arylation of alkenes is documented. Although the process mechanism is not entirely clear, it is assumed that coordinatively unsaturated Ni(0) complexes serve as the basis for the spatial proximity of halobenzenes and alkenes; the subsequent treatment with a base yields arylalkenes.¹³⁸

IV. The formation and cleavage of carbon–metal σ -bonds

Reactions giving carbon–metal σ -bonds are very important from the theoretical and practical standpoints because they allow the synthesis of new organometallic compounds with various useful properties. We shall consider two main types of these reactions, namely, electrochemical alkylation and electrochemical arylation of metal-containing nucleophiles.

1. Electrochemical alkylation

The methods used most widely for the introduction of alkyl groups are based on S_N2 reactions of various organic compounds with metal-containing nucleophiles. The latter can be synthesised conveniently by an electrochemical procedure using reductive activation, which yields metal complexes in low oxidation states. This method was used to prepare the alkyl derivatives of Co,¹³⁹ Fe¹⁴⁰ and Rh porphyrins^{141,142} as well as complexes with other nitrogen-containing macrocyclic ligands, in particular, dimethylglyoximate¹⁴³ and phthalocyanine.¹⁴⁴

A comparative study of alkylation of electrochemically generated nucleophilic Co, Rh, Ir, Ni and Pd complexes with various nitrogen- and sulfur-containing ligands on treatment with butyl bromide was carried out.¹⁴³ Electrochemically activated reactions with transfer of the methyl group from dimethylglyoximate complexes of methylcobalt onto Au(I)¹⁴⁵ and Ni(I)¹⁴⁶ complexes and onto mercury¹⁴⁷ and germanium salts¹⁴⁸ are also known.

2. Electrochemical arylation and vinylation

Using the approach described above, only alkyl fragments can be introduced into the metal coordination sphere. The introduction of aryl and vinyl substituents requires not only electrochemical activation of a metal-containing nucleophile but also an additional activation of the $C(sp^2)$ –Hal bond ($S_{RN}1$ reactions). Theoretical investigation into the electrochemically activated $S_{RN}1$ type reactions was started by Saveant's group.^{12,149–157} The stabilities of the radical anions formed initially, the relative rates of each step of the $S_{RN}1$ process, the most important competing reactions and the types of chain termination have been studied. A number of procedures for preparative electrosynthesis of various organic compounds underlain by $S_{RN}1$ processes have been developed.^{153,158–160}

However, until recently, the authors of only two studies^{161,162} have described examples of electrochemically activated $S_{RN}1$ reactions involving organometallic compounds, namely, the synthesis of aryl and vinyl derivatives of iron porphyrin¹⁶¹ and the reactions of the $[CpM(CO)_3]^-$ anions ($M = Mo, W$) with iodonitrobenzene.¹⁶²

Apparently, this is due to the fact that the double electrochemical activation of both reagents requires that a specified potential be strictly maintained during the reaction. This creates some difficulties for practical implementation of these processes because the reaction product can be subsequently destroyed (compounds containing a carbon–metal σ -bond are usually oxidised and reduced irreversibly with cleavage of this bond). If

the product is reduced at more cathodic potentials than the reaction begins (the activation potential of the initial reactants), the product destruction at the electrode can be avoided.¹⁶¹ Systematic investigations of electrochemically activated arylation in which the reaction product is irreversibly reduced at potentials less cathodic than the activation potential of the reactants have been started^{163–167} in relation to electrochemical arylation and vinylation of anionic iron, molybdenum and tungsten carbonyl complexes.

The general scheme of the reaction is as follows:

$M = Fe, Mo, W$.

Electrochemical electron transfer activates the organic halide by transforming it into a reactive radical and leads to generation of metal-containing nucleophiles as a result of cleavage of the $M-M$ bond in the dimer. The active species that arise react with each other *in situ* to give a σ -organometallic compound.

Activation of the first reactant

Activation of the second reactant

$M = Fe, n = 2; M = Mo, W, n = 3$.

The formation of the σ -organometallic compound

These reactions have been carried out for both aryl halides (p - XC_6H_4Hal : $X = H, Me, Cl, I, COMe, CN, NO_2$; $Hal = I, Br$; C_6F_5X : $X = H, F, Cl, Br$; C_5F_5N) and vinyl halides (Z -, E - $PhCH=CXHal$: $X = H, Ph$; $Hal = I, Br$; Z -, E - $PhCF=CFHal$, Z -, E - $Bu^tCF=CFHal$: $Hal = F, Cl, Br$).

Direct electrochemical activation of this reaction is possible only for those aryl halides that are reduced more readily than the reaction product, a cyclopentadienyldicarbonyliron derivative. This is due to the fact that electrochemical reduction of σ -organometallic compounds of this type is irreversible and is accompanied by $C-M$ bond cleavage. For any other compound, the product resulting from electrochemical activation decomposes immediately at the electrode. It can be seen from Fig. 2 that the region of

Figure 2. Reduction potentials (E^{Red}) (Pt cathode) of aryl iodides p - IC_6H_4X (1) and the products p - $CpFe(CO)_2C_6H_4X$ (2) vs. Hammett σ_p -constants of substituents. Reduction potentials of initial aryl iodides at a Hg electrode (3). The region of possible electrochemical activation of the reaction is hatched.¹⁶³

possible electrochemical activation of the reaction is rather narrow. It can be extended by decreasing the potential of the onset of the reaction, *i.e.*, the potential at which active species are generated.

Three approaches have been proposed to solve this problem. One approach includes fast potential cycling toward a less cathodic region and back; thus, at least some of the product formed at the electrode has time to diffuse into the solution.¹⁶⁴

According to the second approach,¹⁶³ the electrode material is replaced (Hg is used instead of Pt); this allows a significant decrease in the potential at which the reaction starts because this facilitates the reduction of aryl and vinyl halides (see Fig. 2, dashed line). In this case, direct electrochemical activation can be used for iodobenzene, *p*-bromobenzonitrile and other aryl halides (see Fig. 2), the reduction of which at mercury falls into the required potential range, while electrochemical activation of these compounds at platinum is impossible. For vinyl halides studied by Magdesieva *et al.*,¹⁶³ except for β -iodostyrene, the mere replacement of the electrode material does not suffice for electrochemical activation of the nucleophilic vinyl substitution because σ -vinyl derivatives of η^5 -cyclopentadienyldicarbonyliron are reduced more readily than the initial substrate even at mercury.

The third approach¹⁶⁵ implies the use of homogeneous redox catalysis in which a decrease (in magnitude) in the potential of the reaction onset is attained by adding an appropriate reversible $A/A^{\cdot-}$ redox pair, which acts as a mediator[†] by carrying an electron from the electrode to the aryl or vinyl halide.

R is aryl, vinyl.

Owing to the homogeneous redox catalysis, these reactions can be carried out for such substrates for which the replacement of electrode material alone does not result in a positive value of

$$\Delta E = E_{\text{RHal}}^{\text{Red}} - E_{\text{FeR}(\text{CO})_2\text{Cp}}^{\text{Red}}$$

(for example, *p*-iodotoluene, bromostyrenes and *Z*-bromostilbene). In addition, by using this approach, one can increase the yield of nucleophilic substitution products for substrates that formally fall into the region of possible reaction activation upon the replacement of the electrode material but still have too small ΔE values, for example, for iodobenzene (Table 2).

Thus, Magdesieva *et al.*¹⁶⁵ were the first to show experimentally that the use of homogeneous redox catalysis allows the electrochemically activated reactions of organometallic compounds to be performed under conditions where the products are redox-unstable upon direct electrochemical activation. This implies selection of a mediator whose activities with respect to the reactant and the product are appreciably different. This has markedly extended the scope of applicability of electrochemical activation, first of all, for the synthesis of σ -organometallic compounds.

Table 2. Yields of products of direct and mediator preparative electrolysis^a of aryl and vinyl halides in the presence of $[\text{CpFe}(\text{CO})_2]_2$.^{163–165}

Substrate	Potential of electrolysis /V	Product	Preparative yield (%)

^a Electrolysis conditions: Hg, Bu₄ⁿNBF₄ (0.25 mol litre^{–1}), MeCN, Ag⁺/AgCl/KCl, 20 °C. ^b Fp = CpFe(CO)₂. ^c The phthalodinitrile concentration is 5×10^{-4} mol litre^{–1}.

This approach has permitted the preparative synthesis of about twenty aryl and vinyl derivatives of CpFe(CO)₂ containing the C(sp²)–metal σ -bond, particularly high product yields being attained when using homogeneous redox catalysis.

Study of the stereochemistry of the reaction products (Table 3) showed that, irrespective of the configuration of the initial vinyl halide, the product with the *trans*-arrangement of the organometallic group and the organic group always predominates. This is due to the fact that generation of the radical anion is accompanied by isomerisation to give the most stable configuration (Scheme 5).

Table 3. Results of preparative electrolysis^a of vinyl halides RCF=CFX in the presence of the $[\text{CpFe}(\text{CO})_2]_2$ binuclear complex.¹⁶⁷

[†] Study of a wide range of conceivable mediators showed that phthalodinitrile is the compound of choice for this reaction.¹⁶⁵

Using electrochemical activation, it is possible to arylate¹⁶⁸ Co(II) and Co(III) complexes with chelating ligands containing nitrogen and sulfur atoms, for example:

X = Py, Hal.

R = Me, OMe.

The essence of the 'iodonium method' proposed in one study¹⁶⁸ is to use diphenyliodonium salts including those containing various substituents in the benzene ring as arylating agents.

Chel is a chelating ligand.

Not only Co(II) complexes but also Co(III) complexes, which are normally more stable and more readily available, can be introduced in the arylation. However, in this case, electrochemical activation of both reactants is needed.

It is noteworthy that the use of diphenyliodonium salts as arylating agents has obvious advantages over halobenzenes used

traditionally in $\text{S}_{\text{RN}}1$ reactions, because the former provide generation of phenyl radicals upon electrochemical activation at much lower cathodic overpotentials.

3. Electrosynthesis with sacrificial electrodes

Yet another widely used electrochemical approach to the synthesis of organometallic compounds is the use of sacrificial (this is the name for soluble) anodes. In an undivided cell, metal dissolution takes place at the anode and the organic substrate is reduced at the cathode to give anions which should be stable enough to avoid side reactions with the solvent.^{28, 169–171}

Examples of syntheses with anodes made of Ti, Zr, Hf, V, Cr, Mn, Fe, Co, Ni, Cu, Al, Pb, Sn and various ligands are documented.^{172–175}

Kharisov *et al.*¹⁷⁶ have compared the traditional chemical and electrochemical methods for the synthesis of transition metal complexes with nitrogen-containing ligands. An advantage ensured by the use of sacrificial anodes is the possibility of preparing Cu, Ni, Co, Pd, Zn and Cd complexes in one step in high yields.

Electrochemical cleavage of the carbon–metal σ -bond gives in most cases organic radicals the further transformations of which are determined¹⁷⁷ by the applied potential and the solution composition.

V. Electrochemically activated reactions involving 'electron sponges'

When considering electrochemical activation of reactions involving organometallic compounds, two types of processes can be distinguished:

(1) electrochemical activation of various types of bonds (C–Hal, C–M, M–Hal, M–M, *etc.*), resulting in their cleavage to give highly reactive species (cations, anions, radicals);

(2) activation through transfer of one or several electrons accompanied by the change in the electronic structure and, hence, properties of the molecule, but involving no bond cleavage.

In the reactions considered above, activation of the former type takes place. Now we shall give some examples of the latter type of processes.

Systems capable of reversible stepwise addition or release of several (three or more) electrons are referred to as 'electron sponges'. The transfer of an electron onto such systems results in activation of the whole molecule and in the change in its properties (for example, catalytic, spectroscopic and other properties) but does not induce cleavage of any bond. A fairly large number of such systems have been reported;^{178, 179} however, here we restrict ourselves to consideration of two of them, namely, phthalocyanine complexes and fullerene derivatives, for which electrochemically activated reactions involving organometallic compounds are known.

1. Electrosynthesis of exohedral metal complexes of C_{60} and C_{70}

A unique feature of fullerenes and their derivatives is the capability of reversible stepwise addition of up to six electrons, which makes them fairly promising participants of redox processes. Recently,^{180, 181} we proposed an electrochemical method for the synthesis of exohedral complexes of C_{60} and C_{70} , namely, $C_{60}ML_2$ [$M = Pd, Pt$; $L_2 = (Ph_3P)_2$, bis(diphenylphosphino)ferrocene (dppf) or diphenylphosphinocymanthrene] and $C_{70}Pt(PPh_3)_2$ (a mixture of two isomers) from simple and stable inorganic salts (MCl_2) or complexes of platinum group metals (ML_2Cl_2).

Reactive complexes of zerovalent metals sensitive to atmospheric oxygen can be generated *in situ* using electrochemically generated C_{60}^{2-} or C_{70}^{2-} dianions as reducing agents. In this case, fullerene plays a dual role acting simultaneously as an electron transporter (mediator) and as one of structure-forming reagents.

An advantage of this method is the possibility of preparing a pure monometal complex containing no polymetallated fullerenes. This is related to the fact that the electron transfer is followed by the fast reaction of C_{60} with the ML_2 compound formed *in situ*, which is formed in an exactly equimolar amount.

This approach has also been used to prepare new exohedral heteropolymetallic complexes of [60]fullerene containing Pd, Fe and Mn atoms.^{182, 183}

dba is dibenzylideneacetone;

2. Electrochemically activated reactions of phthalocyanines

Typical examples of 'electron sponges' are mono- and diphthalocyanine metal complexes.

Recently, it has been found¹⁸⁴ that some diphthalocyanine complexes are able to undergo eight reversible and quasi-reversible redox transitions in the anodic and cathodic regions. Owing to this feature, they are rather promising participants of various redox processes, in particular, electrocatalytic ones. In Section III.1, we presented examples of electrocatalytic reduction of CO_2 by various complexes with macrocyclic nitrogen-containing ligands, including phthalocyanine complexes. Now we consider one more example of an electrochemically activated reaction of phthalocyanines in which the electrochemical transfer of an electron is used for catalyst activation.

The binding of CO_2 by epoxides resulting in the formation of alkylene carbonates is known¹⁸⁵ to be catalysed by metal phthalocyanines. However, this reaction proceeds under rigorous conditions, *i.e.*, in an autoclave at high pressure and temperature. With electrochemically reduced forms of metal phthalocyanines used as catalysts, this reaction was found⁷⁴ to proceed at 20 °C and under atmospheric pressure, in conformity with the scheme

$R = Me, CH_2Cl.$

The electrochemical activation of the catalyst and the subsequent nucleophilic attack occur in the following way:

Thus, electrochemically reduced forms of metal phthalocyanines exhibit much higher catalytic activities than neutral forms. Both mono- and diphtalocyanine complexes can be used as catalysts in this reaction; however, the latter offer an

advantage, namely, in this case, the electrochemically activated binding of CO_2 can be carried out at a low cathodic polarisation (the potentials of the first redox transition of Pc_2M range from +0.01 to -0.65 V vs. Ag/AgCl/KCl).^{74, 104, 186}

A study of the influence of the catalyst immobilisation mode on the efficiency of the catalytic process showed that the highest efficiency is observed in the case of amino-substituted mono- and diphtalocyanine complexes (NH_2PcM and $\text{NH}_2\text{Pc}_2\text{M}$, respectively) electropolymerised on smooth electrodes. Turnover numbers as high as 10^4 – 10^5 have been achieved for these catalysts, which is close to the efficiency of natural enzymes.¹⁸⁷

Monomer	NH_2PcCu	NH_2PcCo	NH_2PcPd	$\text{NH}_2\text{Pc}_2\text{Lu}$	$\text{NH}_2\text{Pc}_2\text{Er}$
Catalyst turnover number in 75 min	2.65×10^5	4.7×10^3	1.05×10^3	1.4×10^4	7.0×10^3

It is of interest that carboxy-containing adducts formed under the action of phthalocyanine complexes and biotin (the co-enzyme which binds CO_2 and transports it to organic molecules *in vivo*) are structurally similar: in both cases, they contain a fragment similar to carbamic acid (Scheme 6).

Scheme 6

The above data indicate that the simulation of functioning of the active sites of enzymes operating by the proton transfer mechanism by processes occurring by a redox mechanism is possible but only at the level 'the same intermediate (in this particular case, the resonance-stabilised planar N anion) — the same product',¹⁸⁸

* * *

The information presented here demonstrates that, although numerous studies on electrochemically activated reactions involving organometallic compounds have been performed, the list of types of these reactions is quite limited. The vast majority of publications are devoted to transformations in the coordination sphere of transition metal complexes and electrocatalysis. Therefore, development of new electrochemical approaches to the synthesis of organometallic compounds and conduction of reactions involving them remains to be quite a topical task. In this review, we attempted to demonstrate the extensive potential of organic electrochemistry and thus facilitate implementation of electrochemical methods in the routine practice of chemists working with organometallic compounds.

Modern methods for the synthesis of peptide – oligonucleotide conjugates[†]

E M Zubin, E A Romanova, T S Oretskaya

Contents

I. Introduction	239
II. Synthesis of peptide – oligonucleotide conjugates in solutions	240
III. Solid-phase synthesis of peptide – oligonucleotide conjugates	254
IV. Conclusion	262

Abstract. The published data on the methods of chemical solution and solid-phase synthesis of peptide – oligonucleotide conjugates are reviewed. The known methods are systematised and their advantages and disadvantages are considered. The approaches to the solution synthesis of peptide – oligonucleotide conjugates are systematised according to the type of chemical bonds between the fragments, whereas those to the solid-phase synthesis are classified according to the procedure used for the preparation of conjugates, *viz.*, stepwise elongation of oligonucleotide and peptide chains on the same polymeric support or solid-phase condensation of two presynthesised fragments. The bibliography includes 141 references.

I. Introduction

Complexes of nucleic acids with proteins play an important role in the storage and transmission of genetic information. These supramolecular structures include ribosomes, chromatin, viruses and complexes of nucleic acids with enzymes and regulatory proteins. It is of note that these structures maintain their stability by virtue of protein – nucleic acid (NA) non-covalent interactions.

Protein – NA complexes the components of which are linked by covalent bonds have been known since long ago^{1–3} and became the subject for detailed investigations aimed at elucidation of their chemical structures and functions in the cell. The most convenient tools for the study of such complexes are model peptide – nucleotide conjugates.

The first peptide – oligonucleotide conjugates with phosphoramidate, phosphodiester, amide and ester bonds between the fragments were synthesised by researchers at the Department of Chemistry of M V Lomonosov Moscow State University led by M A Prokof'ev and Z A Shabarova.^{3,4} In the late 1960's – early 1970's, these scientists performed the synthesis of the first oligo-

nucleotide peptides, *viz.*, mixed biopolymers containing oligonucleotide and peptide fragments.^{5,6} However, at that time these studies were not extended further, primarily because of the lack of clearcut definitions of molecular-biological tasks which might be solved through the use of peptide – oligonucleotide conjugates.

The situation changed dramatically in the mid-1980's when it was first suggested to improve the intracellular transport of antisense oligonucleotides through their covalent attachment to various peptides able to penetrate the cell membrane. Noteworthy, the interest in peptide – oligonucleotide conjugates arose simultaneously with notable improvement of existing techniques for the formation of peptide and internucleotide bonds and the development of the solid-phase methodologies which eventually led to complete automation of oligonucleotide and peptide synthesis.

A vast number of papers on peptide – oligonucleotide conjugates published in the last 10–15 years brought forth the necessity to systematise the existing techniques of their synthesis. Previous studies on the synthesis of peptide – oligonucleotide conjugates were briefly described in the reviews^{7–10} published in the early 1990's and devoted to a broader field, *viz.*, the synthesis of oligonucleotide derivatives.

The present review includes two main sections describing the synthesis of peptide – oligonucleotide conjugates in solution and on insoluble solid supports. The methods for the preparation of oligonucleotide conjugates with amino acids and proteins fell outside the scope of the review, since each of these groups of methods is a subject for independent reviews.

In considering the methods for the synthesis of peptide – oligonucleotide conjugates in solution, the main criterion for the systematisation of the published data was the type of the chemical bond between the two components of the conjugate molecule, while the procedure for the preparation of conjugates (stepwise elongation of oligonucleotide and peptide chains on the same polymeric support or solid-phase condensation of two presynthesised fragments) was used as a criterion of choice in the analysis of solid-phase methods.

Here we do not touch upon the problems relevant to the structures of the intermediate and target compounds, for in the absolute majority of studies correct analysis has been carried out and the most advanced physicochemical approaches, particularly, standard procedures for the isolation of oligonucleotides and

[†]This review is dedicated to the memory of M A Prokof'ev and Z A Shabarova, Professors of M V Lomonosov Moscow State University and outstanding pedagogues and scientists who have laid the groundwork for the synthesis of compounds considered.

peptide–oligonucleotide conjugates have been employed. Nor did we consider the prospects of the application of peptide–oligonucleotide conjugates in antisense biotechnology, because these problems were analysed in the reviews published by Gait *et al.*¹¹ and Tung and Stein¹² in 2000. The latter publication describes the preparation of peptide–oligonucleotide conjugates, albeit in a very concise form, without going into details about the chemical reactions involved in the synthesis of hybrid molecules.

Such a limitation of the range of problems under consideration has made it possible to focus the main attention on the description of various approaches to the synthesis of peptide–oligonucleotide conjugates and the formation of covalent bonds between the oligonucleotide and peptide fragments of the conjugates and to perform a detailed analysis of the problems involved.

The principles underlying the classification and nomenclature of peptide–oligonucleotide conjugates have not been finally established yet. There exist several types of naming for the peptide–oligonucleotide conjugates. Some authors propose to consider these compounds as peptide derivatives containing an oligonucleotide substituent in the side chain. Based on this principle, it was proposed to term compounds comprising amino acid (peptide) and nucleoside (nucleotide) residues as ‘nucleo-amino acids’ and ‘nucleopeptides’.¹³ In the abbreviated form, the name of the oligonucleotide is indicated in parentheses immediately after the symbol designating the corresponding amino acid, *e.g.*, H-Ala-Ser(pATAT)-Ala-OH. This approach is often used for compilation of names of conjugates where the peptide components are linked to oligonucleotides through a phosphodiester bond formed by the OH group of the hydroxy amino acid residue and the terminal phosphate of the oligonucleotide.

An alternative approach to the nomenclature of this class of mixed biopolymers was suggested by Z A Shabarova.⁴ All compounds containing amino acid (peptide) and nucleotide (oligonucleotide) fragments were termed as peptide–nucleotide conjugates. The name of a concrete compound is made up of two components, *viz.*, the name of a nucleotide residue and the name of an amino acid (peptide). Between these names, the designation of the type of the linkage is placed in parentheses. Thus a compound in which the phenylalanine residue is linked to uridine 5'-phosphate by a phosphoramidate bond will be termed as uridyl-(5'→N)-phenylalanine. Such nomenclature has been extensively used to describe peptide–nucleotide conjugates with a phosphodiester or a phosphoramidate bond between the fragments.

The main difficulties arise in the compilation of names for those conjugates where the oligonucleotide and peptide components are connected through a special linker possessing a complex structure. In this case, the conjugate actually consists of three components. The authors of the overwhelming majority of publications prefer to give more general names to such compounds. In foreign literature, it is the term ‘peptide–oligonucleotide conjugates’ (‘hybrids’) that has become especially popular.

II. Synthesis of peptide–oligonucleotide conjugates in solutions

1. Conjugates with phosphodiester bonds between the fragments

Studies of covalent complexes isolated from adenoviruses, polyoviruses and certain bacteriophages^{2,3} have demonstrated that the protein component of these compounds is linked to the nucleic acid through a phosphodiester bond formed by the OH group of the hydroxy amino acid and the 5'-terminal phosphate group of the polynucleotide.

X = $-\text{CH}_2-$, $-\text{CH}_2\text{CH}_2-$, $-\text{CH}(\text{CH}_3)-$, $-\text{CH}_2\text{C}_6\text{H}_4-$;

R, a polynucleotide chain;

B, hereinafter, a heterocyclic base.

It has been found that topoisomerase I-induced transformations of DNA involve the formation of a DNA–protein structure in which the protein is covalently bound to the cleavage site of a double helix chain through a tyrosine residue.¹⁴

In order to simplify the analysis of complex NA–protein structures, it seems expedient to use model compounds, *e.g.*, peptide–oligonucleotide conjugates of the phosphodiester type. In this context, the main attention is given to the development of efficient procedures for the synthesis of these compounds. Thus van Boom *et al.*¹⁵ have proposed to this end phosphorylation of the hydroxy group of a peptide by the 5'-phosphate group of an oligonucleotide. Partially protected dinucleoside phosphate **1** and the N-blocked dipeptide amide, Nps-Ala-Tyr-NH₂ (**2**) (Scheme 1), were used as the key compounds.¹⁵ An alternative

approach to the synthesis of peptide–oligonucleotide conjugates of the phosphodiester type is based on the reaction of an *O*-phosphorylated peptide and an oligonucleotide with a free 5'-hydroxy group.

In both cases, the investigators had to solve at least two problems, *viz.*, to choose an optimum method for the activation of the phosphate residue and to search for adequate procedures for the protection of all functional groups of the peptide and the oligonucleotide which are not to be phosphorylated or involved in the condensation. It is of note that the removal of the protective group should be carried out under mild conditions to prevent side reactions.

2-Chlorophenyl bis(benzotriazolido) phosphate in pyridine was used for the phosphorylation and simultaneous activation of dinucleoside phosphate **1**. The dipeptide **2** was added to the activated derivative formed in the presence of *N*-methylimidazole to give a fully protected peptide–oligonucleotide conjugate **3** in 80% yield. The latter was isolated by column chromatography on silica gel. Of extreme importance is the fact that the condensation of the oligonucleotide and peptide components leads to the formation of a phosphotriester bond between them. In an alternative procedure for the synthesis of compound **3**, the hydroxy group of the tyrosine constituent of the peptide is phosphorylated by the bifunctional phosphorylating reagent after which dinucleoside phosphate **1** is added to the reaction mixture. The yield of the peptide–oligonucleotide conjugate **3** prepared by this method was 78%.

Deprotection of the functional groups in compound **3** giving the targeted product **4** was carried out using the following reaction sequence.¹⁵ First, both 2-chlorophenyl phosphate-protective groups were removed by treatment with the oximate ion. The main difficulty in this deprotection is connected with the presence of an additional aryloxy group in one of the phosphotriesters formed through the tyrosine side chain. Since in this case the pK_a values of the leaving groups are close to that of the remaining aryloxy group, the possibility of selective scission of the 2-chlorophenyl group under the action of *syn*-4-nitrobenzaloxime and N^1,N^1,N^3,N^3 -tetramethylguanidine was problematic.

In order to examine the possibility of selective removal of the 2-chlorophenyl protective group, the authors performed the synthesis of a model compound **5**.

The reaction products formed upon its deprotection did not contain dipeptide **2**. The structure of H-Ala-Tyr(pU)NH₂ was confirmed by ³¹P NMR spectroscopy. Thus, it was concluded that the 2-chlorophenyl phosphate-protective group could be selectively removed with *syn*-4-nitrobenzaloxime and N^1,N^1,N^3,N^3 -tetramethylguanidine.¹⁵

The removal of the 3'-*O*-acetyl group from compound **3** was effected by treatment with triethylamine in aqueous methanol. The 2-nitrophenylsulfenyl (Nps) and the 2'-*O*-tetrahydropyranyl (THP) groups were cleaved at room temperature by treatment with hydrogen chloride in methanol for 3 h and with aqueous HCl (pH 2) for 14 h.

The study by the same group of Dutch investigators¹⁶ is considered to be a logical continuation of their previous work.¹⁵ An attempt was undertaken to develop a reliable procedure for the preparation of peptide–oligonucleotide conjugates of the phosphodiester type with the DNA fragment linked to the peptide through a serine or a threonine residue. As a matter of fact, the problem in the synthesis of such peptide–oligonucleotide con-

jugates is associated with the high lability of the phosphodiester bond. This circumstance significantly complicates the deprotection and restricts the range of the reagents used.

The analysis of published data^{3,4} prompts a conclusion that the stabilities of the phosphodiester bonds in oligonucleotidyl-(5'→O)–peptides depend on the nature of the hydroxy amino acid due to the difference in the mechanisms of cleavage of the phosphodiester bonds. If the tyrosine residue is involved, the bond is stable in moderately acidic and alkaline media, but is cleaved under strongly alkaline conditions in exactly the same way as in ordinary phosphoric acid diesters. If the phosphodiester bond involves a serine or a threonine residue, this undergoes β-elimination in alkaline media with the liberation of a phosphomonoester group, *i.e.*, of an oligonucleotide containing 5'-terminal phosphate. In the case of serine, the peptide fragment formed as a result of this reaction contains a dehydroalanine residue (Scheme 2).

Scheme 2

$R^1 = \text{H, Me; } R^2, \text{ polynucleotide chain.}$

The hydrolytic stabilities of serine and threonine derivatives are different,³ the latter being more resistant to alkaline treatment.

The conjugates **6a,b**

$R = \text{H (a), Me (b)}$

were prepared¹⁶ using a procedure similar to that described above. *S*-*p*-Tolyl bis(benzotriazolido) phosphothioate (**7**) was used as a phosphorylating reagent, since the *p*-tolylsulfenyl group (Mps) is split off under mild conditions.¹⁶

The yield of compound **6a** was 80%. Compound **6b** was prepared in a relatively low yield (50%), which can be attributed to low solubility of the dipeptide Nps-Ala-Thr-NH₂ in a dioxane–pyridine mixture.

Removal of the Mps group from the completely protected peptide–oligonucleotide conjugate **6a** was performed by treatment with an excess of silver acetate in aqueous pyridine. The splitting of the Mps group was completed in 48 h at room temperature. However, the deprotection of the internucleotide phosphate by the oximate ion led to the cleavage of the phosphodiester bond between the components of the hybrid molecule **6a** by the β -elimination mechanism (^{31}P NMR spectroscopic data). It is of note that the removal of the phosphate-protective groups in compound **6b** using the same reagents did not affect the phosphodiester bond. Tetrabutylammonium fluoride has proved to be a milder reagent for the splitting of the 2-chlorophenyl protective group. The removal of Nps and THP groups was performed with 0.01 M HCl (pH 2) (0–5 °C, 16 h).

The stabilities of the peptide–oligonucleotide conjugates H-Ala-Ser(pTT)-NH₂ and H-Ala-Thr(pTT)-NH₂ in alkaline media have been studied.¹⁶ Studies by ^{31}P NMR spectroscopy have demonstrated that H-Ala-Ser(pTT)-NH₂ was completely hydrolysed by 0.15 M NaOH (20 °C, 25 min) to form the dinucleotide pTT, whereas no complete hydrolysis of H-AlaThr(pTT)-NH₂ occurred after 9 h treatment with alkali under identical conditions.

In further studies, the same group of investigators used this approach to obtain conjugates with a heterooligonucleotide component.^{17, 18} The problem arising in such a synthesis relates to the necessity of protection of exocyclic amino groups of the heterocyclic bases. The authors had to abandon the use of acyl protective groups employed in routine oligonucleotide syntheses, because their removal by treatment with concentrated ammonia leads to the cleavage of the phosphodiester bond between the oligonucleotide and the peptide formed with the involvement of the hydroxy group of serine or threonine. This could result in the base-catalysed racemisation of amino acid residues. Therefore,

the recourse to the protective groups commonly employed in peptide synthesis was made in the synthesis of peptide–oligonucleotide conjugates.

Van Boom *et al.*¹⁵ have protected the NH₂ groups of adenine and cytosine with the Nps group. The latter is relatively easily introduced, is stable under conditions of phosphorylation and increases the stability of N-glycosidic bond of purine nucleosides in acid media. However, an attempt to synthesise *N*²-nitrophenylsulfenyldeoxyguanosine failed.¹⁸ Therefore, advantage was taken of *N,N*-di-*n*-butylformamidine protection (N=CHNBu₂, DNB) of the exocyclic NH₂ group of guanine, which withstands column chromatography on silica gel and can be removed by mild treatment with hydrazine. It should be noted that it was exclusively amides of *N*-protected peptides that have been used as starting components for the synthesis of peptide–oligonucleotide conjugates in early studies,^{15, 16} while later Dutch investigators used peptides with terminal carboxy groups protected as allyl (All)¹⁷ or anthraquinon-2-ylmethyl (Maa) esters.¹⁸

The approaches to the synthesis of the peptide–oligonucleotide conjugates H-Phe-Tyr(pATAT)-NH₂, H-Phe-Tyr(pGC)-NH₂ and H-Phe-Ser(pGC)-Ala-OH (see Refs 17, 18) are, on the whole, similar to those proposed in earlier studies,^{15, 16} but the procedures used for the deprotection of the intermediate fully protected peptide–oligonucleotide conjugates **8**–**10** have been modified: Nps-protection was cleaved with 2-mercapto-pyridine, while 3'-levulinoyl (Lev) and DNB protections were removed by hydrazine hydrate.

The phosphotriester method has initially been used to prepare H-Ala-Ser(pATAT)-Ala-OAll.¹⁷ The yield of the fully blocked peptide–oligonucleotide conjugate was 64%. The removal of protective groups was carried out by the same method as that used for compound **8**. An alternative approach consisting of phosphorylation of the tripeptide Nps-Ala-Ser-Ala-OAll by 2-chlorophenyl bis(benzotriazolido) phosphate and subsequent reaction of the activated tripeptide derivative with the partially protected tetramer ATAT was inefficient. The phosphorylation of the hydroxy group of serine led to the formation of the undesired symmetrical product.

These difficulties were successfully overcome through the use of the phosphoramidite method.¹⁷

The tripeptide **11** was first treated with equimolar amounts of 1*H*-tetrazole and the phosphitylating reagent **12** in acetonitrile after which equimolar amounts of the tetramer **14** and 1*H*-tetrazole were added to the phosphite **13** formed. The duration of the reaction was 18 h. The phosphite unit in the resulting conjugate was oxidised to the phosphate by treatment with *tert*-butyl hydroperoxide.

The notable advantage of this method is the use of the allyl protective group in the phosphotriester bridge between the tripeptide and the oligonucleotide in the completely protected peptide–oligonucleotide conjugate **15**, which is easily removed with aqueous pyridine. The only disadvantage of the phosphotriester and phosphite versions of H-Ala-Ser(pATAT)-Ala-OAll synthesis is that the carboxy group of the C-terminal amino acid could not be recovered by transition metal complexes.

Of special interest are the studies by Japanese investigators^{19,20} who have developed an original procedure for the preparation of peptide–oligonucleotide conjugates of the phosphodiester type, *viz.*, H-Ala-Tyr(pUU)-OH (**16**) and H-Ala-Ser(pTT)-Phe-OH (**17**) based on the chemistry of phosphothioates.

Synthesis of the phosphorylated dipeptide component **18** was carried out using the Boc-strategy (Scheme 3).¹⁹

In the first step, the partially protected tyrosine derivative **19** was phosphorylated by *S,S*-diphenyl phosphodithioate (PSS) in the presence of isoduroldisulfonyl chloride (DDS). *N*-protected alanine was added to the phosphorylated tyrosine derivative **20** after deprotection of the amino group. *N,N'*-Dicyclohexylcarbodiimide and 1-hydroxybenzotriazole were used as the condensation reagent in the formation of the peptide bond. Selective splitting of one phenylthio group in the derivative **21** was achieved by treatment with triethylammonium hypophosphate in pyridine.¹⁹

The phosphorylated tripeptide **22** was prepared in a similar way.²⁰ In this case, the hydroxy group of serine was phosphorylated by *S,S*-bis(*p*-methoxyphenyl) phosphodithioate (MPSS).

Scheme 3

However, treatment of compound **22** with a solution of triethylammonium hypophosphate in pyridine yielded MPSS rather than compound **23**.²⁰ Presumably, this was due to β -elimination of phosphodithioate. Therefore, selective removal of one *p*-methoxyphenylthio group was achieved by milder treatment with bis(tributyltin) oxide which afforded compound **24**.

The syntheses of partly protected dinucleotide components **25** and **26** (Schemes 4 and 5) made use of PSS and DDS as bifunctional condensation reagents. The uracil and thymine N^3 -TcBoc protective group can be removed by reduction with zinc in acetylacetone under neutral conditions.

In the synthesis of the target peptide–oligonucleotide conjugate **16**, compounds **18** and **25** were introduced into the reaction with DDS and 3-nitro-1,2,4-triazole (Scheme 4). The fully protected peptide–oligonucleotide conjugate **27** was obtained in 73% yield.¹⁹

The use of the same reagents in the synthesis of the peptide–oligonucleotide conjugate **17** (Scheme 5) results in the formation of both the target compound **17** and the tripeptide containing a dehydroalanine residue. Therefore, the reaction was carried out in the presence of *N*-methylimidazole and an excess of triisopropylbenzenesulfonyl chloride (TPSCI).²⁰ Successive deprotection of compounds **27** and **28** afforded the conjugates **16** and **17**, respectively. The phosphate groups were deprotected with an excess of $(\text{Bu}_3\text{Sn})_2\text{O}$. The TcBoc, Phac and TcEoc groups were cleaved by reduction with zinc in acetylacetone. The 2'-*O*-tetrahydropyranyl groups were removed from compound **27** using a standard procedure (0.01 M HCl, pH 2).

Scheme 4

Scheme 5

2. Conjugates with phosphoramidate bonds between the fragments

From the historical point of view, mixed biopolymers with the phosphoramidate bonds between the oligonucleotide and the peptide fragments were the first to be synthesised. The possibility of modification of the internucleotide phosphate group was demonstrated by Prokof'ev, Shabarova *et al.*^{5,21} in the example of dinucleoside phosphates (Scheme 6).

Scheme 6

(a) $(\text{PhO})_2\text{P}(\text{O})\text{Cl}$; (b) H-Ala-Phe-OH .

Treatment of dinucleoside phosphate **29** containing protected hydroxy groups with diphenylphosphochloridate yielded the corresponding non-symmetrical pyrophosphate **30**. The latter represented an active phosphorylating reagent. Reaction of pyrophosphate **30** with the dipeptide H-Ala-Phe-OH is accompanied by nucleophilic substitution at the internucleotide phosphorus atom; the role of the leaving group is played by the diphenyl phosphate anion. The advantages of this method are as follows: (i) the synthesis of pyrophosphate does not affect heterocyclic base residues; (ii) pyrophosphate can be introduced into a reaction with the nucleophile without preliminary isolation. The yield of the target product **31** was 75%. However, this method⁵ gave satisfactory results only in the case of deoxyribo derivatives; in the presence of a protected 2'-hydroxy group, the degree of conversion was only 10%.

An alternative approach to the synthesis of peptide–oligonucleotide conjugates of the phosphoramidate type was developed by a group of Novosibirsk investigators.^{22–25} The α -amino group of the peptide reacts with preactivated 3'- or 5'-terminal phosphate of the oligonucleotide. The advantage of this approach is the possibility to use non-protected fragments of nucleic acids. This, in turn, is due to the fact that the phosphate residue is selectively activated with a mixture of triphenylphosphine and 2,2'-dipyridyl disulfide in the presence of the nucleophilic catalyst *N*-methylimidazole (Scheme 7). Under these conditions, the internucleotide phosphate groups and the reactive centres of heterocyclic bases are not involved. The mechanism of this activation of phosphoric acid monoesters is considered in detail in the review by Zarytova.²⁶

In the study,^{22,23} the 5'-terminal phosphate group was activated in a mixture of dimethylformamide and dimethyl sulfoxide. The oligonucleotides were solubilised in organic solvents as cetyltrimethylammonium (cetavlon) salts. The activation of the phosphate residues of the oligonucleotide gives rise to *N*-methylimidazolide which reacts with the amines with $\text{p}K_a$ values in a very

Scheme 7

$\text{X} = \text{OMe}, \text{NH}_2$.

broad range; with an increase in pK_a , the rate of the phosphoramidate bond formation increases. The guanidine group of arginine in the peptides H-Pro-Arg-Val-OMe and H-(Leu-Arg) $_n$ -Gly-NH $_2$ ($n = 2-4$) is basic. In order to prevent the reaction of the latter with the activated phosphate group of the oligonucleotide, the peptides were introduced into the reaction in the form of trifluoroacetate salts. Under these conditions, the guanidine group remains protonated throughout the reaction and the role of the main nucleophilic centre after selective deprotonation by triethylamine is played by the α -amino group of the peptide.

The presence of a P–N bond in the peptide–oligonucleotide conjugates formed was confirmed by ^{31}P NMR spectroscopy and acid hydrolysis under conditions of cleavage of the phosphoramidate bond (0.1 M HCl, 18 h). The target peptide–oligonucleotide conjugates were isolated by reversed-phase HPLC in 70%–85% yields. It was noted²³ that the addition of the peptide to the oligonucleotide increases the hydrophobicity of the latter. In the reversed-phase HPLC, the retention time of the reaction product increases in comparison with that of the original oligonucleotide.

The method described above was used for the conjugation of a synthetic analogue of the peptide antibiotic netropsin with oligothymidylic and oligodeoxyadenylic acids.²⁴ In this case, the peptide was attached to the 3'-end of the oligonucleotide. The yields of the conjugates **32** were 30%–50%.

32 $n = 2-5$; R, fragment of the oligonucleotide chain.

A somewhat different approach was proposed for the synthesis of covalent complexes of non-modified oligonucleotides and their thiophosphate analogues with netropsin (Nt) or yet another peptide antibiotic, *viz.*, distamycin (Dst).²⁵

Automated phosphoramidite oligodeoxyribonucleotide synthesis was used to prepare oligonucleotides bearing, at their 3'- or 5'-ends, hexaethylene glycol linkers with phosphate groups. This was followed by the activation of the terminal phosphate groups by redox reagents of the types Ph_3P and Py_2S_2 in the presence of 4-dimethylaminopyridine (DMAP), after which a peptide antibiotic (Nt or Dst) was added to the activated oligonucleotide together with an excess of DMAP. The latter is thought²⁵ to be necessary for neutralisation of the positive charges of the amidine and guanidine groups.

R, fragment of the oligonucleotide chain.

Presumably,²⁵ a covalent P–N bond formed between the antibiotic and the NA fragment involves the amidine group of the antibiotic. Indirect evidence can be derived from the fact that the rates of hydrolysis of oligonucleotide netropsin and acetamidine derivatives under the action of concentrated aqueous ammonia are identical. Apparently, the hydrolysis is accompanied by deamination:

R¹, fragment of the oligonucleotide chain, R², residue of the antibiotic.

A group of investigators representing the Moscow research team led by Z A Shabarova²⁷ have developed a method for the carbodiimide-induced activation of terminal phosphate groups of oligonucleotides by *N*-hydroxybenzotriazole (HOBT). HOBT esters are rather stable in aqueous media and can effectively phosphorylate nucleophilic reagents with the formation of covalent bonds (Scheme 8). Amino acids and peptides can be used as nucleophilic reagents.

Scheme 8

This was applied to the synthesis of the Gly-Gly-(5'→N)-(pTCTAG) conjugate²⁸ and to the synthesis of oligodeoxyribonucleotides with the antibiotic polymyxin B1, which represents a polycationic peptide attached to the 5'-terminal phosphate group.²⁹ The yields of the product reached 80%. An undecanucleotide conjugate has been designed and successfully prepared with 3'-terminal phosphate attached to the antibiotic daunomycin and the 5'-terminal phosphate attached to polymyxin B1, the latter serving to facilitate the penetration of the oligonucleotide through the cell membrane. This conjugate was isolated by polyacrylamide gel electrophoresis (PAGE); its total yield was 20%.

The extension of these methods²⁷⁻²⁹ to RNA derivatives was a logical continuation of the studies.³⁰ Conditions for effective synthesis of HOBT esters of 5'-oligoribonucleotides were selected. The formation of a specific complex of this duplex with the peptide Tat was demonstrated in the example of a synthetic RNA complex possessing a binding site for the protein Tat HIV-1. The covalent coupling of the activated RNA duplex to the peptide proceeded with 20%–30% efficiency and did not require any additional activation. Thus, the peptide Tat–TAR RNA complex is an example of effective covalent coupling of a protein to RNA within a specific complex.

Synthesis of a conjugate of a triplex-forming oligonucleotide with a functionally important peptide has recently been described. Such a conjugate is a convenient tool for the study of modulation of gene expression.^{31, 32}

3. Conjugates with amide bonds between the fragments

The studies^{33–40} are devoted to the synthesis of peptide–oligonucleotide conjugates with the amide bond between the fragments formed as a result of the reaction of the activated α -carboxy group of the peptide with the aliphatic NH_2 group incorporated into the oligonucleotide.

The aliphatic amino group is usually attached to the 5'- or the 3'-end of the oligonucleotide through a polymethylene spacer in the course of automated phosphoramidite synthesis. Commercially available 6-aminoethyl 2-cyanoethyl *N,N*-diisopropylphosphoramidite, the amino group of which is protected by the 4-monomethoxytrityl (MMTr) group, a convenient reagent for the preparation of DNA fragments with 5'-terminal NH_2 groups.

The synthesis of oligonucleotides containing a 3'-aminoalkyl group is carried out with the use of a special UV-cleavable polymeric support with a photolabile anchor containing a terminal aminohexanol group (Scheme 9). The attachment of the first nucleotide is performed in an automated DNA synthesiser, whereas the splitting of the oligonucleotide with the 3'-terminal amino group incorporated is effected by UV irradiation.⁴¹ The main advantage of this method is that the presence of a photolabile anchor group facilitates the synthesis of protected oligonucleotides with only the aliphatic amino group free.

Such a partially protected oligonucleotide was introduced into a condensation with one of the two *N*-blocked tripeptides, viz., Fmoc-Gly-Gly-Gly-OH (Fmoc is 9-fluorenylmethoxycarbonyl), or Fmoc-Gly-Gly-His-OH (see Scheme 9). The activation of the carboxy groups in the tripeptides was carried out by a $\text{Ph}_3\text{P}-\text{Py}_2\text{S}_2$ system in the presence of DMAP. The reaction was carried out in dimethylformamide at room temperature because of the possibility of cleavage of the Fmoc group and concomitant oligomerisation of the tripeptide under more drastic conditions. The yield of the peptide–oligonucleotide conjugates after deprotection and isolation by ion-exchange HPLC or PAAG electrophoresis was 89%–99%.

The condensation of short peptides and oligonucleotides using redox reagents was shown⁴² to be accompanied by epimerisation of the C-terminal amino acid residue. Model experiments showed

that the degree of epimerisation reached 30% under these conditions (^1H NMR spectroscopic data).

An attempt has been made³⁴ to prepare peptide–oligonucleotide conjugates with long peptide chains. In order to activate the terminal carboxy group of the peptide, the authors used (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP).³⁴ However, mass spectrometric analysis performed after deprotection of the peptide–oligonucleotide **33** formed and isolation of the target product revealed that its peptide component contains only two amino acid residues (compound **34**).

It is suggested³⁴ that the cleavage of the peptide component at the amide bond between the serine and glycine residues was due to $\text{N} \rightarrow \text{O}$ acyl migration. Apparently, the free OH group of serine liberated upon treatment with ammonia attacks the amide bond between the serine and glycine residues, which is followed by the scission of the peptide chain due to hydrolysis of the ester bonds. The use of milder procedures for the removal of protective groups (0.4 M NaOH in methanol, 17 h) did not give any positive results either. This problem could be overcome by replacing the glycine residue by the alanine residue in order to create steric hindrances in the site of possible nucleophilic attack. Some other changes necessary for further formation of a stable helical complex between the peptide–oligonucleotide conjugate and the complementary NA target were also effected, viz., the α -amino group of the peptide was protected by the acetyl group and an additional tetraethylene glycol bridge was introduced between the 3'-terminal nucleotide and the alkylamine in order to separate the peptide fragment from the DNA chain. In this case, the yield of the conjugate **35** was 72%.

Scheme 9

GPG, controlled pore glass;

DMTr, 4,4'-dimethoxytrityl protective group; PyBOP, (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate.

The peptide–oligonucleotide 3',5'-bisconjugates **36** were successfully obtained using the polymeric support mentioned above in the first step. The peptide–oligonucleotide 3'-conjugates were synthesised according to Scheme 9 after which the 5'-terminal HO group was made to react with commercially available 6-aminoethyl 2-cyanoethyl *N,N'*-diisopropylphosphoramidite to which another peptide was then attached.³⁵

R¹, R², peptide residues.

The use of protected oligonucleotides with 3'-terminal carboxy groups for the synthesis of peptide–oligonucleotide conjugates was a natural continuation of these studies.³⁶ A UV-cleavable polymeric support was also employed.

The covalent bond between the 3'-end of the oligonucleotide and the N-end of the peptide is easily formed even in the case of spatial hindrance created by the N-terminal amino acid. Excellent results were obtained in the coupling of tetrapeptides; the conjugates were obtained in 89%–95% yields.

Special mention should also be made of a synthesis of a series of peptide conjugates by coupling them to non-protected oligonucleotides T₆ and T₁₀ containing 5'-terminal NH₂ groups using PyBOP as the condensation reagent.³⁷

Synthesis of covalent oligonucleotide complexes with a synthetic analogue of the peptide antibiotic CC-1065 has been described.³⁸

R¹, oligonucleotide chain, R² = CONH₂, Boc.

This method includes condensation of 2,3,5,6-tetrafluorophenyl ester of a peptide and a deprotected oligonucleotide bearing a 5'- or 3'-terminal amino group. The reaction is carried out in dimethyl sulfoxide. No detailed description of the synthesis of the DNA fragments containing a 5'- or 3'-terminal aminohexyl residue is provided. The oligonucleotides were introduced into the reaction as cetavlon salts. The yields of the condensation products were 60%–90% (HPLC data). It is noted that precipitation of the reaction products by the addition of a 2% solution of LiClO₄ in acetone and their further isolation by reversed-phase HPLC decreases the total yield to 15%–50%.

An interesting approach to the synthesis of peptide–oligonucleotide conjugates containing an amide bond was proposed by Swiss investigators.³⁹ Their method is based on the Wolff rearrangement. Diazo ketone **37** was used as a peptide component, and an oligothymidylate, as an oligonucleotide. The reaction was carried out in dimethylformamide. The diazo ketone **37** is decomposed upon UV irradiation with abstraction of the nitrogen molecule to give carbene **38** which undergoes the Wolff rearrangement to be further converted into ketene **39** (Scheme 10). The latter reacts with oligothymidylate **40** containing a 5'-terminal amino group. The yield of the peptide–oligonucleotide conjugate

Scheme 10

Z = PhCH₂OCO.

41 is 35%. The attempts to introduce diazo ketone **37** into the reaction with heteropolymeric DNA molecules were unsuccessful. The authors attribute this phenomenon to the poor solubilities of the heteropolymers in dimethylformamide. The presence in the reaction mixture of water molecules competing with oligonucleotides for the reaction with ketenes is an alternative explanation for the low yields.

The approaches discussed above to the synthesis of oligonucleotide peptides largely entail the use of reactions occurring in organic solvents. An original procedure for the formation of covalent bonds between peptides and oligonucleotides in aqueous solutions based on the chemical ligation method has been developed.⁴⁰ This consists in approaching the reacting groups in the terminal fragments of the oligonucleotides *I* and *II* as a result of complementary interactions of these oligonucleotides with the complementary adjacent sites of the oligonucleotide *III* (Scheme 11).

Scheme 11

The peptides used in the study⁴⁰ were prepared in the form of carboxythionic acids by solid-phase synthesis on a polymeric support. Treatment of these peptides with Ellman's reagent [5,5'-dithiobis(2-nitrobenzoic acid)] gave the carboxythionic acid *S*-ester. The latter reacted with an oligonucleotide containing a 2'-*O*-methyl-5'-deoxy-5'-thiouridine to give the oligonucleotide peptide **42** with the thioester bond (Scheme 12). The reaction was carried out for 30 min at 25 °C in a buffer solution (pH 8.0) in the presence of spermidine. The product formed **42** is stable at room temperature for 24 h, but is easily hydrolysed at 37 °C over the same period.⁴⁰

Scheme 12

The condensation of the peptide linked to a single-stranded fragment of the oligonucleotide *I* with the oligonucleotide *II* containing 3'-terminal 3'-amino-3'-deoxythymidine within the DNA duplex is the key step in the synthesis of peptide–oligonucleotide conjugates possessing amide bonds (see Scheme 11). A DNA duplex represents a highly ordered system; in its cleavage site, the terminal 3'-amino group of one oligonucleotide and the thioester group of the other peptide are located in close proximity to one another and are spatially oriented in a definite manner owing to the interactions stabilising the double helix. As a consequence, the chemical reaction is characterised by high selectivity and high rate, which are unattainable for this type of conversion occurring outside the helical complex. Under optimum conditions (2–4 mmol of spermidine, pH 8, 37 °C), the condensation was completed in 15–30 h; the peptide–oligonucleotide conjugates were obtained in good yields (60%–85%). Owing to the weakly alkaline medium, the 3'-amino group remained non-protonated, while the presence of spermidine in the reaction mixture favoured additional stabilisation of the DNA duplex.

This approach allows simultaneous synthesis of several peptide–oligonucleotide conjugates possessing different structures. This is possible when an oligonucleotide with a 3'-amino group is involved in the simultaneous formation of two different DNA duplexes as has been demonstrated in the study under discussion.

Peptides of various lengths underwent condensation with oligonucleotides. However, reactions with short peptides encountered serious difficulties because of possible formation of cyclic structures. This is due to the fact that the α -amino group of the peptide, along with the 3'-amino group of the DNA fragment, can attack the carbonyl carbon atom resulting in the formation of a cyclic peptide. Moreover, yet another prerequisite for efficient condensation is that the C-terminal amino acid residue of the peptide did not contain a branched side chain, *i.e.*, its C-end should be devoid of isoleucine or threonine residues.

The use of a non-modified oligonucleotide with a 3'-terminal hydroxy group in the condensation is also noteworthy.⁴⁰ Here, the formation of an ester bond between the peptide and the DNA fragment occurs; the yields of peptide–oligonucleotide conjugates with ester bonds are lower than those with amide bonds. In

contrast to the amide bond, the ester bond is easily hydrolysed in alkaline media (0.01 M NaOH) at 25 °C for 1 h.

A more recent report⁴³ describes selective non-matrix chemical ligation of modified RNA containing the 5'-*S*-thioester group and polypeptides with N-terminal cysteine residues which affords peptide–5'-RNA conjugates (Scheme 13).

Scheme 13

This reaction included transthioesterification and subsequent spontaneous intramolecular rearrangement resulting in the formation of a peptide bond. The authors observed high selectivity of ligation (50% yield of the conjugate of 102-membered RNA with a 13-membered peptide) at low (micromolar) concentrations of the reactants. This reaction proceeds under non-denaturing conditions favouring the preparation of NA–protein conjugates with simultaneous preservation of the native structure of the protein. The synthesis of peptides carrying N-terminal cysteine residues does not present a problem. The 5'-terminal phosphothioate residue can be easily introduced into a ribo- or deoxyribonucleic acid either chemically or enzymatically.

The term 'native ligation' (by analogy with condensation of two unprotected peptide fragments, one of which contains a C-terminal *S*-carboxythioate group and the other one contains an N-terminal cysteine, which is routinely used in peptide chemistry⁴⁴) was used^{45,46} to describe a new procedure for the preparation of peptide–oligonucleotide conjugates **43** (in the absence of a template).

R^1 , fragment of an oligonucleotide chain,
 R^2 , fragment of a peptide chain.

This method is based on the reaction of the peptide **44** modified by the introduction of the *S*-thioester group in its N-end with an oligonucleotide containing a 5'-terminal cysteine residue which is introduced using compound **45**.

R^1, R^2, R^3 , side chains of amino acids.

S-Benzyl thiosuccinate **44** was obtained in the last step of a standard automated peptide synthesis (Fmoc strategy). The *O*-*trans*-4-(*N*^α-Fmoc-*S*-*tert*-butyl-L-cysteiny)aminocyclohexanol phosphoramidite **45** was attached to the 5'-end of the oligonucleotide in the course of a standard solid-phase phosphoramidite synthesis. The preparation of the phosphoramidite synthon **46** based on 4-hydroxypiperidine has also been described.⁴⁶

The peptide **44** and the oligonucleotide modified by compound **45** (or **46**) after deprotection and detachment from the resin were condensed without additional purification in water–organic solvents to which tris(2-carboxyethyl)phosphine (in order to remove the *S*-*tert*-butyl group *in situ*) and thiophenol (in order to increase the efficiency of thiol exchange) were added.

Some reactions between peptides and oligonucleotides of various sequences and lengths have been described and the ways to increase the efficiency of their synthesis have been considered.⁴⁵ The peptide–oligonucleotide conjugate **43** was the main product in all cases; sometimes, its yield reached 75%. The side reaction, *i.e.*, intramolecular cyclisation involving the succinyl fragment of the peptide, took place only with glycine at the N-end. No doubt, further experiments are necessary in order to optimise the composition of the solvent, reaction conditions (particularly, for long-chain peptides with a secondary structure). However, even now it is quite clear that the method in question⁴⁵ can be used for the preparation of oligonucleotide conjugates with a very broad range of peptides with small restrictions for amino acid sequences. This approach has obvious advantages over the method considered above for the synthesis of peptide–RNA conjugates,⁴³ since it allows the use of peptides with thioesters at their C- and N-ends and a 5'-cysteinyl-substituted oligonucleotide prepared by a standard phosphoramidite procedure. The method⁴³ allows the use of exclusively N-terminal cysteine-containing peptides and RNA modified with 5'-phosphothioate.

4. Conjugates with sulfide bonds between the fragments

The optimum variant of peptide–oligonucleotide synthesis seems to be the one in which the reactive group of the oligonucleotide reacts selectively with the reactive group of the peptide, whereas other functional groups of both macromolecules are not involved. For example, the conjugation can be effected by the addition of thiols to maleimides.

R^1, R^2 , an oligonucleotide or a peptide chain fragments.

The sulfhydryl or the maleimide active groups are first introduced into the oligonucleotide or the peptide using various reagents. It should be noted, however, that the role of a reaction centre can be played by the HS group of the cysteine residue initially present in the peptide. It is preferable, as a rule, that the sulfhydryl group is localised in the oligonucleotide, whereas the maleimide group, in the peptide.^{47–58} An alternative variant^{59–63} is that the HS group of the N- or C-terminal cysteine residue reacts with the maleimide group incorporated into the oligonucleotide chain.

In both cases, the reaction is carried out in aqueous or water–organic media (pH 6.0–7.2) at room temperature. The peptide is almost always taken in an excess (from 4 to 15 equiv.); in only one study, the ratio between the two components of the reaction mixture was 1 : 1.⁴⁸ The reaction time varies from 1 to

20 h. The yields of the conjugates vary within a sufficiently broad range, *viz.*, from 30% to 90%.

The formation of a thioether bond between the oligonucleotide and the peptide can also take place as a result of a nucleophilic attack of the HS group at the carbon atom of the halogenoacetyl derivative. For this purpose, the halogenoacetic acid residue is incorporated into oligonucleotides or peptides.^{64–72}

R^1, R^2 , an oligonucleotide or a peptide chain fragments.

As a rule, the oligonucleotide containing an iodoacetyl group reacts with an excess of the cysteine-containing peptide in neutral media at room temperature.^{64–67} The reaction time is 12–20 h. The yields of the conjugates usually vary from 55% to 98%. Reed *et al.*⁶⁸ performed the synthesis in a weakly alkaline medium (pH 8.3). The authors cite interesting results concerning the dependence of the reaction rate on the net charge of the peptide. Thus the reaction of a modified oligonucleotide with a peptide containing one arginine residue and four lysine residues (the net charge is +5) is complete within a few minutes. In the case of the other two peptides with the net charges of +1 and zero, the reaction time is 3 and 20 h, respectively. The authors presume that the increase in the condensation rate is caused by electrostatic interactions of the negatively charged phosphates in the DNA molecule with the positively charged side groups of lysine and arginine of peptides.

The synthesis of peptide–oligonucleotide conjugates in which two DNA fragments are linked through a peptide bridge has been described (Scheme 14)⁶⁴ with H-Cys(SBu^t)-(Arg)_n-Cys-NH₂ ($n = 3, 5, 7$) as a bridge.

R^1, R^2 , fragments of oligonucleotide chains; $n = 3, 5, 7$.

Initially, the free HS-group of the C-terminal cysteine residue reacted with the iodoacetyl group localised at the 5'-end of one oligonucleotide. In order to prevent the removal of the *S*-*tert*-butyl group, it was necessary to carry out the reaction in a neutral medium. After termination and chromatographic isolation of the peptide–oligonucleotide conjugate, the second thiol group was deprotected by treatment with a large excess of tributylphosphine at room temperature for 4 h. Taking into consideration low solubility of tributylphosphine in water, the removal of the protective group was carried out in a biphasic water–dichloromethane system.

The authors presume that tributylphosphine has a salient advantage over dithiothreitol which is widely used for the reductive cleavage of the S–S bond. On termination of the reaction, the excess of dithiothreitol should be removed, whereas in reactions with tertiary phosphine the separation of the organic phase from

the aqueous phase is sometimes sufficient. It was found that complete cleavage of the *S*-*tert*-butyl group should be carried out first, and only after this has been done, another oligonucleotide containing an iodoacetyl group at its 3'-end is to be added to the reaction mixture. Otherwise, the removal of the *S*-protective group occurs at a slow rate, since iodoacetic acid and its amide can form quaternary phosphonium salts with Bu₃P.

The reaction of the HS group of the N-terminal cysteine residue of the peptide–oligonucleotide conjugate with the electrophilic centre of the second oligonucleotide proceeded in a weakly alkaline medium, which made it possible to increase the yield of the target product. It should be noted also that all the reactions were carried out in a lithium chloride solution.⁶⁴ The reason lies in poor solubility of the peptide–oligonucleotide conjugate in water due to the interactions of the phosphate groups of DNA with positively charged guanidine groups of arginine, which are attenuated by the presence of lithium chloride. At the same time, the oligonucleotide pairs containing a peptide bridge are readily soluble in water because they contain an excessive (with respect to the guanidine groups) amount of negatively charged phosphates.

This approach was also used to prepare the conjugate **47** the two peptide fragments in which were attached to the 3'- and 5'-ends of the oligonucleotide.

In the studies,^{69–72} the bromoacetic acid residue was introduced into the peptide fragment prior to the condensation with an oligonucleotide containing an HS group. The bromoacetyl derivative of the peptide was taken in excess (from 5 to 25 equiv.). The reaction was carried out at room temperature for 5–20 h. The yield of the target product was 70%–100%. The effect of the medium acidity (pH 7.0, 7.5, 7.9 and 8.5) on the completeness of the reaction and the dependence of the reaction rate on temperature have been studied.⁶⁹ It was found that the peptide–oligonucleotide conjugate was formed in quantitative yield in less than 3 h at 40 °C and pH 7.0 and 7.5.

The publication⁷² devoted to the synthesis of the complex fluorescently labelled peptide–oligonucleotide conjugate **48** provides an illustrative example of a successful application of the above-described procedure to the synthesis of peptide–oligonucleotide conjugates. This was preceded by the synthesis of 19–25-membered oligodeoxyribonucleotide phosphothioates containing a 5'-terminal protected thiol group and an amino group at the end of the linker attached to its 3'-end. This bisfunctionalised oligonucleotide was introduced into the reaction with a fluorescein isothiocyanate (FITC) fluorescent label at the 3'-amino group; the thio group was then deprotected and reacted with the *N*-bromoacetyl derivative of the peptide.

Special emphasis is laid on the possibility of performing large-scale synthesis of the conjugate **48**. The success of this synthesis depended on the development of a new procedure for deprotection

of oligonucleotides in which the oligomers were treated with a mixture of dipyridyl disulfide and concentrated ammonia in the presence of phenol and methanol. This deprotecting mixture enables splitting of the oligonucleotide from the polymeric support, liberation of the 3'-terminal amino group, deprotection of the phosphate and amino groups of heterocyclic bases and the conversion of the 5'-terminal thioacetyl protective group into the pyridyl disulfide group. The presence of phenol in the deprotecting mixture makes it possible to avoid the side reaction associated with a large-scale synthesis. Usually, the deprotection of internucleotide phosphates affords an electrophile, *viz.*, acrylonitrile (CH₂=CHCN), which reacts with the nucleophilic sulfur of the (oligonucleotide–linker–SH) system to give the undesirable product oligonucleotide–linker–SCH₂CH₂CN.

The synthesis of peptide–oligonucleotide conjugates based on the reaction of peptidyl chloromethyl ketone with an oligonucleotide containing a 3'-terminal thio group has been described (Scheme 15).⁷³

Scheme 15

The conjugation of the oligonucleotide with the peptide was carried out in a water–organic solution (pH 7.5) at room temperature for 12–16 h. The yield of the target product was 60%.

Activated esters of ϵ -maleimidohexanoic (**49**),^{47, 48} 3-maleimidobenzoic (**50**),^{51, 53, 54, 59, 60} β -maleimidopropionic (**51**)^{55, 56} and 4-maleimidomethylcyclohexanecarboxylic (**52**)^{57, 61–63} acids were used as heterobifunctional reagents for the incorporation of the maleimide group into peptides and oligonucleotides.

R = H, SO₃Na.

In the study,⁴⁸ the α -amino group of the peptide was acylated by the reagent **49** in water at pH 7.0 for the incorporation of the maleimide group into the peptide. This reaction was also carried out in methanol in the presence of triethylamine.⁴⁷ In the majority of cases, the peptide was prepared by solid-phase synthesis; after deprotection, the free α -amino group was acylated by one of the above-mentioned bifunctional reagents in the presence of 1-hydroxybenzotriazole.^{51, 53–56}

Low storage stability of maleimide peptide derivatives containing lysine residues in aqueous media was noted.⁵¹ A complex mixture of reaction products is formed after a period of 3–4 days as a result of the reaction of the ϵ -amino groups of lysine residues with the maleimide group. To prevent side reactions, it is proposed to introduce the modified peptide into the reaction immediately after its detachment from the polymeric support.

It was recommended to incorporate the bromoacetic acid residue into peptides by performing the acylation of the peptide ϵ -group by bromoacetic acid anhydride in the course of the solid-phase synthesis.^{69–71}

The synthesis of maleimide derivatives of oligonucleotides includes two steps, *viz.*, the automated oligonucleotide synthesis followed by modification of the oligomeric chain formed by 6-(4-monomethoxytrityl)aminoethyl 2-cyanoethyl *N,N*-diisopropylphosphoramidite.^{59–62} The aliphatic amino group was introduced into the predetermined position of the DNA fragment using a commercially available 3'-phosphoramidite derivative of the modified nucleoside **53**.⁶³

After splitting of the oligonucleotide from the polymeric support and removal of protective groups, the aliphatic amino group reacted with one of the heterobifunctional reagents **49–52** containing a maleimide group (pH 7–8). The average yields of the oligonucleotide maleimide derivatives are 60%–70%.

The methods for the preparation of oligonucleotides containing iodoacetic acid are similar. The amino group attached to the 3'- or 5'-end of the oligonucleotide through a hexamethylene bridge is acylated by *N*-hydroxysuccinimide ester^{64–66} or iodoacetic anhydride in a water–organic mixture.⁶⁸

5. Conjugates with disulfide bonds between the fragments

To this point, we have dealt with various procedures for the synthesis of conjugates, the oligonucleotide and peptide components of which were linked by stable covalent bonds. However, the development of techniques for the synthesis of peptide–oligonucleotide conjugates with easily cleavable bonds between the fragments is a no less important task. Such a bond can be represented by an S–S bond, which can be formed and cleaved under conditions acceptable for various biological processes.

The synthesis of conjugates with disulfide bonds between their peptide and oligonucleotide fragments can be carried out using three main approaches. First, this is in the oxidation of the HS groups of the oligonucleotide and the peptide with atmospheric oxygen with the formation of a disulfide bridge. In this case, the peptide is taken in an excess, the yield of the conjugate is 60%.⁶¹ However, according to Azhayev *et al.*⁷⁴ the yields of peptide–oligonucleotide conjugates prepared by this method are extremely low (0.4%–23%).

The other two approaches consist of the activation of the HS group of the oligonucleotide or the peptide with 2,2'-dipyridyl disulfide.^{61, 74–81}

R^1, R^2 , oligonucleotide or peptide chain fragments.

The reaction is carried out under mild conditions at room temperature.

Unprotected peptides and oligonucleotides can form non-covalent complexes due to electrostatic interactions of the negatively charged phosphates of DNA with positively charged side groups of the peptides. Such complexes are precipitated from solutions. Having regard to this circumstance, potassium chloride and acetonitrile, which neutralise molecular charges and facilitate their dissolution, are added deliberately to the reaction mixture.⁷⁶ It is also recommended to carry out the synthesis of the conjugates in 90% formamide.⁷⁴

The introduction of the *S*-(3-nitro-2-pyridylsulfenyl)cysteine residue (Cys^{Npys}), which is Boc-protected at the α -amino group, is a distinctive feature of a conjugation method.^{51, 69} It is noteworthy that the Npys-protective group is resistant to acid treatment. After cleavage from the polymeric support and removal of protective groups (with the exception of the Npys group), the peptide formed in the solid-phase synthesis is introduced into the reaction with a DNA fragment containing an HS-group under mild conditions. The reaction of the HS group of the oligonucleotide with the Npys-protected thiol group of the cysteine of the polypeptide yields a conjugate with the S–S bond between the peptide and the oligonucleotide fragments.

It should be noted that the HS group can be introduced into oligonucleotides in several ways. First, it can be attached to the 3'- (see Refs 54 and 56) or 5'-end (see Refs 51, 53, 55) of the DNA fragment using linkers of various lengths. Second, the synthesis of a protected nucleoside 3'-phosphoramidite containing a thiol group can be followed by its introduction into any predetermined position of the oligomeric chain by the automated oligonucleotide synthesis.

Earlier it was mentioned that it is cysteine-containing peptides that are usually coupled to oligonucleotides. However, some methods permit the introduction of HS groups into peptides devoid of the cysteine residues. Thus β -mercaptopropionic acid was attached to the N-terminal amino acid residue in the course of solid-phase peptide synthesis.⁷⁴

6. Synthesis of conjugates using a carbonyl derivative of one of the fragments

Syntheses of conjugates considered below are based on the reaction of carbonyl compounds with nucleophiles. The indisputable advantage of the carbonyl groups is that they do not require additional activation and their reactions proceed with high selectivities.

Dialdehyde derivatives of nucleic acids were extensively used in previous studies, *e.g.*, in the structural elucidation of the monomeric components of RNA and DNA. The methods for the introduction of aldehyde groups into carbohydrate fragments

of nucleic acids and the properties of the thus modified derivatives have recently been reviewed.^{82, 83}

Lebleu *et al.*^{84–89} have performed a successful synthesis of peptide–oligonucleotide conjugates based on dialdehyde oligonucleotide derivatives. After periodate oxidation, the oligonucleotide with a 3'-terminal ribo fragment was subjected to condensation with poly(L-lysine) followed by reduction by sodium cyanoborohydride. The linkage between the peptide and the oligonucleotide fragments was effected through the morpholine ring formed.

A (2'→5')(A)_n-polyribonucleotide prepared by enzymatic synthesis was used as an oligonucleotide with a 3'-terminal ribo fragment;⁸⁴ in the case of oligodeoxyribonucleotide, this was introduced with the help of T4 RNA ligase;⁸⁵ the ribo fragment was the first to be attached to a polymeric support and the oligonucleotide was prepared by the automated synthesis.⁸⁷

The early works of Lebleu *et al.*^{84–87} reported the antisense properties of conjugates of dialdehyde oligonucleotide derivatives with peptides and their possible applications in the study of various biological systems. The results of testing of the complexes for the ability to inhibit replication of HIV-1 were published later (the oligonucleotide fragment of the complex was found to be complementary to the translation initiation centre of the Tat-protein).^{88, 89} Some sequence-specific antiviral effects of these compounds were observed.

In the study,⁹⁰ the electrophilic centres of oligonucleotides were generated enzymatically: the uracil residues were cut off from the oligonucleotide chain using uracil–DNA glycosylase to obtain the apurine/apyrimidine fragments. This was followed by modification of the aldehyde-containing oligonucleotides by various ligands carrying an amino group. In particular, the attachment of tripeptides to such oligonucleotides has been described (Scheme 16).

R¹, R², oligonucleotide chain fragments.

A highly efficient selective procedure for oligonucleotide synthesis involving the formation of oximes and thiazolidines has recently been proposed.⁹¹ In their search for an 'ideal' conjugation

procedure, *i.e.*, the simplest one-step reaction between a free peptide and an oligonucleotide under physiological conditions, the authors made their choice in favour of two novel types of binding groups, *viz.*, the oxime and the thiazolidine groups.

The synthesis of conjugates involving the formation of an oxime (reaction of an aldehyde with an aminooxy derivative) and thiazolidine (reaction of the aldehyde with 1,2-aminothiol) is shown in Scheme 17.

The aldehyde or the aminooxy group were incorporated into the oligonucleotide fragment at the 5'-end, while the peptide contained the corresponding complementary group, *viz.*, the aminooxy- or the 1,2-aminothiol groups for the reaction with the aldehyde-containing oligonucleotide or the α-N-glyoxyloyl group for the reaction with the aminooxy oligonucleotide derivative.

5'-Modified oligonucleotides were prepared by the standard automated synthesis using the corresponding modified 3'-phosphoramidite derivatives in the final step.⁹¹ In turn, the N-terminal position or the side chain of lysine in the peptides was functionalised by introducing the aldehyde or the aminooxy groups by means of oxidative cleavage of the serine residue or using *N*-Boc-*O*-(carboxymethyl)hydroxylamine, respectively. The thiazolidine ring between the peptide and the oligonucleotide is formed in

Scheme 17

R¹, fragment of the peptide chain,
R², fragment of the oligonucleotide chain.

those cases where the original peptide is modified by attachment of cysteine at the N-end or at the side chain of lysine.

Oxime can also be formed in the DNA duplex. In this case, the 5'-aldehyde-containing oligonucleotide is hybridised with the complementary DNA chain and the DNA duplex formed is introduced into the reaction with a peptide carrying the aminoxy group. This strategy opens up fresh opportunities for post-synthetic modifications of single- and double-stranded DNA.

The formation of an oxime bond between the oligonucleotide and the peptide fragments occurs at a high rate and with high selectivity. However, oligonucleotides possessing aminoxy groups are seldom introduced into reactions with peptides carrying aldehyde groups, since such oligonucleotides easily react with any carbonyl groups and are therefore not very convenient. Those peptide-oligonucleotides in which the oligonucleotide and the peptide fragments are linked through the thiazolidine ring are less stable than those containing an oxime bond.

Later, the same authors⁹² reported the synthesis of conjugates using oligonucleotides with 3'-terminal carbonyl groups. The 3'-terminal aldehyde group was generated by mild periodate oxidation of a 1,2-aminoalcohol attached to the 3'-end of the oligonucleotide in the automated synthesis on a standard commercially available polymer. The oligonucleotide thus prepared reacted with a peptide containing an aminoxy group similarly to the 5'-aldehyde-containing oligonucleotide.⁹¹

Simultaneously, another group of investigators⁹³ published a paper devoted to the synthesis of peptide-oligonucleotide conjugates from oligonucleotides containing 5'-terminal aminoxy groups and peptides containing N-terminal lysine groups with the side chains modified by the reaction with levulinic anhydride, *i.e.*, peptides with N-terminal keto groups. In this case, the binding of the oligonucleotide and the peptide fragments occurred due to formation of the oxime bond.

The preparation of conjugates involving the formation of oximes has been described by Dey and Sheppard.⁹⁴ The keto group was introduced into the C(5)-position of the oligonucleotide uracil through a spacer.

III. Solid-phase synthesis of peptide-oligonucleotide conjugates

The performance of chemical reactions on insoluble polymeric supports is one of the main techniques in modern organic synthesis. The idea underlying this method is virtually versatile and applicable to a wide variety of biopolymers and their analogues. In the past few decades, the solid-phase method has become a routine procedure in the synthesis of peptides and oligonucleotides; therefore, investigators give considerable attention to the development of strategies and tactics of chemical synthesis of peptide-oligonucleotide conjugates which is partly or completely performed on a solid phase.

This strategy is based on the construction of amino acid and nucleotide sequences which includes either stepwise elongation of peptide and oligonucleotide chains on the same solid support or

condensation of the two preformed fragments. The second route implies the attachment of a preformed peptide to an oligonucleotide synthesised on a solid phase and immobilised on a polymeric support.

In development of the strategy of chemical synthesis of peptide-oligonucleotide conjugates, special emphasis is laid on the choice of optimum methods for the formation of amide and phosphodiester bonds and a search for the most adequate combinations of protective groups designed for peptides and nucleic acid fragments and conditions for the deprotection (the latter should be selected with due regard to the stability of the target peptide-oligonucleotide conjugates). The choice of method for the formation of a bond between the peptide and the oligonucleotide fragments is also of great importance.

1. Stepwise synthesis of peptide and nucleotide fragments on a single solid support

The synthesis of oligonucleotides and peptides includes a series of repeated operations involving structurally similar monomeric components. The sequential synthesis of the oligonucleotide and the peptide fragments of the hybrid molecule on a single solid support can raise serious problems connected with the impossibility, in principle, of combining some standard procedures inherent in the solid-phase oligonucleotide and peptide syntheses. Therefore, meticulous selection of methods and optimisation of experimental protocols are necessary in order to ensure acceptable yields of target products and to avoid the formation of by-products.

In 1972, M A Prokof'ev, Z A Shabarova *et al.* published a paper of fundamental importance⁶ in which they gave the first description of a solid-phase synthesis of peptide-oligonucleotide conjugates (Scheme 18).

The authors used a classical Merrifield support, which represents a chloromethylated styrene-divinylbenzene (2%) copolymer. The synthesis of the peptide fragment was carried out using Boc-protected amino acids and *N,N'*-dicyclohexylcarbodiimide (DCC) as a condensation reagent. The choice of amino acids was determined so as to avoid complications resulting from the splitting of the target product off the polymer. The first nucleotide was attached to the peptidyl polymer by the so-called pyrophosphate method, which consists in the activation of the phosphate group of the nucleotide owing to the formation of mixed anhydride with diphenyl phosphate. This reaction was carried out in dry DMF in the presence of a tenfold excess of thymidine 5'-phosphate-diphenyl phosphate mixed anhydride (20 °C, 100 h). The elongation of the oligonucleotide chain was carried out by the phosphodiester method. The condensation was performed in dry pyridine in the presence of a five- or a tenfold excess of 3'-*O*-acetylthymidine 5'-phosphate and a fivefold excess of dicyclohexylcarbodiimide with respect to thymidyl-(5'→N)-Phe-Gly-Phe. The deprotection of the 3'-hydroxy group of the nucleotide was carried out in alkaline aqueous dioxane (pH 9). Such a treatment ensured a practically complete removal of acetyl protection without splitting of the dinucleotidyl-(5'→N)-peptide off the polymer.

The final step included hydrolysis of the ester bond between the polymer and the trinucleotidyl-(5'→N)-peptide. The authors encountered serious difficulties because of both steric hindrances and the impossibility of using strong acids, which might result in cleavage of the phosphoramidate bond. The maximum extent of cleavage of the ester bond (10%) is achieved by treating the oligonucleotidyl-(5'→N)-peptide with NaOH in aqueous dioxane.

In its modern modification, this approach combines stepwise synthesis of the peptide from the C-end and subsequent elongation of the oligonucleotide chain on the peptidyl polymer by the phosphoroamidite method (Scheme 19). If the peptide is devoid of hydroxyamino acid residues, the synthesis of the DNA fragment should be preceded by incorporation of a hydroxy group into the peptidyl polymer. For this purpose, the α -amino group is acylated by a bifunctional reagent which contains an activated

Scheme 18

carboxy and a protected hydroxy group. This promotes the insertion of a linker between the N-end of the peptide and the oligonucleotide.

Scheme 19

a. Solid support

The success of a solid-phase synthesis largely depends on the correct choice of solid support. The most popular support is controlled pore glass (CPG).^{95–102} It is common practice to use CPG with a pore diameter of 500 Å. The synthesis of peptide–oligonucleotide conjugates on silica gel (Fractosil) has also been described.¹⁰⁰ However, in a more recent publication¹⁰² the same authors had to admit that the use of CPG was preferable, since this solid support allows the synthesis of the target product in higher yields even at lower specific loading with the first monomeric unit. At the same time, some investigators (see, *e.g.*, Refs 103–105) call into question the expediency of CPG application, since the synthesis of the peptide fragment on this support affords products with shorter chains in addition to the target oligomer. In the authors' opinion,^{53, 103} the formation of short peptide chains can

be avoided through the use of a copolymer of polyethylene glycol with polystyrene (PEG-PS). In a series of publications by Spanish investigators,^{104–113} the use of a copolymer of styrene with 1% divinylbenzene has proved to be especially efficient in peptide synthesis.

b. Introduction of an anchor group

The first amino acid, which is to become a C-terminal residue in the peptide fragment to be synthesised, is attached to the support through the ester bond. In order to effect the esterification reaction between the amino acid and the solid support, the latter should contain reactive groups. Special methods for chemical modification of the support are being developed.

The use of polystyrene modified by aminomethyl^{106–109} or *p*-methylbenzhydrylamine^{109, 110} groups as a polymeric support is reported. In the first step, the NH₂ group of the support was acylated by *N*-protected leucine used as an internal standard. After removal of the amino protective group, the leucyl polymer was treated with a bifunctional reagent, *viz.*, 3-nitro-4-(2-hydroxyethyl)benzoic acid (**54**)^{106–110, 113} or *N*-(9-hydroxymethylfluoren-2-yl) succinamide (**55**).¹⁰⁹

The presence of a bridge between the support and the C-terminal amino acid residue allows splitting of the target product from the solid phase under very mild conditions under the action of base. The linkers can be attached directly to the support, *e.g.*, to PEG-PS containing an amino group.^{53, 103}

The use of *N*-protected 6-aminohexyl succinate **56** as a linker has been described.⁵³

Commercially available CPG containing 3-aminopropyl groups was used^{95–97, 100–102} for the synthesis of peptide–oligo-

nucleotide conjugates. In this case, chemical modification of the solid support was reduced to the acylation of 3-aminopropyl groups by activated esters of 4-hydroxybutyric^{95–97} or 10-hydroxydecanoic acid^{100–102} with the hydroxy groups protected as acid-labile dimethoxytrityl and pixyl (9-phenyl)xanthen-9-yl derivatives. Two additional ϵ -aminocaproic acid molecules were introduced between the 4-hydroxybutyric acid residue and the aminopropyl support.⁹⁷ Lukhtanov *et al.*⁹⁹ used porous glass modified by an extended linker containing a terminal NH_2 group. The latter was acylated with the activated ester **57**.

It is of note that the addition of the first amino acid to the support and the formation of the amide bond in the course of solid-phase synthesis of peptide fragments are usually carried out by the methods involving carbodiimide, activated esters or symmetrical anhydrides.

c. Protective groups

Temporary protection of α -amino groups of amino acids is mainly accomplished using Boc^{53, 99, 101–103, 106–110} or Fmoc^{95–98, 100} groups. Sequential solid-phase synthesis of peptide and oligonucleotide fragments demands protection of reactive side groups of certain amino acid residues. Protective groups are selected in order to ensure selective removal of other groups. The Fmoc^{53, 101, 103, 104} or the Boc group^{95, 96} are most commonly used for the protection of ϵ -amino groups of lysine; trifluoroacetyl (Tfa)¹⁰⁴ and 1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl (Dde)¹⁰⁰ protective groups are used less frequently. The latter withstands splitting of the N^α -Fmoc group by treatment with 20% piperidine in DMF. The β -carboxy group of aspartic acid is protected by conversion into 9-fluorenylmethyl ester.^{53, 103, 106, 108} The possibilities for the protection of the indole (in) ring of tryptophan are rather limited. N^in -Formyl protection is one of them. It is stressed¹⁰⁴ that the use of this protection in the synthesis of peptide–oligonucleotide conjugates prevents the formation of side product. Marchan *et al.*¹⁰⁴ have succeeded in obtaining Boc-Arg(Fmoc)₂-OH which can be used in the solid-phase synthesis of the peptide fragment of the conjugate.

It is known¹¹¹ that unprotected amide groups of asparagine or glutamine residues in the peptide fragments of conjugates can undergo phosphorylation during subsequent elongation of the oligonucleotide chain. However, this side reaction proceeds at a very low rate which excludes the necessity of blocking side groups of asparagine and glutamine.^{53, 104}

Grandas *et al.*^{109, 110, 112} protected the hydroxy group of homoserine by the dimethoxytrityl group leaving the HO groups of serine, threonine and tyrosine unprotected.^{106–110} Other authors¹⁰¹ recommend protecting the hydroxy groups of serine as allyl carbonates. Assuming that the use of the Fmoc-strategy of solid-phase peptide synthesis may result in partial cleavage of this protective group, the authors gave preference to the Boc-strategy.

Despite the vast variety of techniques for the protection of the imidazole (im) ring of histidine, no ideal protective group has been

found for this compound. In the synthesis of peptides containing this amino acid, N^im -benzyloxymethyl protection was used and deprotection was effected by catalytic hydrogenolysis over palladium black in the presence of cyclohexa-1,4-diene. According to Truffert *et al.*,¹⁰² such a treatment should not have any negative effect on the stability of the oligonucleotide fragment of the conjugate. However, this method can hardly be considered satisfactory, since the authors failed to completely remove the peptide–oligonucleotide conjugate formed from the catalyst's surface.

The use of the Boc or the Fmoc groups for the protection of the imidazole ring of histidine cannot be recognised as very convenient either. The reason is that treatment of the peptide–oligonucleotide conjugate with trifluoroacetic acid to remove the N^im -Boc group can result in hydrolysis of the N-glycosidic bonds in purine nucleotides, whereas the N^im -Fmoc group is rather labile under conditions of the solid-phase synthesis. In the authors' opinion,¹⁰² the tosyl (Tos) group is especially convenient for the protection of the imidazole ring of histidine. This group is removed under the action of 1-hydroxybenzotriazole commonly added to the reaction mixture in order to inhibit racemisation in the formation of the peptide bond promoted by DCC. Two procedures for the protection of the imidazole ring of histidine by the tosyl and 2,4-dinitrophenyl groups have been developed by Beltrán *et al.*¹¹⁰ These authors share the opinion that 1-hydroxybenzotriazole can be replaced by tetrazole which has proved to be an efficient reagent when combined with DCC. The analysis of reversed-phase HPLC data led the authors to conclude that the use of Boc-His(Tos)-OH and deprotection of the imidazole ring immediately prior to the elongation of the oligonucleotide chain is the most efficient approach to the solid-phase synthesis of the peptide fragment.

d. Introduction of the linker

After termination of solid-phase synthesis of the peptide component of the conjugate containing a hydroxy amino acid residue,[‡] deprotection of the α -amino group is followed by its repeated selective protection by introducing the phenylacetyl (Pac)^{106–108, 113} or the acetyl (Ac) group^{109, 110} after which the oligonucleotide synthesis is performed (Scheme 20).

If the peptide fragment of the conjugate is devoid of hydroxy amino acids, deprotection is followed by acylation of the free α -amino group by a compound containing an activated carboxy group and a protected hydroxy group.^{53, 95–103} *p*-Nitrophenyl *O*-pixyl-4-hydroxybutyrate,^{97, 99} *p*-nitrophenyl^{100, 101} and pentafluorophenyl¹⁰² *O*-dimethoxytrityl-10-hydroxydecanoates and compound **58**^{53, 95, 96, 103} are used as acylating reagents.

The incorporation of the aliphatic OH group into the peptide and its further selective deprotection make the synthesis of the DNA fragment possible.

[‡] For incorporation of homoserine into the peptide chain, N^α -Pac-*O*-DMTr-Hse is introduced into the condensation reaction in the form of the triethylammonium salt.^{109, 110}

Scheme 20

e. Synthesis of the oligonucleotide fragment

In the studies^{95–102} where CPG was used as a solid support, automated solid-phase phosphoramidite synthesis of an oligonucleotide component of a conjugate was carried out according to a standard protocol. If a copolymer of styrene with ethylene glycol^{53, 103} or a copolymer of styrene with 1% divinylbenzene^{106–113} are used as polymeric supports, the standard procedures had to be modified in order to increase the yields in each step of the oligonucleotide synthesis. These modifications include a severalfold increase in the time required for implementation of all the main steps of internucleotide bond formation, the use of 5-(2-nitrophenyl)tetrazole instead of tetrazole and a significant increase in the concentration of the nucleotide solution in dichloromethane.

In the overwhelming majority of studies, the elongation of the oligomeric chain was carried out in the direction 3'→5' except for the cases where 5'-phosphoramidites of protected deoxynucleosides were used as monomeric components.^{106–108} Labile protective groups^{106, 108, 109, 113} were used together with acyl ones for the protection of exocyclic amino groups of heterocyclic bases. For instance, the *N,N*-dimethylformamidine and *tert*-butylphenoxyacetyl groups were used for the protection of the NH₂ groups of adenine and guanine, while the isobutyryl and the *tert*-butylphenoxyacetyl groups were used for cytosine.

f. Cleavage of conjugates from the solid support and deprotection of functional groups

The problem which has to be solved for the successful solid-phase synthesis of peptide–oligonucleotide conjugates by stepwise elongation of peptide and oligonucleotide chains is to find optimal conditions for the deprotection of functional groups and cleavage of the bonds between the conjugate and the support. Thus it is not recommended to liberate the conjugate from the support by treatment with strong acids or by using acid-labile protective groups because of the risk of partial apurinisation of DNA. For this reason, in the majority of studies post-synthetic treatments were carried out under mild basic conditions. The apprehensions that alkaline treatment might lead to racemisation of the amino acid residues at the α -carbon atom were not confirmed.⁵³ It was noted also that alkaline treatment of conjugates in which the peptide is linked to the oligonucleotide through a serine residue favours the cleavage of the phosphodiester bond between the two fragments.^{3, 4} This reaction includes cleavage of the C–O bond and occurs as base-catalysed β -elimination (see Scheme 2). However, a detailed analysis of this problem showed¹⁰⁸ that treatment of conjugates with a concentrated aqueous ammonia–dioxane mixture (1 : 1) at room temperature for 15–24 h did not cause the cleavage of the bond between the oligonucleotide fragment and the serine residue.

A convenient procedure was developed^{106–109} for the liberation of peptide–oligonucleotide conjugates from the solid phase by treatment with 0.05 M tetrabutylammonium fluoride in tetrahydrofuran at room temperature for 30–60 min. Such treatment ensures simultaneous removal of β -cyanoethyl protective groups from internucleotide phosphates and splitting of the 9-fluorenylmethyl ester of aspartic acid. This is followed by deprotection of exocyclic amino groups of heterocyclic bases under the action of a mixture of concentrated aqueous ammonia and dioxane (1 : 1) at room temperature for 15–18 h. The latter procedure was also carried out at 55 °C (see Ref. 110). Apparently, more drastic conditions were required for the removal of the isobutyryl protective group from the exocyclic amino group of the guanine base in the DNA fragment. The same procedure was used for the removal of some other protective groups, *e.g.*, the tosyl and the 2,4-dinitrophenyl groups (from histidine).

However, an attempt of de la Torre *et al.*⁵³ to liberate a peptide–oligonucleotide conjugate from the polymeric support (PEG-PS) using tetrabutylammonium fluoride failed. It was assumed that polyethylene glycol, which is a constitutive element of the support, prevents β -elimination catalysed by the fluoride

ion. The use of tetrabutylammonium fluoride is also unacceptable for the liberation of those peptide–oligonucleotide conjugates in which the components of the conjugate are linked through the hydroxy group of tyrosine. In this case, the two parts of the hybrid molecule are linked through a phosphotriester bond. It is therefore quite probable that the nucleophilic attack of the fluoride ion at the phosphorus atom will be accompanied by the cleavage of the P–O bond with the formation of a stable phenoxide ion. Therefore, Robles *et al.*¹⁰⁹ proposed to use a mixture of concentrated aqueous ammonia and dioxane (1 : 1) at 55 °C for 18 h for the liberation of the peptide–oligonucleotide conjugate from the solid support. It should be noted that the carboxy group of the C-terminal amino acid is converted into the amide group under these conditions.

The use of concentrated aqueous ammonia for the cleavage of peptide–oligonucleotide conjugates from the solid support and concomitant removal of protective groups yielded a mixture of products.^{53, 96} This can be explained by the fact that the cleavage of the ester bond under the action of concentrated ammonia is accompanied by the formation of both an amide and an ammonium salt. Prior to ammonolysis, the oligonucleotide–peptidyl polymer was treated with a solution of 0.5 M 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in acetonitrile.⁵³ This made it possible to remove the *N*⁶-Fmoc and β -cyanoethyl groups and to cleave the 9-fluorenylmethyl ester of aspartic acid. In the authors' opinion, this reaction order should exclude the conversion of the ester into the amide.

In order to liberate the protected peptide–oligonucleotide conjugate from the support, Truffert *et al.*¹⁰⁰ used a 50% solution of ethanolamine in absolute ethanol (60 °C, 30 h). The final product was obtained in the form of monoethanolamide in a very low yield. To increase the yield, Truffert *et al.*^{101, 102} used 0.1 M NaOH instead of ethanolamine. Under these conditions, hydrolysis of the ester bond between the peptide–oligonucleotide conjugate and the support is completed in 2 h at room temperature and is accompanied by a simultaneous removal of other protective groups, *e.g.*, the β -cyanoethyl groups from internucleotide phosphates, the tosyl group from histidine, the allyloxycarbonyl group from serine and the Fmoc or Dde groups from lysine. The authors note that deprotection of exocyclic amino groups of adenine, cytosine and guanine requires no less than 24 h.

The use of the Boc-protection for the side amino group of lysine is undesirable, since its removal proceeds under rather drastic conditions [treatment with trifluoroacetic acid and 1,2-ethanedithiol (9 : 1) for 5 min^{95, 96}] which may lead to hydrolysis of *N*-glycosidic bonds in the oligonucleotide fragment and subsequent destruction of the target product.

2. Sequential synthesis of oligonucleotide and peptide fragments on the same solid support

In the studies considered above, peptide–oligonucleotide conjugates were prepared by stepwise synthesis, *viz.*, the peptide fragment of the hybrid molecule was first synthesised on a solid phase after which it was possible to proceed to the synthesis of the oligonucleotide chain. In an alternative approach, the DNA fragment is synthesised first. The main limitation of this method is the impossibility of using the Boc-strategy for the peptide synthesis.

The solid-phase synthesis of oligonucleotides with a 5'-terminal reactive NH₂ group has been described.^{114–117} To this end, the 5'-amino-5'-deoxythymidine residue was incorporated into the oligomeric chain in the final step of automated phosphoramidite synthesis. The nucleoside thus modified plays the role of a linker between the oligonucleotide and the peptide fragments of the conjugate. The Fmoc-strategy was used for the elongation of the peptide chain by Bergmann and Bannwarth¹¹⁴ (Scheme 21); the activation of the carboxy group was carried out *in situ* using *O*-(benzotriazol-1-yl)-*N,N,N'*-tetramethyluronium hexafluorophosphate (HBTU). The allylic group was selected as the phosphate-protective group instead of the β -cyanoethyl group

Scheme 21

commonly used for this purpose, because in this study the Fmoc-group was removed by a strong base (DBU) instead of piperidine. For the same reason, the solid-phase synthesis was carried out on modified CPG. To ensure the stability of the bond between the oligonucleotide and the support during DBU treatment, a sarcosine residue was incorporated into the anchor group.

After termination of the synthesis of the peptide fragment, synthesis of another oligonucleotide chain was begun with the use of 2-cyanoethyl *N,N*-diisopropylphosphoramidites of 2'-deoxynucleosides. This procedure afforded conjugates in which two DNA fragments were linked through a peptide fragment. These were liberated from the solid support by consecutive treatment with $\text{Pd}[\text{PPh}_3]_4$ and morpholine in a $\text{DMSO}-\text{THF}-\text{dioxane}-0.5\text{ M HCl}$ mixture (2:2:2:1) at 60°C for 3 h and then with 30% aqueous ammonia at room temperature for 2 h. It should be noted that the bond between the peptide and the second oligonucleotide is of a phosphoramidate type, which is not cleaved in the post-synthetic deprotection of the peptide-oligonucleotide conjugate and its liberation from the solid support.

An analogous synthetic scheme was developed for the preparation of conjugates in which the oligonucleotide fragment is a heteropolymer.^{115, 116}

Special mention should be made of one of the most recent studies carried out by Bleczinski and Richter¹¹⁷ which describe a procedure for the preparation of cyclic peptide-oligonucleotide conjugates. Fmoc-protected amino acids and All-protected nucleoside phosphoramidites were used as the starting compounds. This approach was used to obtain the cyclic hybrid Glu-Leu-T**T*-DP-Lys (**59**) (T* is 5'-amino-5'-deoxythymidine, DP is 3-hydroxy-2,2-dimethylpropionic acid). The amide bond of the 'head-to-tail' type was formed by the ϵ -amino group of lysine and the γ -carboxy group of glutamic acid. The structure of compound **59** was confirmed by ^1H NMR spectroscopy and MALDI-TOF mass spectrometry. The cyclic conjugate appeared to be resistant to exo- and endonucleases. By varying the peptide fragment, it was possible to obtain an analogous 39-membered ring.

3. Synthesis of peptide-oligonucleotide conjugates on solid supports with a bifunctional branched anchor group

An approach to the synthesis of peptide-oligonucleotide conjugates proposed in the early 1990's¹¹⁸⁻¹²¹ and further successfully developed in the studies carried out in the past three years¹²²⁻¹²⁵ is of considerable interest. The oligonucleotide

syntheses were performed on solid supports with branched anchor groups containing HO and NH_2 groups. The presence of this group allows sequential attachment of monomeric units, first, of one type and then, of another type, on the same support. Post-synthetic treatments result in a hybrid molecule in which the oligonucleotide and the peptide fragments are connected through a linker. The distinctive feature of this method is that the bifunctional[§] linker is attached directly to the solid phase rather than to one of the fragments of the synthetic conjugate. 3-Aminopropane-1,2-diol¹¹⁸ and 6-amino-2-hydroxymethylhexan-1-ol¹¹⁹ can be used as linkers. The hydroxy and amino functions are protected by the DMTr and Fmoc groups commonly used for this purpose.

In these studies,^{118, 119} the peptide fragment was synthesised first. In the peptide synthesis, the ϵ -amino group of lysine was protected by the Boc group; the hydroxy group of serine and the thiol group of cysteine were protected by the *tert*-butyldimethylsilyl (TBDMS) and trityl (Tr) groups, respectively, whereas the amino groups of adenine and guanine were protected by the 2-(acetyloxymethyl)benzoyl group, while those of cytosine were protected by the acetyl group.

The main difference in the approaches proposed by Canadian¹¹⁸ and American¹¹⁹ investigators consists in the choice of an insoluble support and the method for its chemical modification.

The polymer employed by the Canadian investigators Juby *et al.*¹¹⁸ was commercially available Teflon to which 5'-*O*-dimethoxytrityl-2',3'-di-*O*-acetyladenosine was attached through an extended linker. The first step was the selective removal of the DMTr protective group from the 5'-hydroxy group followed by the introduction of a protected 3-aminopropane-1,2-diol residue using the amidite strategy to yield derivative **60** (Scheme 22). This was employed for the peptide and then for the oligonucleotide synthesis. After completion of the peptide and oligonucleotide syntheses, the functional groups were deprotected under mild conditions by treatment with ethylenediamine in absolute ethanol (1:1) at 55°C for 1 h. (This procedure for the removal of protective groups was specially developed in the synthesis of oligonucleotide methylphosphonate derivatives.) The cleavage of the target product from the solid phase was carried out in two steps. At first, the *cis*-glycol group of the 2',3'-di-*O*-acetyl

[§]It would be more correct to speak about a tri- rather than about a bifunctional linker, since it contains one more reactive group involved in the formation of a covalent bond with a solid support.

Later, the same authors¹²⁵ performed the synthesis of the peptide–oligonucleotide conjugate **63** using a polymeric support with a branched linker.

4. Synthesis of oligonucleotide peptides by fragment condensation

The essence of this method is in the formation of a covalent bond between the presynthesised peptide and the oligonucleotide after completion of the automated oligonucleotide synthesis but prior to the cleavage of the nucleic acid fragment from the solid support. The main advantage of this approach is that one component of the conjugate is not exposed to the effect of chemical reagents used for the synthesis of the other component as is the case with sequential solid-phase synthesis of peptide–oligonucleotide conjugates.

Very often, peptide–oligonucleotide conjugates are prepared by the reaction of an oligonucleotide containing free 5'-hydroxy groups and immobilised on an insoluble support with a peptide phosphoramidite derivative in the presence of tetra-zole.^{108, 111, 126–133} The peptide phosphoramidite derivatives can be prepared in good yields by the reaction of the hydroxy group of serine or tyrosine with a standard phosphitylating reagent.^{108, 126–132} It was also proposed to phosphitylate the C-terminal amide group of the peptide.^{111, 133}

As in the case of other methods for the synthesis of peptide–oligonucleotide conjugates, the main efforts of investigators were directed at a search for the mildest conditions for post-synthetic treatment. This is especially important in those cases where the formation of the phosphodiester bond between the oligonucleotide and the peptide fragments of the conjugate involves the serine residue. Such compounds destroy under alkaline conditions. In contrast, those molecules, which contain phosphoramidate bonds, are unstable in strongly acidic media.

van Boom *et al.*¹²⁸ protected the α -amino group of the peptide by the *p*-nitrobenzyloxycarbonyl group and the ω -carboxy groups of aspartic and glutamic acids were converted into *p*-nitrobenzyl esters. These protective groups are removed simultaneously with a sodium dithionite–sodium hydrogencarbonate mixture. The exo-

cyclic amino groups of the heterocycles were protected by the 2-(*tert*-butyldiphenylsilyloxymethyl)benzoyl group. Oxalic acid served as a linker between the first nucleoside and the polymer.¹²⁸ Liberation of the target product from the solid phase with simultaneous deprotection of heterocyclic bases and internucleotide phosphates was carried out using tetrabutylammonium fluoride in aqueous pyridine.

It is known that allyloxycarbonyl and allyl protective groups are split off under mild conditions. These groups were used^{129–131} for the protection of the functional groups of the oligonucleotide (exocyclic amino groups of heterocyclic bases, internucleotide phosphates) and the peptide (terminal NH₂ and COOH groups) fragments. These protective groups are easily removed by a palladium complex in the presence of diethylammonium formate.

The synthesis of peptide–oligonucleotide conjugates containing nucleotidyl-(5'→O)-serine fragments was performed using protection of the lateral carboxy group of aspartic acid by any of the three esters, *viz.*, 9-fluorenylmethyl, benzyl or 2-(2-nitro-4-acetylphenyl)ethyl esters.¹⁰⁸ The exocyclic amino groups of adenine residues were protected by benzoyl or *N,N*-dimethylformamidino group. The cleavage of the peptide–oligonucleotide conjugate from the solid support and removal of protective groups were carried out using three different methods, *viz.*, by treatment with concentrated aqueous ammonia, potassium carbonate or lithium hydroxide in a methanol–dioxane mixture. It is of note that the authors¹⁰⁸ failed to correctly characterise the target product and to confirm its structure by mass spectrometry and amino acid analysis data.

The methods for the synthesis of conjugates containing an amide bond between the oligonucleotide and the peptide fragments were considered in the section devoted to the solution synthesis of peptide–oligonucleotide conjugates (see Section II.3). The difficulties reported in the publications^{38, 39} could be largely overcome by performing the solid-phase condensation of the oligonucleotide and the peptide components, which significantly increased the yield of the target product. The decomposition of diazoketone **37** (see Scheme 10) was carried out in the presence of silver benzoate rather than under UV irradiation in the apprehension that in the latter case the reaction rate would decrease due to partial absorption of energy by the solid support (polystyrene or CPG).³⁹

The condensation of the pentapeptide Ac-Ala-Tyr-Gln-Val-Phe with tri- and tetranucleotides containing 5'-terminal 5'-amino-5'-deoxythymidine residues and immobilised on a solid phase was reported by Tetzlaff *et al.*¹¹⁵ However, these authors drew attention to the low efficiency of this reaction, which they attributed to the low solubility of the peptide in dimethylformamide.

The recently published data deserve special mentioning. Thus, Gait *et al.*^{134, 135} used the following approach for the incorporation of an aliphatic amino group into the DNA fragment: the 5'-hydroxy group of the CPG-linked oligonucleotide following removal of the terminal DMTr protective group was activated by *N,N*-carbonyldiimidazole and introduced into the reaction with a diamine (Scheme 25). When PyBOP was used as a condensation reagent in the presence of 1-hydroxybenzotriazole, the degree of racemisation at the α -carbon atom of the C-terminal amino acid was very small. Nevertheless, peptides containing C-terminal

$n = 3, 6, 12$.

glycine were selected for conjugation to oligonucleotides, since in this case the α -carboxy group of the peptides could be activated without any risk of racemisation. A tetrapeptide containing non-polar amino acid residues and an octapeptide built up of polar amino acids were used as peptide fragments, while various homo- (e.g., T₁₂) and heterooligonucleotides were used as oligonucleotides. The conjugation of both peptides to T₁₂ proceeded with high efficiency.^{134, 135} However, the yields of peptide–oligonucleotide conjugates prepared by condensation with heterooligonucleotides were very low. The authors failed to explain the reason for this phenomenon. Neither did the changes in experimental conditions, *i.e.*, the use of PEG-PS instead of CPG, a larger peptide excess (10 instead of 5 equiv.) and higher temperature (40 °C), give any positive result.

It was suggested that the main problem is related to poor solubility of protected heterooligonucleotides in dimethylformamide due to their high hydrophobicity. This problem was overcome by selective removal of β -cyanoethyl protective groups by triethylamine in acetonitrile which caused some increase in the yields of the target products. In the majority of cases, the elongation of the linker containing the amino group also had a beneficial effect on the conjugate yields.

A modification of this reaction was employed¹³⁶ in the condensation of a presynthesised peptide with a blocked oligonucleotide immobilised on a solid phase and containing a linker attached to the C(2')-atom of the carbohydrate fragment (Scheme 26). Oligodeoxyribonucleotides employed contained either three modified nucleosides, *viz.*, 2'-(3-aminopropionyl)-amino-2'-deoxy-*arabino*-adenosine, 2'-(3-aminopropionyl)amino-2'-deoxyuridine or 2'-amino-2'-deoxy-*arabino*-adenosine.

Scheme 26

First, the Fmoc-protected amino group attached to the C(2')-atom of the carbohydrate fragment of one of nucleotide residues either directly or through a linker was selectively deprotected with 50% morpholine in dimethylformamide for 1 h. Then the oligonucleotide with the free NH₂ group reacted with a protected peptide fragment.

Two short peptides, *viz.*, *N*^α-Fmoc-Leu-Gly and *N*^α-Fmoc-Tyr-D-Ala-Phe-Gly, were selected as peptide fragments. In both cases, the C-terminal amino acid residue was represented by a glycine residue. The latter circumstance is very important, since in this case the activation of the carboxy group of the peptides was not accompanied by racemisation due to the absence of a chiral carbon atom in the glycine molecule.

The reaction of the *N*^α-blocked peptide with the oligodeoxyribonucleotide immobilised on CPG-500 was carried out in anhydrous dimethylformamide in the presence of HBTU and ethyldiisopropylamine. The reaction was complete within 1–2 h and gave high yields (80%–90%). In the final step, the conjugate was cleaved from the solid support and the functional groups of the oligonucleotide and the peptide components were deprotected.

The use of the solid-phase method requires large excesses of the peptides and the condensation reagent. This increases the efficiency of formation of the amide bond; the excesses of dimethylformamide-soluble reagents are easily removed by thorough washing of the support.

The main advantage of Fmoc protection of amino groups is that this can be removed in two ways. The first approach entails post-synthetic treatment of the oligonucleotide with saturated aqueous ammonia. The second approach consists of the removal of the Fmoc group with morpholine in an anhydrous medium, which allows selective deprotection of the aliphatic amino group of the oligonucleotide. Under these conditions, the oligonucleotide is not split from the support, and its other functional groups remain protected.

An approach proposed by Zubin *et al.*¹³⁶ allows simultaneous attachment of several peptide fragments to the oligonucleotide, since the modified nucleoside fragment containing an aliphatic amino group can be inserted into any predetermined position of the oligomeric chain and the number of inserts is not limited in principle. Another salient advantage of this approach is that the 5'- and 3'-ends of the oligonucleotide fragment of the conjugate remain free, which allows the attachment of various reporter groups, *e.g.*, radioactive or fluorescent labels.

Certain difficulties arise when this method is used for the synthesis of oligonucleotide conjugates with larger peptides. The problem is associated with the activation of carboxy groups. Moreover, this method demands the use of large excesses of peptides, which is hardly justified from the economical point of view.

The approach based on successive attachment of small peptide fragments to oligonucleotides is an alternative. After attachment of the first fragment, the *N*^α-Fmoc group has to be removed, after which the next fragment is introduced into the reaction. *N*^α-Fmoc-Leu-Gly and *N*^α-Fmoc-Tyr-D-Ala-Phe-Gly were used for the synthesis of oligodeoxyribonucleotide conjugates with peptides containing four and eight amino acid residues.

A similar ideology is shared by Hwang and Greenberg^{137, 138} who have succeeded in incorporating 2'-modified phosphoramidite synthons into different positions of the oligonucleotide chain in the course of automated synthesis. The amino group at the C(2') atom of the synthon was protected by the photolabile protective group (X).

Scheme 27

DIPEA is diisopropylethylamine.

Linker is $-(CH_2)_6-$, $-Gly-NHCO(CH_2)_6-$, $-Gly-Gly-Gly-NHCO(CH_2)_6-$;

(a) EtNPr₂ⁱ; (b) RH (RH is H-Gly-Gly-Gly-NEt₂ or H-Leu-Ala-Lys(Tfa)-Leu-NEt₂); (c) NH₃·aq.

The attachment of tripeptides to the modified oligonucleotides **64** and **65** afforded the corresponding conjugates with satisfactory (70%–80%) yields.

The synthesis of photodegradable peptide-oligonucleotide conjugates designed for detection of target NA sequences by the MALDI mass spectrometry methods has been described (Scheme 27).¹³⁹

The photodegradable conjugate contains an oligonucleotide probe for target DNA or RNA sequences and a peptide mass marker easily detectable by mass spectrometry after hybridisation and subsequent photodegradation of the conjugate.

A special polymer with ketoxime functional groups was proposed for oligonucleotide synthesis (Scheme 28).^{140,141} The anchor group (linker) was attached to the support through an ester bond. The use of such supports facilitates the cleavage of the target product under the action of nucleophiles, the role of a nucleophile can be played by the peptide fragment.

IV. Conclusion

The analysis of published data suggests that no versatile method for the synthesis of peptide-oligonucleotide conjugates of any structure exists. This is due to the fact that several factors play crucial roles in the synthesis of peptide-oligonucleotide conjugates, viz., the type of modified nucleic acid fragment, the amino acid sequence, the size of the peptide, the conjugation procedure and the type of bond connecting the two parts of the hybrid molecule. The possibility of varying these parameters within a sufficiently broad range and of using their different combinations have given a strong impetus to the appearance of numerous publications devoted to novel methods for the synthesis of peptide-oligonucleotide conjugates. However, because of serious limitations of each of these methods, very few of them have found

wide acceptance in the preparative synthesis of peptide-oligonucleotide conjugates. In this connection, a search for optimal approaches to the synthesis of peptide-oligonucleotide conjugates still remains a very urgent task.

The authors thank A V Kachalova for her valuable assistance in the preparation of this review.

This work has been carried out within the framework of the program 'Leading scientific schools' (Grant No. 00-15-97944) and 'The universities of Russia' (Grant No. 015.07.02.027) and with the financial support of the Grant 'Wellcome Trust' (Grant No. 057361).

Theoretical studies of transition metal complexes with nitriles and isocyanides

M L Kuznetsov

Contents

I. Introduction	265
II. Electronic structures of complexes and the nature of coordination bonds	265
III. Spectroscopic properties of coordinated ligands	274
IV. Reactivities and mechanisms of reactions with coordinated ligands	276
V. Conclusion	281

Abstract. Theoretical studies of transition metal complexes with nitriles and isocyanides are reviewed. The electronic structures and the nature of coordination bonds in these complexes are discussed. The correlation between the electronic structures of transition metal complexes with nitriles and isocyanides and their structural properties, spectroscopic characteristics, and reactivities are considered. The bibliography includes 121 references.

I. Introduction

It is known that free nitriles ($N \equiv CR$) and isocyanides ($C \equiv NR$) containing no strong acceptor substituents R are poorly reactive or even inert in a number of processes, for example, in nucleophilic addition. If these molecules are involved as ligands in transition metal complexes, the situation reverses because complex formation leads to activation of nitrile and isocyanide ligands. Reactions, which proceed under drastic conditions, if at all, with free nitriles and isocyanides, every so often occur under relatively mild conditions with coordinated ligands. In some reactions with coordinated ligands, the rate is increased by a factor of 10^{18} as compared to that in the reaction with the corresponding free ligand.^{1–4} Nitriles and isocyanides thus activated can be used in the synthesis of new compounds with the $C-O$, $C-N$, $C-C$, $C-S$ and $C-P$ bonds, which cannot be prepared without resorting to transition metals. Cycloaddition of the corresponding reagents to the inner-sphere nitrile and isocyanide ligands affords tetrazoles and oxadiazolines, respectively, which are widely used in pharmacology.

The design of new antitumour drugs is yet another field of application of nitrile complexes. Thus the imino-ether compounds *trans*-[PtCl₂{NH=C(OMe)Me}₂] prepared by the nucleophilic addition of methanol to the [PtCl₂(NCMe)₂] complex exhibited high antitumour activity.^{5,6} This result was unexpected because *cis* isomers of platinum complexes with N-donor ligands generally show higher antitumour activity as compared to the corresponding *trans* isomers.

Coordinated nitriles also find application in catalysis. For example, large-scale production of acrylamide and nicotinamide is based on catalytic (including, catalysis by metal ions^{4,7–9}) hydrolysis of nitriles. Metal-promoted hydrolysis of nitriles and isocyanides can be used for detoxication of industrial wastes containing these compounds. Finally, some nitrile complexes of transition metals possess nonlinear-optical properties.^{10,11}

Interesting properties of transition metal complexes with nitriles and isocyanides and their wide industrial applications have given impetus to a substantial increase in the number of publications devoted to these compounds. The results of experimental studies of their reactivities have been surveyed in reviews.^{1,4,12–17} However, the data from theoretical investigations of nitrile and isocyanide coordination compounds were not systematised. At the same time, transition metal complexes with other ligands have been extensively studied by quantum-chemical methods[†] in the last decade. These investigations were motivated primarily by the necessity of interpreting and systematising the ever-growing body of experimental information. Besides, theoretical methods are sometimes the only tool in studying unstable compounds and intermediates formed in the course of many chemical reactions.

In this review, the results of theoretical investigations of transition metal complexes with nitriles and isoelectronic isocyanides are generalised. The electronic structures and the nature of coordination bonds in these compounds are discussed. The correlations between the electronic structures of these complexes and their structural characteristics, spectroscopic properties, and reactivities are considered. Studies concerned with analysis of interactions between ligands and some transition metals are partially included for comparison.

II. Electronic structures of complexes and the nature of coordination bonds

Two models, *viz.*, the ligand field theory and the Dewar–Chatt–Duncanson (DCD) model, are most commonly used for the qualitative description of the nature of coordination bonds in transition metal complexes. The latter model is applied to complexes containing ligands with multiple bonds. These theories are based on the molecular orbital method and treat the formation of coordination bonds as a result of interactions between the valence

[†] The results of theoretical studies of transition metal complexes (primarily, carbonyl, carbene, carbyne and π -complexes) are surveyed in reviews.^{18–24}

orbitals of the ligand and the metal atom. Of particular interest is the elucidation of the character of the highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbitals because they are primarily responsible for the chemical reactions and determine the spectroscopic and other physical properties of compounds.

Systematic studies of nitrile and isocyanide complexes by quantum-chemical methods were started only recently and most of the publications date back to 1990s.[‡] The DCD model^{25,26} is commonly used for the description of these complexes. According to this model, the metal–ligand coordination bond involves the σ -component, which originates from the transfer (donation) of the electron density from the occupied σ -orbitals of the ligand to the unoccupied d -orbitals of the metal atom, and the π -component resulting from π -back donation. By π -back donation is meant the electron density transfer from the highest occupied d -orbitals of the metal atom to the free valence antibonding π^* -orbitals of the ligand resulting in two-electron stabilisation of the frontier MOs of the complex. In addition, the π -component of the coordination bond often includes the contributions of the highest occupied π -orbitals of the ligand whose interactions with the occupied d -orbitals of the metal atom lead to destabilisation of the HOMOs (Fig. 1).

Figure 1. Scheme of formation of the HOMO of complexes containing ligands with multiple bonds.

(a) Ligands possessing strong π -acceptor properties, (b) ligands possessing weak π -acceptor properties.

Apparently, the contributions of the π - and π^* -MOs of the ligand to the HOMO of the complex are determined by the relative energies of the valence orbitals of the metal atom and the ligand. The $d(\text{M})-\pi^*$ -MO(ligand) interaction prevails in the HOMOs of the complexes with ligands possessing strong π -acceptor properties [for example, the carbon(II) oxide or carbyne ligands] because the valence occupied d -orbitals of the metal atom are closer in energy to the π^* -MOs than to the π -MOs of the ligand (Fig. 1a), whereas the $d(\text{M})-\pi$ -MO(ligand) interaction dominates the HOMOs of the complexes with ligands exhibiting weak π -acceptor properties, such as nitriles, because the energies of the highest occupied d -orbitals of the metal atoms are similar to those of the occupied π -MOs of the ligand (Fig. 1b).

Until very recently, the extended Hückel theory (EHMO) was most commonly used in calculations of MOs of nitrile and isocyanide complexes. However, higher-level approximations, viz., the Hartree–Fock method (HF), the functional density theory (DFT), the second-order Møller–Plesset theory (MP2), etc., have found application in the last few years. The next section covers the results of studies devoted to the electronic structures and the nature of coordination bonds in transition metal complexes with isocyanides and nitriles.

[‡] It should be noted that theoretical studies devoted to isocyanide complexes and, particularly, to nitrile complexes are much smaller in number than those dealing with carbonyl compounds or π -complexes.

1. Electronic structures of isocyanide and nitrile complexes

The nature of coordination bonds and reactivities of the molybdenum diisocyanide complex *trans*-[Mo(CNMe)₂(dppe)₂] (dppe = Ph₂PCH₂CH₂PPh₂) and the rhenium isocyanide complexes *trans*-[Re(CNR)Cl(dppe)₂] (R = H, Alk, Ar) were studied.^{27,28} It was found that two of the highest occupied MOs of the molybdenum complex and the HOMOs of the rhenium complexes are formed *via* interactions of the d -orbitals of the metal atom with the π - and π^* -MOs of isocyanide. The HOMO of the molybdenum complex (Fig. 2) is bonding for the Mo–C bond and antibonding for the C≡N bond due to the predominant contribution of the π^* -MO of the ligand to the HOMO responsible for the π -back donation effect. However, the π -component of the metal–ligand bond is rather weak because of the small coefficients with which the AOs of the α -carbon atom are included into the HOMO of the complex under consideration. The contributions of the π - and π^* -MOs of isocyanide to the HOMOs of the rhenium complexes are approximately equal (the HOMO is a nonbonding orbital with respect to the Re–C bond).

The electronic structures of the [Pd₂(CNR)₂(μ-η³-L)₂] (L is indenyl) and [Pd₄(μ-CNR)₄(μ-OAc)₄] complexes, the model compounds [Pd₂(μ-CNH)₂(OH)₄]⁴⁻ and [Pd₂(μ-CNH)₂(OH)₄]²⁻ and the [Ni₂(CNH)(PH₂CH₂PH₂)₂] complex were examined at the EHMO level of theory.^{29,30} The highest occupied MOs of the last two mentioned complexes consist of the π_d^* -orbitals of the {Pd₂(OH)₄}²⁻ or {Ni₂(PH₂CH₂PH₂)₂} fragment and the π^* -MO of isocyanide. It was noted that the interaction between these orbitals in the former complex is rather weak. The lowest unoccupied MO of the nickel complex is a purely $\pi^*(\text{CNH})$ -orbital. For the indenyl complexes, the energy gap between the HOMO and LUMO was demonstrated to be rather large. As a consequence, these complexes exist in the singlet state, which accounts for the formation of the Pd–Pd bond.

The MOs of the model binuclear complex [Pd₂(CNMe)₄Cl₂] were calculated by the extended Hückel method³¹ with the aim of obtaining qualitative information on the nature of the frontier MOs and examining the dependence of the compositions of the MOs on the internuclear Pd–Pd distance and the torsion angle θ between the planes of two {Pd(CNMe)₂Cl} fragments. The orbitals of the metal atom make the major contribution to the HOMO and LUMO, the orbitals of the C α atom of isocyanide also making a particular contribution (the antibonding character of the Pd–C bond), whereas the AOs of the N β and C γ atoms of the isocyanide ligand contribute insignificantly to these orbitals. The composition of the MOs is virtually insensitive to variations in the torsion angle θ and the internuclear Pd–Pd distance.

The electronic structures and the nature of the coordination bonds in the isocyanide complexes M(CNBu^t)Me(CO)₂·(η⁵-C₅R₅) and the isomeric compounds [M(η²-CMe=NR')·(CO)₂(η⁵-C₅R₅)] and [M{η³-CH₂=CHNBu^t}(CO)₂(η⁵-C₅R₅)] (M = Mo, W; R = H, Me; R' = Prⁱ, Bu^t) were discussed based on the data from photoelectron spectroscopy and the results of EHMO calculations of the molecular orbitals carried out for model compounds.³² In the isocyanide complexes, the two highest occupied MOs are centred on the metal atom but the π^* -MOs of the carbonyl and isocyanide ligands also make particular contributions to these MOs giving rise to π -back donation [the π -MO(CNR) also makes a certain contribution to these MOs of the complexes].

Although the isocyanide ligands in many complexes possess noticeable π -acceptor properties, the contributions of the π - and π^* -MOs of the ligand to the HOMOs of the complex are in some cases insignificant and the HOMOs are centred on the metal atom. Thus calculations for the frontier MOs of the model complexes

Figure 2. Correlation diagram of the MOs in the *trans*-[Mo(CNMe)₂(dppe)₂] complex.²⁷

[Ag₂(CNMe)₄X₂] (X = Cl, Br, I) (**1**),³³ [PtRh(CNBut)₂.(CN)₂(dmpm)₂]⁺ (dmpm = Me₂PCH₂PMe₂) (**2**), *trans*-[Rh(CNBut)₂(PPh₃)₂]⁺ (**3**)³⁴ and [M(CNH)₄]⁺ (**4**) (M = Cu, Ag)³⁵ demonstrated that the HOMOs are localised predominantly on the metal atoms. The orbitals of the halogen atoms in the complexes **1** and the *s*-orbitals of the carbon atom of the isocyanide ligand in the complexes **4** also make contributions to the HOMOs of these complexes. The lowest unoccupied MOs of the complexes **1** and **4** are the π^* -orbitals of the CNR fragment, whereas the LUMOs of the complexes **2** and **3** consist of the p_z (Rh), π^* (CN), p_z , d_{xz} (P) and p (Pt) atomic orbitals.

The compositions of the frontier MOs in the tetranuclear linear [M₄(CNMe)₈(PH₃)₂]²⁺ clusters (M = Pd, Pt) were studied by the EOMO method.^{36,37} The highest occupied and lowest unoccupied MOs are the σ_a^* -orbitals of the metal atom. The next 18 occupied MOs of the clusters are centred on the metal atom, whereas 4 unoccupied MOs following after the LUMO are the π^* -orbitals of CNMe.

The introduction of other ligands exhibiting strong π -acceptor properties into isocyanide complexes often leads to weakening of π -back donation of the electron density from the *d*-orbitals of the metal atom to the π^* -orbitals of isocyanide. This weakening is particularly noticeable when a strong π -acceptor is in the *trans* position with respect to the isocyanide ligand, which actually reflects the mutual trans effect of two π -acceptors. In contrast, the introduction of a ligand exhibiting pronounced donor properties (for example, the chloride ligand) in the *trans* position with respect to isocyanide leads to enhancement of the π -acceptor properties of

isocyanide and strengthening of π -back donation. Thus several highest occupied MOs in the *trans*- and *cis*-[(PH₃)₂(CO)₂W.(CNMe)($\equiv$ CCH=CH₂)]⁺ complexes containing one carbyne ligand and two carbonyl ligands (strong π -acceptors) along with the isocyanide ligand are composed predominantly of the orbitals of the metal atom and the carbonyl and carbyne ligands with a very small contribution of the AOs of the nitrogen atom of isocyanide (Figs 3 and 4).³⁸

The nature of the coordination bond in the isocyanide complexes [Cp₂Ta(CNMe)(η^2 -CH₂=CH-CH=CH₂)]⁺ (Cp is the cyclopentadienyl ligand) (**5**), [Cp₂Ta(CNMe)₂]⁺ (**6**) and [Cp₂M(CNMe)]^{0/+} (M = Ta, Zr) was examined based on the results of DFT calculations³⁹ with full geometry optimisation of different isomers of these complexes. Analysis of the theoretical and experimental structural data (the linearity of the isocyanide molecule, the equal CN bond lengths in free and coordinated isocyanides) and examination of the energy components of the coordination bond showed that π -back donation is of secondary importance in the interaction between isocyanide and tantalum in the complex **5**, which contains other strong π -acceptors. In this case, the interaction between the metal atom and the ligand is predominantly Coulombic in character. In the complex **6**, which contains no other π -acceptor ligands except for isocyanide, the Ta $\rightarrow$ CNR π -back donation becomes essential.

Three orbitals, *viz.*, the *d*-orbital of the metal atom and the π - and π^* -orbitals of isocyanide, contribute to the π -component of the coordination bond between the metal atom and the isocyanide ligand. The interactions between these orbitals give rise to three

Figure 3. Correlation diagram of the MOs in the *trans*-[(PH_3)₂(CO)₂W(CNMe)($\equiv\text{CCH}=\text{CH}_2$)]⁺ complex.³⁸

Figure 4. Composition of the HOMOs in the tungsten isocyanide complexes *trans*- and *cis*-[(PH_3)₂(CO)₂W(CNMe)($\equiv\text{CCH}=\text{CH}_2$)]⁺.³⁸

molecular orbitals two of which, viz., $\pi_{d-\pi(\text{L})}$ (MO1) and $\pi_{d-\pi^*(\text{L})}^*$ (MO3), are formed primarily from the d -orbitals of the metal atom and the π - or π^* -orbitals of the ligand. These MOs produce the bonding and antibonding combinations for the metal–ligand bond, respectively (Fig. 5). In some cases, the third orbital (MO2) is the HOMO of the complex derived from a linear combination of the $\pi_{d-\pi(\text{L})}^*$ - and $\pi_{d-\pi^*(\text{L})}$ -orbitals. The contribution of the unoccupied π^* -orbital of the ligand to the MO2 of the isocyanide complexes is often larger than the contributions of the occupied π -MOs of the ligand although the participation of the latter remains essential. As a result, the MO2 orbital either remains nonbonding with respect to the metal–ligand bond or becomes weakly bonding. Actually, as can be seen from Fig. 6, the formation of the MO2 leads to a substantial decrease in the electron density on the C^α and C^γ atoms, whereas the electron

Figure 5. Three-orbital interaction between the frontier MOs of the metal atom and the ligand.

Figure 6. Polarisation effect of the nonbonding HOMO.

density on the nitrogen atom increases resulting in polarisation of the corresponding MO. This polarisation of orbitals in cyanide, carbonyl and nitrogen complexes was described by R Hoffmann⁴⁰ as early as 1977. At the same time, the contributions of the π - and π^* -MOs of isocyanide to the HOMO are very small in the presence of other (in addition to CNR) ligands possessing strong π -acceptor properties. In the latter case, the properties of such complexes are not always correctly interpreted in terms of the qualitative DCD model.

On the whole, the compositions of frontier MOs determining the π -component of the coordination metal–ligand bond in nitrile complexes is similar to those in isocyanide compounds. The EHMO calculations were carried out for the model nickel nitrile complex $[\text{Cp}(\text{PH}_3)\text{Ni}(\text{N}\equiv\text{CC}_6\text{H}_4\text{NH}_2)]^+$ (**7**).¹⁰ Figure 7 shows the correlation diagram of the MOs describing interactions between the molecular orbitals of the $[\text{Cp}(\text{PH}_3)\text{Ni}]^+$ fragment and the nitrile ligand upon the formation of the complex **7**. The most important result of this interaction is σ -donation of the

electron density from the occupied σ -orbitals of the nitrile ligand (σ_1 - and σ_2 -MOs), which are bonding with respect to the CN group, to the unoccupied d_{z^2} -orbital of the metal atom. In addition to the above-mentioned two σ -orbitals, the third lower-energy σ -orbital of the nitrile ligand (it is omitted in the figure), which is antibonding with respect to the CN bond, also makes a contribution to this interaction. The authors of the cited study believed that the last-mentioned contribution [which leads to a decrease in occupancy of the $\sigma^*(\text{CN})$ -orbital upon coordination] is mainly responsible for strengthening of the CN bond on going from the free ligand to the complex.

In addition to the σ -component, the coordination bond in the complex **7** also involves the π -component (interactions between the occupied d -orbitals of nickel and the π -orbitals of the nitrile ligand). Both π - and π^* -MOs contribute to the resulting MOs of the complex. The highest occupied MO derived from a linear combination of three orbitals $a'' + \lambda_1\pi_{||} + \lambda_2\pi_{||}^*$ is a nonbonding orbital with respect to the N and C atoms. The contribution of the $\pi_{||}$ -orbital of the ligand to the HOMO only insignificantly overrides the contribution of the $\pi_{||}^*$ -orbital from which it was concluded that the metal–ligand π -interaction has its origin in very weak π -donation of the electron density from the ligand to metal.

In transition metal complexes, nitriles exhibit both weak π -donor and weak π -acceptor properties, which is yet another important characteristic of the electronic structures of this class of

Figure 7. Scheme of the interactions between the MOs of the $[\text{Cp}(\text{PH}_3)\text{Ni}]^+$ and $\text{NCC}_6\text{H}_4\text{NH}_2$ fragments upon the formation of the complex **7**. For the nitrile ligand, only the orbitals belonging to the nitrile group are shown.¹⁰

coordination compounds. Hence, the total contribution of the π -orbitals of nitrile (both π and π^*) to the frontier MOs of the complex is, generally, insignificant and the latter orbitals are often centred on the metal atom. The results of EHMO or HF calculations of the electronic structures of the model nitrile complexes $[\text{CpFe}(\text{NCMe})(\text{PH}_3)_2]^+$, $[\text{CpFe}(\text{N}\equiv\text{CCH}_2\text{C}_6\text{H}_4\text{O}.\text{P}_3\text{N}_3(\text{OH})_5\text{-}p)(\text{PH}_3)_2]^+$ (see Ref. 41) and $[\text{CpFe}(p\text{-N}\equiv\text{C}.\text{C}_6\text{H}_4\text{NO}_2)(\text{PH}_3)_2]^+$ (see Ref. 11) indicate that the HOMOs of all complexes consist predominantly of the d -orbitals of the iron atom although the π^* -orbitals of the nitrile ligand in the latter compound also make a particular contribution to the MO, which is the closest in energy to the HOMO, thus providing the π -dative interaction. Analogous results were obtained in the DFT calculations of the molecular and electronic structures of the model nickel complexes $[\text{LNi}\{\text{N}\equiv\text{CN}=\text{C}(\text{NH}_2)_2\}(\text{NH}_3)_3]$ (**8**) and $[(\text{NH}_3)_3\text{Ni}\{\text{N}\equiv\text{CN}=\text{C}(\text{NH}_2)\text{NHNi}(\text{NH}_3)_2\text{L}\}]$ (**9**) (L is 1,2-diazolidine).⁴²

Figure 8. Interactions between the orbitals of the metal atom and the nitrile ligand in the complex **9**.⁴²

The ground state of the complex **9** is quintuplet, whereas the energies of the triplet and singlet states are higher by 46.9 and 381.4 kJ mol⁻¹, respectively. The singly occupied MOs are centred on the d_{z^2} - and d_{xy} -orbitals of Ni¹ and the $d_{z^2-y^2}$ - and $d_{x^2-y^2}$ -orbitals of Ni². The lower-energy doubly occupied MOs are composed of the d_{yz} - and d_{xz} -orbitals of the Ni¹ and Ni² atoms with a particular contribution of the π^* -MO of nitrile. The latter orbital is responsible for insignificant π -back donation of the electron density from the orbitals of the Ni² and Ni¹ atoms to the orbitals of the ligand. The side-to-side interaction between the orbitals of the Ni¹ atom and the nitrile ligand (Fig. 8) is rather unusual for the high-spin Ni(II) ion.

Kuznetsov *et al.*^{43,44} reported the results of theoretical studies of the platinum nitrile complexes *trans*-[Pt(NCMe)₂Cl₂] (**10**),

Figure 9. Compositions of the HOMOs in the complexes **10**–**12** when they contain two linear acetonitrile ligands (a) and when one of the acetonitrile ligands has an angular structure (b).⁴⁴

[Pt(NCMe)Cl₅][−] (**11**) and *trans*-[Pt(NCMe)₂Cl₄] (**12**). Figure 9 presents the compositions of the HOMOs of the complexes **10–12** when they contain two linear acetonitrile ligands (*a*) and when one of the acetonitrile ligands has a bent structure (*b*). Calculations performed for the complexes **10–12** at different levels of theory (HF and MP2) and with different basis sets demonstrated that several of the highest occupied MOs of these complexes are formed from the orbitals of the chlorine atoms or, in the case of *trans*-[Pt(NCMe)₂Cl₂], from the orbitals of the metal atom without a noticeable contribution of the orbitals of acetonitrile.

Recently, similar results were obtained by Pombeiro and co-workers³⁸ for the tungsten complexes *trans*- and *cis*-[(PH₃)₂(CO)₂W(NCMe)(≡CCH=CH₂)]⁺ (Fig. 10).

Figure 10. Compositions of the HOMOs in the tungsten nitrile complexes *trans*- and *cis*-[(PH₃)₂(CO)₂W(NCMe)(≡CCH=CH₂)]⁺.³⁸

One of the highest occupied MOs of the {(PH₃)₂.(CO)₂W(≡CCH=CH₂)}⁺ fragments (the first orbital in the case of the *trans* isomers and the second orbital in the case of the *cis* isomers) is derived from a linear combination of the *d*-orbitals of the metal atom with the π - and π^* -MOs of two CO ligands. Due to a large contribution from the π^* -orbitals, the HOMO is bonding relative to the W–C bond and antibonding with respect to the C–O bond. This is indicative of the presence of π -back donation from the metal atom to the π^* -MO of a strong π -acceptor such as CO. Two other highest occupied MOs of the {(PH₃)₂(CO)₂W(≡CCH=CH₂)}⁺ fragments of the *cis* and *trans* isomers are composed of the *d*-orbitals of the metal, which also interact with the π - and π^* -MOs of one of the CO ligands and with the orbitals of the carbyne ligand. Upon the formation of the nitrile complex [(PH₃)₂(CO)₂W(NCMe)(≡CCH=CH₂)]⁺ from the {(PH₃)₂(CO)₂W(≡CCH=CH₂)}⁺ and {NCMe} fragments, the composition of the highest occupied MOs of the former fragment remains virtually unchanged and the orbitals of the nitrile ligand make an insignificant contribution to the HOMO of the complex (see Fig. 10).

In the study,⁴⁵ calixarene complexes of Ta and Nb, including those containing the coordinated acetonitrile molecule, were synthesised, their spectroscopic parameters and structural characteristics were determined, and the molecular orbitals were calculated by the Fenske–Hall method.⁴⁶ In the [Cp*Ta(NCMe)(calix[4]arene)] complex (Cp* = η^5 -C₅Me₅), the bonding interaction between nitrile and metal involves the *d*_{z²}(Ta)- and *p*_z(N)-orbitals *via* σ -bonding (Fig. 11) and the HOMO of the complex is centred on the atoms of the calixarene ligand.

The *ab initio* calculations for the tetranuclear copper(I) clusters [Cu₄(NCMe)₂L₂] (L is 2,6-dimethylaniline, 6-ethyl-*o*-toluidine or *p*-toluidine)⁴⁷ demonstrated that the *p*-orbitals of the iodine atoms make major contribution to the HOMO of the complex, whereas the LUMO is formed from the *p*-orbitals of copper. It was noted that the orbitals of acetonitrile make no substantial contribution to the frontier MOs of the complex.

Figure 11. Correlation diagram of the MOs in the nitrile complex [Cp*Ta(NCMe)(calix[4]arene)].⁴⁵

The main difference between the nitrile and isocyanide complexes is associated with weaker π -acceptor properties of nitriles compared to those of isocyanides due to which the contributions of the π - and π^* -MOs of the ligand to the MOs of the complex compensate each other and the corresponding molecular orbital is nonbonding.

The total contribution of the π - and π^* -orbitals of the ligand to the HOMOs in nitrile complexes is smaller than that in isocyanide complexes, which is also indicative of weaker π -acceptor properties of the nitrile ligands. As a result, the π -component of the coordination bond in nitrile complexes is often negligible as compared to the σ -donor or Coulombic component (see below). Hence, the DCD model must be applied to the description of the properties of the nitrile complexes with caution. Finally, analysis of the compositions of the frontier MOs of acetonitrile and methyl isocyanide⁴⁸ demonstrated that nitriles are weaker σ -donors than isocyanides due to substantially lower energy of the valence occupied σ -orbitals of NCR compared to those of CNR.

2. Structural features of metal complexes with nitriles and isocyanides

Back π -donation of the electron density from metal to the ligand has a substantial effect on the geometric parameters of the complexes. Actually, an increase in the occupancy of the π^* -antibonding orbitals of the ligand must lead to weakening of the multiple C≡N bond in the ligand and, consequently, its length must slightly increase on going from the free ligand to the complex. To the contrary, the metal–ligand bond becomes stronger due to additional π -interaction resulting in shortening of the metal–ligand bond compared to those in the related complexes in which π -back donation is absent.

In the early studies by Sarapu and Fenske,^{49,50} the presence of π -back donation in isocyanide complexes was confirmed by the X-ray diffraction data. The Mn–C(CNMe) bond length in the [Mn(CNMe)₂(CO)₃Br] complex is 0.10–0.14 Å smaller than the sum of the covalent radii of Mn and the *sp*-hybridised carbon atom, which indicates that this bond in the complex is partially double. The results of X-ray diffraction studies are in agreement with the data from theoretical calculations of MOs by the Fenske–Hall method. In particular, the substantial occupancies of the π^* -MOs of the isocyanide ligand in the [Mn(CNMe)_n(CO)_{5–n}Br] (*n* = 0–4), [Mn(CNMe)_n(CO)_{6–n}]⁺ (*n* = 0–6), [Mn(CN)(CO)₅], [Mn(CN)₆]^{5–} and [Fe(CNMe)₆]²⁺ complexes are indicative of the efficient electron density transfer from the *d*-orbitals of metal to the π^* -MO of isocyanide in spite of

the presence of such a strong π -acceptor as the CO ligand. A comparison of the occupancies of the π^* -MOs of the isocyanide and carbonyl ligands shows that the latter is the stronger π -acceptor than isocyanide and that π -back donation of the electron density from the d -orbitals of metal to the π^* -MOs of the carbonyl ligand is more pronounced than that to the π^* -orbitals of the isocyanide ligand.

It does not always happen that the expected elongation of the $C\equiv N$ triple bond takes place on going from the free ligand to the complex. For example, the calculated $C\equiv N$ bond length in the *trans*- and *cis*- $[(PH_3)_2(CO)_2W(CNMe)(\equiv CCH=CH_2)]$ complexes (1.145 and 1.147 Å, respectively) is 0.011–0.013 Å smaller than that in the free ligand.³⁸ The interactions of the $[MCP_3]^+$ fragment (M = Ti, Zr, Hf) with such ligands as NCMe, CNMe and CO, which afford the corresponding $[MLCP_3]^+$ complexes, were examined.⁵¹ It was demonstrated that the M–L bond length calculated by the DFT method increases in the series $Ti < Hf < Zr$ and $CO < CNMe < NCMe$. The authors of the cited study attributed the former tendency to the relativistic effects, which were taken into account for Hf. An increase in the M–L bond length on going from CO to NCMe correlates with weakening of the π -acceptor properties of the ligands in this series.

The variations in the $C\equiv O$ and $C\equiv N$ bond lengths on going from the free ligand to the complex are less evident. These bond lengths depend on two opposite effects.⁵² One effect, *viz.*, σ -donation from the ligand to metal $L \rightarrow M$, must lead to shortening of the $C\equiv N(O)$ bond because the corresponding occupied σ -orbital of the ligand, which is involved in the formation of the M–L σ -bond, is antibonding. Consequently, coordination of the ligand must lead to a decrease in the electron density on the σ^* -orbital, which is antibonding for the $C\equiv N$ or $C\equiv O$ bond, resulting in its strengthening. The opposite effect, *viz.*, π -back donation from metal to the ligand, must lead to elongation of the $C\equiv N$ or $C\equiv O$ bond due to an increase in the electron density on the π^* -MO of the ligand upon coordination. Taking into account weakening of the π -acceptor properties of the ligands (more precisely, a decrease in the ratio between the π -acceptor and σ -donor abilities) on going from CO to NCMe, one would expect a decrease in $\Delta r = r(C\equiv X)_{\text{comp}} - r(C\equiv X)_{\text{free}}$ (X = O, N) in this series. However, the results of calculations demonstrated that the $C\equiv O$ bond length increases upon coordination, the $C\equiv N$ bond length in isocyanide complexes decreases, whereas the corresponding bond length in nitrile complexes remains virtually unchanged (Table 1). To account for this phenomenon, the energy characteristics of the M–L bond were analysed. The energy of this bond (E_{bond}) was divided into three components $E_{\text{bond}} = -(\Delta E_{\text{Coul.}} + \Delta E_{\text{Pauli}} + \Delta E_{\text{oi}})$, where $\Delta E_{\text{Coul.}}$ characterises the Coulombic component of the M–L interaction, ΔE_{Pauli}

represents the exchange repulsion and ΔE_{oi} accounts for the contribution of the bonding orbital interaction. The sum $\Delta E_{\text{Pauli}} + \Delta E_{\text{oi}}$ represents the orbital energy (ΔE_{orb}). The results of analysis showed that the maximum contribution of $\Delta E_{\text{Coul.}}$ to the energy of the bond E_{bond} is observed in the case of isocyanide complexes, whereas this contribution in the case of carbonyl and nitrile complexes is much lower (see Table 1), which is responsible for additional shortening of the $C\equiv N$ bond in the $[M(CNMe)Cp_3]^+$ complexes. The lowest orbital energies ΔE_{orb} were found for nitrile complexes, which results in intermediate values of Δr .

It should be noted that π -back donation sometimes leads to a bent distortion of the ligand. Thus the geometry of coordinated isocyanide can be described as intermediate between two structures:

Apparently, a predominance of a particular form is determined by the relative contributions of the π -acceptor and σ -donor components to the metal–ligand bond. When the σ -donor ($L \rightarrow M$) component substantially dominates over the π -acceptor ($M \rightarrow L$) component, the ligand adopts a linear conformation. In contrast, when π -back donation becomes dominant, the multiplicity of the M–L bond increases, whereas the multiplicity of the $C\equiv N$ bond decreases, which could cause a bent distortion of the isocyanide ligand.^{39, 53}

Actually, according to the X-ray diffraction data,^{54–58} the isocyanide ligand has a linear structure in most of isocyanide complexes of transition metals in high oxidation states in which π -back donation is manifested to only a small extent, if at all. At the same time, the isocyanide ligand has an angular structure in complexes of transition metals in low oxidation states in which efficient electron density transfer occurs from the d -orbitals of metal to the π^* -MO of the ligand,^{59, 60} the C–N–C angle being contracted to 140°.

The correlation diagrams of the MOs for linear and angular methyl isocyanide⁴⁸ show that the bent distortion of the ligand leads to an increase in the energy of the π -MO and this orbital becomes the highest occupied MO, whereas the energy of the π^* -MOs decreases (Fig. 12a). Hence, the bent distortion leads to a noticeable enhancement of the π -acceptor properties of the CNMe ligand, its σ -donor properties being virtually unchanged because the energy of the π -MO in the angular ligand is only 0.008 a.u. higher than the energy of the σ -MO in the linear ligand and the π -MO is localised on the terminal carbon atom to a much lesser extent.

Table 1. The M–L, $C\equiv N$ and $C\equiv O$ bond lengths in the $[MLCP_3]^+$ complexes (M = Ti, Zr, Hf; L = CO, CNMe, NCMe), the energies of the coordination bonds and their components.

Complex	Bond lengths / Å		E / kJ mol ^{−1}			
	M–L	$C\equiv N$ ($C\equiv O$)	$\Delta E_{\text{Coul.}}$	ΔE_{Pauli}	ΔE_{oi}	E_{bond}
$[Ti(CO)Cp_3]^+$	2.09	(1.15)	−282	476	−302	108
$[Ti(CNMe)Cp_3]^+$	2.15	1.17	−337	414	−246	169
$[Ti(NCMe)Cp_3]^+$	2.18	1.16	−233	261	−164	136
$[Zr(CO)Cp_3]^+$	2.25	(1.14)	−228	365	−247	110
$[Zr(CNMe)Cp_3]^+$	2.30	1.17	−309	345	−218	182

Note. The calculated $C\equiv O$ and $C\equiv N$ bond lengths in the free CO, CNMe and NCMe ligands are 1.14, 1.18 and 1.16 Å, respectively.

Figure 12. Walsh diagrams for the bent distortions of the methyl isocyanide (a) and acetonitrile (b) molecules (the data from the study⁴⁸).

Analysis of the linear and angular structures of the nitrile ligand NCMe (Fig. 12b) demonstrated that acetonitrile exhibits very weak π -acceptor properties due to a small degree of localisation of the π^* -MO on the terminal N atom although the energy of the π^* -MO of the nitrile ligand determined in the study⁴⁸ is comparable with the energy of the π^* -MO of the isocyanide ligand. The bent distortion of the NCMe ligand must lead to weakening of its acceptor properties due to the total destabilisation of the π^* -MO. At the same time, the authors of the cited study⁴⁸ believed that essential localisation of the π -MO(NCMe) on the C and N atoms of the $C\equiv N$ bond makes acetonitrile a potentially strong π -donor ligand. These π -donor properties of the nitrile ligand are responsible for the deviation of the $M-N-C$ fragment from linearity, which is frequently observed in experimental studies. However, as shown in Section II.1, the fact that the contributions of the π -orbitals of nitriles to the HOMOs of the complexes are small refutes this assumption.

Somewhat different distributions of the frontier MOs for acetonitrile and the model NCH structure were found in the study⁶¹ (Fig. 13). The authors believed that the bent distortion of the NCH ligand leads to mixing of the σ - and π_y -orbitals and their reorientation so that overlapping of these orbitals with the orbitals of the metal atom is enhanced in the case of the lateral coordination of the nitrile ligand through the $C\equiv N$ triple bond. Hence, the bent distortions of the nitrile ligands lead to enhancement both of their donor and acceptor properties. The lateral coordination of nitrile leads to a decrease in the energy of the LUMO of the ligand and, consequently, π -back donation in nitrile π -complexes becomes substantial.

Thus the NCC fragment of the ligand is linear in the case of the standard σ -coordination of nitriles to transition metals, whereas

Figure 13. Walsh diagram for the bent distortion of the NCH molecule and the frontier MOs of the angular acetonitrile molecule (the data from the study⁶¹).

the nitrile ligand undergoes a bent distortion due to substantial π -back donation in the case of the lateral π -coordination through the $C\equiv N$ triple bond. Actually, geometry optimisation of the model complex $[CpW(\eta^2-NCH)(CO)(HC=C=O)]$ by the DFT method⁶¹ gave the $N-C-H$ angle of 135.6° .

Analysis of the electronic structures of the tungsten complexes $[W(NCH)Cl_2(PH_3)_3]$ and $[CpW(NCMe)(CO)\{C(SiH_3)=C=O\}]$ demonstrated that the π^* -MOs of the ligand contribute significantly to the highest occupied MOs of the complexes (in the case of $[CpW(NCMe)(CO)\{C(SiH_3)=C=O\}]$, to the highest occupied MO, which is the closest in energy to the HOMO) (Fig. 14).

The effect of the nature of the ligand, primarily, of its donor and acceptor properties, on the geometric parameters of other

Figure 14. Correlation diagrams of the MOs in the $[W(NCH)Cl_2(PH_3)_3]$ (a) and $[CpW(NCMe)(CO)\{C(SiH_3)=C=O\}]$ (b) complexes.⁶¹

fragments in complexes was considered in the study.⁶² In the cited study, the results of *ab initio* calculations for a series of $[\text{TaL}'(\text{OH})_2\text{H}_2]^+$ complexes with various L and L' ligands, including NCMe, were discussed (the geometry optimisation was carried out by the MP2 method). The trans effect of the ligand L on the phosphine ligand (the Ta–P distance was used as a measure of the trans effect) was considered using the $[\text{TaL}(\text{PH}_3)(\text{OH})_2\text{H}_2]^+$ complexes as an example.

Depending on the nature of the ligand L, the Ta–P distance was found to decrease in the series $\text{CH}_3^- > \text{H}^- > \text{NH}_2^- > \text{BF} > \text{CS} > \text{PH}_3(\text{A}) > \text{OH}^- > \text{CO} > \text{CN}^- > \text{F}^- > \text{NC}^- > \text{Cl}^- > \text{Br}^- > \text{I}^- > \text{NH}_3 > \text{NCMe} > \text{PH}_3(\text{B}) > \text{N}_2$. The relative stabilities of the isomers **A** and **B**

($\Delta E_{\text{AB}} = E_{\text{A}} - E_{\text{B}}$) change in the following series: $\text{F}^- < \text{OH}^- < \text{Cl}^- < \text{Br}^- < \text{NC}^- < \text{I}^- < \text{CH}_3^- < \text{CN}^- < \text{NCMe} < \text{NH}_3 < \text{N}_2 < \text{H}^- < \text{NH}_2^- < \text{PH}_3 < \text{CO} < \text{CS} < \text{BF}$ (Table 2). The ligands exhibiting strong π -donor properties reside in the left side of this series, *i.e.*, the π -donor ability of the ligands L decreases from left to right. From the above series it follows that there is no correlation between the σ -donor properties (trans effect) and the π -donor (acceptor) properties of the ligands.

It was found that the hydride atoms in the complexes **A** and **B**, which are located in the *trans* positions with respect to each other, are shifted from the stronger π -donor toward the stronger π -acceptor. If the ligands possess both weak π -acceptor and weak π -donor properties, the bent distortion is caused by the ligand exhibiting the strongest static trans effect and the hydride atoms are shifted toward the weaker σ -donor. It was proposed⁶² that the unusual bent distortion of the H–Ta–H fragment is determined by these π -donor and π -acceptor (rather than by σ -donor) properties of the ligands L.

From the above-considered data, it is evident that π -back donation sometimes has a substantial effect on the structural parameters of the complexes. One of the indicators of the efficient π -back donation is the bent distortion of the CNC or NCC fragment. However, in actual practice this distortion is uncommon even in the case of transition metal complexes in low oxidation states and, hence, the linearity of CNC or NCC cannot serve as proof of weak π -acceptor properties of the ligand in the complex.

In the general case, the relative length of the $\text{C}\equiv\text{N}$ multiple bond in transition metal complexes with nitriles and isocyanides also cannot be considered as a reliable criterion for the degree or even existence of π -back donation because the length of this bond is substantially influenced not only by two opposite effects, *viz.*, σ -donation and π -back donation, but also by the Coulombic component.^{39,51} A comparison of a series of related complexes showed that the M–L bond length is a more reliable criterion for the degree of π -back donation.

Table 2. Relative energies of the **A** and **B** isomers of the $[\text{TaL}(\text{PH}_3)(\text{OH})_2\text{H}_2]^+$ complexes.

III. Spectroscopic properties of coordinated ligands

1. Vibrational spectra

Stretching vibrational frequencies of the $\text{C}\equiv\text{N}$ and $\text{C}\equiv\text{O}$ bonds in transition metal complexes with nitriles and carbonyls[§] are influenced by several factors, including σ -donation of the electron density from the ligand to the metal atom, π -back donation from metal to the ligand and the Coulombic component of the coordination bond. σ -Donation from the ligand to metal leads to strengthening of the $\text{C}\equiv\text{N}$ and $\text{C}\equiv\text{O}$ bonds and, consequently, to an increase in their vibrational frequencies, whereas π -back donation from metal to the ligand causes weakening of these bonds and, hence, a decrease in the corresponding vibrational frequencies. In complexes with strong π -acceptor ligands, such as CO (and in some cases CNR), the latter effect generally dominates over the former as a result of which the $\nu(\text{CN})$ and $\nu(\text{CO})$ frequencies for the complexes are lower than those for the free ligands.

Actually, lowering of the $\nu(\text{CO})$ and $\nu(\text{CN})$ vibrational frequencies on going from the free ligand to the complex was predicted theoretically and observed experimentally for many carbonyl complexes as well as for a series of transition metal complexes with isocyanides (predominantly, with metals in low oxidation states).^{39,59,63,64} However, complex formation with isocyanides possessing weaker π -acceptor properties as compared to CO often leads to an increase in the $\nu(\text{CN})$ frequency. Thus theoretical analysis of the force constants and $\nu(\text{CN})$ vibrational frequencies for the $[\text{Mn}(\text{CNMe})_n(\text{CO})_{5-n}\text{Br}]$ ($n = 0-4$), $[\text{Mn}(\text{CNMe})_n(\text{CO})_{6-n}]^+$ ($n = 0-6$) and $[\text{Fe}(\text{CNMe})_6]^{2+}$ complexes demonstrated that the $\nu(\text{CN})$ frequency for the complexes is higher than that for the free ligand, which indicates that σ -donation dominates over π -back donation.⁵⁰

At the same time, detailed theoretical studies of the nature of coordination bonds in transition metal complexes demonstrated that the $\nu(\text{CN})$ and $\nu(\text{CO})$ stretching vibrational frequencies generally cannot serve as a reliable criterion for the degree of $\text{L} \rightarrow \text{M}$ donation and $\text{M} \rightarrow \text{L}$ π -back donation even for complexes with such a strong π -acceptor as carbon(II) oxide. Examples are provided by the so-called 'non-classical' carbonyl complexes, for instance, $[\text{Os}(\text{CO})_6]^{2+}$ and $[\text{Ir}(\text{CO})_6]^{3+}$. In their spectra, the $\nu(\text{CO})$ frequency is higher than that in the spectrum of the free ligand. The reason is that Coulombic interactions are of paramount importance in the formation of coordination bonds in non-classical carbonyl complexes and these interactions ultimately determine the $\nu(\text{CO})$ frequency.^{65,66} In transition metal complexes with isocyanides, which are weaker π -acceptors than CO, Coulombic interactions can exert a stronger effect on the $\nu(\text{CN})$ frequency compared to that of π -donation, which often leads to an additional increase in this vibrational frequency upon complex formation.

In nitrile complexes, the above-described tendencies are further enhanced because the nitrile ligands exhibit very weak π -acceptor properties and rather weak σ -donor properties. In this case, the Coulombic component of the metal–ligand interaction often exerts primary control over the $\nu(\text{CN})$ frequency. This fact is confirmed by the preliminary data from analysis of the natural bond orbitals performed for the *cis*- $[\text{Re}(\text{NCMe})\text{Cl}(\text{PH}_3)_4]$ and *trans*- and *cis*- $[\text{Re}(\text{NCMe})\text{Cl}(\text{PH}_3)_4]^{+/2+}$ complexes.⁶⁷ Generally, the $\nu(\text{CN})$ vibrational frequencies for nitriles are shifted to the high-frequency region on going from the free ligand to the complex.^{68–78} At the same time, there are examples of low-frequency shifts of this band upon coordination of nitriles with metals in the lowest oxidation states^{79–81} but these shifts are much smaller than those in the spectra of analogous isocyanide complexes. Finally, it should be noted that the low-frequency

[§]Spectroscopic properties of carbonyl compounds are considered for comparison.

shifts of $\nu(\text{CN})$ for nitrile η^2 -complexes in which the ligand is coordinated through the $\text{C}\equiv\text{N}$ bond are rather high,^{82–84} which indicates that this is virtually a double bond.

The spectroscopic properties of nitrile complexes were examined in several theoretical studies. Thus the vibrational spectra of the platinum complex $[\text{Pt}(\text{NCMe})\text{Cl}_3]^-$ were calculated and described in detail.⁶⁹ The $\nu(\text{CN})$ band in the spectrum of the complex is shifted by 113 cm^{-1} to the high-frequency region as compared to its position in the spectrum of free acetonitrile. Interestingly, analogous high-frequency shifts of $\nu(\text{C}\equiv\text{N})$ ($95\text{--}117\text{ cm}^{-1}$) were found for the adducts of acetonitrile with Lewis acids BF_3 and BCl_3 (Ref. 85) in which π -back donation is, in principle, impossible.

It was demonstrated that the calculated $\nu(\text{CN})$ frequency decreases from 2209 cm^{-1} for the free $\text{N}\equiv\text{C}-\text{N}=\text{C}(\text{NH}_2)_2$ ligand to 2189 and 2143 cm^{-1} upon coordination of the ligand to nickel (complexes **8** and **9**, respectively).⁴² The calculated $\text{C}\equiv\text{N}$ bond length increases from $1.163\text{ \AA}$ (in the free ligand) to 1.178 and $1.187\text{ \AA}$ (in the complexes **8** and **9**, respectively), which correlates with a change in the $\nu(\text{CN})$ vibrational frequency. However, the order in which the calculated $\nu(\text{CN})$ frequencies change is inconsistent with the experimental series $\mathbf{8} > \text{N}\equiv\text{C}-\text{N}=\text{C}(\text{NH}_2)_2 > \mathbf{9}$.

The vibrational spectra of acetonitrile coordinated to the Li^+ and Na^+ ions were calculated at the HF/6-31G and HF/6-31G** levels of theory.⁸⁶ Coordination leads to a substantial increase in the intensities of the $\nu(\text{C}\equiv\text{N})$, $\nu(\text{C}-\text{C})$ and $\delta(\text{CH}_3)$ vibrations but calculations demonstrated that their frequencies change only slightly.

Finally, mention may be made of the study⁸⁷ in which the vibrational spectra and the nature of the Fermi resonance for ruthenium isocyanide complexes **13** and **14** were analysed by the DFT method.

$\text{R} = \text{MeC}_6\text{H}_4$ (**13**), Bu^t (**14**).

In the case of the neutral complexes and their reduced forms, Fermi resonance appears due to the interaction between the fundamental frequency $\nu(\text{C}\equiv\text{N})$ [2094 (**13**), 2010 (**13**⁻), 2131 (**14**) and 2028 cm^{-1} (**14**⁻)] and the vibrational overtone B_2 (**13** and **13**⁻) or E (**14** and **14**⁻) involving deformation of the $\text{C}\equiv\text{N}-\text{C}$ fragment as the major component.

In some experimental studies (see, for example, the review⁴), it was found that the change in the $\nu(\text{C}\equiv\text{N})$ frequency correlates with the reactivities of nitrile and isocyanide complexes with respect to nucleophilic and electrophilic addition. It was shown that complexes for which the parameter $\Delta\nu(\text{C}\equiv\text{N}) = \nu(\text{C}\equiv\text{N})_{\text{comp}} - \nu(\text{C}\equiv\text{N})_{\text{free}}$ is negative are readily subjected to electrophilic attack. If $\Delta\nu(\text{C}\equiv\text{N}) > 0$, complexes are involved in nucleophilic addition at the β -carbon atom. If the contribution of π -back donation to the coordination bond is essential, the β -atom of the ligand becomes more nucleophilic due to the electron density transfer from the d -orbitals of metal to the π^* -MO of the ligand thus facilitating electrophilic attack. In contrast, if π -back donation makes only an insignificant contribution upon the formation of the coordination bond, the electron density transfer from the σ^* -orbitals of the ligand to the d -orbitals of metal leads

to enhancement of electrophilicity of the β -atom of the ligand, which facilitates the nucleophilic attack. However, detailed theoretical studies providing the interpretation of this correlation are lacking.

2. Electronic spectra and excited states

Theoretical and experimental investigations devoted to the electronic spectra and the nature of excited states of nitrile and isocyanide complexes are rather scarce. Most of the calculations were carried out in a one-electron approximation. Several electronic states of the bis(isocyanide) complexes of nickel(II) peroxo $\text{NiO}_2(\text{CNH})_2$ were studied by the unrestricted HF and CI methods.⁸⁸ It was demonstrated that the singlet state $^1A_1$ is the ground electronic state of the complex. The first excitation state is the triplet $^3B_1$ with the energy parameter $\Delta E(^3B_1-^1A_1) = 47.60\text{ kJ mol}^{-1}$. The authors of the cited study considered the electron density distribution (ρ) and its Laplacian ($\nabla^2\rho$) and analysed the natural orbitals.

Photophysical properties of the model mononuclear copper clusters CuL_n^+ ($\text{L} = \text{NH}_3$, NCMe , $\text{C}_5\text{H}_5\text{N}$; $n = 1\text{--}4$) were described.⁸⁹ These properties were interpreted with the use of the Hartree–Fock method. The nature of the low-energy excited states was examined, their energies were determined, and the assignments of the metal-to-ligand charge transfer (MLCT) bands in the spectra of these complexes were made. The first excited state of the $[\text{Cu}(\text{NCMe})_4]^+$ complex ($^3B_3$) is formed due to MLCT and the second excited state ($^3B_1$) is formed through electron transfer from the $3d$ - to $4s$ -orbitals of the metal (Table 3). The assignments of these bands in the emission spectra of these complexes were performed.⁸⁹

Table 3. Energies of the first excitation states (ΔE) and changes in the Mulliken electronic populations of the $4s$ -, $4p$ - and $3d$ -orbitals of the copper atom with respect to the ground state for the $[\text{Cu}(\text{NCMe})_4]^+$ complex.

State	ΔE /a.u.	ΔCu			
		$4s$	$4p$	$3d$	total
$^3B_3$	0.159	0.062	0.393	-0.786	-0.331
$^3B_1$	0.164	0.900	0.050	-0.796	0.156
$^3A_1$	0.179	0.905	0.056	-0.827	0.135

The nature of the low-energy excited states of the $[\text{Ag}_2(\text{dmb})_2\text{X}_2]$ complexes ($\text{X} = \text{Cl}$, Br , I ; dmb is 1,8-diisocyanop-menthane) was discussed based on the experimental data and the results of EHMO calculations.³³ The charge-transfer bands in the electronic absorption spectra were assigned and their nature was studied. The broad band in the region of $250\text{--}350\text{ nm}$ was assigned to the electron transfer from the HOMO ($\text{HOMO} - n$) to the LUMO ($\text{LUMO} + n$): $d(\text{Ag}_2)/p(\text{X}) \rightarrow \pi^*(\text{CNR})$.

A comparison of the photoelectron spectra of the $[\text{CpM}(\text{CNBu}^t)(\text{CO})_2\text{Me}]$ and $[\text{CpM}(\text{CO})_3\text{Me}]$ complexes ($\text{M} = \text{Mo}$ or W) showed³² that the replacement of the carbonyl ligand by isocyanide leads to destabilisation of the d -orbitals of the metal atom, which is manifested in shifts of stretching bands in the spectrum of the isocyanide complex to lower energies by $0.73\text{--}0.83\text{ eV}$. An analogous result was obtained in the study⁹⁰ dealing with iron pentacarbonyl $\text{Fe}(\text{CO})_5$ and the iron isocyanide complexes $\text{Fe}(\text{CNR})(\text{CO})_4$ ($\text{R} = \text{Me}$, Bu^t , SiMe_3 , Ph). The higher energies of the occupied π -MOs of the isocyanide ligand compared to those of CO (the electron ionisation energy for the π -MOs of the corresponding free ligands are 12.46 and 16.91 eV) leads to enhancement of the destabilising interaction between the valence occupied d -orbitals of metal and the occupied π -MOs of the isocyanide ligand and to weakening of the stabilising $d(\text{M})-\pi^*(\text{L})$ interaction in the pentacarbonyl complexes resulting in an increase in the HOMO energy. Hence, it was concluded that

Figure 15. Correlation diagram of the MOs in the $\text{trans-}[\text{Rh}(\text{CNBUt})_2(\text{PPh}_3)_2]^+$ (a) and $[\text{PtRh}(\text{CNBUt})_2(\text{CN})_2(\text{dmpm})_2]^+$ (b) complexes.³⁴

the isocyanide ligand is a better π -donor but a poorer π -acceptor as compared to the carbonyl ligand.

Analysis and the assignments in the electronic spectra of the $\text{trans-}[\text{Rh}(\text{CNBUt})_2(\text{PPh}_3)_2]^+$ and $[\text{PtRh}(\text{CNBUt})_2(\text{CN})_2(\text{dmpm})_2]^+$ complexes (dppm = $\text{Ph}_2\text{PCH}_2\text{PPh}_2$) were carried out based on the results of EHMO calculations for the model compounds $\text{trans-}[\text{Rh}(\text{CNBUt})_2(\text{PPh}_3)_2]^+$ and $[\text{PtRh}(\text{CNBUt})_2(\text{CN})_2(\text{dmpm})_2]^+$ (Fig. 15).³⁴ Two intense absorption bands at 397 and 317 nm in the spectrum of the former complex were assigned to the transitions $d_{z^2}(\text{Rh}) \rightarrow p_z(\text{Rh})/\pi^*(\text{CNR})/p_z, d_{xz}(\text{P})$ and $d_{yz}(\text{Rh}) \rightarrow p_z(\text{Rh})/\pi^*(\text{CNR})/p_z, d_{xz}(\text{P})$, respectively. The bands at 473 and 348 nm in the spectrum of the latter compound were assigned to the transitions $d_{z^2}(\text{Rh})/d_{z^2}(\text{Pt}) \rightarrow p_y(\text{Rh})/\pi^*(\text{CNR})/p_z, d_{xz}(\text{P})$ and $d_{yz}(\text{Rh}) \rightarrow p_y(\text{Rh})/\pi^*(\text{CNR})/p_z, d_{xz}(\text{P})$, respectively, the electron transfer from the d -orbitals of Rh to the π^* -MO of the ligand contributing significantly to the former band.

Among other studies devoted to examination of the spectroscopic properties of the complexes under consideration, noteworthy is the investigation⁹¹ in which the spin-spin coupling constants J_{HD} for the $[\text{OsL}(\text{NH}_3)_4(\eta^2\text{-H}_2)]^{(\epsilon+2)+}$ compounds (where $\text{L} = \text{Me}_2\text{CO}$, H_2O , MeCOO^- , Cl^- , H^- , $\text{C}_5\text{H}_5\text{N}$, NCMe , NH_3 , NH_2OH or CN^-) were calculated by the DFT method. For the acetonitrile complex, the constant J_{HD} is 20.8 Hz. The dependence of J_{HD} on the internuclear H–H distance was discussed.

IV. Reactivities and mechanisms of reactions with coordinated ligands

1. Isomerism and coordination modes

The coordination modes of ligands in complexes were discussed in theoretical studies.^{38, 67, 92–94} The relative stabilities of the trinuclear platinum and palladium isocyanide clusters $[\text{M}_3(\text{CNH})_2(\mu\text{-dppm})_3]^{2+}$ ($\text{M} = \text{Pt}$, Pd) with different coordination modes of the CNH ligand (isomers A–D) were studied based on the results of EHMO calculations:⁹²

According to these results, the stability of the clusters A–D changes in the series $\text{A} > \text{B} > \text{C} > \text{D}$. This order is inconsistent with the experimental data, which provided evidence that the configuration C is most stable for the platinum complex. Apparently, more precise calculation methods are necessary for the correct description of the energy characteristics.

The stabilities of the monodentate (A) and chelate (B) configurations of the model complex $[\text{Li} - \text{O} - \text{PH}_2 = \text{CH} - \text{C} \equiv \text{N}]$ were analysed theoretically (HF/6-31G*⁹³).

Calculations demonstrated that the chelate configuration of the complex is 112.6 kJ mol^{−1} more stable than the monodentate form in spite of the fact that it is characterised by the unusual Li–N≡C angle (91°).

The reactions of the Li⁺ ion with the NCH and NCMe molecules were studied by the semiempirical MNDO method and EPR spectroscopy.⁹⁴ Geometry optimisation of the LiNCH complexes revealed three minima corresponding to the structures A–C.

The heats of formation of these isomers are 46, 163 and 113 kJ mol⁻¹, respectively. The activation energy of the **C** → **B** conversion is 8 kJ mol⁻¹, which indicates that there is little likelihood that the structure **C** exists under the experimental conditions.

The geometric isomerisation of transition metal complexes was examined in the studies.^{38,67} The preliminary study of the rhenium(I) complexes *trans*- and *cis*-[ReLCl(PH₃)₄] (L = NCMe, CNMe or CO) revealed that the *cis* isomers are more stable in the presence of weak π -acceptor ligands (L = NCMe), whereas the *trans* isomers are more stable in the presence of strong π -acceptor ligands (L = CO and CNMe).⁶⁷

L = NCMe, CNMe, CO.

The opposite tendency was found for the model tungsten complexes [(PH₃)₂(CO)₂WL(≡CCH=CH₂)]⁺ (**15**) and [(H₂PCH₂CH₂PH₂)(CO)₂WL(≡CCH=CH₂)]⁺ (**16**) (L = Cl⁻, NCMe, CNMe or CO),³⁸ which contain such a strong π -acceptor as the carbyne ligand in addition to the nitrile or isocyanide ligands. If the ligand L is a strong π -acceptor (L = CO, CNMe), the *cis* isomers are more stable (L and the carbyne ligands are in the *cis* positions) (Table 4). In contrast, if the ligand L is a weak π -acceptor (L = NCMe) or an efficient σ -donor (L = Cl⁻), the *trans* isomers become more stable. The relative stabilities of the *cis* isomers compared to those of the *trans* isomers increases in the series Cl⁻ < NCMe < CNMe < CO in accordance with enhancement of the π -acceptor properties of the ligands (more precisely, with the net π -acceptor minus σ -donor abilities of the ligand). Theoretical predictions about the relative stabilities of the geometric isomers were confirmed by the experimental data on the *trans* → *cis* isomerisation of the tungsten isocyanide complexes.

L = Cl⁻, NCMe, CNMe, CO.

L = NCMe, CNMe, CO.

Based on the results of theoretical investigations^{38,67} and experimental studies,^{95–98} it can be assumed that configurations with σ -donor ligands and strong π -acceptor (in particular, CNR) ligands or with weak π -acceptor ligands (for example, NCR) and strong π -acceptor ligands in the *trans* positions are thermodynamically more stable for octahedral transition metal complexes in low oxidation states. Structures containing two strong π -acceptors, a weak π -acceptor and a σ -donor or two weak π -acceptors in the *trans* positions are less stable than the corresponding *cis* isomers. In contrast, for complexes with metals in

Table 4. Relative energies of the *trans*- and *cis* isomers of the complexes **15** and **16**.

L	$\Delta E = E_{trans} - E_{cis} / \text{kJ mol}^{-1}$	
	HF//HF	MP2//HF
[(PH ₃) ₂ (CO) ₂ WL(≡CCH=CH ₂)] ⁺		
Cl ⁻	-26.08	-27.05
NCMe	-12.56	-14.49
CNMe	11.60	10.63
CO	35.71	35.71
[(H ₂ PCH ₂ CH ₂ PH ₂)(CO) ₂ WL(≡CCH=CH ₂)] ⁺		
NCMe	-18.34	
CNMe	4.81	
CO	36.68	

high oxidation states, structures with σ -donor ligands and weak π -acceptor ligands in the *trans* positions or with σ -donor ligands and strong π -acceptor ligands in the *cis* positions appear to be stable. The question of whether these conclusions have a general character calls for further investigations.

2. Nucleophilic addition reactions

Theoretical studies of the reactivities of compounds, in general, and complexes, in particular, are usually carried out with the use of frontier orbital theory.⁹⁹ According to this theory, if the reactivity of the compound is determined predominantly by the energies and compositions of the highest occupied and lowest unoccupied MOs (the so-called frontier orbitals) whose interactions are responsible for the formation of new bonds, the reaction is orbital-controlled. If the reaction (in particular, nucleophilic and electrophilic addition) is determined predominantly by the distribution of the effective charges on the atoms involved in formation of a new chemical bond, the reaction is charge-controlled.

Among various reactions with coordinated nitriles, the nucleophilic addition at the nitrile C≡N group is of paramount importance. These reactions were considered in numerous experimental studies and reviews. The reactions of such nucleophiles as water, amines, alcohols,^{4, 100–104} thiols,^{105, 106} phosphines,^{107–109} hydrazines¹¹⁰ and oximes^{111–114} with nitrile complexes lead to the addition of the nucleophile at the carbon atom of the C≡N group, which is generally accompanied by migration of the proton from the nucleophile to the nitrile nitrogen atom. Examples of the reactions of coordinated nitriles with a number of nucleophiles are presented in Scheme 1 (all products are arbitrarily shown in the *E* configurations). It was noted that coordinated nitriles are more reactive in nucleophilic addition reactions than the free ligands, the complexes of metals in high oxidation states being more reactive than those bearing metals in low oxidation states.

Theoretical studies concerned with activation of nitriles with metals and the reactivities of coordinated nitriles in nucleophilic addition reactions are few in number. The reactions of oximes with nitriles and hydrolytic processes have received the most study (see Section IV.3). Activation of nitriles upon complex formation is often qualitatively explained by a decrease in the electron density on the carbon atom of nitrile upon its coordination to the metal atom and, as a consequence, by the enhancement of electrophilicity of the β -carbon atom thus facilitating the attack of the nucleophile on this atom. However, theoretical studies^{43, 44, 69} demonstrated that this interpretation is in doubt. Thus it was found⁶⁹ that the effective charges on the C and N atoms of the nitrile ligand, which were calculated according to Lowdin scheme, are increased on going from free acetonitrile to the [Pt^{II}(NCMe)Cl₃]⁻ complex (Table 5), i.e., the electron density on these atoms decreases due to which the ligand becomes more accessible to nucleophilic attack. However, calculations of the

effective charges according to Mulliken gave another charge density distribution and opposite results. Thus the effective charge on the carbon atom of nitrile was found to decrease on going from NCMe to $[\text{Pt}^{\text{II}}(\text{NCMe})\text{Cl}_3]^-$.

The reactivities and activation of platinum nitrile complexes in the nucleophilic addition at the $\text{C}\equiv\text{N}$ triple bond were examined.^{43,44} The *ab initio* calculations of the effective charge distributions in free acetonitrile and three platinum complexes, viz., *trans*- $[\text{Pt}^{\text{II}}(\text{NCMe})_2\text{Cl}_2]$ (**10**), $[\text{Pt}^{\text{IV}}(\text{NCMe})\text{Cl}_5]^-$ (**11**) and *trans*- $[\text{Pt}^{\text{IV}}(\text{NCMe})_2\text{Cl}_4]$ (**12**), by the HF and MP2 methods with differ-

ent basis sets demonstrated that the effective positive charge on the carbon atom of nitrile calculated according to Mulliken changes only slightly on going from the free ligand to the complex and is virtually independent of both the oxidation state of the metal atom and the total charge on the complex ion (Table 6).

Activation of nitriles in the complexes **10–12** can be partially accounted for by the orbital control. In the context of the theory of frontier orbitals, the formation of a new chemical bond upon nucleophilic addition results from the interaction between the HOMO of the nucleophile and the LUMO of nitrile. In this case, the reactivity must depend on the relative energies of these orbitals. If the reaction involves the same nucleophile, the reactivity must be governed by the energy of the LUMO of nitrile. Actually, calculations showed that the energies of the LUMOs of the complexes **10–12** are 1.5–3.5 eV lower than the energy of the LUMO (π^* -MO) of acetonitrile, which provides an explanation for the activation of MeCN in complexes. At the same time, the energy of the LUMO changes non-monotonically and insignificantly on going from **10** to **12** in spite of the noticeable enhance-

ment of the reactivity in this series of compounds. In addition, the LUMOs of the starting nitrile complexes do not virtually involve the orbitals of acetonitrile although the nucleophilic attack occurs at the carbon atom of the nitrile group (see Fig. 9a).

The nucleophilic addition reactions of oximes with the complexes **10**–**12** were accompanied by a change in the geometry of the acetonitrile fragment from linear to angular, which corresponds to a change in hybridisation of the β -C atom from sp to sp^2 . Apparently, the change in hybridisation must cause the rearrangement of the valence molecular orbitals and substantial variations in their composition and energy. Analysis of the Walsh diagrams⁴⁴ demonstrated that the change of the conformation of coordinated acetonitrile from linear to angular leads to a decrease in the energy of the LUMOs of the complexes by 0.3–0.8 eV and to variations in the compositions of the lowest occupied MOs such that the orbitals of the carbon and nitrogen atoms of nitrile contribute significantly to the LUMOs (Fig. 9b). According to the theory of frontier orbitals, this bent distortion of acetonitrile facilitates the nucleophilic addition at the β -C atom.

With the aim of providing the more rigorous description of the relative reactivities of nitriles and their platinum complexes **10**–**12**, the activation and reaction energies of the interaction of formaldoxime with these complexes were calculated. It was found that the activation energy decreases and the absolute value of the reaction energy increases in the series NCMe–**10**–**11**–**12** (Table 7), which is consistent with the enhancement of the reactivity of these compounds. Hence, activation of nitriles in complexes and their relative reactivities can be described on the basis of kinetic (a decrease in the activation energy) and thermodynamic (an increase in the reaction energy) factors.

Table 7. Activation energies of the rate-limiting step (E_a /kJ mol^{−1}) and the energy effects (ΔE /kJ mol^{−1}) of the reactions of NCMe and the complexes **10**–**12** with formaldoxime.

Compound	E_a	ΔE
NCMe	275.16	−3.85
10	265.53	−66.61
11	253.93	−75.32
12	237.52	−91.73

The mechanism of nucleophilic addition of oximes to acetonitrile and the complexes **11** and **12** was examined in detail.^{43, 115} The possible transition states and the reaction coordinates were calculated. Under non-catalytic conditions, these reactions proceed through the formation of the four-membered cyclic transition state **A** (Scheme 2).

Nucleophilic and electrophilic addition to coordinated nitriles and isocyanides at the $C \equiv N$ triple bond are of great practical importance because these reactions allow one to prepare com-

pounds possessing valuable properties, which cannot be synthesised without the use of transition metals. Nowadays, these processes call for further extensive theoretical investigations.

3. Catalytic reactions

One of the most promising and practically important directions in the theoretical chemistry of transition metal complexes is concerned with catalytic reactions whose mechanisms often cannot be studied in detail without application of theoretical methods. Actually, the idea of metal complex catalysis assumes that intermediates formed in the course of the reaction are highly labile due to which they often cannot be detected experimentally.

The mechanisms of catalytic reactions with the use of transition metal complexes have been the subject of much investigation, but the studies devoted to reactions involving nitrile complexes are few in number. Thus the mechanism of hydrolysis of acetonitrile adsorbed on Zn^{2+} ion-exchange zeolite was studied in detail by the DFT method.¹¹⁶ The reaction involves three main steps, *viz.*, hydration, isomerisation and desorption of the product. The first step includes two different processes, *viz.*, the initial activation of the reagents and the primary nucleophilic attack of the water molecule on Zn or nitrile. Of eight possible mechanisms of the first step (involving one water molecule), two mechanisms (A and B) shown in Scheme 3 are preferable (in this scheme and in Scheme 4, the calculated heats of formation of intermediates (in kJ mol^{−1}) are given below the formulae in parentheses).¹¹⁶

The first mechanism involves activation of nitrile upon coordination followed by the nucleophilic attack of the water molecule on the oxygen atom of zeolite and concerted elimination of the OH group with the simultaneous nucleophilic attack at the carbon atom of nitrile. The second mechanism (in the presence of an excess of water) consists in primary adsorption of the H₂O molecule on zeolite followed by the cleavage of the O–H bond

Scheme 3

Scheme 2

and migration of the proton on the oxygen atom of zeolite, coordination of acetonitrile to the zinc atom and migration of the OH group from metal to the carbon atom of nitrile.

The second step (isomerisation) involves conformational changes of the iminol fragment and migration of the proton from the OH group to the N atom through the formation of a four-membered transition state (or a six-membered state with the participation of the water molecule).

The third step, *viz.*, desorption of acetamide, consists in the formation of the hydrogen bond between the hydrogen atom of the OH group and the new water molecule followed by the proton transfer from the water molecule to the nitrogen atom (Scheme 4) and desorption of acetamide by itself, which either occurs directly or proceeds with the participation of acetonitrile or water molecules.

The mechanism of nickel-catalysed hydrogenation of nitriles giving rise to amines was proposed.¹¹⁷ According to the results of EHMO calculations, the addition of the first hydrogen atom most probably leads to the attack at the carbon atom of nitrile to produce imidoethylidenes $\text{CH}_3\text{CH}=\text{N}=[\text{Ni}]$. Then either the second proton adds to the β -carbon atom to form the nitrene intermediate $\text{CH}_3\text{CH}_2-\text{N}=[\text{Ni}]$ or the imidoethylidene products undergo dimerisation.

4. Other reactions

Hydrogenation of quinoline (Q) catalysed by $[\text{Ru}(\text{NCMe})_2(\text{CO})] \cdot \text{H}(\text{PR}_3)_2[\text{BF}_4]$ was studied by the CNDO/2 method.¹¹⁸ The bond between the metal atom and the acetonitrile ligand, which is located in the *trans* position with respect to the hydrogen atom, is weaker than that with another acetonitrile ligand located in the *cis* position with respect to this hydrogen atom. This arrangement facilitates the replacement of the former nitrile ligand in the reaction with Q although the reaction at the latter ligand also

can proceed to a considerable extent. Based on the results of calculations and taking into account the data from kinetic and chemical studies,¹¹⁹ the mechanism of this reaction was suggested.

In the experimental and theoretical investigation of the coordination transformations of the indenyl (Ind) ligand in the $[(\eta^5\text{-Ind})\text{MoL}_2(\text{CO})_2]^{0/+}$ complexes (L are various ligands, including NCMe and CNMe),¹²⁰ the $\eta^5 \rightarrow \eta^3$ -transformation of indenyl due to the addition of one more acetonitrile molecule to the $[(\eta^5\text{-Ind})\text{Mo}(\text{NCMe})_2(\text{CO})_2]^+$ complex was considered {this reaction did not proceed with the $[(\eta^5\text{-Ind})\text{Mo}(\text{CNMe})_2(\text{CO})_2]^+$ complex}. The driving forces for these processes were discussed based on the results of DFT and EHMO calculations.

The mechanism of the reaction of acetonitrile with dimeric lithium amide $[\text{LiNH}_2]_2$ (**17**) was examined by the MP2 and DFT methods and by the semiempirical methods (PM3 and MNDO).¹²¹ The reaction involves deprotonation of acetonitrile accompanied by the formation of the dianionic $[(\text{CH}_2\text{CN})/(\text{NH}_2)]^{2-} \cdot 2 \text{Li}^+$ complex (**18**) (Scheme 5).

The first step of the reaction affords the adduct of NCMe with the dimer of lithium amide (adduct **19**). This adduct is transformed into the 'open' dimeric complex **20**, which requires energy consumption of 47.7 kJ mol^{-1} (the MP2/6-31 + G*/MP2/6-31 + G* level, Table 8). Then, the migration of the proton from the CH_3 group of acetonitrile to the amino group occurs through the formation of a transition state (TS) to produce complex **21**. Finally, elimination of NH_3 gives rise to the reaction product **18**. Calculations by the PM3 method demonstrated that the intramolecular mechanism (including solvation) is 37.7 kJ mol^{-1} energetically more favourable than the intermolecular mechanism involving two dimeric molecules of lithium amide.

The driving forces for the chemical, electrochemical and photochemical activation of CO_2 by transition metal (Ir or Ni) complexes containing the isocyanide ligands were discussed relying on analysis of frontier molecular orbitals.³⁰

V. Conclusion

To summarise, theoretical methods can successfully be used for the solution of practically important problems, such as investigations of electronic and geometric structures, spectroscopic properties, reactivities and reaction mechanisms of coordination compounds containing nitrile and isocyanide ligands. However, in spite of the fact that transition metal complexes with nitriles and isocyanides belong to an important class of coordination compounds (from both fundamental and applied standpoints), the theoretical chemistry of these compounds remains a poorly studied field of the modern coordination chemistry and applied quantum chemistry due, apparently, to the difficulties in describing coordination bonds in isocyanide and, particularly, in nitrile complexes.

In most cases, complexes with strong π -acceptor ligands, such as carbonyls, in which π -back donation most often prevails, are successfully described with the use of the Dewar–Chatt–Duncanson (DCD) model. However, this model must be applied to the interpretation of the properties of isocyanide complexes and, particularly, of nitrile complexes with caution because, being weak π -acceptors, nitriles and often isocyanides, form coordination bonds in which π -back donation is of secondary importance. The σ -component and Coulombic interactions make a large (and often the major) contribution to the coordination bonds in these compounds. As a result, there are often no direct correlations of the properties of these complexes with the π -acceptor ability of the ligand or with the difference between the π -acceptor and σ -donor properties.

Studies of the reactivities of coordination compounds are of paramount importance in modern chemistry. This problem is most efficiently solved by the combined employment of experimental and theoretical methods. Early in the development of applied quantum chemistry, theoretical analysis of the reactivities was restricted to examination of the electronic structures of the starting compounds. However, recent studies demonstrated that detailed data on the reaction mechanisms with consideration for all possible transition states and intermediates are necessary for the correct description of the chemical properties. A knowledge of the mechanisms and driving forces for chemical reactions helps essentially in the design of chemical experiments and target-directed syntheses. Modern computation tools and theoretical methods allow one to study the reactivities of complexes using high-level approximations. There is no doubt that theoretical studies of transition metal complexes, including those with nitrile and isocyanide ligands, will attract ever increasing interest in the near future.

Microwave radiation in analytical chemistry: the scope and prospects for application

I V Kubrakova

Contents

I. Introduction	283
II. Some aspects of the influence of electromagnetic fields on solutions	283
III. Specific features of chemical reactions in a microwave field	286
IV. Microwave-assisted sample preparation in chemical analysis	289
V. Conclusion	291

Abstract. The key aspects of the effect of microwaves on the physicochemical processes in solutions and heterogeneous systems are analysed. Good prospects for the use of microwave radiation for intensifying various types of interaction are demonstrated in relation to dissolution, hydrolysis of organic and inorganic substances, complex formation by metal ions in solution and in the sorbent phase, oxidation of organic compounds, and synthesis of coordination and organic compounds. Specific features of analytical operations with microwave treatment are considered and the trends of development of analytical methods using microwaves are discussed. The bibliography includes 137 references.

I. Introduction

In recent years, a breakthrough has taken place in the development of instrumental methods used in inorganic and organic analysis, such as electrothermal atomic absorption spectrometry (ETAAS), inductively coupled plasma atomic emission spectrometry (ICP AES), inductively coupled plasma mass spectrometry (ICP MS), chromatographic and GC/MS techniques, *etc.* This is due to the need for more stringent control of technological processes, development of the analytical groundwork for the search for new raw material sources, aggravation of the environmental problems related to industrial environment pollution. Meanwhile, traditional methods used to prepare samples for analysis, which are time-consuming, comprise many stages and require large amounts of reagents, held up the elaboration of modern quick analytical procedures and hampered implementation of the most important parameters of instrumental methods. Development of more advanced methods for preparing a substance for determination of its composition has become a highly topical task in modern analytical chemistry.

The efficiency of analysis is largely determined by the rate and completeness of the underlying physicochemical processes. The search for ways of affecting these processes and controlling them in various fields of chemistry and technology has resulted in

extensive use of physical fields¹ and in the design of photochemical, catalytic and ultrasonic methods. Nevertheless, an increase in temperature has the most crucial effect on reactions in solutions and heterogeneous systems. However, slow heat transfer from the source to the sample and within the sample creates insurmountable obstacles which preclude substantial acceleration of processes under conditions of conventional (thermal) heating. An alternative way of raising the temperature of reaction mixtures is fast bulk heating on exposure to electromagnetic radiation of the microwave range.

Microwave heating differs from the traditional one by the greater volume and time gradients involved and by the fact that solutions and components of heterogeneous systems differing in composition possess unequal abilities to absorb the energy of radiation. In addition, charged species and dipoles present in the solution become oriented in the electromagnetic microwave field, which has an influence on their interaction.² This changes the yields of reaction products³ and gives rise to some specific effects² observed only under microwave heating conditions. No unambiguous interpretations of these phenomena have been proposed; an approach to investigation of chemical processes induced by microwave radiation (MW) includes comparison of the reaction rates, the compositions and yields of the resulting compounds, and the activation energies of reactions proceeding under thermal and microwave heating.⁴

This review describes systematically the available data on the use of MW for the intensification of chemical reactions, first of all, those which underlie analytical operations.

II. Some aspects of the influence of electromagnetic fields on solutions

Numerous chemical reactions proceed in aqueous solutions or, at least, in the presence of water.⁵ The processes taking place in solutions, in particular, in aqueous ones, are mediated by interactions of the reactants with the solvent. These electrostatic interactions result in the formation of ions, solvation shells and assembled structures; this may prevent the initial substances from reacting with each other. The application of external physical fields, including electromagnetic fields, not only activates diffusion and mass transfer in solutions but also gives rise to additional effects upon electrostatic interactions, namely, it changes the degree of ordering of the solvent and the structure of solvation shells of ions, deforms the electron shells of atoms and molecules, facilitates reactions between species, increases the reaction efficiency, and accelerates chemical reactions. These phenomena can be of different natures such as the influence of the field on

electrostatic interactions in solutions (an additional effect of external field), an increase in the system's intrinsic energy due to heating or the direct effect on charged species. An increase in temperature and the electric field effect have the most pronounced influence on the structure of water and solutions. Under exposure to MW, these factors are closely interrelated.

Now we consider the mechanisms of microwave heating in more detail. Microwave radiation is a form of non-ionising electromagnetic radiation whose frequency is intermediate between the infrared (IR) and radio-frequency ranges, namely, 300 to 30 000 MHz (wavelengths from 1 m to 1 cm). Since these waves are actively used in radio- and telecommunications, for industrial purposes, in science and in medicine, four frequencies are stipulated by international rules, a frequency of 2450 MHz (12.2 cm) being utilised most often. In recent years, radiation of this type is so widely employed to accelerate chemical processes and to solve applied analytical problems that some researchers have spoken about a new line of research called microwave chemistry;^{2,6} nevertheless, the data on the chemical aspects of the action of MW on reaction systems are sparse.

The mechanism of interaction of MW with matter involves absorption of the electromagnetic radiation energy by the material and scattering of the energy as heat. Although the microwave frequency corresponds to the rotational movement of molecules, in the condensed state where no free molecular rotations take place, as opposed to the gas phase, the absorption of energy immediately results in its redistribution between molecules and homogenous heating of the medium. Thus, microwave heating is a bulk phenomenon; the physical aspects of the effect of MW on a substance are described in detail in monographs dealing with the theory of dielectrics (see references in Ref. 2) and in some other studies.⁷⁻⁹

As MW passes through solutions, the transfer of energy occurs by two mechanisms, namely, due to re-orientation of the solvent dipoles in an alternating electric field and due to migration of ions of the solute, *i.e.*, through dipole rotation and ion conduction. The induced thermal motion is superimposed onto the solvent structure disordering, which is due to the orienting action of the field. The significance of each factor is dictated by the nature of the process and the reactants. It is worth noting that back in 1933, Bernal and Fowler,¹⁰ introduced the notion of 'structural temperature', according to which the influence of ions (*i.e.*, charged species which form some electric field) on water (solvent) can be likened to the action of an increase or decrease in temperature. These views can be useful for the understanding of the specific features of chemical reactions under microwave heating when the same outcome is attained at the same or even lower temperature than upon thermal heating.²

The mechanism of dipole rotation is the major one in the case of pure water or other solvents with low degrees of dissociation. The heating rate and the temperature that can be obtained largely depend on the radiation frequency, the initial temperature of the solution and on the solvent properties, in particular, the dielectric constant. Figure 1 shows the experimental curves characterising the microwave heating of water and some organic solvents.

The dielectric properties of free and bound (present as aggregates in a substance) water molecules are somewhat different;¹¹ as a consequence, they possess different capacities for absorbing the microwave radiation energy. This difference can be clearly seen when examining drying in a microwave oven of ferrimanganese concretion samples (FMC),¹² which are layered structures binding water molecules in different ways. When dried under conventional conditions, FMC initially lose the absorbed water and then the water incorporated in the structure of the minerals.¹³ A similar stepwise removal of water also occurs in a microwave field, and the curves for the loss of weight by the samples during microwave heating for several minutes reveal the presence of different H₂O forms. This selectivity in the absorption of the radiation energy by the solvent molecules bound in different ways has also been used^{11, 14, 15} in microwave extraction techni-

Figure 1. Effect of microwave radiation on the variation in the temperature (T) of solvents (1–5) and the pressure (P) of the vapour (1'–5') in a closed vessel: (1, 1') dimethyl sulfoxide; (2, 2') water; (3, 3') propan-2-ol; (4, 4') dichloromethane; (5, 5') hexane (t is the time of microwave treatment).

ques.[†] The stepwise pattern of variation of the absorptivity of aqueous solutions of alcohols, indicating the presence of different molecular structures, has also been noted in other publications.^{16, 17}

Yet another mechanism of the microwave heating is related to the effects of conduction, which may be due to electrophoretic ion migration in solution or the transfer of charged species in a solid upon application of an electromagnetic field. The contribution of the ion conduction mechanism in solutions is determined by the sizes, charges and the electrical conductivity of ions;⁸ in addition, this value depends on the interaction of ions with solvent molecules. The ion conductivity depends on the concentration, ion mobility and the solution temperature. Compounds with high dissociation constants absorb efficiently the microwave energy.

The relative contribution of each of the two mechanisms of transformation of the MW energy (dipole rotation and ion conduction) depends substantially on the temperature. For small molecules such as water molecules or molecules of other solvents, the dielectric loss caused by the contribution of the dipole rotation

[†] The term 'microwave extraction' is often used in the literature to describe the extraction of useful components of different natures by any solvent on exposure to MW. Here, this term is used to imply the extraction of organic components by organic solvents.

decreases with an increase in the temperature.^{8, 18} Conversely, the dielectric loss due to ion conduction increases with an increase in the sample temperature, and the effect of MW on charged species becomes more significant. Due to the diversity of factors which influence the warming-up of a solution exposed to MW, modelling of this process is currently considered to be impossible,² although a physical model that allows the calculation of the change in the solution temperature in an open system has been proposed, the mechanisms of gaining and losing energy through the solution have been analysed,¹⁹ and the theoretical aspects of the microwave heating of solids have been considered.^{20, 21}

It is generally believed among the analysts who use laboratory microwave systems mainly for the routine digestion of samples that fast heating is the major or the only consequence of action of a microwave field on solutions. Indeed, the MW frequency approximately corresponds to the frequency of the rotation of molecules but the energy of a quantum per mole ($\sim 1 \text{ J mol}^{-1}$) is too low to cleave not only chemical bonds (the energy of a C–H bond is 350 kJ mol^{-1}) but also hydrogen ($\sim 20 \text{ J mol}^{-1}$) and even van der Waals bonds (2.5 J mol^{-1}).¹¹ However, regarding chemical transformations, the changes in the structures of the solvent and solvated ions are especially important because, as noted above, it is the solvation shells that hamper the occurrence of reactions involving ions and molecules; the electron density redistribution in molecules and conformational changes induced by an electromagnetic field are equally important.

It can be seen from Fig. 2 that an electromagnetic field brings about a substantial change in the state of the ion shell; as a consequence, the ion should become much more reactive and accessible for a nucleophilic attack. The electron density shifts very rapidly (in 10^{-14} s)²³ (electron polarisation), and then it is 'fixed' in the field with the given frequency over a period of $2.5 \times 10^{-9} \text{ s}$; the positions of the ions and molecules themselves change to a much lesser extent. During the indicated period, a field-activated ion present in aqueous solution can participate in $10-10^3$ collisions. This is important, for example, when microwave heating is used to accelerate substitution in the inner coordination spheres of complexes with inorganic ligands or in the molecules of organic compounds where steric factors and configurations of the reacting species are rather significant. In particular, acceleration of complexation caused by microwave

treatment has been observed for various elements and sorbents in different sorption regimes at the same temperature as in the case of traditional heating.²⁴⁻²⁶ Note that the displacement of the electron density in an electromagnetic field does not depend on the temperature and can be attributed to so-called non-thermal effects.

Direct evidence for the change in the state of solvated (hydrated) species in a microwave field has also been obtained. Circular dichroism measurements provided experimental data on the change in the spatial structure of protein molecules, which is known to be largely formed due to hydration of polar groups in the polypeptide chains by water molecules. Experiments carried out[‡] at different temperatures with either thermal or microwave heating of an aqueous solution of erythropoietin demonstrated that thermal heating at 65°C is equivalent to exposure to MW at 45°C over a period of time which makes only 7% of the overall experiment duration (recall the Bernal and Fowler's structural temperature).

We have also observed destruction of colloid particles of soil in an MW field; thus the microstructure of the particles formed by hydrated layers was identified; the solution temperature did not exceed 50°C .

Microwave treatment can induce additional thermal effects related to the nature of the influence of the radiation on the system. In the case of conventional heating, the number of boiling centres in the solution bulk is much smaller than that near the surface. The microwave heating takes place from the inside, uniformly throughout the whole bulk; therefore, the temperature of the solution is higher than the temperature of the surroundings (vessel walls, the gas phase above the solution, *etc.*).²⁷ As a result, the solution can be heated to a temperature exceeding its boiling point under atmospheric pressure, which has been shown experimentally using various physical methods^{2, 3} (Table 1).

Table 1. Change in the boiling point (b.p.) of liquids of different natures under microwave radiation conditions.^{2, 3}

Solvent	b.p. /K		$\Delta \text{b.p. /K}$
	traditional heating	microwave heating	
Water	373	377	4
Methanol	338	357	19
Ethanol	352	376	24
Propan-2-ol	355	373	18
Tetrahydrofuran	339	354	15

Ethyl acetate	351	368	17
Dimethylformamide	426	443	17
Diisopropyl ether	342	358	16

One more mechanism of interaction of MW with the matter is possible in heterogeneous systems, which is due to interface phenomena (interfacial polarisation). The thermal effects thus arising are used to heat mixtures of dielectrics with compounds that poorly absorb the MW energy.²⁸ The non-uniformity of heating caused by different abilities of substances to absorb the MW energy gives rise to non-trivial results upon bulk removal of water, synthesis on solid surfaces and the preparation and use of catalysts.^{2, 29} The difference in the ability of the initial reactants

Figure 2. Change in the state of the ionic environment in a microwave field (a) and electrophoretic effect (b).²²

[‡] We carried out these studies together with N V Bovin (Institute of Bioorganic Chemistry, Russian Academy of Sciences).

and reaction products to absorb the MW energy can give rise to self-catalysed reactions.³⁰

The course of chemical processes and the composition of the resulting products are influenced by one more important factor, the time gradient of heating ($\Delta T/\Delta t$), which is much higher in the case of microwave treatment than in the case of conventional heating of solutions. When several competing reactions with different rate constants take place simultaneously, the probabilities of formation of particular products in the very narrow temperature range under the action of MW can differ appreciably from those observed under conventional heating. The same is true for equilibrium processes in which the rate constants for the forward and back reactions are different. This fact has been considered³¹ as the reason for the higher selectivity of some processes of organic synthesis under microwave heating.

III. Specific features of chemical reactions in a microwave field

This Section covers the main types of reactions widely used in analytical practice.

1. Hydrolysis of inorganic and organic compounds

The effect of MW on reaction systems is most pronounced in the case where the radiation energy is absorbed directly by a reactant. In some cases, a reactant acts simultaneously as the reaction medium. Evidently, MW should have a substantial influence on hydrolysis because water efficiently absorbs energy of electromagnetic radiation.

Hydrolysis induced by MW has been used to synthesise organic compounds,^{32,33} to cleave the peptide bonds in proteins when determining their amino acid composition,^{34,35} and to study the composition of a number of other natural compounds.^{35,36}

Hydrolysis of inorganic compounds in a microwave field has been studied³⁷ in relation to the exceptionally stable polynuclear iridium sulfate complexes. The uncertainty in elucidation of the composition of these complexes is the main cause for the analytical problems arising during determination of iridium in sulfate solutions by various methods. The mononuclear chloride complex of iridium was prepared upon hydrolysis and destruction of the iridium sulfate complex on exposure to MW with subsequent transformation of the resulting aqua hydroxo complex into the chloride complex on treatment with NaCl in HCl. Microwave irradiation accelerates deprotonation and hydrolysis. The degree of transformation of sulfate complexes of iridium into the chloride complexes is linearly dependent on temperature, which indicates a substantial contribution of thermal effects to acceleration of the reaction. However, it has not yet been explained why the metal is stabilised in the higher oxidation state under the action of MW.

The rigorous conditions of hydrolysis, namely, concentrated acid and elevated temperature, ensure the cleavage of most of hydrolysable bonds in organic compounds. However, in many cases, these conditions also promote undesirable side processes, in particular, destruction of either initial compounds or reaction products. The efficiency of using microwave treatment for performing such reactions was first demonstrated by Majetich and Hicks.³⁸ Of special importance is the choice of conditions for mild and, simultaneously, selective hydrolysis for the removal of protective groups. Under microwave heating, the occurrence of these reactions is markedly facilitated.³³

Microwave-enhanced hydrolysis has been used for analytical purposes in the synthesis of macrocyclic compounds³⁹ that have found application as reagents for determination of metals. Acid hydrolysis of *p*-toluenesulfonyl protective groups under conditions of thermal or microwave heating has been studied in relation to a number of macrocyclic compounds and their linear fragments.^{40,41} The possibility of stepwise hydrolysis under the action of radiation and, hence, targeted control of reaction products has been demonstrated. Compounds have been synthesised that could not be prepared in the given reaction system

upon thermal heating. The achieved effects are caused, most likely, by the sharp increase in the temperature of the reaction mixture under conditions of microwave heating (to 200 °C for 2 min), which is due, to some extent, to the absorption of the radiation energy by the substrate;⁴ according to some views,⁴² this substantially activates the reactions.

2. Complexation of metal ions with organic reagents

The kinetic inertness of the coordination compounds of a number of metals towards substitution is often an obstacle hampering the practical use of complexation reactions.⁴³ The use of MW for the solution of various problems related to complexation has been described only in a few publications. For example, it was demonstrated that coordination compounds of transition and noble metals, in particular, chromium, ruthenium, iridium, platinum and gold, with organic ligands can be synthesised efficiently under microwave heating.^{44,45} The analytical aspects of complexation of inorganic ions in solutions and in the phase of complexing sorbents under the action of MW (sorptional collection of palladium and rhodium⁴⁶ and chromium²⁶ using nitrogen-containing sorbents, the formation of complexes by the platinum metal and chromium in solutions) have been considered.^{25,47–50} A reaction with microwave heating between cadmium or cobalt ions and immobilised reagents, bromothiazole and 1-(2-pyridylazo)-2-naphthols,⁵¹ prepared using MW, has been described.⁵² The possibility of synthesising coloured compounds of platinum metals for spectrophotometric determination of metals in a flow system on exposure to radiation has been demonstrated.^{53,54} A study⁵⁵ has been devoted to the targeted synthesis of binuclear tetraacetate, the initial compound for the coulometric determination of rhodium, in the solution to be analysed. The general regularities of MW-assisted complexation identified for the above-listed systems are considered below.

a. Complex formation in solutions

The reactions of metal ions with nitrogen-, sulfur- or oxygen-containing reagents under routine conditions can involve ligand desolvation and conformational changes, hydrolysis and desolvation of metal ions, changes in the metal oxidation state (usually, reduction to a more labile state), and the formation of a complex (metal–ligand interaction), which is complicated in some cases by the formation of polynuclear complexes.^{47,49,56} For complexation under microwave heating conditions, it is most often impossible to separate the contributions of thermal effects and the field effects on the electrostatic interactions of particles. According to the Arrhenius equation, the rate constants of the slowest reactions increase most appreciably as the temperature rises. The orienting action of the field can play a crucial role in the case of sterically hindered transformations, for example, those involving large molecules of organic compounds which react with metal ions according to the nucleophilic substitution mechanism.

The most comprehensive information on the intensification of complexation under the action of MW has been obtained for platinum metal compounds (Table 2) some chemical forms of which are extremely inert towards ligand substitution.⁴³ It was found that radiation substantially intensifies the reduction of metals (at the same temperature),^{25,50,57} markedly shortens the reaction time and often makes it possible to exclude the use of stabilising additives. The composition of complexes thus formed does not change. The labilising action of MW is so pronounced that the efficiency of complexation does not depend on the initial form of the metal. This allows the use of MW for reagent-free activation of inert coordination compounds.⁵⁸

b. Complex formation in the sorbent phase

The sorption of metal ions on sorbents with fixed complexing groups depends not only on the chemical reaction but also on the diffusion of metal ions both from the solution to the sorbent (outer diffusion) and in the sorbent pores (inner diffusion). It was noted that in the reaction of cobalt ions with the modified silicic

Table 2. Effect of microwave radiation on the time (*t*) of metal complexation with organic reagents in solution.

acid xerogel, microwave heating increases the rates of both the outer and inner diffusion.⁵¹ Acceleration of diffusion processes on treatment with physical fields of various natures has also been described in other publications.^{20, 21, 59–61}

The extraction of noble metals by the POLYORGS IV sorbent containing 3(5)-methylpyrazole groups has been studied under static conditions.^{12, 46} The action of MW substantially accelerates the process (which takes place at the solution boiling point) both for rhodium, which reacts with sorbent groups by a complex-formation mechanism,⁶² and for palladium and platinum (which react by the ion-exchange mechanism⁸). Similar results have been obtained for sorption on POLYORGS XI-H,²⁴ the degree of rhodium collection in a microwave field being higher than that with conventional heating. The observed acceleration of sorption has been explained by the influence of the electromagnetic field on the state of the complex ion and electrostatic interactions in solution. Under conventional conditions, similar results can be attained by adding alkali metal salts, which destroy the structure of the solvation shells of ions; however, the effect of a microwave field is much greater.¹²

Microwave treatment has markedly enhanced the efficiency of collection of chromium ions, especially Cr(VI), by the DETATA sorbent.^{26, 63} Almost complete separate extraction of Cr(III) and Cr(VI) from solutions with pH 7 and 3, respectively, can be attained only using MW. An EPR study of the possible changes in the Cr(III) coordination sphere during the reaction with the aminocarboxy groups of the sorbent showed that the spectra of the complexes obtained at room temperature with conventional heating and in a microwave field are identical. This indicates that the same complex species of Cr(III) are formed under different conditions and that the factors influencing the reaction rate make the predominant contribution to the increase in the efficiency of sorption extraction of chromium on exposure to MW. Obviously, the same factors increase the efficiency of preconcentration of chromium ions by sorption in a flow regime and make it possible to increase the solution flow rate from 0.4–0.5 to 10 ml min^{–1}. Similar results have been obtained in a study of the reaction of cadmium ions with silicic acid xerogels modified by organic reagents.⁵¹

3. Oxidation of organic compounds by inorganic acids

Oxidation of an organic matrix with nitric acid is a widely used analytical operation. Study of the mechanism of oxidation of organic compounds including natural products in a microwave field^{64–67} showed that, as in the case of traditional heating, the

major reaction products include, apart from carbon dioxide and water, nitro-substituted aromatic acids, which decompose at temperatures above 260 °C. The same composition of the oxidation products obtained in the conventional and microwave heating modes suggests that the reactions follow the same pathways. However, the rates of oxidation are substantially different: decomposition of organic matrices at the same temperature is much faster with microwave heating than with traditional heating both in open and closed systems.^{67, 68} No unambiguous interpretation of this fact can be found in the literature; therefore, it seems important to compare the quantitative characteristics, for example, the activation energies (*E*_a) of the processes that take place under different conditions. The first attempt to solve this complicated experimental problem was made by Pratt,⁶⁹ who showed that the *E*_a values for the oxidation of amino acids (phenylalanine and tryptophan) with nitric acid under conditions of conventional and microwave heating are equal.[¶]

Bacci *et al.*⁷¹ were the first to use heating of the reaction system by microwave radiation when determining the thermodynamic functions and kinetic parameters. Microwave heating at a rate of 6.0–7.5 K min^{–1} was combined with simple photometric recording of the absorbance of the resulting complex. This technique appears efficient because the experiment can be carried out quickly and no temperature gradients exist in the solution; however, special experimental equipment is required.

In recent years, continuous temperature variation⁷² has been used to estimate the activation energies of various processes ranging from enzymic reactions to evaporation of atoms in electrothermal atomic-absorption spectrometry (dynamic method). This method is based on a logarithmic dependence of a parameter proportional to the concentration of an element or a substance in the analytical volume on the reciprocal temperature. This dependence is used to calculate the activation energy of the process using the Arrhenius equation from the slope of the straight line plotted in the ln *P*–*T*^{–1} coordinates, where *P* is the sought-for parameter (in particular, pressure) and *T* is absolute temper-

¶ Only sparse data on determination of *E*_a under conditions of microwave treatment can be found in the literature. The researchers' opinions concerning the coincidence of the activation energies of processes carried out with traditional and microwave types of heating are different. For example, the activation energy for sintering of alumina calculated for microwave heating⁷⁰ is several times lower than the *E*_a value for this process carried out with traditional heating. Apparently, this is due to the specific character of microwave heating, namely, high temperature and time gradients and a change in the ratio of contributions of various reactions to the overall process under these conditions. A refined mathematical model describing the temperature–time distribution in solid metal oxides heated by MW has been reported.²⁰

§ Acceleration of cation exchange processes has also been described by Mingo and Baghurst.⁷

ature. An important aspect in using the dynamic method is substantiation of the applicability of experimental results to the construction of the Arrhenius plot and determination of the thermodynamic characteristics of the processes.

Modern commercially produced laboratory microwave systems are equipped with fibre-optics sensors for direct measurement of the temperature of the reaction mixture, by monitoring systems of the pressure in the vessel and facilities for data recording in graphical and digital forms at 1–30 s intervals. Hence, this equipment can be used to study processes during which the pressure in the system varies together with the temperature, in particular, due to the formation of gaseous reaction products. This formed the basis of a mathematical model for the kinetics of a chemical reaction⁴ proceeding in a closed vessel under the action of MW, which was developed in the simple approximation of homogeneous distribution of the temperature and pressure in the system. The above-considered dynamic method for determination of the activation energy for the oxidation of organic compounds by nitric acid from the experimental exponential dependence of the system pressure on the reciprocal temperature of the reaction mixture was substantiated.

Microwave oxidation of individual organic compounds (amino acids, stearic acid, monosaccharides) forming the basis for the most important natural products (proteins, fats and carbohydrates) has been studied.^{73,74} Figure 3 shows the temperature and pressure variation in the system vs. time during the oxidation of phenylalanine by nitric acid; Figure 4 presents the Arrhenius dependence of the total pressure in the system, which is proportional, in the chosen approximation,⁴ to the rate constant

Figure 3. Effect of microwave radiation on the variation of temperature (1) and pressure (2) in a closed vessel during oxidation of phenylalanine by nitric acid.⁷⁴

Figure 4. Arrhenius dependence of pressure on temperature during oxidation of phenylalanine by nitric acid under conditions of microwave heating ($E_a = 50.1 \text{ kJ mol}^{-1}$).⁷⁴

for the oxidation, on the reciprocal temperature. The data for the calculation of the activation energies for the oxidation of some model compounds and natural products are listed in Table 3. These values fall in the normal range of the E_a values typical of reactions of this type carried out with traditional heating (40–120 kJ mol^{-1})⁷⁵ and are correlated with the strengths of chemical bonds in the molecules of these compounds.

The approach to the determination of the activation energy of oxidation used in this work was implemented within the framework of formal kinetics and the views of the collision theory in which the pre-exponential factor $A = zN$ in the Arrhenius equation $k = A \exp[-E_a/(RT)]$ reflects the influence of the steric factors (N) and the number of collisions (z). In addition, this approach does not contradict interpretation of the results obtained in terms of the transition state theory. In this case, the activation energy correlates with the enthalpy of formation of the activated complex, and the pre-exponential factor is correlated with entropy. The former correlation leads tacitly to a fundamentally important conclusion stating that the reaction pathway remains invariant irrespective of whether it is induced by microwave or traditional thermal heating, and the latter correlation attests to an important role of the entropy factor, *i.e.*, the orienting influence of the electrical component of a microwave field on the reacting species. Thus, acceleration of chemical reactions by microwave radiation is due to kinetic factors. Hence, microwave heating can be used not only to affect physicochemical processes in solutions or heterogeneous systems but also for fast determination of the quantitative characteristics of reactions and modelling of kinetically hindered transformations.

4. Synthesis of organic compounds

Within the scope of this review, which is mainly devoted to the processes used in the chemical analysis and accelerated by microwaves, it is also pertinent to touch upon some aspects of organic synthesis. First, for many reactions involving organic compounds, the reaction mechanisms, the roles of the solvent and the composition of the reaction mixture and reaction conditions have been studied in sufficient detail. This makes easier the identification of the effects caused by the additional external treatment and promotes the understanding of the general mechanisms of the microwave influence on chemical transformations. Most of the results unexplainable in terms of thermal effects alone and most studies analysing the patterns of MW influence on the course of reactions refer to the processes of organic synthesis.^{2,3,42} Second, diverse compounds of the organic nature (solvents, extractants, polymer-based sorbents, complexing reagents including macroheterocycles) play an enormous role in analytical research, and development of methods for preparing them remains a topical task.

The extensive use of MW for synthetic purposes started in 1986.^{76,77} Acceleration in a microwave field of many organic reactions such as elimination, esterification, cycloaddition, isomerisation, substitution, hydrolysis, dehydration, condensation, *etc.*, has been noted.^{2,3,42} In some cases, the reaction time

determined on the basis of the product yield can be shortened by three orders of magnitude.⁷⁸ The reaction conditions are exceptionally diverse — at atmospheric or elevated pressure, in a flow, in aqueous or non-aqueous solutions, on a solid surface^{2, 42, 79} and in the solid phase.⁸⁰ A laboratory setup has been elaborated for microwave organic synthesis⁸¹ carried out at high pressures (up to 100 atm) and at a temperature of up to 260 °C.

The decrease in the solution viscosity, heating of the solution to a temperature higher than the boiling point, change in the electron density distribution in the molecules of organic compounds and in the contribution of the products of competing reactions are, apparently, the main factors inducing the effects observed when organic reactions are carried out under microwave radiation. It has been shown⁸² that the kinetics and the order of reactions do not depend on the method of heating. However, some abnormal features may arise on exposure to MW.⁸³ In competing reversible reactions,³¹ the rate of warming-up of the reaction mixture plays the most important role because the ratios of the products formed are different at different temperatures. Fast microwave heating allows one to perform the reaction at a strictly specified temperature and to minimise the duration of the temperature variation step and, hence, to avoid conditions that may bring about the formation of undesirable products. In some cases, the abnormally high selectivity and substantial yields of the reaction products for the reactions taking place in the presence of catalysts or on supports after the removal of a solvent, can be explained by the selective heating of separate sections of the surface on which the reaction takes place, due to the microwave irradiation. A sharp increase in the yield (from 2% to 92%) of the product of intramolecular rearrangement of unsaturated ketones has been noted⁸⁴ (the results were obtained from conventional and microwave heating, respectively, at the same temperature; the publication cited contains no kinetic data⁸⁴). The synthesis of acetylene in a yield of >90% by microwave cracking of benzene has been reported⁸⁵ (the thermal cracking of benzene scarcely takes place). The reaction mode also has a certain influence on the product yields. For example, the increase in the yields of products in some organic reactions induced by microwave radiation was reported to be more pronounced in the flow mode than in closed vessels.⁸⁶ This fact was attributed² to the higher surface area of the reaction mixture in the case of flow systems, because the action of MW on the surface increases the contribution of the interfacial polarisation mechanism.

It has been suggested in a review⁴² generalising the results of a large number of synthetic studies dealing with the use of MW that, if the radiation energy is absorbed only by the solvent, the acceleration of reactions with respect to those proceeding by conventional heating will not be significant. If the radiation interacts with either the reactants or intermediate compounds, the increase in the reaction rate can be appreciable. The absorption of the radiation energy by not only the solvent but also the reacting substances is observed, in particular, for polymerisation processes.^{87–89} This makes it possible to control the conditions of synthesis with high accuracy and to reduce the energy expenditure by a factor of 10–20. The polymers produced in this way often possess better physical properties, for example, higher strengths,³ than the polymers synthesised with conventional thermal heating,⁴² although the structures of both types of polymer are similar.

The conditions used to conduct reactions are diverse, and the outcome depends appreciably on the type of the process, the nature of the solvent and the reactants, the radiation power and the way of irradiation,⁴² because these factors determine the degree of action of MW on the reaction system. For example, variation of the conditions of emulsion polymerisation of acrylates allows, apart from shortening of the polymerisation time by a factor of 60,⁹⁰ the synthesis of poly(*p*-nitrophenyl acrylates) with molecular masses ranging from 40 000 to 180 000.

IV. Microwave-assisted sample preparation in chemical analysis

The preparation of samples for the measurement of the analytical signal from a particular component can include drying, ashing, mineralisation, decomposition (dissolution) and preconcentration (matrix separation). The sample pretreatment operations are based on various chemical reactions and physicochemical interactions involving components of the sample. Many of these reactions (hydrolysis, oxidation, complexation) have been considered above; their typical features observed under microwave heating also remain valid for sample pretreatment processes. Despite the obvious similarity of the occurrence of chemical reactions under thermal and microwave heating, significant additional effects can be attained in the latter case by using the specificity of warming-up induced by radiation. The development of microwave-assisted sample preparation techniques has been the subject of hundreds of papers, two monographs^{2, 8} and several reviews.^{11, 15, 18, 58, 63, 91–95}

1. Drying

Owing to the direct absorption of the MW energy by H₂O molecules, heating and vaporisation of water present in the pores of a material proceed much faster than under conventional conditions. Unlike the situation with traditional heating, warming-up of the material becomes less pronounced as water is removed, and by the end of the process, the sample temperature decreases.

It is expedient to carry out microwave-induced drying for individual substances, for example, in the preparation of inorganic specimens,⁹⁶ or in those cases where the accuracy of analysis is not subject to stringent requirements. This is due to the fact that it is difficult to select conditions for the microwave drying of materials with mixed or variable composition⁹⁷ because water molecules bound to the matrix in different manners absorb the MW energy to different extents. If a determination reproducibility equal to several percent is admissible, drying in microwave ovens has a substantial effect.^{2, 12, 98} The results of early studies on the use of microwave drying are summarised in a monograph,² and the most recent achievements along this line have been reported.⁹⁹ An interesting way of using MW for drying of silicic acid gels in the preparation of modified xerogels has been proposed.⁵¹

2. Ashing and fusion

These operations involve no direct action of MW on the substance under analysis; as in the case of conventional heating, the material is warmed up by the muffle furnace walls, which are heated extremely rapidly (in several minutes) to 1200 °C due to the efficient absorption of the radiation energy by silicon carbide, which is the material of the internal walls.⁸ As a consequence, the time required for the furnace to be heated is markedly shortened and the efficiency of the method increases. The duration of the ashing decreases several-fold because of the use of forced convection; fusion can also be carried out 1.5–2.0 times faster.

3. Digestion

One of the most important applications of microwave systems in analysis is to decompose samples having highly diverse compositions and origins. Since the first publication¹⁰⁰ dealing with the use of a microwave oven to accelerate the sample pretreatment appeared in 1975, numerous expedients and techniques of microwave decomposition suitable for virtually any type of object have been developed; they are covered in the above-mentioned monographs^{2, 8} and reviews.^{18, 58, 63, 91–95} We shall note only typical features of this method for sample digestion.

Decomposition of substances on treatment with inorganic acids is a heterogeneous reaction the rate of which can be determined by either diffusion processes or interactions at the solid–solution interface. In both cases, treatment with MW substantially accelerates the processes involved. The regularities

considered above established for individual reactions (shortening of the reaction time, decrease in the reactant ratio down to stoichiometric amounts, an increase in the completeness of reactions) are clearly manifested in decomposition processes.

Microwave digestion is carried out using the same reagents (most often, acids and their mixtures) as that induced by conventional heating.[†] Treatment can be carried out both in usual open vessels made of materials which slightly absorb MW (glass, quartz or fluoroplastic) and in closed systems at elevated temperatures and pressures. This allows the mixture under analysis to be heated to a temperature markedly exceeding the boiling point of the used acid under normal pressure; therefore, both the rate and the degree of transfer of the sample into a solution become much higher. An important advantage of microwave-assisted digestion in closed vessels is low pressure with a relatively high temperature (see Figs 1, 3), due to the fact that radiation causes heating of the liquid but not of the gas phase.

Since the temperature of decomposition dictates the range of applicable acids, an increase in this temperature often makes it possible to replace high-boiling perchloric, sulfuric or phosphoric acid by hydrochloric or nitric acid, which are more convenient for digestion. In some cases, the higher degree of sample dissolution at higher temperatures makes it possible to eliminate the stage of fusion of the residue after sample dissolution in acids.

It is fairly useful to apply microwave heating for decomposition of organic matrices (biological and clinical objects, pharmaceutical preparations, foodstuffs, forages, food raw materials and ecosystem components). In this case, the time of analysis can be appreciably reduced. Decomposition of organic matrices can be carried out in both closed and open systems. The use of open systems is recommended for working with large amounts (up to 10 g) of materials when considerable amounts of gaseous products of oxidation are evolved during the process. In combination with modern, highly sensitive methods of analysis (for example, atomic spectroscopy techniques such as ETAAS, ICP AES or ICP MS) in which determination of elements at a level of $10^{-6}\%$ – $10^{-5}\%$ can be accomplished using fractions of a gram of the material, closed or flow systems are used more frequently. Flow setups represent a step towards automation of the analysis, attained by connecting a flow system for sample digestion to the injecting device of a spectrometer. The samples are commonly introduced in the systems as suspensions in acids.^{101,102} The publications describing the use of microwave heating for decomposition of organic matrices are devoted, most of all, to determi-

nation of trace elements and identification of the species containing them in environmental and biological objects by instrumental methods.^{18,26,65–67,103–106}

Decomposition of inorganic matrices often requires drastic conditions; therefore, for this purpose, it is expedient to use closed vessels, which are applicable up to a temperature of $\sim 350^\circ\text{C}$ and a pressure of 200 atm.^{107–109} These conditions may ensure dissolution of the most complex geological specimens (for example, those containing noble metals), poorly soluble oxides (such as niobium and tantalum oxides), metals, alloys or catalysts.^{18,110,111} The use of microwave setups including automated or robotised ones acquires special significance in the analysis of radioactive specimens.¹¹² Data on the time required for preparation of some substances for the analysis using traditional and microwave heating procedures are compared in Table 4.

The main causes for the intensification of sample digestion in the case of microwave treatment include high rate and uniformity of heating of the reaction mixture; exceeding of the boiling point corresponding to the given pressure; and local effects (warming-up of the solvent in the sample pores, *i.e.*, actually, in a confined space, and sample destruction under high pressure; selective heating of components of heterogeneous systems; reflection of the radiation to the near-surface layer of the solution in the case of digestion of metallic samples). Indeed, according to our data, the dissolution of gold alloys under microwave heating is twice as fast as that at the same temperature achieved by conventional heating.

The specific features of microwave digestion have a substantial influence on the metrological characteristics of the results. Due to good reproducibility of decomposition conditions, it is possible to obtain solutions of virtually identical compositions from identical samples, which is favourable for the reproducibility of the subsequent determination. The work with stoichiometric or nearly stoichiometric reactant ratios leads to a considerable decrease in the blank correction. A decrease in this value is also attained owing to use of closed or flow systems, which eliminates the loss of the analyte as volatile compounds and the ingress of contaminants from air; in combination with the use of high-purity chemicals, this brings the analysis closer to the 'clean room' conditions.¹¹³ In addition, simplification of the composition of the reaction mixture allows some sample pretreatment operations to be avoided, which also improves the metrological characteristics of the analysis as a whole. Mention should be made of high productivity and economic efficiency of the microwave techniques, and their flexibility in combination with preconcentration and instrumental determination.^{2,4,58}

The most promising approach to the substantiated selection of digestion conditions consists in modelling with the use of individual compounds of various classes. This approach was used, for example, to establish the conditions for the oxidation of model organic compounds by nitric acid. Kingston and Jassie¹¹⁴ showed

[†] However, due to specific features of microwave heating and the change in the kinetics of chemical reactions, the conditions chosen for thermal digestion can be regarded only as the starting point in microwave procedures.

Table 4. Comparison of the times of digestion of various samples in the conventional and microwave heating modes.^{4,22}

Sample type	t_1 /h ^a	Microwave digestion conditions	t_2 /min ^b	t_1 / t_2
Biological objects (trace components)	8	HNO ₃ or its mixtures with HF and HCl, closed systems	1.5–30	16–100
Geological objects (macrocomposition)	6	HNO ₃ , HCl, closed systems	4	90
Geological objects (trace components)	4–16	HF and HCl, HF and HNO ₃ , closed or open systems	10–20	24–32
Objects with an organic matrix (trace components)	8–16	HNO ₃ , closed systems	10–20	24–64

Soils, dust	8	HF, HNO ₃ , closed systems	20	24
High-purity compounds	8–24	HF, HNO ₃ , closed systems	12	40–120
Waste water	6	HNO ₃ , closed systems	10	60

^a Time of traditional sample pretreatment. ^b Time of microwave pretreatment.

that carbohydrates, proteins and fats are oxidised on exposure to MW at 140, 150 and 160 °C, respectively. Later, the activation energies for the oxidation of a number of model organic compounds were determined; these data were shown to be suitable as the basis in choosing for conditions for decomposition of natural products.⁷⁴

The principles of selection of the conditions for microwave decomposition depending on the sample weight, the rate of temperature rise, the volume of the reaction mixture and the total volume of the vessel have been considered in detail by Knapp.¹¹⁵

4. Preconcentration of traces of elements

Exposure to radiation permits fast preconcentration of trace amounts of metals by evaporation⁹⁹ or by using organic sorbents that react with metal ions according to complex-formation or ion-exchange mechanism. Preconcentration by sorption is carried out in either the static or dynamic mode. Preconcentration of platinum group metals and chromium on nitrogen-containing complexing sorbents has been reported.^{104, 110}

5. Identification of the element forms (speciation)

Analysis with the use of MW, which provides simultaneously specific chemical treatment and fast heating of the system, permits selective isolation of analytical forms of elements without changing their chemical composition in the sample. The compounds are collected using organic solvents or mixtures based on inorganic acids.¹¹⁶ This expedient was used for mass-spectrometric identification of chemical species containing mercury,¹¹⁷ tin¹¹⁸ and heavy metals.¹¹⁹

6. Extraction of organic impurities

Of special interest are recent studies dealing with the selective microwave-assisted extraction of toxic organic compounds into organic solvents.¹¹ These studies would undoubtedly serve as a significant stage in the development of organic analysis methods, first of all, chromatographic techniques. The advantages (considerable acceleration and an increase in the degree of extraction of the organic impurities to be determined) are caused in this case by the increase in the temperature of the extraction system by several tens of degrees. A highly important specific feature of microwave extraction is the fact that this method allows selective collection of components either through selective heating of the phase or a separate component of the system (for example, free water molecules in plant cells), depending on its dielectric properties, or through choosing an organic solvent that would selectively extract one or another component. In addition, the consumption of organic solvents and, hence, the amount of toxic wastes markedly decrease, which is beneficial from the environmental standpoint.^{14, 15}

An interesting version of microwave-assisted extraction is the withdrawal of volatile organic compounds to the gas phase through microwave heating of a matrix containing a polar solvent (water). The gas phase which does not absorb MW does not warm up, and under certain conditions, it virtually does not contain solvent vapour due to the non-equilibrium character of the system. Determination of the impurities of relatively volatile organic compounds in solid matrices such as soils is also possible; the most polar substances are the first to be evaporated. Upon irradiation of solid materials containing moisture, the selectivity of determination is due to the separate transition to the gas phase of components characterised by different vapour pressures.^{11, 14}

The principles of selection of the conditions for the extraction of organic impurities (biologically active nutritional compounds, antioxidants, UV stabilisers of plastics, pesticides, polyaromatic hydrocarbons, phenols, organometallic compounds and other contaminants) in microwave systems and comparison of the results with traditional methods have been reported.^{11, 14, 15}

7. Determination of the contents of total nitrogen and phosphorus

Under conditions of traditional heating, sample digestion, which is the limiting step in determination of the total nitrogen, takes 2 to 6 h. Since sulfuric acid, used in the Kjeldahl method, efficiently absorbs microwave radiation, the time it takes for the reaction mixture to warm up to 400 °C can be shortened from 45 min to 3–6 min. The introduction of an additional oxidant (Caro's acid) and the use of special techniques make it possible to reduce both the duration of decomposition of the organic matrix and the time of cooling the mixture and also to simplify titration. The problems of the traditional Kjeldahl determination of nitrogen and the capabilities of the microwave modification of this analysis have been considered quite comprehensively in a publication.¹²⁰ The results of application of microwave methods for determination of nitrogen¹²¹ and phosphorus¹²² in the analysis of environmental objects have been generalised.

V. Conclusion

The significance of MW for analytical chemistry grows continuously and rapidly. In the 1970s, there were only seven publications devoted to analysis using MW; in the 1980s, the number of publications increased to 132, while over a period of only four years, from 1991 to 1995, according to the data of a review,¹⁸ 166 more studies were published. About 1000 studies related to the application of MW in analysis have now been published. The main topics considered in these studies are related to sample digestion, drying and ashing under the action of MW. The microwave-assisted sample preparation has underlain new-generation analytical techniques — fast and highly efficient methods having good metrological characteristics; this reduces the gap between the existing power of instrumental determination of elements and the level of sample pretreatment techniques and extends the range of objects that can be analysed by routine methods. Due to the versatility of microwave methods, it is possible to design integrated analytical sequences consisting of inseparably connected operations and meant for the determination of a wide range of substances and materials, instead of separate procedures. This field of analytical chemistry is being vigorously developed.

The design of multipurpose analytical schemes on the basis of minimisation of the number of operations and integration of operations in space and in time¹²³ implies, first of all, improvement of the sample preparation step and convenient combination of this step with instrumental determination. The most promising lines of development of inorganic analysis with the use of MW were outlined by Matusiewicz and Sturgeon.⁹¹ They believe that the goals of using MW should include the decrease in the number of analytical operations and the time required to perform them through intensification of chemical processes, integration of operations, development of on-line analysis and speciation methods and implementation of rational hybrid methods. Generally, these trends correspond to the general principles of the development of analysis discussed in a number of publications.^{123–129}

Attempts to develop general approaches to the design of analytical schemes based on the microwave sample pretreatment, to improve individual stages and to implement integrated sequences of operations in a microwave field within a single system have been undertaken.^{6, 130, 131} An approach proposed in our study¹² and developed further under the name 'total microwave sample preparation' (which implies sample pretreatment in which all operations are carried out under the action of MW, are interrelated and often combined with one another)¹³² is regarded to be one of the major directions in the microwave-assisted sample preparation.² In the development of hybrid methods and analytical schemes for analysing unique samples by high-sensitivity instrumental methods, non-traditional combinations (in particular, those with the use of micromethods, *i.e.*, techniques and expedients for working with small amounts of the analyte) are

fairly promising. The methods of sample preparation with the use of MW are suitable for complex analytical objects, both for elements and matrices such as geological (ores, rocks), environmental (foodstuffs and raw materials, biological preparations, natural water, soil), industrial (high-purity substances, concentrates, metals, alloys, second-hand raw materials) containing heavy, rare and noble elements as macro- and micro- components. The use of MW substantially improves characteristics of analysis, not only that carried out by advanced instrumental methods but also of the analysis performed by well-known traditional methods, thus providing an increase in the potential of the existing analytical equipment. Owing to the microwave pretreatment, it is possible to reduce several-fold the duration of analysis, decrease the consumption of chemicals and energy expenditure, and to reduce the required man-hours.

In addition to ultra-trace analysis of components, which is associated with specific conditions (clean chemistry), one more important analytical problem that has appeared quite recently is elaboration of methods for determination of the forms in which elements exist. Microwave methods, which possess great potential due to the diversity of operations carried out in a microwave field and the flexibility of combinations with instrumental methods, are undoubtedly promising in this respect. Microwave systems are used to increase the efficiency of multistep procedures of successive selective acid extraction of various chemical forms of metals, sample digestion and extraction with organic solvents. Sample derivatisation, *i.e.*, preparation of a derivative convenient for the subsequent instrumental determination of the element, is also carried out directly in the microwave oven; this is done in open, closed or flow systems.^{2, 116, 117} By combining microwave pretreatment with atomic and mass spectrometry or liquid and capillary gas chromatography, hybrid methods have been developed, which shorten the time of analysis by a factor of 20–100.^{130, 131, 133, 134}

Yet another important feature of microwave methods is the possibility of preparing metals as convenient analytical forms and as complexes that are difficult to prepare by traditional methods due to kinetic restrictions. A simple procedure for preparation of the required analytical forms under the action of MW increases the efficiency of rather long-lasting classical spectrophotometric, fluorescence, luminescence, sorptional, electrochemical and other methods that are sensitive to the form of element existence in solution. The correlation between the specified conditions of reactions and the quantitative and qualitative composition of the products provides the possibility of targeted synthesis of both inorganic complexes and macrocyclic reagents^{40, 41} or polymers.^{4, 90}

The embodiment of the potential of microwave methods is determined by the development of instrumentation, increase in the efficiency of the control of process parameters, and the decrease in the cost of equipment. Thus an increase in the speed of analysis can be achieved by two methods: by increasing the number of samples treated simultaneously [in closed systems, this can be 52 (see Ref. 135)] and by using flow systems in which, according to the data of CEM company, 180 samples can be prepared over a period of 3 h. The metrological characteristics of analysis can be improved, for example, by using steel autoclaves in combination with microwave heating by focused radiation; in Matusiewicz's opinion,¹⁰⁸ this ensures faster heating, a higher pressure, and a better reproducibility of results. A promising technique is the use of microwave flow setups for digestion and preconcentration coupled with automated determination. The scopes of the two approaches are analysed in a publication.⁶⁶ Flow setups appear to be the optimal devices for the design of automated systems, although other facilities (for example, open and robotised devices^{2, 136, 137}) can also serve as parts of these systems used to solve particular analytical problems. Undoubtedly, with the advent of new technologies and materials, novel engineering solutions for the implementation of microwave heating will also arise (the ways of radiation supply; the design of the vessels, flow systems, automated injection units and types of coupling with instrumental

determination) and new ways of controlling the parameters (temperature, pressure) and of the 'parameter–process' feedback will appear. This will give rise to a new generation of laboratory microwave systems.

The possibility of conversion of microwave devices from a fairly advanced facility used for routine sample pretreatment into a tool for investigation of the regularities of chemical transformations appears to be of fundamental importance.^{69, 71, 73, 80} The change in the kinetic parameters of reactions on exposure to radiation with maintenance of invariable thermodynamic properties of the system allows quantitative investigations of the slow physicochemical processes, simulation of various reactions in model systems and, thus, provides a way for predicting the results of processes taking place under real conditions. This is of interest from both theoretical and practical standpoints, for example, for the perfection of complex technological processes involving a series of reactions with participation of many components.

The development of the theoretical basis of microwave sample pretreatment is a topical subject. Further studies along this line should probably be related to in-depth investigations of the interaction of MW with substances of different chemical nature (solvents, analytes, structural components of microwave systems); research into the influence of physical parameters of MW (frequency and intensity) on the course of physicochemical processes in solutions or heterogeneous systems. This would enable researchers to ensure selective transfer of energy to the reaction system components and, thus, to propose new in kind routes to the solution of analytical problems. In addition, extension of the range of chemical processes taking place under the action of MW, in particular, study of the influence of MW on catalytic and enzymic processes, organic synthesis, preparation of coordination compounds and polymerisation is also important for modern analytical methods.

Titanocene derivatives containing titanium – carbon σ -bonds

V A Knizhnikov, N A Maier

Contents

I. Introduction	295
II. Methods for the synthesis of titanocene derivatives containing Ti – C σ -bonds	295
III. Reactions of titanocene derivatives containing Ti – C σ -bonds	304

Abstract. The published data on the major methods for the synthesis and chemical conversions of titanocene derivatives containing titanium – carbon σ -bonds are systematised. The bibliography includes 288 references.

I. Introduction

The chemistry of dicyclopentadienyltitanium (titanocene) derivatives is one of the most rapidly developing branches of the chemical science. The interest in titanocene derivatives is partly due to their ability to catalyse various chemical processes, *e.g.*, polymerisation, isomerisation and hydrogenation of alkenes, cyclotrimerisation of acetylene derivatives, fixation of molecular nitrogen under mild conditions and many other reactions. These compounds acquire increasing popularity as additives to fuels and high-temperature lubricants, rubber accelerators, lacquer and water-repellent components, antiknock compounds, *etc.*

Among other compounds of the titanocene series, titanocene derivatives containing Ti – C σ -bonds are still the least known due to the thermal instabilities of the majority of representatives of this class and, to some extent, their high sensitivities to oxygen and atmospheric moisture. High reactivities of titanocene derivatives containing Ti – C σ -bonds with various organic and inorganic substrates and the presence of several reaction centres in some of them open broad prospects for their application in both organic synthesis and in the preparation of diverse organometallic compounds including novel representatives of the known types of titanocene derivatives. The published data on the major methods for the synthesis of titanocene derivatives containing Ti – C σ -bonds isolated from various reaction mixtures in individual state and the most typical chemical transformations are considered. The principal characteristics of titanocene derivatives (colour, solubility, air resistance, thermal stability, structure, *etc.*) have been described in the majority of the original papers and therefore fall outside the scope of this review.

II. Methods for the synthesis of titanocene derivatives containing Ti – C σ -bonds

1. Reactions of titanocene halides with organic derivatives of non-transition metals

Reactions of titanocene dihalides with organolithium, -sodium, -magnesium or -aluminium compounds constitute a classical method for the synthesis of titanocene σ -derivatives; depending on the reagent ratio, both mono- and dialkyl- or diaryl derivatives can be prepared.

Dimethyltitanocene (**1**) was prepared by the reaction of titanocene dichloride (**2**) with an excess of methylolithium, methylmagnesium halides or lithium tetramethylaluminium at reduced temperatures. Diethyl ether is the most convenient solvent for such syntheses.^{1–5}

Cp = C₅H₅; MeX = MeLi, MeMgHal, LiAlMe₄.

Dimethyltitanocene derivatives **3** containing various substituents in π -bound cyclopentadienyl ligands are prepared from the corresponding dichlorides.

MeX = MeLi, MeNa, MeMgHal, Me₃Al.

Cp ¹	Cp ²	Ref.
C ₅ H ₄ Me	C ₅ H ₄ Me	6
C ₅ Me ₅ (Cp*)	C ₅ Me ₅	2, 6
1,2,3-Me ₃ C ₅ H ₂	1,2,3-Me ₃ C ₅ H ₂	6
C ₅ Me ₄ H	C ₅ Me ₄ H	6–8
C ₅ Me ₄ (CH ₂ CH ₂ CH = CH ₂)	C ₅ Me ₄ (CH ₂ CH ₂ CH = CH ₂)	9

The binuclear titanocene-like complex **6**²³ with a bridging (dimethylsilylidene)dicyclopentadiene ligand and the complex **7**²⁴ in which the role of a bridge is played by biphenyl-2,2'-diyl have been synthesised.

The reaction of titanocene dichloride (**2**) with phenyllithium or phenylmagnesium halides gave diphenyltitanocene Cp_2TiPh_2 .^{4, 25–28} Diphenyltitanocene derivatives containing substituents in both π -bound cyclopentadienyl ligands, such as compound **8**, and σ -bound phenyl rings, such as compounds **9**, have been described.

The reaction of titanocene dichloride (**2**) or its derivatives with benzylmagnesium chloride or benzyl lithium results in dibenzyltitanocene derivatives Cp_2TiBn_2 ,^{31–33} $(\text{C}_5\text{H}_4\text{Me})_2\text{TiBn}_2$,³³ $(\text{C}_5\text{H}_4\text{SiMe}_3)_2\text{TiBn}_2$ ³³ and $[(\text{C}_5\text{H}_4)_2\text{SiMe}_2]\text{TiBn}_2$.¹⁶

Syntheses of titanocene derivatives in which σ -bound organic radicals contain a heteroatom, *e.g.*, $\text{Cp}_2\text{Ti}(\text{CH}_2\text{SiMe}_3)_2$,^{34–37} $[(\text{C}_5\text{Me}_4)_2\text{SiMe}_2]\text{Ti}(\text{CH}_2\text{SiMe}_3)_2$,¹⁹ $[(\text{C}_5\text{H}_4)_2\text{SiMe}_2]\text{Ti}(\text{CH}_2\text{SiMe}_3)_2$,²¹ $\text{Cp}_2\text{Ti}(\text{CH}_2\text{GeMe}_3)_2$,³⁷ $\text{Cp}_2\text{Ti}(\text{CH}_2\text{SPh})_2$,^{38, 39} $\text{Cp}_2\text{Ti}(\text{CH}_2\text{PPh}_2)_2$,⁴⁰ $\text{Cp}^*(\text{Cp})\text{Ti}(\text{CH}_2\text{PPh}_2)_2$,⁴¹ *etc.*, have been described.

Thiophene⁴² or trichlorothiophene (compounds **10a,b**) can be used as σ -bound substituents.⁴³

X = H (**a**), Cl (**b**).

The reaction of titanocene dichloride (**2**) with cyclopentadienylsodium afforded tetracyclopentadienyltitanium in which two cyclopentadienyl ligands were linked by π -bonds, whereas the other two ligands, by σ -bonds.^{44–47} Presumably, this complex underwent rapid (on an NMR time scale) $\pi \rightleftharpoons \sigma$ rearrangement of the ligands at 20 °C.^{46, 48}

The reaction of an excess of ferrocenyllithium with titanocene dichloride (**2**) results in diferrocenyltitanocene Cp_2TiFc_2 ($\text{Fc} = \text{C}_5\text{H}_5\text{FeC}_5\text{H}_4$).⁴⁹ The reaction of titanocene dichloride (**2**) with an excess of 2-(dimethylaminomethyl)ferrocenyllithium (**11**) yields the symmetrical complex **12**. Under similar conditions, bis(pentamethylcyclopentadienyl)titanium dichloride yields the monoferrocenyl-substituted complex **13**.⁵⁰

The reaction of titanocene dichloride (**2**) with *o(m)*-carboran-1-ylmethylmagnesium bromides leads to carboranyl-substituted titanocenes **14a,b** and **15**.^{51, 52} Dicyclopentadienylbis(*o*-carboranyl-methyl)titanium **14a**, contrary to the majority of titanocene derivatives containing Ti–C σ -bonds, is stable in air at 20 °C over a long period of time and is decomposed only on melting at 185 °C.

R = H (**a**), Me (**b**).

Titanocene dichloride (**2**) reacts with an excess of sodium, lithium or magnesium acetylenide to give titanocene diacetylenides $\text{Cp}_2\text{Ti}(\text{C}\equiv\text{CR})_2$, where R = Ph,^{53–55} SiMe_3 ,^{56, 57} CF_3 ,⁵⁸ Et, Prⁿ, Buⁿ, Bu^t (see Ref. 56), cyclo-C₆H₁₁, Ph₂CHCH₂, *n*-C₆H₁₃,⁵⁵ Fc, Rc (Rc = C₅H₅RuC₅H₄),⁵⁹ $(\text{C}\equiv\text{CR})_2 = (\text{C}\equiv\text{C}-2-\text{C}_6\text{H}_4-\text{C}\equiv\text{C}-2-\text{C}_6\text{H}_4-\text{C}\equiv\text{C})$.⁶⁰ Similar compounds were prepared from titanocene dichloride derivatives containing substituents in cyclopentadienyl rings, *viz.*, $\text{Cp}'_2\text{Ti}(\text{C}\equiv\text{CR})_2$, where Cp' = C₅H₄Me: R = Ph, cyclo-C₆H₁₁, *n*-C₆H₁₃, Ph₂CHCH₂,⁵⁵ SiMe_3 ,⁵⁶ Cp' = C₅H₄SiMe₃: R = Ph, SiMe_3 ,⁵⁶ $\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}$,⁶¹ Fc,^{59, 62} Rc;⁵⁹ Cp' = C₅H₂Me₃, R = SiMe_3 ,⁶³ Cp' = Cp*, $(\text{C}\equiv\text{CR})_2 = (\text{C}\equiv\text{C}-2-\text{C}_6\text{H}_4-\text{C}\equiv\text{C}-2-\text{C}_6\text{H}_4-\text{C}\equiv\text{C})$,⁶⁰ Cp' = C₅H₄CH₂CH₂NMe₂: R = SiMe_3 ,⁶⁴ Cp' = C₅H₄X (X = Ph₂P, Ph₂P=O, Ph₂P=S), R = Bu^t (see Ref. 65).

Symmetrical dicyclopentadienyltitanium derivatives with other σ -bound organic groups, *e.g.*, Cp_2TiBu^n (see Ref. 66), Cp_2TiEt_2 ,⁶⁷ $\text{Cp}_2\text{Ti}[\text{C}(\text{Ph})=\text{CMe}_2]_2$,⁶⁸ $\text{Cp}_2\text{Ti}(\text{CF}=\text{CF}_2)_2$,⁶⁹ and $[\text{Me}_2\text{Si}(\text{C}_5\text{H}_4)_2]\text{TiBu}^n_2$ (see Ref. 18), have been synthesised.

The reactions of titanocene dichloride (**2**) or its derivatives containing substituents in the cyclopentadienyl ligands with

organodilithium or -dimagnesium compounds yield metalla-cycles. Thus titanaindans **18a,b**,⁷⁰ **19a**¹⁸ and **19b**¹⁹ were prepared from the dichlorides **2**, **16**, **17a,b** and 1,2-bis(chloromagnesio-methyl)benzene.

R = H (**2**, **18a**), SiMe₃ (**16**, **18b**).

R = H (**a**), Me (**b**).

The dilithium derivative **20** was used for the preparation of substituted titanaindan **21**.⁷¹

Titanaindene **22** is produced by the reaction of titanocene dichloride (**2**) with the dilithium derivative **23**.⁷²

The reaction of titanocene dichloride (**2**) with 2,2'-dilithiobiphenyl⁷² or 2,2'-dilithiooctafluorobiphenyl⁷³ gave titanafluor- enes **24a,b**.

X = H (**a**), F (**b**).

Diverse titanacyclic compounds Cp₂TiL₂ have been described in which the cyclic structures are formed owing to the ligands L₂.

Titanocene dichloride (**2**) reacts with 1,1-dimethyl-1-sila-3-magnacyclobutane (**25**) to give thermally stable 3,3-dimethyl-1,1-dicyclopentadienyl-1-titana-3-silacyclobutane (**26**).⁸¹

1-Titana-3-metallacyclobutanes **27** and **28** were prepared by the reactions of bis(bromomagnesiomethyl)titanocene with dichlorodimethylgermane⁸² or titanocene, zirconocene and hafnocene dichlorides.⁸³

M = Ti, Zr, Hf.

1,1-Dicyclopentadienyl-1-titana-2-methylidenecyclobutane (**29**) was synthesised by the reaction of titanocene dichloride (**2**) with vinyltitanium in THF in the reagent ratio of 1:2.^{84,85} Presumably, this reaction proceeds *via* divinyltitanocene, which is rearranged into 2-methylidenetitanacyclobutane **29** at temperatures above -78°C .

Monoalkyl- or monoaryl titanocene chlorides are formed upon treatment of titanocene dichloride (**2**) with equimolar amounts of organolithium or -magnesium compounds. Thus methyltitanocene chloride derivatives **30** were prepared using methyltitanium, methylmagnesium chloride or trimethylaluminium.

MeX = MeLi, MeMgCl, Me₃Al.

The reaction of titanocene dichloride (**2**) or its analogue containing a bridging dimethylsilylene group with an equimolar amount of benzylmagnesium chloride gave Cp₂Ti(Bn)Cl (see Ref. 86) and [Me₂Si(C₅H₄)₂](Bn)TiCl.¹⁷

Chlorotitanocene derivatives Cp₂TiCl(L) containing bulky ligands [e.g., L = CH₂CH₂CHR¹CR²=CH₂, where R¹ = R² = H; R¹ = H, R² = Me; R¹ = Ph, R² = H; L = CH₂CMe₂CHCR¹=CR²CR³=CH₂, where R¹ = R² = R³ = H; R¹ = R² = H, R³ = Me; R¹ = Me, R² = R³ = H; R¹ = R³ = H, R² = Me; R¹ = R² = Me, R³ = H] were synthesised by the reaction of titanocene dichloride (**2**) with the corresponding organomagnesium compounds.⁹⁵

Titanocene dichloride derivatives containing substituents in the cyclopentadienyl ligands react with sodium acetylenides (charge ratio 1 : 1) to give the monoacetylenides Cp₂TiCl(C≡CR) [Cp' = C₅H₄Me, C₅H₄SiMe₃, R = Ph, SiMe₃ (see Ref. 56); Cp' = C₅H₄SiMe₃, R = C≡CEt (see Ref. 61)].

The reaction of titanocene dichloride (**2**) with pentafluorophenyllithium in ether yields bis(pentafluorophenyl)titanocene (**32**) and pentafluorophenyltitanocene chloride (**33**).²⁹ The monopentafluorophenyl titanocene derivative **34** was prepared by treatment of cyclopentadienyl(*tert*-butylcyclopentadienyl)titanium dichloride with pentafluorophenylmagnesium bromide.⁹⁶

The chlorotitanocene derivatives **35** containing various alkyl-, aryl-, alkenyl- and other σ-bound ligands were synthesised by reactions of equimolar amounts of the corresponding dichlorides with organomagnesium or -lithium compounds.

Dicyclopentadienyltitanium(III) monoacetylenides are formed as side products upon treatment of titanocene dichloride (**2**) with an excess of acetylenides $\text{EC}\equiv\text{CR}$ (E = BrMg, Na, Li; R = Ph, Et, Prⁿ, Buⁿ, Bu^t, SiMe₃).⁵⁶ The formation of a dicyclopentadienyltitanium(III) derivative $\text{Cp}_2\text{Ti}(2\text{-MeOCH}_2\text{C}_6\text{H}_4)$ proceeds through preliminary reduction of Ti(IV) to Ti(III) in the reaction of titanocene dichloride (**2**) with an equimolar amount of bis(2-methoxymethylphenyl)magnesium in THF. This is the first Ti(III) derivative in which the titanium atom is coordinated by oxygen. A similar reaction with bis(2-*N,N*-dimethylamino-methylphenyl)magnesium¹¹⁵ affords the Ti(III) complex $\text{Cp}_2\text{Ti}(2\text{-Me}_2\text{NCH}_2\text{C}_6\text{H}_4)$. Reactions of Cp_2TiCl_2 with sterically hindered lithium alkyls devoid of β -hydrogen atoms, such as LiCHPh_2 or $\text{LiCH}(\text{SiMe}_3)_2$ yield the Ti(III) complexes Cp_2TiR [R = Ph_2CH , $(\text{Me}_3\text{Si})_2\text{CH}$]. Dicyclopentadienyltitanium(III) chloride was found to be the intermediate product of these reactions.¹¹⁶

Treatment of titanocene dichloride (**2**) with *n*-butyllithium yields Cp_2TiH which adds to allylamines **43** and **44** to give 1-titana-2-azacyclopentanes **45** and **46**.¹¹⁷

The binuclear complex **47** was prepared by the reaction of dicyclopentadienyltitanium(III) chloride with *N,N'*-bis(*o*-lithium-phenyl)-*N,N'*-di(*n*-butyl)ethylenediamine **48**.⁷⁴

The reaction of dicyclopentadienyltitanium(III) chloride with lithium tetramethylaluminate in toluene at 0°C was used to prepare the complex $\text{Cp}_2\text{Ti}(\mu\text{-Me})_2\text{AlMe}_2$ containing two bridging methyl groups.¹¹⁸ The titanocene derivatives $\text{Cp}_2\text{Ti}(\mu\text{-Cl})(\mu\text{-CH}_2)\text{AlMe}_2$ (see Ref. 119) and $\text{Cp}_2\text{Ti}(\mu\text{-CH}_2)_2\text{PPhR}$ (R = Me, Ph)¹²⁰ containing bridging methylene groups have also been synthesised.

The reaction of titanocene dichloride (**2**) with isopropylmagnesium chloride in a nitrogen atmosphere at temperatures below -78°C affords $[\text{Cp}_2\text{TiPr}]_2\text{N}_2$ with a coordinated nitrogen molecule.¹²¹ The complexes $[\text{Cp}_2\text{TiR}]_2\text{N}_2$ [R = CH_2Bu^t , CH_2SiMe_3 , 3-MeC₆H₄, 2,6-Me₂C₆H₃,¹²² $\text{C}(\text{Me})=\text{CHMe}$ (see Ref. 107)] were prepared from dicyclopentadienyltitanium(III) chloride and organomagnesium compounds under similar conditions.

The phosphine titanocene derivatives **49** containing σ -bound methyl- or trimethylsilylmethyl groups were synthesised by the reaction of the phosphine complexes **50** with organolithium compounds.¹²³

R = Me, Me_3SiCH_2 .

It was shown that the complexes $[\text{Cp}_2\text{TiR}_2]\text{M}$ (M = Li, Na; R = Me, Et, Prⁱ) stable only at low temperatures are formed upon treatment of titanocene dichloride (**2**) with an excess of organolithium or -sodium reagents at temperatures below -70°C .¹²⁴ The complex $[\eta^5\text{-(C}_5\text{HMe}_4)_2\text{Ti}(\eta^1\text{-C}\equiv\text{C}-\text{C}\equiv\text{CSiMe}_3)_2]^- [\text{Li}(\text{THF})_2]^+$ was isolated and characterised by X-ray diffraction analysis. This is the first complex in which the Li atom is located between the inner triple bonds of the ethynyl ligands.¹²⁵

2. Synthesis of titanocene σ -derivatives using unsaturated organic compounds

Reactions resulting in metallacyclic titanocene complexes containing Ti–C σ -bonds can arbitrarily be divided into three groups:

1. Formation of a metallacycle by cross-linking of two unsaturated compounds including those π -coordinated by a metal atom;
2. Formation of a titanacycle by incorporation of an unsaturated compound into the Ti–C σ -bond;
3. Addition of molecules containing several multiple bonds to dicyclopentadienyltitanium derivatives.

The first type of reactions include reduction of titanocene dichloride (**2**) with naphthalenesodium¹²⁶ or metallic magnesium^{127, 128} in the presence of diphenylacetylene resulting in 1,1-dicyclopentadienyl-2,3,4,5-tetraphenyl-1-titanacyclopentadiene (**51**).

It is believed¹²⁹ that this reaction proceeds through the reduction of titanium(IV) to titanium(II) with subsequent formation of the tolan–titanocene π -complex **52**. Supporting evidence is provided by the fact that 1,1-dicyclopentadienyl-2,3,4,5-tetraphenyl-1-titanacyclopentadiene **51** is formed as a result of interaction of the complex **52** with tolan,¹²⁹ while treatment of the intermediate compound **52** with water gives the binuclear complex **53**.¹²⁷

Titanacyclopentadienes **54a,b** were synthesised by the reaction of the tolan–titanocene complex **52** with phenylacetylene or hex-3-yne.¹³⁰

$R^1 = \text{Ph}$, $R^2 = \text{H}$ (**a**); $R^1 = R^2 = \text{Et}$ (**b**).

The dimerisation of alkynes and the formation of titanacyclopentadienes **51** and **55a–d** occur in the reaction of the diphosphine–titanocene complex **56** with acetylene, dimethylacetylene or methylacetylene or of the titanocenedicarbonyl **57** with tolan or diacetoxyacetylene.

Compound	R^1	R^2	Ref.
55a	H	H	131–133
55b	Me	Me	134
55c	Me	H	133
55d	OC(O)Me	OC(O)Me	135
51	Ph	Ph	135

1,1-Dicyclopentadienyl-2,3,4,5-tetraphenyl-1-titanacyclopentadiene (**51**) was prepared by treatment of the titanocene complex with bis(trimethylsilyl)acetylene **58**¹³⁶ or of the π -allyl titanium(III) complex **59**¹³⁷ with an excess of tolan. The titanacycle **51** is also formed in a photochemical reaction of dimethyltitanocene (**1**) with tolan in pentane.^{138–140}

In contrast to the reaction of the bis(trimethylsilyl)acetylene–titanocene complex **58** with tolan, its reaction with mono-substituted alkynes yields alkenyltitanocene acetylenides.¹⁴¹

$R = \text{Ph}$, Me_3Si , $\text{Me}(\text{CH}_2)_3$.

The reaction of titanocene with bis(trimethylsilyl)butadiyne gives the titanacyclopentadiene derivative **60**.¹⁴²

Cross-linking of ethylene and acetylene ligands and the formation of 1,1-bis(pentamethylcyclopentadienyl)-1-titanacyclopent-2-ene derivatives **61a,b** take place in the reaction of bis(pentamethylcyclopentadienyl)(ethylene)titanium (**62**) with methyl- or dimethylacetylene.¹⁴³

$R = \text{H}$ (**a**), Me (**b**).

Compounds containing a titanacyclopentene fragment were prepared by reactions of (acetylene)(trimethylphosphine)di(cyclopentadienyl)titanium with ethylene¹⁴⁴ and by reactions of (diphenylacetylene)di(cyclopentadienyl)titanium with tricyclo[5.2.1.0^{2,8}]deca-2,5,8-triene.¹⁴⁵

Acetylene–titanocene complexes enter into heterocyclisation reactions with carbonyl compounds. Thus the tolan–titanocene complex **52** reacts with an equimolar amount of acetone^{146, 147} or benzaldehyde¹⁴⁷ to yield titanadihydrofuran metallacycles.

$R^1 = R^2 = \text{Me}$; $R^1 = \text{Ph}$, $R^2 = \text{H}$.

The titanadihydrofuran derivatives **63a,b** are formed by reactions of acetone or acetaldehyde with dimethylacetylene–titanocene (**64**)¹³⁴ or acetylene(trimethylphosphine)–titanocene (**65**)¹⁴⁴ complexes.

$R^1 = \text{H}$, $R^2 = \text{Me}$; $R^1 = R^2 = \text{Me}$.

The reaction of carbon dioxide with alkyne–titanocene π -complexes results in the binuclear σ -vinylcarboxylate complexes **66**. Their oxidation by atmospheric oxygen gives titanadihydrofuranones **67**.

R = Ph,^{148–150} SiMe₃,^{149, 150} Me.¹³⁴

Titanadihydrofuranone (**67**) (R = H) was prepared by the reaction of carbon dioxide with the trimethylphosphinacetylene–titanocene complex **65**.¹⁴⁴ The reaction of the ethylene–titanocene complex **68** with CO₂ yields titanatetrahydrofuranone.¹⁴³

The reaction of dimethyltitanocene (**1**) with alkynes in boiling benzene in the dark is a typical reaction of the second type, which consists in the formation of titanacycles due to incorporation of unsaturated compounds into the Ti–C σ -bond. In the first step, methyl(vinyl)titanocene complexes **69a–e** are formed; in the case of R = Ph¹⁵¹ and C₆F₅ (see Ref. 152), these complexes were isolated in an individual state. In the second step, methane is abstracted from the complexes **69a–e** resulting in the titanacyclobutene derivatives **70a–e**.^{151, 153} In-depth studies of these reactions have been carried out.¹⁵⁴

R = Et (**a**), Prⁿ (**b**), Ph (**c**), Me₃Si (**d**), C₆F₅ (**e**).

Titanacyclobutene derivatives were prepared by the reaction of bis(pentamethylcyclopentadienyl)titanium chloride with propargyl bromides in the presence of samarium diiodide with subsequent treatment of the reaction mixture with an equimolar amount of the corresponding halide.^{155, 156}

R¹ = H; R² = Bn; R¹ = Me, R² = MeC $\equiv$ CCH₂, Bn;

R¹ = Ph, R² = Bn, PhC $\equiv$ CCH₂; X = Hal.

Diphenyl-substituted titanacyclobutene **70c** was synthesised by the reaction of titanocene dichloride (**2**) with tolan and trimethylaluminium. This reaction proceeds *via* the intermediate vinyl derivative **71**.¹⁵⁶

Thermal reactions of alkynes with diphenyltitanocene are also accompanied by insertion of alkyne into the Ti–C σ -bond. It is believed^{157, 158} that the phenylenetitanium complex **72** is formed in the first step as a result of splitting of the benzene molecule from diphenyltitanocene. Subsequent insertion of alkyne into one of the Ti–C σ -bonds results in titanaindenes **73a–c**.

R¹ = R² = Ph (**a**), R¹ = R² = C₆F₅ (**b**), R¹ = SiMe₃, R² = Ph (**c**).

Analogous reactions yielding mixtures of substituted titanaindenes **74a–d** occur on heating of *m*- or *p*-tolyltitanocenes in the presence of alkynes.¹⁵⁹ The formation of a complex mixture of reaction products in the case of the *m*-tolyl derivative is explained by the fact that this compound yields a mixture of isomeric phenylenetitanium complexes **75** and **76** upon heating.¹⁵⁹

Titanaindene **73a** was prepared by reduction of titanocene dichloride (**2**) with magnesium in the presence of tolan and *o*-bromofluorobenzene.¹²⁸

Heating of diphenyltitanocene derivatives in the presence of alkenes results in titanaindenes **77**.¹⁶⁰

R¹ = H, Me; R² = H, Me, Buⁿ.

The 1,1-dicyclopentadienyl-1-titanacyclobut-2-ene derivatives **70c,d,f–h** were prepared by the reaction of alkynes with the titanium–aluminium complex **78** in the presence of pyridine^{161, 162} or with carbene–titanocene complexes **79**.^{163–165}

$\text{R}_3^1 = \text{Me}_3, \text{Me}_2\text{Ph}, \text{Et}_3$; $\text{R}^2 = \text{R}^3 = \text{Ph}$ (**70c**), SiMe_3 (**70d**);

$\text{R}^2 = \text{CMe}=\text{CH}_2$, $\text{R}^3 = \text{Et}$ (**70f**); $\text{R}^2 = \text{Et}$, $\text{R}^3 = \text{CMe}=\text{CH}_2$ (**70g**);

$\text{R}^2 = \text{CEt}=\text{CH}_2$, $\text{R}^3 = \text{Me}$ (**70h**).

Alkylidenetitanacyclobutenes **80** are formed in reactions of alkynes with the titanocenevinylidene complexes **81**.¹⁶⁶

$\text{R}^1 = \text{Ph}, \text{Pr}^n, n\text{-C}_5\text{H}_{11}$; $\text{R}^2 = \text{H}, \text{Pr}^n, n\text{-C}_5\text{H}_{11}, \text{Ph}$; $\text{R}^3 = \text{Pr}^n, \text{Ph}, \text{SiMe}_3$.

The titanacyclobutane derivatives **82a–d** result from reactions of trisubstituted alkenes with the carbene–titanocene complexes **79**.^{163–165} Titanacyclobutenes **83a–c** were prepared by the reaction of terminal alkenes with titanium–aluminum complexes in the presence of 4-dimethylaminopyridine (DMAP).^{91,167} The titanium–aluminum complex **78** yields the titanabicyclopentane derivative **84** in the reaction with 3,3-dimethylcyclopropene.¹⁶⁸

$\text{R}_3^1 = \text{Me}_3, \text{Me}_2\text{Ph}, \text{Et}_3$; $\text{R}^2 = \text{R}^3 = \text{H}$; $\text{R}^4 = \text{Bu}^n$ (**a**);

$\text{R}^2 = \text{R}^3 = \text{H}$, $\text{R}^4 = \text{Bu}^t$ (**b**), $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{R}^4 = \text{Me}$ (**c**);

$\text{R}^2 = \text{R}^4 = \text{Me}$; $\text{R}^3 = \text{H}$ (**d**).

Compounds 83	Cp^1	Cp^2	R^1	R^2	Ref.
a	C_5H_5	C_5H_5	Me	Pr^i	167
b	$\text{C}_5\text{H}_4\text{Me}$	$\text{C}_5\text{H}_4\text{Me}$	Bu^t	H	91
c	C_5H_5	$\text{C}_5\text{H}_4\text{Me}$	Bu^t	H	91

Titanacyclobutane derivatives react with alkynes to give titanacyclobutenes and the corresponding alkenes. Thus titanacyclobutenes **70c,i** were synthesised from diphenylacetylene and titanacyclobutenes **83c–e**.

Titanacyclobutenes	Cp^1	Cp^2	R	Titanacyclobutenes	Ref.
83e	C_5H_5	C_5H_5	Bu^t	70c	169, 170

$\text{R}^3 = \text{Ph}$, $\text{R}^4 = \text{Me}$; $\text{R}^3 = \text{Ph}$, $\text{R}^4 = \text{SiMe}_3$.

Reactions of titanacyclobutane complexes with 1,1-dimethyl- and 1-isopropyl-1-methylallenes result in the formation of alkylidenetitanacyclobutene derivatives **80** ($\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Pr}^i$; $\text{R}^3 = \text{R}^4 = \text{H}$).^{172,173}

Some reactions of titanacyclic complexes with unsaturated or carbonyl compounds are accompanied by expansion of the metallacycle. Thus 1,1-dicyclopentadienyl-3,4-diphenyl-1-titanacyclopentadiene reacts with phenylacetylene to give a nine-membered titanacycle **86**. 1,1-Dicyclopentadienyl-2,3,4,5-tetraethyl-1-titanacyclopentadiene forms a similar cyclic derivative **87** in a reaction with diethylacetylene.¹⁷⁴

Insertion of aliphatic ketones into the Ti–C σ -bond of the titanacyclobutene derivatives **70** results in six-membered metallacycles **88**.¹⁷⁵

$\text{R}^1 = \text{R}^2 = \text{Ph}$; $\text{R}^3 = \text{R}^4 = \text{Me}$; $\text{R}^3 = \text{Me}$, $\text{R}^4 = \text{Ph}$, $\text{CH}_2 = \text{CH}$;

$\text{R}^3 = \text{Ph}$, $\text{R}^4 = \text{cyclo-C}_3\text{H}_5$; $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$; $\text{R}^3 = \text{Me}$, $\text{R}^4 = \text{Me}, \text{Ph}$.

Reactions of 1,1-dicyclopentadienyl-1-titana-2,3-diphenylcyclobut-2-ene **70c** with aldehydes yield mixtures of isomeric titanadihydropyrans **88** and **89**.¹⁷⁵

$\text{R} = \text{Me}, \text{Ph}, \text{Bn}$.

The expansion of the metallacycle also takes place in reactions of 1,1-bis(pentamethylcyclopentadienyl)-1-titanacyclopentane **90** with methylidenecyclopropane or 1-methylidene-2-phenylcyclo-

propane¹⁷⁶ and the ketene–titanocene complex **91** with ethylene.¹⁷⁷

R = H, Ph.

The metallacyclic compounds **92** were prepared by reactions of the carbene–titanocene complex with ketenes.¹⁷⁸

R = H, Ph.

Reactions of bis(trimethylphosphine)titanocene (**56**) with 1,2-diphenylcyclopropene,¹⁷⁹ δ -enones and δ -inones belong to the third type of reactions leading to the formation of titanacyclic compounds.¹⁸⁰

A reaction of the bis(trimethylsilyl)acetylene–titanocene complex **58** with diynes was used for the preparation of bicyclic titanacyclopentadiene derivatives **93**.¹⁸¹

n = 2, R = Me, Bu; n = 4, R = Et.

The reaction of the bis(trimethylsilyl)acetylene–titanocene complex **58** with 1,4-diphenylbuta-1,3-diyne results in titanacyclocumulene **94**,¹⁸² while the reaction with acetone azine gives the 1-titana-2,3-diazacyclopent-3-ene derivative **95**.^{183, 184}

The reaction of di(carbonyl)di(cyclopentadienyl)titanium (**57**) with 1,1,3,3-tetramethyl-2-thiocarbonylcyclohexane gives a monomeric alkylidenetitanathiirane containing a η^2 -(C–S)-bound thioetone ligand.¹⁸⁵ The reaction of di(carbonyl)di(cyclopentadienyl)titanium (**57**) with bis(trifluoromethyl)thioetone yields a titanacycle in which the titanium atom is bound to two thioetone ligands.¹⁸⁶

3. Miscellaneous methods for the synthesis of titanocene σ -derivatives

In some cases, addition of various substrates to π -bound organic ligands of titanocene derivatives results in the formation of Ti–C σ -bonds.

Treatment of di(η^5 -cyclopentadienyl)(η^2 -ethylene)titanium (**68**) with alcohols, phenols^{187, 188} and water¹⁸⁸ gave mono- and binuclear derivatives of ethyltitanocene.

R = Me, Et, Ph.

The reactions of acetylene titanocene complexes with alcohols or phenols yielded σ -alkenyl complexes **96**.^{187, 188}

R¹ = Ph, Me; R² = Me, Et, Ph.

Bis(η^5 -pentamethylcyclopentadienyl)(η^3 -allyl)titanium (**97**) reacts with allyl bromide to give the titanacyclobutane complex **98**.¹⁸⁹

Reactions of the cationic π -allyl complex **101** with benzylmagnesium chloride or propiophenone enolate lead to the titanacyclobutane derivatives **99** and **100**.¹⁹⁰

Bis(pentamethylcyclopentadienyl)titanium hydride reacts with alkenes to give the σ -alkyl derivatives $\text{Cp}_2^*\text{TiCH}_2\text{CH}_2\text{R}$ ($\text{R} = \text{H}, \text{Me}$).¹⁰⁸

Reactions of bis(trimethylphosphine)titanocene (**56**) with an equimolar amount of 3,3-disubstituted cyclopropanes afford the titanocene(vinylcarbene) complexes **102**.¹⁹¹ The complex **102** ($\text{R}^1 = \text{R}^2 = \text{Ph}$) was prepared together with the complex $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2 = \text{C} = \text{C} = \text{CPh}_2$ by treatment of titanocene dichloride with two equivalents of butyllithium in the presence of trimethylphosphine and 3,3-diphenylcyclopropane.¹⁹²

$\text{R}^1 = \text{R}^2 = \text{Me}, \text{Ph}$; $\text{R}^1 = \text{Me}, \text{R}^2 = \text{Ph}$.

Reduction of titanocene dichloride (**2**) by isopropylmagnesium halides in the presence of methylidenecyclopropanes, methylenecyclobutane or methylenecyclopentane results in the di(cyclopentadienyl)(cycloalkylmethyl)titanium(III) complexes **103** and **104**.¹⁹³

$\text{R}^1, \text{R}^2, \text{R}^3, \text{R}^4 = \text{H}, \text{Me}$.

$n = 1, 2$; $\text{X} = \text{Cl}, \text{Br}$.

Titanium enolates of the formula $\text{Cp}_2^*\text{TiMe}(\text{OCR}^1 = \text{CR}^2\text{R}^3)$ were prepared by heating bis(pentamethylcyclopentadienyl)dimethyltitanium(IV) in the presence of epoxides, *e.g.*, cyclohexene oxide, *cis*- and *trans*-but-2-ene oxides.¹⁹⁴

The titanocene sulfide and titanocene oxide complexes **105** enter into [2+2]-cycloaddition reactions with alkynes to give titanaoxa- (**106a**) and titanathiacyclobutenes (**106b**).^{195, 196}

106a: $\text{X} = \text{O}$; $\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Me}, \text{Bu}^t, \text{Ph}, 4\text{-MeC}_6\text{H}_4$; $\text{R}^1 = \text{R}^2 = \text{Ph}$;

106b: $\text{X} = \text{S}$; $\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 = \text{H}, \text{R}^2 = \text{Ph}, \text{Me}_3\text{Si}$.

The azatitanacycles **107** and **108** are prepared by the reaction of the complex **109** with acetylene or ethylene, respectively. Reactions of the complex **109** with phenyl- or trimethylsilylacetylene yield acetylenides **110**.¹⁹⁷

$\text{R} = \text{Ph}, \text{Me}_3\text{Si}$.

Some titanocene derivatives containing Ti—C σ -bonds were prepared by the reduction of titanocene dichloride (**2**) in the presence of unsaturated compounds. Thus its reduction by magnesium in the presence of Schiff's bases prepared from α, β -unsaturated aldehydes yields titanazacyclopentenes **111**.¹⁹⁸

$\text{R}^1 = \text{Bu}^t, 4\text{-MeC}_6\text{H}_4, \text{R}^2 = \text{H}$; $\text{R}^1 = \text{cyclo-C}_6\text{H}_{11}, \text{R}^2 = \text{Me}$.

Reduction of bis(pentamethylcyclopentadienyl)titanium dichloride by magnesium in the presence of 1,4-bis(trimethylsilyl)buta-1,3-diene (**112**) results in the η^3 -enyne complex **113**.¹⁹⁹

Reduction of bis(trimethylsilyltetramethylcyclopentadienyl)-titanium dichloride by magnesium in THF in the presence of bis(trimethylsilyl)acetylene gives $\eta^5: \eta^1\text{-}[\text{C}_5\text{Me}_4\text{Si-Me}_2\text{CH}_2]$. $[\eta^5\text{-C}_5\text{Me}_4(\text{SiMe}_3)]\text{Ti(III)}$.²⁰⁰

Reactions of ylides $\text{Me}_{3-n}(\text{Me}_2\text{N})_n\text{P}=\text{CH}_2$ ($n = 1, 2$) with titanocene dichloride yield complexes $\text{Cp}_2^*\text{TiCl}(\text{CH}=\text{PR}^1\text{R}^2)$, where $\text{R}^1 = \text{NMe}_2, \text{R}^2 = \text{Me}$; $\text{R}^1 = \text{Me}, \text{R}^2 = \text{NMe}_2$.²⁰¹

Reactions of the titanocene(dicarbonyl) **57** with alkyl iodides gave the acyl complexes $\text{Cp}_2\text{Ti}[\text{C}(\text{O})\text{R}]$, where $\text{R} = \text{Me}, \text{Et}, \text{Pr}^i, \text{Bu}^n$ (see Refs 202, 203). Acyl titanocene halide derivatives are also formed upon treatment of the titanocene(dicarbonyl) **57** by organic acid chlorides^{202, 203} or by treatment of alkyl(titanocene) halides with carbon monoxide.²⁰⁴

III. Reactions of titanocene derivatives containing Ti—C σ -bonds

Reactions of titanocene derivatives containing Ti—C σ -bonds are little studied. The published data on the reactivities of these compounds are conventionally divided into two groups, *viz.*, reactions involving Ti—C σ -bonds and those with retention of these bonds.

1. Reactions with retention of Ti—C σ -bonds

Reactions of halide derivatives of titanocene σ -complexes with organometallic derivatives of non-transition metals belong to the most typical reactions of this type. Thus reaction of alkyl- or aryltitanocene chlorides with organolithium compounds was used for the preparation of the complexes **114**, which contain two different σ -bound organic radicals.

Cp^1	Cp^2	R^1	R^2	Ref.
C_5H_5	C_5H_5	Me	Ph	205
C_5H_5	C_5H_5	Me	4-MeOC ₆ H ₄	205
C_5H_5	C_5H_5	Me	4-MeC ₆ H ₄	205

C ₅ Me ₅	C ₅ Me ₅	CH=CH ₂	Me	209

^a X = SiMe₃, 3,5-(Me₂NCH₂)₂C₆H₃, 4-NCC₆H₄, 4-C₅H₄N, Fc, 4-I-3,5-(Me₂NCH₂)₂C₆H₂.

In some cases, synthesis of this type of compound is complicated by side reactions. Thus the attempts to prepare non-symmetrical ethyltitanocene derivatives by the reaction of bis(pentamethylcyclopentadienyl)ethyltitanium chloride with methylolithium, benzylpotassium or vinylolithium yielded only the ethylene complex Cp₂Ti(η²-C₂H₄) concomitantly with the liberation of the corresponding hydrocarbon. Treatment of bis(pentamethylcyclopentadienyl)vinyltitanium chloride **115** with benzylpotassium or dimethylphosphinomethylolithium gave the complex (η⁵-C₅Me₅)(C₅Me₄CH₂)Ti–CH=CH₂.²⁰⁹ The reaction of the complex **115** with vinylolithium yields 1,1-bis(pentamethylcyclopentadienyl)-1-titana-2-methylidenecyclobutane (**116**).²⁰⁹ Presumably, bis(pentamethylcyclopentadienyl)divinyltitanium (**117**), which is formed in the first step of this reaction, is decomposed to give the derivative **118**. The latter adds the ethylene molecule at the Ti=C bond to give the final product **116**.

Apparently, reactions of phenyltitanocene chloride with butyl-, vinyl- or benzylolithium afford the intermediates Cp₂Ti(Ph)R (R = Buⁿ, CH=CH₂, Bn) which are further converted into phenyldicyclopentadienyltitanium(III).²⁰⁹

Treatment of alkyl- or aryltitanocene chlorides with alkali metals alcohols^{90, 96, 210–213} or thiolates^{87, 214} or with lithium amides²¹⁵ results in the replacement of chlorine atoms.

M = Na, Li; Cp¹ = Cp² = C₅H₅; R¹ = C₆F₅, R² = Me, Et; R¹ = Me, R² = CH=CH₂; R¹ = 2-thienyl, R² = 2,4,6-(NO₂)₃C₆H₂, 3,4-(NO₂)₂C₆H₃; Cp¹ = C₅H₅, Cp² = C₅H₄CH(Me)Ph, R¹ = C₆F₅, R² = 2-MeC₆H₄; R¹ = R² = Me.

R¹ = Me, R² = 4-NH₂C₆H₄; R¹ = 2-thienyl, R² = Bn, 2-thienyl.

Reactions of 2-thienyltitanocene chloride with potassium 2,4-dichlorophenoxyacetate, mercury(I) benzoate or silver trifluoroacetate were used for the preparation of the corresponding 2-thienyltitanocene acylates (**119**).²¹⁶

M = K, R = 2,4-Cl₂C₆H₃OCH₂; M = Hg, R = Ph; M = Ag, R = CF₃.

The reaction of pentafluorophenyltitanocene chloride with sodium hydroxide occurs with the retention of the Ti–C σ -bond and results in the substitution of the hydroxy group for the chlorine atom.²¹¹

Some transformations of dicyclopentadienyltitanium(III) derivatives under the action of various oxidants, which may even include dimethylzinc, dimethylcadmium and PbCl₂, occur with the retention of the Ti–C σ -bond. Thus reaction of ethyl-, phenyl- or vinylbis(pentamethylcyclopentadienyl)titanium with dimethylzinc^{217, 218} or dimethylcadmium²¹⁷ afforded methyltitanocene derivatives along with metallic zinc or cadmium.

R = Et, Ph, CH=CH₂; M = Zn, Cd.

The methylbis(pentamethylcyclopentadienyl)titanium derivatives Cp₂^{*}Ti(Me)X, where X = Cl, OMe, N = CHBu^t, are also formed in the oxidation of the corresponding Cp₂^{*}TiX derivatives by dimethylzinc or -cadmium.^{217, 218} It is noted²¹⁷ that dimethylmercury does not enter into such reactions.

Alkyl- or acyldicyclopentadienyltitanium(IV) chlorides were prepared by oxidation of σ -alkyl- or σ -acyldicyclopentadienyltitanium(III) derivatives by lead dichloride.^{109, 219}

Treatment of dicyclopentadienyltitanium(III) derivatives with diphenyl disulfide is also accompanied by the oxidation of Ti(III) to Ti(IV) with the retention of the Ti–C σ -bond.^{102, 103, 107}

R¹ = C(O)CMe=CHMe; 2,6-Me₂C₆H₃N=CR²,

R² = Me, Et, Buⁿ.

In some cases, reaction of dicyclopentadienyltitanium(III) σ -derivatives, *e.g.*, complexes **120** and **121**, with iodine also occurs with the retention of the Ti–C σ -bond resulting in titanium(IV) derivatives.^{103, 220}

R¹ = Me, R² = 2,6-Me₂C₆H₃; R¹ = Ph, 2-MeC₆H₄,

R² = 2-MeC₆H₄, 2,6-Me₂C₆H₃.

R¹ = Ph, 2-MeC₆H₄; R² = 2-MeC₆H₄, 2,6-Me₂C₆H₃.

Sometimes, reduction of titanocene σ -derivatives occurs with the retention of the metal–carbon σ -bond. Thus the reaction of alkyltitanocene chlorides with zinc or magnesium yields titanium(III) complexes.^{40, 104}

M = Zn, Mg; R = C₆F₅, Me, CH₂SiMe₃, CH₂PPh₂.

Reaction of titanaindan **122** with naphthalenesodium occurs with the opening of the metallacycle and the formation of the complex **123**.²²¹

In some cases, the role of reducing agents for titanocene σ -derivatives is played by organolithium compounds. Thus the reaction of di(cyclopentadienyl)diphenyltitanium(IV) with phenyllithium in ether results in the reduction of Ti(IV) to Ti(III) and the formation of diphenyl(cyclopentadienyl)titanium(III) and diphenyltitanium(II). Diphenyl(cyclopentadienyl)titanium(III) is formed first. An excess of phenyllithium causes the decomposition of the Ti(III) complex, the diphenyltitanium being the final product.^{222, 223}

Reactions with retention of the Ti–C σ -bond include the formation of complex bimetallic compounds based on titanocene σ -derivatives. Thus reactions of diphenyltitanocene with diphenylzinc or triethylaluminium yield the binuclear complexes $(\text{C}_5\text{H}_4)_4\text{Ti}_2\text{Ph}_2\text{Zn}$ (see Ref. 224) and $[\text{Cp}(\text{C}_5\text{H}_4)\text{TiHAlEt}_2]_2$ in which Ti and Al atoms are linked through a bridging hydride ligand (see Ref. 225).

It is of note that the derivatives of the type $\text{Cp}_2\text{TiX}_2\text{AlR}_2$ (X = Cl, I, Br; R = Alk, Ar) are the most well-studied titanium–aluminium complexes;²²⁶ however, they do not contain Ti–C σ -bonds and are therefore not considered in this review.

The bimetallic Ti(III) complexes in which the alkali metal ion was incorporated between the acetylenide fragments (tweezer complexes) were synthesised from titanocene acetylenides and its derivatives containing substituents in the cyclopentadienyl ligands. Thus the complexes **124** were prepared by the reaction of $(\eta^5\text{-C}_5\text{HMe}_4)_2\text{Ti}(\eta^1\text{-C}\equiv\text{CSiMe}_3)_2$ with alkali metals in toluene.^{63, 227}

M = Li, Na, K.

A similar complex $[(\eta^5\text{-C}_5\text{HMe}_4)_2\text{Ti}(\eta^1\text{-C}\equiv\text{CC}\equiv\text{CSiMe}_3)]^- [\text{Li}(\text{THF})_2]^+$ (see Ref. 125) was prepared by treatment of bis-(tetramethylcyclopentadienyl)(4-trimethylsilylbuta-1,3-dienyl)titanium in THF with an excess of 1-lithio-4-(trimethylsilyl)buta-1,3-diyne.

Bis(alkynyl)titanocenes are very good chelating ligands owing to their ability to form bimetallic complexes with copper(I), iron(II) and silver salts. Thus reactions of bis(trimethylsilylcyclopentadienyl)bis(trimethylsilylethynyl)titanium with CuCl , FeCl_2 and various silver salts yield the complexes **125a–g**.

Compounds 125	M	X	<i>n</i>	Ref.
a	Cu	Cl	1	228, 229
b	Fe	Cl	2	228, 230
c	Ag	Cl	1	230
d	Ag	CN	1	230
e	Ag	SCN	1	230
f	Ag	NO ₂	1	230
g	Ag	ClO ₄	1	230

In the reaction of the complex **125a** with lithium acetylenides, the chlorine atom is replaced by the ethynyl group to give complexes of the general formula $(\eta^5\text{-C}_5\text{H}_4\text{SiMe}_3)_2\text{Ti}(\eta^1\text{-C}\equiv\text{CSiMe}_3)_2\text{CuC}\equiv\text{CR}$, where R = SiMe₃, Bu^t, Ph.²²⁹ The structurally similar copper and silver complexes $(\eta^5\text{-C}_5\text{H}_4\text{SiMe}_3)_2\text{Ti}(\eta^1\text{-C}\equiv\text{CSiMe}_3)_2\text{MR}$, where M = Cu, Ag and R = 2,4,6-Me₃C₆H₂, have been synthesised.²³¹

Bis(trimethylsilylcyclopentadienyl)bis(ferrocenylethynyl)titanium (**126**) reacts with nickel tetracarbonyl or tetrakis(triphenylphosphine)palladium to give the complexes **127**⁶⁹ and **128**.²³²

Reaction of the complex **126** with silver hexafluorophosphate yields the complexes **129a–c** in which the silver ion is bound to the four triple bonds of the acetylenic groups.²³³ Compounds **129d,e** were prepared analogously.

R¹ = H, R² = Fc (**a**); R¹ = Me₃Si, R² = Fc (**b**);
R¹ = H, R² = (C≡C)₂Fc (**c**); R¹ = Me₃Si, R² = Ph (**d**);
R¹ = Me₃Si, R² = Rc.

Bis(trimethylsilylcyclopentadienyl)(trimethylsilylethynyl)titanium and bis(trimethylsilylcyclopentadienyl)(hexa-1,3-diynyl)titanium chlorides form the complexes $[(\text{C}_5\text{H}_4\text{SiMe}_3)_2\text{Ti}(\text{R})\text{Cl}]$. CuBr [R = C≡CSiMe₃,²³⁴ C≡C–C≡CEt (see Ref. 61)] with copper(I) bromide. The complexes **130** were synthesised from

R¹ = Me₂NCH₂CH₂, R² = Me₃Si, MX_n = AgCl;
R¹ = Ph₂P, Ph₂P(O), Ph₂P(S); R² = Bu^t, MX_n = CuCl, Mo(CO)₄;
R¹ = Me₃Si, R² = Ph, MX_n = CoCO.

dialkynyltitanocene derivatives containing various substituents in the cyclopentadienyl ligands.^{65, 235}

The reaction of the triyne titanacycles **131** with bis(cyclooctadiene)nickel $\text{Ni}(\text{COD})_2$ yields the binuclear complexes **132**.⁶⁰

$\text{Cp}^1 = \text{Cp}^2 = \text{C}_5\text{H}_5, \text{C}_5\text{Me}_5$.

Dicyclopentadienylbis(diphenylphosphinomethyl)titanium and bis(dicyclopentadienyldiphenylphosphinomethyl)titanium oxide form the complexes $[\text{Cp}_2\text{Ti}(\text{CH}_2\text{PPh}_2)_2\text{Rh}(\text{CO})\text{Cl}]_2$ (see Ref. 40) and $\text{O}[\text{Cp}_2\text{TiCH}_2\text{PPh}_2]_2\text{Rh}(\text{CO})\text{Cl}$ ²³⁶ with dicarbonylrhodium chloride. The cationic complex $[\text{Cp}_2\text{Ti}(\text{CH}_2\text{PPh}_2)_2\text{Rh}(\text{COD})]^+[\text{BPh}_4]^-$ was prepared by treatment of dicyclopentadienylbis(diphenylphosphinomethyl)titanium with the rhodium complexes $[\text{L}_2\text{Rh}(\text{COD})]^+[\text{BPh}_4]^-$, where $\text{L} = \text{Ph}_3\text{P}, \text{COD}$.²³⁷

The reaction of titanacumulene (**133**) with dicyclopentadienylzirconium occurs with the cleavage of the central $\text{C}=\text{C}$ bond and results in the formation of the heterodimetallic titanocene–zirconocene complex **134** with a σ, π -alkynyl bridge.¹⁴²

2. Insertion into Ti–C σ -bonds

Transformations of titanocene derivatives occurring with insertion of various fragments into Ti–C σ -bonds have been described.

Thus isocyanides are inserted into the Ti–C σ -bonds of alkyl- or aryltitanocenes **36** to give the titanacycles **135** at 20 °C. At the same time, at -78 °C the reaction of the complexes **36** with isocyanides yields exclusively the adducts $\text{Cp}_2\text{TiR}^1\text{-R}^2\text{NC}$.

R^1	R^2	R^3	Ref.
H	Et	2,6-Me ₂ C ₆ H ₃	102
H	Bu	2,6-Me ₂ C ₆ H ₃	102
H	Me	2,6-Me ₂ C ₆ H ₃	102, 103
Me	Me	2,6-Me ₂ C ₆ H ₃	109
H	Ph	2-MeC ₆ H ₄	220
H	Ph	2,6-Me ₂ C ₆ H ₃	220
H	2-MeC ₆ H ₄	2-MeC ₆ H ₄	220
H	2-MeC ₆ H ₄	2,6-Me ₂ C ₆ H ₃	220

Insertion into the Ti–C σ -bond takes place in the reaction of cyclohexyl isocyanide with dimethyltitanocene (**1**)²³⁸ or the methylidenetitanacyclobutene complexes **136**¹⁶⁹ as well as in reactions of *tert*-butyl isocyanide with 1-oxa-5-titanacyclopentanes **137**²³⁹ or bis(methylethynyl)titanocene **138** in the presence of dimethylanilinium tetraphenylborate.²⁴⁰

$\text{R} = \text{Me}, \text{Ph}$.

$\text{R} = \text{Me}, \text{Et}, \text{Pr}^i$.

As in the case of isocyanides, reactions of alkyltitanocenes with nitriles at low temperatures give the adducts $\text{Cp}_2\text{TiR}^1\text{-R}^2\text{CN}$ ($\text{R}^1 = \text{Ph}, 2\text{-MeC}_6\text{H}_4, \text{Bn}, \text{C}_6\text{F}_5$; $\text{R}^2 = \text{Me}, \text{Bu}^t, \text{Ph}, 2\text{-MeC}_6\text{H}_4, 2,6\text{-Me}_2\text{C}_6\text{H}_3$).²⁴¹ An increase in the temperature leads to dimerisation of the nitrile ligand.²⁴²

$\text{R}^1 = \text{Ph}, 2\text{-MeC}_6\text{H}_4, \text{Bn}, \text{C}_6\text{F}_5$; $\text{R}^2 = \text{Ph}, \text{Me}, 2\text{-MeC}_6\text{H}_4$.

Treatment of methyltitanocene chloride with equimolar amounts of nitriles in the presence of sodium tetraphenylborate gives the complexes **139** which further yield the azaalkylidene derivatives **140** due to the insertion of the nitrile molecule into the Ti–C bond.^{243, 244}

$\text{R} = \text{Me}, \text{Pr}, \text{Ph}, \text{Bu}^t$.

In this reaction, trimethylsilyl cyanide is isomerised into the corresponding isocyanide, which forms an η^2 -iminoacyl complex $[\text{Cp}_2\text{Ti}(\text{CMe} = \text{NSiMe}_3)(\text{C} \equiv \text{NSiMe}_3)]^+ \text{BPh}_4^-$ with methyltitanocene chloride (see Ref. 244).

Reactions of the titanaluminium complex $\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2(\mu\text{-CH}_2)\text{AlMe}_2$ or 2-*tert*-butyl-1,1-bis(cyclopentadienyl)-1-titanacyclobutane with *tert*-butyl cyanide in the presence of trimethylphosphine or 4-(*N,N*-dimethylamino)pyridine gives first the vinylimide complexes **141**, which react with an excess of nitrile to yield the 2,6-diaza-1-titanacyclohexa-2,5-diene derivative **142**.^{245, 246}

L = PMe₃, 4-Me₂NC₅H₄N.

2,6-Diazatitanacyclohexa-2,4-dienes **142** (R = Bu^t, Ph) are formed upon refluxing of *tert*-butyl or phenyl cyanide with dimethyltitanocene (**1**) in benzene.¹⁵¹

R = Bu^t, Ph.

The direction of reactions of titanocene σ -derivatives with carbon monoxide depends on the reaction conditions and the structure of the organometallic compound. Thus treatment of alkyl-, aryl- and vinylcyclopentadienyltitanium(III) derivatives as well as ethyl- or methyltitanocene chlorides with carbon monoxide leads to the insertion into the Ti–C σ -bond eventually resulting in the acyltitanocene complexes **143**.^{109, 204, 247, 248}

Cp ¹	Cp ²	R	T / °C	Ref.
C ₅ H ₅	C ₅ Me ₅	Me	–70	106

C ₅ H ₅	C ₅ Me ₅	Me	0	247
C ₅ H ₅	C ₅ Me ₅	n-C ₅ H ₁₁	0	247
C ₅ H ₅	C ₅ H ₅	C(Me)=CHMe	20	106, 248
C ₅ H ₅	C ₅ H ₅	2-MeC ₆ H ₄	20	106, 248

The products of CO insertion into the Ti–C bond (**144–146**) were prepared by treating acetonitrile(methyl)titanocene tetraphenylborate²⁴³ or the corresponding titanacyclopentane and titanaoxacyclopentane derivatives^{77, 239} with carbon monoxide.

R = Me, Et, Prⁱ.

Reactions of chromium and tungsten hexacarbonyls with the methyl(vinyl)titanocene derivative **147** occur as the insertion of CO into the Ti–C σ -bond and the formation of the bimetallic complexes **148**.¹³

Cp¹ = C₅Me₄(CH₂)₂NMe₂, Cp² = C₅Me₅; M = Cr, W.

In contrast to alkylcyclopentadienyltitanium(III) derivatives, pentafluorophenyltitanocene reacts with carbon monoxide (25 °C, 1 atm) with the formation of the carbonyl complex Cp₂Ti(CO)C₆F₅.²⁴⁷ Photochemical reactions of dimethyl- or diphenyltitanocene with carbon monoxide^{25, 140} or treatment of dibenzyltitanocene^{204, 249} and titanaindan derivatives **18a, b**⁷⁰ in benzene with carbon monoxide gave the titanocenedicarbonyl Cp₂Ti(CO)₂. It was noted that the reaction of carbon monoxide with dibenzyltitanocene in pentane is sometimes associated with the intermediate formation of the benzylacyl complex Cp₂Ti(COBn)Bn.²⁴⁹

Reactions of some titanocene derivatives with carbon dioxide also occur by insertion into the metal–carbon σ -bond. Thus the photochemical reaction of dimethyltitanocene with carbon dioxide in pentane (16 °C, 20 h) results in methyltitanocene acetate Cp₂Ti(Me)[OC(O)Me].²⁵⁰ Passage of carbon dioxide through a solution of dimethyltitanocene in toluene at 80 °C leads to the insertion of CO₂ simultaneously into two Ti–C σ -bonds resulting in the titanocene diacetate Cp₂Ti(OC(O)Me)₂.²⁵¹

Treatment of diphenyltitanocene with carbon dioxide in xylene at 80–90 °C gives the titanacyclic compound **149**.^{251, 252}

It is believed that compound **149** is formed as a result of insertion of carbon dioxide into the phenylenetitanium complex **72** formed upon splitting of the benzene molecule from diphenyltitanocene.

Reactions of η^2 -iminoacyl complexes with carbon dioxide occur by insertion of CO₂ into the Ti–Alk bond and yield dicyclopentadienyltitanium(III) acylates **150**.¹⁰²

R = Me, Et, Buⁿ.

The product of insertion into the Ti–C σ -bond **151** was obtained in the reaction of the binuclear complex **152** with CO₂.²⁵³

The insertion into the Ti–C σ -bond and the formation of *O*-sulfates take place in the treatment of dimethyl-, diphenyl- or bis(2-thienyl)titanocenes^{254–256} and methylchloro- or methyl-(pentafluorophenyl)titanocenes^{254, 257, 258} with sulfur dioxide.

$R^1 = \text{H}, R^2 = \text{Me, Ph, 2-thienyl}; R^1 = R^2 = \text{Me}.$

$R^1 = \text{CH(Me)Ph}, R^2 = \text{C}_6\text{F}_5; R^1 = \text{H}, R^2 = \text{Cl, C}_6\text{F}_5.$

The reaction of carbon disulfide with vinylindicyclopentadienyltitanium(III) gives the paramagnetic insertion product $\text{Cp}_2\text{Ti}[\text{SC(S)CMe}=\text{CHMe}]$.¹⁰⁷

3. Cleavage of Ti–C σ -bonds

Whereas the π -bond between the cyclopentadienyl ligand and the titanium atom is stable in acidic media, the Ti–C σ -bonds are easily cleaved by acids. Thus dialkyl- and diaryltitanocene derivatives react with an excess of hydrogen chloride to give the corresponding titanocene dichlorides.

Cp^1	Cp^2	R	Ref.
C_5H_5	C_5H_5	Ph	259

C_5H_5	C_5H_5	Fc	49
		Me	260
$\text{C}_5\text{H}_4\text{Me}$	$\text{C}_5\text{H}_4\text{Me}$	$\text{C}\equiv\text{CR}^a$	56
$\text{C}_5\text{H}_4\text{SiMe}_3$	$\text{C}_5\text{H}_4\text{SiMe}_3$	$\text{C}\equiv\text{CR}^a$	56

^a R = Et, Prⁿ, Buⁿ, Bu^t, Me₃Si, Ph.

Titanocene dichloride is prepared by treatment of titanacycles, such as 1,1-dicyclopentadienyl-1-titanacyclopentane,⁷⁸ 1,1-dicyclopentadienyl-1-titanafluorene,⁷³ titanacyclopentadienes **54a,b**,¹³⁰ or titanabicyclopentane **84**,¹⁶⁸ with an excess of hydrogen chloride.

The complexes $\text{Cp}^1\text{Cp}^2\text{TiCl}_2$ containing two different π -bound cyclopentadienyl ligands were prepared by the reaction of hydrogen chloride with the titanocene derivatives $\text{Cp}_2^1\text{Ti}(\text{Cp}^2)\text{Cl}$ in which the two cyclopentadienyl ligands were linked by π -bonds and one cyclopentadienyl ligand, by σ -bonds.^{261, 262}

Reactions of dialkyl- or diaryltitanocenes with equimolar amounts of hydrogen chloride result in the cleavage of only one Ti–C σ -bond and yield alkyl- or aryltitanocene chlorides $\text{Cp}^1\text{Cp}^2\text{Ti}(\text{R})\text{Cl}$ and $\text{Cp}_2^1\text{Ti}(\text{R})\text{Cl}$, where $\text{Cp}^1 = \text{C}_5\text{H}_5$, $\text{Cp}^2 = \text{C}_5\text{Me}_4\text{H}$; R = Me, Ph, 4-MeC₆H₄;⁷ $\text{Cp}^1 = \text{Cp}^2 = \text{C}_5\text{H}_5$, R = 2-thienyl,²¹⁴ 3,4,5-trichloro-2-thienyl.⁴³ The cationic complex $[\text{Cp}_2\text{TiMe}]^+\text{BF}_4^-$ was prepared by the reaction of dimethyltitanocene with an equimolar amount of fluoroboric acid.²⁶³

In contrast to the majority of titanocene σ -derivatives, bis(*o*-carboranylmethyl)- and bis(pentafluorophenyl)titanocenes are relatively stable in acidic media and are converted into titanocene dichloride only after prolonged boiling with hydrochloric acid.^{24, 45} The retention of the σ -bond between the titanium

atom and the perfluorophenyl ligand was also observed in the treatment of methylsulfinates and perfluorophenyltitanocene alcohols $\text{Cp}(\text{C}_5\text{H}_4\text{CHMePh})\text{Ti}(\text{C}_6\text{F}_5)(\text{O}_2\text{SMe})$ (see Ref. 257) and $\text{Cp}(\text{C}_5\text{H}_4\text{CHMePh})\text{Ti}(\text{C}_6\text{F}_5)\text{OR}$ (R = Me, 2-MeC₆H₄) with hydrogen chloride.⁹⁶

The cleavage of Ti–C σ -bonds takes place upon treatment of alkyl- or aryltitanocenes with organic acids. Thus dimethyltitanocene reacts with equimolar amounts of acetic,²⁰⁵ benzoic or 2-phenylpropionic acids²⁶⁴ with cleavage of one of methyl groups eventually resulting in the corresponding methyltitanocene acylates.

R = Me, Ph, CH(Me)Ph.

Treatment of dimethyltitanocene with an excess of phenylpropionic or trifluoromethanesulfonic acid results in the replacement of two σ -bound methyl groups by acid residues.^{265, 266} The reaction of pyridine-2,6-dicarboxylic acid with dimethyltitanocene yields the complex **153**.²⁶⁰

The formation of titanocene diacylates takes place in the reaction of bis(2-thienyl)titanocene **10a** with 3,5-dinitrobenzoic, perfluorobenzoic and trifluoro-, trichloro- and tribromoacetic acids.⁴²

R = 3,5-(NO₂)₂C₆H₃, C₆F₅, CF₃, CCl₃, CBr₃.

The reaction of methyltitanocene chloride with benzoic or phenylacetic acids afforded mixtures of titanocene dichloride with the corresponding titanocene diacylates $\text{Cp}_2\text{Ti}[\text{OC}(\text{O})\text{R}]_2$; their formation is due to symmetrisation of the intermediate chlorotitanocene acylates $\text{Cp}_2\text{TiCl}[\text{OC}(\text{O})\text{R}]$.²⁶⁷ The formation of a Cp_2TiMe_2 , $\text{Cp}_2\text{TiMe}[\text{OC}(\text{O})\text{CF}_3]$ and $\text{Cp}_2\text{Ti}[\text{OC}(\text{O})\text{CF}_3]_2$ mixture is also observed upon treatment of 1,1,3,3-tetracyclopentadienyl-1,3-dititanacyclobutane with trifluoroacetic acid.¹⁶⁷ Reactions of (2-thienyl)titanocene chloride with trichloro- and tribromoacetic, perfluorobenzoic or 2-nitrobenzoic acids gave the corresponding chlorotitanocene acylates.²¹⁶

R = CCl₃, CBr₃, C₆F₅, 2-NO₂C₆H₄.

It is of note that treatment of some methyltitanocene alcohols $\text{Cp}_2\text{TiMe}(\text{OR}^1)$ (R¹ is benzyl, menthyl, bornyl) with benzoic or diphenylacetic acids results in the cleavage of the alkoxide ligand (rather than the methyl ligand) and affords the methyltitanocene acylates $\text{Cp}_2\text{Ti}(\text{Me})\text{OC}(\text{O})\text{R}^2$, where R² = Ph, CHPh₂.²⁶⁷

Ti–C σ -bonds are cleaved upon the action of hydrogen chloride on alkyl- or aryl[dicyclopentadienyltitanium(III)] and their complexes with molecular nitrogen or

nitriles.^{103, 105, 112, 241, 268} The titanocene monochloride formed at low temperatures (-78°C) is oxidised to titanocene dichloride at 20°C .

The Ti–C bond is also cleaved under the action of some alcohols and phenols on titanocene derivatives. Thus reactions of dimethyltitanocene with an equimolar amount of alcohols bearing bulky radicals gave the methyltitanocene alcoholates $\text{Cp}_2\text{Ti}(\text{Me})\text{OR}$ [R is benzyl, menthyl, bornyl,²⁶⁷ $\text{CHMeC}_8\text{H}_{17}$, CMePh_2 , CHPr^nPh , CHPhBn , $\text{CH}_2\text{CH}=\text{CHPr}^n$ (see Ref. 264)]. Titanocene trifluoromethanesulfonate alcoholates $\text{Cp}_2\text{Ti}(\text{O}_3\text{SCF}_3)(\text{OR})$, where R = Me, Me_3Si , $\text{Me}_2\text{Bu}^t\text{Si}$, are formed upon treatment of methyltitanocene trifluoromethanesulfonate with the corresponding alcohols.²⁶⁵ Reactions of dimethyltitanocene with (+)-(2*R*,3*R*)-dimethyl and (+)-(2*R*,3*R*)-dibutyl tartrates²⁶⁹ and reactions of diphenyltitanocene with 2,2-dimethylpropane-1,3-diol²⁷⁰ yielded the binuclear complexes **154** and **155**, respectively.

R = Me, Bu^n .

A bimetallic complex was also formed when chromotricarbonyl(hydroxymethyl)benzene was used.²⁷¹

The reaction of bis(2-thienyl)titanocene (**10a**) or (2-thienyl)titanocene chloride with picric acid, 4-hydroxybiphenyl or 3,4-dimethylphenol afforded the corresponding titanocene diphenolates and chlorotitanocene phenolates.²¹³

R = 2,4,6-(NO_2) $_3\text{C}_6\text{H}_2$, 4- PhC_6H_4 , 3,4- $\text{Me}_2\text{C}_6\text{H}_3$.

The cleavage of the Ti–C σ -bond by propane-1,3-dithiol has been described.²⁷²

Treatment of dialkyl- or diaryltitanocene derivatives with halogens results in the cleavage of the metal–carbon σ -bonds to give the corresponding titanocene dihalides Cp_2TiX_2 (X = Cl, Br, I).^{31, 42, 56, 73, 78, 79, 273, 274} It was shown that the reaction of

(2-thienyl)titanocene derivatives with iodine proceeds in a step-wise manner; the σ -bound thienyl group is split off in the first step.^{275, 276}

X = 3,4- $\text{Me}_2\text{C}_6\text{H}_3\text{O}$, PhS, Ph_2N , Cl, 2-thienyl.

Treatment of alkyl- or aryldicyclopentadienyltitanium(III) derivatives with an excess of halogens occurs as the cleavage of the Ti–C σ -bond and the oxidation of the titanium atom leading to the formation of titanocene dihalides.^{105, 112, 268}

Substitution of chlorine atoms for σ -bound alkyl or aryl ligands takes place in the reaction of dialkyl- or diaryltitanocenes with mercury dichloride.

The cleavage of σ -bound pentafluorophenyl ligands in bis-(pentafluorophenyl)titanocene under the action of TiCl_4 (see Ref. 255) or BCl_3 was observed.³⁵ The cleavage of Ti–C σ -bonds and the formation of titanocene dichloride takes place upon treatment of dicyclopentadienyl-2,4-bis(trimethylsilyl-ethynyl)-3,5-bis(trimethylsilyl)titanacyclopenta-2,4-diene with S_2Cl_2 ,²⁸⁰ as well as upon treatment of $\text{Cp}_2\text{Ti}[\text{C}\equiv\text{CFc}]_2$ with nickel chloride.⁶²

Exchange reactions of methyl and phenyl groups for halogen atoms upon treatment of dimethyl- or diphenyltitanocene with titanocene dihalides have been studied.²⁵¹

R = Me, Ph; X = F, Cl, Br, I.

It was found that reaction rates decrease in the following order: $\text{I} > \text{Br} > \text{F} > \text{Cl}$ for dimethyltitanocene and $\text{I} > \text{Cl} > \text{Br} > \text{F}$ for diphenyltitanocene.

Heating of dimethyl- or diphenyltitanocene with chloroform or carbon tetrachloride is also accompanied by the cleavage of Ti–C σ -bonds resulting in titanocene dichloride.^{277, 279} Heating of diphenyltitanocene with benzyl chloride yields a titanocene dichloride–(cyclopentadienyl)titanium trichloride mixture.²⁸¹ 1,1-Dicyclopentadienyl-1-titanacyclobutane reacts with benzyl or allyl chloride to give alkyltitanocene chlorides $\text{Cp}_2\text{Ti}(\text{CH}_2\text{R})\text{Cl}$ (R = Bn, All).²⁸²

Cleavage of Ti–C σ -bonds takes place upon treatment of diphenyltitanocene with benzoyl peroxide.^{283–285} When this reaction is carried out in isopropyl alcohol, titanocene dibenzoate $\text{Cp}_2\text{Ti}(\text{O}_2\text{CPh})_2$ is formed as the major product. The dicyclopentadienyltitanium fragment is destroyed in ether or benzene to give the cyclopentadienyltitanium dibenzoate $\text{CpTi}(\text{O}_2\text{CPh})_2$. In contrast to reactions of diphenyltitanocene with benzoyl peroxide, treatment with 3- or 4-nitrobenzoyl peroxides is not accompanied by the cleavage of the titanocene fragment and the corresponding titanocene bis(nitrobenzoates) are formed.²⁸⁶

The Ti–C σ -bonds of methyl- or butyltitanocenes are split off under the action of pyridine derivatives.²⁸⁷

$\text{R}^1 = \text{Me, Bu}$; $\text{R}^2 = 2\text{-Me, 2-Ph, 2-CH}=\text{CH}_2$.

Reactions of thienyltitanocene chloride with acetylacetone, benzoylacetone or dibenzoylmethane gave the corresponding chlorotitanocene β -diketonates.²⁸⁸

$R^1 = R^2 = \text{Me}$, Ph; $R^1 = \text{Ph}$, $R^2 = \text{Me}$.

* * *

The data presented demonstrate high reactivities of titanocene derivatives containing Ti–C σ -bonds. The ease and selectivity of reactions involving these bonds, the possibility of titanium to exist in different oxidation states and the formation of complex bimetallic compounds suggest that titanocene σ -derivatives are promising reagents for fine organic and organometallic syntheses.

VI. Conclusion	324

Abstract. Data on the study of the influence of accelerated ion beams on polymeric materials are generalised. The mechanisms of chemical processes occurring in a polymer matrix upon ion implantation and resulting in crucial changes in the electrical conductivity, microhardness, hydrophilicity and other characteristics of the irradiated polymer surface are discussed. Main fields of applications of ion-implanted polymeric materials are considered. The bibliography includes 188 references.

I. Introduction

Long-term ion bombardment of a polymer causes important transformations of the material, accompanied by the formation of specific modifications of amorphous hydrogenated carbon which exhibits conducting properties. Ion irradiation is also responsible for an increase in the conductivity of initially dielectric polymers (*e.g.*, polyimide and polyethylene) by 10 to 15 and even 18 orders of magnitude. Studies carried out in the last decade allowed one to gain a deeper insight into the mechanisms of ion bombardment induced processes in polymeric materials and showed that varying the main parameters of ion irradiation (energy and mass of implanted ions, implantation dose, ionic current) has a significant effect on the formation of a carbonaceous phase in the implanted layer. These studies also revealed the possibility of effective control of not only conducting and optical, but also tribological, hydrophilic and hydrophobic properties of the irradiated polymer surface.

Salient features of ion implantation into polymeric targets have been reviewed.^{1–6} However, the emphasis was placed on systematisation of the data on the nature of the conducting properties of ion-implanted polymers. This review (i) concerns the character and mechanisms of chemical reactions occurring in the polymer matrix during ion irradiation to high fluences and (ii) analyses the role of these processes in the formation of the properties of ion-implanted layers formed at the surface of polymeric materials.

II. Peculiarities of the interaction of high-energy ions with polymeric target

Specific effects of ion irradiation on polymeric samples are first of all due to very high density of energy transferred to the irradiated target. Energy loss of incident ions in polymer matrices can be as high as tens and even hundreds of electron-volts per 1 Å of track length. Energy deposition occurs within a very small volume along the ion track and takes a very short time ($\sim 10^{-13}$ s).⁷ Taking into account the fact that the bond dissociation energies in polymers do not exceed 10 eV (*e.g.*, 4.3 eV for the C–H and 9.3 eV for the C=N bond), the energy deposited by the stopping projectile is high enough to break a large number of chemical bonds within the track volume even in the case of implantation of ions with medium energies (from tens to hundreds of kiloelectron-volts). This, in turn, creates prerequisites for essential transformations in the irradiated polymer during ion bombardment.

The character of chemical processes induced in the polymer matrix by ion implantation is strongly affected by two fundamentally different mechanisms of energy transfer from the incident ions to the polymer, namely, by inelastic (electronic excitations) and elastic (nuclear) collisions.⁷ The former mechanism leads to excitation and ionisation of polymer molecules and (also as a result of fast subsequent neutralisation) to the formation of a large number of mobile radical species (first of all, H[•] radicals) and macroradicals. Nuclear collisions are accompanied by massive rupture of chemical bonds due to displacement of atomic nuclei and by transfer of rather high energy to the polymer matrix in the form of phonons.⁷ Once the deposited energy is sufficiently high, the displaced atoms can, in turn, create their own track cascades.^{1,7} The contribution of each mechanism to the overall energy loss of an incident ion is characterised by its stopping power, S_n (for 'nuclear') and S_e (for 'electronic' energy loss), which represents the change in the ion energy caused by its interaction with the polymer matrix per unit path length. The S_n and S_e values depend on the energy and mass of incident ions. High-energy light ions deposit their energy mostly by electronic excitations, while heavy ions lose their energy nearly completely by nuclear collisions.^{7,8} As the ion slows down, the contribution of each mechanism to the overall energy loss substantially changes (*e.g.*, a feature of the implantation of light-element ions is an increase in the relative weight of 'nuclear' energy loss at the end of the ion track^{7,8}).

Thus, stopping of ions is accompanied by deposition of rather high energy within the ion tracks and is followed by the formation of radicals, secondary ions and electrons. A certain fraction of

electrons (the so-called δ -electrons) have energies high enough to escape the primary ion track.^{7,9} The tracks of δ -electrons (secondary tracks) form a region called 'penumbra'¹⁰ in which the excitation and ionisation of the polymeric material also occurs. For ions with energies of the order of 100 keV to 1 MeV per nucleon, the radius of the primary track lies between 5 and 10 Å¹¹ while the penumbra radius can reach 50 to 100 Å (this estimate was obtained for water which differs only slightly in stopping power from most polymers).^{10,11} Compared to the ion track, the density of energy deposited in the penumbra is an order of magnitude lower^{1,9-11} and the processes occurring in this region can be considered as pure radiation processes. Energy deposition occurs mainly within the track core which is thus heated to very high temperatures. Heating is due to electrons confined within the track by a strong electric field¹² perpendicular to the track axis and to direct transfer of vibrational energy to polymer by nuclear collisions.⁷ The 'thermal spike' model allows estimation of temperature within a cylindrical track as a function of the radial distance (r) and time (t) elapsed after passage of an ion as follows:¹³⁻¹⁶

$$T(r, t) = \frac{T_0}{1 + 4\delta t/r_0^2} \exp \left[-\frac{(r/r_0)^2}{1 + 4\delta t/r_0^2} \right],$$

$$T_0 = \frac{S}{\pi \rho C_V r_0^2},$$

where T_0 is the initial temperature (at the instant the thermal spike is created), δ is the thermal diffusivity of the condensed medium in which the ion slows down, r_0 is the radius of the ion track, S is the overall stopping power for the incident ion, ρ is the density of the polymer and C_V is the heat capacity of the polymer. The T_0 values corresponding to the implantation of ions with energies ranging from 0.1 to 1 MeV into various polymers can be as high as $\sim 10^4$ K, while quenching of the track down to the temperature of a polymeric target under ion irradiation [$\sim 100-150$ °C (see Refs 17 and 18)] takes $10^{-9}-10^{-10}$ s. This formula provides only a rough estimate of the parameters of the thermal pulse produced upon passage of a high-energy ion; nevertheless, it allows one to estimate the main parameters (including the time parameters) of the thermal effects accompanying ion implantation. It should be noted that the experimental estimate of the temperature of the electron cloud created during ionisation of the atoms within the ion track can be obtained from analysis of the C (KVV) spectrum of the Auger electrons generated in the ion bombarded amorphous carbon (this is closely related to the conditions in heavily implanted polymeric materials); the theoretical estimate of the T_0 value is in reasonable agreement with the experimental results of these experiments.¹⁹

Build up of the dose of implanted ions leads to basic changes in the character of ion-induced processes. Initially, a pristine polymer is ion bombarded until accumulation of a certain dose D_f corresponding to complete coverage of the surface of the polymer sample with ion tracks. Further implantation occurs into the polymer exposed to ion irradiation. In this case, the processes in the polymeric target represent a specific kind of pulse thermoradiolysis since the products of radiochemical reactions formed within and in the vicinity of the track region and those accumulated in the polymer matrix during previous irradiation are involved in the thermally induced reactions occurring in the thermal spike.

III. Chemical processes occurring during ion bombardment of polymers

Studies of the effect of ion irradiation on various polymeric materials showed that implantation to high doses leads to carbonisation of the surface of the polymer sample and to the formation of specific surface forms of amorphous hydrogenated carbon.²⁰⁻²⁴ Carbonisation occurs efficiently if the energy loss per

unit track length (or the linear energy transfer, LET) of incident ions exceeds a particular threshold value (15 to 20 eV Å⁻¹ for aliphatic polymers¹). Accumulation of carbon in the implanted layer is accompanied by evolution of a large amount of dihydrogen (usually, the major gaseous product of ion implantation), low-molecular-mass hydrocarbons (first of all, acetylene) and CO and CO₂ in the case of oxygen-containing polymers (Table 1).^{1,24-28}

Table 1. Relative yields of molecular products formed during irradiation of polymer surface with 200 keV He⁺ ions.^{1,24}

Molecular species (fragment)	Polyethylene	Polystyrene	Polyimide
H ₂	1 ^a	1 ^b	1
CH ₄	0.02	0.01	—
C ₂ H ₂	0.11	0.53	0.05
C ₃ H ₅	0.01	0.004	—
C ₆ H ₆	—	0.013	—
CO			2
CO ₂			1

Note. All values were normalised to the yield of dihydrogen.

^a The absolute yield is 4.8 hydrogen molecules per 100 eV adsorbed by the polymeric target.¹

^b The absolute yield is 1.15 hydrogen molecules per 100 eV adsorbed by the polymeric target.¹

The amount of gaseous products formed in ion-induced, radiochemical pyrolytic processes exponentially decreases as the surface of a polymeric target is covered by ion tracks:^{1,5}

$$Q = Q_0 \exp(-\varepsilon D),$$

where Q_0 and Q are the initial and current yields of the detected gaseous product, respectively; ε is the cross-section of the reaction accompanied by gas evolution (based on the ε value, one can estimate the reaction volume in which ion-induced thermoradiolysis occurs); and D is the implantation dose. Clearly, the ε^{-1} value allows estimation of D_f for a polymer irradiated under particular implantation regime.^{1,5} For ions with energies of the order of hundreds of kiloelectron-volts, the cross-sections of ion-induced reactions accompanied by gas evolution are $\sim 10^{-14}-10^{-15}$ cm² (see Refs 1, 5, 29). Since the radiation processes accompanied by evolution of dihydrogen also occur within the penumbra, the cross-section of the reaction of H₂ liberation is somewhat larger than those of the reactions of formation of hydrocarbons (CO and CO₂) released immediately in the intra-track region.³⁰

The fact that radiochemical processes in the penumbra allow cross-linking of polymer chains is of great importance. For instance, the yield of cross-linking for electron beam irradiated polyethylene (this regime is analogous to the action of δ -electrons) is 3 to 5 times higher than the chain scission yield.³¹ In this case, radiation-induced cross-linking of the polymer occurs even at low fluences, which are two orders of magnitude lower than D_f for medium-range energy ions.^{5,32} This must strongly affect the course of ion-induced pyrolytic processes. This conclusion is, in particular, supported by the fact that, in contrast to pristine polyethylene, thermal degradation of radiochemically cross-linked polyethylene leads to the formation of a solid carbonaceous phase with pronounced semiconductor properties rather than a mixture of liquid hydrocarbons.³³

Radiolysis products are involved in the intra-track pyrolytic processes or are accumulated within the implanted layer to be consumed at later stages of ion irradiation. High-temperature pyrolysis in the track and its immediate vicinity is accompanied by scission of polymer chains. This provides the possibility of cyclisation of radiochemically generated unsaturated linear chain fragments by the intramolecular Diels–Alder mechanism (aromatic hydrocarbons are much more stable than linear unsaturated hydrocarbons).

turated hydrocarbons at temperatures above 800 °C). As the track is cooled down, the newly formed aromatic fragments and analogous fragments present in the pristine polymer and released upon thermoradiolysis are linked together, thus being stabilised due to extension of the conjugation system.³

According to data from mass-spectrometric analysis, the exhaust gases evolved during ion implantation include hydrogen and hydrocarbons with different molecular masses.^{1,24,34} Usually, the most abundant product is acetylene which is the most stable acyclic unsaturated hydrocarbon at high temperatures. Large amounts of saturated hydrocarbons (methane, ethane) are produced by ion irradiation of polypropylene and polybutylene.³⁴ Despite the fact that the exhaust rate of the gases evolved can be as high as hundreds of metres per second,¹⁶ most of them have no time to leave the heating zone during the dispersal time of the thermal spike. Evidently, a fraction of these hydrocarbons can react before escaping the track region; however, the contribution of such processes to the formation of the end products of thermoradiolysis is still to be clarified.

In deeper stages of ion implantation, polynuclear compounds (in essence, they represent primary carbon-containing cluster structures) and other thermoradiolysis products (unsaturated compounds, stable macroradicals) formed in the track region are involved in the growth of carbon clusters. For both aliphatic and aromatic polymers irradiated by ions with medium energies (hundreds of kiloelectron-volts) carbonisation of their surfaces nearly goes to completion at implantation doses of 5×10^{15} to 10^{16} cm^{-2} and subsequent ion bombardment causes only slight changes in the composition of the implanted layer.^{35,36} Noteworthy is that no full carbonisation of the polymer surface occurs. For instance, implantation of polyethylene with 150 keV F^+ ions ($S_e/S_n \approx 5$) leads to an increase in the concentration of carbon in the implanted layer from 33% (in the pristine polymer) to 40%.³⁵

The extent of dehydrogenation of ion irradiated polymers rapidly increases with increasing energy transferred from the incident ions by nuclear collisions. In particular, saturation of carbon concentration in the implanted layer is reached at 65% for implantation of polyethylene with 150 keV As^+ ions ($S_e/S_n \approx 0.3$).³⁵ If the electronic stopping mechanism dominates, dehydrogenation is of low efficiency. This can be rationalised by delocalisation of excitations over sufficiently large carbon clusters. Direct cleavage of chemical bonds upon nuclear collisions is more efficient to provide deep dehydrogenation of the polymer matrix. The extent of carbonisation that can be reached in this case is first of all controlled by the trapping of hydrogen radicals by broken carbon bonds. A profound dehydrogenation (concentration of bound hydrogen less than 10%) can be achieved with electronic deposition mechanism when ions with energies of several tens of MeV are implanted in a polymer target.²¹ In this case, the formation of broken bonds, due to migration of excitations, is concentrated at the edges of growing carbon clusters and carbonaceous phase produced by high-fluence implantation exhibits the Raman spectrum similar to that of ion-implanted graphite.²¹

Implantation of high-energy ions can provide prerequisites for intra-track formation of fullerenes C_{60} and C_{70} . This is supported by the results of mass-spectrometric analysis of gaseous products evolved during implantation of poly(vinylidene chloride) with ions with energies of the order of several tens of megaelectron-volts³⁷ and by the data of chromatographic analysis of the products extracted from the ion-implanted layer on the surface of polyimide irradiated with 5 MeV Li^+ ions.^{38,39} Taking into account modern concepts of the mechanism of fullerene formation in plasma (vapour phase),^{40–45} one can assume that the synthesis of bulky carbon structures involves coalescence of polycyclic radicals (e.g., combining of six perdehydronaphthalene radicals to yield the C_{60} molecule⁴⁵). This must be favoured by shrinking of the reaction volume upon track 'collapse'.⁴⁴ Fullerene formation can also occur *via* polyynes⁴³ (products of deep dehydrogenation of polymers or intra-track conversion of

acetylene) which lose their stability as the molecular chain is lengthened. This reaction is to be exothermic, since the enthalpy of formation of polyynes (27 kcal mol^{-1} per carbon atom⁴⁶) is much larger than that of fullerene ($9.08 \text{ kcal mol}^{-1}$, see Ref. 47). Accumulation of alkynyl groups in the polymer matrices irradiated with high-energy ions⁴⁸ suggests the possibility of polyyne formation during ion implantation.

The composition of the polymer matrix can strongly affect the composition of the products of ion-induced thermoradiolysis. This can be best exemplified by halogenated polyolefins. Ion irradiation of perfluorinated polyolefins results in lower unsaturated perfluorocarbons (C_2F_4 , C_2F_6) as major gaseous products since the energy of the C–F bond is higher than those of the C–H and C–C bonds.²⁴ Because of this, detectable carbonisation of ion irradiated polytetrafluoroethylene (PTFE) can be reached only at very high doses⁴⁹ while the implantation is accompanied by erosion of the polymer sample⁵⁰ (up to perforation²⁴). Ion bombardment of partially halogenated aliphatic polymers causes radical-induced dehydrohalogenation^{1,18,23,27} accompanied by dehydrogenation and evolution of acetylene (Table 2). Accumulation of double bonds in the polymer matrix accelerates dehydrohalogenation and the newly formed polyenes are involved in the formation of the carbonaceous phase. It is believed that efficient ion-induced carbonisation of poly(vinyl chloride)^{1,18} is favoured by the fact that thermolysis of this polymer can occur at low temperatures ($\sim 200^\circ\text{C}$, see Ref. 51).

Table 2. Relative yields of molecular products formed during irradiation of polytetrafluoroethylene²⁴ and Tefzel (copolymer of ethylene and tetrafluoroethylene)²³ with 200 keV Si^+ ions.

Product	PTFE	Tefzel
H_2	—	4.34
C_2H_2	—	0.87
HF	—	3.91
C_2F_4	1	1
C_2F_6	2.05 ^a	0.35 ^a

Note. All values were normalised to the yield of C_2F_4 .

^a Determined from the yield of the CF_3^+ fragment detected in the mass spectrum.

Ion-induced thermoradiolysis of organosilicon polymers leads to gradual accumulation of $\{\text{SiO}_4\}$ clusters at the irradiated surface due to the lack of efficient mechanisms of silicon sublimation. The loss of most of methyl groups in polymethylsiloxane as the result of bombardment with 5 keV Ar^+ leads to the formation of carbon–silicate composite, the composition of which varies from $\text{Si}_{1.3}\text{CO}_{2.0}$ at the surface to $\text{Si}_{1.5}\text{CO}_{2.5}$ in the depth, with silicon atoms in this composite being directly bound to oxygen ones.⁵² Noteworthy is that implantation of a copolymer of polydimethylsilane and methylphenylsilane, $[\sim \text{Si}(\text{CH}_3)_2 - \text{SiPhCH}_3]_n$, with 2 MeV Ar^+ ions leads to the formation of silicon carbide as a result of cleavage of the Si–Si and C–H bonds and by elimination of methyl side groups.⁵³

Depending on the mechanism of energy deposition by incident ions to the polymer matrix, strongly different thermoradiolysis can be induced. The distinctions are due to the fact that nuclear collisions involve direct nonselective (in essence, random) breakage of chemical bonds, whereas an electronic excitation can migrate over a rather long distance during the lifetime of the excited state ($\sim 10^{-12} \text{ s}$) (according to calculations for an aliphatic chain,⁵⁴ the mean path length of electronic excitation can amount to 100 monomer units) and therefore energy deposition by 'electronic' stopping implies scission of the weakest bonds. This makes possible selective initiation of chemical reactions in the polymer matrix, especially in the case of ion irradiation of heterochain polymers.

Implantation of polyimide with 90 keV N^+ ions or 150 keV Ne^+ ions ($S_e/S_n > 6.5$) leads to cleavage of bonds between aromatic rings⁵⁵ and to transformation of imido groups into amido groups without fragmentation.^{56, 57}

This process occurs simultaneously with dehydrogenation of polyimide and causes the loss of some carbonyl groups⁵⁸ accompanied by the evolution of CO (major gaseous product formed during ion irradiation of polyimide).²⁴

A feature of the irradiation of aromatic poly(ether sulfone) under analogous conditions ($S_e \gg S_n$) is the fast transformation of sulfone groups into sulfoxide ones and then, at high fluences, into sulfide groups in the reactions involving mobile radical species $H^\cdot$.^{6, 59}

During ion irradiation of aliphatic polysulfones the reduction of sulfone groups and their elimination in the form of sulfur dioxide occur in comparable yields.⁶⁰

The formation of hydroxy groups in the polymer matrix was revealed in the study of low-dose ion implantation of poly(ethylene terephthalate) (PETP) under conditions where the electronic stopping prevails.⁶¹

This allows rapid accumulation of unsaturated groups in the ion-implanted layer on the PETP surface [these groups are accumulated in PETP faster than in, e.g., poly(butylene terephthalate)⁶²]. Ion-induced processes occurring during bombardment of PETP by high-energy ions (with energies of the order of several tens of megaelectron-volts and, correspondingly, with large S_e values) proceed by the same mechanism.⁶³ Implantation of this material with ions with energies of the order of several hundreds of megaelectron-volts leads to profound dehydrogenation of the irradiated polymer, accompanied by accumulation of alkynyl groups in the ion-implanted layer.⁴⁸ Peculiar to polystyrene and polyimide implanted in this regime is the formation of

groups containing triple bonds [e.g., isocyanate ($-\text{N}=\text{C}=\text{O}$) and cyanate ($-\text{O}-\text{C}\equiv\text{N}$) end groups for polyimide].⁴⁸

Thus, if energy transfer to the polymeric target is mainly by electronic excitations, the bridging bonds are broken and functional groups undergo transformations (as a rule, towards the reduction of heteroatoms), whereas aromatic fragments remain intact and can be involved in the formation of polycyclic fused structures. Heterocycles with asymmetrical delocalised π -electron systems are much less stable. For instance, experiments on electron beam irradiation of poly(2-vinylpyridine) (in this case, energy is deposited in the polymeric target solely by electronic excitations) showed that the pyridine ring rapidly breaks down with the formation of amino groups⁶⁴ in contrast to the aromatic rings in polyimide that are stable under these conditions.^{6, 64}

A consequence of the increased contribution of a collision term to the overall energy loss of the stopping ions is the change in the character of processes occurring in the polymeric target. In particular, destruction of highly stable aromatic rings is made possible. For instance, irradiation of aromatic poly(ether sulfone) with 50 keV As^+ ions ($S_n/S_e = 5.6$) causes not only the transformation of sulfone groups, but also the release of acetylene and the formation of 1,4-substituted butadiene.⁶⁵ Similarly, implantation of polyimide with ions that lose their energy mostly by nuclear collisions is accompanied by breakage of aromatic rings and formation of acetylene²⁴ and by nonselective degradation of imido groups resulting in the formation of various products (Fig. 1).^{6, 66–68} Similar products were also detected during *in vacuo* thermal decomposition of polyimide.⁶⁷ However, their concentrations are substantially different from those in the ion-implanted layer (see Fig. 1) because these products are formed in two different ways, *viz.*, in the course of several concurrent radical processes (ion implantation) and in consecutive chemical transformations of the polymer matrix (thermal decomposition).

The overall picture of the processes occurring during ion-induced thermoradiolysis of heteroatom-containing polymers can be described as follows. Until build up of a certain implantation dose corresponding to D_f (a single track regime) the polymer matrix undergoes dehydrogenation and some other unambiguously identifiable chemical transformations. The pathways of

these processes are first of all determined by the ratio of energy transfer from the implanted ions by electronic excitations and by nuclear collisions. Within this implantation dose, the overall concentration of heteroatoms in the ion-implanted layer (nitrogen atoms in irradiated polyimide^{6,67} or sulfur atoms in irradiated polysulfone^{6,59}) can remain virtually constant (Figs. 1 and 2) while the energy of the implanted ions is expended for structural rearrangement of the polymer.⁶ Aromatic fragments released in this stage are fused to form 'pre-carbon' structures. These processes can occur involving the heteroatoms incorporated into the pyridine, pyran and thiopyran rings. Because of this, a large fraction of heteroatoms (first of all, sulfur and nitrogen) is retained in the implanted layer in chemically bound form even at high implantation doses.⁶

IV. Peculiarities of the morphology and properties of ion-implanted layer

Electron microscopy studies of ion-implanted polymers revealed the formation of carbon aggregates of a size up to several tens of nanometres in polymeric targets implanted with high doses.²³ Using the small-angle neutron scattering technique, it was established that these aggregates are comprised of small carbon clusters.⁶⁹ In particular, it was found that high-dose irradiation of PETP films with 50 MeV B⁺ ions leads to the formation of nanoclusters of size 6 to 7 nm separated by ~13 nm and united into spherulites of diameter up to 50 nm in the implanted layer.⁶⁹ This is consistent with the results obtained by optical spectroscopy, according to which the build up of implantation dose is accompanied by a shift in the edge of the optical absorption band of the irradiated polymer towards the long-wavelength region due to extension of the conjugated system in the growing carbon clusters. The magnitude of the shift indicates that the size of the clusters formed during implantation with medium energy ions is at most several nanometres.^{70–72} Using an approach developed for amorphous carbon,⁷³ the mean size of a carbon cluster grown in the implanted layer can be estimated as follows:

$$E_g = 2|\beta|N^{-0.5},$$

where E_g is the optical gap, β is the resonance integral (according to EHT calculations, $\beta = 2.9$ eV) and N is the number of rings in the compact two-dimensional carbon cluster (fragment of graphite sheet). As the implantation dose D increases, the E_g value exponentially decreases^{71,72}

$$E_g = E_{g0} + A \exp(-\eta D),$$

where E_{g0} is the energy gap corresponding to the largest clusters that can grow under the given implantation regime, η is the cross-section of the growth reaction of carbon clusters and A is a constant. The growth rate of the carbon nanophase and the η value depend first of all on the nature of the polymer,⁷¹ while the E_{g0} value is mainly determined by the mass and energy of ions implanted.^{3,72} Implantation of light ions with energies ranging from 100 to 300 keV into polyolefins and polystyrene saturates the E_g values at 0.6 eV,^{70–72} which corresponds to clusters with a mean size of 2.7 nm (~75 rings). Peculiar to the irradiation of polyamide-6 under analogous conditions is the formation of smaller clusters ($N \sim 60$, $E_g = 0.76$ eV, see Ref. 72). The fact that there exists a limiting size of carbon clusters for a given implantation regime can be rationalised^{3,72} by delocalisation of the energy of incident ions over the carbon network and by expenditure of this energy for cleavage and formation of carbon bonds accompanied by trapping of the H[•] radicals. Not counting subtle details, this produces no significant variations in the medium-range order of the implanted layer. In this case, an increase in the implantation dose causes gradual growth of small carbon clusters up to the limiting size.⁷⁰ For polyamide-6, the formation of smaller carbon clusters is a result of the incorporation of a heterocyclic nitrogen atom into the growing cluster (due to, e.g., the formation of pyridine rings).⁷² The outermost heteroatoms cannot play the role of nucleation sites of the carbon clusters and their presence in the clusters reduces the size of extended regions of the π -electron conjugation system and, as a consequence, the effective size of carbon clusters determined from electronic spectra.^{3,72}

An increase in the size and concentration of carbon clusters in the ion-implanted layer with the implantation dose is accompanied by an increase in the concentration of paramagnetic centres (radicals stabilised by delocalisation of their π -electrons over the π -electron system of the carbon nanophase).^{25,65,74,75} There is a correlation between the increase in the ESR signal during implantation and completion of dehydrogenation of the polymer matrix.^{17,29} At high implantation doses where the possibilities of further carbonisation are exhausted the prerequisites are created for compensation of the terminated carbon bonds by their recombination that results in the decrease of spin concentration.^{17,29,65,74,76,77} This effect can be readily traced for polyimide,²⁹ polyacrylonitrile⁷⁴ and other polymers containing a large number of groups that can be efficiently fused during thermoradiolysis. Aliphatic polymers are characterised by a much lower yield of carbon clusters compared to polymers with conjugated bonds. In this case, the spin concentration plotted as a function of implantation dose exhibits no extremum (Fig. 3) even at high fluences (10^{17} cm⁻²).^{75,78} As the dose increases, the ESR line becomes narrower due to extension of the π -electron conjugated system in the ion-implanted layer.^{29,74,78} Studies of temperature dependence of the ESR linewidth and of the effect of oxygen pressure on the ESR spectrum revealed the formation of quasi-two-dimensional degenerate electron gas in the carbonaceous layer on the surface of heavily implanted polymers ($D > 2 \times 10^{16}$ cm⁻² for polyethylene and polyimide irradiated with 100 keV B⁺ ions).^{75,78,79}

A salient feature of the morphology of the ion-implanted layer is the presence of nanopores that are formed along the trajectories of projectiles. Pore mouths can be clearly seen in, e.g., atomic force microscopy images of the PETP surface irradiated with low doses of heavy high-energy ions.⁸⁰ Implantation of low-energy (100–200 keV) ions is also accompanied by the formation of a developed pore system. This is indicated by the possibility of spontaneous incorporation of molecular iodine from the vapour phase^{81,82} and Pb²⁺, Fe³⁺, K⁺ and Cl⁻ ions (see Refs 83–85) and some bulky molecules (a carborane complex of cobalt,⁸⁶ amino acids⁸⁷) from aqueous solutions into the implanted layer and by the possibility of extension of the oxidation of radical

Figure 3. Dependences of the average number of carbon rings (N) in carbon cluster and of the dc conductivity (σ) (a), concentration of unpaired spins (C_s) and ESR linewidth (b) on the implantation dose for polyethylene irradiated with 100 keV B^+ ions.⁷⁵

centres across the whole width of the implanted layer.^{35, 88–90} Sometimes, changes in the polymer density along the track of the implanted ion are insufficient to ensure the pore formation. In this case, slow oxygen diffusion *via* ion-induced defects occurs along the so-called latent tracks (the regions in which locally reduced density appeared in the polymer matrix during passage of an ion). For ion irradiated polypropylene, the oxidation front propagates in the implanted layer with a velocity which does not exceed $4 \times 10^{-5} \text{ nm s}^{-1}$ and complete oxidation takes several weeks,³⁵ whereas the oxidation of polyethylene irradiated under the same regime is completed virtually immediately after the vacuum–open air transition.³⁵ According to IR spectroscopy data, oxygen fixation in the ion-implanted layer is accompanied by the formation of carbonyl^{88, 91} and hydroxy groups.⁹²

Trapped oxygen is accumulated in the domains with high density of the broken carbon bonds formed during implantation; therefore, the character of oxygen distribution in the irradiated polymer contains information on the structure of the implanted layer.^{3, 35, 89, 93} Rutherford backscattering spectroscopy studies showed that the concentration of trapped oxygen in the irradiated polyethylene monotonically increases during ion irradiation⁹⁰ and reaches a maximum value at fluences of $(1–5) \times 10^{14} \text{ cm}^{-2}$ for heavy ions^{35, 93} and at $5 \times 10^{15} \text{ cm}^{-2}$ for light ions.⁸⁸ The total amount of oxygen assimilated within the implanted layer can be rather large (the concentration of oxygen in polyethylene irradiated with 150 keV F^+ ions at a fluence of $5 \times 10^{15} \text{ cm}^{-2}$ is 0.24 per carbon atom⁸⁸). Using the depth profiles of oxygen trapped in the implanted layer, it was found that the role played by the ‘electronic’ and ‘nuclear’ stopping mechanisms in the generation of dangling carbon bonds is dependent on the implantation dose.^{88, 93} If a pristine or slightly dehydrogenated polymer is ion irradiated, the formation of free valences in the growing carbonaceous phase is first of all a result of ‘electronic’ energy loss. If a partially carbonised polymer is implanted, the carbon bonds are

mainly broken by nuclear collisions, whereas the energy transferred to the irradiated polymeric target by electronic excitations dissipates in carbon structures or is expended for their rearrangement. Therefore, even for irradiation with heavy ions characterised by large S_n/S_e ratios the oxygen depth profile reconstructed from the Rutherford backscattering spectra corresponds to the ‘electronic’ loss distribution at low fluences ($\sim 10^{14} \text{ cm}^{-2}$) and to the ‘nuclear’ loss distribution at higher fluences.^{3, 88, 93}

At high fluences, a well-developed carbonaceous phase can form by linking individual carbon clusters. In this case, the concentration of oxygen scavengers substantially reduces and the concentration of oxygen in the implanted layer and the yield of carbonyl groups per implanted ion rapidly decrease as fluence increases.⁹³ The minimum concentration of trapped oxygen in the implanted layer corresponds to maximum enrichment of this layer with carbon as a result of ion-induced thermoradiolysis.⁸⁹ It should be noted that in polyethylene and polyamide-6 heavily implanted with medium-range energy (100–200 keV) light (*e.g.*, B^+ , see Refs 94 and 95) and heavy (*e.g.*, Sb^+ and As^+ , see Refs 3, 89, 93) ions the spatial region of maximum carbonisation is beneath the polymer surface.^{75, 95, 96} This can be illustrated by the depth profile of the relative concentration of carbon in the near-surface layer and by the presence of an additional maximum of the concentration of trapped oxygen on the surface of irradiated samples (in this case, the oxygen depth profile exhibits two peaks, see Fig. 4). The ‘buried’ carbonaceous layer is separated from the surface by a layer of non-carbonised, radiation damaged polymer.^{75, 94, 96} This effect can be rationalised by higher heat release at the track ends of implanted ions and by lateral spread of the thermoradiolysis zone within the collision cascade region.³

Figure 4. Depth profiles for trapped oxygen (1) and for an increase in the carbon concentration (2) in polyethylene irradiated with 150 keV As^+ ions at a fluence of $5 \times 10^{16} \text{ cm}^{-2}$ (according to Ref. 89).

Rutherford backscattering studies of the implant distribution (for implantation with heavy ions) and neutron depth profiles (for implantation with light ions) showed that sometimes high penetrability of the implanted layer allows the implant to diffuse out of the irradiated polymer. The pore system produced by the tracks of implanted ions provides conditions for specific gas transport reactions. In these situations the implant is either not detected^{97, 98} or the experimental depth profile differs from the corresponding calculated depth profile to such a high extent^{99, 100} that this can be explained by neither changes in the polymer density due to carbonisation and ion-induced erosion of the surface of the sample nor by backscattering of ions at high fluences. These effects are observed if the implant is incapable of bonding to the polymer matrix or if the interaction between the implant and matrix results in volatile products (here, heating of the polymeric target to moderate temperatures is sufficient for complete sublimation of the implant). This is characteristic of, *e.g.*, implanta-

tion of noble gas ions^{97,98} and F^+ ions in polyolefins.⁸⁸ In the latter case, volatile fluorocarbons are formed. Volatile compounds are also formed during implantation of PTFE with Sb^+ ions, which is accompanied by sublimation of antimony fluorides.⁴⁹ However, if the flux of implanted ions is rather low, the noble gas ions are retained in the polymeric target (e.g., Xe^+ ions in poly(ether sulfone),²¹ Kr^+ ions in polyimide¹⁰¹), but they diffuse out of the ion-implanted layer with time.¹⁰²

In the case of implantation of polymeric targets cooled down to 90 K, the depth profile of noble gas ions (in particular, xenon¹⁰³) matches the corresponding calculated depth profile to an accuracy of 10%.

Diffusion of low-molecular-mass compounds formed in the interaction of thermalised implanted ions with the polymer matrix (including the interaction on storage) can have a significant effect on the spatial distribution of the implant. For instance, phosphorus implanted into a molecular film based on a dianthrylidene derivative of γ -substituted pyrone diffuses towards the surface of the irradiated sample (probably, in the form of phosphines). The interaction with dioxygen causes phosphorus fixation in the form of corresponding oxides.¹⁰⁴ As a result, the phosphorus depth profile in the implanted layer appears to be bimodal. The first maximum corresponds to medium projected range of the implanted ions while the second maximum is at the surface of the sample.¹⁰⁴ High mobility is also characteristic of implanted lithium (the form in which lithium is transferred is unknown). A fraction of lithium ions diffuses towards the surface of irradiated polymers.^{105,106} Substantial redistribution of boron implanted into various polymers is illustrated by Fig. 5. According to XPS data, the boron escaped from the polymer bulk is oxidised.¹⁰⁸ The formation of volatile alkylboron compounds during implantation of boron ions has been suggested;³ this is indicated by the fact that, according to cryochemical atomic-beam experiments,¹⁰⁹ elemental boron readily reacts with hydrocarbons. The interaction with dioxygen and atmospheric moisture results in volatile oxidised alkylboron compounds and alkylboric acids. This is responsible for the possibility of thermally induced desorption of implanted boron¹¹⁰ and for complete disappearance of boron from the implanted layer upon long-term storage.⁹⁷

Obtaining mobile implant at low fluences implies that the stopping ions transfer to the polymer a rather high energy (15–20 eV $\text{\AA}^{-1}$, see Ref. 105) which is sufficient for occurrence of efficient thermoradiolysis and provides a necessary decrease in the density of the material of the polymeric target within the track region of implanted ions. Under these conditions, diffusion occurs

Figure 5. Boron depth profiles for polyethylene (1) and polyamide (2) irradiated with 100 keV B^+ ions ($D = 5 \times 10^{16} \text{ cm}^{-2}$, see Refs 3 and 93) and calculated depth profile for boron implanted into polyethylene (3) (results of Monte Carlo simulation using the TRIM code¹⁰⁷). R_p is the theoretical projected range of the implanted ion.

nearly completely along ion tracks.¹⁰⁶ On the other hand, the formation of developed carbonaceous phase in heavily irradiated polymer samples creates a barrier to diffusion of the implant towards the surface.¹¹¹

The reduction conditions which are created in the surface layer during the bombardment of a polymeric target by metal ions favours the formation of metal nanophase.¹¹² This process was studied taking polymethylphenylsiloxane and epoxy resins implanted with Ag^+ , Fe^+ and Co^+ ions as examples (see Refs 113–118). It was found that the morphology of the newly formed metal nanophase is to a great extent controlled by the viscosity of the polymer matrix. Ion implantation of polymers in the viscous-flow state is accompanied by the formation of spherical nanoparticles with narrow size distribution, while transition of the polymer matrix to the glassy state leads to the formation of facet metal structures in the implanted layer.¹¹⁴ Spherical metal nanoparticles are also formed in polyimide implanted with 150 keV copper, zinc and silver ions in high doses [$D = (1-5) \times 10^{17} \text{ cm}^{-2}$],^{119,120} whereas the implantation of polyimide with W^+ ions causes the formation of a tungsten carbide nanophase.¹²¹

A consequence of essential structural changes in the polymer matrix, caused by ion bombardment is a substantial change in the polarity of the polymer surface (Fig. 6). This can be due to both degradation of initial (if they exist) and formation of new polar groups. The latter can be formed either immediately during implantation (for heteroatom-containing polymers) or as a result of the oxidation of radical centres due to contact with dioxygen. For instance, transformation of an imide group into an amido group during low-dose implantation of 90 keV N^+ ions into polyimide leads to a more than twofold decrease in the polar component of the surface free energy.⁵⁶ A decrease in the surface polarity was also observed in the course of ion irradiation (Sb^+ , 150 keV) of polyamide-6,⁴⁹ whereas ion irradiation of PETP (N^+ , 90 keV) accompanied by transformation of ester groups into hydroxy groups leads to an insignificant (by 30%) increase in the surface polarity.⁶¹ These rearrangements of the polymer surface occur at low irradiation doses. Polarity of heavily implanted samples first of all depends on the presence of carbonyl groups formed involving uncompensated bonds of carbon atoms at the boundaries of the carbonaceous phase. For aliphatic polymers (polyethylene, polypropylene) the formation of carbonyl groups is the main factor responsible for a substantial increase in the polarity of the polymer surface at any dose.^{49,88} An increase in the surface polarity of polysiloxanes after ion implantation is due to the formation of nanodispersed SiO_2 phase inclusions in the implanted layer.⁵²

The sorption properties of irradiated polymers are affected by the developed system of nanopores in the implanted layer and by ion-exchange character of the sorption sites inside the pores (the

Figure 6. Polar component of the surface free energy (γ_p) of polyimide (1) and PETP (2) films irradiated with 90 keV N^+ ions plotted as a function of the implanted dose (according to Refs 56 and 61).

adsorption capacity of irradiated polyethylene and polypropylene with respect to cations is 2 to 5 times higher than with respect to anions^{84, 85}).

Carbon-containing species formed during ion implantation reinforce the polymer surface. In some instances the microhardness of the irradiated surface can be substantially increased (up to 50 to 70 times^{122–126}). These effects were observed for various polymers, namely, polyimide,^{28, 123, 126} polystyrene,^{122, 123} polyethylene,^{92, 127} PETP,²⁸ polycarbonate $\{[\sim\text{OC}_6\text{H}_4\text{C}(\text{CH}_3)_2-\text{C}_6\text{H}_4\text{OCO}\sim]_n\}$,¹²⁸ partially fluorinated polyethylene,²³ poly(ether ether ketone) $\{[\sim\text{OC}_6\text{H}_4\text{OC}_6\text{H}_4\text{COC}_6\text{H}_4\sim]_n\}$ ¹²⁹ and some other polymers irradiated with different (mostly light and not too heavy) ions with energies ranging from 100 keV to 1 MeV. The microhardness of carbonaceous products is first of all determined by the character of interconnectivity within the carbon cluster aggregates.²⁰ High microhardness requires that the incident ions deposit their energy mainly by electronic excitations (this provides the formation of carbon clusters) and the energy loss by nuclear collisions be relatively small. Though nuclear collisions are responsible for the formation of random links between the clusters, a general trend is towards an increase in the microhardness with an increase in the relative weight of energy loss by electronic excitations (Fig. 7).^{122, 130} However, since the displacement energy of an sp^3 -hybridised carbon atom (80 eV for diamond) is much higher than that of an sp^2 -hybridised carbon atom (30 eV for graphite),⁵ one can expect that nuclear collisions lead to gradual accumulation of domains with predominant sp^3 -hybridisation of carbon atoms and increased microhardness of the ion-implanted layer.

Figure 7. Microhardness of a polystyrene surface irradiated with Ar⁺ ions plotted as a function of irradiation dose (a) and of the relative weight of energy transferred from the incident ion to polymer by electronic excitations and nuclear collisions (b).¹²²
Ion energy /keV: 1000 (1), 500 (2) and 200 (3).

One of the most important consequences of ion implantation is the onset of conductivity of initially dielectric polymers. It is of great importance that the conductivity of irradiated polymers is due to the formation of carbon-containing structures in the implanted layer rather than ion doping. Therefore the conductivity, which is proportional to the optical absorption of the carbonaceous phase,¹³¹ only indirectly depends on the nature of implanted ions, being mainly determined by the energy loss during the stopping of ions.^{1, 17, 21, 129} Since the conducting phase in the ion-implanted layer is formed by discrete carbon clusters and their associates, the onset of conductivity in an irradiated polymer upon build up of implantation dose has a threshold character (see Fig. 3) and the transition from dielectric to conductor can be considered as percolation transition.^{5, 17, 29, 132} The dependence of the dc conductivity, σ , on the implantation dose is given by the formula:^{1, 17, 29, 132}

$$\sigma \sim (D - D_c)^t,$$

where D_c is the critical dose corresponding to the percolation threshold.

Thermoradiolysis in the implanted layer occurs under conditions of gradual coverage of the surface of polymeric target with ion tracks. Nevertheless, the formation of an infinite conducting cluster is, as a rule, observed at implantation doses corresponding to a smaller fraction of the surface covered with ion tracks compared to those predicted by the two-dimensional percolation problem. For instance, the percolation threshold for polyimide irradiated with 500 keV N⁺ ions corresponds to a coverage factor of 0.3 (see Ref. 29), whereas theory predicts that percolation in an ideal two-dimensional system must occur at a critical coverage of ~ 0.45 . This suggests some ordering in the carbonaceous phase and is also supported by large values of the exponent t in the above-mentioned formula for the polymers that are prone to form carbon clusters [polyimide,²⁹ polyacrylonitrile,¹⁷ poly(2,6-dimethylphenylene oxide),¹⁷ molecular films based on perylene derivatives¹⁸]. In this case, the t values estimated from the slope of the linear dependence $\log \sigma \sim \log(D - D_c)$ can be as high as 4–5 if energy deposition during implantation occurs mainly by nuclear collisions and even as high as 7–8 if the electronic stopping prevails. On the other hand, for poorly carbonised polyethylene irradiated with 100 keV B⁺ ions the percolation threshold corresponds to $D_c = 1.5 \times 10^{15} \text{ cm}^{-2}$ (i.e., in this case, $D_c > D_f$) and the exponent t in the above-mentioned formula does not exceed a value of 2.^{75, 133}

As the irradiation dose increases, a system of conducting ‘islands’ separated by potential barriers is formed within the implanted layer.^{1, 18, 134} The nanostructured carbonaceous phase formed in the immediate vicinity of the percolation threshold acquires semiconductor properties.¹³⁵ Studies of temperature dependence of the conductivity of some irradiated polymers [polyethylene, poly(ether ether ketone),^{21, 136} etc.] showed that the formation of developed carbonaceous phase at high implantation doses causes transition from one-dimensional to three-dimensional conductivity. A similar phenomenon was observed for polyimide heavily implanted with 90 keV N⁺ ions⁵⁶ and for polyamide-6 irradiated with 150 keV Sb⁺ ions.⁴⁹ For polymers which are prone to undergo carbonisation during irradiation [e.g., poly(*p*-phenylenebenzobisoxazole), poly(*p*-phenylenebenzobisthiazole), poly(benzimidazobenzophenanthroline)], the conductivity of the ion-implanted layer formed at high implantation dose (Kr⁺, 200 keV, $D = 4 \times 10^{16} \text{ cm}^{-2}$) is close to the metal conductivity.^{137, 138}

At implantation doses close to D_c , the conductivity of implanted polyethylene can be increased by 3 orders of magnitude by diffusion doping with molecular iodine.⁸⁰ However, the doping effect is unstable and ion-implanted polyethylene takes the initial value of the electrical resistance much faster than changes in the concentration of the trapped iodine diffusing out of the implanted layer occur.¹³⁹ It should be noted that it is difficult for molecular iodine vapours to penetrate the implanted layer in heavily irradiated polymers due to destruction of the system of track channels caused by the formation of the carbon nanophase.^{81, 139} Doping of irradiated polyethylene with FeCl₃⁸⁴ and treatment of ion-implanted polyimide with molecular chlorine lead to an increase in the conductivity by two orders of magnitude (despite the fact that addition of chlorine to some unsaturated bonds occurs simultaneously in the latter case).¹⁴⁰

The conductivity of the implanted layer is strongly dependent on the peculiarities of the morphology of the carbonaceous phase (the size of carbon clusters, character of their linking in aggregates, the presence of heteroatoms). As a result, the electrical resistance of different polymers that were ion implanted under the same conditions can differ by several orders of magnitude, e.g., the specific resistance of polyethylene and polyimide irradiated with 1 MeV Xe⁺ ions ($D = 10^{16} \text{ cm}^{-2}$), is 6.8×10^{-3} and $30 \Omega \text{ cm}$, respectively (see Ref. 55). The conductivity of the implanted layer

is also determined by the implantation regime and, in particular, by the energy of the implanted ions, by the presence (or absence) of forced cooling of the polymer sample (polyimide films irradiated in the absence of forced cooling have lower electrical resistance than those irradiated in the presence of forced cooling¹⁴¹), film thickness (thick films exhibit lower conductivity due to efficient cooling of the implanted layer during irradiation²⁵). Nevertheless, a general trend is towards an increase in the conductivity of irradiated polymers with increasing energy of implanted ions. The highest conductivity is observed if energy deposition by incident ions occurs mostly by an 'electronic' mechanism.^{21, 65, 123, 130, 142}

V. Prospects for practical applications of ion-implanted polymers

Initially, interest in studies of the effect of ion irradiation on polymers was due to fabrication of resists (both negative and positive) for lithographic processes with submicron resolution. Detailed reviews concerning the cross-linking–chain scission effects observed at very low implantation doses (10^{11} – 10^{12} cm⁻²) and responsible for changes in the solubility of irradiated polymers have been reported.^{1, 143} On the other hand, the possibility of initiation of essentially different radiolytic and thermoradiolytic processes (cross-linking–fragmentation of polymer chains at low implantation doses, transformations of functional groups at implantation doses comparable with D_f and carbonisation of polymers at high implantation doses) by ion irradiation allows control of the sorption, tribological, optical and conducting properties of the polymer surface. This opens up new fields of practical applications of polymeric materials.

Implantation of PETP with heavy high-energy ions is accompanied by the formation of latent tracks in the polymer. This makes possible perforation of polymer films 10–20 µm thick by hydrolytic etching and fabrication of membranes with a controllable number of identical pores.^{144–146} The pore diameter can be varied over a wide range (0.01–5 µm) by varying the duration of etching. Studies of the character of energy loss of α -particles in perforated PETP films obtained using this procedure allowed one to trace the changes in the shape of membrane channels in different stages of etching.¹⁴⁷ It was found that the channels have rather long cylindrical sections (up to 2/3 of the overall thickness of the polymer film) that are transformed into conical pore mouths.¹⁴⁷ Cylindrical channels with smooth walls can also be formed by etching ion irradiated polyimide in the presence of hydrogen peroxide¹⁴⁸ and hypochlorites.¹⁴⁹ On the other hand, typical of many polymers [e.g., poly(methyl methacrylate),¹⁴⁸ polycarbonate,¹⁴⁶ etc.] is the formation of channels with irregular shape and broad size distribution. High uniformity of etching channels in PETP is due to some features of latent track structure.^{146, 150, 151} The track core, which is at most several nanometers in radius, represents a degraded, rapidly soluble polymer containing a large number of isolated pores¹⁵² and surrounded by a shell of radiochemically cross-linked polymer.^{80, 146, 150} The shell diameter is 50 to 60 nm for implantation of xenon ions (1 MeV per nucleon) and is much larger than the penumbra diameter.^{80, 150} This can be explained by the formation of cross-links due to recombination of macroradicals formed in the interaction of polymer chains with knock-on hydrogen atoms¹⁴⁶ (including those formed as a result of hydrodynamic shock accompanying the passage of high-energy heavy ions¹⁵³). Probably, high spatial selectivity of etching is to some extent due to ordering of the polymer structure as a result of reorientation of the macromolecules along the ion tracks.⁶³ It should be noted that forced orientation of polymer molecules along the direction of ion flux can be observed not only during implantation of high-energy ions, but also in the case of ion irradiation with energies of the order of several kiloelectron-volts¹⁵⁴ at a fluence of $\sim 5 \times 10^{15}$ cm⁻².

The formation of surface pores, changes in the polar component of the surface free energy and the appearance of specific adsorption sites as a result of ion bombardment can have both

positive^{52, 155–162} and negative¹⁵⁶ effects on the efficiency of adsorption of living cells on the polymer surfaces (e.g., polystyrene,^{156, 158, 159} polyurethane,^{160, 161} polymethylsiloxane,⁵² collagen,^{156, 162} etc.). This opens up new possibilities of control of biocompatibility of polymeric materials. As a rule, cell adsorption efficiency nonmonotonically depends on the implantation dose (i.e., it is determined not only by the effects of changes in hydrophilicity) and reaches a maximum value at implantation doses that are somewhat lower than D_f .^{158, 160} It was also shown that changes in the dynamics of plasma protein adsorption on the surface of silicon rubber induced by irradiation with 150 keV H₂⁺, N₂⁺, Na⁺ and Ne⁺ ions leads to nearly complete suppression of thrombogenicity.¹⁶³

At low ion implantation doses, the refractive index, n , of a polymer increases with the polymer density. In some instances a relative increase in the refractive index can be substantial. In particular, poly(methyl methacrylate) is known to lose methoxy groups upon ion irradiation and undergo gradual transformation into an analogue of cross-linked polyethylene.¹⁶⁴ For this polymer, the $\Delta n/n$ ratio can be as high as 0.3 (see Refs 165 and 166) and the dependence of the refractive index on the implantation dose is nearly linear up to $D \approx 10^{15}$ cm⁻². At higher doses, the polymer becomes turbid due to carbonisation.¹⁶⁶ This allows the formation of light guides and other optical devices (couplers, interferometers) on the polymer surface.^{167–169} It is of great importance that the use of high-energy ions characterised by a shift of maximum energy loss towards the track end allows fabrication of 'buried' (including crossed) light guide structures at a depth from several to several tens of micrometres under the surface of a polymer sample (depending on the energy of implanted ions).^{167, 170}

Fabrication of nonlinear optical devices in the form of metal particles dispersed in a dielectric matrix¹⁷¹ by implantation of polymer with corresponding metal ions is a difficult task since the optical density of the polymeric host increases with the implantation dose. On the other hand, one can expect that the formation of a metal nanophase during ion irradiation of the polymers containing chemically bound metal ions will occur at low implantation doses.

As mentioned above, carbonisation of polymers at high implantation doses leads to a substantial increase in their microhardness,²⁸ which can be as high as 22 GPa¹²³ (cf. a value of less than 12 GPa for martensite steel) and is comparable with the hardness of diamond-like carbon films. The best results were obtained in the case of simultaneous implantation of ions with different mass and energy, i.e., characterised by different penetration depth and responsible for different degrees of carbonisation of polymers.²⁸ An increase in hardness of the surface of implanted polymers [polyimide,^{123, 126, 172} polystyrene,^{122, 123} polycarbonate,^{128, 173} pristine^{92, 127} and partially fluorinated polyethylene,²³ poly(2,6-dimethylphenylene oxide),¹⁷⁴ etc.] is accompanied by reduction of their electrical resistance¹²² and causes substantial improvement of wear resistance.^{122, 124} The latter parameter nonmonotonically depends on implantation dose since an increase in hardness of the implanted layer makes it more brittle and causes a gradual decrease in its adhesion to the polymeric support. The dramatic decrease in the friction coefficient upon ion irradiation observed for polycarbonate^{173, 175} and poly(2,6-dimethylphenylene oxide)¹⁷⁴ seems to be to a great extent due to an increase in hydrophilicity of the polymer surface, which favours the formation of a surface layer of chemisorbed water with good antifrictional properties.

The carbonised surface layer substantially improves the chemical stability of irradiated polymers towards organic solvents; however, this layer is porous and therefore provides no perfect protection of the polymeric support.¹⁷⁶ High-dose implantation of low-energy (25–40 keV) Si⁺, Al⁺, Y⁺, Y²⁺ and Y³⁺ ions leads to suppression of erosion of the surface of polyimide, PETP and some other polymers exposed to a flux of oxygen atoms (under conditions corresponding to Earth orbit space environment) due to the formation of a composite oxide-carbon coating.¹⁷⁷

Polymers irradiated to high doses represent an unusual electrode material, the surface properties of which can vary depending on the ratio of the concentrations of sp^2 - and sp^3 -hybridised carbon atoms in the implanted layer. Since the carbon clusters responsible for conductivity of the implanted layer are small, their oxidation under anodic polarisation observed in the absence of depolarisers is accompanied by irreversible loss of the electrochemical activity of irradiated polymers.⁷⁵ On the other hand, for initially conducting polymers (polyaniline,¹⁷⁸ polypyrrole,¹⁷⁹ polythiophene,¹⁸⁰ polybithiophene,¹⁸¹ polyethoxythiophene,¹⁸² polyethylenedioxythiophene¹⁸²) that lose their electrochemical activity as a result of degradation of the π -electron system at low implantation doses ($D < 10^{15} \text{ cm}^{-2}$)¹⁸⁰ the surface of the polymeric electrode exhibits recovery under anodic polarisation due to electrochemical oxidation of the carbonaceous phase.^{179, 181, 183} The possibility of ion-induced passivation of conducting polymers towards the processes of electrochemical polymerisation^{181, 183} and electrochemical deposition of metals^{179, 180, 182} allows one to change the surface profile of polymeric electrodes¹⁸¹ and to form metal patterns with micrometre resolution.^{179, 180, 182}

The possibility of varying the conducting properties of implanted polymers opens up new prospects for fabrication of microelectronic systems including the formation of conducting strips on the surface of polymeric materials,¹⁸⁴ fabrication of planar resistors with variable electrical resistance which can be varied over a wide range,² thermistors and bolometers.² Ion implantation can be used for development of more complex polymer-based electronic devices, namely, diodes and transistors. It is of great importance for fabrication of polymeric electronic devices (in particular, p - n -junctions^{185, 186} and conducting channels of field-effect transistors¹⁸⁷) that many of the initially conducting polymers with well-developed π -electron conjugation systems [e.g., poly(p -phenylenevinylene), polyacetylene]^{186, 187} exhibit resistance towards ion-induced dehydrogenation. Therefore, they can be doped by implantation of ions with medium-range energies ($\sim 30 \text{ keV}$). Under these conditions, purely chemical doping of p -type for implantation of iodine ions and of n -type for implantation of alkali metal ions can be accompanied by the effects associated with the formation of structural defects in the polymer matrix (e.g., as a result of electron capture from the π valence band of polyparaphenylene by the lower-lying sp^2 -electron energy levels corresponding to dangling bonds of carbon atoms¹⁸⁸). The possibility of fabrication of unusual electronic switching devices (analogues of field-effect transistors^{3, 75, 94, 96}) based on implanted, initially dielectric polymers (polyethylene, polyamide-6) with a 'buried' carbonaceous phase separated from the surface by a dielectric layer $\sim 10 \text{ nm}$ thick was also demonstrated. This layer can be made more uniform by electrochemical polymerisation of dielectric poly(o -phenylenediamine) in the pores of the implanted layer.⁷⁵ The spatial characteristics of this structure allow the 'buried' layer to act as a conducting channel of the field-effect transistor. The ac resistance of such a channel changed by more than four orders of magnitude upon applying an external electric field.^{3, 75, 94}

VI. Conclusion

The above-mentioned experimental results indicate that ion irradiation of polymers causes some specific phenomena that currently should be considered within the framework of a special division of high-energy chemistry. Ion-induced processes in polymeric targets represent a kind of pulse thermoradiolysis which occurs in the subnanosecond time scale and sometimes under conditions of massive ('non-thermodynamic') breakage of chemical bonds by nuclear collisions. The energy deposited by the incident ions in the polymer matrix is rather high; however, carbonisation of the polymer surface observed in this case cannot be reduced to simple 'graphitisation' of the polymer within the track of the stopping ion.

The formation of the carbonaceous phase on the polymer surface with an increase in the implantation dose involves some consecutive stages essentially differing in character of the corresponding ion-induced reactions. These stages include (1) dehydrogenation of a polymer (this occurs, as a rule, simultaneously with the radiation-induced cross-linking of the polymer) and transformation of functional groups, which results in the formation of 'pre-carbon' structures; (2) growth of carbon clusters, the limiting size of which is determined by the energy of implanted ions; (3) aggregation of carbon clusters and the formation of conjugated and non-conjugated bonds. The energy loss of high-energy ions affects the composition of the newly formed nanostructured carbonaceous phase more than the nature of the irradiated polymer. On the other hand, subtle variations of the short- and medium-range order of the carbonaceous nanophase, which determine such fundamental properties as conductivity and microhardness, depend on the mechanism of ion-induced thermoradiolysis and are very sensitive to the composition of the irradiated polymeric target. By and large, this type of influence of the polymer nature on the properties of ion implantation products can be considered as specific memory effect.

Figure 8 presents a diagram which qualitatively outlines main consequences of ion irradiation of polymers. By varying the irradiation dose one can control the rheological, sorption, conducting, electrochemical and optical properties of polymers and their microhardness, wear resistance and biocompatibility.

Figure 8. Principal transformations in the implanted layer and related changes in the physical and chemical properties of the polymer surface irradiated with different ion doses at energies between 0.1 and 1 MeV.

Thus, ion irradiation is a promising method of targeted modification of polymer surfaces. Build up of implantation doses causes processes of fundamentally different nature which can be controlled by varying the energy and masses of the implanted ions. All potentialities of this experimental technique and detailed mechanisms of physicochemical processes accompanying ion implantation of polymeric materials require further study.

The author expresses his gratitude to the Basic Research Foundation of Belarus for financial support of the experiments on the synthesis of nanostructured carbon materials by ion implantation techniques.

VIII. Conclusion	341

Abstract. The state-of-the-art of investigations into the development and perfection of the most promising class of chemical power sources, namely, rechargeable lithium batteries, is considered. The main problems of designing the batteries with a metallic lithium electrode are formulated and the use of alternative negative electrodes is substantiated. Special attention is paid to the studies dealing with the principles of the performance of lithium-ion batteries as well as the key directions for the perfection of these devices, which mainly concern the elaboration of new materials for lithium-ion batteries. A separate section is devoted to the consideration of polymeric electrolytes for lithium and lithium-ion batteries. The bibliography includes 390 references.

I. Introduction

A new type of chemical power source, namely, lithium cells with aprotic electrolytes appeared for the first time in the early 1970s and later gained wide acceptance.^{1,2} Thus, a long-standing idea of scientists, *viz.*, to build a chemical power source with the most active reductant, *i.e.*, an alkali metal, was materialised. The use of such a reductant allowed one to enhance both the operational voltage of a power source and its energy density.

In contrast to primary cells (one-shot cells) with lithium anodes, which were developed relatively quickly and successfully and are used now as the power sources in portable devices of every-day and special equipment, the history of the development of rechargeable lithium batteries has been very dramatic.^{3,4}

II. The main problems in the development of rechargeable batteries with lithium anodes.

Primary cells designed for operation under ordinary conditions can be divided into two classes: cells with liquid and solid cathodes. For liquid cathodes-oxidants, thionyl chloride and sulfur dioxide, which simultaneously form the basis of the electrolytes, are used most often. Exhibiting high values of power and energy densities and operating in a wide range of temperatures, the cells with liquid oxidants represent, however, a fire hazard and are explosive and, hence, are used only in special equipment. For cells with solid cathodes, oxides of manganese, copper and certain other metals serve as the active cathodic materials, together with iron sulfide and fluorocarbons. Electrolytes in such cells represent solutions of certain lithium salts (perchlorate, hexafluoroarsenate, tetrafluoroborate, *etc.*) in organic nonaqueous aprotic solvents (propylene carbonate, dimethoxyethane, tetrahydrofuran, γ -butyrolactone and various mixtures). Depending on the cathodic material type, the working voltage of the cells can approach 3 V (for manganese dioxide and fluorocarbons) or 1.5 V (for copper oxide and iron sulfide); in the latter case, lithium cells and conventional cells based on the manganese dioxide–zinc system are interchangeable. It is the primary cells with aprotic electrolytes that are considered as the analogues of rechargeable (secondary) cells.

The reactions which proceed in primary cells with aprotic electrolytes are similar to those in secondary cells. In both types of cells, the discharge involves the same processes, *viz.*, the anodic dissolution of lithium and the cathodic insertion of lithium into the lattice of the positive electrode material. The charging in a secondary cell represents the reverse processes. The materials for positive electrodes on which the cathodic insertion and anodic extraction (in other words, cathodic intercalation and anodic deintercalation) of lithium proceed reversibly were found back in the late 1970s. Titanium and molybdenum disulfides can serve as examples of such compounds.

The main problem arisen concerns the choice of the negative electrode material. Its discharge, *i.e.*, cathodic deposition of lithium poses complications typical of electroplating practice. It is known that the lithium surface in aprotic electrolytes is coated with a thin passive film (its thickness does not exceed several nanometres) as a result of chemical reactions with the electrolyte components, namely, the organic solvent and anions. This film has the properties of a solid electrolyte with conduction in lithium

ions and adequately protects lithium from the reactions with the electrolyte (*i.e.*, prevents self-discharge).

On the cathode, the deposition of lithium results in the formation of dendrites and, in many cases, the film formed during charge–discharge cycles envelopes individual lithium microparticles preventing their electric contact with the support. Such a phenomenon called ‘encapsulation’ manifests itself in the fact that every charging step removes a part of lithium from the further operation. That is why, the secondary cells with metallic lithium electrodes should contain lithium in amounts exceeding (from 4- to 10-fold) its stoichiometric value; hence, the specific capacity decreases from the theoretical value of 3828 to 380–800 mA h g^{−1}. Moreover, the formation of dendrites increases the probability of short-circuiting and, hence, makes the cells inflammable and explosive.

Various methods for the treatment of the cathodic surface and a search for additives to the electrolyte that would prevent the dendrite formation during cathodic deposition of lithium yielded positive results. For example, it was shown that, being added to a propylene carbonate electrolyte, even trace amounts of hydrogen fluoride favour lithium deposition as a dense fine-grain continuous layer rather than in the form of dendrites.^{5,6} The beneficial effect achieved by treating the lithium surface with carbon dioxide (or, simply, by adding either CO₂ as such or substances evolving CO₂ into the electrolyte upon their reactions with lithium) has been repeatedly mentioned.^{7,8} It was suggested⁹ to modify the lithium surface by applying monomolecular layers of non-ionic surfactants, particularly, dimethyl ether of poly(ethylene glycol) and a dimethylsiloxane–propylene oxide copolymer. Electrolytes that prevent the dendrite formation even in the absence of additives were also found. For example, a solution of lithium hexafluoroarsenate in 1,3-dioxolane (this solution also contained tributylamine which prevents dioxolane polymerisation).^{10–12}

III. Practical developments in the field of metallic lithium cells.

Despite the fundamental obstacles in the development of secondary cells with metallic lithium electrodes, attempts were made to establish their commercial production. Thus in 1987, Moli Energy Ltd (Canada) started serial production of AA-size batteries (which corresponds to the Russian size of 316)[†] with positive electrodes made of molybdenum disulfide. The cells possessed the following characteristics: an initial voltage of 2.3 V, a capacity of 600 mA h for a discharge at a current of 0.2 A up to the final voltage of 1.3 V. In certain cases, the discharge to the final voltage of 1.1 V allowed one to reach a discharge capacity of 800 mA h. According to the reports by manufacturers, their cells had a cycle life of several hundred charge–discharge cycles; however, these results were disputed by some experts and consumers. In fact, a cycle life of 100 charge–discharge cycles could be claimed. In 1989, a modernised version of a secondary cell was developed which contained a positive electrode of molybdenum sulfide with a composition of Mo₆S₈. This cell had a higher discharge voltage (from 2.3 to 1.8 V) and a higher capacity (up to 1000 mA h) and allowed a high-current discharge (up to 1 A).

The characteristics of the secondary cells fabricated by Moli Energy Ltd could have been considered adequate even despite a considerable voltage decrease during the discharge and a short real cycle life, but the reliability of the cells proved to be

insufficient. In the summer of 1989, incidences of ignition of primary lithium cells were observed, as well as failures of the secondary cells produced by this firm, which made them stop the production.

At the Jet Propulsion Laboratory of the California Institute of Technology (USA), secondary cells with positive electrodes of titanium disulfide have been developed; however, no attempt has been made to organise their serial production mainly due to their low cycle life, namely, 100–200 charge–discharge cycles. The same situation was observed with the cells developed by Honeywell, Eveready Battery Co. Inc. (USA) and the United Design and Technology Bureau ‘Orion’ at the Novocherkassk Polytechnical Institute (Russia). Engineers of Matsushita Electric Industrial Co. (Japan) have developed AA-size rechargeable batteries of a higher quality using manganese dioxide as the active substance for positive electrodes. The batteries had a discharge voltage in a range from 3.2 to 2.0 V and a capacity of 800 mA h at the beginning of cycling and 600 and 450 mA h after 60 and 200 charge–discharge cycles, respectively.

At present, Tadiran (Israel) is engaged in the development of rechargeable batteries with metallic lithium electrodes; however, the prospects of their application are still vague. It was reported¹³ that, for AA-size cells, the gravimetric power density of 125–140 W h kg^{−1} and the volumetric power density of 280–315 W h dm^{−3} at a service life of 250 full depth charge–discharge cycles were achieved.¹³ [The depth of discharge (dod) or the cycling depth of a battery is the capacity fraction realised during the discharge from the total capacity designed into a rechargeable battery.] The reliability of these cells was not confirmed, but it was reported that explosions are ruled out even for substantial overcharges. However, in certain cases, the cells mildly leaked (without explosions) due to overheating.

IV. Materials alternative to metallic lithium

The attempts to solve the problems associated with the use of metallic lithium in negative electrodes involved substitution of lithium alloys for lithium. Lithium–aluminium alloys were assumed to be the most promising candidates. On such an electrode, the lithium concentration decreases during the discharge (lithium is etched out of alloys) and increases during the charge. The chemical activity of lithium in an alloy is somewhat lower as compared with that of metallic lithium; hence, the potential of an alloy-based electrode is more positive (by ~0.2–0.4 V) than the potential of an electrode of pure lithium. This results, on the one hand, in a decrease in the working voltage and, on the other hand, in a weakening of the alloy interaction with the solvent, *i.e.*, reduces the probability of self-discharge.

Disk-shaped rechargeable batteries of the VL 2020 model developed by Matsushita Electric Industrial Co. involved negative electrodes made of a lithium–aluminium alloy and positive electrodes of vanadium oxide. Such batteries were characterised by a rated capacity[‡] of 20 mA h being discharged from 3.2 to 2.0 V, their cycle life was ~1000 charge–discharge cycles for a 10% dod and ~450 cycles for a 20% dod. At the Jet Propulsion Laboratory of the California Institute of Technology (USA), specimens of cells were built with advanced characteristics: their cycle life reached 600 charge–discharge cycles at 50% dod.

Indeed, the small dod values typical of these batteries make their specific characteristics inferior as compared with secondary cells with lithium electrodes. A principal drawback of lithium–aluminium alloys consists in the fact that they change substantially their specific volumes during the cycling. A deep discharge can result in embrittlement and crumbling of the electrode. That is why, no further progress was observed in the field using lithium–aluminium alloys as the material for negative electrodes.

[†] In Russia, the sizes of cylindrical cells may be designated in accordance with three types of nomenclature: the GOST (State Standard) (three-digit numbers: 283, 286, 314, 316, 373, *etc.*), the recommendations by the International Electrotechnical Commission (R06, R03, R4, R6, R20, *etc.*) and the USA nomenclature (AAA, R, AA, D, *etc.*). Thus a cell with a diameter of 14.5 mm and a height of 50.5 mm may be designated as AA, 316 and R6; a cell of a diameter of 34.2 mm and a height of 61.5 mm may be designated as D, 373 and R20. Tables comparing different designations of cell sizes are available (*e.g.*, in Ref. 2, p. 216).

[‡] The rated capacity is a capacity realised in a 5 h discharge to a final voltage of 2.5 V.
